Sun damage is considered a contributing etiologic factor, and solar elastosis is a common background on which rosacea histologic features are superimposed. However, rosacea prevalence is not increased in outdoor workers, sun damage in nonfacial locations does not progress to a rosacea phenotype, and photoprovocation studies in rosacea patients have not demonstrated increased cutaneous sensitivity to acute ultraviolet exposure.[9,17,20,21]

It has long been debated whether oral and topical antimicrobial agents for rosacea exert their effects by anti-inflammatory or antimicrobial mechanisms. The concept of microbe-induced, follicle-based inflammation in rosacea is controversial. It is unclear whether commensal organisms such as *Propionibacterium acnes* and *Demodex folliculorum*, which reside in hair follicles and sebaceous glands, trigger folliculocentric inflammatory papules in rosacea patients.[9] Alternatively, a hypersensitivity reaction may be triggered by these microbes or by mite-associated bacteria such as *Bacillus oleronius*.[22] Compelling arguments in favor of a microbe-induced mechanism for papulopustular rosacea (PPR) include the observation that nonsteroidal anti-inflammatory drugs and corticosteroids do not clear rosacea papules and pustules as effectively as oral tetracyclines. Furthermore, benzoyl peroxide is quite effective for papules and pustules in rosacea patients who tolerate this drug.[10] It remains unclear whether clinical improvement of PPR requires a quantitative reduction of *P. acnes*.

CLINICAL FEATURES

Erythematotelangiectatic rosacea (ETR) is characterized by persistent facial erythema and flushing along with telangiectases, central face edema, burning and stinging, roughness or scaling, or any combination of these signs and symptoms (Fig. 81-1). Mild, moderate,

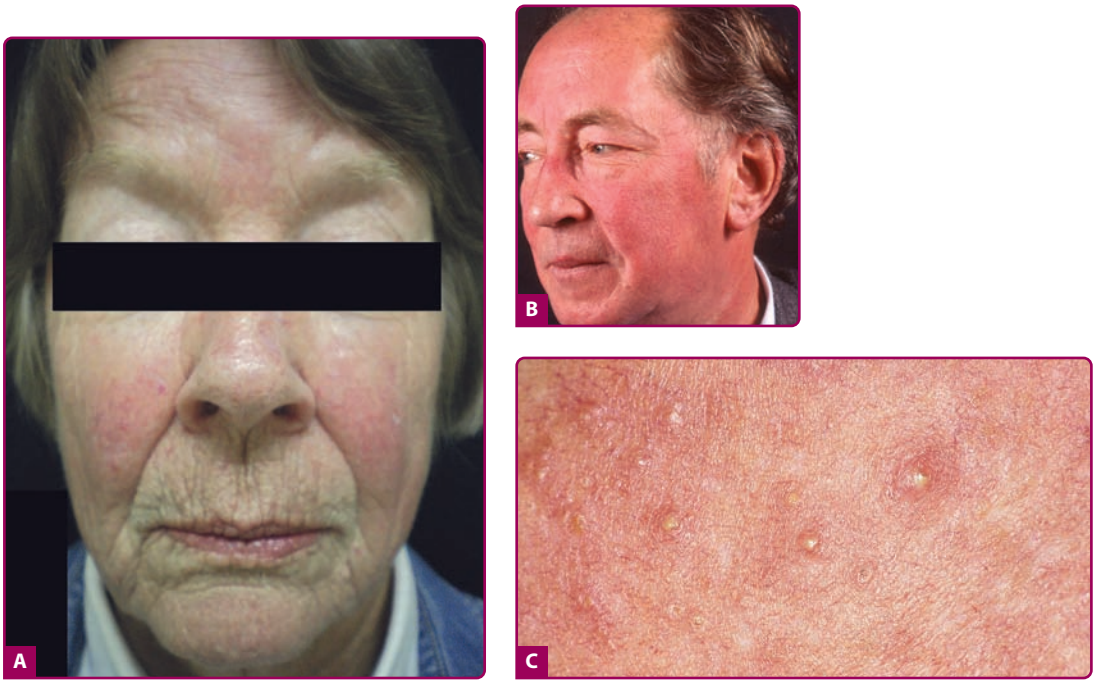

Figure 81-1 **A.** Erythematotelangiectatic subtype, mild. **B.** Erythematotelangiectatic subtype, severe. **C.** Close-up detailing the common occurrence of erythematotelangiectatic and papulopustular subtype overlap.

Figure 81-2 **A.** Papulopustular subtype. There is persistent erythema with papules and tiny pustules. Mild subtype. **B.** Severe form of the papulopustular subtype.

and severe subtypes are recognized. In contrast, PPR manifests as persistent, central-face erythema with papules and pustules that predominate in convex areas (Fig. 81-2).[9] Again, mild (see Fig. 81-2A), moderate, and severe forms (see Fig. 81-2B) are distinguished. Burning and stinging of the facial skin may occur in PPR, but occurs less commonly compared with ETR. Flushing is often less severe in PPR compared with ETR. In both subtypes, erythema spares the periorbital areas. Edema can be mild or severe. Severe edema may take on the plaque morphology of solid facial edema.[1,23] This occurs most often on the forehead and glabella and it less commonly affects the eyelids and upper cheeks.

Phymatous rosacea is characterized by patulous follicular orifices, thickened skin, nodularities, and irregular surface contours in convex areas (Fig. 81-3). Here also, mild, moderate, and severe subtypes are distinguished.

Figure 81-3 **A.** Phymatous subtype. Moderate subtype with patulous follicular orifices, thickened skin, and nodularities on nose and cheeks. **B.** Severe rhinophyma.

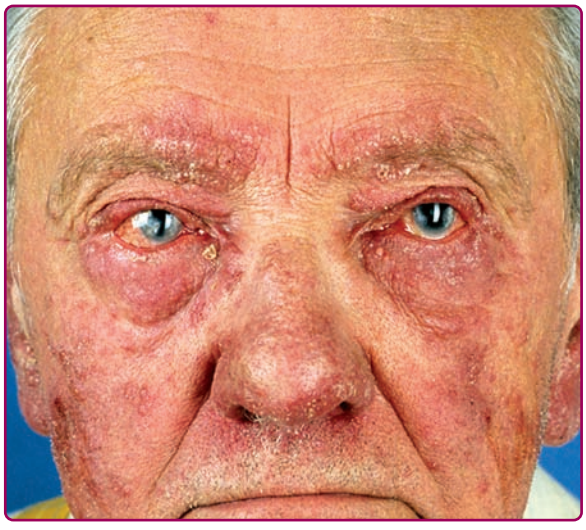

Figure 81-4 Ocular subtype, severe. This patient has blepharitis, conjunctivitis, and keratitis.

Phyma most often occurs on the nose (rhinophyma), but may also develop on the chin (gnathophyma), forehead (metophyma), eyelids (blepharophyma), and ears (otophyma).[24] Women with rosacea do not develop phyma, perhaps for hormonal reasons, but they can manifest sebaceous or glandular features characterized by thickened skin and large follicular orifices.[9]

Ocular rosacea may develop before cutaneous symptoms in up to 20% of affected individuals[25] (Fig. 81-4). In half of patients, ocular symptoms develop after skin symptoms. In a minority, skin and eye symptoms present simultaneously.[26] Ophthalmic rosacea severity does not coincide with cutaneous rosacea severity. Ocular involvement may manifest as blepharitis, conjunctivitis, iritis, scleritis, hypopyon, and keratitis; mild, moderate, and severe subtypes are recognized (see Fig. 81-4).[26] Blepharitis is the most common feature, characterized by eyelid margin erythema, scale, and crust, with the variable presence of chalazia and staphylococcal infections due to underlying meibomian gland dysfunction.[25] Photophobia, pain, burning, itching, and foreign body sensation may be part of the ocular symptom complex. In severe cases, rosacea keratitis may lead to vision loss.

Granulomatous rosacea is considered the only true rosacea variant.[1] Granuloma formation is a histologic feature of the condition; the clinical features of granulomatous rosacea include yellow–brown or red papules or nodules that are monomorphic and located on the cheeks and periorificial facial skin[27] (Fig. 81-5). Upon diascopy, these papules reveal apple-jelly-like change in color similar to sarcoidosis or lupus vulgaris. The background facial skin is otherwise normal. Other signs and symptoms of rosacea are not required to make a diagnosis of granulomatous rosacea.

HISTOPATHOLOGY

Rosacea is a clinical diagnosis; histology may be helpful when the facial distribution is atypical or when

Figure 81-5 Granulomatous rosacea. There are multiple monomorphic red and yellow brown papules that, on diascopy, show apple-jelly-like color.

granuloma formation is suspected. In ETR, a sparse, perivascular lymphohistiocytic infiltrate is accompanied by dermal edema and ectatic venules and lymphatics.[16] Severe elastosis may be present. Similar features are found in the papulopustular subtype, but the inflammatory infiltrate also surrounds hair follicles and sebaceous glands. Phymatous rosacea is characterized by prominent elastosis, fibrosis, dermal inflammation, sebaceous hyperplasia, and hypertrophy of sebaceous follicles.[16,28] Epithelialized tunnels undermine the hyperplastic tissue and are filled with inflammatory debris. *D. folliculorum* mites may be found in all types of rosacea within the follicular infundibula and sebaceous ducts.[28]

DIFFERENTIAL DIAGNOSIS

(Fig. 81-6)

Systemic diseases that must be differentiated from rosacea include polycythemia vera, connective tissue disorders (lupus erythematosus, dermatomyositis), carcinoid syndrome, mastocytosis, and neurologic causes of flushing. Neurologic causes include brain tumors, spinal cord lesions, orthostatic hypotension, migraine headaches, and Parkinson disease.[29] Unilateral auriculotemporal flushing may follow parotid gland injury or surgery.[30]

Medication-induced flushing has been associated with all vasodilators, calcium channel blockers, nicotinic acid (niacin), morphine, amyl and butyl nitrite, cholinergic drugs, bromocriptine, thyroid releasing hormone, tamoxifen, cyproterone acetate, systemic steroids, and cyclosporine.[29,31] The flush associated with nicotinic acid may be blocked with aspirin or indomethacin.[32] Disulfiram, chlorpropamide,

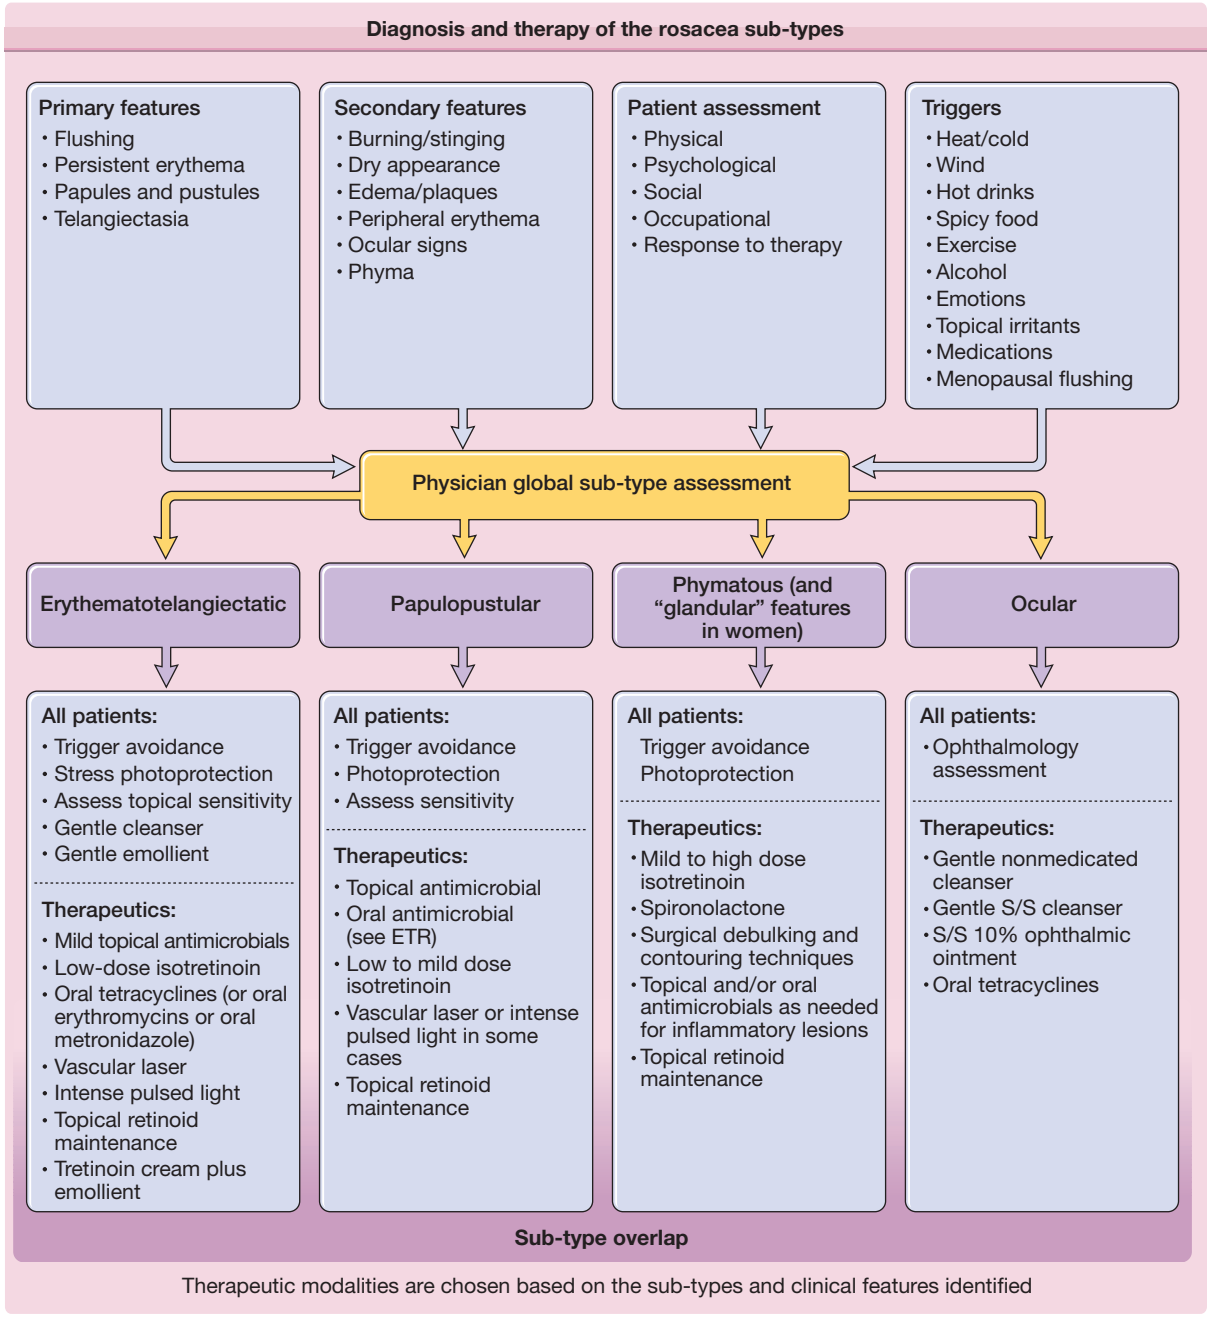

Figure 81-6 Approach to patient. Diagnosis and therapy of the rosacea subtypes. [a]Regimen recommendation based on author experience. ETR = erythematotelangiectatic; S/S = sodium sulfacetamide/sulfur.

metronidazole, phentolamine, and cephalosporins induce flushing when they are combined with alcohol.[29] Amiodarone has induced rosacea and multiple chalazia.[33] Food additives, including sulfites, sodium nitrite, nitrates, and monosodium glutamate, may also cause flushing.[29] Dumping syndrome following gastric surgery is characterized by flushing, sweats, tachycardia, and abdominal pain.

Cutaneous conditions that may mimic rosacea include topical steroid-induced acneiform eruption (formerly steroid-induced rosacea), acne vulgaris, perioral dermatitis, inflammatory keratosis pilaris, and chronic photodamage. In particular, acne vulgaris (see Chapter 80) and rosacea may coexist, although rosacea most often begins and reaches its peak incidence in the decades after acne declines. The primary differentiating feature between acne vulgaris and rosacea is the presence of open and closed comedones in acne alone.[2]

Rosacea fulminans, also known as *pyoderma faciale* and *rosacea conglobata*, occurs mainly in women in their 20s.[2,34,35] It is characterized by the sudden onset of confluent papules, pustules, nodules, and draining sinuses on the chin, cheeks, and forehead within a background of diffuse facial erythema. Rosacea fulminans has proved controversial in its classification and

was not included as a rosacea subtype or variant by the NRS Expert Committee.[1,2]

Perioral dermatitis (see Chapter 82) differs from rosacea in its facial distribution, signs, symptoms, and patient demographic. It is characterized by perioral, and sometimes periorbital, microvesicles, micropustules, scaling, and peeling. It affects younger women and also occurs in children. Central face erythema and inflammatory papules are not features of perioral dermatitis.[9] Therapy includes topical and oral antimicrobials. Perioral dermatitis is exacerbated by topical steroid use.

Steroid-induced acneiform eruption (see Chapter 80) can mimic PPR. With prolonged use of topical steroids on the face, monomorphic inflammatory papules may develop.[1] The treatment is discontinuation of the topical corticosteroid and initiation of an oral tetracycline, a topical antimicrobial, a topical calcineurin inhibitor, or a combination of these agents.[36,37] This regimen is generally continued for 1 to 3 months, and relapse does not tend to occur as long as topical steroids are not reintroduced.

In chronic photodamage (see Chapter 90), telangiectases and erythema are prominent features. However, unlike rosacea, actinic damage affects the periphery of the face and neck, the upper chest, and the posterior auricular skin. Hyperpigmentation and hypopigmentation are additional feature of sun damage not observed in rosacea. Chin involvement is both mental and submental in rosacea, while in chronic photodamage there is submental sparing.[9]

THERAPY

Before implementing therapy, rosacea trigger factors specific to each individual must be identified (see Fig. 81-6).[10] Patient education should stress trigger avoidance. Other key aspects of prevention include the daily application of gentle, broad-spectrum ultraviolet A and ultraviolet B sunscreen, hat use, avoidance of midday sun, and seeking shade. Physical sunscreens (zinc or titanium based) are best tolerated. Chemical sunscreens are better tolerated when barrier protective silicones (dimethicone, cyclomethicone) are included.[38]

Cosmetic intolerance and facial skin sensitivity are common features of the erythematotelangiectatic and papulopustular subtypes, perhaps due to inherent barrier dysfunction or facial vascular hyperreactivity.[39] As many as 75% of these individuals may experience burning, stinging, pruritus, or dryness and scaling in affected areas. Avoidance of harsh products and ingredients, including astringents, toners, menthol, camphor, and sodium lauryl sulfate, is important when sensitivity is present.[40] A soap-free cleanser applied with the fingers is best tolerated. A protective, gentle emollient should be applied once or twice daily before application of other products. Light liquid foundation makeup is the best choice for patients with sensitivity. Green-tinted makeup can be applied before foundation to further mask red areas.[40]

TOPICAL THERAPY

The topical agents approved by the US Food and Drug Administration (FDA) for rosacea include 15% azelaic acid gel, 0.75% and 1% metronidazole (available in cream, gel, and lotion vehicles), and 10% sodium sulfacetamide with 5% sulfur (available in cleanser, cream, suspension, and lotion vehicles). Each has proved effective for clearance of inflammatory papules and pustules and for erythema reduction when applied once daily.[41] Twice-daily application or combinations of these agents may be necessary when topical monotherapy is inadequate. Metronidazole and azelaic acid are pregnancy category B, whereas sodium sulfacetamide and sulfur is category C. Azelaic acid may be associated with initial tingling or burning that can disappear with continued use. Sodium sulfacetamide/sulfur medicated cleansers are better tolerated in sensitive patients compared with "leave-on" topical formulations that may increase burning and stinging.[42] Daily use of a barrier repair emollient is important in these patients.

Off-label topical formulations used for rosacea include benzoyl peroxide, clindamycin, erythromycin, calcineurin inhibitors, and topical retinoids.[10] Benzoyl peroxide is effective for clearance of papules and pustules, but should be avoided in sensitive patients.[10] Twice-daily topical clindamycin was more effective than oral tetracycline for the eradication of pustules in one series.[43] Tacrolimus ointment and pimecrolimus cream are most beneficial for topical, steroid-induced acneiform eruptions, but they may offer a useful therapeutic alternative in some patients with rosacea. Niacinamide-containing facial emollients may improve stratum corneum barrier function and hydration, and have shown benefit as adjunctive topical therapy in rosacea.[44]

"Manual" therapy should also be considered adjunctively in rosacea patients. Facial massage is performed in the direction of the lymphatic flow, according to Soybe's technique, beginning at a central location on the face (the glabella and nose) and pressing the fingers in a sweeping motion toward the inferolateral face (the mandibles and lateral neck).[17] This can help to mobilize edema and speeds clearance of dermal inflammation.

Tretinoin cream promotes connective tissue remodeling and minimizes dermal inflammation with long-term use.[45–47] Topical retinoids have demonstrated benefit for rosacea in small clinical series.[48,49] The clinical response to retinoids is delayed in the rosacea setting; generally 4 to 6 months of use is required to see significant effects. Because of their potential for irritation and concerns regarding promotion of angiogenesis, retinoids are often avoided for rosacea. However, their long-term use does not appear to promote the development of telangiectasia. Retinoids inhibit vascular endothelial growth factor production by cultured human skin keratinocytes via their anti-AP1 transcription factor activity.[50,51] The use of barrier emollients in conjunction with gradual introduction of topical retinoids allows them to be tolerated early on in treatment when retinoid dermatitis is a problem. Topical retinoids are especially useful for long-term maintenance in rosacea.

α-Adrenergic receptor agonist topical therapies (brimonidine, oxymetazoline) require further study

to characterize their efficacy and safety for ETR; however, their vasoconstrictive properties represent a novel approach for the treatment of telangiectasia and erythema.[52,53]

ORAL THERAPY

Topical management of rosacea is possible and generally preferable, especially when considering issues of antimicrobial resistance and the risks associated with long-term use of oral antibiotics. Furthermore, because rosacea is photoaggravated in many affected individuals, photosensitizing oral agents must be used with caution in this population. Oral antimicrobials in particular are useful short-term tools that can achieve rapid control of symptoms, but long-term topical maintenance should be the eventual therapeutic goal. In 2006, Oracea (doxycycline, USP, 40 mg) became the first oral therapy to be FDA-approved for rosacea.

For moderate to severe flushing or erythema, short-term oral therapy (2 to 4 months) with a tetracycline or isotretinoin may be useful for initial control. Tetracyclines achieve faster reduction of papules, pustules, and erythema when compared with isotretinoin, and since the 1950s, rosacea has been treated and maintained with both antimicrobial and subantimicrobial dosages of the tetracyclines.[54,55] Relapses occur in approximately one-fourth of patients after 1 month off tetracycline, and in over one-half of patients at 6 months off therapy.[55] Therefore, topical maintenance therapy is advised. Oral tetracyclines should be avoided in pregnant women and in those contemplating pregnancy.

In one small series, a significant reduction of facial cutaneous blood flow, measured by laser-Doppler, was achieved in isotretinoin-treated patients (30 mg daily for 10 weeks), whereas no significant change in facial blood flow was observed in those treated with 250 mg of tetracycline twice daily for 10 weeks.[56] Low-dose isotretinoin (10 to 40 mg daily or less than 0.5 mg/kg/day) can be effective and is better tolerated in rosacea patients.[57–59] Isotretinoin is teratogenic, and its use is strictly monitored in women of child-bearing potential.

Other oral agents used for rosacea include macrolides, metronidazole, antiandrogenic agents (oral contraceptives, spironolactone, and cyproterone acetate), β blockers, clonidine, naloxone, and selective serotonin reuptake inhibitors.[10,60–66] In patients with a history of acne vulgaris or overlap of acne vulgaris with rosacea, spironolactone in low doses (25 to 50 mg daily) and/or oral contraceptive pills may prove helpful. When high levels of *Demodex* exacerbate rosacea, or in cases refractory to tetracyclines, ivermectin may be a useful adjunctive therapy. It can be given as a single 0.2 mg/kg dose repeated once weekly or once monthly as needed for symptom control.[67]

LASER AND LIGHT THERAPY

(See Chapter 239)

Vascular lasers and intense pulsed light (IPL) therapy are useful alternatives to oral rosacea therapies; they may be used adjunctively with topical and oral rosacea regimens for faster and more complete symptom resolution. These nonablative modalities can eliminate telangiectasia, reduce or eliminate erythema, reduce papule and pustule counts, and they appear to extend the duration of remission. Their drawbacks are cost and side effects, which may include transient erythema, edema, purpura, blistering, dyschromia, burns, and, rarely, scarring.

Vascular lasers include short and long wavelength devices with a variety of pulse durations. Short wavelength lasers emit light that is selectively absorbed by oxyhemoglobin absorption peaks that occur at 541 nm and 577 nm. This allows for superficial vessel destruction without collateral tissue damage. Short wavelength lasers include the pulsed dye laser (585 nm or 595 nm), long pulsed dye laser (595 nm), the potassium-titanyl-phosphate laser (532 nm), and the diode-pumped frequency-doubled laser (532 nm).[68–70] Long wavelength vascular lasers can eradicate deeper and larger vessels by targeting the oxyhemoglobin spectral peaks at 800 nm and above 1,000 nm. These lasers include the long pulsed Alexandrite (755 nm), the diode laser (810 nm), and the neodynium:yttrium-aluminum-garnet laser (1,064 nm).[10]

The success and tolerability of laser therapy for rosacea have been improved by modified pulse duration parameters and by advances in epidermal cooling mechanisms. Longer pulse durations can deliver equivalent energy at a slower rate to heat vessels uniformly and gently, minimizing tissue trauma and purpura. Epidermal cooling gels and sprays prevent epidermal damage and can help to minimize pain, erythema, and edema and help to ensure safe delivery of laser energy. Generally, two to four laser treatments are required to achieve best outcomes for rosacea; purpuric treatment settings may eradicate telangiectasia more quickly. Multiple laser passes and pulse-stacking on larger vessels may improve treatment outcomes when subpurpuric settings are utilized.[71]

Unlike laser devices that emit a single wavelength, IPL (broadband light) emits a broad wavelength spectrum, ranging from approximately 550-nm visible light to 1,200-nm infrared light. Filters are used to establish the short end of the spectrum, which varies depending on the device. Fluence and pulse width also vary with the system used. IPL may cause transient erythema, transient hyperpigmentation, or hypopigmentation, and, rarely, purpura, burns, and scarring.[72] Epidermal cooling mechanisms are necessary to protect the epidermis. IPL effectively reduces facial erythema and telangiectases and is generally well tolerated.[72–74] Vascular lasers and IPL may also impact rosacea by inducing fibroblasts to increase dermal collagen production, perhaps achieving some degree of dermal remodeling and rejuvenation.[75–77]

TREATMENT OF PHYMA

Oral isotretinoin monotherapy is beneficial for early to moderate phymatous change.[24] Advanced phyma is treated with surgical therapy or the combination

of surgery followed by isotretinoin therapy. Surgical approaches to the reshaping of rhinophyma have included cold scalpel tangential excision, heated scalpel excision, electrocautery, dermabrasion, laser ablation, tangential excision combined with scissor sculpturing, radiofrequency electrosurgery, or a combination of these approaches.[24,78–83] Techniques that use partial thickness tangential excision and contouring with preservation of the underlying sebaceous glands allow spontaneous reepithelialization within 2 to 3 weeks, result in minimal scarring, and give an excellent aesthetic result with a low risk of recurrence.[83]

TREATMENT OF OCULAR ROSACEA

Ophthalmologic referral should be made for patients with ocular symptoms. For mild blepharitis, careful use of a gentle nonmedicated or sodium sulfacetamide/sulfur cleanser may be used once to twice daily as initial therapy. Sodium sulfacetamide 10% ophthalmic ointment is also effective for control of blepharitis. When topical management is inadequate, oral tetracyclines are generally effective.[7,25,26]

SUMMARY

To effectively treat rosacea, practitioners must recognize the clinical spectrum of rosacea phenotypes and what lies outside that spectrum. Subtyping of rosacea is a useful guide to establish a multimodality approach to therapy. Therapeutic success is achieved by inducing remission of signs and symptoms, and by minimizing and controlling relapses. Ultimately, early recognition of this disorder, some key behavioral modifications, and the combination of sunscreen and topical agents can achieve safe, effective, and long-term control of rosacea, while avoiding the risks of oral pharmaceuticals and the financial strain of laser and light therapies.

Chapter 82 :: Perioral Dermatitis

:: Leslie P. Lawley & Sareeta R.S. Parker

PERIORAL DERMATITIS AT A GLANCE

- Inflammatory skin disorder of young women and children.
- Small papules, vesicles, and pustules in perioral, periorbital, and/or perinasal distribution.
- Treatment: stop topical corticosteroid use; initiate 2- to 3-month course of systemic antibiotics (tetracycline family or erythromycin) and/or topical metronidazole.

Perioral dermatitis is characterized by small, discrete papules and pustules in a periorificial distribution, predominantly around the mouth. Because this condition can involve areas other than the perioral region, the term periorificial dermatitis has been proposed for this disorder.[1,2] The classic presentation is an eruption with overlapping features of an eczematous dermatitis and an acneiform eruption. Although initially described in young women of 15–25 years of age, perioral dermatitis is now recognized to occur in children as well.[3] A subset of perioral dermatitis shows granulomas when lesional skin is examined histologically. Several names have been used to describe this granulomatous form of perioral dermatitis, including granulomatous perioral dermatitis, facial Afro-Caribbean childhood eruption, and granulomatous periorificial dermatitis.[2,4,5]

HISTORICAL ASPECTS

The first reports describing perioral dermatitis appeared in the 1950s; various names were given to the condition, however, there was a lack of defining clinical criteria. In 1957, Frumess and Lewis described a "light sensitive seborrheid" that is generally accepted as the first account of what was later termed *perioral dermatitis* by Mihan and Ayres in 1964.[6,7] Later descriptions

by Cochran and Thomson[8] and Wilkinson, Kirton, and Wilkinson[9] further defined this disorder, and more recently the term *periorificial dermatitis* has been proposed.[2] The condition was first described in children in the late 1960s.

EPIDEMIOLOGY

Adult perioral dermatitis predominantly affects women. Pediatric perioral dermatitis may have a slight female preponderance and is seen equally among those of different races.[1,10] The granulomatous form of perioral dermatitis has been reported mostly in children of prepubertal age.[5] Perioral dermatitis can occur as early as 6 months.[1] An increased prevalence in African-American children has been reported, but more recent reviews do not support this finding.[2,11]

ETIOLOGY AND PATHOGENESIS

A relationship of perioral dermatitis to the misuse of topical corticosteroids (fluorinated or nonfluorinated) has been well established.[12] Patients often reveal a history of an acute steroid-responsive eruption around the mouth, nose, and/or eyes that worsens when the topical corticosteroid is discontinued. Dependency on the use of the topical corticosteroid may develop as the patient repeatedly treats the recurrent eruption. In other cases, the condition may worsen with the application of topical corticosteroids, especially in the granulomatous variant of perioral dermatitis, which usually occurs in prepubertal children.[2] Perioral dermatitis has been reported in patients using inhaled corticosteroids[13] and with inadvertent facial exposure to topical corticosteroids.[14] However, perioral dermatitis is not always linked to topical corticosteroids.[9] The exact cause of perioral dermatitis in these other cases is unclear. Although isolated reports of affected siblings exist,[2,15] no clear genetic predisposition has been noted, nor have specific environmental exposures been consistently implicated. Of note, the disease is predominant in young women, yet no link to hormonal causes has been found. The initial reports of photosensitivity by Frumess and Lewis[6] were not further substantiated, nor were theories of microbiologic causes such as infection with *Candida*, fusiform bacteria, or *Demodex folliculorum*.[16] Cases of allergic contact with fluorides or other components in toothpaste and dentifrices have also been reported, however, use of these agents after clearing of the perioral dermatitis without further eruption has also been described. Patch testing in a small series of patients led to few positive results, and these were not considered relevant.[9]

In the past, authors have considered the relationship of perioral dermatitis to acne rosacea, however, the clinical features are distinct (see Section "Differential Diagnosis"). In perioral dermatitis, the histopathologic findings are variable and are dependent on the form of perioral dermatitis. In a histopathologic review of 26 patients with the nongranulomatous form, follicular spongiosis and eczematous changes were prominent features, suggesting that perioral dermatitis is distinct from rosacea.[17] A lymphohistiocytic infiltrate and occasional plasma cells were noted in a perifollicular and perivascular distribution in this series. In granulomatous perioral dermatitis, histopathology demonstrates follicular hyperkeratosis, edema and vasodilatation in the papillary dermis, perivascular and parafollicular infiltrates of lymphocytes, histiocytes, and polymorphonuclear leukocytes with occasional epithelioid granulomas and giant cells, similar to the histopathologic changes in acne rosacea.[5,18]

Figure 82-1 Typical perioral dermatitis. The eruption is confined to the nasolabial folds and the skin of the chin.

CLINICAL FINDINGS

The primary lesions of perioral dermatitis are discrete and grouped erythematous papules, vesicles, and pustules (Figs. 82-1 and 82-2). The lesions are often symmetric but may be unilateral and appear in the perioral, perinasal, and/or periocular regions (Figs. 82-2 and 82-3 and eFigs. 82-3.1 and 82-3.2 in online edition). In a retrospective review of 79 children with perioral

Figure 82-2 Perioral (granulomatous periorificial) dermatitis. This child shows the typical small papules studding the area around the mouth and eyes.

Figure 82-3 Perioral dermatitis, granulomatous form: child with densely aggregated periorificial erythematous and edematous papules.

dermatitis, isolated perioral involvement was present in only 39%, and in rare cases nonperioral regions were involved exclusively.[1] Background erythema and/or scale may be present. A distinct 5-mm clear zone at the vermilion edge is well described (Fig. 82-2). The granulomatous variant of perioral dermatitis presents with small flesh-colored, erythematous, or yellow–brown papules, some with confluence, and shares the distribution of perioral dermatitis in adults (Fig. 82-3). In addition, lesions have been reported to appear on the ears, neck, scalp, trunk, labia majora, and extremities.[1,11]

Occasionally, an associated burning sensation or itching is reported, and intolerance to moisturizers and other topical products is described.[1,9] In a few cases of granulomatous perioral dermatitis, an associated blepharitis or conjunctivitis has been reported.[11] Systemic findings and regional lymphadenopathy are absent.

DIFFERENTIAL DIAGNOSIS

(Box 82-1)

The differential diagnosis of nongranulomatous and granulomatous perioral dermatitis is outlined in Box 82-1.[19–24] Both forms of perioral dermatitis lack systemic symptoms and a thorough history and physical examination are generally sufficient to establish the diagnosis. However, in some cases histopathological evaluation of lesional skin, chest radiography, and/or

BOX 82-1 DIFFERENTIAL DIAGNOSIS OF PERIORAL DERMATITIS

DISORDER	DISTINGUISHING CLINICAL FEATURES
Nongranulomatous Perioral Dermatitis	
Most Likely	
Rosacea	Involves the nose, facial convexities; persistent erythema, and telangiectasias
Seborrheic dermatitis	Accentuated at nasolabial folds; scale
Allergic contact dermatitis	Consider musical instruments, toothpaste/dentrifices, latex gloves, dental appliances, and lipstick
Irritant contact dermatitis	Common in children (from saliva, foods)
Lip-licking cheilitis	Common in children; scale, well demarcated border
Consider	
Acne vulgaris	May involve chest and back; comedones
Gram-negative folliculitis	Predominance of pustules
Demodex folliculorum infestation	Pustules, pruritus; often immunocompromised host[19]
Acrodermatitis enteropathica	Infants with acral and/or diaper dermatitis; zinc deficiency
Tinea facei	KOH positive for hyphal elements
Psoriasis	Involvement of other cutaneous sites common
Impetigo	Honey-colored crusts
Eosinophilic folliculitis-HIV related	Immunocompromised host
Granulomatous Perioral Dermatitis	
Most Likely	
Granulomatous rosacea	Flushing, telangiectases, pustules, and edema; similar histopathologic features
Consider	
Familial juvenile systemic granulomatosis (Blau syndrome)	Synovial cysts, uveitis, granulomatous arthritis, camptodactyly, papular rash
Fungal or mycobacterial infection	
Lupus miliaris disseminatus faciei	
Benign cephalic histiocytosis	Diffuse distribution on the face
Sarcoidosis	Rare in children; reported cases may represent Blau syndrome
Zirconium dermatitis	May involve axillae

BOX 82-2 TREATMENT FOR PERIORAL DERMATITIS

	TOPICAL	DOSE	SYSTEMIC	ADULT DOSE
First line	Metronidazole	Apply bid	Tetracycline	250–500 mg p.o. bid
			Doxycycline	50–100 mg p.o. bid
			Minocycline	50–100 mg p.o. bid
Second line	Erythromycin or clindamycin	Apply bid	Erythromycin	400 mg p.o. tid
				Or
	Sulfur preparations	Apply bid		30–50 mg/kg/day p.o.
	Azelaic acid	Apply bid		divided tid[a]

[a]Pediatric dose

ophthalmologic examination may be necessary, particularly with the granulomatous variant.[11] Sarcoidosis in young children is rare and often accompanied by systemic signs and symptoms such as weight loss, fatigue, joint pains, lymphadenopathy, and uveitis.[5,25] At least some of the reported cases of sarcoidosis in young children represent Blau syndrome with underlying mutations in *CARD15/NOD2* (see Chapter 134).[11,26]

COMPLICATIONS

The majority of cases of perioral dermatitis and granulomatous perioral dermatitis resolve without sequelae or relapse. However, there are rare reports of scarring.[5]

PROGNOSIS AND CLINICAL COURSE

Perioral dermatitis is usually a self-limited disorder that evolves over a few weeks and resolves over months or rarely years. The condition may take on a waxing and waning course, often with a tendency to progress (granulomatous form). If treated with topical corticosteroids alone, recurrent episodes on withdrawal of therapy or with continuing therapy are typical. With appropriate intervention the condition resolves with rare recurrences.

TREATMENT

(Box 82-2)

If topical corticosteroids are being used, they should be discontinued. If fluorinated corticosteroids are being applied, initial substitution with a low-potency hydrocortisone cream may minimize a flare of the dermatitis. Patients should be educated about the link between application of topical corticosteroids and exacerbation of the dermatitis.

In most cases, effective therapy is oral tetracycline, doxycycline, or minocycline, for a course of 8 to 10 weeks, with a taper over the last 2 to 4 weeks. In children under 8 years of age, nursing mothers, or tetracycline-allergic patients, oral erythromycin is recommended. Not uncommonly, patients require continued low-dose systemic antibiotic therapy for months or sometimes years to maintain control. In recalcitrant cases, isotretinoin may be considered.[27]

Topical antibiotic therapy, most commonly with topical metronidazole, should be initiated concurrently with the systemic antibiotic. For milder cases, topical metronidazole alone may suffice.[1,28,29] In a retrospective review of 79 children, best outcomes were associated with the use of topical metronidazole, oral erythromycin, or both.[1] Response is generally noted within 2–3 months. Other options include topical clindamycin or erythromycin, topical sulfur-based preparations, and topical azelaic acid.[30] Reports of successful use of topical calcineurin inhibitors exist, particularly in adults; however, caution is advised given the occasional reports of granulomatous eruptions after the use of these agents.[31–35] Ointment preparations should generally be avoided in the treatment of perioral dermatitis. Photodynamic therapy with topical 5-aminolevulinic acid has shown promise for treating perioral dermatitis in one report.[36]

PREVENTION

The only widely accepted factor that may predispose to the development of perioral dermatitis is the use of topical corticosteroids. Avoiding facial skin exposure to these products may prevent the eruption in some cases.

SECTION 14

Disorders of the Eccrine and Apocrine Glands

Chapter 83 :: Biology of Eccrine and Apocrine Glands

:: Theodora M. Mauro

SWEATING AT A GLANCE

- Humans have 2–24 million sweat glands.
- Up to 10 L/day of sweat is produced by acclimatized individuals.
- The three eccrine cell types are (1) clear (secretory), (2) dark (mucoid), and (3) myoepithelial (contractile).
- Hypothalamic temperature is the strongest stimulus for sweating.
- Acetylcholine is the major stimulus secreted by sympathetic nerves.
- Botulinum toxin inhibits sweating by preventing acetylcholine release.
- Oxidative metabolism of glucose is a major source of eccrine gland adenosine triphosphate.
- Ductal reabsorption conserves NaCl.
- In individuals with cystic fibrosis, mutated chloride channels increase NaCl loss.
- Bacteria are necessary for apocrine odor.
- Odiferous precursors secretion is controlled by the MRP8 encoded by *ABCC11*.
- Adrenergic stimulation controls apocrine gland secretion.

In humans, sweat glands generally are found as two types, (1) eccrine and (2) apocrine. Eccrine-gland sweat allows the body to control its internal temperature in response to thermal stress. Apocrine gland function is more obscure but likely includes pheromone production.

DEVELOPMENT OF ECCRINE SWEAT GLANDS

Humans have approximately 2–4 million sweat glands.[1] Sweat glands are found over nearly the entire body surface, and are especially dense on the palms, soles, forehead, and upper limbs.[2] Analgen of eccrine sweat glands first appear in the 3.5-month-old fetus on the palms and soles (see Chapter 7), then develop in the axillary skin in the fifth fetal month, and finally develop over the entire body by the sixth fetal month.[3] The analog of the eccrine sweat gland, which developed from the epidermal ridge, is double layered, and develops a lumen between the layers between the fourth and eighth fetal months. By the eighth fetal month eccrine secretory cells resemble those of the adult; by the ninth fetal month myoepithelial cells form.

ANATOMY AND FUNCTION OF ECCRINE SWEAT GLANDS

Two distinct segments, the secretory coil and the duct, form the eccrine sweat gland. The secretory coil secretes an isotonic sweat, while the duct resorbs Na^+ and Cl^-, thus producing sweat to cool the body while preserving Na^+ and Cl^- body stores.

SECRETORY COIL

The secretory coil contains three distinct cell types: (1) clear (secretory), (2) dark (mucoid), and (3) myoepithelial.[4] The clear and dark cells occur in approximately equal numbers but differ in their distribution (Fig. 83-1). While the dark cells border the apical (luminal) surfaces, the clear cells rest either directly on the basement membrane or on the on the myoepithelial cells. The clear cells directly access the lumen by forming intercellular canaliculi (Fig. 83-2). Spindle shaped contractile myoepithelial cells lie on the basement membrane and abut the clear cells. The adult secretory coil is approximately 2–5-mm long, and approximately 30–50 μm in diameter. Heat accumulation results in larger sweat glands and ducts, and their dimensions,

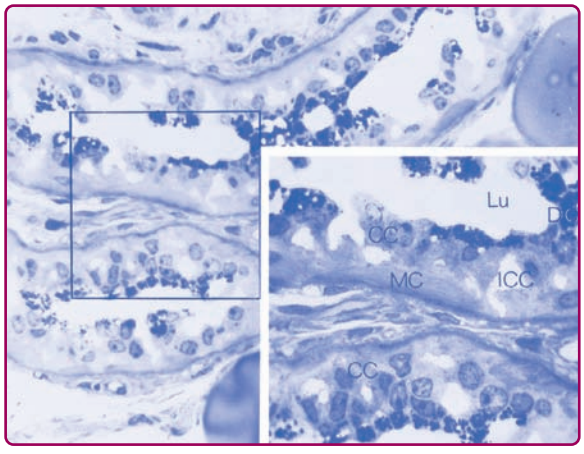

Figure 83-1 Light photomicrograph of the secretory coil of an acetylcholine-stimulated monkey palm eccrine sweat gland. A 1-m thick section was cut from an Epon-embedded specimen and stained with methylene blue. Inset: A higher-power view of the area marked by the square. CC = clear cell; DC = dark cell; ICC = intercellular canaliculi; Lu = lumen; MC = myoepithelial cell.

in turn, correlate with enhanced sweat output.[5] Clear cells contain abundant mitochondria and an autofluorescent body, called the lipofuscin granule, in the cytoplasm. The clear cell plasma membrane forms many villi. The clear cell secretes water and electrolytes. Dark cells have a smooth cell surface and contain abundant dark cell granules.[4] The function of dark cells are unknown. Myoepithelial cells contain actin filaments[6] and are contractile,[7,8] producing pulsatile sweat.

DUCT

The eccrine sweat duct consists of an outer ring of peripheral or basal cells and an inner ring of luminal

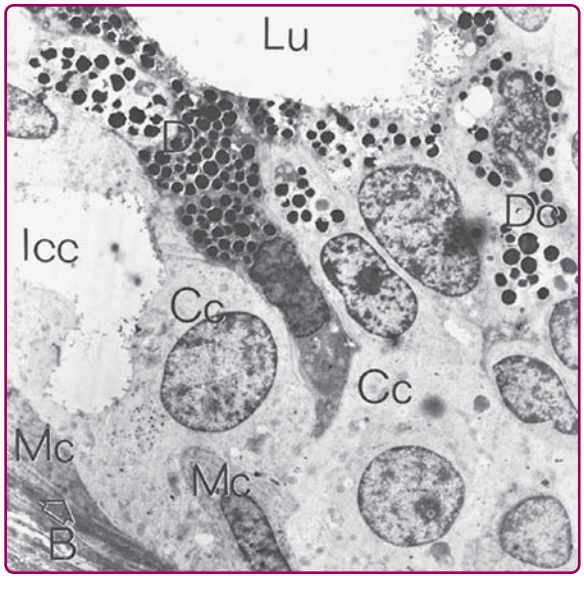

Figure 83-2 Electron micrograph of the secretory coil of a human eccrine sweat gland. B with arrow = basal lamina; other symbols are the same as in Fig. 83-1.

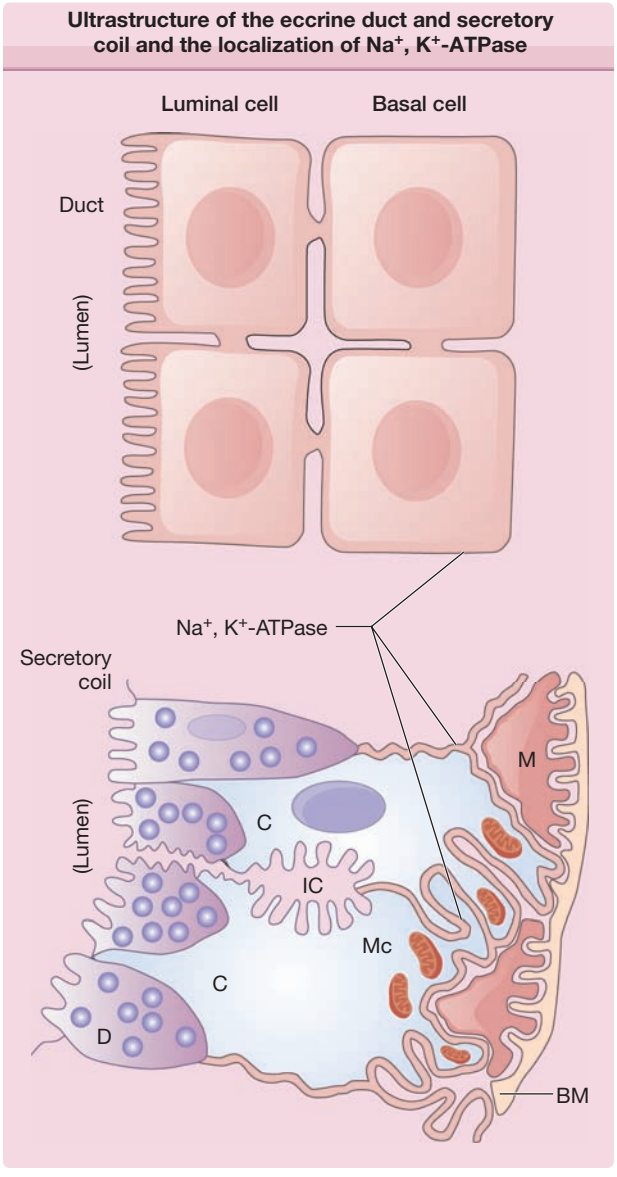

Figure 83-3 Drawing of the ultrastructure of the eccrine duct and secretory coil and the localization of Na^+, K^+-adenosine triphosphatase (ATPase). The thick lines indicate the localization of Na^+, K^+-ATPase. BM = basement membrane; C = clear cell; D = dark cells; IC = intercellular canaliculi; M = myoepithelial cell; Mc = mitochondria.

or cuticular cells. It seems that the proximal (coiled) duct is functionally more active than the distal straight portion in pumping Na^+ for ductal Na^+ reabsorption, because Na^+, K^+-adenosine triphosphatase (ATPase) activity and the number of mitochondria are higher in the proximal portion (Fig. 83-3).[4,7,9,10] In contrast, the luminal ductal cells have fewer mitochondria, much less Na^+, K^+-ATPase activity, and a dense layer of tonofilaments near the luminal membrane, which is often referred to as the *cuticular border*. The cuticular border provides structural resilience to the ductal lumen, which may dilate whenever ductal flow of sweat is blocked. The entire structural organization of the duct is well designed for the most efficient Na^+ absorptive

function. The luminal membrane serves as the absorptive surface by accommodating both Na^+ and Cl^- channels, and the basal ductal cells serve in Na^+ pumping by providing maximally expanded Na^+ pump sites and efficient energy metabolism. The lumen and the duct contain β-defensin, an antimicrobial, cysteine-rich, low-molecular-weight peptide.[11,12] In the epidermis, the duct spirals tightly upon itself.

NEURAL CONTROL OF ECCRINE SWEATING

The preoptic hypothalamic area plays an essential role in regulating body temperature: local heating of the preoptic hypothalamic tissue activates generalized sweating, vasodilatation, and rapid breathing, whereas local cooling of the preoptic area causes generalized vasoconstriction and shivering. The elevation of hypothalamic temperature associated with an increase in body temperature provides the strongest stimulus for thermoregulatory sweating responses, while cutaneous temperature exerts a weaker influence on the rate of sweating.[13] On a degree-to-degree basis, an increase in internal temperature is about nine times more efficient than an increase in mean skin temperature in stimulating the sweat center. The local temperature effect is speculated to be due to increased release of periglandular neurotransmitters.

The sweating in menopausal "hot flashes" reinforces the concept of a central hypothalamic mechanism for thermal sweating, but also shows that the response of individuals to the same changes in core temperature can vary. Although hormonal factors influence sweating during menopause, excessive sweating does not correlate simply with hormonal levels. Instead, menopausal hot flashes seem to be due to a hypersensitive brain response (particularly the hypothalamus, but perhaps the insula, anterior cingulate, amygdala, and primary somatosensory cortex as well). In asymptomatic menopausal women and premenopausal women, the core temperature can change up to 0.4°C (33°F) without eliciting a response. In symptomatic postmenopausal women, changes as small as 0.1°C (32°F) trigger peripheral vasodilation and sweating. Why the brain is hypersensitive to small changes in core temperature is poorly understood, but increased levels of brain norepinephrine appear to influence the response to small changes in core temperature through their action on α_2-adrenergic receptors in the brain; higher levels of the norepinephrine metabolite 3-methoxy-4-hydroxyphenylglycol have also been found in symptomatic menopausal women than in asymptomatic women. Decreased norepinephrine release is postulated as the mechanism by which clonidine relieves hot flashes in symptomatic women. Decreased core temperature may be the reason that women with decreased body mass index tend to have fewer symptoms, even though their estrogen levels probably are lower than those in women with increased body mass index. Levels of estrogen, luteinizing hormone, and β-endorphins also were originally thought to influence hot flashes, but later studies have suggested no association.[14]

INNERVATION. Efferent nerve fibers originating from the hypothalamic preoptic sweat center descend through the ipsilateral brainstem and medulla and synapse in the intermediolateral cell columns of the spinal cord without crossing (although sympathetic vasomotor fibers may partially cross).[15] The myelinated axons rising from the intermediolateral horn of the spinal cord (preganglionic fibers) pass out in the anterior roots to reach (through white ramus communicans) the sympathetic chain and synapse. Unmyelinated postganglionic sympathetic class C fibers arising from sympathetic ganglia join the major peripheral nerves and end around the sweat gland. The supply to the skin of the upper limb is commonly from T2 to T8. The face and the eyelids are supplied by T1 to T4, so that resection of T2 for the treatment of palmar hyperhidrosis is likely to cause Horner syndrome. The trunk is supplied by T4 to T12 and the lower limbs by T10 to L2. Unlike the sensory innervation, a significant overlap of innervation occurs in the sympathetic dermatome because a single preganglionic fiber can synapse with several postganglionic fibers.

The major neurotransmitter released from the periglandular nerve endings is acetylcholine (Ach), an exception to the general rule of sympathetic innervation, in which noradrenaline is the peripheral neurotransmitter. In addition to ACh, adenosine triphosphate (ATP), catecholamine, vasoactive intestinal peptide, atrial natriuretic peptide, calcitonin gene-related peptide, and galanin have been localized in the periglandular nerves. The significance of these peptides or neurotransmitters in relation to sweat gland function is not fully understood.

Botulinum toxin interferes with ACh release. Its heavy chain binds the neurotoxin selectively to the cholinergic terminal and the light chain acts within the cells to prevent ACh release. Type A toxin cleaves sensory nerve action potential-25, a 25-kDa synaptosomal-associated protein; the type B light chain cleaves vesicle-associated membrane protein (also called *synaptobrevin*). Botulinum toxins are used for symptomatic relief of hyperhidrosis.[16] A more detailed description can be found in Chapters 84 and 255.

DENERVATION. In humans, the sweating response to intradermal injection of nicotine or ACh disappears within a few weeks after denervation of the *postganglionic* fibers,[17] while the sweating response to heat ceases immediately after resection of the nerves. In contrast, after denervation of *preganglionic* fibers (due to spinal cord injuries or neuropathies), pharmacologic responsiveness of the sweat glands is maintained from several months to 2 years, even though their thermally induced sweating is no longer present.[18]

EMOTIONAL SWEATING

Sweating induced by emotional stress (emotional sweating) can occur over the whole skin surface in some individuals, but it is usually confined to the palms, soles, axillae, and the forehead. Emotional sweating on the palms and soles ceases during sleep,

whereas thermal sweating occurs even during sleep if the body temperature rises. Because both types of sweating can be inhibited by atropine, emotional sweating is cholinergically medicated.

PHARMACOLOGY OF THE ECCRINE SWEAT GLAND AND SWEATING RATE

Sweat glands respond to cholinergic agents, α- and β-adrenergic stimulants, and other periglandular neurotransmitters, such as vasoactive intestinal peptide and ATP. Periglandular ACh is the major stimulant of sweat secretion, and its periglandular concentration determines the sweat rate in humans. When dissociated clear cells are stimulated in vitro by cholinergic agents, they lose K^+ & Cl^-, increase intracellular Ca^{2+}, and shrink, mimicking actions seen in vivo.[19] Striking individual differences exist in the degree of sweating in response to a given thermal or physical stress. In general, males perspire more profusely than females.[20] The sweat rate in a given area of the skin is determined by the number of active glands and the average sweat rate per gland. The maximal sweat rate per gland varies from 2 to 20 nL/min^2. Sweat rate increases during acclimatization, but the morphologic and pharmacologic bases of the individual and regional differences in sweating rate during acclimatization are still poorly understood (Fig. 83-4). In thermally induced sweating, the sweat rate can be mathematically related to the body and skin temperatures in a given subject only in the low sweat rate range. Cholinergic stimulation yields a five to ten times higher sweating rate than does β-adrenergic stimulation. α-Adrenergic stimulation (by phenylephrine) is no more potent than isoproterenol (ISO) (a β-adrenergic agonist) in humans in vivo.[21] Whereas cholinergic sweating begins immediately on intradermal injection, β-adrenergic sweating requires a latent period of from 1 to 2 minutes, which suggests that the intracellular mechanism of sweat induction may be different for methacholine and for ISO. Because the sweat rate in response to adrenergic agents is rather low, it may be reasonable to surmise that adrenergic stimulation in periglandular nerves may be involved in the regulation of sweat gland function but not in the induction of sweat secretion. One consequence of dual cholinergic and adrenergic innervation is to maximize tissue accumulation of cyclic adenosine monophosphate, which may be instrumental in stimulating the synthesis of sweat and glandular hypertrophy of the sweat gland. The possibility that periglandular catecholamine is directly involved in emotional sweating or sweating associated with pheochromocytoma[22] may be ruled out, because these sweating responses can be blocked by anticholinergic agents.

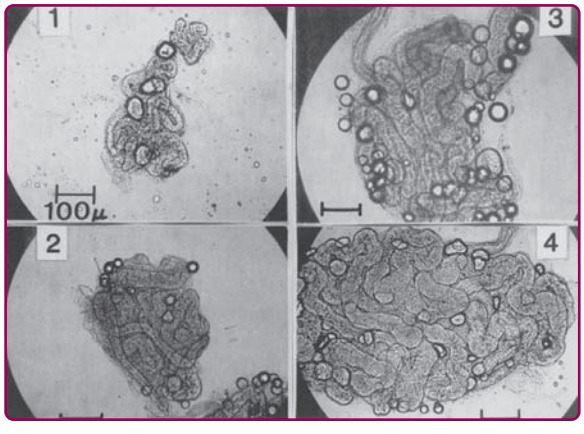

Figure 83-4 Individual variation in the size of the sweat gland in four male adults, aged 22–28 years. Sweat glands were isolated from skin biopsy specimens obtained from the upper back behind the axilla. Subject 1 is a sedentary man who does not exercise regularly, whereas subject 4 is a well-acclimatized athletic individual.

PHARMACOLOGY AND FUNCTION OF ECCRINE MYOEPITHELIUM

The periodicity of sweat secretion in vivo is caused by the periodicity of central nerve impulse discharges, which occur synchronously with vasomotor tonus waves. Myoepithelial contraction occurs with cholinergic stimulation, but neither α- nor β-adrenergic agents induce tubular contraction.[23] While the myoepithelium may contribute to sweat production via pulsatile contractions, it also seems to provide structural support for the secretory epithelium, especially under conditions in which stagnation of sweat flow (due to ductal blockade) results in an increase in luminal hydrostatic pressure.[8]

ENERGY METABOLISM

Sweat secretion is mediated by the energy (i.e., ATP)-dependent active transport of ions, so a continuous supply of metabolic energy is mandatory for sustained sweat secretion. Endogenous glycogen stored in the clear cells can sustain sweat secretion for less than 10 minutes; thus the sweat gland must depend almost exclusively on exogenous substrates for its energy metabolism. Mannose, lactate, and pyruvate are used nearly as readily as glucose; other hexoses, fatty acids, ketone bodies, intermediates of the tricarboxylic acid cycle, and amino acids are either very poorly used or not used as substrates. The physiologic significance of lactate or pyruvate utilization by the sweat gland is not yet clear. However, because the plasma level of glucose (5.5 mM) is much higher than that of lactate (1–2 mM) or pyruvate (less than 1 mM), glucose may play a major role in sweat secretion. Oxidative metabolism of glucose is favored as the major route of ATP formation for secretory activity.[23]

COMPOSITION OF HUMAN ECCRINE SWEAT

INORGANIC IONS. Sweat is formed in two steps: (1) secretion of a primary fluid containing nearly isotonic NaCl concentrations by the secretory coil, and

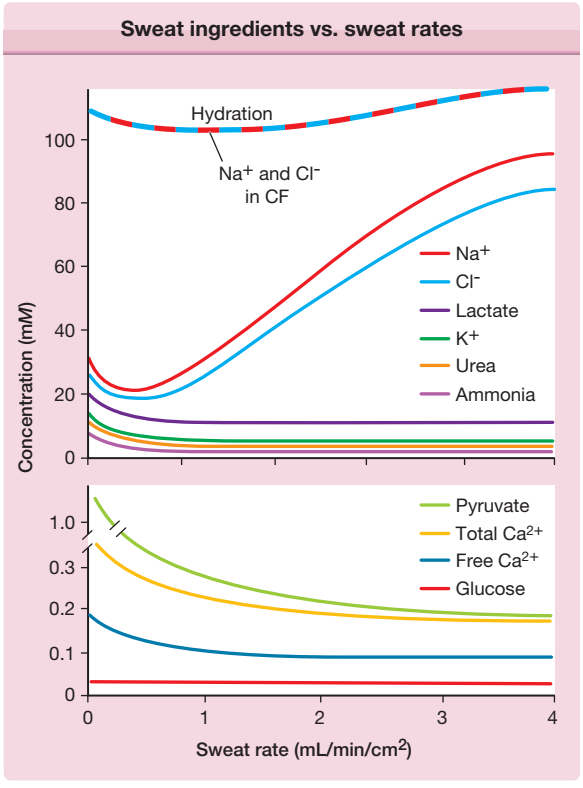

Figure 83-5 Relationship between the concentration of sweat ingredients and the sweat rate in thermally induced human sweat in normal individuals and in persons with cystic fibrosis (CF).

(2) reabsorption of NaCl from the primary fluid by the duct. Although a number of factors affect ductal NaCl absorption, the sweat rate (and thus the transit time of sweat) has the most important influence on final NaCl concentration. Sweat NaCl concentration increases with increasing sweat rate to plateau at around 100 mM (Fig. 83-5). Potassium (K^+) concentration in sweat is relatively constant. It ranges from 5 to 10 mM, which is slightly higher than plasma K^+ concentration. HCO_3^- concentration in the primary sweat fluid is approximately 10 mM, but that of final sweat is less than 1 mM, which indicates that HCO_3^- is reabsorbed by the duct, presumably accompanied by ductal acidification.[24] Sweat NaCl concentration is increased in individuals with cystic fibrosis. Aquagenic wrinkling of the palms (whitened, wrinkling, and papillation of the palms after brief water exposure) is seen more frequently in carriers and patients with cystic fibrosis (see Chapter 84).

LACTATE. The concentration of lactate in sweat usually depends on the sweat rate. At low sweat rates, lactate concentration is as high as 30–40 mM, but it rapidly drops to a plateau at around 10–15 mM as the sweat rate increases. Acclimatization is known to lower sweat lactate concentrations, whereas arterial occlusion rapidly raises sweat NaCl and lactate concentrations and reduces the sweat rate.[23] Sweat lactate is probably produced by glycolysis of glucose by the secretory cells.[25]

UREA. Urea in sweat is derived mostly from serum urea.[26] Sweat urea content is usually expressed as a sweat–plasma ratio (S/P urea). S/P urea is high (2–4) at a low sweat rate range but approaches a plateau at 1.2–1.5 as the sweat rate increases.

AMMONIA AND AMINO ACIDS. Ammonia concentration in sweat is 0.5–8 mM,[27] which is 20–50 times higher than the plasma ammonia level. The concentration of sweat ammonia is inversely related to the sweat rate and sweat pH. Free amino acids are present in human sweat,[27] although it is not clear what proportion of measured amino acids derive from epidermal contamination.

PROTEINS INCLUDING PROTEASES. The concentration of sweat protein in the least contaminated, thermally induced sweat is approximately 20 mg/dL, with the major portion being low-molecular-weight proteins (i.e., MW <10,000). Because sweat samples collected by simple scraping, and even those collected with a plastic bag, can be massively contaminated with plasma or epidermal proteins, previous reports on the presence of α- and γ-globulins, transferrin, ceruloplasmin, orosomucoid, and albumin[28,29] and immunoglobulin E must be carefully reexamined. The sweat samples collected over an oil barrier placed on the skin (the least-contaminated sweat) contain no or trace of γ-globulin and a very small amount of albumin. Yokozeki et al[30] also reported the presence of cysteine proteinases and their endogenous inhibitors in sweat and the sweat gland. Dermcidin is an antimicrobial peptide produced and secreted in sweat.[31] Other organic compounds reported to be present in sweat include histamine,[32] prostaglandin,[33] and vitamin K-like substances.[34] Sweat also contains traces of pyruvate and glucose. Sweat glucose increases concurrently with a rise in plasma glucose level. Some orally ingested drugs, including griseofulvin,[35] ketoconazole,[36] amphetamines,[37] and various chemotherapeutic agents,[38] are secreted in sweat.

MECHANISMS OF SWEAT SECRETION

Several distinct sequential processes lead to eccrine gland sweat production[39]: (1) stimulation of the eccrine sweat gland by ACh via increased intra cellular Ca^{2+}; (2) Ca^{2+}-stimulated loss of cellular K^+, Cl^-, and H_2O, which leads to eccrine gland cell shrinkage; and (3) volume-activated transcellular plus paracellular fluxes of Na^+, Cl^-, and H_2O, which leads to net flux of largely isotonic NaCl solution into the glandular lumen. These processes are illustrated in Fig. 83-6.

Sweating initially is stimulated when ACh is released from periglandular cholinergic nerve endings in response to thermal or emotional stimuli. ACh binds to cholinergic receptors on the clear cell plasma membrane, stimulating intracellular Ca^{2+} release and influx, and increasing cytosolic Ca^{2+} concentrations. Increased intracellular Ca^{2+}, in turn, opens Ca^{2+}-sensitive Cl^- and K^+ channels in the clear cell basolateral membrane, which allows Cl^- and K^+ to escape. Because H_2O follows K^+ and Cl^-, to maintain cell iso-osmolarity, the cell shrinks.[39,40]

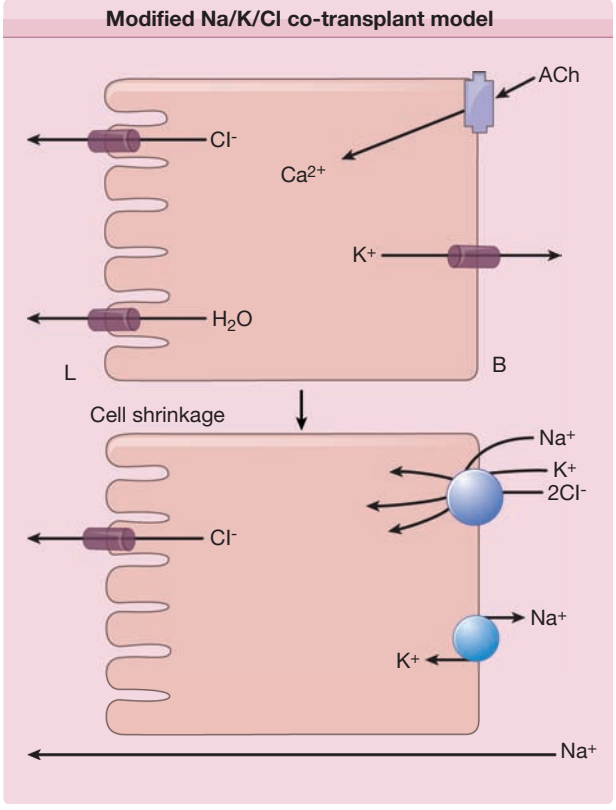

Figure 83-6 Modified Na/K/2Cl cotransport model for the ionic mechanism of cholinergic eccrine sweat secretion. Periglandular neurotransmitters, such as acetylcholine (ACh), bind to receptors on the basolateral membrane, which leads to increased intracellular Ca^{2+}; this in turn activates K^+ and Cl^- channels, mediating K^+, Cl^-, and H_2O efflux from the cell. The resulting cell shrinkage activates the basolateral $Na^+/K^+/2Cl$ antiporter, which leads to Na^+, K^+, and Cl^- influx. The Na^+ and K^+ fluxes are recycled across the basolateral membrane by the Na^+, K^+-adenosine triphosphatase. In contrast, Cl^- fluxes flow unopposed into the lumen, causing an electrical gradient that drives Na^+ exit from the tissue into the lumen via a paracellular pathway. Net fluxes: H_2O, Cl^-, and Na^+ (isotonic) flow into the lumen. pH of the secreted fluid is neutral. Paracellular Na^+ fluxes across the cell junction are indicated with an arrow at the bottom of the figure. B = basolateral membrane; L = luminal or apical membrane; arrows = conductive flux of ions through ionic channels.

This decrease in cell volume sets off a second cascade of cell signaling events. First, decreased cell volume stimulates the NKCC1[41] class of Na/K/2Cl cotransporters, which carry Na^+, K^+, and $2Cl^-$ into the cell in an electrically neutral fashion (i.e., two cations and two anions cancel out net charges). The resulting increase in cytosolic Na^+ activates the Na^+, K^+-ATPase, located in the basolateral membrane, which recycles Na^+ and K^+ across the basolateral membrane. The net movement of the negatively charged Cl^- ion across the apical membrane into the lumen in turn drives the positively charged Na^+ ion into the lumen as well, along a paracellular pathway. Therefore, the final product of glandular secretion is the net movement of Na^+, Cl^-, and H_2O into the glandular lumen to form the isotonic NaCl precursor of sweat.

ACh-induced sweating, which constitutes the bulk of sweat production, appears to be mediated by intracellular Ca^{2+}, as detailed earlier. In contrast, adrenergic-induced sweating appears to be mediated by increased intracellular cyclic adenosine monophosphate.[41]

MECHANISM OF DUCTAL REABSORPTION

Because the production of large sweat volumes could lead to dangerous losses of NaCl, the sweat duct has evolved to reabsorb NaCl, which minimizes electrolyte loss, even at high sweat volumes (Fig. 83-7).

Ductal Na^+ reabsorption is accomplished through the coordinated activities of intracellular enzymes and plasma membrane ion channels, pumps, and exchangers. These mechanisms not only reabsorb electrolytes but also acidify the sweat, which results in a final sweat product that is hypotonic and acidic. Na^+ reenters the duct cells through the apical membrane via amiloride-sensitive[42] epithelial Na^+ channels (ENaC)[42] and is transported across the basolateral membrane by ouabain-sensitive[10] Na^+, K^+-ATPase pumps. Cl^- transport appears to be both transcellular and paracellular, with the cystic fibrosis transmembrane regulator (CFTR) Cl^- channels playing an important role in transcellular fluxes.[43] In cystic fibrosis, CFTR Cl^- channels are mutated, and eccrine duct Cl^- reabsorption is defective, although not completely abolished.[24] Na^+ is increased in the duct and the sweat at the skin surface.[44] Unlike in the lung, CFTR mutations do not lead to increased ENaC-mediated Na^+ influx, which suggests that the CFTR–ENaC interactions seen in other tissues differ from that in the eccrine duct. Sweat acidification appears to be mediated via the enzyme carbonic anhydrase, the HCO_3^-/Cl and Na^+/H^+ exchangers, and the V-type H^+ ATPase. The intracellular enzyme carbonic anhydrase catalyzes HCO_3^- and H^+ production. Intracellular HCO_3^- is cleared via the HCO_3^-/Cl antiporter, whereas H^+ is pumped into the luminal sweat by the V-type H^+ ATPase.[45] The Na^+/H^+ antiporter NHE1 (Na^+/H^+ exchanger isoform 1)[44,46] found in the basolateral membrane, is important in intracellular pH regulation.

Several drugs are known to modify ductal NaCl reabsorption. When aldosterone is injected systemically or locally, the Na/K ratio in sweat begins to decrease within 6 hours, reaching a nadir at 24 hours and returning to the preinjection level in 48–72 hours.[44] Na^+ deprivation stimulates both renin and aldosterone secretion, but high thermal stress per se [a single 1-hour exposure of humans to a temperature of 40°C (104°F)] is a potent stimulator of renin and aldosterone secretion in either the presence or absence of sodium deprivation. In an in vitro sweat gland preparation, neither acetazolamide (a carbonic anhydrase inhibitor) nor antidiuretic hormone changed ductal or secretory function. However, more potent carbonic anhydrase inhibitors, such as topiramate,[47] have been reported to induce oligohidrosis.

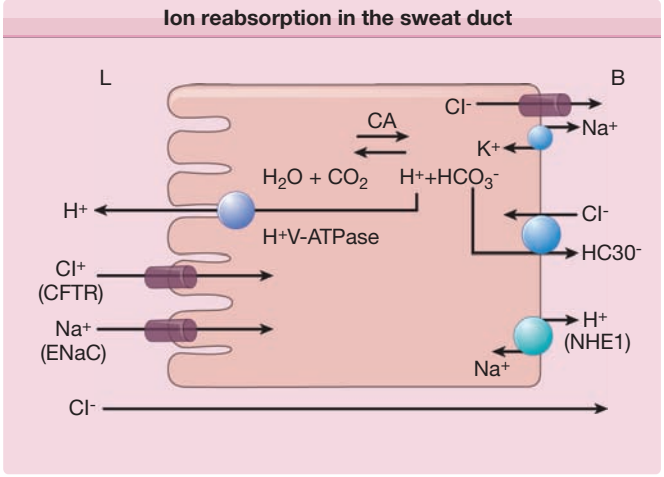

Figure 83-7 Illustration of ion reabsorption in the sweat duct. Na^+ enters the apical (luminal) membrane through epithelial Na^+ channels (ENaC) and is transported across the basolateral membrane by Na^+, K^+-adenosine triphosphatase (ATPase). Cl^- enters the cell through the cystic fibrosis transmembrane regulator Cl^- channel (CFTR) and also is transported across the lumen via a paracellular pathway. H^+ generated by the enzyme carbonic anhydrase (CA) is pumped into the lumen by a V-type H^+ ATPase (H^+ V-ATPase). Intracellular pH homeostasis is maintained by parallel HCO_3^-/H^+ and Na^+/H^+ (NHE1) exchangers. The activity of these enzymes, transporters, and channels results in H^+ secretion and Na^+ and Cl^- reabsorption, which produces a final sweat that is hypotonic and acidic. Paracellular Cl^- fluxes across the cell junction are indicated with an arrow at the bottom of the figure. B = basolateral membrane; L = luminal or apical membrane; arrows = conductive flux of ions through ionic channels.

APOCRINE SWEAT GLAND

In addition to the eccrine sweat glands, described earlier, apocrine sweat glands are found in humans, largely confined to the regions of the axillae and perineum.[48] They do not become functional until just before puberty; thus, it is assumed that their development is associated with the hormonal changes at puberty, although the exact hormones have not been identified.

ANATOMY

Apocrine glands are coiled and localized in the subcutaneous fat near the dermis. The gland consists of a single layer of cuboidal or columnar cells. These secretory cells rest on a layer of myoepithelial cells.[49] The duct is composed of a double layer of cuboidal cells, and empties into hair follicle infundibulum.

Like the eccrine gland, the myoepithelium fulfills dual functions in both providing structural support and pumping out preformed sweat.

β-adrenergic receptors and purinergic receptors have been identified on apocrine glands. However, nerve fibers and muscarinc receptors have not been identified, suggesting that any cholinergic stimulation acts humorally.[50]

FUNCTIONS

A number of functions have been attributed to the apocrine glands, including roles as odoriferous sexual attractants, territorial markers, and warning signals. These glands play a role in increasing frictional resistance and tactile sensibility as well as in increasing evaporative heat loss in some species. The production of pheromones by the apocrine glands of many species is well established.[51]

Because the apocrine glands of humans do not begin to function until puberty and are odor producing, it is attractive to speculate that they have some sexual function, which may now be vestigial. There are high levels of 15-lipoxygenase-2 in the secretory cells of the apocrine gland. Its product, 15-hydroxyeicosatetraenoic, a ligand for the nuclear receptor peroxisome proliferator-activated receptor-γ, may function as a signaling molecule and in secretion or differentiation.[51] For nonhuman furred primates, apocrine glands may have a purpose in thermoregulation as well.

COMPOSITION OF SECRETION

When it is first secreted, the apocrine sweat of humans is milky, viscid, and without odor. Apocrine sweat contains three types of precursors: fatty acids, sulfanyl alkanols and odiferous steroids, which are converted by bacteria on axillary skin, particularly corynebacterium striatum, into odiferous substances. Secretion of amino acid and steroid precursors is controlled by an ATP-dependent efflux pump multidrug resistance protein 8 (MRP8), encoded by the gene *ABCC11*, which is expressed in apocrine sweat glands. Axillary odor is significantly reduced in Asian populations that carry a single nucleotide polymorphism (SNP) in this gene, which also affects earwax characteristics.[52]

MODE OF SECRETION

Apocrine (decapitation), holocrine and merocrine types of secretion have been reported in apocrine glands. Cannulation of the duct of the human apocrine sweat gland has shown that secretion is pulsatile, and it is assumed that contractions of the myoepithelial cells surrounding the secretory cells are responsible for these pulsations.[53]

CONTROL OF SECRETION

The apocrine sweat glands of humans respond to emotive stimuli only after puberty. They can be stimulated by either epinephrine or norepinephrine given locally or systemically. Studies have shown that the apocrine glands are controlled mainly by adrenergic agonists[52]; although some cholinergic control also has been reported.[49,54] This is in contrast to the eccrine glands, which are under cholinergic control.

Although an intact nerve supply is a functional requirement of apocrine sweating, the demonstration of nerve endings or varicosities in close proximity to the glands has been difficult.[49,55] Local capillary circulation likely assists in conveying transmitter substance to the sweat gland cells, a form of neurohumoral transmission.

As would be expected, drugs that affect adrenergic systems also have an effect on apocrine sweat glands. Adrenergic neuron-blocking agents inhibit sweating, as do drugs that deplete the stores of transmitter substance in adrenergic neurons. Drugs that block specific adrenergic receptors also inhibit sweating, but the types of receptors that must be blocked differ in various species. The type of receptor that mediates the response of the apocrine glands of humans has not been elucidated.

Chapter 84 :: Disorders of the Eccrine Sweat Glands and Sweating

:: Robert D. Fealey & Adelaide A. Hebert

HYPERHIDROSIS AND ANHIDROSIS AT A GLANCE

- Primary focal (essential) hyperhidrosis:
  - Affects over 6 million young people worldwide.
  - Excessive palmar sweating affects quality of life.
  - Effective treatments (stratified to match the severity) include topical agents, iontophoresis, oral anticholinergics, and botulinum toxin.
  - Endoscopic thoracic sympathetic surgery is a last-line choice for severe hyperhidrosis.
- Localized, large areas of hyperhidrosis may be compensatory.
  - Clue to loss of sweating elsewhere.
  - Determine location of sudomotor lesion and underlying cause by thermoregulatory sweat testing combined with direct and axon reflex sweat evaluation.
- Patterns of anhidrosis provide objective evidence of small nerve fiber and/or eccrine gland involvement in many neurologic and dermatologic disorders.
- Analysis of sweat composition continues to be diagnostic in cystic fibrosis.
- Determination of sweat-derived antimicrobial peptides may provide evidence of impaired innate defense in skin disorders such as atopic dermatitis and neutrophilic eccrine hidradenitis.

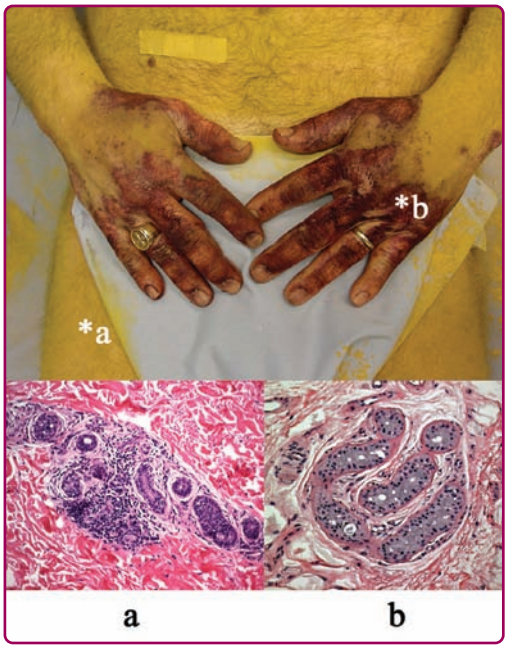

Figure 84-1 A patient with an acquired idiopathic anhidrosis shows anhidrotic (*yellow*) and sweating (*purple*) staining of sodium alizarin sulfonate (alizarin Red S) indicator powder. Punch skin biopsy from an anhidrotic skin site (a) shows marked perieccrine lymphocytic infiltration of sweat gland secretory coils, whereas sweating skin (b) shows normal sweat gland morphology. The presence of perieccrine inflammation prompted immunomodulatory therapy with corticosteroids and pulsed methotrexate and a trial of topical tacrolimus.

Disorders of eccrine sweating can occur for many different reasons, including dysfunction of the thermoregulatory centers in the brain's central autonomic network, changes in the spinal sympathetic preganglionic, ganglionic, or postganglionic neurons/axons or in the muscarinic (M3) cholinergic synapse on sweat glands. Abnormalities of eccrine sweat formation by the secretory coil and sweat ductal cells may occur or ductal disruption or occlusion may develop, preventing delivery of sweat to the skin surface.

A review of the normal anatomy and physiology of eccrine sweat glands and sweating may be found in Chapter 83. This chapter focuses on neurologic and dermatologic disorders that cause focal or generalized abnormalities of sweating, highlighting an exciting interface where disorders are better understood, diagnosed, and treated based on recognition of the integrated function of nerves, skin, and the immune system (Fig. 84-1). There are a variety of techniques that can be used clinically and in research of sweating that are discussed online. Table 84-1 is a comprehensive table based on disorders with increased or decreased sweating—some diseases are discussed in this text–the others are discussed online. Many are disorders related to nervous system structural, functional and inherited disorders; therefore any patient with a sweating disorder should be evaluated carefully for internal medicine diseases and neurologically by consultants in some cases.

Figure 84-2 A patient with segmental anhidrosis (*yellow*) with compensatory left-sided hemihyperhidrosis (*purple*) due to a right greater than left-sided upper thoracic spinal cord injury (sodium alizarin sulfate indicator powder).

VISUAL EXAMINATION OF THE SKIN

The physical examination continues to be important in the diagnosis of sweating disorders. For example, the skin of an infant with cystic fibrosis is much saltier than infants without cystic fibrosis and when collected sweat is dried, it forms fern-like crystals. Infants with widespread sweat loss may present with "fever of unknown origin." Taking note of the beads of sweat on the palms and soles of a young adult goes a long way to making a diagnosis of primary focal (essential) hyperhidrosis. In uremia, the evaporation of sweat with high urea concentrations results in the deposition of urea on

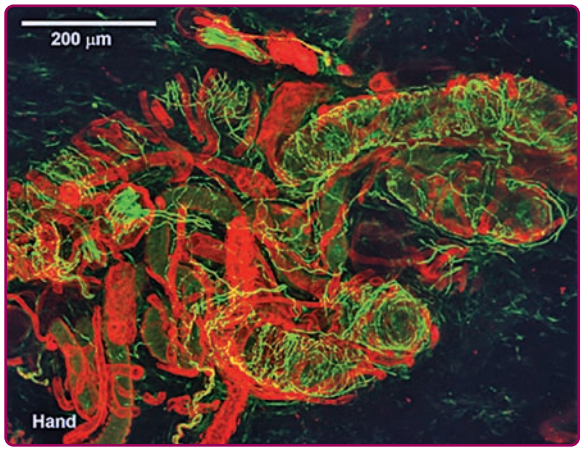

Figure 84-3 Secretory tubules, nerve fibers, and blood vessels in a normal human sweat gland fluorescently stained by immunohistochemical and lectin methods and visualized via laser scanning confocal microscope. Immunoreactive staining of nerves with protein gene product 9.5 antibody (*green staining*) shows axons wrapped around secretory tubules. TABLE 84-1
Classification of Disorders of Eccrine Sweating

Primary Focal (Essential) Hyperhidrosis
Palmoplantar, axillary, craniofacial, generalized hyperhidrosis

Secondary Causes of Focal Hyperhidrosis

Due to cerebral infarction
- Frontal opercular infarct
- Brainstem stroke

Associated with spinal cord injury
- Autonomic dysreflexia
- Posttraumatic syringomyelia
- Orthostatic hypotension triggered

Associated with other central nervous system disorders
- Chiari type I and II malformation
- Myelopathies due to infarction, syringomyelia, tumor
- Cold-induced sweating syndrome
- Olfactory hyperhidrosis

Associated with peripheral nervous system disorders
- Peripheral motor neuropathy with autonomic dysfunction
- Dermatomal or focal hyperhidrosis due to nerve trunk irritation
- Compensatory segmental hyperhidrosis (postsympathectomy, Ross syndrome, pure autonomic failure)
- *Gustatory sweating*
- *Physiologic*
- *Idiopathic*
- *Postherpetic*
- *Post nerve injury (postsurgical, diabetic autonomic neuropathy, postinfectious, tumor invasion)*
- Lacrimal sweating
- Harlequin syndrome
- Idiopathic, localized hyperhidrosis
- Idiopathic unilateral circumscribed hyperhidrosis
- Postmenopausal localized hyperhidrosis

Associated with local skin disorders
- Blue rubber bleb nevi
- Eccrine angiomatous hamartoma
- Tufted angioma
- Glomus tumor
- Burning feet syndrome
- Pachydermoperiostosis
- Granulosis rubra nasi
- Pretibial myxedema
- POEMS (polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes) syndrome

Secondary Causes of Generalized Hyperhidrosis

Associated with central nervous system disorders
- Episodic hypothermia with hyperhidrosis (Hines–Bannick or Shapiro syndrome)
- Posttraumatic or posthemorrhagic "diencephalic epilepsy"
- Fatal familial insomnia and Parkinson disease

Associated with fever and chronic infection
- Tuberculosis, malaria, brucellosis, endocarditis

Associated with metabolic and systemic medical diseases
- Hyperthyroidism, diabetes mellitus, hypoglycemia, hypercortisolism, acromegaly

Associated with malignancy
- Leukemia, lymphoma, pheochromocytoma, Castleman disease, carcinoids, renal cell cancer

Medication-induced
- See Table 84-3
- Neuroleptic malignant syndrome
- Serotonin syndrome, other medications

Toxic syndromes
- Alcohol, opioid withdrawal, delirium tremens

Associated with central and peripheral nervous system disorders
- Familial dysautonomia (Riley–Day), Morvan fibrillary chorea

Primary Autonomic Disorders with Acquired Anhidrosis

Isolated sudomotor disorders
- Progressive isolated segmental anhidrosis
- Idiopathic pure sudomotor failure
- Chronic idiopathic anhidrosis

Sudomotor plus other autonomic disorders
- Ross syndrome
- Pure autonomic failure
- Autoimmune autonomic neuropathy

Secondary Autonomic Disorders Associated with Anhidrosis

Central nervous system lesions (stroke, tumor, infection, infiltration, trauma, etc.)
- Hypothalamic lesions
- Brainstem lesions
- Spinal cord lesions

Degenerative disorders
- Multiple system atrophy, dementia with Lewy body disease, Parkinson disease—autonomic failure

Peripheral Nerve Lesions Causing Anhidrosis
- Hereditary sensory and autonomic neuropathy types I, II, IV (congenital insensitivity to pain with anhidrosis)
- Guillain–Barré syndrome (acute inflammatory demyelinating polyneuropathy)
- Diabetic autonomic neuropathy
- Amyloidosis
- Lepromatous neuropathy
- Lambert–Eaton myasthenic syndrome
- Alcoholic neuropathy
- Fabry disease
- Idiopathic small-fiber neuropathy
- Erythromelalgia
- Sympathectomy and other surgical lesions
- Harlequin syndrome

Anhidrosis due to toxins, pharmacologic agents and heat exposure
- *Botulism*
- Ganglionic blockers, anticholinergics, carbonic anhydrase inhibitors
- Opioids
- Heat hyperpyrexia and heat stroke

Anhidrosis Associated with Diseases of Skin and Sweat Glands

Anhidrosis due to physical agents damaging skin
- Trauma, burns, pressure, scar formation, radiation therapy

Anhidrosis due to congenital and acquired skin diseases
- Fabry and other congenital metabolic diseases
- Congenital ectodermal dysplasia
- Ichthyosis
- Neutrophilic eccrine hidradenitis
- Sjögren syndrome
- Systemic sclerosis (scleroderma)
- Incontinentia pigmenti
- Segmental vitiligo
- Bazex–Dupre–Christol syndrome

Disorders affecting the sweat duct
- Miliaria
- Palmoplantar pustulosis
- Psoriasis
- Lichen planus
- Atopic dermatitis

Disorders with abnormal sweat composition
- Atopic dermatitis (reduced dermcidin levels)
- Cystic fibrosis (increased chloride concentration)

the skin, referred to as *uremic frost*. Patients with craniofacial hyperhidrosis may develop a darkened hue to their skin known as *chromhidrosis*. Focal or segmental compensatory hyperhidrosis may be apparent on examination. Dry, atrophic skin may be seen in areas affected by small-fiber neuropathy. Disorders affecting the sweat duct (miliaria or psoriasis, for example) are often diagnosed via visual inspection of the skin.

DISORDERS OF SWEATING

Table 84-1 organizes disorders of sweating into the six categories discussed in this chapter.

PRIMARY FOCAL (ESSENTIAL) HYPERHIDROSIS

CLINICAL MANIFESTATIONS AND PATHOMECHANISM

Primary focal (essential) hyperhidrosis is one of the most common disorders of eccrine sweating.[16] This condition is defined as focal visible, excessive sweating of at least 6-months' duration without apparent cause with at least two of the following characteristics: (1) bilateral and relatively symmetric sweating; (2) the sweating impairs daily activities; (3) a frequency of at least one episode per week; (4) an age of onset before the age of 25 years; (5) a positive family history; (6) cessation of sweating during sleep.[17] A national survey estimated that hyperhidrosis affects 2.8% of the US population, and that half of those affected experience excessive sweating of the axillae.[18] Hyperhidrosis of the palms, soles, axillae, and, to a lesser extent, craniofacial and groin regions may occur at any time irrespective of temperature, stress, or pleasure. Primary focal hyperhidrosis does not manifest when the patient undergoes general anesthesia and augmentation with thermal stimuli and physical exertion is not uncommon. Sweating may be continuous or phasic; when continuous, sweating is most troublesome in summer. Phasic outbursts with minor emotional activity are similar year round.

Severe primary focal hyperhidrosis interferes with many activities of daily living and patients report a reduced quality of life[19] Avoiding a handshake can lead to professional embarrassment, and avoidance of touch can lead to social or interpersonal seclusion and other symptoms of social anxiety disorder. Symptoms begin in childhood or around puberty and affect either sex equally. A family history is present in approximately one-fourth of patients. The disorder persists for years with occasional spontaneous improvement after 35 years of age.

The central autonomic network control of emotional sweating is distinct from the preoptic-anterior hypothalamic controller of thermoregulatory sweating. The anterior cingulate cortex, which orchestrates the sweat response from the palms and soles, may modulate hypothalamic output inappropriately. These patients have less reflex bradycardia than control subjects in response to the Valsalva maneuver or facial immersion, but a higher degree of cutaneous vasoconstriction in response to finger immersion in cold, suggesting that they have increased sympathetic outflow passing through the T2–T3 ganglia.[20] Ventilated capsule recordings of palmar sweating provide further evidence of emotionally triggered, centrally derived sweat output. Such sweating is augmented at rest, bilaterally synchronous, and pulsatile (eFig. 84-3.1 in online edition).

The severity of primary focal hyperhidrosis ranges from intermittent, slightly moist palms and soles to daily sweat drippage from hands and feet, requiring the frequent use of towels.

TREATMENT

Treatment involves determining the severity and distribution of the disorder, ruling out other causes of hyperhidrosis, and selecting a modality of therapy appropriate to age of the patient and severity of the disorder. Some current treatment methods are shown in Box 84-1. Treatment begins with discussing the nature of the disorder and discerning patient wishes and expectations. Mild cases of axillary and palmar sweating are controlled via topical application of aluminum chloride hexahydrate or glycopyrrolate, an anticholinergic agent. Care should be taken to have the aluminum chloride applied to completely dry skin as use of the agent on moist skin can result in the formation of a weak hydrochloric acid that can result in discomfort, and burning and peeling of the skin surface. This irritation can be managed by cessation of therapy for a few days and the use of a class VII topical steroid cream. Oral glycopyrrolate, oral or transdermal clonidine, transdermal scopolamine, or oral topiramate[21] can be administered if topical agents alone are not helpful or are too irritating. Control of palmar-plantar sweating is sometimes possible using tap water (or a solution of glycopyrrolate) iontophoresis. Intradermal injection of botulinum toxin (BTX), (onabotulinumtoxinA) is appropriate for treatment of focal areas, such as axillae, palms of hands, soles of feet and groin, and is effective for 2–8 months per treatment.[22] Facial hyperhidrosis can be treated with oral or topical[23] glycopyrrolate.

Immunohistochemical studies show sweat glands appear structurally normal in hyperhidrotic patients before BTX therapy, whereas after therapy the luminal area of the gland and protein gene product 9.5 (neural marker) staining is diminished. This suggests that BTX therapy induces long-standing functional denervation of the sweat glands. However, growth-associated protein 43, indicative of axonal sprouting, is increased, suggesting reinnervation may eventually take place.[24]

Repeat BTX injections do not demonstrate a diminished duration of efficacy.[25] Pain with palmar botulinum injections is common and several techniques are in use to minimize this.[26,27] Iontophoresis of BTX in solution has been successfully tried with better control

BOX 84-1 TREATMENTS FOR HYPERHIDROSIS

TYPE OF HYPERHIDROSIS	TREATMENT	FORMULATION	ROUTE OF ADMINISTRATION AND DOSAGE
Craniofacial, gustatory	Glycopyrrolate	0.5%–2% Vanicream base or roll-on lotion; 1- to 2-mg tablet	Topical, once to twice daily. Tablet started at 1 mg bid; increase prn up to 2 mg three to four times daily.
	Clonidine	0.1-mg tablet, 0.1–0.3 mg/day, transdermal patch	Oral incremental increases up to 0.6–1.2 mg/day in two or three divided doses; 0.1 mg/day patch first week increased weekly up to two 0.3 mg/day patches.
Craniofacial, gustatory Paroxysmal localized	Donnatal extend tab	Phenobarbital, USP (3/4 gr.) 48.6 mg Hyoscyamine Sulfate, USP 0.3111 mg Atropine Sulfate, USP 0.0582 mg Scopolamine Hydrobromide, USP 0.0195 mg	One tablet orally every 12 hr.
	Topiramate	25-mg tablet	Begin 25 mg twice daily; increase each dose weekly by 25 mg up to 100–200 mg daily in two divided doses.
Axillary, palmar-plantar, craniofacial	Aluminum chloride	20% aluminum chloride in anhydrous ethyl alcohol; 12% aluminum chloride in sodium carbonate water	Topically, nightly, until desired sweat reduction achieved. Then taper to once weekly; follow *Physicians' Desk Reference* directions carefully for each body region to maximize effect and minimize skin irritation.
Axillary	Over the counter clinical strength antiperspirant	Aluminum Zirconium Trichlorohydrex Gly 20% anhydrous	Apply to axillae twice a day
Palmar–plantar	Iontophoresis unit	Patient-controlled current, 15–30 mA using tap water; glycopyrrolate can be added, making a 0.1% solution	Immerse hands, feet for 30 min once or twice daily, or 20 min at each site every 2–3 days, or 10 min at each site three to five times weekly; anode site is most effective so switch sides after one-half of each treatment; direct current more effective, but AC current less painful and may be used part of time; glycopyrrolate solution enhances effect. Most modern iontophoresis unit do not require switching of anodes.
Palmar–plantar, axillary, gustatory, recalcitrant	Botulinum toxin A injection	2–5 units of botulinum toxin	Given via high intradermal injections to ~1 cm^2 iced/anesthetized skin areas; for botulinum toxin A, total of 12–20 injections (50 units total) given per axilla, 50–75 injections in the palm/each foot; benefit lasts 2–8 months; reinjection is effective.
	Glycopyrrolate	1- to 2-mg tablet	Tablet started at 1 mg bid; increase 1 mg each week as tolerated up to 2 mg three to four times daily.
Axillary	Local incision	Liposuction and curettage of sweat glands in dermis	Define area of involvement with starch-iodide Minor test or equivalent; small incisions with sharp suction-curettage cannula; usually permanent, 40%–70% reduction in sweating achieved.
Palmar, axillary; documented severely affected cases resistant to other treatment modalities	Sympathetic surgery	Various procedures affecting the T2, T3, and/or T4 sympathetic ganglia and connections	Invasive, video-assisted endoscopic thoracic procedure preferred; intraoperative monitoring of hand/finger skin blood flow/temperature suggested; sympathotomy (disconnection of sympathetic chain between T2 and stellate ganglia done to minimize compensatory hyperhidrosis; selective T3 sympathectomy may have less compensatory hyperhidrosis; T2–T4 sympathectomy done for axillary hyperhidrosis has high incidence of compensatory hyperhidrosis on trunk and gustatory hyperhidrosis.

of sweating than with water alone.[28,29] However, the cost effectiveness of this has been questioned.

Only the most severe cases of palmar hyperhidrosis not responding to conservative treatment may be considered for surgical management. Many patients have been successfully treated with endoscopic, upper thoracic sympathectomy[30] (eFig. 84-3.2 in online edition); however, the best procedure to use is still being investigated.[10,30–36] These surgical procedures carry the risk of creating minor to severe compensatory hyperhidrosis in body segments below the treated area (see eFig. 84-3.3 in online edition) as well as much less common surgical complications of wound infection, Horner's syndrome, pneumo- or hemothorax, and atelectasis. Long-term surveys of patients having undergone thoracic sympathectomy for treatment of palmar hyperhidrosis have illustrated that many patients wish they had not undergone the procedure due to the compensatory sweating that developed after the surgery.[37,38]

Another surgical option for axillary hyperhidrosis is tumescent suction curettage, which is performed in an outpatient setting. In one limited study of 63 subjects, greater than 75% were still satisfied with their reduction in sweating 2 years after treatment.[39]

(Secondary causes of localized hyperhidrosis are discussed online only.)

SECONDARY CAUSES OF LOCALIZED HYPERHIDROSIS

GUSTATORY SWEATING

Localized sweating on lips, forehead, scalp, and nose while eating hot and spicy foods occurs physiologically in many people via a trigeminovascular reflex. Pathologic gustatory hyperhidrosis is asymmetric, intense, and may produce patches of sweating on the trunk and even extremities. The cause is aberrant regeneration of damaged and undamaged facial parasympathetic fibers, destined for salivary glands, which instead supply facial sweat glands that have been sympathetically denervated. Thus, gustatory stimuli that previously caused parotid, salivary gland, or gastric secretion now also cause sweating in the distribution of the damaged sympathetic nerve. The most common occurrence is in Frey syndrome, in which sweating occurs in the distribution of the auriculotemporal nerve after an injury, abscess, or surgery in the parotid region.[50] Frey syndrome can be seen in infants and children, often following birth trauma with forcep delivery, but two cases of familial, bilateral Frey syndrome without birth trauma have also been reported.[51] Gustatory sweating may follow upper thoracic and cervical sympathectomy,[50,52–54] facial herpes zoster, or chorda tympani injury and has been reported in cluster headache, diabetic neuropathy,[55–57] encephalitis, syringomyelia, and invasion of the cervical sympathetic trunk by a tumor.[58] The exact distribution can be delineated with indicator powder on the face, neck, and upper trunk while the subject chews and is photographed. Treatment with topical scopolamine, clonidine,[53] glycopyrrolate,[59,60] aluminum chloride, or BTX injection[61,62] can be effective; rarely, intracranial section of the glossopharyngeal nerve or tympanic neurectomy is needed.

FEVER AND CHRONIC INFECTION

Malaria, tuberculosis, brucellosis, and subacute bacterial endocarditis may present with fever and generalized hyperhidrosis due to exogenous bacterial pyrogens that stimulate phagocytic leukocytes to produce endogenous pyrogen [interleukin 1 (IL-1) and IL-6, tumor necrosis factor (TNF), and γ-interferon]. These cytokines act not only as circulating hormones, but also as intrinsic modulators in the brain. Signals that stimulate IL-1 production in the brain include humoral factors, such as circulating IL-6 and activation of peripheral C fibers and vagal afferents. These effects can raise "set-point" temperature (producing fever), while simultaneously activating antipyretic mechanisms (eventually producing drenching sweats).[75]

METABOLIC AND SYSTEMIC MEDICAL PROBLEMS

Increased sweating has been reported in diabetes mellitus, hypoglycemia, congestive heart failure, thyrotoxicosis, hyperpituitarism, dumping syndrome, carcinoid syndrome, and alcohol and drug withdrawal. Sweating is increased (especially in males) in acromegaly (in which the size of sweat gland acini and the density of innervation to the sweat glands is greater than in controls) and is decreased in growth hormone deficiency (GHD).

Some studies of GHD pre- and posttreatment, using histochemistry for acetylcholinesterase and immunohistochemistry for the neuropeptide vasoactive intestinal polypeptide and protein gene product 9.5, a general neural marker, have shown increased sweat gland acinar size and periacinar innervation and pilocarpine iontophoresis sweat rate after GH therapy. However, other studies have shown that even treated GHD subjects still sweat less than controls implying permanent eccrine gland hypofunction and androgen deficiency as a cofactor of reduced sweating.

HYPERHIDROSIS AND MALIGNANCY

Hodgkin disease is characterized by the triad of fever, sweating, and weight loss; night sweats may be the only symptom and 31 of 100 patients present with "B"-cell symptoms (fever, weight loss, sweating).[76] The excessive production of IL-1 by activated macrophages is implicated as the cause of temperature instability.[77] IL-1 is known to induce an abrupt increase in the synthesis of prostaglandin E_2 in the preoptic anterior hypothalamic region, causing an elevation of the temperature "set point." Excessive production of IL-6 by Hodgkin lymphoma cells[78] is also implicated as cause

of fever and subsequent night sweating. Advanced solid tumors may also cause sweating via immunologic mechanisms relating to TNF-α and effect of ILs on central thermoregulation.

The symptomatic triad of excessive and inappropriate paroxysmal sweating, tachycardia, and pounding headaches (associated with increased blood pressure) almost assures the diagnosis of pheochromocytoma as the cause of hyperhidrosis. Anti-α- and β-adrenergic therapy is a mainstay of this disorder, with a rare patient developing sweat gland necrosis during preoperative therapy.

GENERALIZED HYPERHIDROSIS DUE TO MEDICATIONS/TOXINS

Hyperhidrosis is frequently associated with serotonin (5-hydroxytryptamine) reuptake inhibitors, opioids, and sometimes with prostaglandin inhibitors (naproxen). The serotonin syndrome and the neuroleptic malignant syndrome include hyperthermia, labile blood pressure, hyperhidrosis, rigidity, agitation and confusion. The mechanisms may relate to 5-hydroxytryptamine (2A) and dopamine receptor antagonism. The hyperhidrosis that commonly occurs during acute and chronic administration of opioids is mainly due to stimulation of mast cell degranulation, resulting in the release of histamine.[79] Excessive sweating can occur in as much as 45% of patients taking methadone.[80] Hyperhidrosis is also a recognized side effect of transdermal fentanyl.[81] Sweating in combination with hypertension, nausea, and mydriasis characterizes acute opioid and alcohol withdrawal. Despite their well-recognized anticholinergic effects, tricyclic antidepressants occasionally cause hyperhidrosis due to their sympathomimetic effect. The presumed mechanism is inhibited reuptake of norepinephrine, leading to stimulation of peripheral adrenergic receptors and a generalized diaphoretic response. Cholinergic agonists such as pilocarpine and bethanechol and reversible cholinesterase inhibitors such as pyridostigmine can increase sweating directly or indirectly via activation of M3 cholinergic receptors on sweat glands. See Table 84-2 for an abbreviated listing by drug class, example, and mechanism of hyperhidrosis and Table 84-3 for a complete listing of medications reported to cause hyperhidrosis.

TABLE 84-2
Some Drugs that can Cause Hyperhidrosis

Class	Examples	Probable Mechanism
Anticholinesterases	Pyridostigmine	Cholinesterase inhibition
Antiglaucoma agents	Physostigmine Pilocarpine	Cholinesterase inhibition for physostigmine; muscarinic cholinergic agonism for pilocarpine
Bladder stimulants	Bethanechol	Muscarinic cholinergic agonist
Opioids	Fentanyl Hydrocodone Methadone Morphine Oxycodone	Histamine release; alteration of central thermoregulation
Serotonin-selective reuptake inhibitors	Citalopram Duloxetine Escitalopram Fluoxetine Fluvoxamine Mirtazapine Paroxetine Trazodone Venlafaxine	Serotonergic effect on hypothalamus or spinal cord
Sialogogues	Cevimeline Pilocarpine	Muscarinic cholinergic agonist
Tricyclic antidepressants	Amitriptyline Desipramine Doxepin Imipramine Nortriptyline Protriptyline	Norepinephrine reuptake inhibition with stimulation of peripheral adrenoreceptors

TABLE 84-3
Some Drugs that can Cause Hypohidrosis

Class	Common Examples	Mechanism
Anticholinergics	Glycopyrrolate Hyoscyamine Scopolamine Propantheline Dicyclomine Belladonna Atropine	Antimuscarinic effect
Antiepileptics	Topiramate Zonisamide Carbamazepine	Carbonic anhydrase inhibition for topiramate and zonisamide; central anticholinergic effect for carbamazepine
Antihistamines	Cyproheptadine Diphenhydramine Promethazine	Antimuscarinic effect
Antihypertensives	Clonidine	Central antiadrenergic effect
Antipsychotics and antiemetics	Chlorpromazine Clozapine Olanzapine Thioridazine Quetiapine	Antimuscarinic effect
Antivertigo	Meclizine Scopolamine	Antimuscarinic effect
Bladder antispasmodics	Darifenacin Oxybutynin Solifenacin Tolterodine	Antimuscarinic effect
Gastric antisecretory	Propantheline	Antimuscarinic effect
Muscle relaxants	Cyclobenzaprine Tizanidine	Uncertain, possibly inhibition of spinal excitatory interneurons; possible central and peripheral antimuscarinic effect
Neuromuscular paralytics	Botulinum toxins	Cleavage of synaptosomal-associated protein-25 (SNAP-25) inhibiting presynaptic release of Ach
Opioids	Fentanyl Hydrocodone Methadone Morphine Oxycodone	Elevation of hypothalamic set point; calcium channel antagonism
Tricyclic antidepressants	Amitriptyline Desipramine Doxepin Imipramine Nortriptyline Protriptyline	Antimuscarinic effect (marked for amitriptyline, doxepin; moderate for imipramine and protriptyline; low for nortriptyline)

ANHIDROSIS DUE TO TOXINS AND PHARMACOLOGIC AGENTS

BOTULINUM TOXIN. BTX type A (onabotulinumtoxinA) and B both exhibit a dose-responsive suppression of sweating when injected intra- and subcutaneously (see Chapter 255). This chemodenervation of sweat glands is caused by the structural architecture of BTX with its heavy chain binding to the nerve cell, and its light chain catalyzing the proteolysis of one of the three SNARE (soluble *N*-ethylmaleimide-sensitive factor-attachment protein receptor) proteins preventing vesicle membrane fusion and therefore the release of ACh and transmission of the nerve impulse. This unique property has made BTX (especially type A) very popular for the treatment of localized hyperhidrosis of the axilla and palms and skin areas affected by gustatory sweating. More widespread anhidrosis can occur with BTX as well as organophosphate ingestion as a consequence of bioterrorism.[114]

Figure 84-4 Thermoregulatory sweat test (*left inset*) in a patient with lepromatous leprosy. Note the well-defined anhidrotic areas of the extremities (*yellow*) with greater involvement distally in cooler body regions. The patient's skin (*right inset*) showed ill-defined, scaling, and erythematous to hyperpigmented patches. Patchy loss of pinprick sensation in the distal feet and toes was noted. Skin biopsy from the right forearm (*background photo*) shows numerous acidfast bacilli (*red staining*) in a background of lymphohistiocytic inflammation. (Fite, ×600.) (Fite stain and skin photo used with permission from the Mayo Clinic Department of Dermatology.)

PHARMACOLOGIC AGENTS. Many pharmacologic agents can cause anhidrosis, especially those that are anticholinergic and interfere with the binding of ACh at M3 muscarinic receptor on sweat glands. Blockade at the sympathetic ganglionic level can inhibit sweating and cause orthostatic hypotension. Recently, oligohidrosis in children has been reported in those taking the carbonic anhydrase (CAII) inhibitors zonisamide and topiramate and studies show reduction in axon reflex-mediated sweating compatible with an effect on the sweat gland. Such observations and the location of CAII in the secretory coil clear cells and at the apex of the ductal cells suggest that the formation of HCO_3^- and H^+ by CAII plays a significant role in sweat fluid secretion.[115,116]

μ-OPIOID AGONISTS. μ-Opioid agonists (e.g., morphine) tend to inhibit warm-sensitive neurons in the hypothalamus. This action raises the body's set-point temperature, allowing core temperature to rise substantially. This results in anhidrosis even in a hot environment. After opioid drug levels drop, set-point temperature drops below the elevated core temperature, producing profuse sweating.[79] Clonidine and α_2-adrenergic agonists can suppress sweating, probably by reducing norepinephrine's effect on hypothalamic thermoregulatory neurons. The drug can be effective in Shapiro syndrome, essential hyperhidrosis, and postmenopausal sweating.

HEAT HYPERPYREXIA AND HEAT STROKE

Heat hyperpyrexia and heat stroke are states of thermoregulatory failure of sudden onset that are characterized by general anhidrosis, hyperpyrexia [rectal temperature greater than 40.5°C (105°F)], and disturbances of the central nervous system. The exact cause of this disorder is unknown. The picture is generally one of environmental stress, too severe for the thermoregulatory system, which suddenly collapses. In the early stages, sweating may still be present and the patient rational, but the rectal temperature may be greater than 40.5°C (105°F). Within minutes, anhidrosis, mental confusion, coma, and/or seizures may appear. The diagnosis should be suspected from the clinical setting of activity in extreme heat and rectal temperature greater than 40.5°C (105°F); it should be accepted with the additional presence of anhidrosis, hot, dry skin, and any degree of central nervous system manifestations. If untreated, the disorder is uniformly fatal. In treated cases, the mortality is approximately 35%.

ANHIDROSIS ASSOCIATED WITH OTHER DISORDERS OF SKIN AND SWEAT GLANDS

ANHIDROSIS DUE TO DAMAGE FROM PHYSICAL AGENTS

Localized anhidrosis can occur whenever sweat glands are damaged by surgery or trauma, scar formation, cutaneous neoplasms, radiation therapy, infection, inflammation of the skin, granulomatous lesions, scleroderma, or vasculitis. Delivery of sweat to the skin surface may be impaired in a variety of dermatoses and papulosquamous diseases, presumably because of poral occlusion. Blister formation with sweat gland necrosis has been reported during intoxication with barbiturates, methadone, diazepam, carbon monoxide, amitriptyline, and clorazepate. Similar changes may occur in coma induced by hypoglycemia and other neurologic events, suggesting the changes are due in part to pressure over skin areas not usually subject to pressure. Radiation-induced dermatitis can abolish eccrine function in a dose-dependent fashion. Mantle irradiation (usually in the 25- to 50-Gy range) often produces a permanent loss of eccrine gland function, which tends to be discovered incidentally when previously treated patients undergo autonomic testing (see eFig. 84-4.2 in online edition). Keratotic changes blocking the eccrine duct with or without syringoma-like ductal

proliferation have been described. Similar changes have been noted with breast cancer radiation therapy. Congenital ectodermal dysplasia (see Chapter 142), acantholytic dermatosis (Grover disease; see Chapter 51), cholinergic urticaria (see Chapter 38), and various forms of ichthyosis (see Chapter 49) may also be associated with altered sweating.

ANHIDROSIS DUE TO CONGENITAL AND ACQUIRED SKIN DISEASES

STORAGE DISEASES. Sweat gland cellular inclusions that can be identified on skin biopsy include membrane-bound vacuoles in secretory cells in the mucopolysaccharidoses, intracytoplasmic lipid in Niemann–Pick and Sandhoff storage diseases, inclusions in adrenoleukodystrophy, maltase deficiency, and periodic acid-Schiff (PAS)-positive granules in the outer duct cells in Lafora myoclonic epilepsy.

NEUTROPHILIC ECCRINE HIDRADENITIS. Lesions are most often painful, pruritic, erythematous plaques or papules developing on the limbs, trunk, neck, face, and ears. Most commonly reported is chemotherapy-associated neutrophilic eccrine hidradenitis (NEH), typically occurring within 2 weeks of initiation of multiagent antineoplastic therapy. Fever and neutropenia may occur and the disorder is usually self-limited (lasting several weeks). Necrosis of eccrine secretory coils and associated epithelium with surrounding dense neutrophilic neutrophilic infiltrate that characterizes NEH is seen histologically (see eFig. 84-4.3 in online edition). A direct toxic effect of the drug on eccrine glands is suspected and recurrences with repeated chemotherapy may occur. Treatment with colchicine and dapsone has been beneficial. Another category of NEH appears due to bacterial infection. Biopsied lesions have grown *Serratia, Staphylococcus, Enterococcus, Pseudomonas*, and *Nocardia*.[117] Community outbreaks due to swimming pool water contamination with *P. aeruginosa* have been described. Spontaneous resolution in weeks is common, although some patients receive antibiotics. It is not known whether susceptible individuals have deficient innate dermcidin antimicrobial peptide secretion in sweat (see Section "Disorders Affecting the Sweat Duct") or if changes in sweat duct structural proteins produce reduced barrier protection against infection.

A recent case of NEH due to *Streptococci* showed the presence of human β-defensin 2, an epithelial antimicrobial peptide, in lesional epidermis and the eccrine duct; however, levels of dermcidin, a recently discovered antimicrobial peptide constitutively expressed in human eccrine sweat glands and secreted into sweat, were not determined. Dermcidin levels have been reported to be reduced in atopic dermatitis and have recently been shown to activate normal human keratinocytes.[118]

Recurrent, palmoplantar NEH has been increasingly reported in otherwise healthy children between 1 and 15 years of age. Vigorous exercise with heavy sweating and damp, occlusive footwear are possible risk factors.[119] Spontaneous resolution in 3–4 weeks is common, but repeated bouts with subsequent exercise occur. Treatment with cool compresses and topical steroids and rest has provided symptomatic relief. NEH has been described in association with Behçet disease[120] and human immunodeficiency virus infection. A possible treatment for NEH-Behçet is an anti-TNF-α agent, such as infliximab, which has been effective for other manifestations of Behçet disease[121,122] (see eTable 84-1.1 in online edition for summary of NEH).

SJÖGREN SYNDROME AND SCLERODERMA. Variable degrees of anhidrosis can occur in Sjögren syndrome (see Chapter 161). Most often patchy areas of anhidrosis occur on proximal and/or distal limbs, compatible with a small-fiber neuropathy. Case reports of widespread anhidrosis and heat intolerance associated with dry eyes and dry mouth, positive extractable nuclear antigen panel, and lymphocytic infiltrates of minor salivary glands exist.[123,124] Skin biopsies have shown perieccrine infiltrates in some patients, but not in others. The failure of the anhidrotic skin on TST to respond to ACh/pilocarpine iontophoresis in one report suggests that autoantibodies to the muscarinic (type 3, M3) cholinergic receptor interfere with eccrine gland function.[125–128] M3 cholinergic receptors predominate on salivary glands and sweat glands, which further supports an association. The stage of the immune-mediated response may determine whether lymphocytic infiltration is present or not.[129]

The aquaporin 5 (AQP5) water channel has been identified in the apical plasma membrane of sweat gland cells,[130] and mobilization of these channels may influence sweat production.[131] The effects of drugs or disease on these channels at this time are speculative with regard to sweat gland disorders. Preliminary evidence of autoantibody-mediated alterations in M3 cholinergic receptor activation and AQP5 expression in salivary gland cells of Sjögren's syndrome patients raises the possibility that some patients with disturbances of sweating may turn out to have AQP5 channelopathies.[21]

Atrophic sweat glands and focal anhidrosis have been noted in patients with linear scleroderma. The forehead is most commonly affected.[132]

INCONTINENTIA PIGMENTI. Hypohidrosis has also been noted in the hypopigmented streaks and patches on the legs, arms, and scalp of ten women with incontinentia pigmenti.[133] Skin biopsies reveal a lack of eccrine sweat glands and hair follicles at these sites. Hypohidrosis has also been described in segmental vitiligo, but not the generalized or acrofacial types.[134,135] Anhidrosis of the face and neck has also been reported in members of a family with "follicular atrophoderma, basal cell carcinoma, and hypotrichosis," a rare X-linked, dominantly inherited syndrome (Bazex–Dupre–Christol syndrome). Milia and sweat duct occlusions may occur, but are inconstant features of the disease.[136]

DISORDERS AFFECTING THE SWEAT DUCT

MILIARIA. Miliaria results from disruption of sweat ductal integrity[137] with consequent sweat secretion into layers of the epidermis. Ultraviolet light exposure, resident organisms on skin, and repeated sweating episodes are facilitating factors. Focal anhidrosis can occur and persist for several weeks, much longer than the miliaria in affected skin regions. Based on clinical and histopathology findings, miliaria is subdivided into four groups: (1) miliaria crystallina; (2) miliaria rubra; (3) miliaria pustulosa; and (4) miliaria profunda.

Miliaria crystallina (sudamina) consists of superficial, subcorneal, noninflammatory vesicles that easily rupture when rubbed with a finger (Fig. 84-5). They are common in infants in warmed environments, including in intensive care units where medications employed (cholinergic and adrenergic agents) may be stimulating sweating and aggravating the problem.[138,139]

Miliaria rubra (prickly heat) results when obstructed sweat migrates into the epidermis as well as the upper dermis, causing pruritic inflammatory papules around the sweat pores (see eFig. 84-5.1 in online edition). This disorder is common in infants, but also occurs in children and adults after repeated episodes of sweating in a hot, humid environment. The eruption usually subsides within a day after the patient moves to a cool environment. However, anhidrosis associated with miliaria takes 2 weeks (the time needed to repair the affected epidermal sweat duct unit by epidermal turnover) to recover completely. Some of the eruptions of miliaria rubra become pustular, resulting in miliaria pustulosa. Miliaria profunda results when the sweat leaks into the deeper dermis. During exposure to intense heat or after local injection of cholinergic agents, the affected skin can be uniformly covered with multiple discrete, flesh-colored papules that resemble gooseflesh. Ductal blockade at various levels is the immediate cause of miliaria. However, investigators do not agree on why the sweat escapes the duct at different levels (causing different subgroups of miliaria) nor on what causes the ductal blockade and/or ductal leakage at different levels.

Figure 84-5 Miliaria crystallina. Note the delicate, drop-like vesicles without erythema.

It is puzzling that the morphologic evidence of ductal blockade, such as keratin rings, PAS-positive proteins, or clusters of microorganisms, is rarely seen by light microscopic observation of miliarial lesions. Thus, Holzle and Kligman speculated that the keratin rings and PAS-positive proteins are the consequence but not the cause of ductal damage. The role of resident organisms especially *Staphylococcus epidermidis* has been proposed as a leading predisposing factor in miliaria.[140,141] Indeed, there was a linear correlation between the severity of miliaria rubra and the number of cocci in experimental miliaria under a plastic film. The development of experimental miliaria could be markedly suppressed by pretreatment of the skin with hexachlorophene or pyrithione.[140]

OTHER DISORDERS AFFECTING THE SWEAT DUCTS. Abnormalities of the epidermal portion of the spiraling sweat duct (acrosyringium) with altered sweat delivery to the skin surface are present in several disorders with immunohistologic evidence of neurogenic inflammation of skin. The presence of vanilloid receptors and neuropeptide fibers containing substance P and calcitonin-gene related protein in the acrosyringium may explain the presence of mast cell and other mediators of inflammation with subsequent impairment of sweating.[142–144]

DISORDERS WITH ALTERED COMPOSITION OF SWEAT

ATOPIC DERMATITIS. Dermcidin is a recently discovered antimicrobial peptide with a broad spectrum of activity. It is constitutively expressed in human eccrine sweat glands and secreted into sweat. Recent evidence suggests deficient amounts of sweat-derived antimicrobial peptides may play a role in skin inflammatory disorders characterized by increased bacterial colonization of the skin, such as atopic dermatitis.[143,145] Dermcidin and other antimicrobial proteins and peptides may have a therapeutical potential as topical anti-infectives in several skin diseases because of their broad spectrum of antimicrobial activity, the low incidence of bacterial resistance and their function as immunomodulatory agents.[118,146,147]

CYSTIC FIBROSIS. Sweat chloride ion concentration can determine the integrity of the CFTR Cl^- channel and provide diagnostic information for cystic fibrosis.[15] This in vivo assay may prove useful in studying the effectiveness of CF gene therapy. In vitro studies of the CFTR Cl^- activity from sweat glands obtained via skin biopsy are presently under evaluation as markers of the efficiency of CF-gene delivery and expression in sweat gland epithelial cells.[148] The saltier sweat may be responsible for the frequent observation of the aquagenic wrinkling of the palms (AWP) syndrome in CF patients.[149,150]

AQUAGENIC WRINKLING OF PALMS (AWP) SYNDROME. AWP is an uncommon disease characterized by the rapid and transient formation of edematous whitish plaques on the palms on

exposure to water.[151] Although the exact cause of this condition is unknown, hyperplastic glandular epithelium and aberrant AQP5 staining in the patient's sweat glands suggest that AWP stems from dysregulation of sweating.

Chapter 85 :: Disorders of the Apocrine Sweat Glands

:: Christos C. Zouboulis & Fragkiski Tsatsou

Apocrine glands are adnexal glands that are distributed in the scalp, the axillae, the anogenital region, the eyelids (Moll's glands), the external auditory meatus (ceruminous glands), and the mammary glands. Apocrine glands can also be found in a more limited distribution on the face and abdomen. Apocrine glands are quiescent until puberty. Embryologically, apocrine glands develop from the upper bulge of the hair follicle late in the fourth month of gestation, with continued development as long as hair follicles develop. A primary epithelial germ (hair germ) grows down from the epidermis and forms an apocrine gland, sebaceous gland, and hair follicle. Apocrine glands are composed of three components: (1) the intraepithelial duct, (2) the intradermal duct, and (3) a coiled gland in the deep dermis or at the junction of the dermis and subcutaneous fat, which contains the secretory portion. The coiled gland consists of one layer of secretory cells around a lumen that is about ten times the diameter of its eccrine counterpart. Contractile myoepithelial cells, a hyaline basement membrane, and connective tissue surround the coiled gland. The predominant mode of apocrine secretion is decapitation, a process where the apical portion of the secretory cell cytoplasm pinches off and enters the lumen of the gland. Apocrine sweat consists mainly of sialomucin. Apocrine sweat is more viscous and produced in much smaller amounts than eccrine sweat (which actually is the wet portion of axillary sweat). The exact function of apocrine glands is unclear, although they are thought to represent scent glands. Their primary sympathetic stimulation is adrenergic.[1]

Four disorders are considered in this chapter: two primary disorders of the apocrine glands, namely (1) apocrine bromhidrosis and (2) apocrine chromhidrosis; and two secondary disorders, (1) Fox–Fordyce disease and (2) hidradenitis suppurativa (acne inversa), in which apocrine glands become secondarily affected.

APOCRINE BROMHIDROSIS

APOCRINE BROMHIDROSIS AT A GLANCE

- *Apocrine bromhidrosis* refers to an offensive or unpleasant body odor arising from apocrine gland secretions.
- Chronic disorder, most often developing in the axillae, but may also involve the genitals or plantar aspect of the feet.
- The best-characterized short chain fatty acid causing odor is ε-3-methyl-2-hexenoic acid.
- Should be distinguished from eccrine bromhidrosis.
- Surgical removal of affected glands may be effective.

Body odor, *osmidrosis*, is a common phenomenon in a postpubertal population. *Bromhidrosis* refers to body odor, which is excessive or particularly unpleasant and *apocrine bromhidrosis* to such an offensive odor that arises from apocrine glands. It is most often mentioned in the axillae. This condition may contribute to impairment in an individual's psychosocial functioning. The terminology in the literature is sometimes confusing, using *osmidrosis* to imply offensive odor, and *bromhidrosis* to imply osmidrosis in the setting of concomitant hyperhidrosis.[2]

EPIDEMIOLOGY

Disease onset after puberty is common and tends to be more prevalent in African-American populations. There is no geographic predilection, although summer months or warm climates may aggravate the disease. Poor personal hygiene may also be a contributing factor.[3]

ETIOLOGY AND PATHOGENESIS

Apocrine secretions are responsible for odor production, primarily through bacterial action on its components. It is accepted that the odorous steroids, the so-called pheromones, among them 16-androstenes, 5α-androstenol, and 5α-androstenone, contribute to osmidrosis.[4,5] 5α-Reductase type I is expressed in apocrine glands. Individuals with osmidrosis have increased levels of 5α-reductase in their apocrine glands. Because this enzyme catalyzes the conversion of testosterone to 5α-dihydrotestosterone, levels of 5α-dihydrotestosterone may be greater than testosterone in the skin of affected individuals.[6] The biotransformation of these steroids is complex and further research is required to delineate these pathways.

Moreover, the axilla hosts many different bacteria, most of which are Gram-positive ones. Bromhidrosis has been particularly associated with the action of aerobic *Corynebacterium* species. Eccrine bromhidrosis may develop from the action of bacteria on keratin that has been softened by eccrine secretions. In addition, the bacterial action on apocrine secretions produces ammonia and short chain fatty acids. The best-characterized short chain fatty acid is ε-3-methyl-2-hexenoic acid.[7] This acid is delivered to the surface of the skin on two binding proteins, apocrine-secretion binding proteins (ASOB1 and ASOB2). ASOB2 has been identified as apolipoprotein D.[8]

The effect of hyperhidrosis (excessive eccrine sweat secretion) on osmidrosis and bromhidrosis is unclear. Some have advocated that excessive eccrine sweat improves apocrine bromhidrosis by flushing away excessive apocrine secretions. Others have postulated that eccrine sweat augments apocrine bromhidrosis by encouraging local spread of apocrine sweat components and enhancing the moist environment in which bacteria flourish.[3]

CLINICAL FINDINGS

HISTORY. Patients complain of an unpleasant body odor. The axillae are the most common affected site, although the genitals or plantar feet may also be affected. The diagnosis is usually clinical. What constitutes a "normal" amount of body odor varies considerably among individuals and ethnic groups. In Asian populations, only slight odor is often considered diagnostic.[9,10]

CUTANEOUS LESIONS. Physical examination of the affected individual is usually unremarkable.

LABORATORY TESTS. There are no associated laboratory abnormalities.

PATHOLOGY. Although some reports do not reveal any abnormalities in the apocrine glands of affected individuals, an increase in the numbers and size of apocrine glands has also been reported.[9]

DIFFERENTIAL DIAGNOSIS

Apocrine bromhidrosis should be distinguished from eccrine bromhidrosis, which is far less common (see Chapter 84). Eccrine secretions are distributed in a generalized fashion, are usually odorless, and serve a thermoregulatory function. A plantar location is characteristic for eccrine bromhidrosis. Certain foods (garlic, curry, alcohol), drugs (bromides), toxins, or metabolic causes (disorders of amino acid metabolism) may result in eccrine bromhidrosis (Box 85-1).

TREATMENT

GENERAL MEASURES. Frequent washing of the axillae, use of a deodorant or antiperspirant

BOX 85-1 DIFFERENTIAL DIAGNOSIS OF APOCRINE BROMHIDROSIS

- Eccrine bromhidrosis
  - Fish odor syndrome (trimethylaminuria)
  - Phenylketonuria
  - Sweaty feet syndrome
  - Odor of cat syndrome
  - Isovaleric acidemia
  - Hypermethioninemia
  - Food, drug, toxin ingestion
- Liver failure (fetor hepaticus)
- Renal failure
- Nasal foreign body in children
- Poor hygiene
- Olfactory hallucinations
- Body dysmorphic disorder

From Rehmus W et al: Bromhidrosis. In: *emedicine*, edited by T McCalmont et al (http://www.emedicine.com), 2005.

(aluminum chloride), perfumes, and changing of soiled clothing can help. Removal of axillary hair may minimize odor by preventing bacteria and sweat accumulation on the hair shafts. Antibacterial soaps or topical antibacterial agents may also be of benefit.

NONSURGICAL THERAPY. The injection of botulinum toxin A has been reported to successfully treat genital[11] and axillary bromhidrosis.[12] The frequency-doubled, Q-switched Nd:YAG laser has also been reported to be an effective noninvasive therapy for axillary bromhidrosis.[13]

SURGERY. Several surgical measures have been investigated in the treatment of apocrine bromhidrosis. Patient selection is important because surgery is potentially associated with postoperative scar formation, prolonged healing times, infection, and other complications. Upper thoracic sympathectomy has been successful in treating apocrine bromhidrosis either in isolation or in association with palmar hyperhidrosis.[2] Surgical removal of the culprit apocrine glands can be achieved either by the removal of subcutaneous tissue in isolation or in combination with axillary skin.[14–16] Surgical subcutaneous tissue removal has also been used in association with CO_2 laser ablation.[17] Although surgical excision may be highly efficacious, depending on the depth of tissue removed and surgical technique used, regeneration and return of apocrine function/osmidrosis and bromhidrosis may develop. Superficial liposuction,[18] tumescent superficial liposuction with curettage,[19] and ultrasound-assisted liposuction[20] have efficacy in the management of apocrine bromhidrosis. In a series of 375 patients, more than 90% reported a satisfactory reduction in odor.[20] Another technique with reported efficacy is ultrasonic surgical aspiration of axillary apocrine glands with endoscopic confirmation.[21] This technique uses ultrasound to liquefy fat and sweat glands. In contrast, laser hair removal may be associated with intensification of bromhidrosis.[22]

PROGNOSIS AND CLINICAL COURSE

Apocrine bromhidrosis is a chronic and nonremitting condition. Patients with apocrine bromhidrosis often feel self-conscious and embarrassed by their condition and may develop impairment with psychosocial functioning.

APOCRINE CHROMHIDROSIS

APOCRINE CHROMHIDROSIS AT A GLANCE

- Rare, chronic condition characterized by the secretion of colored sweat.
- Axillary and facial involvement is most common. Areola involvement has been reported.
- Caused by an increased number of lipofuscin granules in the luminal secretory cells of the apocrine glands.
- Secretions may be yellow, blue, green, brown, or black.
- Wood's light examination may demonstrate fluorescence of secretions and stained clothes.
- Adequate therapy is lacking. Reports of efficacy with manual expression, capsaicin, and botulinum toxin.

Apocrine chromhidrosis is a rare condition characterized by the secretion of colored apocrine sweat. Two variants of apocrine chromhidrosis are recognized: (1) axillary and (2) facial. Involvement of the mammary areola has also been described.[23,24] Yonge first recognized facial chromhidrosis in 1709. Shelley and Hurley described this entity in 1954 and associated it with an increased number of lipofuscin granules in apocrine glands.[25]

EPIDEMIOLOLGY

Apocrine chromhidrosis is a rare disease. The worldwide prevalence is unknown. Onset of apocrine chromhidrosis is usually at puberty, at the time of increased apocrine gland activity. The disease persists throughout life, improving in the aged. It is reported most commonly in African-Americans.[26] Geographic predilections have never been described. Most of the

cases reported in the literature involve women; however, there is a lack of sound scientific evidence supporting a female preponderance.

ETIOLOGY AND PATHOGENESIS

The pigment responsible for causing apocrine chromhidrosis is lipofuscins that are produced in the apocrine secretory cells and excreted to the skin surface. Lipofuscin is a golden-colored pigment that is not specific to apocrine glands. In apocrine chromhidrosis, the lipofuscin granules are in a higher state of oxidation, thereby imparting various colors of pigment, such as yellow, green, blue, or black. Higher states of oxidation produce darker colors.[23] It is uncertain why this only develops in some individuals.[27]

One case of facial chromhidrosis was successfully treated with capsaicin. Nerve endings with receptors for substance P have been found around eccrine sweat glands, suggesting that substance P, a potent vasodilator, may play a role in sweat production and apocrine chromhidrosis.[28]

CLINICAL FINDINGS

HISTORY. Individuals with apocrine chromhidrosis often describe a sensation of warmth, a prickling sensation, or tingling feeling before apocrine gland secretion. Triggers for colored sweating are usually emotional or physical stimuli.[26] The morbidity associated with apocrine chromhidrosis stems from the emotional distress experienced by affected individuals.[29] Staining of undershirts and handkerchiefs are common complaints.

CUTANEOUS LESIONS. Individuals with apocrine chromhidrosis develop colored sweat in the axillae or face (Fig. 85-1). Mammary areolar involvement has also been described.[23] The pigment produced ranges in color from yellow, blue, green, brown, to even black. The quantity of pigmented sweat produced is usually quite small (approximately 0.001 mL at each follicular orifice).[30] The droplets are odorless and dry quickly. Dried secretions appear as dark flecks within affected areas. Axillary involvement causes staining of shirts and undergarments. Facial chromhidrosis commonly develops close to the lower eyelid, including the malar cheeks, and occasionally the forehead.[29,30] Colored sweat can also be manually expressed by squeezing in the affected area. Such a maneuver may also be therapeutic.[26]

SPECIAL TESTS. An examination of yellow, blue, or green secretions using a Wood's light (360 nm) produces a characteristic yellow fluorescence. Black or brown pigment rarely autofluoresces.[26] Secretions can be manually expressed if not present at the time of examination. Stained clothing may also fluoresce with Wood's lamp examination.[31] Apocrine glands can be stimulated to produce colored secretions by the injection of epinephrine or oxytocin.

LABORATORY TESTS. It is reasonable to check a complete blood cell count to exclude a bleeding diathesis, homogentisic levels in urine to exclude alkaptonuria, and bacterial and fungal cultures of affected areas to exclude pseudo-eccrine chromhidrosis.[27]

Figure 85-1 (**A**) Blue-black sweat produced in a patient with facial apocrine chromhidrosis after gentle squeezing of the cheeks (Reproduced with permission from Chang YC, Anderson N, Soeprono F. Bilateral facial pigmentation. *Dermatology Online J*. **13**(3):16, 2007), (**B**) blue-black apocrine pigmentation of the axilla and the inflammatory boils of a male patient with hidradenitis suppurativa.

PATHOLOGY

The luminal cells of the apocrine sweat glands have an eosinophilic cytoplasm, a large nucleus, and may contain lipofuscin, iron, lipid, or periodic acid-Schiff-positive and diastase-resistant granules.[32] Under light microscopy using hematoxylin–eosin staining, an increased number of (yellow–brown) lipofuscin granules may be present in the apical portion of luminal secretory cells of the apocrine glands. The number of granules varies. Additionally, autofluorescence of paraffin-embedded nonstained sections can be demonstrated using a 360-nm wavelength.[31] The granules are positive on periodic acid-Schiff stains. Schmorl stain may also be weakly positive.[33]

DIFFERENTIAL DIAGNOSIS

Apocrine chromhidrosis must be distinguished from eccrine chromhidrosis (Box 85-2; see Chapter 84). True eccrine chromhidrosis is very rare and occurs when water-soluble pigments are excreted from eccrine glands after the ingestion of certain drugs, such as quinines. *Pseudo-eccrine chromhidrosis* refers to the development of colored sweat when surface compounds or molecules mix with sweat to produce pigment. A classic example of this type is the formation of blue sweat in copper workers.[33] Extrinsic dyes, paints, fungi, and chromogenic bacteria (e.g., *Corynebacterium* species) are other causes of pseudochromhidrosis.[27]

TREATMENT

Adequate therapy for chromhidrosis is lacking. Manual expression of colored secretions may result in a temporary improvement in symptoms for the following 48–72 hours.[28] Botulinum toxin type A has reported to be successful in one patient with facial chromhidrosis. This patient experienced a substantial reduction in pigmented sweat and the results were sustained for 4 months.[34] Capsaicin is a topical cream that depletes and prevents reaccumulation of substance P levels in unmyelinated, slow-conducting type C sensory fibers. Case reports have demonstrated efficacy of capsaicin in the treatment of facial chromhidrosis.[28]

BOX 85-2 DIFFERENTIAL DIAGNOSIS OF APOCRINE CHROMHIDROSIS

- Eccrine chromhidrosis
  - Quinine ingestion
- Pseudo-eccrine chromhidrosis
  - Blue sweat with copper exposure
  - Extrinsic dyes, paints
- Alkaptonuria (ochronosis)
- Hyperbilirubinemia
- Hematohidrosis (bleeding diathesis)
- Chromogenic bacteria (e.g., *Corynebacterium* species), pseudomonas

From June K et al: Chromhidrosis. In: *emedicine*, edited by G Burg et al (http://www.emedicine.com), 2005.

PROGNOSIS AND CLINICAL COURSE

Apocrine chromhidrosis is a chronic disease that improves in old age as apocrine gland activity diminishes. Disease-associated morbidity is a result of psychosocial dysfunction experienced by affected individuals.

FOX–FORDYCE DISEASE

FOX–FORDYCE DISEASE AT A GLANCE

- An uncommon eruption characterized by pruritic skin-colored to pink papules localizing mainly to axillae and genitofemoral area.
- More than 90% of patients are female, and onset tends to be after puberty.
- Likely a result of intraluminal plugging of follicular infundibula, causing apocrine duct obstruction, rupture, and inflammation.
- The most consistent pathologic finding is hyperkeratosis and plugging of the follicular infundibula.
- Topical clindamycin, surgery, or other treatments may be of benefit.

Fox–Fordyce disease is an uncommon eruption characterized by pruritic follicular papules that localize to anatomic regions that bear apocrine glands.[35] George Henry Fox and John Addison Fordyce originally described it in 1902 in two patients with axillary involvement.[36] In 1925, Fischer hypothesized that Fox–Fordyce was a disease of the apocrine glands.[37] Shelley and Levy introduced the term *apocrine miliaria* as a synonym for this disease.[38]

EPIDEMIOLOGY

Approximately 90% of patients with Fox–Fordyce disease are female. Age of onset tends to be after puberty, with most patients between 13 and 35 years of age.[38] The incidence of this disorder is unknown. There is no reported ethnic or racial predilection.

ETIOLOGY AND PATHOGENESIS

FOLLICULAR PLUGGING. The triggers for the development of Fox–Fordyce disease are largely

unknown. Shelley and Levy hypothesized that the clinical manifestations of this disease are a result of intraluminal keratin plugging of the follicular infundibula, causing obstruction of the apocrine duct, rupture, and inflammation.[38] Although blockage of the apocrine duct seems important in disease development, experimentally plugging the duct has not clinically reproduced disease manifestations.[39] One case report detailed the development of Fox–Fordyce disease associated with obstruction of apoeccrine sweat glands.[40]

GENETICS. Genetics likely plays a role in disease development. This disease has been reported in two patients with Turner syndrome[41] and one patient with a small deletion on chromosome 21.[42] The disease has also been reported in identical male twins,[43] one set of siblings,[44] and in father and daughter.[45]

HORMONES. Hormonal influences on disease have been debated. Disease onset after puberty and improvement with pregnancy and estrogens lends support to a hormonal influence.[36,46] However, hormonal studies in one patient with Fox–Fordyce did not reveal any abnormalities.[47] Additionally, development before puberty has also been described.[48]

CLINICAL FINDINGS

HISTORY. Patients describe the development of pruritic papules at the time of puberty with gradual worsening. Pruritus can be triggered by emotional excitement or sweating.

CUTANEOUS LESIONS. Fox–Fordyce disease manifests as numerous symmetrically distributed skin-colored to slightly yellow or red follicular, dome-shaped papules that are equidistant from one another and characteristically intensely pruritic (Fig. 85-2). These papules may resemble lichen planus, lichen nitidus, folliculitis, or syringomas (Box 85-3). Excoriations may be prominent. Apocrine-rich areas are affected, most commonly the axillae. Other areas involved include the pubic area and perineum, mammary areola,[7] presternal area, periumbilical area, and upper inner thighs. Only sparse hair growth is seen in the affected area. Apocrine sweat is not produced in affected areas.

BOX 85-3 DIFFERENTIAL DIAGNOSIS OF FOX–FORDYCE DISEASE

- Lichen planus
- Lichen nitidus
- Folliculitis
- Multiple syringomas

Figure 85-2 Numerous skin colored to browning papules involving the axilla a woman with Fox-Fordyce disease (Reproduced with permission from Chae KM, Marschall MA, Marschall SM. Axillary Fox-Fordyce disease treated with liposuction-assisted curettage. *Arch Dermatol*. **138**:452-454, 2002.)

PATHOLOGY

Although the clinical features in patients with Fox–Fordyce disease are quite uniform, pathologic findings can vary considerably. The most distinct, relatively consistent pathologic finding is perifollicular foamy macrophages (xanthomatous infiltrates).[49] These cells expressed CD68 but lack expression of carcinoembryonic antigen, gross cystic disease fluid protein 15, and periodic acid-Schiff with diastase digestion. Perifollicular mucin, fibrosis, and mast cells in the infiltrate can also be observed. Dilation and hyperkeratosis of the follicular infundibula can also be seen and were previously considered as a histological sign of Fox–Fordyce disease. Other findings include spongiosis and solitary dyskeratotic cells throughout the infundibular epidermis, vacuolar changes at the dermal–epidermal junction in conjunction with some lymphocytes, cornoid lamella in the follicular infundibula with eosinophilic keratinocytes directly below the parakeratotic column, and few lymphocytes in the dermis surrounding the infundibula.[35] It has been suggested that transverse histologic sectioning of the specimen is the most effective and efficient method to demonstrate the characteristic pathologic features of Fox–Fordyce disease.[50]

TREATMENT

NONSURGICAL THERAPY. Treating Fox–Fordyce disease is difficult. Avoidance of excessive sweating or heat may minimize symptoms and flares. Clindamycin with propylene glycol has demonstrated efficacy in small case series in both eliminating symptoms and resolving papules.[44,51] Topical tretinoin 0.1%, although potentially irritating, has also demonstrated efficacy.[52] Topical pimecrolimus ointment has been shown effective.[53] Systemic isotretinoin led to almost complete clearance of lesions, but lesions recurred within 3 months after isotretinoin discontinuation.[42] Other reported medical therapies include oral contraceptives,[54] testosterone,[55] topical or intralesional corticosteroids,[56] ultraviolet light,[57] and X-rays.[47]

SURGERY. Electrocoagulation,[58] surgical excision,[59] and liposuction-assisted curettage[60] have all demonstrated efficacy.

PROGNOSIS AND CLINICAL COURSE

Fox–Fordyce disease is a chronic disease characterized by intermittent flares. It rarely remits. Infection or folliculitis may develop secondary to trauma caused by scratching.

HIDRADENITIS SUPPURATIVA/ ACNE INVERSA

HIDRADENITIS SUPPURATIVA AT A GLANCE

- Common disorder with a point prevalence of 1.0% and female preponderance.
- A chronic and recurrent disorder, usually developing after puberty and most commonly involving the genitofemoral area or axillae.
- Primary pathogenic event is believed to be follicular occlusion with subsequent inflammation, secondary adnexal gland involvement, fibrosis, and scarring.
- Pathologic features may include follicular hyperkeratosis, folliculitis, abscess formation, sinus tract formation, fibrosis, and granuloma formation.
- Surgery may sometimes be curative; clindamycin/rifampicin, hormonal treatments, some immunosuppressive medications and certain biologics (infliximab, adalimumab) may benefit some patients.

Hidradenitis suppurativa/acne inversa (HS) is a rather common, multifactorial, chronic and debilitating inflammatory skin appendage disorder with a notoriously underestimated burden of disease. The first International Hidradenitis Suppurativa Research Symposium (2006, Dessau, Germany) formulated the following definition: HS is a chronic, inflammatory, recurrent, debilitating skin disease (of the hair follicle) that usually presents after puberty with painful, deep-seated, inflamed lesions in the apocrine gland-bearing areas of the body, most commonly the axillary, inguinal, and anogenital regions.[61]

EPIDEMIOLOGY

Conflicting reports have provided a varying assessment of HS epidemiology. A current study recorded an HS prevalence of 1% in a representative sample of the French population (n = 10,000).[62] In a previous study, a point prevalence of up to 4.1% based on objective findings, and a 1-year prevalence of 1% based on patient recall was found.[63] It seems to be more common in females, with reported female–male ratios ranging from 2:1 to 5:1. The reason for female preponderance is unknown. HS rarely develops before puberty or after menopause, although persistence into menopause is not uncommon.[64] The average age of onset is 23 years.[65] Although the disease may develop in any apocrine gland-bearing skin, genitofemoral lesions are more prevalent in women, whereas axillary involvement does not demonstrate a gender predilection.[63,66,67]

ETIOLOGY AND PATHOGENESIS

HS is a disease of the terminal hair follicle associated with lymphohistiocytic inflammation, granulomatous reactions, sinus tracts, and scarring.[61,68] A consistent finding in histological studies of HS is a follicular occlusion due to hyperkeratosis, regardless of disease duration, whereas an isotopic hyperplasia of follicular epithelium is evident.[69] This leads to occlusion of the apocrine gland with subsequent follicular rupture, perifollicular inflammation and possible secondary infection, giving rise to clinical findings.[69–71] The concept of the follicular occlusion tetrad stems from the concept that HS, acne vulgaris, pilonidal sinus, and dissecting cellulitis share follicular occlusion as an inciting event that eventually leads to disease expression.

ADNEXAL STRUCTURES. Classically, HS was thought to represent a primary disorder of apocrine glands, and was also referred to as *apocrinitis*.[72] The anatomic location of disease in apocrine-bearing skin has supported this concept. Shelley and Cahn provided additional support of this concept by hypothesizing that poral occlusion of the apocrine duct reproduced the clinical and pathologic lesions using their experimental model.[73] More recent publications have refuted the concept that this primary event in HS

is apocrine gland inflammation and postulate that apocrine glands become secondarily affected.

GENETIC FACTORS. A family history of HS may be elicited in 26% of patients.[74] Several studies have not demonstrated HLA associations.[75,76] Others studies have suggested an autosomal dominant mode of inheritance with single gene transmission.[77–89] The group of experts, who participated at the first International Symposium has accepted that HS has to be a polygenic disease with sporadic cases having defects in a number of critical genes involved in its pathogenesis and familial cases with probably highly penetrant defect(s) in one of these genes.[61] A genome-wide scan in a four-generation Chinese family identified a first locus for HS at chromosome 1p21.1–1q25.3 into a 76-Mb region flanked by the markers *D1S248* and *D1S2711*.[90] This locus could not be confirmed by others groups.[68,91]

In a study of six Han Chinese families with familial disease, frameshift or termination mutations in the γ-secretase complex were identified at 19p13 suggesting that haplosufficiency might play a role in HS in familial cases.[92]

ASSOCIATED DISEASES. The coexistence of HS and Crohn disease, particularly with perianal involvement, has been associated with a more fulminant course.[80–83] Perianal Crohn disease may be clinically indistinguishable from perianal HS. A pilot study carried on ten HS patients detected no CARD15/NOD2 polymorphisms, found to be associated with Crohn disease.[93] This finding adds evidence to the fact that HS has to be distinguished from Crohn disease and its HS-like cutaneous manifestations.[94] Other reported associations include pyoderma gangrenosum,[84] nephrotic syndrome, and amyloidosis,[85] Dowling–Degos disease,[86] and arthropathy.[87–89] A current systematic literature review reported that follicular occlusion disorders, inflammatory bowel diseases, especially Crohn disease, spondyloarthropathy, other hyperergic diseases, genetic keratin disorders associated with follicular occlusion and squamous cell carcinoma are the most common HS comorbid diseases. A first classification of these major comorbidities and their possible genetic background revealed a list of chromosome loci and genes, which could be HS candidates. Most of these diseases belong to the group of autoinflammatory disorders, where Th17 cell cytokines seem to play a central role.[95]

HORMONES AND ANDROGENS. The tendency of HS to develop at puberty or postpuberty suggests an androgen influence. Additionally, disease flares have been reported postpartum,[86,96] in association with the oral contraception pill, and in the premenstrual period (approximately 50% of patients).[97] Antiandrogen therapy has also demonstrated therapeutic benefit in some studies.[98–101] However, no biochemical evidence of hyperandrogenism was found in 66 women with HS.[102] Additionally, unlike the sebaceous glands, the apocrine glands are not affected by androgens. Thus, the influence of androgens on HS is unclear.

OBESITY. Obesity is unlikely to be a causal factor in HS but is often regarded as an exacerbating factor by increasing shearing forces, occlusion, keratinocyte hydration, and maceration.[86,103,104] Obesity may also exacerbate disease by creating a state of androgen excess.[77] Weight reduction is recommended for overweight patients and may help to control disease.[66] A current multivariate analysis showed a strong association with body mass index [odds ratio = 1.1 (1.1–1.2)].[62]

BACTERIAL INFECTION. The role of bacterial infection in HS is unclear. It is believed that the pathogenic role is indirect, similar to the role of bacteria in acne. Bacterial involvement is thought by some authors to occur secondarily. Routine cultures are often negative, but numerous bacteria have been recovered from lesions. *Staphylococcus aureus* and coagulase-negative *Staphylococci* are most frequently isolated.[105,106] However, other bacteria, including *Streptococci*, Gram-negative rods, and anaerobes, have also been identified. These are likely to be colonizing bacteria rather than causative bacteria,[86,107] a concept that could explain the increased expression of Toll-like receptor 2 as well as of β-defensin 2 and psoriasin in HS lesions.[108,109]

SMOKING. The use of tobacco products is more common in HS patients than in healthy controls.[110,111] One study determined that 70% of their 43 patient cohort with perineal HS were smokers.[112] It is postulated that smoking affects polymorphonuclear cell chemotaxis.[64] Multivariate analysis showed a strong association with current smoking (odds ratio = 12.6, 95% CI 8.6–18.4).[62] Smoking cessation may improve the clinical course of the disease.

CLINICAL FINDINGS

HS is a chronic disease with a variable clinical course.[113–115] The diagnosis of HS is clinical, and a biopsy is rarely needed (Box 85-4). Clinical diagnostic criteria are wide and include recurrent disease, scarring, and multifocal location.[66]

One of the most obvious hallmarks of the disease is the restriction to the skin areas affected.[113–115] The disease is essentially limited to the intertriginous areas, although aberrant lesions may occur. The sites affected in order of decreasing frequency include: axillary, inguinal, perineal and perianal, mammary and inframammary, buttocks, pubic region, chest, scalp, retroauricular, and eyelid.[64] HS is not acne: closed comedones are not seen, since the deep part of the follicle appears to be involved and not its superficial compartments, as seen with acne affecting convex skin surfaces. HS inflammatory lesions are initially transient, but gradually become intransigent and associated with significant scarring.[61,115]

SEVERITY. Three stages of disease are recognized and named after Hurley (I–III)[116] In the primary stage, abscesses develop in isolated locations. The secondary

stage involves the development of sinus tracts with scars bridging individual lesions. The tertiary stage shows coalescing lesions with scarring and sinus tracts, inflammation, and chronic discharge.

The disease onset is insidious and shows variable severity. Otherwise healthy postpubertal individuals initially may experience slight discomfort or pruritus. After this, a tender papule or deep-seated nodule (0.5 to 2.0 cm) ensues (eFig. 85-2.1 in online edition). Pustules may also be visualized (eFig. 85-2.2 in online edition). This nodule may slowly resolve or may expand and coalesce with surrounding nodules to form large painful inflammatory abscesses. These abscesses are rounded without central necrosis and may resolve or rupture spontaneously, producing a purulent discharge (Fig. 85-3). Eventual healing may result in scarring with fibrosis (Fig. 85-4), dermal contractures and rope-like elevation of the skin (Fig. 85-5), and double-ended comedones (eFig. 85-5.1 in online edition). Sinus tracts may also develop (Fig. 85-6). Sinuses have been

Figure 85-3 A ruptured draining abscess involving the groin of a male patient with hidradenitis suppurativa.

Figure 85-4 Area of scarring with associated fistules involving the axilla of a male patient with hidradenitis suppurativa.

reported to involve deep tissue, including muscle and fascia, urethra, and bowel. The process then recurs in an adjacent area or different apocrine-bearing site.[66]

LABORATORY TESTS. Patients with acute lesions of HS may demonstrate an increase in the erythrocyte sedimentation rate or *C*-reactive protein. If there is any concern over infection, then deep cultures (not skin surface) from lesions should be conducted and submitted for bacterial, tuberculosis, and fungal cultures.[117]

Figure 85-5 Large scars and fistule pseudo-comedones at the buttocks of a male patient with severe hidradenitis suppurativa involving the anogenital area.

Figure 85-6 Sinus tract formation developing in the vulva of a woman with hidradenitis suppurativa. (Used with permission from Dr. L. Edwards.)

SPECIAL TESTS. Ultrasonography of the follicles and dermis may reveal abscess formation and abnormalities in the deep part of the follicle, but is rarely indicated.[117] Magnetic resonance imaging features of the skin and subcutaneous tissue have been described. Such features included marked thickening of the skin, induration of the subcutaneous tissues, and multiple subcutaneous abscesses.[118]

PATHOLOGY

The early lesions of HS demonstrate follicular hyperkeratosis. Epidermal psoriasiform hyperplasia and subepidermal interfollicular inflammatory infiltrate have been additionally observed in a current report.[69] The deep part of the follicle appears to be involved. Dermal features include perifolliculitis, active folliculitis or abscess, sinus tract formation, fibrosis, and granuloma formation. There is evidence of an inverse relationship between fibrosis and inflammation, supporting the concept that fibrosis corresponds to areas of chronic involvement.[119] Histologic feature examination of adnexal structures reveals inflammation of the apocrine glands in only one-third of cases. Interestingly, involvement of eccrine glands (25%) has been reported to be more common than apocrine glands (12%).[120,121] Poral occlusion or cyst formation may be noted. The subcutis may demonstrate some fibrosis, fat necrosis, or inflammation.[70,71]

A reduction in the percentage of NK cells over time and a lower monocyte response to triggering by bacterial components was observed in patients with HS.[122] Compared with normal skin, increased numbers of TLR2-expressing infiltrating macrophages ($CD68^+$) and dermal dendrocytes ($CD209^+$) was detected in HS lesions.[108] In addition, a striking $CD8^+$ lymphocyte epitheliotropism was identified.[69]

COMPLICATIONS

QUALITY OF LIFE. Patients with HS experience a significant degree of morbidity when quality of life is measured by the Dermatology Life Quality Index.[123] The highest scores relate to disease-associated pain. Quality of life measurements are lower than other dermatologic diseases that have been investigated using this tool.[124] Loss of workdays is a socioeconomic consequence. Women lose significantly more days of work (mean, 2.9 days) than men (mean, 1.7 days).[117] A significant positive correlation of fair degree between HS severity and life quality index was detected.[125]

SYSTEMIC COMPLICATIONS. Local infection may develop and lead to septicemia. A case of lumbosacral epidural abscess has been reported.[126] Anemia or leukocytosis may be detected, but does not tend to be significant clinically.[127,128]

LOCAL COMPLICATIONS. Scarring may limit mobility. Anal, urethral, or rectal strictures may develop from chronic genitofemoral inflammation. Urethral fistulas have also been reported.[129] Additionally, disfiguring persistent penile, scrotal, or vulvar lymphedema due to blockade or destruction of local lymph drainage routes subsequent to chronic and recurrent inflammation may develop,[130] giving rise to significant functional impairment. Once this complication appears, no medical treatment is effective and surgical reconstruction may be necessary.[131] Squamous cell carcinoma (SCC) may rarely develop in chronically inflamed and scarred areas in individuals with long-standing disease.[132,133] SCC has been reported in 3.2% of patients with perianal HS lasting 20–30 years. Malignant transformation affects mainly men with a long-term history of genitoanal HS, whereas HPV has been detected in these genitoanal tumoral lesions, principally HPV-16.[133] These carcinomas tend to be more aggressive locally and are associated with a high incidence of metastatic disease and mortality (up to 50%). One case of paraneoplastic neuropathy has been described in association with SCC complicating severe perineal HS.[134] Clinicians should have a low threshold for biopsying any nonhealing lesion localizing to an area of chronic HS. One case-controlled Swedish study found that the overall incidence of malignancy, including nonmelanoma skin cancer, is increased in patients with HS.[135]

TREATMENT

The objective of patient management is prevention of the development of primary lesions as well as resolution, amelioration, or regression of secondary disease features such as scarring or sinus tract formation. The literature reveals only few randomized controlled studies, several case series, and a plethora of case reports.

Assessing severity is a prerequisite to manage individual patients; the classification of Hurley[113] is still useful: stage I is manageable with systemic drugs, stage II may benefit from medical treatment and from limited excisions of locally recurring lesions, stage III requires radical surgery (Box 85-5). On the other hand, the modified Sartorius score is more sensitive and

BOX 85-5 PROPOSAL FOR A GLOBAL ALGORITHM OF TREATMENT OF HIDRADENITIS SUPPURATIVA/ACNE INVERSA

HS STAGE	TREATMENT
Hurley stage I	Clindamycin 300 mg 2–3×/day (alternatively minocycline 100 mg/day) and rifampicin 300 mg 2×/day p.o. for 4–12 week (to potentate: clindamycin 300 mg 2–3×/day iv during the first 5 days of treatment) For females with signs of hyperandrogenism/hyperandrogenemia (additionally): hormonal antiandrogen with cyproterone acetate (up to 100 mg/day)
Hurley stage II	Step 1: As stage I Step 2: Limited excisions of locally recurring lesions
Hurley stage III	Step 1: As stage I Step 2: Infliximab (5 mg/kg) (alternatively adalimumab 40 mg) once or twice (Step 3: Ultrasonography of the area to be excised) Step 4: Wide excision of the involved area

useful in evaluating disease severity in clinical studies[125] (Box 85-6).

MEDICAL TREATMENT. Treatment is often disappointing, which has a significant negative impact on the patient's quality of life. Although topical and systemic antibiotics are effective, supportive evidence for bacterial etiology is lacking. In an evidence-based analysis of standard treatments and recent advances in the therapy of HS, only treatment with topical clindamycin 1% solution,[136] oral clindamycin and rifampicin, or with the hormonal antiandrogen cyproterone acetate 100 mg/day achieved an evidence level 2 and a recommendation grade B.[137] In three retrospective studies, 164 HS patients have received clindamycin 300 mg 2×/day and rifampicin 300 mg 2×/day for 10–12 weeks.[138–140] Thirty-two experienced complete remission of HS of between 1 and 4 years after only one course of treatment, and further two patients achieved remission after substituting clindamycin with minocycline (100 mg/day) because of transient diarrhea. Twenty-one patients were unable to complete the course of treatment because of side effects, mostly diarrhea. Most responders have not subsequently relapsed. A randomized controlled study comparing topical clindamycin with systemic tetracycline did not reveal a statistical difference.[141]

Intralesional corticosteroids may be of benefit for patients with an isolated number of tender lesions.[142] Practically, such treatment may not be appropriate for individuals with extensive disease and is not appropriate for areas of chronic inflammation.

Oral isotretinoin is ineffective in the treatment of HS. In a study with 358 HS patients interviewed and

examined for the effect of previous treatment with oral isotretinoin, only 16.1% declared an improvement.[143] In a previous study with 68 patients, 23.5% were cleared during therapy, whereas only 16.2% maintained improvement during a follow-up period of up to 6 months.[144] One case report described an individual with severe vulvar HS who, after treatment with prednisolone and then long-term isotretinoin (more than 1 year), remained disease free at 10 months posttreatment.[145] The other systemic retinoids, acitretin and etretinate, have also demonstrated limited efficacy in disease management.[146,147]

Hormonal therapy does have some reported success. In a double-blinded study, the antiandrogen, cyproterone acetate (50 mg), in conjunction with ethinyl estradiol (50 µg), resulted in complete or partial clearance at 18 months posttreatment in 50% of patients.[99,100] In a retrospective study with 64 female HS patients antiandrogen therapy was superior to oral antibiotic therapy (55% vs. 26%). Female patients presenting with HS should prompt investigations for underlying PCOS and insulin resistance.[148] The 5α-reductase inhibitor, finasteride (1 mg), may also have a weak limited effect on disease management.[101,149]

Intramuscular human immunoglobulin (HIG; 1,320–1,980 mg sc/m) administered in five HS patients led to >50% improvement in four patients.[150]

In a pilot study, 22 patients with Hurley's grade I and II were treated with 90 mg/day zinc gluconate; 8 complete remissions (CR) and 14 partial remissions were observed. When CR was obtained, the treatment was progressively decreased; 4 out of 22 patients experienced side effects, mainly gastrointestinal.[151]

Emerging data on the efficacy of biologics as monotherapy[152–154] did not fulfill the expectations initially, since etanercept and efalizumab showed a minor effectiveness in a few open and was ineffective in one controlled study (Box 85-7).[155–160] In contrast, infliximab, a chimeric monoclonal antitumor necrosis factor antibody, has demonstrated efficacy in several case reports with severe HS patients in both open and a controlled study, although the results seem transient and

are associated with significant toxicity as long-term treatment.[161–168] Small case series with adalimumab exhibited even more promising results but controlled studies are still missing.[169–171]

Case reports or small case series have also shown therapeutic success with other systemic therapies, including systemic corticosteroids, azathioprine, cyclosporine, dapsone, and methotrexate.[86,172–176]

Local therapies have also been recently examined. A single patient with aggressive perianal HS has responded favorably to wide surgical excision in conjunction with perilesional granulocyte-macrophage colony-stimulating factor injections.[177] A small case series demonstrated the efficacy of treatment of persistent painful nodules with cryotherapy. Healing time in these patients was lengthy (18–42 days).[178] Finally, the first case of botulinum toxin A successfully treating HS has been reported. In this case, injections into the axillae resulted in a 10-month remission.[179] Topical 15% resorcinol peel in 12 women with HS Hurley stage I or II led to a significant decrease in pain and a reduction in mean duration of the painful abscesses.[180]

Photodynamic therapy (PDT) as treatment for HS has recently been described in three small case series, but is neither established nor has been standardized.[181–184] Moreover, pulsed dye laser-mediated photodynamic therapy was not successful in a pilot study with four self-controlled cases.[185]

SURGERY. Surgical removal of all involved tissue, beyond clinically involved margins, is an effective treatment modality.[186–190] Postoperative recurrences may occur. Some authors have advocated the use of CO_2 laser[191,192] or the neodymium-doped yttrium aluminum garnet laser[193,194] for surgical ablation of tissue. The modality of closure has been a topic of debate. Overall, healing by secondary intent is thought to provide the best outcome. Primary closure, grafting, or flaps have been extensively used, but may be associated with poorer results.[195–201] In one series of 106 patients, there was a 70% recurrence rate requiring subsequent operation in the primary closure cohort and no recurrence in the split-thickness graft and flap groups.[202] A more limited surgical approach also plays a role in disease management. Deroofing or marsupializing of recurrent troublesome lesions or sinus tracts may aid with local control.[203] Lancing an inflammatory lesion is of limited benefit and should be discouraged.[195,204,205] A study with 200 patients has shown that enclosure of gentamicin after primary excision of HS lesions can reduce the number of complications 1 week postoperatively but it was ineffective on the long-term recurrence rate.[206] Ultrasonography can identify the true extent of lesions in HS, which may be of use in the preoperative planning.[207,208]

RADIOTHERAPY. Several authors have reported radiotherapy to be successful in the treatment of HS. Given the often young patient population with HS, long-term side effects must be considered.[209,210]

BIOMARKERS. Soluble interleukin-2 receptor (sIL-2R) and tumor necrosis factor-α serum levels were found increased in HS and especially sIL-2R correlated well with Hurley's grade.[211,212] Both serologic markers may be used as a valuable marker for disease staging and evaluation of treatment in patients with HS.

SECTION 15

Disorders of the Hair and Nails

Chapter 86 :: Biology of Hair Follicles

:: George Cotsarelis & Vladimir Botchkarev

BIOLOGY OF HAIR FOLLICLES AT A GLANCE

- The primary purpose of hair in humans is to influence social interactions.
- Hair follicle development depends on interactions between epithelial and mesenchymal cells. The genes important for this interaction are slowly being elucidated.
- Genes important for hair follicle development also play a role in hair follicle cycling.
- The hair follicle bulge possesses stem cells important for the continual regeneration of the follicle during cycling.
- Hair pigmentation depends on melanocyte stem cells and differentiated cells in the follicle. Many genes important for melanocyte behavior and hair pigmentation have been defined.

EVOLUTION AND FUNCTION OF HAIR

Hair is found only in mammals, where during the course of evolution its primary roles were to serve as insulation and protection from the elements. However, in contemporary humans, hair's main purpose revolves around its profound role in social interactions. Loss of hair (alopecia) and excessive hair growth in unwanted areas (hirsutism and hypertrichosis) can lead to significant psychological and emotional distress that supports a multibillion-dollar pharmaceutical and cosmetic effort to reverse these conditions.

Fundamental understanding of hair growth and its controls is increasing and result in new treatments for alopecia.[1,2] These advances resulted from the interest of developmental biologists and other investigators in the hair follicle as a model for a wide range of biologic processes. As each hair follicle cyclically regenerates, it recapitulates its initial development. Many growth factors and receptors important during hair follicle development also regulate hair follicle cycling.[3–10] The hair follicle possesses keratinocyte and melanocyte stem cells (MSCs), nerves, and vasculature that are important in healthy and diseased skin.[11–13] To appreciate this emerging information and to properly assess a patient with hair loss or excess hair (see Chapter 88), an understanding of the anatomy and development of the hair follicle is essential.

EMBRYOLOGY

Morphologically, hair follicle development has been divided into eight consecutive stages, several of which are illustrated in Fig. 86-1. Each stage is characterized by unique expression patterns for growth factors and their receptors, growth factor antagonists, adhesion molecules, and intracellular signal transduction components.[14–16] Promising advances in understanding the molecular mechanisms behind hair follicle development arose through the discovery that mammalian counterparts (homologs) of genes important for normal *Drosophila* (fruit fly) development also affect hair follicle development. *Decapentaplegic [Dpp/bone morphogenetic protein (BMP)], Engrailed (en), Homeobox (hox), hedgehog/patched (hh/ptc), notch, wingless/armadillo (wg/wnt/catenin) genes are all critical for hair follicle and vertebrate development in general.*[17–19] These genes were all first discovered in *Drosophila*, thus, most of the names assigned to them describe the peculiar appearance (phenotype) of the flies carrying mutations in these genes.[20]

Follicle formation begins on the head, and then moves downward to the remainder of the body in utero. The first hairs formed are lanugo hairs, which are nonpigmented, soft, and fine. Lanugo hair is typically shed between the 32nd and 36th weeks, although approximately one-third of newborns still retain their lanugo hair for up to several weeks after birth.

Patterning genes, called *homeobox genes*, which are precisely organized in the genome so that they are

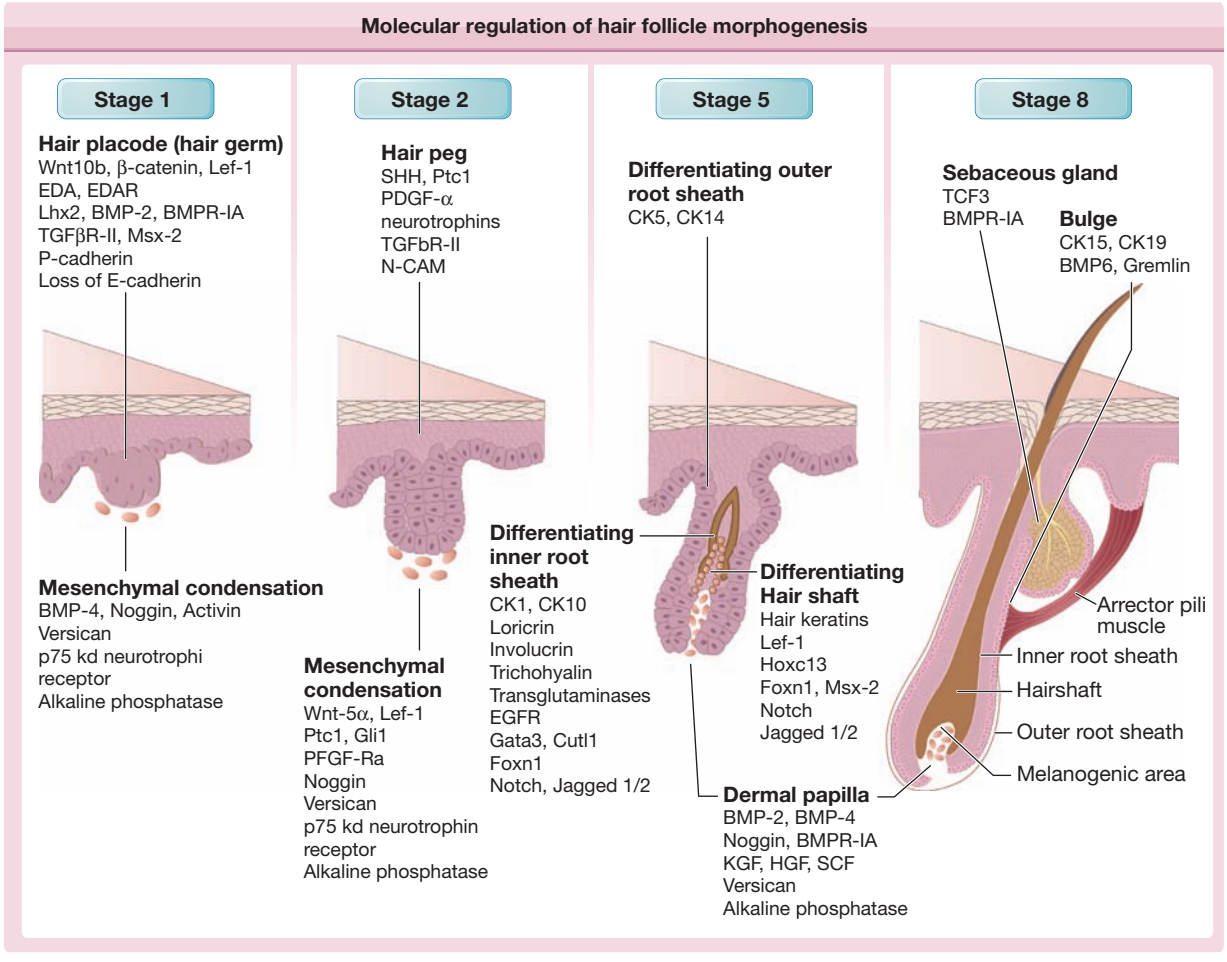

Figure 86-1 Molecular regulation of hair follicle morphogenesis. The scheme shows the expression of different growth factors, their receptors, adhesion, and cell matrix molecules, transcriptional regulators in hair follicle epithelium, and mesenchyme during distinct stages of hair follicle development. BMP = bone morphogenetic protein; BMPR-IA = bone morphogenetic protein receptor, type IA; CK = keratin 5; Cutl1 = cut-like 1; E-cadherin = epithelial cadherin; EDA = ectodysplasin; EDAR = ectodysplasin receptor; EGFR = epidermal growth factor receptor; Foxn1 = forkhead box N1; Gata3 = GATA binding protein 3; Gli1 = glioma-associated oncogene homolog 1; HGF = hepatocyte growth factor; Hoxc13 = homeobox C13; KGF = keratinocyte growth factor; Lef-1 = lymphoid enhancer factor 1; Lhx2 = LIM homeobox 2; N-CAM = neural cell adhesion molecule; P-cadherin = placental cadherin; PDGF-α = platelet-derived growth factor α polypeptide; PFGF-Rα = platelet-derived growth factor receptor α; Ptc1 = patched1; SCF = stem cell factor; Shh = sonic hedgehog; TCF3 = transcription factor 3; TGF-βR-II = transforming growth factor-β receptor 2.

expressed in strict temporal sequences and spatial patterns during development, likely are responsible for the nonrandom and symmetric distribution of hair follicles over the body.[21,22] In adult mice, homeobox gene expression reappears in hair follicles and serves to maintain normal hair shaft production.[6] *Engrailed*, a type of homeobox gene, is responsible for dorsal–ventral patterning, and mice lacking *engrailed* develop hair follicles on their footpads.[23]

Although hair follicles and hairs all share the same basic anatomy, their growth, size, shape, pigmentation, and other characteristics differ widely, based on body location and variation among individuals. Many of these characteristics are established during development but are then profoundly altered by hormonal influences later in life. We are beginning to understand the genes controlling hair length, curl and distribution because of elegant genetic studies on dogs. These studies reveal that fibroblast growth factor-5 (FGF-5), Keratin 71, and R-spondin 2 influence length, curl and distribution respectively.[24] In humans, thicker hair found in Asians is associated with increased activity of *ectodysplasin receptor (EDAR)*,[25] the receptor of ectodysplasin (*EDA*) (see below).

The size of many types of follicles changes drastically several times throughout life. For example, lanugo hair follicles, which produce hair shafts several centimeters long, convert to vellus follicles that produce small hairs that protrude only slightly from the skin surface. Later in life, vellus follicles on the male beard enlarge into terminal follicles that generate thick, long hairs. On the scalp of genetically

predisposed individuals, terminal follicles miniaturize and form effete, microscopic hairs.

EPITHELIAL PLACODE OR PRIMARY HAIR GERM

In the human fetus, hair follicles develop from small collections of cells, called *epithelial placodes*, which correspond to stage 1 of hair follicle development and first appear around 10 weeks' gestation (see Fig. 86-1). The epithelial placode then expands to form the "primary hair germ" whose progeny eventually generate the entire epithelial portion of the hair follicle.[26]

The cells of the hair placode and germ express placental cadherin and become oriented vertically, losing their desmosomes, hemidesmosomes, and epithelial cadherin, which decreases their adhesion to their neighbors.[27–29] Dermal cells beneath the hair placode form a cluster (or condensate), which later develops into the dermal papilla.[30]

Hair follicle formation depends on a series of mesenchymal/epithelial interactions.[30] An initial signal arises in the mesenchyme (primitive dermis) and instructs the overlying epithelium to form an appendage, indicated by the appearance of regularly spaced placodes (see Fig. 86-1). The second signal arises from the epithelial placode and causes an aggregation of cells in the underlying mesenchyme that will eventually form the dermal papilla. Finally, a signal from this primitive dermal papilla initiates proliferation and differentiation of placode cells, ultimately leading to formation of a mature follicle. These reciprocal signals pass through the intervening basement membrane, which undergoes alterations in its morphology and chemical composition that may alter its ability to sequester growth factors and binding proteins, thus possibly modulating the epithelial/mesenchymal interactions.

Many of these regulatory molecules important for the formation of the hair follicle have been defined, but how they interact to generate hair follicles in an otherwise homogeneous epithelium is yet to be determined. In one model, the spacing and size of placodes are regulated by a dermal signal, which varies in character in different body regions. The dermal signal occurs uniformly within each body region and triggers the activation of promoters and repressors of follicle fate in the epithelium that then compete with one another, resulting in the establishment of a regular array of follicles.[15,31] Differences in the levels of promoter and repressor activation could account for regional differences in the size and spacing of follicles. Consistent with this model, several positive and negative regulators of hair follicle fate are initially expressed uniformly in the epidermis and subsequently become localized to placodes.

One of the earliest molecular pathways that positively regulates hair follicle initiation is the WNT/β-catenin pathway. β-Catenin is the downstream mediator of WNT signaling. WNT proteins bind to receptors on the cell membrane and, through a series of signals, inhibit the degradation of cytoplasmic β-catenin. β-Catenin then translocates to the nucleus, forming a complex with the LEF/TCF family of transcription factors and resulting in expression of downstream genes.[15,31] Activation of this β-catenin pathway appears necessary for establishing epithelial competence—a state in which the epithelial tissue has the potential to form a hair follicle. Normally, the β-catenin pathway is inactive in the adult epidermis, but by artificially activating β-catenin in epidermal basal cells of adult transgenic mice, hair follicles develop de novo.[32] This remarkable finding could eventually have therapeutic implications, although constant activation of this pathway in the hair follicle also results in pilomatricomas and trichofolliculomas, two types of relatively rare cutaneous tumors.[32,33]

EDA, a molecule related to tumor necrosis factor, and its receptor (*EDAR*) also are part of another major pathway that stimulates early follicle development in both mice and humans.[34] *EDA* gene mutations cause X-linked anhidrotic ectodermal dysplasia, a syndrome associated with decreased numbers of hair follicles, and defects of the teeth and sweat glands (see Chapter 142).[35] The *EDAR* gene is mutated in autosomal recessive and dominant hypohidrotic ectodermal dysplasias, causing identical phenotypes to those resulting from *EDA* mutations. The mouse *Edar* gene is expressed ubiquitously in the epithelium before placode formation, and then becomes restricted to placodes, whereas the *Eda* gene is ubiquitously expressed even after placode formation.[36] Mice with mutations in these genes have the same phenotype as humans with similar mutations, and mice overexpressing Eda in the epidermis show formation of the "fused" follicles due to the loss of proper spacing between neighboring hair placodes.[37,38] Humans with more active *EDAR* genes have thicker hair.[25]

In contrast to EDA and EDAR, which promote hair follicle development, members of the BMP family inhibit follicle formation. *Bmp2* is expressed diffusely in the ectoderm, but then localizes to the early placode and underlying mesenchyme, while *Bmp4* is expressed in the early dermal condensate.[39,40] BMP signaling inhibits placode formation, whereas neutralization of BMP activity by its antagonist Noggin promotes placode fate, at least in part via positive regulation of lymphoid enhancer factor 1 (Lef-1) expression.[39,41–43] Mice lacking Noggin have fewer hair follicles than normal and retarded follicular development.[43] The Notch pathway also appears to play a role in determining the follicular pattern. The Notch ligand Δ-1 is normally expressed in the mesenchyme underlying the placode[44–46] and, when misexpressed in a small part of the epithelium, promotes and accelerates placode formation while suppressing placode formation in surrounding cells.[44,47]

Another secreted protein present in the follicular placode that plays a major role in epithelial-mesenchymal signaling is sonic hedgehog (Shh).[48,49] Skin from mice lacking Shh have extremely effete hair follicles with poorly developed dermal papillae.[50–52] Patched1 (Ptc1), the receptor for Shh, is expressed in the germ cells and the underlying dermal papilla, suggesting that Shh may have both autocrine and paracrine inductive properties necessary for hair

germ and dermal papilla formation.[53] Patched is the gene deficient in basal cell nevus syndrome (see Chapter 116).[19]

THE BULBOUS PEG OR HAIR BUD

In the next stage of development, the bulbous peg or hair bud (or stage 2 of hair follicle development, see Fig. 86-1) is formed by elongation of the hair germ into a cord of epithelial cells. The mesenchymal cells at the sides of the peg will develop into the fibrous sheath of the hair follicle, and those at the tip of the peg will develop into the dermal papilla. The deepest portion of the follicle peg forms a bulbous structure that surrounds the underlying mesenchymal cells destined to become the dermal papilla. These epithelial cells will become the matrix of the hair follicle, which gives rise to the hair shaft and inner root sheath. The outer root sheath forms two bulges on the side of the hair follicle forming an obtuse angle with the surface of the skin. The superficial bulge will develop into the sebaceous gland. The deeper bulge serves as the future site of epithelial stem cells that generate the new lower follicle during hair follicle cycling. The arrector pili muscle usually attaches in the bulge area, and contraction of the muscle causes a more vertical orientation of the hair shaft leading to "goose bumps." In the axillae, anogenital region, areolae, periumbilical region, eyelids (the specialized glands of Moll), and external ear canals, a third bulge develops superficial to the sebaceous gland bud and gives rise to the apocrine gland.

As the hair follicle bulb appears during the bulbous peg stage, at least eight different cell layers constituting all of the components of the mature hair follicle are formed. Understanding which genes determine specific cell lineages within the follicle is an important question. GATA-3 is important in inner root sheath differentiation.[54] Notch1, a membrane protein involved in determining cell fate through cell–cell interactions and intracellular signal transduction, and its ligands Serrate1 and Serrate2 are expressed in matrix cells destined to form the inner root sheath and hair shaft.[46,55] Notch1 appears to control the phenotype of keratinocytes as they leave the bulb matrix and differentiate into specific cell types.[56]

MATURE HAIR FOLLICLE

The central lumen where the hair shaft will emerge is formed by necrosis and cornification of epithelial cells in the infundibulum. As the hair shaft is produced, several signaling pathways are involved in the control of its differentiation. Wnt/β-catenin/Lef-1 signaling plays an important role in hair shaft formation, and ectopic expression of Wnt3 in the hair follicle outer root sheath causes hair shaft fragility.[57,58] Hair shaft keratin genes contain binding sites for Lef-1,[59] which translocates to the nucleus after activation of the WNT/β-catenin pathway. WNT signaling probably regulates expression of hair shaft keratin genes, because nearly all of these genes contain Lef-1 binding sites in their promoter regions.[60]

BMP signaling is also essential for proper differentiation of the inner root sheath and hair shaft, because conditional deletion of BMP receptor type 1A in keratinocytes results in profound alterations of the inner root sheath and hair shaft formation.[61–63] Several other putative transcription factors control hair shaft differentiation, including HOXC13,[6] a homeobox protein, and the WHN gene,[64–66] which is mutated in nude mice and rarely in humans with hair, nail, and immune defects.[67,68]

This process of hair follicle formation is repeated in several waves, with the formation of secondary follicles alongside the initial follicle. The follicles are primarily clustered into groups of three and possess an oblique orientation with a similar angle to their neighbors.

ANATOMY

HAIR TYPES

After formation of the lanugo hair that is characteristic of the prenatal period, there are two major types of hair classified according to size (Table 86-1). Terminal hairs are typically greater than 60 µm in diameter, possess a central medulla, and can grow to well over 100 cm in length. The duration of the growing stage (anagen) determines the length of the hair. The hair bulb of terminal hairs in anagen is located in the subcutaneous fat. In contrast, vellus hairs are typically less than 30 µm in diameter, do not possess a medulla, and are less than 2 cm in length. The hair bulb of vellus hairs in anagen is located in the reticular dermis. Terminal hairs are found on the scalp, eyebrows, and eyelashes at birth. Vellus hairs are found elsewhere, and, at puberty, vellus hair follicles in the genitalia, axillae, trunk, and beard area in men transform into terminal hair follicles under the influence of sex hormones. Terminal hair follicles in the scalp convert to vellus-like or miniaturized hair follicles during androgenetic alopecia (see Chapter 88).[1,69]

The curvature of the hair varies greatly among different individuals and races, and ranges from straight to tightly curled. Curved hair shafts arise from curved hair follicles. The shape of the inner root sheath is thought to determine the shape of the hair. Curled

TABLE 86-1
Hair Types and Characteristics

Type of Hair	Anagen Duration	Size (Diameter, Length)
Lanugo	1–3 months	40 µm, 1–2 cm
Vellus	1–2 weeks	<30 µm, <2 cm
Terminal	>1 year	>60 µm, 10–>100 cm
Miniaturized	<1 week	<30 µm, <2 cm

hair in cross section is more elliptical or flattened in comparison with straight hair, which is more round. Several genes influencing hair shape have been identified. Mutations in the epidermal growth factor receptor (EGFR) pathway and in insulin-like growth factor binding protein 5 result in curly hair in mice.[70,71]

MICROSCOPIC ANATOMY

The upper follicle consists of the infundibulum and the isthmus, and the lower follicle consists of the suprabulbar and the bulbar areas (Fig. 86-2).[14,66] The upper follicle is permanent, but the lower follicle regenerates with each hair follicle cycle. The major compartments of the hair from outermost to innermost include the connective tissue sheath, the outer root sheath, the inner root sheath, the cuticle, the hair shaft cortex, and the hair shaft medulla, each characterized by distinct expression of the hair follicle-specific keratins (Table 86-2).[72,73]

OUTER ROOT SHEATH. The outer root sheath is continuous with the epidermis (see Fig. 86-2) at the infundibulum and continues down to the bulb. The cells of the outer root sheath change considerably throughout the follicle. The outer root sheath in the infundibulum resembles epidermis and forms a granular layer during its keratinization. In the isthmus, the outer root sheath cells keratinize in a trichilemmal fashion, lacking a granular layer. Trichilemmal keratinization occurs where the inner root sheath begins to slough. Desmoglein expression markedly changes here as well and trichilemmal or pilar cysts retain these characteristics.[74] Keratinocytes in the outer root sheath form the bulge at the base of the isthmus (see Section "Hair Follicle Stem Cells"). These cells generally possess a higher nuclear to cytoplasmic ratio compared with other areas of the follicle. Moving downward, the outer root sheath cells become much larger and contain abundant glycogen in the suprabulbar follicle. In the bulb, the outer root sheath consists of only a single,

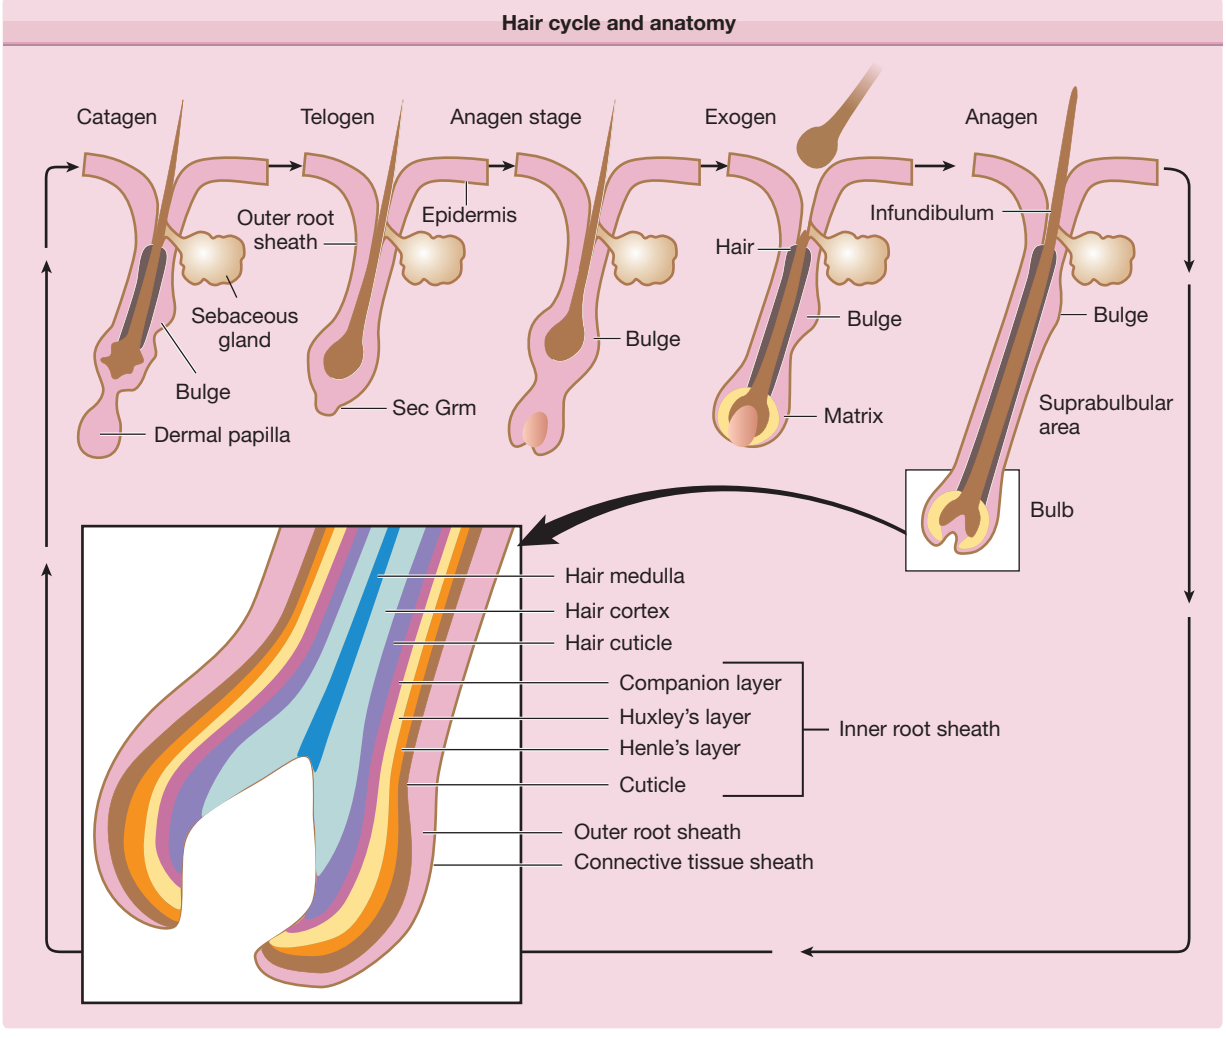

Figure 86-2 Hair cycle and anatomy. The hair follicle cycle consists of stages of rest (telogen), hair growth (anagen), follicle regression (catagen), and hair shedding (exogen). The entire lower epithelial structure is formed during anagen and regresses during catagen. The transient portion of the follicle consists of matrix cells in the bulb that generate seven different cell lineages, three in the hair shaft and four in the inner root sheath. B = bulge; E = epidermis; DP = dermal papilla; H = hair shaft; M = matrix; ORS = outer root sheath; S = sebaceous gland; Sec Grm = secondary germ.

[a]Autosomal dominant mutations of K81 and K86 lead to monilethrix (alopecia due to increased hair fragility).
Data from Langbein L et al: K25 (k25irs1), K26 (k25irs2), k27 (k25irs3), and k28 (k25irs4) represent the type I inner root sheath keratins of the human hair follicle. *J Invest Dermatol* **126**:2377, 2006; and Langbein L, Schweizer J: Keratins of the human hair follicle. *Int Rev Cytol* **243**:1, 2005.

flattened cell layer that can be traced to the base of the follicle.

INNER ROOT SHEATH. The inner root sheath extends from the base of the bulb to the isthmus and contains four parts from outermost to innermost: companion layer, Henle layer, Huxley layer, and the inner root sheath cuticle. The companion layer (see Fig. 86-2) has been referred to as the innermost layer of the outer root sheath, but recent evidence indicates that it is more like inner root sheath than outer root sheath.[75] The companion layer attaches to Henle layer and moves upward with the rest of the inner root sheath; thus, it provides a slippage plane between the outer root sheath, which is stationary, and the inner root sheath.[76] The companion layer is prominent in some follicles (e.g., the beard) compared with others. The cells of the companion layer are flat compared to the cuboidal outer root sheath cells and express a type II cytokeratin, K6hf.[75] Henle layer is one-cell-layer thick and is the first to develop keratohyalin granules and the first to keratinize. Huxley layer is two to four cell layers thick and keratinizes above Henle layer at the region known as *Adamson fringe*. Some cells within Huxley's layer protrude through Henle layer and attach directly to the companion layer. These cells are called *Fluegelzellen* or *wing cells*.[77] The cells of the inner root sheath cuticle partially overlap, forming a "shingled roof" appearance, and they intertwine precisely with the cuticle cells of the hair shaft. This association between the two cuticles anchors the hair shaft tightly to the follicle. The inner root sheath, composed of hard keratins and associated proteins (see Table 86-2), is thought to dictate hair shape by funneling the hair shaft cells as they are produced. The transcription factor, GATA-3, is critical for inner root sheath differentiation and lineage. Mice lacking this gene fail to form an inner root sheath.[54]

HAIR SHAFT. The hair shaft (and inner root sheath) arises from rapidly proliferating matrix keratinocytes in the bulb, which have one of the highest rates of proliferation in the body. The cells of the future hair shaft are positioned at the apex of the dermal papilla and form the medulla, cortex, and hair shaft cuticle (see Fig. 86-2). Immediately above the matrix cells, hair shaft cells begin to express specific hair shaft keratins in the prekeratogenous zone. The differentiation of hair shaft cells in this zone is dependent on the Lef-1 transcription factor. Lef-1 binding sites are present in most hair keratin genes. BMP receptor type 1a is also critical for matrix cell differentiation into the hair shaft, because loss of this receptor prevents hair shaft differentiation.[61–63]

The hair shaft cuticle covers the hair, and its integrity and properties greatly impact the appearance of the hair. Once the hair exits the scalp, the cuticle endures weathering, and it is often completely lost at the distal ends of long hairs. Inside the cuticle, the cortex comprises the bulk of the shaft and contains melanin. The cortex is arranged in large cable-like structures called *macrofibrils*. These, in turn, possess microfibrils that are composed of intermediate filaments. The medulla sits at the center of larger hairs, and specific keratins expressed in this layer of cells (see Table 86-2) are under the control of androgens.[78]

DERMAL PAPILLA. The dermal papilla (see Fig. 86-1) is a core of mesenchymally derived tissue enveloped by the matrix epithelium. It is comprised of fibroblasts, collagen bundles, a mucopolysaccharide-rich stroma, nerve fibers, and a single capillary loop. It is continuous with the perifollicular sheath (dermal sheath) of connective tissue that envelops the lower follicle.

Tissue recombination experiments have shown that the dermal papilla has powerful inductive properties, including the ability to induce hair follicle formation when transplanted below nonhair-bearing footpad epidermis.[76,79] This shows that the tissue patterning established during the fetal period can be altered under appropriate conditions. In human follicle, the volume of the dermal papilla correlates with the number of matrix cells and the resulting size of the hair shaft.[80] In mice, sizes of the hair bulb and hair diameter strongly depend of the proliferative activity of the matrix keratinocytes.[81]

Many soluble growth factors that appear to act in a paracrine manner on the overlying epithelial matrix cells originate from the dermal papilla. Specifically, keratinocyte growth factor (KGF) is produced by the anagen dermal papilla, and its receptor, FGF receptor 2 (FGFR2), is found predominantly in the matrix keratinocytes. Injections of KGF into nude mice produce striking hair growth at the site of injection,[82] suggesting that KGF is perhaps necessary for hair growth and cycling. However, surprisingly, KGF knockout mice develop morphologically normal hair follicles that produce "rough" or "greasy" hair; thus, KGF's effects on hair follicle morphogenesis and cycling appear dispensable or replaceable by other growth factors with redundant functions.[83]

HAIR FOLLICLE INNERVATION. Myelinated sensory nerve fibers run parallel to hair follicles, surrounding them and forming a network.[84] Smaller nerve fibers form an outer circular layer, which is concentrated around the bulge of terminal follicles and the bulb of vellus follicles. Several different types of nerve endings, including free nerve endings, lanceolate nerve endings, Merkel cells, and pilo-Ruffini corpuscles are found around hair follicles.[85] Each nerve ending detects different forces and stimuli. Free nerve endings transmit pain, lanceolate nerve endings detect acceleration, Merkel cells sense pressure, and pilo-Ruffini structures detect tension. Perifollicular nerves contain neuromediators and neuropeptides, such as substance P or calcitonin gene-related peptide, that influence follicular keratinocytes and alter hair follicle cycling.[86–90] Conversely, hair follicle keratinocytes produce neurotrophic factors that influence perifollicular nerves and stimulate their remodeling in hair cycle-dependent manner.[90,91] Merkel cells that are considered neuroendocrine cells also produce neurotrophic factors, cytokines, or other regulatory molecules. Because Merkel cells are concentrated in the bulge area, some have postulated that these secreted factors may influence the cycling of the hair follicle.[92]

PERIFOLLICULAR SHEATH. The perifollicular sheath envelops the epithelial components of the hair follicle and consists of an inner basement membrane called the *hyaline* or *vitreous (glassy) membrane* and an outer connective tissue sheath. The basement membrane of the follicle is continuous with the interfollicular basement membrane. It is most prominent around the outer root sheath at the bulb in anagen hairs. During catagen, the basement membrane thickens and then disintegrates.

Surrounding the basement membrane is a connective tissue sheath comprised primarily of type III collagen. Around the upper follicle, there is a thin connective tissue sheath continuous with the surrounding papillary dermis and arranged longitudinally. Around the lower follicle, the connective tissue sheath is more prominent, with an inner layer of collagen fibers that encircle the follicle surrounded by a layer of longitudinally arranged collagen fibers.[66]

When transplanted under the skin, this perifollicular connective tissue has the remarkable ability to form a new dermal papilla and induce new hair follicle formation.[93] Even when the connective tissue sheath is transplanted to another individual, these follicles survive without evidence of immunologic rejection.

HAIR FOLLICLE CYCLE

Each individual hair follicle perpetually traverses through three stages: (1) growth (anagen), (2) involution (catagen), and (3) rest (telogen).[12] The length of anagen determines the final length of the hair and thus varies according to body site; catagen and telogen duration vary to a lesser extent depending on site. Scalp hair has the longest anagen of 2 years to more than 8 years. Anagen duration in young males at other sites is shorter: legs, 5–7 months; arms, 1.5–3.0 months; eyelashes, 1–6 months; and fingers, 1–3 months. In contrast to most mammals, including mice and newborn humans, in the adult human the hairs of the scalp grow asynchronously. Approximately 90%–93% of scalp follicles are in anagen and the rest primarily in telogen.[94] Applying these figures to the 100,000–150,000 hairs on the scalp indicates that approximately 10,000 scalp hairs are in telogen at any given time. However, because we lose only 50–100 hairs per day, this indicates that telogen is a heterogenous state. The follicles that are shedding their hair shaft are thus in "exogen," which comprises approximately 1% of the telogen hair follicles (see Fig. 86-2 and below). Hair on the scalp grows at a rate of 0.37–0.44 mm/day or approximately 1 cm/month.

HAIR FOLLICLE STEM CELLS

Because the lower portion of the follicle cyclically regenerates, hair follicle stem cells were thought to govern this growth. Historically, hair follicle stem cells were assumed to reside exclusively in the "secondary germ" (see Fig. 86-2), which is located at the base of the telogen hair follicle. It was thought that the secondary

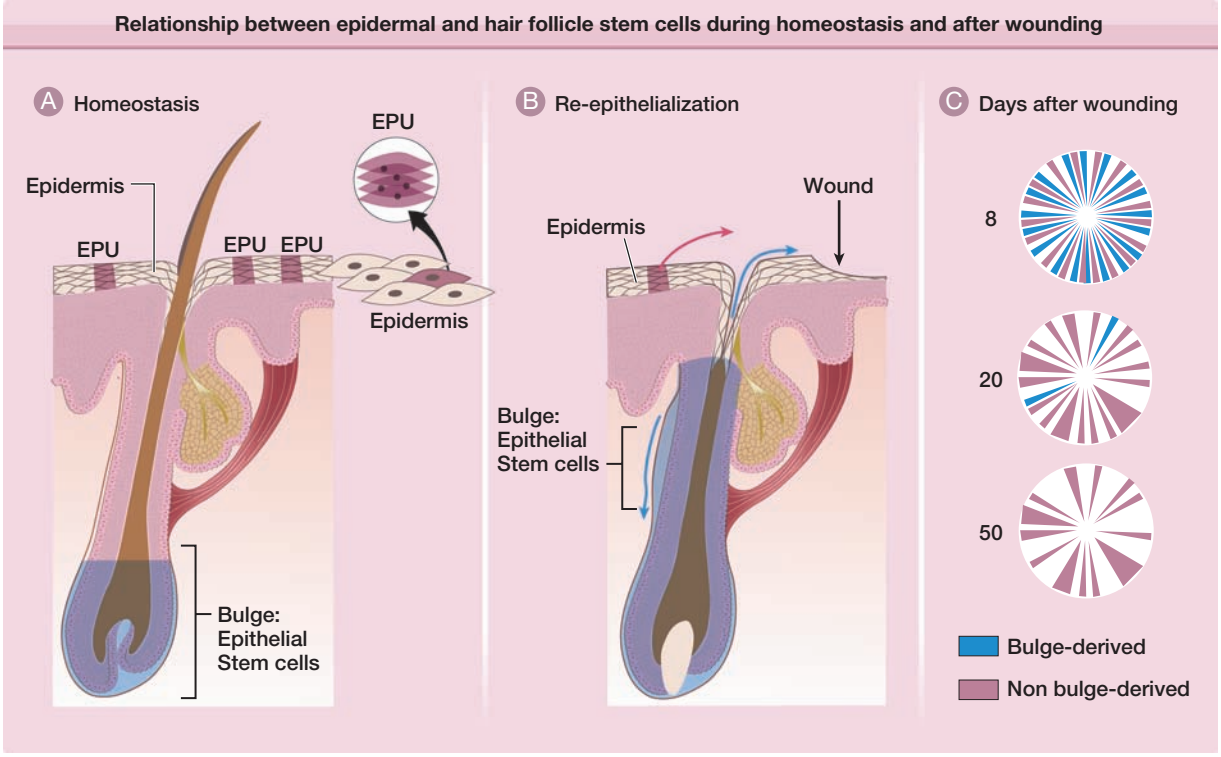

Figure 86-3 Relationship between epidermal and hair follicle stem cells during homeostasis and after wounding. **A.** During normal conditions, epidermal renewal is dependent on cell proliferation within epidermal proliferative units (EPUs), which are clonal populations of cells roughly arranged in hexagonally shaped columns that produce a single outer squame. Epithelial stem cells in the hair follicle bulge do not contribute to epidermal renewal. **B.** After full-thickness wounding, bulge cells contribute cells to the epidermis for immediate wound closure (*blue upward arrow*). Bulge cells also are required for hair follicle cycling (*blue downward arrow*) **C.** Over time, bulge-derived cells diminish, whereas nonbulge-derived cells (from the interfollicular epidermis and infundibulum) appear to predominate in the reepithelialized wound.

germ moved downward to the hair bulb during anagen and provided new cells for production of the hair. At the end of anagen, the secondary germ was thought to move upward with the dermal papilla during catagen to come to rest at the base of the telogen follicle. This scenario of stem cell movement during follicle cycling was brought into question when a population of long-lived presumptive stem cells was identified in an area of the follicle surrounding the telogen club hair.[95] Subsequently, it was shown that the secondary germ is a transient structure that forms at the end of catagen from cells in the lower bulge.[96] The concept that hair follicle stem cells are permanently located in the bulge has now been confirmed using lineage analysis, which showed that the bulge cells give rise to all epithelial layers of the hair follicle.[11,97,98] In line with this, ablation of bulge cells results in destruction of the follicle.[96] These findings support the notion that loss of hair follicle stem cells in the bulge leads to permanent or cicatricial types of alopecia (see Chapter 88).

Progress has been made in defining subsets of cells within the hair follicle that serve as different stem and progenitor populations. Markers that have been shown through genetic lineage analysis to contribute to the perpetual cycling of the hair follicle, include cytokeratin 15 and Lgr5.[96,99] Lgr5, although sometimes touted as an exclusive marker of secondary germ cells, also marks bulge cells. Lgr6, a gene related to Lgr5, is expressed in an area above the bulge in the upper isthmus. The cells marked by Lgr6 migrate to the epidermis during homeostasis and after wounding.[100] In addition to these markers, several others demonstrate the heterogeneity of the hair follicle epithelium.[101]

Are bulge cells the "ultimate" stem cells within the skin epithelium? For example, do they generate epidermis and sebaceous glands during homeostasis and after wounding? To answer these questions, lineage analysis and transgenic techniques were again used. As illustrated in Fig. 86-3, bulge cells do not normally move to the epidermis, but after full-thickness excision of the skin, bulge cell progeny migrate into the wound during reepithelialization.[11,96] These cells comprise approximately 30% of the cells in the regenerated epidermis. The role of bulge cells in sebaceous gland maintenance is still not clear, but is under investigation.

ANAGEN

The formation of a new lower follicle and hair at anagen onset recapitulates folliculogenesis in the fetus. Anagen can be divided into seven stages: (1) stage I—growth of the dermal papilla and onset of mitotic

activity in the germ-like overlying epithelium; (2) stage II—bulb matrix cells envelop the dermal papilla and begin differentiation, evolving bulb begins descent along the fibrous streamer; (3) stage III—bulb matrix cells show differentiation into all follicular components; (4) stage IV—matrix melanocytes reactivate; (5) stage V—hair shaft emerges and dislodges telogen hair; (6) stage VI—new hair shaft emerges from skin surface; and (7) stage VII—stable growth.[102]

During proliferation and migration of keratinocytes into the dermis to reform the new lower follicle, enzymes such as proteases and collagenases appear at the leading edge of the downgrowth, and growth factors and their receptors are upregulated similar to an epithelial wound.[12] Pathways of keratinocyte differentiation that are seen in the epidermis during wound healing, such as expression of keratin 6, are activated. Mice lacking Stat3, a regulator of cell migration in the cutaneous epithelium, show defects in wound healing and a failure of hair follicles to enter anagen,[103] thus further illustrating the similarity between wound healing and the early events of anagen. Remarkably, the dermal papilla in the midst of this degradative milieu survives and moves downward. Neurocutaneous and vascular networks are remodeled.[91,95] Melanocytes proliferate and repopulate the new hair bulb.[104] Finally, a burst of endothelial proliferation and angiogenesis in the dermal papilla marks the time point when the lower follicle is completely restored and is actively producing the new hair shaft.[105]

CATAGEN

The onset of catagen is marked by cessation of the mitotic activity of the matrix cells and by well-coordinated apoptosis in the cyclic portion of the hair follicle.[12,106] Pigment production by melanocytes ceases before matrix cell proliferation stops, thus leading to a nonpigmented proximal end in the telogen club hair (see Fig. 86-2). Melanin is often found in the surrounding dermis and papilla where it is engulfed by macrophages. The perifollicular sheath collapses, and the vitreous or glassy membrane thickens. The lower follicle retracts upward with the dermal papilla. The perifollicular sheath forms a fibrous streamer comprised of fibroblasts, small blood vessels, and collagen.[1] Eventually, the dermal papilla becomes situated immediately below the bulge at the lower portion of the isthmus.

During catagen, the largest follicles, on the scalp for example, shorten their length from 2- to 5-mm-long structures whose deepest portion, the bulb, extends down into the subcutaneous fat to truncated 0.25- to 0.5-mm follicles in telogen. As the basement membrane around the lower follicle thickens, the dermal papilla, protected from the surrounding apoptosis and destruction (perhaps because it expresses Bcl-2, an antiapoptotic factor[12]) condenses and begins to move upward to come to rest below the bulge during telogen. The migration of the dermal papilla from the subcutaneous fat to the dermis during catagen is necessary for continued follicle cycling. This is illustrated by the syndrome of atrichia with papules.[107,108] These patients have mutations in either their hairless gene or in their vitamin D receptor gene, in which case they also have rickets. Mice with similar mutations have the hairless phenotype. We know from these mice that folliculogenesis is normal; however, when the follicles enter catagen for the first time, the lower portion of the follicle does not involute and contract properly, and the dermal papilla remains stranded in the subcutaneous fat.[95] Although bulge cells are still present, no new anagen follicles ever form, presumably because the stem cells cannot interact with the dermal papilla.[95]

The study of mouse mutants has also resulted in several key findings that have increased our understanding of the molecular events at catagen onset. Specifically, Hebert et al[3] discovered that mice lacking the *Fgf5* gene have hair that is 50% longer than their wild-type litter mates, and that mutations in this gene are responsible for the angora phenotype that was described more than 30 years ago. Although these findings were rather unexpected, careful evaluation of *Fgf5* expression throughout the normal hair cycle demonstrated that its expression was upregulated in the outer root sheath and hair matrix cells just before the onset of catagen, suggesting that *Fgf5* may trigger catagen onset. Interestingly, the follicle still eventually entered catagen, even in the absence of FGF-5, suggesting redundancy in the FGF-5 pathway or an intrinsic finite proliferative capability of the matrix cells.[95] Further studies also demonstrated that other FGF family members and their receptors are expressed during anagen, and probably also play a role in the hair follicle cycle.[109] The hair phenotype of FGF-5-deficient mice is substantially reversed by ectopic expression of the antiapoptotic gene *bcl-xL*$_x$ in the outer root sheath, suggesting that regulation of cell survival in the outer root sheath may play a role in control of the hair growth cycle.[110]

Although it has been known for many years that exogenous EGF administered to sheep results in catagen induction,[111] only through more recent transgenic and knockout studies in mice has the importance of the EGFR system in hair cycle regulation been realized.[70,112] For example, knockout mice lacking transforming growth factor-α (TGF-α), the major ligand for EGFR, have abnormal hair follicle development and manifest the waved hair phenotype.[4,5] When EGFR is functionally downregulated in the basal layer of the epidermis and hair follicle using a dominant negative transgenic strategy, the resulting hair is not only waved, but also longer than normal.[70] The transition of the hair follicles from anagen to catagen is delayed in these mice. Hair follicles in mouse skin that completely lack EGFR also do not progress from anagen to telogen.[112] Thus, EGFR and its ligand are required for normal hair follicle development and cycling. Given the complexity of the EGFR family, which includes four receptors (ErbB1–4) and at least six ligands, future studies are needed to clarify the role of individual family members in hair follicle cycling.[113]

In addition to FGF-5 and EGF, neurotrophins and TGF-β1 induce premature catagen. Neurotrophin-3 and brain-derived neurotrophic factor transgenic mice show premature catagen development, and brain-derived neurotrophic factor overexpression leads to

the shortening of hair length by 15%, most likely via stimulation of proapoptotic signaling through p75 kDa neurotrophin receptor.[114,115] TGF-β1 induces premature catagen in isolated human hair follicles and in mouse skin in vivo, and TGF-β1 knockout mice display delay in catagen onset.[116–118]

TELOGEN AND EXOGEN

Once the involution of catagen is complete and a club hair is formed (see Fig. 86-2), the hair follicle prepares the hair for expulsion from the scalp. About 1% of telogen follicles are shed each day. Milner et al[119] have proposed distinguishing hair shedding as a separate phase called *exogen*. Exogen is a highly controlled and timed event in mammals that shed on a seasonal basis. That exogen is an active stage is supported by Headington's description of one type of telogen effluvium he termed *immediate telogen release*.[120] This type of hair loss can be seen soon after starting medications, such as minoxidil, or in response to rapid fluctuations in light/dark cycles. It consists of an increase in shedding of club hairs within weeks of the precipitating event (too soon to be caused by follicles prematurely entering telogen from anagen), suggesting that club hairs that are normally retained in the follicle can be actively shed. The heterogeneity of telogen is further supported by the work of Guarrera and Rebora,[121] who followed individual hairs in situ using macrophotographs for more than 2 years and showed that several months could transpire between hair shedding and regrowth. This "lag period" is normally not present or is very short, but often lasts several months in patients with androgenetic alopecia.

HAIR PIGMENTATION

Hair becomes pigmented as a result of a tightly coordinated program of melanin synthesis and transport from the hair bulb melanocytes to differentiating hair shaft keratinocytes.[122–124] This process is strictly coupled to anagen and ceases during catagen and telogen. Numerous signaling molecules, structural proteins, enzymes, cofactors, and transcriptional regulators control hair pigmentation (Figs. 86-4 and 86-5).[122,124,125]

HAIR MELANOCYTE DEVELOPMENT

Melanoblasts can be identified in the epidermis of human embryos at 50 days of estimated gestational age before the onset of hair follicle morphogenesis.[126–128] These follicular melanocytes originate in the neural crest and migrate first to the dermis and then epidermis.[129] New data reveal that melanocytes in the skin arise from two sources: from neural crest cells migrating in the dorsolateral pathway and from Schwann cell progenitors located in cutaneous nerves.[129a] Commitment of neural crest cells to the melanocyte lineage is regulated by Pax3 and microphthalmia transcription factors (Mitf), which stimulate the expression of dopachrome tautomerase [or tyrosinase-related protein 2 (Trp2)], an enzyme involved in melanin biosynthesis that also functions as an early melanoblast marker.[128] Subsequent steps of melanoblast development (migration into the dermis and epidermis) are controlled by signaling mechanisms activated through endothelin receptor type B and c-kit oncogene (c-kit) receptor, which are mutated in humans with Hirschprung disease and piebaldism, respectively, resulting in formation of unpigmented hairs[129] (see also Chapter 72).

After entering the placode of the developing hair follicle, melanoblasts proliferate and become melanogenically active synchronously with the onset of hair fiber formation.[130] Experimental and genetic data suggest that migration of melanoblasts into the hair follicle and their development toward melanogenically active forms depend on stem cell factor (SCF)/c-kit signaling. SCF is a ligand that binds to its receptor, c-kit. Pharmacologic blockade of c-kit during embryogenesis, as well as genetic ablation of SCF or c-kit in corresponding mouse mutants results in unpigmented hairs.[131–133]

HAIR FOLLICLE MELANOCYTE STEM CELLS AND PIGMENT-PRODUCING MELANOCYTES

MSCs located in the hair follicle bulge generate progeny that repopulate the melanocytes in the new hair bulb formed at the onset of anagen.[103,134] MSCs express Trp2, Bcl-2, Pax3, while other melanogenic enzymes (tyrosinase, Trp1) and signaling molecules (c-kit, endothelin receptor type B, SOX10, Mitf and Lef-1)[135] are expressed at low levels. MSCs can be first detected in the bulge area during late stages of hair follicle morphogenesis and similarly to epithelial stem cells they are quiescent.[134–136] TGF-β signaling plays an important role in controlling MSCs entering into a noncycling (dormant) state during hair follicle (HF) morphogenesis.[137]

Maintenance of MSCs during hair follicle cycling is controlled by TGF-β and Notch-signaling pathways. Notch signaling plays a crucial role in the survival of melanocyte stem cells and immature melanoblasts by preventing apoptosis.[138] Crosstalk between the TGF-β pathway and Bcl2 is also important for maintenance of MSCs, and Bcl2 knockout mice show progressive hair graying due to their depletion.[135–138] Bcl-2 plays a key role in maintenance of MSCs, and Bcl-2 knockout mice show progressive hair graying due to the depletion of MSCs.[139–141] However, Bcl-2 deficiency may be compensated by overexpression of SCF, which rescues loss of MSCs in the hair follicle bulge of Bcl-2 knockout mice.[135]

Melanogenically active melanocytes are located in the hair bulb above the dermal papilla.[104,124] These cells synthesize and transport melanin to hair shaft keratinocytes and express a full set of enzymes and other proteins involved in melanin biosynthesis including tyrosinase, Trp1, Trp2 (in mice), and pMel17 (in humans).[105,135] Keratinocytes, as pigment recipient cells, produce Foxn1 and its target Fgf2 to identify themselves as the targets for pigment transfer.[142]

HAIR CYCLE-DEPENDENT CHANGES IN MELANOCYTES

Hair follicle melanocytes undergo substantial remodeling during hair follicle cycling.[104,124] In telogen, hair follicle melanocytes are found in the bulge, secondary hair germ, and connective tissue.[104] In humans, melanocytes in the telogen hair follicle do not express Trp1 or tyrosinase and do not proliferate. Melanocytes can be visualized by expression of pMel17.[141] Some of these cells also express c-kit receptor, whereas others remain c-kit-negative and represent MSCs.[104,134,135] TGF-β signaling is activated in MSCs when they reenter the quiescent noncycling state during the hair cycle and this process requires Bcl2 for cell survival.[137]

During early anagen, resting melanocytes proliferate, differentiate, and migrate within the hair follicle synchronously with regeneration of the hair follicle bulb. Hair follicle melanocytes are maximally proliferative during early and midanagen, and their transition to melanogenic competence is accompanied by the appearance of Trp1 and tyrosinase proteins.[104,143] However, this process is stringently controlled, and Notch signaling is necessary to prevent differentiation of melanoblasts into pigment-producing melanocytes before they reach the hair bulb, as well as for their proper positioning in the hair matrix.[144]

Similar to embryonic and early postnatal development, SCF/c-kit signaling plays a critical role in repopulation of the bulb with pigment-producing melanocytes. C-kit is expressed on proliferating, differentiating, and melanogenically active melanocytes, whereas overexpression of SCF in the epidermis of transgenic mice significantly increases the number of hair follicle melanocytes and their proliferative activity.[104] Similarly, administration of the ACK45 antibody blocking c-kit signaling dramatically reduces melanocyte number in anagen hair follicles, resulting in hair depigmentation.[104] However, in the next hair cycle, the previously treated animals grow fully pigmented hairs with the normal number and distribution of melanocytes, suggesting that MSCs are not dependent on SCF/c-kit.[104]

During catagen, melanogenic activity in the follicular melanocytes abruptly ceases. Immunohistochemical and electron microscopic data suggest that some pigment-producing melanocytes located above the follicular papilla undergo apoptosis, while others drop into the dermal papilla of the follicle and migrate into the dermis.[145,146]

MOLECULAR CONTROL OF HAIR COLOR

Follicular melanocytes synthesize pigment via a cascade of enzymatic conversions of phenylalanine or tyrosine into brown–black eumelanin or yellow pheomelanin that requires melanogenic enzymes (tyrosinase, Trp1/2, γ-glutamyl transpeptidase,

peroxidase) and essential cofactors, such as 6-tetrahydrobiopterin.[122] The balance between black and yellow pigment synthesis (eumelanin and pheomelanin, respectively) is regulated by signaling through the melanocortin type 1 receptor (MC-1R) that has long been implicated in the control of hair color.[147,148] (See Chapter 72.)

After binding to MC-1R, α melanocyte-stimulating hormone (α-MSH) stimulates adenylyl cyclase, resulting in elevation of intracellular cyclic adenosine monophosphate levels. This leads to increase of transcriptional activity of Mitf that stimulates synthesis of melanogenic enzymes (tyrosinase, Trp1/2) involved in eumelanin formation.[149,150] Pheomelanin synthesis in the hair follicle melanocytes of mice occurs when MC-1R signaling is inhibited by Agouti signal protein (ASP) that competes with α-MSH in binding to MC-1R.[148,149] In mice, ASP expression is positively regulated by BMP signaling, and transgenic mice overexpressing BMP antagonist Noggin show hair darkening.[151] Although ASP is expressed in human skin, its role in human pigmentation remains unclear.[150]

Recent data also demonstrate existence of fully functional proopiomelanocortin/MC-1R system in human hair follicles: MC-1R is expressed by hair follicle melanocytes, whereas its ligands α-MSH and adrenocorticotropic hormone are able to promote proliferation, dentricity, and melanogenesis.[152] Similar effects are seen with another proopiomelanocortin-derived peptide, β-endorphin that interacts with μ-opiate receptor expressed by hair follicle melanocytes.[152] However, signaling through the μ-opiate receptor may regulate hair pigmentation via modulating the activity of protein kinase C-β, a known positive regulator of melanogenesis.[153]

Follicular melanocytes are sensitive to aging, which results in their premature loss and hair graying.[154] In contrast to normally pigmented hair follicles, fewer melanocytes are found in the bulbs of gray hairs; however, these melanocytes still express tyrosinase, synthesize and transfer melanin to keratinocytes.[146] In addition, a population of melanogenically inactive melanocytes (melanoblasts including stem cells) in the outer root sheath is markedly reduced in the follicles producing gray hairs compared to pigmented follicles (Commo et al, 2004). The fact that MSCs are damaged in hair follicles producing gray hairs was confirmed in mice by applying ionizing radiation, which triggered premature differentiation of MSCs in the follicular bulge into mature, pigment-producing melanocytes followed by their depletion and irreversible hair graying.[155] Deficiency of ATM-kinase, a central transducer of the DNA-damage response, sensitizes MSCs to ectopic differentiation, demonstrating its role in protecting MSCs from their premature differentiation.[155]

However, hair graying is also mediated by H_2O_2-induced oxidative damage in the entire hair follicle including the hair shaft, which does not exclusively affect follicle melanocytes, thus suggesting that accumulation of hydrogen peroxide in both keratinocytes and melanocytes is one of the critical factors that underlie biochemical changes in the follicular pigmentary unit of graying hairs.[156]

CONCLUSION

The hair follicle is formed as the result of a complex interplay of signals between epithelium and mesenchyme. The nature of these signals is just now being elucidated, with many molecular pathways important in development also playing roles in hair follicle formation. The product of this process is a miniature organ with distinctive vertical and concentric divisions. Both epithelial stem cells and MSCs in the follicle are important for the constant regeneration of the follicle.

Chapter 87 :: Keratosis Pilaris and Other Inflammatory Follicular Keratotic Syndromes

:: Paradi Mirmirani & Maureen Rogers

KERATOSIS PILARIS AT A GLANCE

- Common condition of keratotic follicular plugging with variable erythema.
- Mainly involves cheeks and extensor arms and thighs.
- Two main patterns—(1) early childhood onset and (2) adolescent onset.
- Usually improves gradually over years.
- Nonspecific histology of follicular orifice distended by keratin plug.
- Variable response to keratolytics.
- Variants:
  - Erythromelanosis follicularis faciei et colli (EFFC): marked erythema and hyperpigmentation.
  - Keratosis rubra pilaris (KRP): erythema not limited to perifollicular area, may be same as EFFC.

Follicular keratosis refers to orthokeratosis involving the follicular ostium and infundibulum. Horny plugs protrude from the orifices, producing a rough sensation on palpation of the skin. It may be isolated [keratosis pilaris (KP)] or associated with other pathologic processes, including follicular inflammation, atrophy, scarring, and alopecia [keratosis pilaris atrophicans (KPA)]. These are reaction patterns that occur alone or as part of a wide variety of syndromes.

KERATOSIS PILARIS

Typical KP is a common condition of keratotic follicular plugging with varying degrees of surrounding erythema. Sometimes, the erythema is so striking that it is the main complaint. The clinical expression of KP varies from subtle to conspicuous, which, along with possible racial differences, may explain the great range of reported prevalences, from 1% to 42%.[1–4] It involves most commonly the extensor aspects of the upper arms (Fig. 87-1) and thighs as well as the face but may rarely be more extensive, extending to the distal limbs and the trunk. There seem to be two patterns. In early childhood, the face and arms are mainly affected and gradual improvement is seen in most cases by later childhood or adolescence. In the other pattern, the onset is in teenage years, and the extensor arms and legs are predominantly involved. It usually improves by the mid-20s. However, in both patterns, the condition may be persistent into later adult life.[5] The histopathologic pattern in skin biopsy specimens is nonspecific, simply showing the follicular orifice distended by a keratin plug.

Treatment is usually with various keratolytics, from simple urea, lactic acid, or salicylic acid preparations to topical retinoids and tazarotene.[6,7] These preparations may aggravate associated erythema, limiting their value.

ASSOCIATIONS OF KERATOSIS PILARIS. Clinical ichthyosis vulgaris (see Chapter 49) is associated with KP[8]; in one series KP was found in 74.3% of patients (Fig. 87-1).[2] Other conditions in which KP is more prevalent or more prominent are atopic disorders, hypothyroidism, Cushing syndrome, insulin dependent diabetes, obesity or high body mass index, and Down syndrome.[9] Follicular keratosis, which may simulate KP, can occur in several nutritional deficiencies, although vitamin A deficiency is most commonly cited (see Chapter 130).[10]

KERATOSIS PILARIS VARIANTS

ERYTHROMELANOSIS FOLLICULARIS FACIEI ET COLLI

Erythromelanosis follicularis faciei et colli (EEFC) is a condition probably related to KP.[11] The suffix "colli"

Figure 87-1 Keratosis pilaris in a characteristic distribution on upper outer arm in a patient with ichthyosis vulgaris.

refers to the neck. EEFC It is seen primarily in adolescents and young adults, most commonly in males. Well-demarcated erythema, hyperpigmentation, and follicular papules involve the preauricular and maxillary areas, usually in a symmetric distribution, with spread in some cases to the temples and sides of the neck and trunk. Atrophy is not a feature. Histopathology is nonspecific, demonstrating a variable degree of follicular hyperkeratosis, dilation of upper dermal vessels, some perivascular inflammatory infiltrate, and hyperpigmentation of the basal layer. There are few reports of EEFC in the literature, however it may be underreported.

KERATOSIS PILARIS RUBRA

Although erythema is often present in typical KP, it is usually mild and limited to the perifollicular skin. When perifollicular erythema is more noticeable, the disorder has been called keratosis pilaris rubra (KPR) or less commonly keratosis follicularis rubra.[12] These findings are usually limited to the cheeks, forehead, and neck (Fig. 87-2). Features that differentiate EFFC from KPR are a lack of reported involvement on the torso and the presence of hyperpigmentation. However the hyperpigmentation noted in EFFC may, at least in part, be related to skin pigmentation type, with darker skin types showing more evidence of hyperpigmentation. Thus it is likely that KPR and EFFC are variants of the same clinical spectrum.

Figure 87-2 Keratosis pilaris rubra with dramatic perifollicular erythema on the cheeks.

KERATOSIS PILARIS ATROPHICANS

KERATOSIS PILARIS ATROPHICANS AT A GLANCE

- A group of rare follicular keratosis conditions with variable degrees of inflammation, and secondary atrophic scarring/and or alopecia.
- Ulerythema ophryogenes (Keratosis pilaris rubra atrophicans faciei) predominantly affects eyebrow area, causing scarring alopecia; occurs with Noonan, cardiofaciocutaneous and other syndromes.
- Atrophoderma vermiculatum—predominantly involves cheeks and leads to a striking honeycomb-like atrophy; mosaic forms described.
- Keratosis follicularis spinulosa decalvans—predominantly involves scalp, leading to severe cicatricial alopecia; associated features include plantar keratoderma and photophobia.

The general term *keratosis pilaris atrophicans* is a group of rare genodermatoses in which the clinical hallmarks is follicular keratosis with variable degrees of inflammation, and secondary atrophic scarring and/or alopecia.[13–15] Three distinct clinical entities that fall under the umbrella of keratosis pilaris atrophicans include ulerythema ophryogenes [UO or keratosis pilaris atrophicans faciei (KPAF)], atrophoderma vermiculatum, and keratosis follicularis spinulosa decalvans (KFSD).

ULERYTHEMA OPHRYOGENES (KERATOSIS PILARIS RUBRA ATROPHICANS FACIEI)

The prefix 'ophryo-' refers to the eyebrow. UO is a form of KPA affecting particularly and initially the eyebrow areas, in some cases extending later to the cheeks and forehead.[13] Scalp and eyelash hair is normal. The onset is within months of birth, with erythema and small keratotic follicular papules involving the lateral one-third of the eyebrows. It may slowly progress through childhood to involve more of the eyebrows and sometimes beyond, leading to alopecia (Fig. 87-3). Progression usually ceases after puberty but the sequelae are permanent. The condition is frequently associated with standard KP that may involve the arms and legs or may be more generalized. The term keratosis pilaris rubra atrophicans faciei is used interchangeably with UO, however some prefer this diagnosis for patients in whom the initial erythema starts on the cheeks as opposed to the eyebrows.

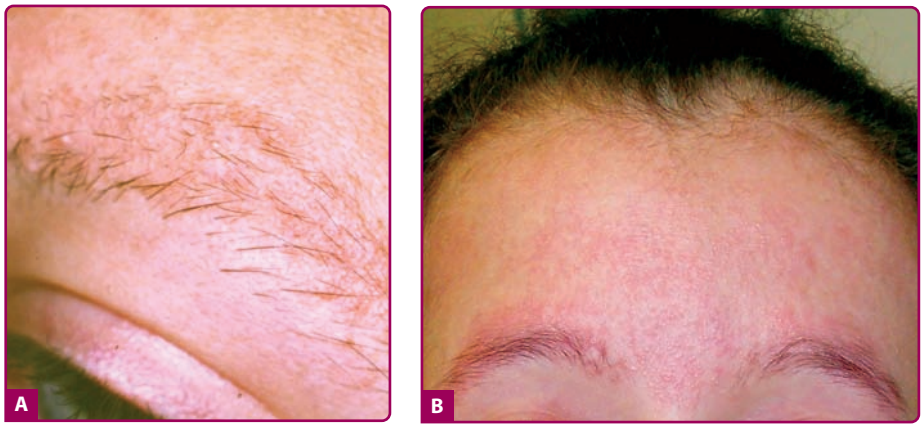

Figure 87-3 **A.** Ulerythema ophryogenes involving eyebrow area with scarring alopecia. **B.** Ulerythema ophryogenes involving the upper face in a patient with Noonan syndrome.

Most cases have followed an autosomal dominant inheritance pattern, with incomplete penetrance.[13] Response to topical corticosteroids, topical retinoids, and keratolytics has been poor. There is one report of a good response to several months' therapy with oral isotretinoin, with lessening of the horny plugs and the erythema.[16] The improvement was maintained for some months after therapy had ceased. Some improvement in erythema was reported with the pulsed tunable dye laser at 585 nm, but the follicular plugging was unchanged.[17]

SYNDROMES ASSOCIATED WITH ULERYTHEMA OPHRYOGENES. UO has been reported in association with isolated woolly hair,[18,19] Noonan syndrome,[19,20] cardiofaciocutaneous (CFC) syndrome,[21,22] Rubenstein–Taybi syndrome,[23] Cornelia de Lange syndrome,[24] and 18p deletion.[25,26] CFC and Noonan syndrome have overlapping clinical features, and both have mutations in genes of the Ras pathways.[27,28] In CFC, mutations have been described in *BRAF*, *KRAS*, *MEK1*, and *MEK2* genes.[27] Whereas in Noonan syndrome, there is primarily mutations of *PTPN11*, but also *KRAS* and *SOS1* genes.[29,30]

Follicular keratosis in Noonan syndrome, if present, is usually limited to the face (Fig. 87-3B) and resembles UO with loss of eyebrow hairs.[19,20] In CFC syndrome, follicular keratosis is often much more extensive, and there may be striking alopecia involving the scalp.[22] The remaining scalp hair in CFC syndrome is brittle and curly.

ATROPHODERMA VERMICULATUM (FOLLICULITIS ULERYTHEMATOSA RETICULATA)

AV is a form of KPA in which the cheeks are predominantly involved, with follicular plugs and pit-like depressions up to 1.5 mm in diameter and a background of erythema. Alopecia and follicular papules are not features of the condition,[22,31] but sparse open and closed comedones and milia may be found.[32] The depressions merge into each other, producing a "worm-eaten," "honeycombed," or reticular appearance (Fig. 87-4). Involvement of the forehead, arm, and leg, as well as the typical cheek area, has been described.[14] However, in general, it is rare for the condition to involve the limbs, and eyebrow involvement does not occur. Standard KP of the extensor aspects of arms and legs is a common associated finding.[31] Unlike the other KPA disorders in which the onset is in infancy, AV usually starts in childhood, between 5 and 12 years old, although later onset has been described[14]; the course is usually one of inexorable worsening. The condition is often sporadic but, in some cases, appears to be inherited as an autosomal dominant trait.[33] Several more or less linear unilateral cases have been described,[34] suggesting a possible mosaic form of the condition.[35] However, it is possible that at least some of these cases may represent examples of nevus comedonicus.[35]

Histopathologic evaluation demonstrates atrophic pilosebaceous units with mild perifollicular and

Figure 87-4 Atrophoderma vermiculatum demonstrating honeycomb atrophy on the cheek of an adolescent girl.

TABLE 87-1
Syndromes with Follicular Atrophoderma as a Feature

Condition	Inheritance	Main Features	Comments
Bazex syndrome (Bazex–Dupre—Christol syndrome)[41]	X-linked dominant	Hypotrichosis, pili torti, hypohidrosis, milia, development of basal cell carcinomas in adolescence.	—
Rombo syndrome[38]	Autosomal dominant	Hypotrichosis, especially of eyelashes, peripheral cyanosis, basal cell carcinomas, and trichoepitheliomas.	—
X-linked dominant chondrodysplasia punctata (Conradi–Hünermann syndrome)[39]	X-linked dominant, lethal in males	Congenital Blaschko-distributed red scaly lesions that resolve in months, replaced by follicular atrophoderma. Cataracts, shortening of limbs, frontal bossing, saddle nose, low-set ears.	Mutation in emopamil binding protein gene, relevant in cholesterol biosynthesis
Congenital ichthyosis, follicular atrophoderma, hypotrichosis, and hypohidrosis[42,43]	Probably autosomal recessive	Congenital, diffuse ichthyosis, hypohidrosis, hypotrichosis. Woolly hair in one pedigree.	Only described in two families so far
Hereditary perioral pigmented follicular atrophoderma associated with milia and epidermoid cysts[40]	Autosomal dominant	Epidermoid cysts and milia.	Follicular atrophoderma limited to face, especially periorally
Nevus comedonicus[44]	Somatic mutation	Blaschko-distributed comedo-like plugs in dilated follicular orifices. Cribriform atrophy follows extrusion of comedones.	Due to somatic mutation of fibroblast growth factor receptor 2, identical to that, which, if present in the germline, causes Apert syndrome

perivascular inflammation. The follicular orifices are dilated and filled with keratin plugs. Numerous dermal horn cysts may be found. There is perifollicular fibrosis and a decrease in elastic fibers in the dermis.[31,36]

Therapy is uniformly unsuccessful and has included topical steroids, topical retinoids, cryotherapy, and derm-abrasion. Favorable results have also been described with carbon dioxide laser in a case in which atrophy was prominent, and pulsed dye laser in a case with a marked erythematous component.[32] Oral isotretinoin suppressed the inflammation in one patient.[37]

SYNDROMES ASSOCIATED WITH FOLLICULAR ATROPHODERMA. Follicular atrophoderma occurs as a feature of several rare syndromes[38–43] and in nevus comedonicus (Table 87-1).[44] As such, these conditions may come into the differential diagnosis of atrophoderma vermiculatum.

KERATOSIS FOLLICULARIS SPINULOSA DECALVANS

The term *KFSD* was first used by Siemens in 1926 who described a scarring follicular condition in 20 members of a large family.[45] The condition begins in infancy with noninflammatory, flesh-colored, spiny lesions affecting hair-bearing areas, especially the scalp (Fig. 87-5) and later eyebrows, eyelashes, and the dorsal of the hands and fingers. Sometimes, more proximal limbs and even the trunk become involved.[45–47] An associated plantar keratoderma may occur, especially over the heels.[15] By puberty, many of the follicular spines have disappeared and are replaced by atrophy. Scarring alopecia of scalp (see Fig. 87-5), eyebrows, and eyelashes becomes apparent in childhood and progresses till puberty. It is often patchy and is rarely total. Facial lanugo hair is absent, and axillary and pubic hair is often thinned.

Photophobia is seen in many patients, and punctate corneal epithelial defects have been seen in some.[47] It is unclear whether there is a primary epithelial defect or whether the corneal changes occur as a result of irritation from distorted remnant lashes and keratotic plugs in eyelash follicles. There are rare reports of other ophthalmologic abnormalities, including cataract and retinal detachment.[48]

Biopsy specimens show follicular based hyperkeratosis, perifollicular and dermal inflammation, fibrosis, and distorted follicles at different stages of the condition.[46] Family studies suggest an X-linked dominant inheritance pattern,[45,47–49] with men often more severely

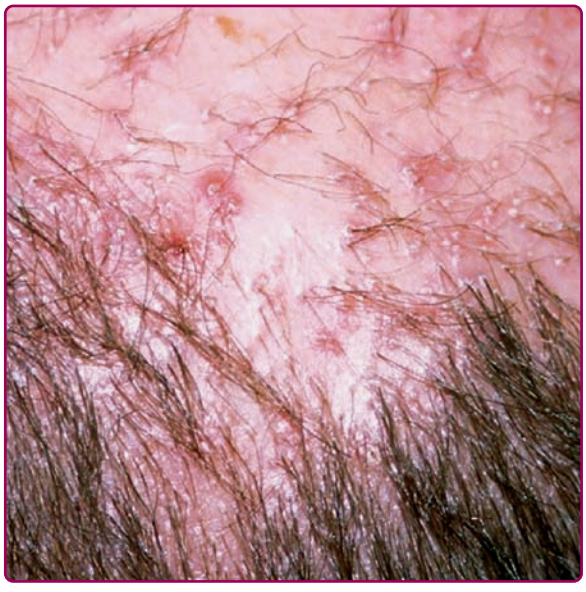

Figure 87-5 Keratosis follicularis spinulosa decalvans with severe scarring alopecia of scalp. (Photograph used with permission from Dr. Peter Hogan.)

affected than women. A mutation in the gene encoding spermidine/spermine *N*(1)-acetyltransferase (SSAT) has been noted in these patients and has been localized to Xp22.13-p22.2.[50] However clinical heterogeneity is likely as there have been identification of pedigrees unlinked to this region as well as rare instances of male to male transmission suggesting an autosomal dominant form.[51,52] In the differential diagnosis of KFSD is ichthyosis follicularis with alopecia and photophobia (IFAP) syndrome [see Section "Ichthyosis Follicularis, Alopecia (Atrichia), and Photophobia Syndrome"].[53] However, features in KFSD not shared by IFAP are involvement of the fingers, late atrophy, and scarring of involved follicles, and the development in some patients of a red–brown telangiectatic pigmentation of cheeks and brows.

In general, treatment of KFSD is unsatisfactory; however, there are isolated reports of improvement in photophobia with oral vitamin A,[47] as well as conflicting reports on the results of dapsone,[51,54] and oral retinoids.[46,55,56]

FOLLICULITIS SPINULOSA DECALVANS

A variant of KFSD has been called *folliculitis spinulosa decalvans* (acknowledging that this name may lead to confusion with the separate entity of folliculitis decalvans).[15,57] This variant is characterized by persistent pustule formation, especially on the scalp. Unlike the typical variant of KFSD, there is more severe inflammation, and it is progressive, rather than stable or remitting after puberty. In addition, the inheritance appears to be autosomal dominant rather than X-linked recessive. Treatment response to isotretinoin has been unsuccessful.[57]

OTHER SYNDROMES WITH FOLLICULAR KERATOSIS AS A SIGNIFICANT FEATURE

Apart from the conditions described in the preceding sections in association with UO, there are other conditions that have follicular keratosis as a significant feature (Table 87-2).

MONILETHRIX

(See Chapter 88)

Monilethrix is an autosomal dominant condition producing a beaded appearance of the hair.[58] Mutations in the human basic hair trichocyte keratins K81, K83, and K86 (formerly hHb1, hHb3, and hHb6, respectively) have been reported.[59–61] However, the failure to demonstrate these mutations in one family suggests the possibility of genetic heterogeneity.[62] A striking follicular keratosis is associated in some pedigrees and may involve the scalp (Fig. 87-6), face, and limbs. Nail onychodystrophy or koilonychia are also variably reported. Genotype/phenotype correlation is not obvious in reported cases in which mutations have been identified.[63,64] The clinical phenotype of autosomal recessive hypotrichosis resembles that of monilethrix. In these patients, there is a defect of the *desmoglein 4* gene, which belongs to the desmosomal cadherin superfamily and is also expressed in the cortex of the hair follicle.[65–67]

KERATOSIS PILARIS AND HEREDITARY KOILONYCHIA

A family has been described with koilonychia and widespread KP, involving all areas of trunk and limbs. Affected family members also showed eyebrow involvement with alopecia, simulating UO/KPAF.[68] The inheritance pattern appeared to be autosomal dominant. Unlike previous cases, there was no monilethrix in this pedigree.

KERATITIS, ICHTHYOSIS, AND DEAFNESS SYNDROME

(See Chapter 49)

TABLE 87-2
Syndromes That May Feature Follicular Keratosis

- Monilethrix
- Keratosis pilaris and hereditary koilonychia
- Hereditary mucoepithelial dysplasia
- Ichthyosis follicularis, alopecia, and photophobia syndrome
- Keratitis, ichthyosis, and deafness syndrome
- Cardiofaciocutaneous syndrome
- Noonan syndrome
- Rubenstein–Taybi syndrome
- Cornelia de Lange syndrome
- 18p deletion

Figure 87-6 Striking follicular keratosis of the scalp in a patient with monilethrix.

Widespread spiny follicular keratosis is a striking feature of keratitis, ichthyosis, and deafness syndrome, a connexin/gap-junction disorder. This autosomal dominant disorder is also characterized by alopecia of scalp, body, eyebrow, and eyelash hair, vascularizing keratitis, and a profound sensorineural hearing loss.[69]

HEREDITARY MUCOEPITHELIAL DYSPLASIA

The characteristic features of hereditary mucoepithelial dysplasia (HMD) are follicular keratosis, nonscarring alopecia with some coarse abnormal hairs remaining, fiery-red palatal and gingival mucosae, photophobia with demonstrable keratitis and corneal vascularization, and psoriasiform hyperkeratotic lesions in the perineal area and often also on the extensor limbs.[70–72] The condition occurs in both sexes, and family studies suggest both autosomal dominant and autosomal recessive patterns of inheritance may be possible. Light microscopic evaluation of skin and mucosae shows dyskeratotic cells in the spinous layer, vacuolated basal cells, and lack of epithelial maturation.[70,72] Electron microscopy shows paucity of desmosomes, cytoplasmic vacuolization, and presence of multilaminar bands and wheat sheaf-like collections of filamentous fibers in the cytoplasm, resembling gap-junction material, and suggesting a disorder of desmosomal or gap junction proteins.[72] However, subsequent studies of several characteristic cases in one pedigree found normal expression of gap junction proteins (connexins 26, 32, and 43), desmosomal proteins (desmogleins 1 and 2, plakoglobin, desmoplakins I and II, and plakophilin 1), adherens junction proteins (β-catenin and E-cadherin), and cytoskeleton proteins (keratins, β-tubulin, vimentin, and actin).[70] Genetic analysis in the studied family excluded the desmosomal cadherins in chromosome 18q12 as candidate genes and ruled out a mutation in connexin 26.[70]

ICHTHYOSIS FOLLICULARIS, ALOPECIA (ATRICHIA), AND PHOTOPHOBIA SYNDROME

The association of ichthyosis follicularis, alopecia, and photophobia was first reported as a syndrome by McLeod in 1909,[73] and for many years additional reported cases of what came to be designated *IFAP syndrome* occurred in males. Affected individuals demonstrate widespread, flesh-colored, spiny, follicular projections with minimal, if any, inflammation (except for inflammatory palmoplantar keratoderma with advancing age), severe alopecia, often total atrichia involving eyebrows and lashes as well as scalp hair, and severe photophobia, often with demonstrable corneal vascularization.[53,74–76] The condition was postulated to be inherited as an X-linked recessive trait, which is supported by the report of the mother and sister of a male patient with classical features of IFAP syndrome having linear lesions of hyperkeratosis, hypohidrosis, and atrophy and a patchy scalp alopecia, distributed along Blaschko's lines.[77] Recently, the gene defect has been mapped to Xp22.11-p22.13 and a missense mutation of the gene, *MBTPS2*, which codes for an intramembrane zinc metalloprotease, has been identified.[78] This gene is essential for cholesterol homeostasis and endoplasmic reticulum stress response.

Patients may have only cutaneous features, but neurologic and skeletal anomalies and recurrent infections have occasionally been described.[44,79–82] Atypical cases have included females with generalized involvement and transmission from mother to daughter[83,84–86]; psoriasiform patches,[80,85,86] particularly involving the perineal area; and hypotrichosis rather than complete atrichia.[86] Some patients with psoriasiform plaques lack the typical spiny follicular projections[80,81] and may represent a different entity,[76] or even a variant of HMD.[86] In support of the latter is the ultrastructural finding of reduced numbers of desmosomes in one patient with IFAP and psoriatic lesions, analogous to what is seen in HMD.[85] Patients with documented mutations in *MBTPS2*, have reportedly had spiny follicular projections during infancy, and the later progressive development of psoriasiform plaques. Treatment of IFAP is usually unsatisfactory, but there are reports of temporary flattening of the follicular keratotic papules and plaques and regrowth of eyelashes with oral acitretin.[87,88]

Chapter 88 :: Hair Growth Disorders

:: Nina Otberg & Jerry Shapiro

APPROACH TO THE PATIENT WITH HAIR GROWTH DISORDERS AT A GLANCE

- Take patient with hair growth disorders serious and provide emotional support.
- Classify hair disorder based on patient's history and clinical pattern (see eTable 88-0.2 in online edition).
- Exclude or confirm common hair growth disorders based on clinical assessment and diagnostic tools (see Table 88-1).
- Find the right treatment for confirmed diagnosis.
- Dispel misconceptions on treatment options and results, and educate patient.

INTRODUCTION

The importance of human hair in view of social communication and sexual attraction is enormous. Thus, diseases that lead to hair loss (alopecia), structural hair shaft defects or excessive hair growth on the body are often accompanied by diminished sense of personal well-being and self-esteem, leading to depressive moods and withdrawal from social interims.

In this chapter, we discuss the biologic basis and clinical presentation of hair growth disorders, give definitions (eTable 88-0.1 in online edition), explain key management principles, and provide practical advice for diagnosis, therapy and patient management.

Two frequently applied terms of alopecia and effluvium need to be characterized. While effluvium typifies the process of hair shedding, alopecia characterizes the final result of this. Both terms are nonspecific; they do not give etiological information of the underlying hair loss (see eTable 88-0.1 in online edition).

Disorders that result in alopecia can be grouped into diffuse, patterned and focal hair loss as well as into scarring (synonym: cicatricial) and nonscarring forms. Scarring forms are characterized by permanent destruction of hair follicular stem cell structure resulting in loss of hair producing capabilities. In contrast, in nonscarring alopecia the hair follicle is not ultimately destroyed and subsequent hair regrowth follows periods of hair shedding. In both, scarring and non scarring alopecia, distribution of hair loss can occur in a diffuse pattern over the whole scalp or be circumscribed, affecting only a few, more or less demarcated areas. Alopecia can also be due to improper or missing follicle development. These rare inherited hair abnormalities can be focal (e.g., aplasia cutis congenita, see Chapter 107) or diffuse (e.g., ectodermal dysplasia, see Chapter 142).

Hair growth disorders caused by structural hair shaft defects can be acquired or inherited. While acquired hair shaft defect are accompanied by increased hair breakage and are usually due to hair grooming practices, inherited hair shaft defects can be grouped into disorders with or without increased hair breakage. Acquired hair shaft disorders are reversible when trigger factors are stopped. Inherited hair shaft disorders cannot be cured, but tend to improve as the patient ages.

PRINCIPLES OF HAIR FOLLICLE BIOLOGY

(See Chapter 86)

TABLE 88-1
Diagnostic Procedures[a]

- Essential procedures
  - Hair pull test to assess scalp hair cycling
  - Hair shaft microscopy
  - Dermatoscope
  - Biopsy (mandatory if scarring alopecia is suspected)
- Additional useful tests
  - Trichogram (hair pluck test)
  - Hair shedding count
  - Potassium hydroxide stain (for suspected fungal infection)
  - Laboratory tests
    - Most commonly performed for hair loss: complete blood cell count, ferritin or iron/total iron binding capacity, thyroid-stimulating hormone, and thyroxine

[a]See online Table 88-1.1 for additional diagnostic procedures.
Data from Olsen EA: Current and novel methods for assessing efficacy of hair growth promoters in pattern hair loss. *J Am Acad Dermatol* **48**:253, 2003.

DIAGNOSTIC TECHNIQUES FOR EVALUATING HAIR GROWTH DISORDERS

HISTORY

A thorough patient history is critical for the development of an initial differential diagnosis and for the relationship with the patient. The patient should be asked about the duration and pattern of the hair problem. Was the problem present at birth, did it evolve gradually over time starting at a certain age or was there a rapid onset? A hair problem that is present at birth leads more to a genetic disorder; certain conditions are more common in children, such as tinea capitis, alopecia areata, or trichotillomania. For example, a rapid onset of hirsutism can lead to the diagnosis of an androgen-secreting tumor. A gradual thinning of fronto-parietal scalp hair fits more to the diagnosis of androgenetic alopecia (AGA) (see eTable 88-0.2 in online edition). Patients with hair loss should be asked if the hair is shedding or thinning and if the hair is coming out "by the root" or if it is breaking off. A patient history includes the family history as well as questions about current and past medication, pregnancy, menses, menopause, thyroid function, diet, past and present health, surgeries, accidents, physical or emotional stress events and hair care practices.

GLOBAL ASSESSMENT AND IMAGING

The global examination of the scalp should first of all assess the overall pattern of the hair problem. It is important to determine density and distribution and if the hair loss is focal or global. Furthermore, the presence of scaling, erythema, erosions, crust or pustules and the presences or absence of follicular ostia should be noted. The clinical examination should also involve the nails, since some disorders, for example alopecia areata, lichen planopilaris (LPP), or ectodermal dysplasia can also affect finger and toe nails. Excessive body hair is oftentimes shaved or epilated. The extent of unwanted terminal hair growth can be evaluated by a patient self-assessment with the help of images (see Section "Hirsutism").

PULL TEST

The pull test is a useful ancillary, qualitative test for the assessment of the ongoing activity of hair loss. The examiner grasps approximately 50–60 hairs and tugs at them from proximal to distal end. Removal of six hairs indicates a positive pull test and active shedding. However, the test can be considered positive if three hairs can be pulled out in several different areas of the scalp. The proximal ends can be examined against a white (for dark hair) or black (for light hair) background. A blunt tip indicates hair breakage; a tapered tip can indicate regrowth or miniaturized hairs. The proximal end of the hair shafts may also be examined with a light microscope to determine, if the hairs break off (blunt ends) or came out as club hairs (telogen hair).

BIOPSY

A scalp biopsy is necessary, particularly when confirming the diagnosis of scarring alopecia. A scalp biopsy should also be considered for the differential diagnosis of TE, diffuse alopecia areata and AGA. The following recommendations were developed at the consensus meeting on cicatricial alopecia in February 2001: one 4-mm punch biopsy including subcutaneous tissue should be taken from a clinically active area, processed for horizontal sections and stained with hematoxylin and eosin. Elastin (acid alcoholic orcein), mucin, and periodic acid-Schiff (PAS) stains may provide additional information. A second 4-mm punch biopsy from a clinically active disease affected area should be cut vertically into two equal pieces. One-half provides tissue for transversely cut routine histological sections; the other half can be used for direct immunofluorescence (DIF) studies.[1,27] Usually only one biopsy from the affected area is necessary for the diagnosis of a nonscarring alopecia; the samples are preferably processed with horizontal sections.

TRICHOGRAM

This technique is a simple method of quantifying hair loss by comparing the proportion of anagen to catagen and telogen hairs. For accurate measurement, patients should avoid washing their hair 3–4 days prior the test. Also perms, dyes, or straightening of hair can alter results and have to be avoided at least 6 weeks prior. A group of about 25–50 hairs should be grasped with a needle holder close to the scalp and plucked sharply in the direction of the hair. The proximal ends of the hair shafts are place on a glass slide in a drop of water and covered with a cover slip. Alternatively, a solution of 1% dimethylcinnamaldehyde in 0.5 N hydrochloric acid can be used, which stains the anagen hairs red due to the presence of protein bound citrulline in the inner root sheath. The roots are than examined by light microscopy with 100-fold magnification. Ten to twenty percent of telogen hair can be regarded as normal (the percentage of anagen hairs is slightly higher in women and children compared to men); a telogen count over 35% is highly suspicious for a TE. By repeating the trichogram over a time period, a hair loss condition can be followed and treatment results can be measured[28] (Fig. 88-1).

Investigation of plucked hairs for spores allows establishing the diagnosis of tinea capitis. In this case the hair should be mounted in 5% potassium hydroxide and gently heated.

ANDROGENETIC ALOPECIA

AGA or pattern hair loss is by far the most common type of hair loss in men and women. Male pattern hair

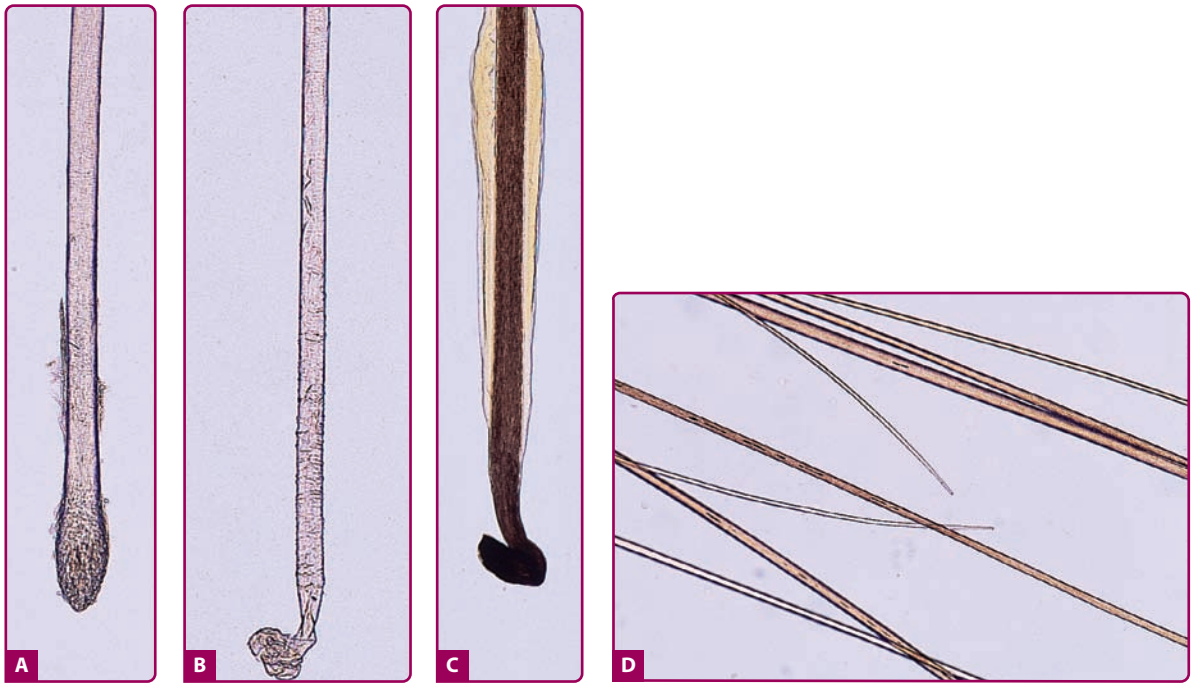

Figure 88-1 **A.** Telogen club hairs have a cornified, depigmented, rounded-up bulb without an attached root sheath. **B.** Loose anagen hair obtained by hair pull: Ruffled cuticle and no attached root sheath. Anagen hairs are recognized clinically by their pigmented, somewhat distorted, malleable bulb. Anagen hairs should not normally be found in a hair pull in patients with alopecia areata. **C.** Comparison with a normal anagen hair obtained by hair pluck. **D.** A newly growing anagen hair has a tapered distal tip rather than the blunt distal end of hairs that have been cut or trimmed or ends that are intrinsically broken. ANDROGENETIC ALOPECIA (AGA) AT A GLANCE

- Most common form of human hair loss.
- Presents as a nonscarring hair loss condition under the influence of androgens (dihydrotestosterone, DHT); androgen susceptibility of the follicles plays an important role.
- Clinical characteristics include a reduction of terminal hair density on the scalp that follows a typical pattern in both genders, with a conversion of terminal to vellus-like hairs and an increase of telogen hair (in an episode of active shedding).
- Classification with gender-specific features (Norwood–Hamilton classification for men and Ludwig classification in women) with clinical overlap.
- FDA approved therapeutic options are: topical minoxidil 2% (women) and 5% (men), oral finasteride 1 mg daily (men), hair restoration surgery, and low laser light.

loss (MPHL) (also known as male AGA, male balding) is an androgen-dependent, genetically determined trait. Female pattern hair loss (FPHL) (or female androgenetic alopecia) is believed to be the same entity. However, the requirement of androgens is less clear-cut than in men and the distribution of hair loss is generally different.[35,36] In both, men and women, AGA is characterized by a progressive decline in the duration of anagen, an increase in the duration of telogen and miniaturization of scalp hair follicles.

EPIDEMIOLOGY

MEN

Estimates of the prevalence of AGA vary widely. Most men will develop some degree of recession of the hairline during their lifetime. A progression to at least type III (see Fig. 88-2) is seen in around 50% of men and women beyond 40 years of age.[37–40,41] The risk of male pattern baldness depends on the family history in the father, the mother, or the maternal grandfather.[42,43] Men whose father had hair loss were twice as likely to have hair loss as men whose father showed no hair loss.

Ethnic variation in the incidence of AGA has been reported. AGA seems to be four times less frequent in men of African ancestry,[44] around three times less frequent in Korean men[45] and approximately 1.5 times

Figure 88-2 Patient with male pattern hair loss, Norwood–Hamilton class III.

less frequent in men originating form China, Japan or Thailand.[46,47]

WOMEN

FPHL is less common than MPHL but shows a similar age-related increase in frequency and severity. However, the condition can start as early as the prepubertal period both in men and women (Fig. 88-3). Around 40% of Caucasian women have developed some degree of FPHL at age 70.[35,48] FPHL seems to be less frequent in Asian woman.[45]

Figure 88-3 Patient with female pattern hair loss, Ludwig typ II.

ETIOLOGY AND PATHOGENESIS

The underlying causes of patterned hair loss have yet to be determined. In men, MPHL appears to result from a combination of androgen hyperactivity, a genetic predisposition to hair loss-related sensitivity to androgen action as well as an androgen-independent genetic predisposition. For females, the condition known as female pattern hair loss (FPHL) may have a more complex etiology. However, androgen action combined with genetic sensitivity to those actions seems to play a dominant role in most cases, and indeed these factors may be present generally in FPHL.

In AGA, large, pigmented hairs, called terminal hairs, are gradually replaced by fine (nearly invisible) colorless vellus hairs.[1,39] This transformation follows a progressive course with each hair cycle in the following manner. Scalp hair develops in three phases[40,49]: (1) a growth phase, or anagen, of approximately 2–6 years; (2) a short (2–3 weeks) phase, catagen, which actually represents the termination of anagen; and (3) transition to the telogen phase. A telogen hair does not grow and is shed from the follicle after about 12 weeks. The transition to catagen results in decreased levels of anagen-maintaining cytokines within the hair follicle. MPHL and FPHL exhibit a progressive decrease in anagen duration with each cycle, producing shorter, thinner hairs.[38] Finally, the interval between late telogen hair shedding (exogen) and new hair growth with initiation of anagen increases, resulting in more follicles without hair and an apparent reduction in scalp hair density.[37]

CLINICAL FINDINGS

The identification of AGA is usually not difficult if the alopecia occurs in a classical clinical pattern. In 1951, Hamilton produced the first grading scale for MPHL. The Hamilton scale ranges from type I to VIII. Whereas type I represents the prepubertal scalp with terminal hair growth on the forehead and all over the scalp, type II and III show gradual frontal mostly M-shaped recession of the hairline, type IV, V and VI show additional gradual thinning in the vertex area, type VII and VIII show a confluence of the balding areas and leave hair only around the back and the sides of the head.[50,90] In 1975 Norwood modified the classification, and included variations on the middle grades III a, IV a and V a, that show a more prominent gradual receding of the middle portion of the frontal hairline and type III vertex which is characterized by a loss of hair mainly in the tonsure area and a frontotemporal recession which never exceeds that of type III.[91] (Fig. 88-4). In 1977, Ludwig introduced a classification for pattern of AGA in women, characterized by a diffuse loss of hair on the crown and persistence of the frontal hairline.[92] In 1994, Olsen noted that women with AGA did not necessarily present with diffuse hair loss over the entire top but rather may have increasing hair loss towards the front, called frontal accentuation or Christmas tree pattern (Fig. 88-5). Women can also

show a male pattern of distribution, as well as men can show a more female pattern.[1]

A thorough scalp exam together with the patient history usually allows a definitive diagnosis.

Standardized global scalp photography, especially of the part area, is very helpful as a qualitative assessment of the progression of the hair loss and as therapy control. A pull test and a trichogram can give information on the ongoing activity of the condition. Videodermoscopy and phototrichogram techniques can be used for therapy control.

The diagnosis can be more difficult if the hair loss is more diffuse over the entire scalp or if it occurs together with other hair loss conditions such as TE, diffuse alopecia areata or mild forms of cicatricial alopecias. A scalp biopsy allows a definitive diagnosis, since it provides information on histological features, the number of terminal and vellus hair per area and the number of anagen and telogen hair.

BOX 88-1 ANDROGENETIC ALOPECIA DIFFERENTIAL DIAGNOSIS

- Telogen effluvium
- Diffuse Alopecia areata
- Trichotillomania
- Secondary syphilis

In women, a laboratory test for ferritin and thyrotrophin-stimulating hormone (TSH) are recommended to rule out sources for and underlying TE. An extensive laboratory workup for androgens is not recommended for a routine visit. Women with irregular periods and/or other signs of androgen excess should be at least checked for free and total testosterone as well as DHEA-S. The best time for the blood work is in the morning of one of the days of her menstrual cycle. She also must be off the pill for at least one cycle.

RISK FACTOR AND ASSOCIATION WITH OTHER DISEASES

An increased risk of coronary heart disease and insulin resistance has been correlated for early vertex balding, especially in young men with hypertension, obesity, and dyslipidemia.[93–95] Early vertex balding has also been correlated with an increased risk of prostate cancer.[96,97]

DIFFERENTIAL DIAGNOSIS

(Box 88-1)

TREATMENT

AGA is a progressive condition with a decrease in hair density of approximately 6% of hair fiber per year.[40] However, increased shedding can occur periodically and the extent of hair loss depends on the genetic predisposition. Currently two pharmaceutical treatments are approved for the therapy of AGA in men: oral finasteride and topical minoxidil.

MINOXIDIL

Minoxidil is a biologic response modifier, which has been shown to halt AGA in many patients and regrow hair to a certain extent. Minoxidil, a piperidinopyrimidine derivative, was noted to cause hypertrichosis when administered orally as an antihypertensive. It is now used as a 2% and a 5% topical treatment in a lotion or foam preparation.

The mechanism of action is not fully understood. A direct effect on the hair follicle cells may be responsible for the effects of minoxidil. It has been shown to have a mitogenic effect on epidermal cells leading to prolonged survival time and induced increased proliferation

of hair follicles in vitro.[98–100] A possible mechanism of action involves a change in calcium homeostasis of cells, as minoxidil is converted to minoxidil sulfate, a potassium channel agonist. Increased potassium channel permeability leads to impaired entry of calcium into cells, thus decreasing epidermal growth factors and enhancing hair growth.[101]

Several clinical trial have shows the efficacy of topical minoxidil. An increase in hair counts probably reflects reversal of miniaturized hairs to thicker, more highly visible terminal hairs. Although studies have been performed on the vertex scalp, the drug also works on the frontal scalp, especially if hairs have not completely miniaturized to vellus-like hairs. Moderate to dense regrowth could be seen in up 30%–45% of patients.[41] Some patients experience an increased shedding in the first 4–6 weeks of application. This positive sign seems to indicate anagen induction with earlier "molting" of telogen hairs from the follicles. The patient should be educated and prepared for this possible side effect to improve compliance. Observed side effects include contact dermatitis in 6.5% of patients and facial hypertrichosis in 3%–5% of women.[102] Most patients do not have a true contact allergy to minoxidil but an irritation from propylene glycol. The 2% lotion with less propylene glycol, other vehicles with butylene glycol or the foam may then be used. To discriminate, which component causes the dermatitis, a patch test or testing the product on the volar forearm (repeated open application test) may be helpful.

Only minimal amounts of minoxidil are systemically absorbed and serum levels are too low to have hemodynamic effects in normotensive or hypertensive patients. Nevertheless, less than one in thousand patients may experience tachycardia and decreased blood pressure. Patients with hypotension or heart problems should be cautious and use the medication with approval from their cardiologist. The cardiac effects suggested in earlier studies could not definitely be linked to minoxidil and may be due to increased incidence of coronary artery disease in subsets of men with AGA.[93]

Topical minoxidil solution is used twice daily (1ml or 25 drops bid). It is also available in a 5% foam. If the hair has been shampooed, the hair and scalp should be at least towel-dry. The lotion or foam should stay on the scalp for at least 4 hours before the next shampoo. The patient should be informed that this is a lifelong treatment. It takes 4–6 months before the medication starts working and that the maximum effect can be expected after 1 year.

FINASTERIDE

Finasteride is a synthetic azo-steroid that has been used for the treatment of AGA in men since 1997. It is a potent and highly sensitive selective 5α-reductase type-2 inhibitor.[59] It binds irreversibly to the 5α-reductase isoenzyme 2 and inhibits the conversion of testosterone to DHT. Finasteride has a pharmacological half-life of around 8 hours. The administration of 1 mg finasteride daily reduces the concentration of DHT in scalp skin by 64%, serum DHT is reduced by 68%.[59] The dose response curve is nonlinear and therefore higher doses do not lead to significantly increased suppression of DHT or greater clinical benefits.[103] In placebo-controlled studies, a significant hair count increase in men with vertex alopecia or frontal AGA could be shown after 6 and 12 months.[104,105] Finasteride stabilizes hair loss in 80% of patients with vertex hair loss and 70% of patients with frontal hair loss. The chance of mild to moderate regrowth is 61% on the vertex and 37% on the frontal scalp.[106] After 24 months of continuous use, 66% of the patients experienced a certain amount of hair regrowth in the vertex area (approximately 10%–25% of the hair the patient lost previously).[107] Most of the patient showed no further hair loss and only a few patients continued to lose hair. Continued use beyond 2 years does not promote continued hair regrowth. Instead the hair density stabilizes with the retention of the newly acquired hair.[107] If successful, the treatment should be continued indefinitely because the balding process continues once treatment ceases.[38] Finasteride was found to be well tolerated with side effects occurring in fewer than 2% of patients. The side effects included decreased libido in 1.8% of the recipients versus 1.3% in the placebo group, erectile dysfunction in 1.3% of the recipients versus 0.7% in the placebo group and decreased ejaculate volume in 0.8% of the recipients versus 0.4% in the placebo group.[108,109] Finasteride 1 mg daily does not affect spermatogenesis or semen production in men aged 19–41 years of age.[110] The effect on prostate volume and serum prostate specific antigen (PSA) in younger men was small and reversible after discontinuation of the drug.[110] Finasteride can decrease PSA levels by 50% in older men.[111] Therefore a baseline PSA should be taken in men over 40 and the family doctor should be advised to double the PSA value while patients are taking finasteride.[106] Long term side effects of 1 mg finasteride daily are yet unknown. A placebo controlled study over 7 years carried out in 9,060 men 55 years of age or older, taking 5mg finasteride per day or placebo, showed that finasteride prevents or delays the appearance of prostate cancer, but a slightly higher risk of high-grade prostate cancer.

Finasteride is not approved for the use in women and its efficacy in FPHL is still controversial. A multicenter double-blind, placebo-controlled, randomized study of finasteride 1 mg/day in postmenopausal women with FPHL showed no differences in anagen:telogen ratio and the terminal hair:miniaturized hair ratio. However, Camacho et al reported hair regrowth using finasteride 2.5 mg/day in 41 women with FPHL and SAHA (seborrhea, acne, hirsutism, and alopecia).[39,49]

DUTASTERIDE

Dutasteride is an inhibitor of type I and II 5α-reductase. It is approved at a dose of 0.5 mg daily for the treatment of symptomatic benign prostatic hyperplasia. Some studies have shown great efficacy in the treatment of MPHL and FPHL.[112–115] However, dutasteride is not FDA approved for use in androgenetic alopecia. More studies are necessary for the evaluation of the safety profile of this drug.

CYPROTERONE ACETATE

The antiandrogen cyproterone acetate (CPA) is a synthetic derivative of 17-hydroxyprogesterone. It acts as an AR antagonist with weak progestational and glucocorticoid activity.[62] It also inhibits the steroidogenic enzyme 21-hydroxylase, reducing the production of aldosterone and to a lesser extent 3-β-hydroxysteroid dehydrogenase, both of which are needed to synthesize cortisol. CPA is available in Europe, Canada and South America. It is usually combined with ethinyl estradiol as a birth control pill. CPA is not approved by the FDA for the treatment of AGA. For the treatment of FPHL a regimen with 100 mg CPA daily on days 5–15 of the menstrual cycle and 50 µg of ethinyl estradiol on days 5–25 or 50 mg CPA daily on days 1–10 of the cycle and 35 µg of ethinyl estradiol on days 1–21 have been suggested.[116] In a randomized 12 months clinical trial in 66 women, 33 women with FPHL used topical minoxidil 2% plus combined oral contraceptive whereas 33 women received CPA 52 mg daily plus ethinyl estradiol 35 µg for 20 days of the cycle. The later combination result in greater hair density in women with hyperandrogenism.[117] Side effects from CPA are irregular menstrual cycles, weight gain, breast tenderness, loss of libido, depression, nausea. Since CPA is an antiandrogen, its use in men is obsolete, unless a gender change is desired.

SPIRONOLACTONE

Spironolactone is a synthetic 17-lactone drug, which is a renal competitive aldosterone antagonist with a mild antiandrogenic effect by blocking the AR and preventing its interaction with DHT. The maximum androgen suppression is reached after 4–12 months; dosages of 200 mg daily are required. Spironolactone may have a preventative effect in FPHL and may reduce shedding in individuals without hyperandrogenism.[118] However, Spironolactone is not approved by the FDA for the treatment of FPHL and, sd sn antiandrogen, should not be used in men. The main side effect is menstrual irregularities, which may be mitigated by decreasing the dose to 50–75 mg/day and adding oral contraceptives or after 2–3 months of therapy. Spironolactone is contraindicated in patients with renal insufficiency, hyperkalemia, pregnancy, abnormal uterine bleeding, and women with genetic predisposition of breast cancer.[116,118]

17α- AND 17β-ESTRADIOL

In Europe topical 17α- or 17β-estradiol are commercially available for the treatment of FPHL. Studies showed an increased in anagen and decreased telogen rates after topical treatment compared with placebo treatment.[119] The underlying pathways of 17α-estradiol induced hair regrowth are unknown. Niiyama et al showed that 17α-estradiol is able to diminish the amount of DHT formed by human hair follicles after incubation with testosterone while increasing the concentration of weaker steroids.[119,120] Recently, it has been shown that hair follicles in women with FPHL express more aromatase activity as compared to male hair follicles. Under the influence of 17α-estradiol, an increased conversion of testosterone to 17β-estradiol and androstenedione to estrone takes place in hair follicles derived from the occiput, which might explain the beneficial effects of estrogen treatment in FPHL. Woman who were taking aromatase inhibitors were shown to develop FPHL more rapidly.[121] Another theory about the effectiveness of estradiol is the systemic induction of SHBG and therefore the reduction of free, bioavailable testosterone.[63] Since estradiol is absorbed through the scalp skin, systemic side effects must be considered, and it cannot be used in men.

LOW-LEVEL LIGHT THERAPY

Laser sources have become very popular in medical and nonmedical areas. Manufacturers and suppliers often guarantee hair regrowth and various devices are available without prescription. The only FDA approved low-fluence laser light device is the Hair Max Laser Comb® (Lexington international, LLC, Boca Raton, FL, United States of America) (FDA approval as a medical device). Paradoxical hair growth has occurred in patients undergoing laser hair removal when relatively low energy fluences were used. The mechanism of action of this phenomenon is unknown. One theory suggests an increase in blood flow in the dermal papilla.[122–124] Low-level laser light sources appear to be safe to use in the treatment of hair loss. More studies are necessary to understand the mechanism of action and to evaluate the efficacy of these devices.

HAIR RESTORATION SURGERY

Hair restoration is the most successful and permanent treatment for AGA in suitable candidates. It includes hair transplantation (HT) and, in skillful hands, scalp-reduction surgery. Suitable candidates for HT are those with reasonable expectations, a donor supply that is adequate to cosmetically improve the recipient area coverage and those without contraindications for surgery. The most dramatic change in cosmetic appearance is achieved in patients with stages Hamilton–Norwood VI and VII, and in patients with anterior accentuation of balding (subtypes IIIa and IVa, "Christmas tree pattern").

With recent advancements in technique and combination with medical treatment, more patients may benefit from the surgical option. Larger numbers of smaller grafts are moved per session, and results have thus become very natural.[125,126] It is possible and advisable to distribute small grafts in between preexisting hairs and thus account for future hair loss. Rational use of the donor area with strip harvesting or FU extraction makes several sessions possible in many patients if they experience progressive hair loss.

HT is based on the principle of donor dominance as shown by androgen-independent follicles retaining their properties when they are transplanted into

androgen-dependent areas. The donor supply is limited by the area of the strip (size of the "safe zone," scalp elasticity) and the density of donor hair.

HT is an outpatient procedure and may take up to 10 hours, depending on various factors, especially the number of grafts. Tumescence anesthesia is used for the donor and recipient areas, sometimes combined with nerve blocks. The most commonly used technique is strip harvesting. It allows for a relatively fast removal of large numbers of hairs leaving a fine line as a scar, which can be minimized with special harvesting and wound closure techniques. The strip is dissected into FUs ("families" of hairs growing together in one connective tissue sheath) under magnification these grafts are then carefully and strategically placed in the balding areas. The recipient side is prepared with small needles or spears, according to the size of the graft. A recent technique involves separately harvesting individual FUs using very small blunt punches (follicular unit extraction (FUE). This procedure is usually more time consuming but avoid a long scar in the occipital area. Follicular unit extraction is indicated in patients who desire to wear a very short hairstyle.

WIGS AND HAIRPIECES

Scalp prostheses are practical for patients who are not candidates for hair restoration surgery, women with extensive hair loss and/or patients without satisfying improvement after using medical therapy. Wigs and hairpieces can provide excellent cosmetic results, especially when they are custom made. It is usually easier to overcome the reluctance to wear a scalp prosthesis if the hair piece blends in nicely with the preexisting hair and is comfortable to wear. Women tend to be less reluctant to wear a wig or hairpiece, especially if the patient is exposing her natural hairline (Figs. 88-6 and 88-7).

DIFFUSE HAIR LOSS

GENETIC

HYPOTRICHOSIS SIMPLEX. Hypotrichosis simplex is characterized by progressive global loss of scalp hair starting during childhood. This autosomal dominant disorder affects both sexes equally; eyebrows and body hair is unaffected by the condition. The pathogenesis is of hypotrichosis simplex is not fully understood. In two families with hypotrichosis simplex, a gene defect in the corneodesmosin gene (adhesin protein) was found[84,127] (Fig. 88-8).

REDUCED OR ABSENT HAIR GROWTH ASSOCIATED WITH ECTODERMAL DYSPLASIA

A failure in normal follicle development in utero can results in a reduction or absence of hair follicles. These developmental disorders are often associated with ectodermal defects. These hereditary syndromes, most frequently show abnormalities of bones, central nervous system, teeth or eyes (see Chapter 142). The most common ectodermal dysplasia, hypohidrotic ectodermal dysplasia, which is characterized by sparse hair,

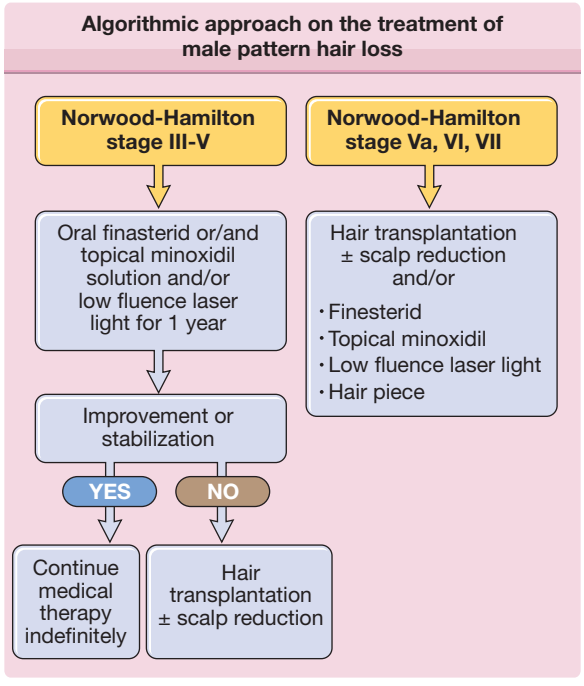

Figure 88-6 An algorithmic approach on the treatment of male pattern hair loss.

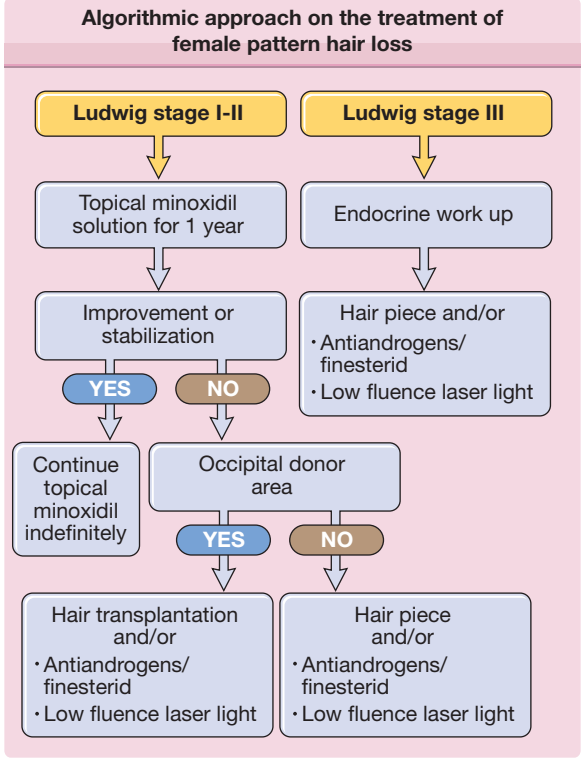

Figure 88-7 An algorithmic approach on the treatment of male pattern hair loss.

Figure 88-8 Hypotrichosis simplex in a 35-year-old woman.

abnormal teeth and reduced or absent sweating, is due to a mutation in the ectodysplasin signaling pathway.[128] This pathway is involved in the early embryogenic formation of the hair follicle.[129–131] Ectodermal dysplasias with hair disorders are discussed in Chapter 142.

ATRICHIA WITH PAPULAR LESIONS

Atrichia with papular lesions is an autosomal dominant hair disorder that presents in infancy. Hair is usually present at birth but alopecia develops within the first year of life. Several years after the development of alopecia, papular follicular cysts often appear.[132] Mutations either in the *hairless* gene or the gene encoding the vitamin D receptor can lead to this phenotype. Hair follicle formation in utero appears to be normal, but massive apoptosis in the hair bulb during the first catagen phase leads to a separation of the dermal papilla from the base of the hair follicle and consequent failure to reenter anagen. The follicular epithelium than undergoes a cystic change. If universal hair loss occurs during the first month of life, atrichia with popular lesions and alopecia areata universalis should be considered as differential diagnosis. If universal alopecia is seen in the family, gene testing and genetic counseling should be considered.

SHORT ANAGEN SYNDROME

The term short anagen hair syndrome applies to a poorly understood clinical presentation of short fine hair in children.[87] The hair fails to grow long due to a shortened anagen phase. Hair density and hair shafts seem to be normal. The condition may improve after puberty. Short anagen hair can be inherited autosomal dominant or can occur sporadically.

LOOSE ANAGEN SYNDROME

Loose anagen syndrome is characterized by an easy epilation of anagen hair. The hair appears to grow slowly and can be pulled out without pain. Hair density can appear normal or reduced and some children may display demarcated areas of incomplete alopecia. The typical patient with loose anagen hair syndrome is 2–5 years of age. The condition more frequently affects girls and hair is most often light blond. The hair loss tends to get better without any treatment once the child grows older. Microscopic examination of gently pulled hair can make the diagnosis; 80%–100% of the hairs are anagen hairs with a ruffled cuticle and no inner root sheath. However, the hair loss can cycle, and it may be hard to gather enough hair with a gentle pull, necessitating collection by the parent at home and later microscopic evaluation. Loose anagen hair syndrome can be familial, sporadic or associated with other developmental defects such as Noonan syndrome or hypohidrotic ectodermal hyperplasia.[133] It is also seen in association with HIV.[134] Hair shaft abnormalities, alopecia areata and trichotillomania have to be considered in the differential diagnosis. (See Fig. 88-9.)

TELOGEN EFFLUVIUM

EPIDEMIOLOGY

The second most common cause of hair loss in women after FPHL is TE. The latter presents as a nonpatterned increase in shedding of terminal hairs, diffusely over the entire scalp, and can produce an apparent thinning of hair in severe cases.[135] While both genders can experience TE, attitudes toward hair loss result in a greater proportion of females who complain. TE can copresent with AGA, particularly in early-onset situations, and this can complicate diagnosis and treatment. TE differs from AGA in that it is not androgen-sensitive,

Figure 88-9 Loose anagen hair syndrome with diffuse hair loss. (From Olsen EA et al: The presence of loose anagen hairs obtained by hair pull in the normal population. *J Investig Dermatol Symp Proc* **4**:258, 1999, with permission.)

does not appear to be inherited and, since it does not involve a terminal- to vellus-hair transition, does not decrease matrix cell volumes or hair shaft diameters.[136] TE also tends to be related to external causes and is often reversed when the exogenous stimuli are removed.

ACUTE TELOGEN EFFLUVIUM

ACUTE TELOGEN EFFLUVIUM AT A GLANCE

- Nonscarring alopecia.
- Sudden conversion of large numbers of actively growing anagen to telogen hair leads to diffuse hair shedding.
- Seen after severe illness, surgery, nutritional deficiency, iron deficiency, childbirth, in association with medications and in patients with thyroid disease.
- Reversible once the initiating factor is eliminated.

ETIOLOGY AND PATHOGENESIS. The pathophysiology underlying TE is best characterized as a premature shift of hairs from the anagen (growth) phase into the catagen (resting) and telogen (terminal) phases. However, there are variants: anagen may be prolonged, or telogen may instead be shortened or prolonged. Which type of shift occurs depends on the stimulus producing the shift, with the main clinical difference being the latency of effluvial onset following the stimulus.

The hair loss that commonly occurs following pregnancy is generally seen 2 or 3 months postpartum, although some individuals can exhibit longer times to onset. While this is classic TE, the mechanism has been shown to involve a delayed transition from anagen to catagen/telogen, which results in a simultaneous shedding of large numbers of terminal hairs.[137] This hair does eventually regrow; however, the returning hair may show changes in texture, color and curliness, and may not attain its previous length. As such, pregnancy (parturition or abortion) may in some cases produce permanent changes in anagen length.[136]

Other perturbations can produce TE, usually involving premature termination of the anagen phase. Some women experience transient TE 2–3 months after discontinuing or changing oral contraceptive medication; the delayed onset of TE in these cases distinguishes it from the anagen effluvium (AE) initiated by certain drugs (see below). In the 1970's, the popularity of fad "crash" diets resulted in many cases TE about 3 months after initiation of these spartan regimens, depending on the severity of weight loss. Sudden deprivation of amino acids and other dietary factors most likely produced the condition, and the hair tended to regrow following cessation of the diets.[136] Surgical procedures, psychological traumas, and febrile illness have all been reported to produce TE events.

Drugs are widely reported to produce temporary hair loss. This is usually, but not necessarily, of the AE variety, since, depending on the causal agent, the time course and severity may suggest a diagnosis of TE to be appropriate. Agents producing TE include cimetidine, enalapril and captopril, imiquimod, metoprolol and propranolol,[138–141] lithium,[142] L-dopa[143] trimethadione,[144] and bromocriptine.[145] The hair loss from administration of etretinate[146] and isotretinoin are problems, more of the AE, as is hair loss that sometimes follows renal dialysis, possibly with hypervitaminosis A.[136] Finally, hair loss occurring following environmental contamination or poisoning, for example with selenium, arsenic, thallium, mercury, and lead, displays an AE-like rapid onset, probably involving a cytotoxicity mechanism.

CLINICAL FINDINGS. TE is characterized by a fairly sudden onset of massive shedding. Anagen hairs are prematurely shifted into telogen hairs and the normal anagen/telogen ratio of 90:10 can switch to 70:10. Women often present with the "bag sign": bringing in bags with hair that they have collected every day or over a couple of days (Fig. 88-10). More than 300 telogen hairs can be shed every day. The global examination of the scalp may show a reduction in hair density especially in the temporal area. The pull test is usually positive (3 or more hairs can be pulled out on different parts of the scalp). A trichogram or phototrichogram can be use to quantify the amount of telogen hair. A scalp biopsy may be helpful to distinguish the condition from diffuse alopecia areata or AGA.

CHRONIC TELOGEN EFFLUVIUM

ETIOLOGY AND PATHOGENESIS. Chronic Telogen Effluvium (CTE) was first proposed in 1996 as a means of distinguishing the abrupt-onset, short-acting

Figure 88-10 Diffuse thinning in a female patient with acute telogen effluvium.

BOX 88-2 CAUSES OF TELOGEN EFFLUVIUM

- Endocrine
  - Childbirth, miscarriage, abortion
  - Hypo- and hyperthyroidism
  - Discontinuation of estrogen-containing drugs
- "Stressful" events
  - Febrile illnesses
  - Catabolic illnesses (e.g., malignancy, "consumptive" chronic infection)
  - Major surgery
  - Major trauma
  - Acute or chronic psychological stress
- Nutritional
  - Rapid weight loss (e.g., "crash dieting")
  - Caloric or protein deprivation
  - Chronic iron deficiency
  - Excessive vitamin A ingestion
- Intoxication
  - Thallium
  - Mercury
  - Arsenic
- Drugs
  - Anticoagulants (including heparin)
  - β Blockers (propanolol)
  - Captopril
  - Cholesterol-lowering drugs
  - Colchicine

type TE, usually caused be exogenous triggers or parturition, from a more durable condition (CTE) that may not be so clearly related to any external event.[147]

A few conditions have been proposed to be underlying stimuli for CTE. While "crash" diets have been pinpointed as potential triggers for acute TE, chronic malnutrition can analogously lead to CTE. Protein deficiency is the likely mechanism in this type of balding. It is less clear whether zinc[148] or biotin deficiencies are also correlated with chronic diffuse hair loss. Although controversial, iron deficiency, as evidenced by decreased serum ferritin and anemia, may be a trigger for CTE.[27,149,150,151] Hypothyroidism has also been associated with CTE (Box 88-2).

CLINICAL FINDINGS. CTE can most commonly be seen in women. Patients report ongoing massive shedding or recurrent episodes of shedding. As a rule of thumb, any diffuse hair shedding lasting longer than 6 months after any triggering event, or after withdrawal from suspected causal drugs, should be considered CTE. The clinical examination can show a normal or reduced hair density. Regrowth of tapered new anagen hair can usually be found. The pull test may be moderately positive. A trichogram or phototrichogram can be used to confirm and quantify the diagnosis. A scalp biopsy is very helpful for the confirmation of the diagnosis and to distinguish the condition other forms of alopecia. Since other types of hair loss disorders, chiefly FPHL/MPHL and alopecia areata, may copresent with TE and CTE, clinicians may be advised to assay serum iron and thyroid hormone concentrations in order to eliminate iron deficiency and hypothyroidism as treatable causes for the patient's baldness.[152]

BOX 88-3 ACUTE TELOGEN EFFLUVIUM DIFFERENTIAL DIAGNOSIS

- Androgenetic alopecia
- Diffuse Alopecia areata
- Trichotillomania
- Anagen effluvium
- Secondary syphilis

DIFFERENTIAL DIAGNOSIS. (Box 88-3)

PROGNOSIS AND CLINICAL COURSE. Both acute and CTE usually resolve once trigger factors are eliminated. However, in CTE triggers may be difficult to identify. Women with TE are often most concerned about complete baldness. The patient has to be reassured that the condition does not lead to complete baldness and that the hair likely grows back around 6 months after removal of the initiating trigger. The patient should understand that the condition is reversible, but that the shedding may persist for a few weeks or months once the initiation factor is eliminated.

TREATMENT

The removal of the cause is the major goal in the treatment of TE. Iron supplementation is recommended if the ferritin level is less than 70 ng/mL.[150,153] Borderline hypothyroidism can be difficult to identify. Women, who complain about hair loss, depression, lack of energy, mental fatigue, cold intolerance, weight gain or/and constipation are suspicious for the diagnosis of hypothyroidism. TSH levels may fluctuate but are usually elevated, with normal or reduced thyroid hormone levels. If a thyroid dysfunction is suspected, the patient should be closely followed by an endocrinologist. Topical 2% or 5% minoxidil solution 1 mL twice daily can be helpful, especially in women with prolonged hair loss with unknown triggers or in patients with drug related hair loss who are unable to discontinue the initiating medication.

ANAGEN EFFLUVIUM

AE is a result of a disturbance of hair follicle matrix cells. The anagen phase is interrupted and the hair falls out 7–14 days after the initiating event without entering catagen or telogen. Two different types of AE can be distinguished: Dystrophic AE and Immediate anagen release. Dystrophic AE can be caused by

chemotherapy, radiation, toxins or alopecia areata. Microscopic investigation of the hair bulbs, obtained from a hair pull test or trichogram, usually shows a tapered tip with the weakened hair shaft broken shortly above the bulb ("dystrophic hair").[1]

Drugs used in chemotherapy quickly produce severe hair loss and even total baldness. A rapid onset undoubtedly indicates an immediate release from anagen hair. Immediate anagen hair release is characterized by an easy release of anagen hairs after gentle pulling. The anagen hair has a broom-shaped, pigmented bulb. Therapeutic agents that can cause immediate anagen hair shedding include vincristine, vinblastine, methotrexate, doxorubicin, and fluorouracil.

Normal appearing anagen hair with inner and outer root sheath can be found to some extent in every AE, but especially in bullous dermatosis of the scalp with sub- or intraepidermal blisters.

Once the initiating trigger is removed, the hair usually regrows after around 120 days. Cases of incomplete recovery following multiagent chemotherapy have been reported.[1] Patients should be advised about scalp prostheses and other forms of head covering.

NONSCARRING FOCAL HAIR LOSS

ALOPECIA AREATA AT A GLANCE

- Nonscarring hair disorder.
- Occurs in both genders equally and can affect every age group, although incidence at younger age is higher.
- Most common form of hair loss in children.
- Clinically presents with well-demarcated round or oval bald spots on the scalp or other parts of the body.
- 5% develop hair loss of their entire scalp hair (alopecia areata totalis), 1% develop alopecia areata universalis (loss of total body hair).
- Nail changes include pitting or sandpaper nails.
- Thought to be an autoimmune disease with a possible heredity component.
- Usually without associated disorders, but can coexist with other autoimmune disorders such as Hashimoto thyroiditis or vitiligo.

ALOPECIA AREATA

EPIDEMIOLOGY. At any given time, approximately 0.2% of the world population is suffering from alopecia areata with an estimated lifetime risk of 1.7%.[154,155] It is a common cause of abrupt-onset hair loss, but occurs less frequent than androgenic alopecia or TE. Both sexes are affected equally. Although it may occur at any age, incidence at younger age is higher. Alopecia areata is the most common form of alopecia seen in children. The familial occurrence is around 15% but expression of the disorder is variable among different family members. 5% of patients suffering from alopecia areata develop hair loss of their entire scalp hair (alopecia totalis), and 1% of patients develop loss of total body hair (alopecia universalis) at some point.

ETIOLOGY AND PATHOGENESIS. Alopecia areata is a chronic, organ-specific autoimmune disease, mediated by autoreactive $CD8^+$ T-cells, which affects hair follicles and sometimes nails.[156–159] Alopecia areata is thought to be an autoimmune disease with inappropriate immune- response to hair follicle associated antigens. A collapse of the normal immune privilege of the anagen hairbulb, probably induced by interferon-γ, may play a key role in the pathogenesis of this disease.[156,159] Melanogenesis-associated autoantigens, which are normally sequestered from immune recognition by a functional hair follicle immune privilege, may be one key target of autoaggressive inflammation in alopecia areata.[160] There is a high frequency of a positive family history of alopecia areata in affected individuals, ranging from 10% up to 42% of cases,[161] and a much higher incidence of a positive family history in early onset alopecia areata.[162] Many patients report the experience of major emotional stress prior to the onset of alopecia. A genome-wide association studies recently showed several loci linked to alopecia areata containing genes controlling both innate and acquired immunity, as well as genes expressed in the hair follicle itself.[163]

Histologically, alopecia areata is characterized by an inflammatory infiltrate, comprised mainly of T-cells, in and around the bulbs of anagen hair follicles ("swam of bees"). However, the classic inflammatory infiltrate may be missing in subacute or chronic forms. Alopecia areata should be in the differential diagnosis whenever high percentages of telogen hairs or miniaturized hairs are present, even in the absence of peribulbar inflammation.

CLINICAL FINDINGS. Alopecia areata is characterized by an acute onset. It typically presents with oval or round, well-circumscribed, bald patches with a smooth surface in a diffuse distribution (Fig. 88-11). Alopecia totalis results in the loss of the entire scalp hair and may occur suddenly or follow partial alopecia (Fig. 88-12). Partial alopecia may be observed in other areas of the body as well. Loss of total body hair is called alopecia universalis and may also occur suddenly or follow of long-standing partial alopecia.

Characteristic hallmarks of alopecia areata are "black dots" (cadaver hairs, point noir), resulting from hair that breaks before it reaches the skin surface. Exclamation point hairs, with a blunt distal end and taper proximally, appear when the broken hairs (black dots) are pushed out of the follicle. Localization of the initial patch is most frequently on the scalp, but may occur on

Figure 88-11 Patient with patchy alopecia areata.

any hair-bearing part of the body. Patches are usually without further symptoms, but may show mild itching and erythema in some cases. Alopecia areata can less commonly present in a diffuse generalized pattern that resembles androgenic alopecia or TE. In the acute stages, gentle pulling from the periphery of bald areas will yield more than 10 hairs. Involvement of nails is common with nail pitting and a sandpaper-like appearance. The disease has been described in association with a variety of other disorders, such as cataracts, thyroid disease, vitiligo, atopic dermatitis, psoriasis, and immunodysregulation polyendocrinopathy enteropathy X-linked syndrome (IPEX), Cronkhite–Canada, and Down syndromes.[164,165]

Clinical features, such as shape and look of the patches, presents of exclamation point hair, nail changes (pitting or sandpaper nails) lead to the diagnosis of alopecia areata. In most patients the physical findings are so characteristic that the diagnosis is obvious. Moreover, positive family history and/or the presence of associated diseases may give further evidence in cases of doubt. Scalp biopsy reveals a generalized miniaturization and a marked increase in catagen and telogen hair follicles. In the acute phase, a peribulbar lymphocytic infiltrate, which has been described as a "swarm of bees" may be found. Sometimes mast cell, plasma cells and eosinophils can also be seen. Laboratory tests to rule out thyroid dysfunction should be performed.

Figure 88-12 Patient with alopecia areata totalis showing some regrowth of fine hair.

BOX 88-4 NONSCARRING FOCAL HAIR LOSS DIFFERENTIAL DIAGNOSIS

- Temporal triangular alopecia
- Tinea capitis
- Early scarring alopecia
- Trichotillomania
- Secondary syphilis (alopecia areolaris)
- Androgenetic alopecia
- Telogen effluvium
- Anagen effluvium

DIFFERENTIAL DIAGNOSIS. (Box 88-4)

COMPLICATIONS.

A relapsing course and progression of hair loss to severe forms of alopecia totalis or universalis are dreaded complications. Missing hair on the scalp and face, including nasal hair and eye lashes/brows can increase the incidence of sunburn and skin cancer, as well as nasopharyngeal and ophthalmologic inflammation. Although the condition is not life threatening, changes in appearance frequently cause a diminished sense of personal well-being and self-esteem, leading to severe depression and withdrawal from social situations.

PROGNOSIS AND CLINICAL COURSE.

The course of the disease is very variable and characterized by an irregular relapsing course, with about 25% of affected individuals having a solitary episode. Spontaneous regrowth of hair is common. Different body areas appear to regrowth independently. About 60% of patients have at least a partial regrowth by 1 year, but this is often followed by repeated episodes of hair loss. About 40% of the relapses occur within the first year, but a large percentage of patients may relapse after 5 years. Hair can regrow white but may change to the patient's natural color over time. Poor prognosis is linked to involvement of the occiput and/or hairline (called the ophiasis pattern if sweeping around the periphery of the scalp), a chronic relapsing course, the presence of nail changes, and onset during childhood.[166–168] The number of patients progressing to alopecia totalis also higher in patients with hair loss from the trunk and extremities.

TREATMENT.

Very little evidence-based data is available for the treatment of alopecia areata;

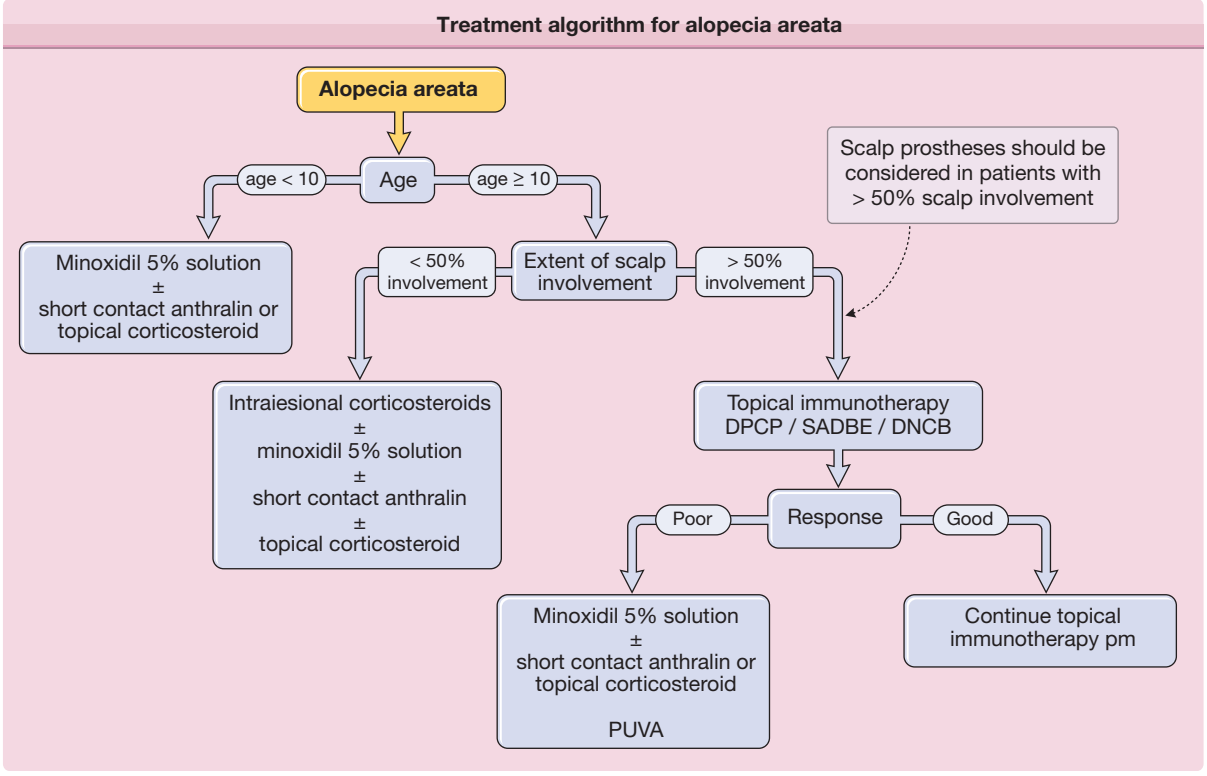

Figure 88-13 Treatment algorithm for alopecia areata. (Copyright © by Jerry Shapiro, Vera Price and Harvey Lui).

recommendations are mainly based on case series and clinical experience. At this time all available treatments for alopecia areata are palliative, only controlling the ongoing episode of hair loss and not curing the condition itself. However, helpful treatment guidelines have been published.[166–168] Fig. 88-13 shows an algorithm for treating alopecia areata based on age and scalp involvement.

CONSERVATIVE MANAGEMENT.

Alopecia areata shows a high rate of spontaneous remission, especially in those patients with a short history and limited scalp involvement. On the other hand, in alopecia totalis and universalis, treatments have a high failure rate. After the discussion of possible risks and benefits of all options, "no treatment" may be a legitimate option for some patients.

Topical Corticosteroids. Superpotent (class I) and potent (class II) topical corticosteroids are widely used to treat alopecia areata. Evidence of efficacy has been proven for class I corticosteroids when applied under occlusion[169] and for class II corticosteroids when used in combination with minoxidil.[170]

Intralesional Corticosteroids. Intralesional corticosteroid (triamcinolone acetonide or triamcinolone hexacetonide) injection is first line therapy for adult patients with less than 50% scalp involvement. Triamcinolone acetonide is used at concentrations from 2.5–10 mg/mL. Treatment are repeated every 4 to 6 weeks, and the total amount injected per session varies from 15–40 mg.[109,166–168,171] An initial response is often seen after 4–8 weeks. Some patients experience indentation of the scalp skin in the injection sites due to a nonpermanent atrophy of the subcutaneous fat. Permanent skin atrophy can occur if the same skin area is injected repeatedly over months and years. If no regrowth can be seen after 4 months of treatment, other treatment options should be considered. Intralesional corticosteroids injections are usually used on the scalp, eyebrows and beard area and can be combined with topical treatment.

Systemic Corticosteroids. Systemic corticosteroids are effective in the treatment of alopecia areata. However, the regrown hair frequently falls out again when the treatment is discontinued. The use of systemic corticosteroids is controversial and largely used on a short-term basis with rapidly advancing hair loss. They should not be used as routine treatments because they do not alter the long-term prognosis and can cause side effects such as striae, acne, obesity, cataracts and hypertension. Dosages vary from initial 20–40 mg prednisone daily tapered down to 5 mg daily in a few weeks or different pulse therapies regiments with short-term high doses of oral prednisolone (100–300 mg) or i.v. methylprednisolone (250 mg).[109,166–168]

Topical Minoxidil. There is some evidence of clinically acceptable hair regrowth using topical minoxidil 5% solution.[172,173] Better results can be achieved when minoxidil is used in combination with class II topical

corticosteroids or anthralin.[170] Minoxidil shows little efficacy in alopecia totalis and universalis.

Anthralin. Anthralin is an irritant that may have a nonspecific immunomodulating effect and is primarily used in the treatment of psoriasis (Chapter 18).[174] Several studies have shown efficacy in the treatment of alopecia areata with cosmetically acceptable improvement varying from 20% to 25% for patchy alopecia areata.[175,176] Anthralin is used as a 0.2%–1.0% cream or ointment. It is usually applied daily to the affected scalp areas and left on for 20–30 minutes for the first 2 week, and then 45 minutes daily for 2 week, up to a maximum of 1 hour daily. Some patient may tolerate overnight therapy.[109,175] When therapy is effective, new hair growth can usually be seen after 2–3 months of treatment. Because of its good safety profile, anthralin can be used safely in affected children. Side effects of anthralin are irritation, scaling, folliculitis and regional lymphadenopathy. Anthralin is not suitable for the treatment of eyebrows and beard area. Patients should be cautious not to get anthralin in the eyes and to protect the treated skin areas from UV irradiation. Brown discoloration of the treated skin and brown staining of clothes and linen may occur. The patient should be advised to rinse off the anthralin with cool or luke-warm water, since hot water increases the likelihood of brown stains of tiles and bathtub.

Topical Immunotherapy. Although not approved by the FDA, topical immunotherapy seems to be the most effective therapeutic option with the best safety profile in the treatment of chronic severe alopecia areata. The exact mechanism of action is not fully understood. A decrease in the peribulbar $CD4^+/CD8^+$ lymphocyte ratio and a shift in the position of T-lymphocytes from the perifollicular area to the interfollicular area and dermis are believed to be responsible for the immunomodulating effect.[177–179] The desired effect of the treatment is the creation of a contact dermatitis. Diphenylcyclopropenone (DPCP) and squaric acid dibutyl ester (SADBE) are the most commonly used contact sensitizers. DPCP and SADBE are compounded in an acetone base and stored in opaque bottles to protect the solution from photodegradation. Applying a small amount of a 2% solution to a small scalp or other area (often the arm) one week prior to treatment initiation sensitizes the patient. The DPCP or SADBE solution is then applied weekly to the scalp, starting at a concentration of 0.0001%. The scalp should not be washed for 48h post treatment and should be protected from UV radiation. Every week the concentration is carefully increased until the patient develops a mild erythema and mild itching. The treatment is continued with this concentration; the highest concentration used is 2%. Success rates vary from 17%–75% with the lowest success rates in patients with alopecia totalis and universalis.[20] Side effects include lymphadenopathy in 100% of patients, severe contact eczema, discoloration of the skin including vitiliginous patches and hyperpigmentation on the scalp and other arts of the body. Greater caution is indicated in patients with atopic dermatitis and dark skin types.

Photo(chemo)Therapy. Ultraviolet B light has been reported to be useful in some patients with alopecia areata.[180] Further therapeutic options include both oral and topical administration of psoralen followed by UVA irradiation (PUVA-therapy). PUVA may affect T cell function and antigen presentation, and possibly inhibits the local immunologic attack against the hair follicle by depleting Langerhans cells.[181] Photo(chemo)therapy shows a very high relapse rate especially after tapering the treatment. The major concern about long term UV irradiation of any kind is its promotion of all types of skin cancer, including melanoma. Therefore phototherapy should only be considered in exceptional cases.[20]

Cyclosporine. Systemic cyclosporine at doses of 4–6 mg/kg/day has been shown to have a beneficial effect in some patients with alopecia areata.[20,182] Side effect of oral cyclosporine include elevated serum transaminases and cholesterol levels, as well as headaches, dysesthesia, fatigue, diarrhea, gingival hyperplasia, flushing and myalgias. Cyclosporine can be combined with low dose oral prednisone and may be considered in patients with severe atopic dermatitis and alopecia areata. However, due to its side effect profile and the high recurrence rate observed after discontinuation, cyclosporine seems to be a relatively impractical treatment for alopecia areata.

Camouflage, Wigs, and Hairpieces. When alopecia is progressive despite treatment and sometimes during treatment for improved cosmesis, extensive alopecia areata of the scalp can be camouflaged with wigs. In women with alopecia areata of the eyebrows, permanent makeup may be considered.

The treating physician should provide psychological support. Local and national alopecia areata support groups (National Alopecia Areata Foundation, www.naaf.org) can be very helpful for patients and their relatives.

TEMPORAL TRIANGULAR ALOPECIA

Temporal triangular alopecia (TTA) is a nonscarring, noninflammatory alopecia that presents with one or more roughly triangular, oval, or lancet-shaped alopecic patches in the fronto-temporal area.[183–185] A few terminal hairs or vellus-like hairs can often be found in the periphery of the affected area and the scalp is normal.[186–190] The lesions are usually asymptomatic and the hair elsewhere on the scalp is of normal density. The patches are mostly unilateral (80%) but can occur bitemporally as well (20%)[34,185,190] (Fig. 88-14). A strip of hair of normal density can be seen between the affected patch and the forehead. Lesions can be present at birth or first appear before school age. TTA has been reported in Asian and Caucasian patients with no sexual predilection. TTA seems to be unresponsive to medical treatment. Hair transplantation or excision is reasonable therapeutic approaches.[191] TTA is often misdiagnosed as alopecia areata.

Figure 88-14 Temporal triangular alopecia.

SYPHILIS

Hair loss is a common symptom of secondary or tertiary syphilis. In its classical form, the hair loss is an irregular, patchy loss of hair scattered throughout the scalp, which has been described as "moth eaten" (Fig. 88-15). Eyebrows may be shed and patchy alopecia may occur in the beard or other hair-bearing areas of the body. Syphilitic alopecia can be very difficult to distinguish from alopecia areata. The presence of plasma cells, lack of peribulbar eosinophils, and abundant lymphocytes in the isthmus are histological features of syphilitic alopecia. Essential syphilitic alopecia occurs in the absence of any other cutaneous sign of secondary syphilis,[192] and is characterized by a diffuse shedding, thereby resembling TE.

CICATRICIAL ALOPECIA

Cicatricial or scarring alopecias comprise a diverse group of scalp disorders that result in permanent hair loss. The destructive process can occur as a primary or secondary cicatricial alopecia. Primary cicatricial alopecia refers to a group of idiopathic inflammatory diseases, characterized by a folliculocentric inflammatory process that ultimately destroys the hair follicle. Secondary cicatricial alopecias can be caused by almost any cutaneous inflammatory process of the scalp skin or by physical trauma, which injures the skin and skin appendages. Regardless of whether a cicatricial alopecia is primary or secondary in nature, all scarring alopecias are characterized clinically by a loss of follicular ostia and pathologically by a replacement of hair follicles with fibrous tissue. Cicatricial alopecias are psychosocially distressing for the affected patient and medico-surgically challenging for the treating physician.

PRIMARY CICATRICIAL ALOPECIAS

CICATRICIAL ALOPECIA AT A GLANCE

- Scarring alopecia occurs in a heterogeneous group of hair disorders of a wide variety of causes.
- The inflammatory process leads to permanent destruction of hair follicular stem cell structure and subsequent replacement with fibrous tissue.
- The destructive process can occur as a primary or secondary cicatricial alopecia
- In each case, the differential diagnosis includes alopecia areata, an alternative form of cicatricial alopecia, temporal triangular alopecia, trichotillomania, and secondary syphilis (alopecia areolaris).
- Loss of hair ultimately occurs with permanent alopecia.
- No evidence-based treatment is available.

EPIDEMIOLOGY. Inflammatory cicatricial alopecias are rare.

ETIOLOGY AND PATHOGENESIS. The mechanisms causing the follicle stem cell destruction are not completely understood, and there is no cure to date. Primary cicatricial alopecias are characterized by an inflammatory infiltrate affecting the upper, permanent portion of the follicles referred to as the infundibulum, and below it, the isthmus of the follicle. The isthmus is the home of pluripotent hair stem cells, which are found in the bulge region where the arrector pili muscle attaches to the outer root sheath. Pluripotent hair follicle stem cells are responsible for the renewal of the upper part of the hair follicle and sebaceous glands,

and for the restoration of the lower cyclical component of the follicles at the onset of a new anagen period.[27,193] Damage to the bulge area and the sebaceous gland with the isthmus, affected either stem cells or sebaceous glands, may result in an incomplete hair cycle and can be associated with chronic follicular inflammation and foreign body reaction.[194] Scarring hair loss is the consequence.[5,195–197]

A working classification on the basis of pathology of scalp biopsy was suggested by the North American Hair Research Society in 2001[27] (Box 88-5).

CLINICAL FINDINGS. Primary cicatricial alopecia usually affects the central and parietal scalp before progressing to other sites of the scalp. Isolated alopecic patches showing atrophy and a lack of follicular ostia with inflammatory changes such as diffuse or perifollicular erythema, follicular hyperkeratosis, pigment changes, tufting, and pustules provide hints to the diagnosis.[20,198] However, clinically visible inflammatory change might be absent in the affected lesions and may present histologically as inflammatory infiltrates in the deep dermis and subcutaneous tissue. Diagnostic tools such as a tenfold magnifying dermatoscope with and without polarized light can help to identify the presence or absence of follicular ostia, perifollicular erythema and follicular hyperkeratosis in the affected areas.

A thorough examination of the entire scalp, a detailed clinical history, and skin biopsies of an active lesion are crucial in the correct diagnosis of cicatricial alopecia. Patient-reported symptoms such as itching or pain might be used as approximate indicators of disease activity but can also be completely absent. The presence of other indirectly related symptoms, such as sun sensitivity, can also help support a particular diagnosis [e.g., discoid lupus erythematosus (DLE)]. A scalp biopsy is necessary to confirm the diagnosis of scarring alopecia, and should be taken as described in Section "Diagnostic Techniques for Evaluating Hair Growth Disorders" under "Biopsy."[1,27,199,200] Keratoses follicularis spinulosa decalvans is a form of cicatricial alopecia associated with follicular plugging that is more fully described in Chapter 87 as well as online.

LYMPHOCYTIC PRIMARY CICATRICIAL ALOPECIAS

CHRONIC CUTANEOUS LUPUS ERYTHEMATOSUS (DISCOID LUPUS ERYTHEMATOSUS).

(See also Chapter 155). Discoid lupus erythematosus (DLE), together with LPP, is the most common cause of inflammatory cicatricial alopecia.[198] Women are more often affected than men and the disease is more common in adults (with first onset typically at the age of 20–40 years) than in children.[201–203]

Systemic lupus erythematosus (SLE) will develop in 26%–31% of children and approximately 5%–10% of adult patients with DLE.[203,204] Patients with DLE are found to have a higher incidence of concurrent alopecia areata. Moreover, DLE has also been associated with verruciform xanthoma and papulonodular dermal mucinosis.[205]

Clinical Presentation. DLE usually presents with one or more erythematous, atrophic, and alopecic patches on the scalp (Fig. 88-16). Follicular hyperkeratosis, hyperpigmentation, hypopigmentation and telangiectasia can be present.[194,206] Hyperpigmentation is frequently found in the center of the lesion. Active lesions can be sensitive or pruritic, and the patient might report a worsening after UV exposure.

Pathology. Characteristic features of early, active DLE lesions are lymphocyte-mediated interface

Figure 88-16 Discoid lupus erythematosus.

dermatitis with vacuolar degeneration of the basal cell layer and necrotic keratinocytes, a thickening of the basement membrane and destruction of sebaceous glands. Elastic fibers are frequently destroyed throughout the reticular dermis.[1,195] The lymphocytic infiltrate is predominantly found in the upper part of the follicle, but can also be found in deeper parts of the follicle, in the interfollicular epidermis and around the periadnexal vessels.[18,207–209] DIF typically shows a linear granular deposition of IgG and C3 at the dermal–epidermal junction. IgM, C1q, and rarely IgA can also be found.

Management and Treatment. Hydroxychloroquine at a dose of 200–400 mg daily in adults or 4–6 mg/kg in children has been shown to be highly effective. A baseline ophthalmologic examination and complete blood count is required before the therapy is started.[201,203] Bridge therapy with oral prednisone (1 mg/kg) tapered over the first 8 weeks of treatment might be helpful in adult patients with rapidly progressive disease.[20,198]

In limited or slowly progressive DLE, intralesional triamcinolone acetonide should be used at a concentration of 10 mg/cc every 4–6 weeks, alone or in addition to oral therapy.[198] Intralesional triamcinolone acetonide can be used with or without topical class I or class II corticosteroids. Topical corticosteroids alone have also been shown to be effective in milder forms of DLE,[1,18,20,203] and oral acitretin and isotretinoin have shown some efficacy.[210,211] Immunosuppressive therapies such as mycophenolate mofetil, methotrexate, or azathioprine should only be considered if the above therapies fail. Multimodal aggressive therapy in rapidly progressive DLE might reverse early alopecic patches and save hair follicles from the destructive process.[212]

LICHEN PLANOPILARIS.

LPP is a follicular variant of lichen planus. Together with DLE, this is the most common cause of primary cicatricial alopecia. LPP can be divided in classic LPP, frontal fibrosing alopecia (FFA), and Graham–Little syndrome. The typical age of onset of classic LPP is around the fifth decade, and women are more often affected than men. Extracranial lichen planus may occur in up to 28% of patients.[196,213,214] FFA predominantly affects postmenopausal women. Graham–Little–Piccardi–Lassueur Syndrome is a very rare condition that predominantly affects female adults. It is characterized by LPP of the scalp, noncicatricial of the eyebrows, axilla, and groin and keratosis pilaris.

Lichenoid drug eruptions can be triggered by many drugs and might present as LPP. Some of the most common drugs, causing lichenoid drug eruption are gold, antimalarials and captopril. Actinic lichenoid drug eruption is confined to sun exposed sites. The most likely drugs to cause this are quinine, and thiazide diuretics.[215–217]

Clinical Presentations of LPP. Classic LPP typically starts at the crown and vertex area. In classic LPP, the affected areas usually show perifollicular erythema and follicular hyperkeratosis. The alopecic areas of LPP are often smaller, irregularly shaped and interconnected, which can lead to a reticulated clinical pattern as compared to DLE. However, overlapping clinical features with those of DLE are frequently seen. Patients complain about itching, burning sensations and sensitivity of the scalp (Fig. 88-17).

Figure 88-17 Extensive lichen planopilaris.

FFA is characterized by a frontal, band-like, or circumferential scarring alopecia.[195] In some cases a few hairs are spared in the original frontal hairline. Follicular hyperkeratosis and perifollicular erythema may be found in a band-like pattern in the frontal hairline. Alopecia of the eyebrows is also frequently seen in FFA (Fig. 88-18). Graham–Little syndrome presents with lesions of classic LPP on the scalp, nonscarring alopecia of axillae, pubic area, and eyebrows as well as keratosis pilaris of the trunk and extremities.

Pathology. The three subgroups of LPP show similar histopathological features. A lymphocytic infiltrate and interface dermatitis are predominantly found in and around the upper permanent part of the hair follicle. Unlike DLE, the vascular plexus is not affected by inflammation and mucin deposits are absent.[195] DIF typically shows globular cytoid depositions of IgM, and rarely IgA, IgG or C3, in the dermis around the infundibulum.[218]

Figure 88-18 Frontal Fibrosing alopecia.

Management and Treatment. First line treatment for moderately active classic LPP lesions is intralesional triamcinolone acetonide at a concentration of 10 mg/cc every 4–6 weeks or in combination with topical class I or class II corticosteroids.[198,211] Literature on the efficacy of oral medication is limited. Oral cyclosporine, retinoids, antimalarials and griseofulvin[194,206,219–222] have been shown to have a positive effect in patients with rapidly progressive LPP. Oral corticosteroids in the first weeks of treatment as bridge therapy might be considered in very active cases. In FFA, a lower dose of intralesional triamcinolone acetonide (2.5–5 mg/cc), or topical application of minoxidil or tacrolimus can be considered, although no effective treatment has been reported yet. The treatment of Graham–Little syndrome is typically similar to the management of classic LPP.

CLASSIC PSEUDOPELADE OF BROCQ.

PPB is classified as an idiopathic lymphocytic primary cicatricial alopecia that predominantly affects the scalp. It is the second most common cause of primary cicatricial alopecia.[196] Women between 30 and 50 years of age are most frequently affected.

Clinical Presentation. Pseudopelade of Brocq usually affects the vertex and occipital area of the scalp. It presents with small flesh-toned alopecic patches with irregular margins. This pattern has been described as "footprints in the snow."[223] PPB can also present as a non-inflammatory centrifugally spreading patch of alopecia, which might be seen as a variant of central centrifugal cicatricial alopecia in Caucasians. Follicular hyperkeratosis and perifollicular or diffuse erythema is mostly absent.[206] Clinically the features may overlap with LPP.

Pathology. Early PPB lesions typically show a sparse to moderate lymphocytic infiltrate around the follicular infundibulum with a complete destruction of the sebaceous glands.[176] In later disease stages, hair follicles are completely replaced by fibrous tracts. Unlike DLE and LPP, interface dermatitis is usually absent and the elastic fibers are preserved and thickened in PPB.[224]

Management and Treatment. Intralesional triamcinolone acetonide at a concentration of 10 mg/cc every 4–6 weeks in combination with topical corticosteroids is the treatment of first choice. Hydroxychloroquine, oral prednisone, and isotretinoin have shown some effectiveness in treating PPB.[196,206,225,226]

CENTRAL CENTRIFUGAL CICATRICIAL ALOPECIA.

CCCA is classified as a lymphocytic primary cicatricial alopecia, primarily affecting women of color. It remains unclear which of the following contribute most to its formation: chemical processing, heat, traction or other traumas.[1,18] CCCA can rarely be seen in Caucasians (sometimes called "central elliptical pseudopelade") and African-American men. Due to clinical and histopathological similarities, it has been debated whether CCCA is a variant of PPB.

Clinical Presentation. CCCA presents with a skin colored patch of scarring alopecia on the crown, gradually progressing centrifugally to the parietal areas. Perifollicular hyperpigmentation and polytrichia might be present.[198] Patients may complain about itching, tenderness and "pins and needle" sensations[227] (Fig. 88-19).

Figure 88-19 Central centrifugal cicatricial alopecia.

Pathology. Limited studies suggest that histopathological features of CCCA seem to be similar to those of PPB.[18,194]

Management and Treatment. Topical corticosteroids and tetracycline have shown to be effective in active progressive cases.[18] Since a multifactorial etiology is debated for CCCA, some dermatologists recommend a switch to more natural, less traumatizing, hair care practices.[1,206,228] Wigs and hairpieces can help camouflage the alopecia and are frequently used by women with CCCA.

ALOPECIA MUCINOSA.

Alopecia mucinosa (AM) can present as indurated, well-demarcated erythematosus or skin colored patches of scarring or nonscarring alopecia that can be accompanied by diffuse hair loss[229] and alopecia of the eyebrows.[230] Grouped follicular papules, follicular cysts and follicular hyperkeratosis may be present in some cases. Early lesions of AM show mucin deposition in the outer root sheath and replacement of the entire pilo-sebaceous unit by pools of mucin in more advanced lesions.[195,230] AM strictly speaking it is not a primary cicatricial alopecia because the hair follicle is not replaced by a true scar.[195] AM can occur idiopathically or in the setting of cutaneous T-cell lymphoma or mycosis fungoides.[231] Cell atypia and monoclonal populations of T-lymphocytes can be present in the idiopathic form of AM as well as in the latter form.[231]

Management and Treatment. A complete workup is necessary to rule out an underlying malignancy such as mycosis fungoides and Sézary syndrome, its advanced endpoint. Oral corticosteroids, minocycline and isotretinoin have been shown to be

effective. Topical and intralesional corticosteroids, dapsone, indomethacin and light therapy have also been used with variable outcomes.[232]

NEUTROPHILIC PRIMARY CICATRICIAL ALOPECIA

FOLLICULITIS DECALVANS. Approximately, 11% of all primary cicatricial alopecia cases are diagnosed with folliculitis decalvans (FD).[194,196] FD predominantly occurs in young and middle-aged adults with a slight preference of the male gender. A bacterial infection involving *S. aureus*, in combination with hypersensitivity reaction to "superantigens" and defect in host cell-mediated immunity have all been suspected as possible pathogenetic factors.[194,234,235]

Clinical Presentation. FD frequently starts at the vertex area of the scalp with erythematous alopecic patches, follicular pustules and follicular hyperkeratosis. Tufted folliculitis is typically found in FD, but can also occur in other cicatricial inflammatory alopecias. Tufted folliculitis is characterized by multiple hairs (5–15) emerging from one single, dilated follicular orifice. In older lesions pustules might be absent but progressive scarring may still continue (Fig. 88-20). An overlap with acne keloidalis is possible since some patients with acne keloidalis not only develop cicatricial lesion on the nape of the neck but also develop progressive cicatricial alopecia that resembles FD in other areas of the scalp. Patients frequently complain about pain, itching and/or burning sensations.

Pathology. Early lesions are characterized by keratin aggregation in the infundibulum with numerous intraluminal neutrophils, as well as an intrafollicular and perifollicular neutrophilic infiltrate.[194,195,206] Sebaceous glands are destroyed early. In advanced lesions, the infiltrate may consist of neutrophils, lymphocytes, and plasma cells and extend into the dermis.[198,206] Hair shaft granulomas with foreign-body giant cells can frequently be found.[194,206] In end-stage lesions, follicular and interstitial dermal fibrosis as well as hypertrophic scarring can be observed.[206]

Management and Treatment. Treatment of FD in general is difficult and disease activity can be noted over many years. Bacterial cultures with the testing of antibiotic sensitivities are recommended. Eradication of *Staphylococcus aureus* with minocycline, erythromycin, cephalosporines, and sulfamethoxazole-trimethoprim has shown some effectiveness. Relapse can often be observed after the antibiotics are discontinued.[20,234,236] If so, the patient might have to stay on low dose antibiotics for many years. Rifampin in combination with clindamycin has shown good response; however, this combination shows a higher incidence of side effects.[234,237] Oral fucidic acid alone or in combination with other agents has also shown to be effective in some patients.[238] Oral therapy should be combined with topical antibiotics such as mupirocin, 1.5% fusidic acid and 2% erythromycin[237,238] and antibacterial cleansers. Intralesional triamcinolone acetonide at a concentration of 10 mg/cc every 4–6 weeks might help to reduce the inflammation and reduces symptoms such as itching, burning, and pain.[20,196] Intranasal eradication of *S. aureus* with topical antibacterial agents have been described to be useful.[206]

DISSECTING FOLLICULITIS. Dissecting folliculitis (DF) (or dissecting cellulites or perifolliculitis capitis abscedens et suffodiens of Hoffman) is related to acne conglobata and hidradenitis suppurativa. These three diseases have been described as follicular occlusion triad. DF predominantly occurs in young men between 18 and 40 years of age.[198] African-American men seem to be more commonly affected compared to Caucasian men. The pathogenesis of DF may include follicular occlusion, seborrhea, androgens and secondary bacterial overpopulation as well as an abnormal host response to bacterial antigens.[239–246]

Clinical Presentation. DF typically presents with fluctuating nodules, abscesses, and sinuses, which frequently show spontaneous discharge of pus, as well as with erythematous, follicular papules and pustules. Initial lesions are mostly found on the vertex and occipital scalp. Multifocal lesions can form an intercommunicating ridge and sero-purulent exudates can be discharged when pressure is applied to one region of the scalp (Fig. 88-21). The lesions can be pruritic and tender. Chronic and relapsing courses result in cicatricial alopecia, which can show hypertrophic or keloidal scars.[246]

Figure 88-20 Folliculitis decalvans.

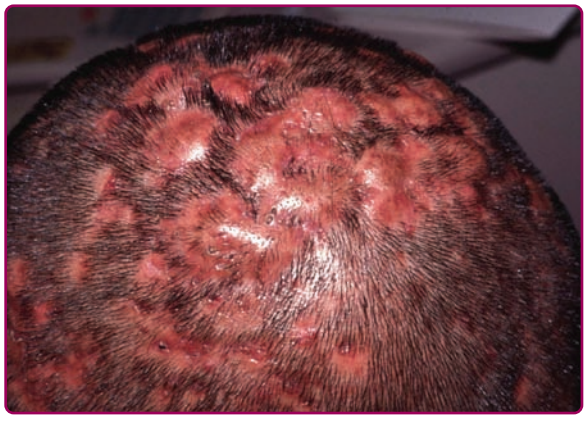

Figure 88-21 Dissecting cellulitis.

Pathology. The main histological feature is an intrafollicular and perifollicular neutrophilic infiltrate with follicular occlusion in early lesions.[195] In more advanced stages, interconnecting sinus tracts lined by squamous epithelium, follicular perforation, perifollicular and deep dermal abscesses are typical findings.[195,206,209]

Management and Treatment. Multimodal treatment has been reported with successful results, such as systemic antibiotics (minocycline, tetracycline, cloxacillin, erythromycin, cephalosporin or clindamycin), intralesional corticosteroids, and oral prednisolone.[247,248] The benefits of systemic antibiotics are most likely due to their antiinflammatory effects rather than to their antibacterial action. Isotretinoin at a dose of 0.5–1 mg/kg/d has shown prolonged remission.[249,250] Incision and drainage of therapy resisted, painful nodules, marsupialization with curettage of the cyst wall, complete scalp extirpation with skin grafting have been reported, but should be an exception for extreme and therapy refractory cases.[250–252]

MIXED PRIMARY CICATRICIAL ALOPECIAS

ACNE KELOIDALIS NUCHAE. Acne keloidalis nuchae (AKN) predominantly occurs in African-American men age 14 to 25. This idiopathic primary cicatricial alopecia might be triggered by trauma (shirt collars) or infection (Demodex or bacteria). Clinically AKN presents with skin-colored follicular papules, pustules and plaques as well as keloid-like scarred lesions in the occipital scalp (Fig. 88-22). Histologically, acne keloidalis is characterized by an acute inflammation with neutrophilic or lymphocytic infiltration and chronic granulomatous inflammation around the isthmus and the lower infundibulum. Treatment is usually difficult and protracted. Monthly intralesional triamcinolone acetonide (10–40 mg/mL) alone or combined with topical 2% clindamycin or oral (tetracyclines) antibiotics is the treatment of first choice.[1,18,194,253,254] Class I or II topical steroids alone or in combination with topical antibiotics for mild cases of AKN as well as cryotherapy and laser therapy have shown some success. Surgical excision of extensive keloidal lesions may be considered but should be reserved for therapy refractory, extensive and symptomatic cases.

Figure 88-22 Acne keloidalis nuchae.

ACNE NECROTICA (VARIOLIFORMIS). Acne necrotica varioliformis is a very rare, chronic condition, which predominantly occurs in adults. Frontal and parietal scalp as well as seborrheic areas of the face are most commonly affected. Acne necrotica presents with umbilicated, pruritic or painful papules that undergo central necrosis. The condition leaves varioliform, or smallpox-like scars.[255,256] Histology shows a suppurative, necrotic, infundibular folliculitis with lymphocytic or mixed inflammatory infiltrate.[256] Oral antibiotics, isotretinoin, intralesional or topical corticosteroids have shown success.[257] Excision of larger scarred areas can be considered.

EROSIVE PUSTULAR DERMATOSIS. Erosive pustular dermatosis is an uncommon disorder predominantly occurring in elderly women.[258,259] The characteristic lesion is a suppurative, necrotic, erosive papule or plaque.[258,260] Histology of early lesions is nonspecific, but older lesions show an extensive, chronic mixed inflammatory infiltrate the dermis and later dermal fibrosis. Treatment include class I or II topical steroids with or without topical antibiotics, systemic antibiotics, and oral isotretinoin.[258,260]

DIFFERENTIAL DIAGNOSIS

(Box 88-6)

PROGNOSIS AND CLINICAL COURSE

Once the hair follicle is destroyed and replaced by fibrous tissue, there is no hope for hair regrowth. Various medical treatment options may fail and the inflammatory process may continue and leave the patient with a disfiguring permanent alopecia.

TREATMENT

The main goal in treating primary cicatricial alopecia is to stop the inflammation and therefore further progression of the disease. If hair loss is already extensive and/or medical treatment fails, patients should be advised about camouflage techniques, hairpieces and wigs. Women with extensive LPP lesion on the crown and vertex benefit highly from a well designed hair piece, which can look very natural, particularly if the

BOX 88-6 DIFFERENTIAL DIAGNOSIS

- Alopecia areata
- Secondary cicatricial alopecia
- Temporal triangular alopecia
- Trichotillomania
- Secondary Syphilis (alopecia areolaris)

frontal hairline is preserved and is usually more comfortable to wear compared to a full wig. Hair restoration surgery including HT and scalp reduction can be an option for burnt out cicatricial alopecia. No disease activity should occurs on the scalp for at least 1 year without therapy. The patient has to be warned about a possible limited graft survival and disease recurrence, which seems to be higher in neutrophilic primary.

SECONDARY CICATRICIAL ALOPECIA

ETIOLOGY AND PATHOGENESIS. In secondary cicatricial alopecias, permanent hair loss is caused by various other scalp conditions not related to the hair follicle. In these conditions, the primary event develops outside the FU and this leads to incidental destruction of the follicle. Possible causes are congenital defects, trauma, inflammatory conditions, infections, neoplasms, and rarely drugs (eBox 88-6.1 in online edition). Permanent, chronic traction alopecia and scars from surgery can be considered secondary scarring alopecias as well.[261]

CLINICAL FINDINGS. A thorough clinical history is crucial in the diagnosis of secondary cicatricial alopecia. Diagnosis in early stages can sometimes be made based on specific clinical and histological features of the underlying disorder. Follicular orifices are lost clinically, and histology shows extensive scarring with fibrosis, loss of elastic fibers and adnexal structures.[261]

DIFFERENTIAL DIAGNOSIS. (Box 88-7)

PROGNOSIS AND CLINICAL COURSE. Prognosis and clinical course of secondary cicatricial alopecia depend on the underlying disease. Once scar tissue has formed and the adnexal structures are destroyed no hair regrowth can be expected.

TREATMENT. Treatment is specific in active conditions, while in localized end-stage lesions, specific medical treatment is no longer efficient and hair restoration surgery techniques become the mainstay of therapy.

TRAUMATIC HAIR LOSS

An acute or chronic mechanical insult to the scalp hair may lead to reversible or irreversible alopecia of the scalp. Traumatic alopecias are usually of three types: (1) acute trauma, (2) prolonged traction, and (3) pressure.

BOX 88-7 DIFFERENTIAL DIAGNOSIS BOX

- Primary cicatricial alopecia
- Alopecia areata
- Temporal triangular alopecia
- Trichotillomania
- Secondary Syphilis (alopecia areolaris)

TRAUMATIC INJURIES

Minimal or severe injuries to the scalp can result in alopecia. It usually presents with fine streaks of hair loss in the injured scalp area, but if the wound borders undergo contusion or destruction, this may result in irregular and large patches of hair loss. Traumatic hair loss can occur after scalp surgery, especially after extensive scalp reduction or large donor strip harvesting in hair restoration surgery, if too much tension is applied with wound closure. This type of hair loss is usually reversible but can also be permanent. Traumatic birth induced alopecia is infrequent; causes include mechanical extractor marks, tears or contusions or resulting infections. Aplasia cutis congenita should be considered in the differential diagnosis of cicatricial alopecia at birth.[1]

TRACTION ALOPECIA

Prolonged traction of the hair may lead to transient or if continued over a period of time, may lead to follicular atrophy, resulting in cicatricial alopecia. Chronic traction can be caused by tight ponytails, braids, heavy dead locks, or extensive use of rollers. Due to ethnic differences in hair fragility and cultural differences in hair styling practices, marginal traction alopecia is more commonly seen in African-American women due to hair braiding and weaving procedures[1] (Fig. 88-23). Patchy traction alopecia in the frontal hairline or temples is commonly seen in Sikh boys, whose hair is usually tight up in a "topknot."[270] Cicatricial alopecia caused by prolonged traction can be treated with HT, if the patient discontinues the injuring hairstyles and sufficient donor hair supply is available.

Figure 88-23 Traction alopecia. (From Wolff K, Goldsmith LA, Katz SI, Gichrest BA, Paller AS: Fitzpatrick's Dermatology in General Medicine. 7th ed. Copyright © The McGraw-Hill Companies, Inc. All rights reserved, with permission.)

TRICHOTILLOMANIA

Trichotillomania (Greek: *tricho* = hair, *tillo* = pull, *mania* = excessive excitement) is a form of traumatic alopecia caused by an irresistible compulsion to pull out or twist or break of one's own hair. Trichotillomania is relatively common with an estimated incidence of 1 million Americans.[1] Two forms of trichotillomania can be distinguished: (1) infantile trichotillomania or (2) early onset trichotillomania, which starts in early childhood is typically of short duration and may resolve spontaneously or with simple interventions.[271,272] Childhood trichotillomania may be seen analogous to other habitual infantile behaviors such as thumb sucking. Boys are more frequently affected. Trichotillomania, which starts around or after puberty, shows a more chronic course and is usually a sign of a more severe underlying psychopathology. It is classified as an impulse control disorder.[273–275] Women are far more often affected than men. The clinical presentation is usually quite distinctive with a single or multiple asymmetrical, occasionally geometrically shaped areas of hair loss on the scalp or other areas of the body (Fig. 88-24). The areas are not smoothly devoid of hairs, as seen in alopecia areata but display short or bristly anagen hair. Telogen hair in the involved area is usually plugged out easily; anagen hair may be plucked out, twisted and broken at various lengths. Regrowing anagen hair needs to reach a certain length before it can be plugged out again. Alopecia areata and tinea capitis should be considered as differential diagnosis. Where doubt remains, a scalp biopsy can be diagnostic, showing a characteristic increase in catagen hair, trichomalacia and pigment casts within the follicular canal secondary to traumatic hair removal. Most important in the therapy of trichotillomania is the education of patient and/or parents and in late onset trichotillomania the treatment of the underlying psychopathology. Especially if patients deny the self-inflicting nature of their hair loss, a referral to a psychiatrist or psychologist is usually refused and treatment becomes difficult.

Figure 88-24 Trichotillomania.

PRESSURE ALOPECIA

Pressure alopecia can occur after a patient was unconscious and completely immobile for a certain length of time. Hair loss is presumably due to ischemia caused by the pressure of the body weight to a certain scalp area. The ischemic injury may lead to permanent hair loss.

HAIR SHAFT ABNORMALITIES

Hair shaft abnormalities are structural defects of the hair shaft. They can be inherited or acquired. Inherited hair shaft abnormalities can be associated with increased hair breakage or can lead to unruliness of the scalp hair.

HAIR SHAFT ABNORMALITIES WITH INCREASED HAIR BREAKAGE

TRICHORRHEXIS NODOSA. Trichorrhexis nodosa can be inherited or acquired. Affected hair shafts develop a breach in the cuticle with separation and fraying of the exposed cortical fibers, which leads to a node-like swelling.[142] The fibers then fracture and the shaft breaks with the resultant appearance of a splayed paint brush or fan-like array (Fig. 88-25). Congenital trichorrhexis nodosa can be present at birth or may develop in the first months of life. In rare cases, Trichorrhexis nodosa can be associated with teeth and nail defects or hyperkeratosis[1] and with metabolic disorders such as argininosuccinic aciduria (see Chapter 131), Menkes syndrome, and trichothiodystrophy.

Acquired trichorrhexis nodosa is much more common. Hair breakage may either occur in the proximal or distal hair shaft. Proximal trichorrhexis nodosa is more commonly seen in African-American women usually after repetitive chemical or hot-comb straightening. Distal trichorrhexis nodosa is mostly secondary

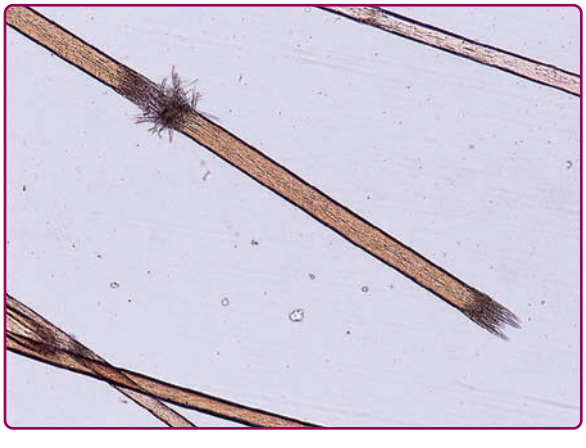

Figure 88-25 Trichorrhexis nodosa. (From Wolff K, Goldsmith LA, Katz SI, Gichrest BA, Paller AS: Fitzpatrick's Dermatology in General Medicine. 7th ed. Copyright © The McGraw-Hill Companies, Inc. All rights reserved, with permission.)

to excessive brushing, teasing or chemical treatment such as bleaching or permanent waves. Patients with trichorrhexis nodosa should be advised to avoid any harsh chemical or physical hair styling practice. Proximal trichorrhexis nodosa may take month to year to resolve even if the initiating hair care is avoided.

TRICHOSCHISIS AND TRICHOTHIODYSTROPHY. Trichoschisis is characterized by a clean transverse fracture of the hair shaft in an area of a focal absence of the cuticle. It is usually, but not specifically, a marker for sulfur-deficient hair in trichothiodystrophy, in which the scalp hair, eyelashes and eyebrows are short and brittle (see Chapter 139). The hair cysteine content is less than one-half normal, primarily from a major reduction and altered composition of the ultrahigh-sulfur matrix proteins.[276] Microscopic examination with polarized light characteristically shows a "tiger tail" pattern with altering light and dark bands, secondary to alterations in the sulfur content[1] (eFig. 88-25.1 in online edition). Various structural abnormalities can be detected by confocal and scanning electron microscopy. These complex alterations make hair shafts in trichothiodystrophy excessively prone to breakage and weathering.[1] Sulfur and amino acid analysis of the hair is diagnostic. Hair shaft abnormalities in trichothiodystrophy identify a group of autosomal recessive disorders that are associated with neuroectodermal abnormalities (eTable 88-1.2 in online edition).

TRICHOCLASIS. Trichoclasis is the common "greenstick" fracture of the hair shaft. It is characterized by a transverse fracture of the shaft, which is splinted partly or completely by intact cuticle. Cuticle, cortex and sulfur content are normal. Trichoclasis does not indicate any specific underlying disease. It can occur in normal hair or may be associated with pili torti.[1]

PILI TORTI AND MENKES SYNDROME

In pili torti, the affected hair shafts are flattened and twisted on their axis, usually through an angle of 180°, with a range of 90°–360° (Fig. 88-26). The twisting occurs in multiple irregular intervals along an otherwise straight hair shaft. Pili torti do not signify a particular abnormality but can be seen in many different syndromes and in the presence of other hair shaft disorders.[277] The way of inheritance in pili torti is mostly autosomal dominate, but can also be autosomal recessive or sporadic. Clinically, the patients may present with patchy alopecia with coarse stubble or longer broken hairs. Hair fragility usually improves after puberty.

Pili torti occurs in combination with trichorrhexis nodosa, trichoclasis, and trichoptilosis in Menkes kinky hair syndrome, also called steely hair syndrome or trichopoliodystrophy. Menkes syndrome is an X-linked recessive multisystem disease, which begins in infancy. It is associated with depigmented hairs, hypopigmentation of the skin, metal retardation, neurologic impairment secondary to degeneration of cerebral, cerebellar, as well as bone and connective tissue degeneration. The clinical features result from a defective copper transport and an accumulation of intracellular copper, which results in a functional deficiency of copper-dependent enzymes. Most patients die by the age of 3 years. In Menkes' syndrome, copper uptake is normal, therefore copper supplementation is ineffective, but copper-histidin given immediately postpartum may prevent or ameliorate the severe neurodegeneration. Low serum concentrations and ceruloplasmin levels are diagnostic.[1]

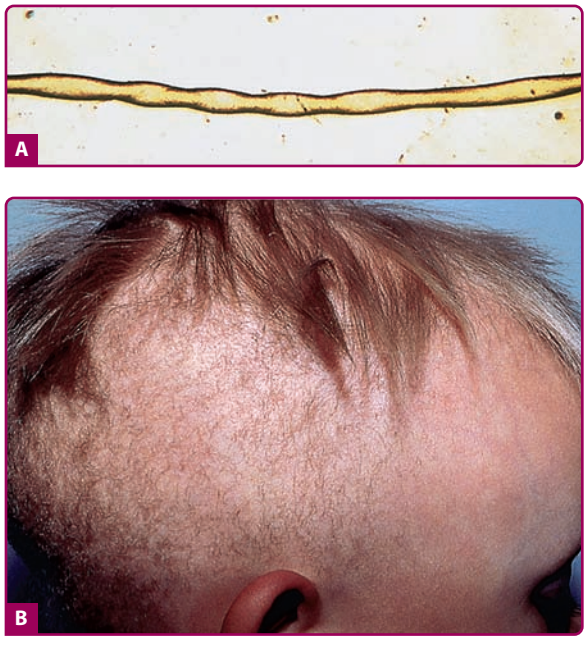

Figure 88-26 Pili torti. **A.** Irregularly spaced 180° twists in hair shaft. (From Whiting DA: Hair shaft defects. In *Disorders of Hair Growth: Diagnosis and Treatment,* edited by EA Olsen. New York, McGraw-Hill, 2003, with permission.) **B.** Brittle broken hair typical of congenital pili torti.

TRICHORRHEXIS INVAGINATA ("BABOO HAIR") AND NETHERTON SYNDROME

Trichorrhexis invaginata is a diagnostic marker for Netherton syndrome, although it also may occur sporadically and in association with other hair shaft abnormalities. Netherton syndrome is an autosomal recessive inherited disorder, characterized by a triad of atopic diathesis, ichthyosiform skin changes and trichorrhexis invaginata (see Chapter 49). The primary hair defect appears to be abnormal keratinization of the hair shaft in the keratogenous zone, allowing intussusception of the fully keratinized and hard distal shaft into the incompletely keratinized and soft proximal portion of the shaft.[278] This leads to the typical "ball-and-socket" deformity (Fig. 88-27). Once the hair fractures, it shows a typical golf tee-shaped the distal end. Affected short, brittle hairs can be distributes over the scalp, which may result in sampling errors. Retinoids and phototherapy may be considered as therapy,

Figure 88-27 Trichorrhexis invaginata (light micrograph ×400). (From Whiting DA: Hair shaft defects. In: *Disorders of Hair Growth: Diagnosis and Treatment,* edited by EA Olsen. New York, McGraw-Hill, 2003, with permission.)

although the condition frequently improves, as the patient gets older.

MONILETHRIX

Monilethrix present with extremely short, brittle, fragile, beaded hairs emerging from a hyperkeratotic follicular orifice. Monilethrix hair shafts show elliptical nodes, 0.7–1 mm apart, with intervening, tapered constrictions that are nonmedullated (Fig. 88-28). These internodes are the predetermined breaking points and often present with longitudinal ridges. Most cases of monilethrix are of autosomal dominant inheritance, with variable expression. In rare cases it is autosomal recessive. It is caused by one of the three genes encoding type II hair keratin (KHb1 or *KRT81*, KHb3 or *KRT83*, and KHb6 or *KRT86*). In the case of autosomal recessive inheritance, the underling gene encodes desmoglein 4 (DSG4). In mildest cases monilethrix is localized to the occiput or the nape of the neck. The hair shaft defect may occur alone or in association with keratosis pilaris, nail and teeth abnormalities, syndactyly, cataracts and physical retardation. Retinoids and topical minoxidil may improve the condition, although monilethrix frequently improves spontaneously with age.[1,279,280]

LOCALIZED AUTOSOMAL RECESSIVE HYPOTRICHOSIS. This rare autosomal recessive disorder present with localized sparse broken hair involving scalp and eyebrows. The gene defect lies in a

Figure 88-28 Monilethrix. Typical beaded appearance of hair as seen under light microscopy (×40). (From Wolff K, Goldsmith LA, Katz SI, Gichrest BA, Paller AS: Fitzpatrick's Dermatology in General Medicine. 7th ed. Copyright © The McGraw-Hill Companies, Inc. All rights reserved, with permission.)

Figure 88-29 Uncombable hair syndrome.

mutation in the gene for desmoglein 4 (DSG4). Unlike Monilethrix, the hair does not present with beading.[281]

HAIR SHAFT ABNORMALITIES ASSOCIATED WITH UNRULY HAIR

Uncombable Hair Syndrome. Uncombable hair syndrome, also known as spun glass hair or pili trianguli et canaliculi is an inherited autosomal dominant trait or a sporadic structural hair abnormality.[282] This unique syndrome is characterized by rigid hair shafts with a triangular or kidney bean-shaped cross section, but irregular forms, such as flattened, heart-shaped and longitudinal grooves may be present. Clinically, the hair is dry, coarse, usually blond to light brown, and with a spangled appearance. The scalp hair is frizzy, unruly, kinky and unmanageable from infancy, grows in multiple directions and cannot be combed flat (Fig. 88-29). Male and female individuals are equally affected. It first occurs more often during early childhood, but it can develop as late as age 12 years. Microscopic analysis of hair samples under polarized light shows a homogeneous band on one edge caused by the shadow thrown as light passes over the pili canaliculi.[283] There is no definitive therapy, but uncombable hair syndrome may improve over time without treatment.[284]

Wooly Hair. Wooly hair is a rare congenital structural anomaly of scalp hair. It is marked by an extreme kinkiness of the hair in Caucasians. Wooly hair can be present at birth or appear in the first months of life. The curls, which have an average diameter of only 0.5 cm, lie closely together and usually make the hair difficult to comb. In addition, the hairs may be more fragile than usual. Hair growth rate is usually normal but the anagen phase may be truncated, with the result that the hairs do not grow to be long. The hair shaft exhibits an elliptical cross section, an axial rotation and a kinked formation. A circumscribed occurrence of wooly hair in the form of a wooly hair nevus[285] is distinguished from the forms that affect the entire scalp. The latter forms are: autosomal dominant wooly hair (hereditary wooly hair) and, the much rarer form, autosomal recessive hereditary wooly hair (familial wooly hair).[286] Autosomal recessive hereditary wooly hair can be syndromic and accompanied by palmoplantar hyperkeratosis and heart anomalies (Fig. 88-30). No treatment is currently available. Harsh physical and chemical

Figure 88-30 Sporadic recessive wooly hair. (From Wolff K, Goldsmith LA, Katz SI, Gichrest BA, Paller AS: Fitzpatrick's Dermatology in General Medicine. 7th ed. Copyright © The McGraw-Hill Companies, Inc. All rights reserved, with permission.)

cosmetic treatments should be avoided. Wooly hair is most pronounced during childhood; the manifestation often becomes less severe in adulthood.

MARIE–UNNA HYPOTRICHOSIS.

Marie–Unna hypotrichosis is of autosomal dominant inheritance and is characterized by sparse or absent hair at birth and variable coarse, wiry hair growth during childhood, affecting scalp and eyebrows. Once the child grows older, scalp hair is lost in a pattern, resembling AGA with scattered thick hair in the balding areas. Body hair is sparse or absent. Male and female individuals are equally affected. Light and electron microscopic examination shows irregular twisting, longitudinal ridging and cuticle peeling. Diffuse follicular hyperkeratosis and facial milia-like lesions may be present. Marie–Unna hypotrichosis results from mutations in the upstream untranslated open reading frame region of the *hairless* gene,[287] which maps to chromosome 8p21.[288] There is no known treatment.

HAIR SHAFT ABNORMALITIES UNASSOCIATED WITH BREAKAGE OR UNRULINESS

Pili Annulati. Pili annulati or ringed hairs occur as an autosomal dominant or sporadic hair shaft abnormality without increased hair breakage. Pili annulati can be present at birth or develop during infancy. It is characterized by altering light and dark bands, which are secondary to air-filled cavities in the cortex.[289] The ringed appearance is clinically only detectable in blond or light brown hair. The gene locus for pili annulati maps to chromosome 12q24.[290,291] No treatment is necessary, although hair care practices should be gentle.

HIRSUTISM

Hirsutism is defined as excessive growth of terminal hair in a male distribution in women.[292] Hirsutism is indicated by a hirsutism score of 8 or more on the Ferriman–Gallwey scale (Fig. 88-31).[61] It must be distinguished from hypertrichosis, generalized excessive hair growth that may be hereditary or result from certain medications in men and women. Hypertrichosis is distributed in a generalized, nonsexual pattern and is not caused by excess androgen (although hyperandrogenism may aggravate it).

HIRSUTISM AT A GLANCE

- Defined as terminal body hair growth in women in a male distribution
- Women with a Ferriman–Gallwey score 8 or higher are considered hirsute
- Women with mild to moderate hirsutism and regular menstrual cycles are most likely diagnosed with idiopathic hirsutism; hormone testing is not necessary
- Hormone testing is necessary in women with moderate to severe hirsutism and all women with hirsutism and irregular menstrual cycles or sign of virilization
- Therapy should always consist of direct hair removal with or without medical therapy

EPIDEMIOLOGY

Approximately 5% of women of childbearing age are suffering from mild to severe hirsutism (Ferriman–Gallwey score 8 or higher).

ETIOLOGY AND PATHOGENESIS

Prior to puberty, body hair is vellus (small, straight, and fair), and the sebaceous glands are small. In response to the increased levels of androgens at puberty, vellus follicles in specific areas develop into terminal hair follicles (larger, curlier, and darker). The growth of terminal body hair (sexual hair) is entirely dependent on the presence of androgens, especially testosterone.[292] Higher androgen levels are required for the growth of beard hair than for pubic and axillary hair. In other areas of the body (for example, the forehead and cheeks), the increased androgen levels dramatically increase the size of the sebaceous glands while the hair remains vellus.

Hirsutism results from an interaction between the androgen level and the sensitivity of the hair follicle to androgens. Some women have hirsutism without evidence of androgen excess ("idiopathic hirsutism").

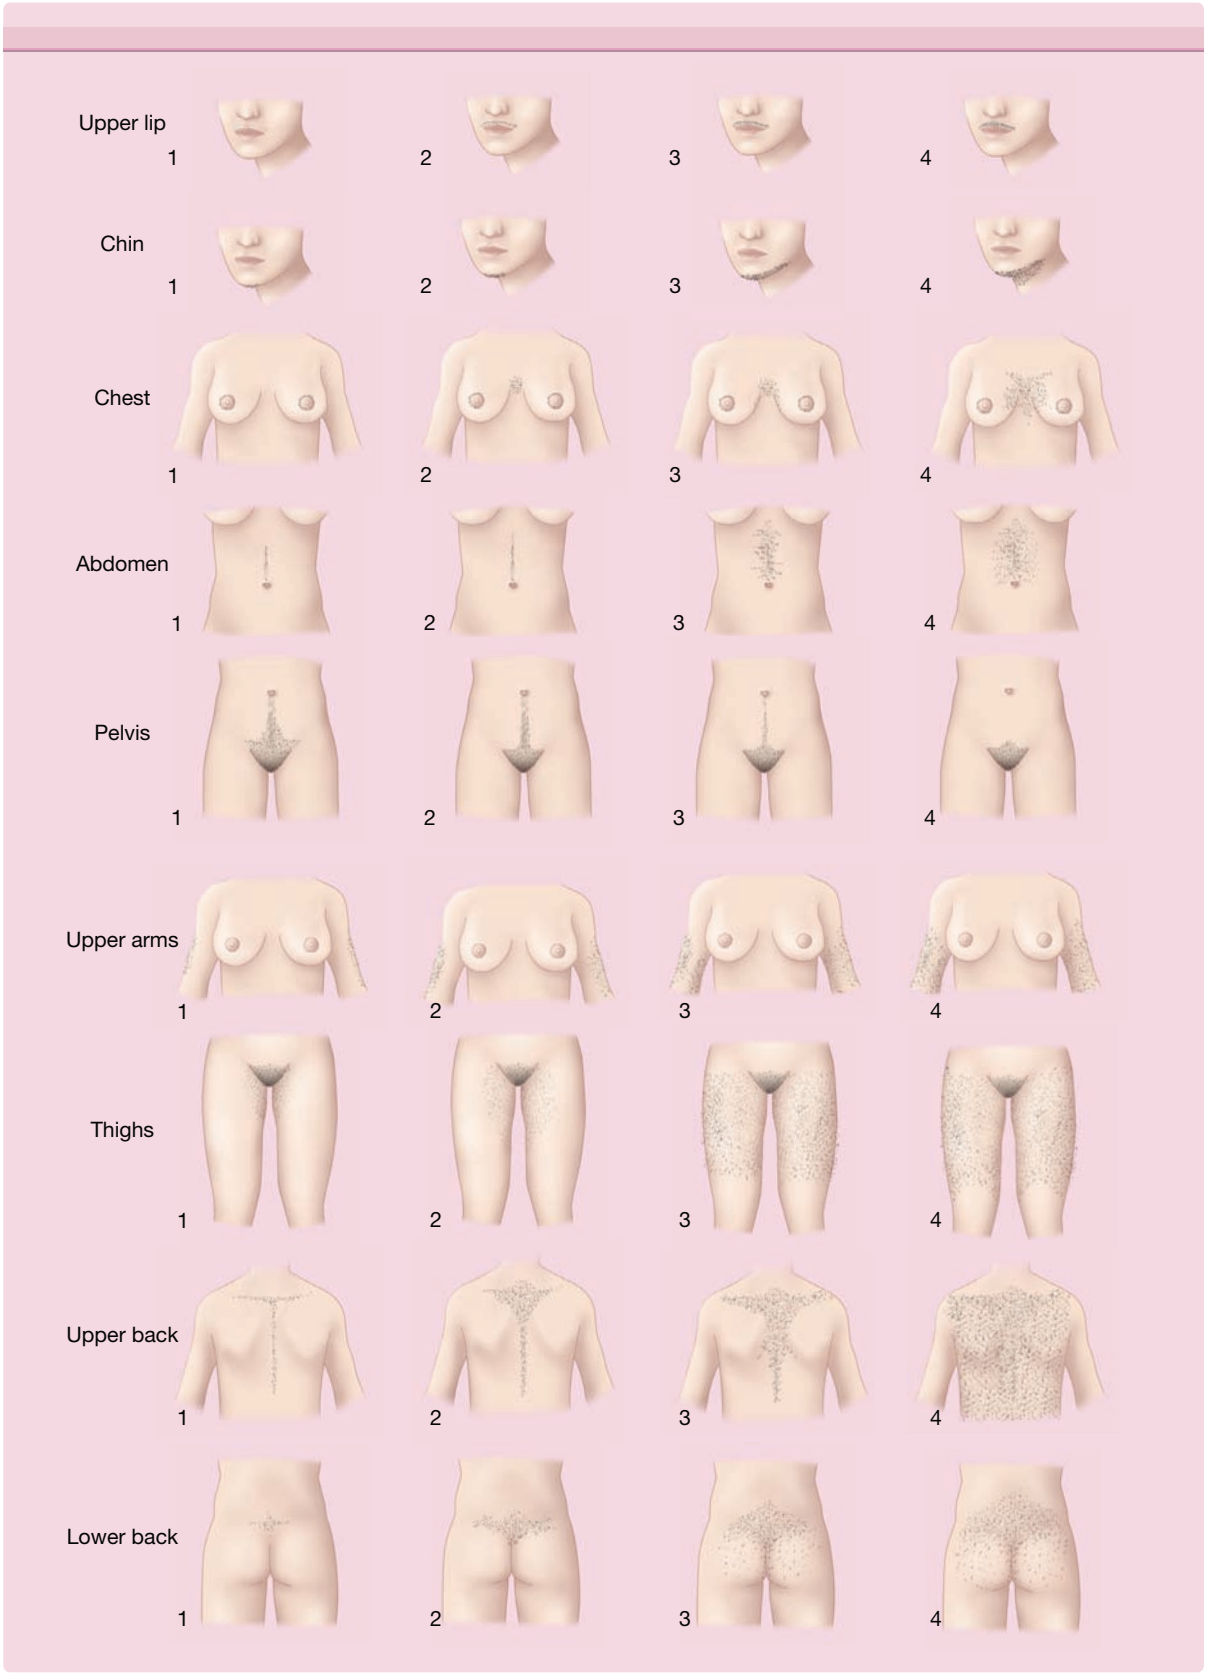

Figure 88-31 Ferriman–Gallwey scale.

Most women with a twofold or greater elevation of androgen levels have some degree of hirsutism, but in others these levels are associated with a "hirsutism equivalent" (acne vulgaris, seborrhea, pattern alopecia, hidradenitis suppurativa, or hyperhidrosis).[292]

Androgen excess relates to an increase in bioactive free testosterone plasma levels. Total testosterone includes the albumin bound and SHBG (sex hormone binding globulin) bound testosterone. Hirsute women commonly have a relatively low level of SHBG and therefore more bioactive testosterone.[62,293,294] Thus, the free testosterone level may be elevated when the total testosterone level is normal. SHBG levels are suppressed by the hyperinsulinemia of insulin-resistance and by androgen excess itself.[62,295] The level of SHBG is also low in persons with hypothyroidism; rarely, it is congenitally absent.[296]

CLINICAL FINDINGS AND DIAGNOSIS

Clinical diagnosis and scoring can be difficult since most women with hirsutism will practice various hair removal techniques. Therefore, it is useful to let the patient rate her degree of hair growth is different skin areas according to the Ferriman–Gallwey score (upper lip, chin and checks, chest, abdomen, pubic area and lower abdomen, arms, legs, upper back and lower back, and buttocks) with the help of images.

LABO RATORY TESTS

If hirsutism is mild (Ferriman–Gallwey score 8–15) and menses are regular with no evidence of risk factors that would suggest a secondary cause, it is reasonable not to pursue laboratory evaluation, given the very high likelihood of idiopathic hirsutism. If hirsutism is moderate or severe (Ferriman–Gallwey score over 15), or there are features to suggest an underlying disorder (Box 88-8), androgen excess must be ruled out. An onset or progression of hirsutism or evidence of virilization (such as clitoromegaly or increasing muscularity) would raise concern for an androgen-secreting neoplasm.[62,297] Since most androgenic drugs are not detected by testosterone assays, the history is particularly important. Medications that cause hirsutism include anabolic or androgenic steroids; thus, whether the patient is an athlete or has endometriosis or sexual dysfunction heightens this risk. Valproic acid is unique in raising plasma testosterone.[298] The high frequency of PCOS as a cause of hirsutism warrants attention to evidence for anovulation (such as menstrual irregularity), obesity, metabolic syndrome, or insulin resistance (acanthosis nigricans or a family history of type 2 diabetes mellitus). If risk factors like menstrual irregularity are present, even normal degrees of focal hirsutism are usually associated with androgen excess.[299] Other disorders to be considered include various endocrinopathies. Cushing syndrome is suggested by the development of truncal obesity, moon facies, buffalo hump, purple striae, or proximal muscle weakness; virilizing congenital adrenal hyperplasia or PCOS by a history of the premature development of pubic hair or acne; hyperprolactinemia by the presence of galactorrhea; and acromegaly by coarsening of the facial features or hand or foot enlargement.[292]

BOX 88-8 HIRSUTISM

- Androgen-secreting tumors
- Adrenal
- Adenoma
- Adenocarcinoma (rare)
- Ectopic adrenocorticotropic hormone-secreting tumor (rare)
- Ovarian
- Gonadal stromal tumor
- Thecoma
- Lipoid tumor
- Functional androgen excess
- Adrenal enzyme deficiencies (congenital adrenal hyperplasia)
- Early onset 21-hydroxylase deficiency
- Late-onset 21-hydropxylase deficiency
- 11β-hydroxylase deficiency
- 3β-ol dehydrogenase deficiency
- Cushing syndrome
- Polycystic ovarian disease
- With or without adrenal contribution
- Hyperthecosis
- "Idiopathic" hirsutism
- Medication/drug use

Hughes CL: Hirsutism. In: *Disorders of Hair Growth: Diagnosis and Treatment*, edited by EA Olsen. New York, McGraw-Hill, 1994, p. 344, Table 14-2.

SPECIAL TESTS

Once androgen excess is confirmed, further tests should be considered such as pregnancy test (if the patient has amenorrhea), pelvic ultrasonography (if an ovarian neoplasm or PCOS is suspected) and measurement of dehydroepiandrosterone sulfate and early morning 17-hydroxyprogesterone (if congenital adrenal hyperplasia or adrenal neoplasm is suspected), and a prolactin level. It may include measurement of thyroid function, adrenocortical function, and IGF-I. Further workup typically begins with dexamethasone suppression testing to determine the source of androgen. If androgen excess is not suppressible by dexamethasone, the presence of Cushing's syndrome, neoplasm, and PCOS must be considered. If androgen excess is dexamethasone-suppressible, an adrenocorticotropic hormone (ACTH) test for congenital adrenal hyperplasia is indicated. If an undetected neoplasm is suggested, further imaging studies may be warranted, such as abdominal computed tomography for adrenal neoplasm.[300]

PROGNOSIS AND CLINICAL COURSE

Hirsutism tends to get more severe as the patient gets older. Underlying disorders associated with hyperandrogenemia as mentioned earlier have to be ruled out.

TREATMENT

The main treatment goals are to remove the existing terminal hair and to prevent further vellus-to-terminal hair transformation. Direct hair removal should be considered for all women with hirsutism. In patients with moderate to severe hirsutism and women with androgen access additional medical therapy is necessary. Direct hair removal can be achieved with nonpermanent techniques such as shaving, depilatories (lasts 12 hours to a few days), waxing, threading and sugaring (lasts up to 4 weeks), or permanent hair removal techniques such as electrolysis (for white and blond hair) and photoepilation (intense pulsed light or laser). Several sessions of photoepilation at intervals of 4–6 weeks are necessary to achieve a satisfying result, since only anagen hair follicles with dark bulb areas can be destroyed by the light source. Topical eflornithine has been shown to slow down the hair cycle and can be used in combination with every hair removal technique.

The first line medical therapy is oral contraceptives, eventually in combination with antiandrogens. Glucocorticoids can be considered for women with hirsutism due to nonclassic congenital adrenal hyperplasia who have a suboptimal response to oral contraceptives and/or antiandrogens, cannot tolerate them, or are seeking ovulation induction. GnRH agonists in women with severe forms of hyperandrogenemia, such as ovarian hyperthecosis, who have a suboptimal response to oral contraceptives and antiandrogens.

HYPERTRICHOSIS

Hypertrichosis is defined as an androgen-independent generalized, increased growth of hair on the body. The hair can be terminal or lanugo. Hypertrichosis can be acquired or inherited. Congenital hypertrichosis lanuginosa is characterized by a generalized overgrowth of silvery blonde to gray lanugo hair at birth or in early childhood. This rare condtion is thought to be of autosomal dominant inheritance with variable expressivity. Most patients display anomalous dental eruptions. Lanugo hair may persist, increase or decrease with age.[301,302] Autosomal dominant Ambras syndrome or Hypertrichosis universalis congenita is characterized by much longer thicker hair distributed over the entire body with accentuation over the face ears and shoulders. Ambras syndrome can be associated with facial dysmorphism and dental anomalies.[303–305] An X-linked dominant congenital generalized Hypertrichosis has been described in a five-generation family with an accentuation on the face and upper body.[302,306] Patients with autosomal dominant or recessive gingival fibromatosis frequently display hypertrichosis, mostly on the face, eyebrows limbs and upper back, which may be associated with seizures and oligophrenia. Hypertrichosis may show a delayed onset until puberty although gingival fibromatosis usually appear with the emergence of the primary teeth[1] (eBox 88-8.1 in online edition).

ACKNOWLEDGMENT

Thanks to Dr. Elise Olsen, an active investigator of hair diseases, and author of this chapter in three previous editions for her contributions to hair research and to this text.

Chapter 89 :: Biology of Nails and Nail Disorders

:: Antonella Tosti & Bianca Maria Piraccini

BIOLOGY OF NAILS

The nail apparatus consists of a horny "dead" product, the nail plate, and four specialized epithelia: (1) the proximal nail fold, (2) the nail matrix, (3) the nail bed, and (4) the hyponychium (Fig. 89-1A). The nail apparatus develops during the 9th embryonic week from the epidermis of the dorsal tip of the digit as a rectangular area, the nail fold that is delineated by a continuous groove.[1] The proximal border of the nail fold extends downward and proximally into the dermis to form the nail matrix primordium. By the 15th week the nail matrix is completely developed and starts to produce the nail plate, which will continue to grow until death. The nail apparatus lies immediately above the periosteum of the distal phalanx. The intimate anatomic relationship between the nail and the bone is responsible for the common occurrence of bone alterations in nail disorders and vice versa. The shape of the distal phalangeal bone also determines the shape and the transverse curvature of the nail.

Fingernails usually present a longitudinal major axis and toenails a transverse major axis. The ratio between length and width is important for the aesthetic appearance of the nails. The size of the nails varies in the different digits. The biggest nail is that of the first toe, which covers approximately 50% of the dorsum of the digit.

Nails have numerous functions. Fingernails not only contribute to the pleasing appearance of the hands, but are very important in protecting the distal phalanges and enhancing tactile discrimination and the capacity to pick up small objects. They are also widely used for scratching and grooming and are an efficient natural weapon. Toenails protect the distal toes and contribute to pedal biomechanics.

NAIL PLATE

(See Fig. 89-1A)

The nail plate is a fully keratinized structure that is continuously produced throughout life (see Fig. 89-1B). It results from maturation and keratinization of the nail matrix epithelium and is firmly attached to the nail bed, which partially contributes to its formation. Proximally and laterally the nail plate is surrounded by the nail folds, which cover its proximal third and lateral margins. At the tip of the digit, the nail plate separates from the underlying tissues at the hyponychium. The nail plate is rectangular, translucent, and transparent. It is curved in both the longitudinal and transverse axes, especially in the toes. The nail plate surface is smooth but frequently shows mild longitudinal ridges that increase with aging (Fig. 89-2). The pattern of these ridges can be used for forensic identification. The bottom of the nail plate shows longitudinal ridges that correspond to the rete ridges of the nail bed. The nail plate is homogeneously pink, except for its free edge, which is white. The pink color of the nail plate is due to the nail bed blood vessels.

The proximal part of the fingernails, especially of the thumbs, shows a whitish, opaque, half-moon-shaped area, the lunula that is the visible portion of the nail matrix. In this area the nail plate attachment to the underlying epithelium is loose. More than 90% of fingernails show a thin distal transverse white band, the onychocorneal band, better defined as the isthmus, which marks the most distal portion of firm attachment of the nail plate to the nail bed.[2,3] This area represents an important anatomic barrier against environmental hazards, and its disruption produces nail plate detachment with onycholysis. The onychocorneal band is separated from the nail plate white free edge by a 1.0–1.5-mm pink band called the onychodermal band.

In transverse sections, the nail plate consists of three portions: (1) dorsal nail plate, (2) intermediate nail plate, and (3) ventral nail plate.[4] The dorsal and the intermediate portions of the nail plate are produced by the nail matrix, whereas its ventral portion is produced by the nail bed. Above the lunula the nail plate is thinner and consists only of the dorsal and intermediate portions. There is a natural line of cleavage between the dorsal and the intermediate nail plate.

The nail plate progressively thickens from its emergence to its distal margin. The mean toenail thickness at the distal margin is 1.65 ± 0.43 mm in men and 1.38 ± 0.20 mm in women. Fingernails are thinner; the mean thickness is 0.6 mm in men and 0.5 mm in women. There is an increase in nail thickness with age, particularly in the first two decades. Nail thickness depends on the length of the nail matrix and nail bed.[5] Thinning of the nails is usually a sign of nail matrix disorders, whereas nail thickening is most commonly a consequence of nail bed disorders.

PROXIMAL NAIL FOLD

(See Fig. 89-1A)

The proximal nail fold is a skin fold that consists of a dorsal and a ventral portion. The dorsal portion is anatomically similar to the skin of the dorsum of the digit but thinner and devoid of pilosebaceous units. The ventral portion, which cannot be seen from the exterior and proximally continues with the germinative matrix, covers approximately one-fourth of the nail plate. It closely adheres to the nail plate surface and keratinizes with a granular layer. The limit between the proximal nail fold and the nail matrix can be histologically established at the site of disappearance of the granular layer.

The horny layer of the proximal nail fold forms the cuticle, which is firmly attached to the superficial nail plate and prevents the separation of the plate from the nail fold. The integrity of the cuticle is essential for maintaining the homeostasis of this region.

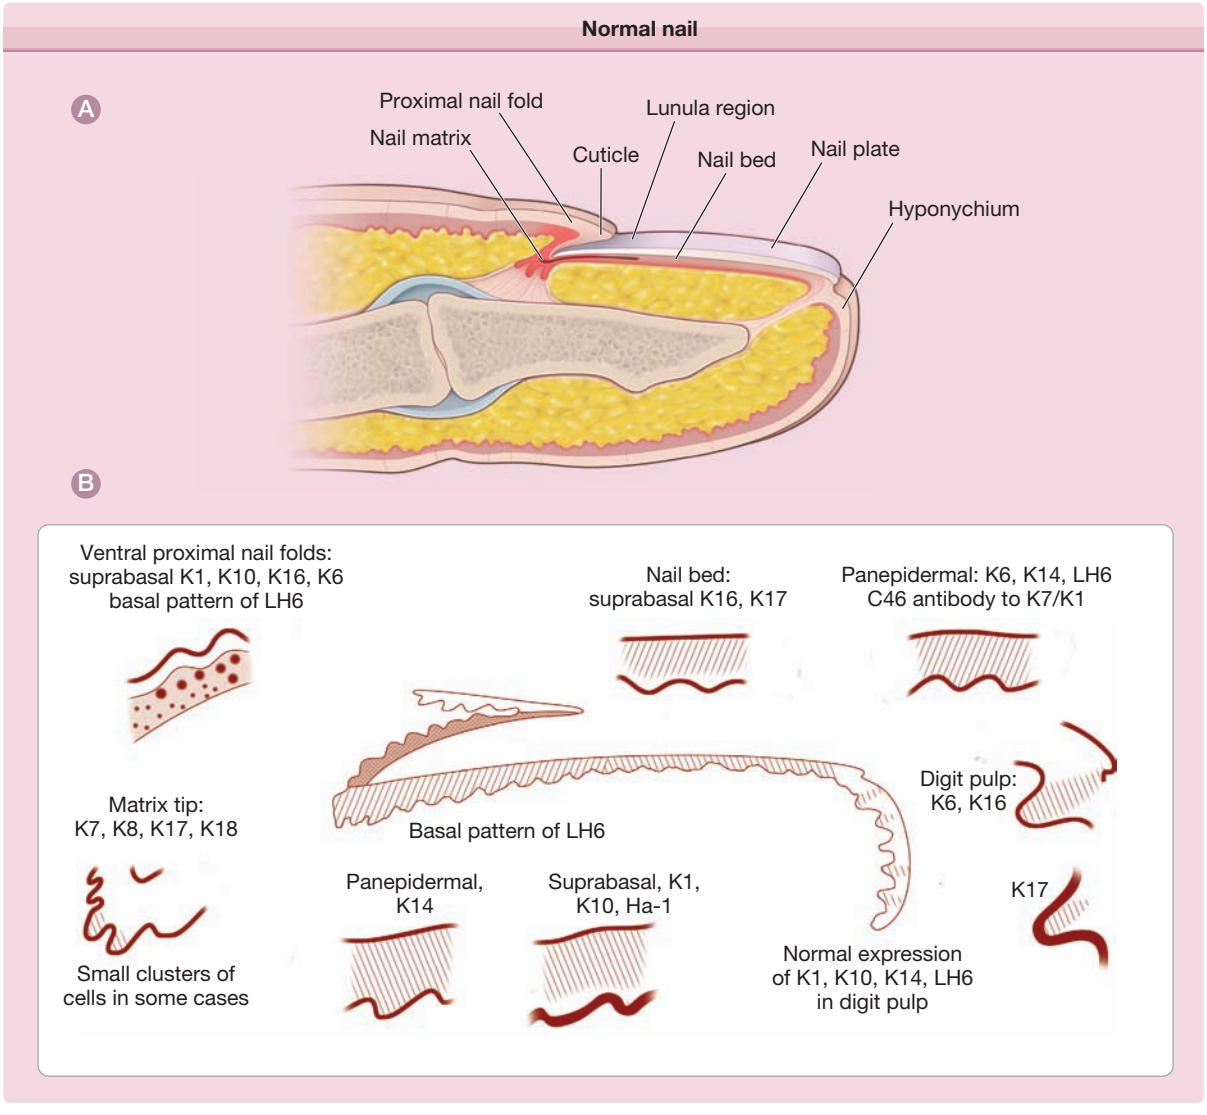

Figure 89-1 **A.** Diagrammatic drawing of a normal nail. **B.** Keratin gene expression at different locations within the nail. (From De Berker D et al: Keratin expression in the normal nail unit: Markers of regional differentiation. *Br J Dermatol* **142**:89, 2000, with permission.)

Figure 89-2 Longitudinal ridging of the nail plate surface. This is commonly observed in the elderly.

The dermis of the proximal nail fold contains numerous capillaries that run parallel to the surface of the skin and may easily be observed in vivo by capillary microscopy. This permits the observation of both the arterial and the venous limbs of the capillaries, which are arranged in parallel rows and appear as fine regular loops with a small space between the afferent and efferent limbs. The morphology of proximal nail fold capillaries is typically altered in connective tissue diseases.[6–8]

NAIL MATRIX

(See Fig. 89-1A)

The nail matrix is a specialized epithelial structure that lies above the mid portion of the distal phalanx.

After elevation of the proximal nail fold, the matrix appears as a distally convex crescent with its lateral horns extending proximally and laterally.

In longitudinal sections the matrix has a wedge-shaped appearance and consists of a proximal (dorsal) and a distal (ventral) portion. Nail matrix keratinocytes divide in the basal cell layer and keratinize in the absence of a granular zone. The site of keratinization (keratogenous zone) of nail matrix onychocytes can be clearly distinguished in histological sections as an eosinophilic area where cells show fragmentation of their nuclei and condensation of their cytoplasm.[1] In this area, nuclear fragments are destroyed by deoxyribonuclease and ribonuclease enzymes. In some conditions nuclear fragments may persist within the intermediate nail plate, producing leukonychia spots. However, these frequently disappear before reaching the nail-free edge, due to the persistence of active DNA and RNA lytic enzymes within the horny nail plate.

Maturation and differentiation of nail matrix keratinocytes do not follow a vertical axis, as in the epidermis, but occur along a diagonal axis that is distally oriented. For this reason, keratinization of the proximal nail matrix cells produces the dorsal nail plate and keratinization of the distal nail matrix cells produces the intermediate nail plate.

In some fingers the distal matrix is not completely covered by the proximal nail fold but is visible through the nail plate as a white half-moon-shaped area, the lunula. The white color of the lunula results from two main anatomic factors: (1) the keratogenous zone of the distal matrix contains nuclear fragments that cause light diffraction, (2) nail-matrix capillaries are less visible than nail bed capillaries because of the relative thickness of the nail-matrix epithelium.[9]

NAIL MATRIX KERATINOCYTES. (See Fig. 89-1B). The nail matrix cells are able to synthesize both "soft" or skin-type and "hard" or hair-type keratins.[10–12] Evaluation of keratin expression in the different constituents of the nail apparatus showed that the nail matrix is the sole site of expression of hard keratin proteins, particularly Ha1 keratin.[13] Data indicate that fibroblasts derived from the nail matrix may induce hard keratin expression in nonnail-matrix keratinocytes.[14]

MELANOCYTES. (See Chapter 72). Nail matrix melanocytes are usually quiescent and therefore not detectable in pathologic sections. However, they possess the key enzymes that are necessary for melanin production, and may become activated by a large number of physiologic and pathologic conditions.[15] Nail matrix melanocyte activation produces diffuse or banded nail pigmentation and is more common in blacks and Japanese than in Caucasians. DOPA-negative (inactive) melanocytes are sparsely present in the nail matrix and in the nail bed.[16] DOPA-positive, activable melanocytes are especially seen in the distal nail matrix, where they are frequently arranged in small clusters among the suprabasal layers of the nail matrix epithelium.[17]

LANGERHANS CELLS. (See Chapter 10). Langerhans cells are more numerous in the proximal than in the distal nail matrix. As in normal epidermis, Langerhans cells are predominantly found in the suprabasal layers. However, they may occasionally be seen within the basal layer of the nail matrix epithelium.

MERKEL CELLS. The presence of Merkel cells in the nail matrix has been demonstrated. Their density is possibly influenced by age, with these cells being more numerous in fetus than in adult nails.[18]

NAIL BED

(See Fig. 89-1A)

The nail bed extends from the distal margin of the lunula to the isthmus and is completely visible through the nail plate. The nail bed epithelium is so adherent to the nail plate that it remains attached to the undersurface of the nail when the latter is avulsed.

The nail bed epithelium is thin and consists of two to five cell layers. Its rete ridges, which are longitudinally oriented, interdigitate with the underlying dermal ridges in a "tongue-and-groove"-like fashion. The nail bed epithelium is a specialized epithelial structure with a horny layer that interlocks to of the inferior border of the nail plate and is responsible for the strong attachment between the two tissues. Nail bed horny layer forms the ventral nail plate, which corresponds to approximately one-fifth of the terminal nail thickness and mass.[19] In pathologic sections, the ventral nail plate is easily distinguishable because of its light eosinophilic appearance. Nail bed keratinization is not associated with the formation of a granular layer. This may appear, however, when the nail bed becomes exposed after nail avulsion.[1]

The nail isthmus is a thin transverse distal band that represents a transitional zone between the nail bed and the hyponychium and exhibits a unique pattern of keratinization, the onycholemmal keratinization, with pale, nucleated keratinocytes. The cornified layer of the nail isthmus closely adheres to the undulating inferior surface of the nail plate preventing onycholysis; the two grow forward together.[3] Keratin expression in the nail bed differs form that of the nail matrix since keratins K6, K16, and K6hf are only expressed in the nail bed.[20] The isthmus differs from nail bed because of a strong suprabasal expression of K10. Transition from isthmus to hyponychium is marked by the disappearance of expression of K6hf and K6/16, and return to expression of K5/17.

HYPONYCHIUM

The hyponychium marks the anatomic area between the nail bed and the distal groove, where the nail plate detaches from the dorsal digit (see Fig. 89-1A). Its anatomic structure is similar to that of plantar and volar skin, and keratinization occurs through the formation of a granular layer. The horny layer of the

hyponychium partially accumulates under the nail plate free margin. The hyponychium is normally covered by the distal nail plate, but it may become visible in nail biters. The architecture of the capillary network of the hyponychium dermis consists in regular capillary loops arranged perpendicularly to the skin, visible as red dots with dermoscopy.

BASEMENT MEMBRANE ZONE

The antigenic structure of the basement membrane zone of the nail is identical to that of the epidermis, and there are no differences in the antigenic composition of the basement membrane zone in the different portions of the nail apparatus.[21] This may explain the involvement of the nails in conditions characterized by mutations of basement membrane-associated genes as well as in autoimmune skin diseases involving the basement membrane zone antigens.[22]

DERMIS

(See Fig. 89-1A)

The nail apparatus is devoid of subcutaneous tissue, and its dermis does not contain pilosebaceous units. The arrangement of the rete ridges varies in the different portions of the nail apparatus. The dermis beneath the proximal nail matrix consists of condensed connective tissue that forms a tendon-like structure connecting the matrix to the periosteum of the proximal phalangeal bone (posterior ligament). A small amount of subdermal fat tissue is present close to the periosteum of the base of the phalanx.[23] The close connection between the lateral horns and the periosteum is possibly responsible for the nail plate's lateral convexity. The rete ridges of the dermis underneath the nail matrix are characteristically long and root-like in shape. The dermis under the distal matrix consists of a loose network of connective tissue containing numerous blood vessels and rare glomus bodies.

The dermis of the nail bed has a unique arrangement with longitudinal grooves and ridges that run from the lunula to the hyponychium.[1] The longitudinal orientation of the capillary vessels within the nail bed grooves explains the linear pattern of nail bed hemorrhages (splinter hemorrhages). The nail bed dermis contains abundant connective tissue networks with connective tissue bundles radiating to the phalangeal periosteum. It contains numerous glomus bodies.

BLOOD AND NERVE SUPPLY

The nail apparatus has an abundant blood supply provided by the lateral digital arteries. These run along the sides of the digits and produce both branches that supply the matrix and the proximal nail fold and arches that supply the matrix and the nail bed. The nail matrix, therefore, has two different sources of blood supply. The nail bed is richly supplied (10–20 cm^2) by encapsulated neurovascular structures containing one to four arteriovenous anastomoses and nerve endings. These glomus bodies are arteriovenous shunts involved in the regulation of the blood supply to the digits related to thermoregulation. The cutaneous sensory nerves, which originate from the dorsal branches of the paired digital nerves, run parallel to the digital vessels.

CHEMICAL PROPERTIES

(See Fig. 89-1B)

The nail plate, like hair, consists mainly of low-sulfur filamentous proteins (keratins) embedded in an amorphous matrix composed of high-sulfur proteins rich in cysteine. Other nail constituents include water, lipids, and trace elements. Nail keratins consist of 80%–90% hard hair-type keratins and 10%–20% soft skin-type keratins. Hard keratins have been identified as the acidic 44K/46K and basic 56K/60K keratins. Soft keratins have been identified as the 50K/58K and 48K/56K keratin pairs.[24] Keratin filaments have a transverse orientation that is parallel to the nail surface. This explains why the nail plate is more susceptible to transverse fractures than to longitudinal fractures. Specific keratins are expressed only in some compartments of the nail unit; for instance, K6a and K6b, K16, and K17 are not expressed in the nail matrix.[13,25,26] Mutations of the genes encoding for these keratins are associated with nail thickening due to nail bed hyperproliferation, as is seen in pachyonychia congenita (PC).[27,28] Nail keratin content and composition, measured as the quantity of carbon (C), nitrogen (N), and sulfur (S) in the fingernails, vary between sexes and in relation to the aging process. Sulfur content is higher in female than in male nails and the opposite is for nitrogen. Carbon content is equal in the two sexes. The carbon content increases with aging, possibly due to loss of inorganic material, and the nitrogen content decreases, while the sulfur content remains stable.[29]

Under normal conditions, the water content of the nail plate is 18%, and most of the water is in the intermediate nail plate.[30] The average water content of the nail plate is significantly lower in winter than in summer.[31)] and varies significantly in time, due to the high porosity of the nail plate, which allows it to be rapidly hydrated and dehydrated. Dehydration is faster when the nails are kept long. When the water content decreases below 18%, the nail becomes brittle; when it increases above 30%, it becomes opaque and soft.[32]

The nail contains less than 5% lipids, mainly cholesterol; the nail plate lipid content is under hormonal control and decreases after menopause.[33] The nail plate also contains traces of several inorganic elements, particularly iron, zinc, and calcium. However, these do not contribute to nail hardness.

PHYSICAL PROPERTIES

The nail plate is hard, strong, and flexible. The hardness and strength of the nail plate are due to its high content of hard keratins and cysteine-rich high-sulfur

proteins, whereas its flexibility depends on its water content and increases with nail plate hydration.[34,35]

The double curvature of the nail plate along its longitudinal and transverse axes enhances nail plate resistance to mechanical stress.[36]

The physical properties of the nail also depend on the arrangement and adhesion of onychocytes in the different portions of the nail plate, as well as on the orientation of the keratin filaments within the nail plate onychocytes.[36] At the ultrastructural level, the corneocytes of the dorsal nail plate are flat, with their shorter diameter perpendicular to the nail plate surface. The average sizes of these cells are 34 µm in length, 64 µm in width, and 2.2 µm in height.[37] Cell adhesion is strong. This portion of the nail is responsible for nail plate hardness and sharpness. The onychocytes of the intermediate nail plate show multiple interdigitations of their cell membranes. The average dimensions of these cells are 40 µm in length, 53 µm in width, and 5.5 µm in height. Cell adhesion is provided by desmosomes. This part of the nail plate is responsible for nail pliability and elasticity. The ventral nail plate is thin and consists of soft keratins. It provides adhesion to the underlying nail bed.

NAIL GROWTH

The nail plate grows continuously in a proximal to distal manner throughout life. The nail plate is "pushed" out by two factors: (1) matrix keratinocytes proliferation and differentiation which makes a new plate, (2) the nail bed which moves slowly, parallel to the direction of the nail growth, toward the inferior border of the nail plate.[3]

Fingernails grow two times faster than toenails, with a mean growth rate in adults of 3.5 mm/month for fingernails and 1.5 mm/month for toenails. The 5th fingernail growth rate is significantly slower than other fingernails and the growth rate of the great toenail significantly faster than other toenails.[38]

Complete replacement of a fingernail requires 100–180 days (6 months). When the nail plate is extracted, it is approximately 40 days before the new fingernail first emerges from the proximal nail fold. After a further 120 days it will reach the fingertip.[39] The total regeneration time for a toenail is 12–18 months. As a consequence of the slow nail growth rate, diseases of the nail matrix only become evident a considerable time after their onset and require a long time to disappear after treatment.

Nail growth rate varies among different individuals and among the different digits of the same individual. It depends on the turnover rate of the nail matrix cells and is influenced by several physiologic and pathologic conditions. Nail growth rate is slow at birth, increases slightly during childhood, and usually reaches its maximum between the second and the third decades of life. It sharply decreases after the age of 50 years.[39]

Conditions that have been associated with a slow growth rate include systemic illness, malnutrition, peripheral vascular or neurologic diseases, and treatment with antimitotic drugs. Nails affected by onychomycosis frequently exhibit a slow growth rate. An arrest of nail growth is a typical feature of yellow nail syndrome. Conditions that have been associated with accelerated nail growth include pregnancy, finger trauma, psoriasis, and treatment with oral retinoids or itraconazole. Accelerated nail growth may cause longitudinal ridging of the nail plate (nail beading).

Due to their slow growth rate, the nails may provide information on pathologic conditions that have occurred up to several months before the time of observation. Drugs, chemicals, and biologic substances accumulate in nails, where they can be detected and measured. Advantages of analyzing nail samples include the ease and noninvasiveness of their collection, the small sample size required for analysis, and the ease of storage at room temperature. The nail of the big toe is the best site for investigation because of its size (big toenail length of an adult: 20 mm) and slow growth rate (about 2 mm/month) permitting to obtain data on exposure to drugs and chemicals over a period of 10 months.[40]

NAIL SIGNS AS A FUNCTION OF THE SITE OF PATHOLOGY[1,32]

(See Table 89-1)

BEAU'S LINES AND ONYCHOMADESIS (NAIL SHEDDING)

Beau's lines result from a temporary arrest of proximal nail matrix proliferation and appear as transverse grooves, often deeper in the central nail plate, that move distally with nail growth. Onychomadesis also results from a temporary arrest in nail matrix activity,

TABLE 89-1
Relation Between Resultant Clinical Manifestations and Location of Pathologic Change

Proximal Matrix	Beau's Lines Pitting Longitudinal striations Longitudinal fissures Longitudinal grooves Trachyonychia
Distal matrix	True leukonychia
Proximal and distal matrix	Koilonychia Onychomadesis
Nail bed	Longitudinal erythronychia Onycholysis Splinter hemorrhages Apparent leukonychia
Nail bed and hyponychium	Subungual hyperkeratosis
Proximal nail fold	Paronychia Periungual erythema

BOX 89-1 CAUSES OF BEAU'S LINES AND ONYCHOMADESIS

- Trauma
  - Manicure
  - Onychotillomania
- Dermatologic diseases
  - Eczema
  - Erythroderma
  - Paronychia
- Systemic conditions
  - Use of certain drugs
  - High fever
  - Viral illness (hand-foot-and-mouth disease; measles)
  - Diarrhea
  - Kawasaki syndrome
  - Peripheral ischemia

and the proximal nail plate is detached from the proximal nail fold by a whole-thickness sulcus. Causes of onychomadesis are the same as those for Beau's lines but are more severe (Box 89-1). Multiple Beau's lines or onychomadesis in the same nail indicates repetitive insults. Measuring the distance of the groove from the proximal nail fold can date the time of the insult leading to Beau's lines. Local trauma, such as from manicures or onychotillomania, or related to local cutaneous disease, particularly dermatitis, periungual erythema, and paronychia, are causes of Beau's lines. Beau's lines or onychomadesis at the same levels in several nails suggest a systemic cause (Fig. 89-3). Most common among these are drugs (especially chemotherapy), high fever, viral illness,[41,42] surgery, and peripheral ischemia. Onychomadesis in children often relates to recent coxsackievirus infection (hand-foot-mouth disease).[41,43]

PITTING

Pits result from small areas of abnormal keratinization of the proximal nail matrix that produce foci of parakeratotic cells in the superficial nail plate. They appear as small punctate depressions of the superficial nail plate, which progress distally and often become more evident with nail growth. Deep and irregularly distributed pits are seen in psoriasis (Fig. 89-4) and atopic dermatitis; geometric and superficial pits are typical of alopecia areata (see Chapters 14, 18, and 88).

ONYCHORRHEXIS (LONGITUDINAL STRIATIONS AND FISSURING)

Onychorrhexis results from diffuse defective keratinization of the proximal nail matrix. The nail plate is usually thinned and presents multiple longitudinal ridges and fissures. Onychorrhexis is a sign of severe nail fragility and typical of lichen planus (see Chapter 26).

Figure 89-3 Beau's lines of several nails after systemic illness. Note involvement of all the nails at the same level.

LONGITUDINAL GROOVES

Longitudinal grooves are usually single and appear as a longitudinal depression of the nail plate (1–2 mm large) due to compression of the nail matrix by tumors of the proximal nail fold.

TRACHYONYCHIA

Trachyonychia results from multiple foci of defective keratinization of the proximal nail matrix. The nails are rough due to excessive longitudinal ridging.

TRUE LEUKONYCHIA

True leukonychia results from defective keratinization of the distal matrix with persistence of parakeratotic

Figure 89-4 Pitting: small punctate depressions of the superficial nail plate. In psoriasis, pits are irregularly distributed and often associated with onycholysis and splinter hemorrhages.

Figure 89-5 Punctate leukonychia due to microtraumas in a child.

cells in the ventral nail plate. The superficial nail plate is structurally normal, but the nail presents opaque white patches or striae, which often disappear before reaching the distal edge of the nail. Punctate leukonychia is due to microtrauma and is typically seen in the fingernails of children (Fig. 89-5). Striate leukonychia of fingernails is a consequence of aggressive manicure. Total or subtotal leukonychia is rare and usually hereditary.

KOILONYCHIA

In koilonychia the nail plate is thin and spoon shaped. Koilonychia is physiologic in the toenails of children. In adults it can be a sign of iron deficiency or occupational damage to the nail plate.

MELANONYCHIA[44]

Melanonychia describes a brown to black color of the nail due to the presence of melanin in the nail plate. It can be caused by activation or proliferation (benign or malignant) of nail matrix melanocytes. The pigmentation may involve the whole nail (total melanonychia) or may be banded, as in transverse melanonychia (rare) or in the most common longitudinal melanonychia (LM). LM may appear as a single band involving one digit, or as multiple bands affecting several digits, which are usually due to melanocyte activation, as is seen in dark-skinned individuals, pregnant women, inflammatory nail disorders, individuals with Laugier–Hunziker syndrome, and those taking certain medications (Box 89-2). LM has also been described in individuals with a variety of systemic disorders, particularly human immunodeficiency virus infection and Addison syndrome. In Laugier–Hunziker syndrome, melanonychia begins during adolescence, affects several digits, and is associated with the presence of lip and/or genital pigmented macules[45,46] (see Chapter 78). Melanonychia due to melanocyte activation may in some cases involve a single digit, as in patients with onychotillomania, with frictional melanonychia of the 4th or 5th toenails (Fig. 89-6), with inflammatory nail diseases, such as psoriasis or lichen planus, or with nail tumors, such as Bowen's disease. A single band of melanonychia deserves a careful evaluation, since it may be a sign of a nail matrix nevus or melanoma (see Chapters 122 and 124). LM of a single nail often deserves biopsy.

BOX 89-2 CAUSES OF LONGITUDINAL MELANONYCHIA

- Race
- Acquired immunodeficiency syndrome
- Inflammatory nail disorders
- Use of certain drugs
- Addison disease
- Pregnancy
- Laugier–Hunziker syndrome
- Trauma

LONGITUDINAL ERYTHRONYCHIA[47]

Longitudinal erythronychia reflects a nail bed disorder and appears as a pink–red longitudinal band of various width extending from the proximal nail to the distal edge. A single band of longitudinal erythronychia is most commonly caused by an onychopapilloma or by another benign or malignant subungual tumor (Fig. 89-7). Multiple bands of longitudinal erythronychia are seen in lichen planus. In Darier's disease bands of longitudinal erythronychia alternate with white longitudinal bands and V-shaped indentations of the nail-free margin (see Chapter 51).

ONYCHOLYSIS

Onycholysis is detachment of the nail plate from the nail bed and can be caused by traumatic, inflammatory, infectious, or neoplastic nail bed disorders. See Section "Onycholysis under Environmental Nail Disorders."

SPLINTER HEMORRHAGES

Splinter hemorrhages appear as red to black small thin longitudinal lines under the nail plate. They are more commonly located in the distal nail plate and represent

Figure 89-6 Frictional melanonychia of the 4th and 5th toenails.

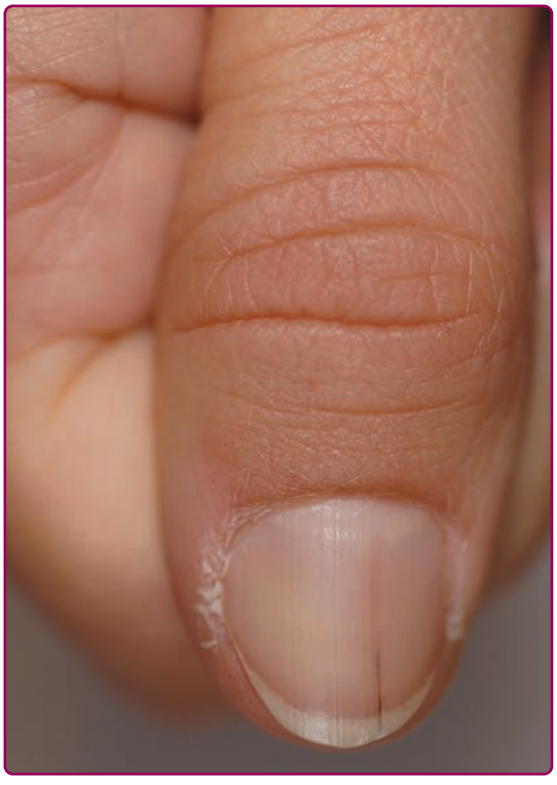

Figure 89-7 Longitudinal erythronychia. The nail plate shows a narrow longitudinal pale pink band that ends with a dark red steak corresponding to a splinter hemorrhage. This clinical feature is typical of onychopapilloma.

rupture of the longitudinally oriented nail bed capillaries (Fig. 89-8). Causes include trauma and inflammatory nail disorders, such as psoriasis.

APPARENT LEUKONYCHIA

In apparent leukonychia the nails are pale white due to nail bed discoloration that fades with pressure.

Figure 89-8 Multiple distal splinter hemorrhages in a manual worker with mild nail psoriasis.

SUBUNGUAL HYPERKERATOSIS

Subungual hyperkeratosis is due to inflammatory disorders that cause an abnormal keratinization of the distal nail bed and hyponychium with accumulation of scales under the distal nail plate. The most common causes include psoriasis, onychomycosis, trauma, contact and atopic dermatitis (see Chapters 13, 14, and 18).

PARONYCHIA

Paronychia is inflammation of the proximal nail fold and presents as painful periungual erythema, sometimes with associated purulence. Acute paronychia is usually caused by infection (see Section "Infectious Nail Disorders"). Chronic paronychia is most commonly due to mechanical or chemical factors. If the periungual area is fluctuant or shows purulence, it should be drained to avoid matrix damage. Topical and/or systemic antibiotics should be administered if bacterial infection is suspected.

NAIL PIGMENTATION

Nail pigmentation is most commonly due to exogenous staining of the nail plate. In this case the proximal margin of the pigmentation follows the shape of the proximal nail fold. Exogenous nail pigmentation is most commonly due to occupational exposures or nail cosmetics. Nail pigmentation due to endogenous causes is rare. The proximal margin of the pigmentation follows the shape of the lunula. Possible causes include drugs, argyria, hemochromatosis, alkaptonuria, and Wilson disease.

HEREDITARY AND CONGENITAL NAIL DISORDERS[48]

(See Table 89-2)

ECTODERMAL DYSPLASIAS

(See Chapter 142)

Nail changes may be associated with hypotrichosis, hypodontia, and hypohidrosis. Most commonly the nails are short, thickened, and hypoplastic.

EPIDERMOLYSIS BULLOSA

(See Chapter 62)

Nail abnormalities are a common feature in most subtypes of epidermolysis bullosa (EB) and have recently been included among the criteria for scoring EB severity.[49] Trauma undoubtedly contributes to the development of nail dystrophy and for this reason the great toenails are more often severely affected. Pachyonychia of the toenails be the first or the only symptom of dominant dystrophic EB (DDEB) in some families (eFig. 89-8.1 in online edition). Junctional and dermolytic EB may produce anonychia.[50]

TABLE 89-2
Hereditary and Congenital Nail Disorders

Ectodermal Dysplasias	Atrophy/Thickening
Epidermolysis bullosa	Partial or total anonychia Pachyonychia Subungual/periungual hemorrhagic blisters Periungual erosions with granulation tissue
Pachyonychia congenita	Onychogryphosis Severe thickening Yellow–brown discoloration
Iso-Kikuchi syndrome	Micronychia/anonychia Hemionychogryphosis
Nail patella syndrome	Hypoplasia/aplasia Triangular lunulae
Congenital malalignment of the hallux	Lateral deviation of the nail plate Lateral/distal embedding of nail Nail thickening Yellow–brown discoloration Transverse ridging

PACHYONYCHIA CONGENITA

(See Chapter 50)

PC is an autosomal dominant genodermatosis characterized by painful keratoderma, nail thickening, oral leukokeratosis, and epidermal cysts. The severity of PC can vary greatly among patients and the most problematic aspect of PC, the painful palmoplantar keratoderma (PPK), have vary in extent from focal to a severe, diffuse PPK.[51] The International Pachyonychia Congenita Research Registry (IPCRR) has compared the PC phenotype with genotype in hundreds of individuals, and have found issues with the classical division into PC1 (Jadassohn-Lewandowski type) and PC2 (Jackson-Lawler). A new molecular classification has been proposed, in which subtypes of PC refer to the mutated keratin gene.[52] Mutations in *KRT6A* account for almost 50% of known cases, while 24% have mutations are in *KRT16*, 23% in *KRT17*, and 3% in *KRT6B*.[53] In contrast to the old classification, in which PC1 was thought to result from mutations in *KRT6a* or 16, and PC2 from mutations in *KRT6b* or 17, the clinical features of the former subtypes overlap. For example, cysts (a feature of PC2 and not PC1) most commonly occur in individuals with either a *KRT17* mutation or *KRT6a* mutation.

Nail abnormalities are a constant feature and develop during infancy to early childhood, although a late-onset variety of PC has been described.[54] In typical cases the 20 nails are thickened, very difficult to trim, darkened, and with an increased transverse curvature. Nail thickening is a consequence of nail bed hyperkeratosis and is more evident on the distal half of the nails, which have an upward angling. Recent evidence indicates that PC may also present with very subtle nail changes and that there is not a good correlation between mutations detected at molecular level and clinical phenotype. Severity may even vary among family members with the same gene mutation.[55,56]

Figure 89-9 Nail patella syndrome: nail hypoplasia of the 1st and 2nd fingers.

NAIL PATELLA SYNDROME

Nail abnormalities in nail patella syndrome may involve all fingernails or may be limited to the thumbs, which are always the most severely affected digits (Fig. 89-9). Nail hypoplasia is usually more marked in the medial portion of the nail. The shape of the lunula is typically triangular.[48]

CONGENITAL MALALIGNMENT OF THE HALLUX

Congenital malalignment of the hallux is the most common cause of ingrowing (ingrown) nails and is usually diagnosed when the child starts to walk. The great toenail shows a lateral deviation that produces embedding of the lateral side of the nail plate (Fig. 89-10). The digit is painful and the toenail often shows Beau's lines and

Figure 89-10 Congenital malalignment of the big toenail associated with mild disto-lateral ingrowing on the medial side.

DSO = distal subungual onychomycosis; PSO = proximal subungual onychomycosis; WSO = white superficial onychomycosis; TO = total onychomycosis.

onycholysis. Congenital malalignment may be unilateral or bilateral. Spontaneous improvement may occur, and most children do not have symptoms by the age of 2 years.[57] Inflammation due to lateral ingrowing can be managed by daily massaging of the lateral nail fold with creams containing steroids, antibiotics, and urea. Surgical treatment may be necessary if nail symptoms are severe and do not subside with growth.[58,59]

INFECTIOUS NAIL DISORDERS

(See Table 89-3)

ACUTE PARONYCHIA

Acute paronychia is most commonly due to *Staphylococcus aureus* infection and typically affects a child's fingernail. Predisposing factors include nail biting or sucking and occupational traumas. The proximal nail fold is painful, erythematous, and swollen. Pus may be discharged after pressure (see Chapter 176). The differential diagnosis includes herpes simplex virus infection (see Chapter 193) and Hallopeau's acrodermatitis (see Chapter 21), both of which have a typical relapsing course. Suspicion of *Herpes simplex*-virus infection should arise when the pain intensity is disproportionate to the clinical symptoms and the disease is recurrent. The treatment of choice depends on the extent of the infection. If diagnosed early, acute paronychia without obvious abscess can be treated nonsurgically, often with topical antibiotics alone. If an abscess has developed, incision and drainage must be performed. Oral antibiotics with Gram-positive coverage against *S. aureus*, such as cephalexin, amoxicillin with clavulanic acid, and clindamycin, are effective.

GREEN NAILS

Bacteria are not capable of attacking a healthy nail plate. The Gram-negative bacterium *Pseudomonas aeruginosa* may colonize the dorsal or ventral nail plate under propitious conditions, such as chronic paronychia or onycholysis. The presence of *Pseudomonas* is revealed by characteristic green–black nail pigmentation due to pyocyanin staining. Topical application of a few drops of diluted bleach or chlorhexidine solution two or three times a day clears the pigmentation in a few weeks. Administration of systemic antibiotics is unnecessary.

ONYCHOMYCOSIS[60,61]

For a detailed description of the onychomycoses, see Chapter 188. Onychomycosis is a common toenail disease, and its prevalence increases with age.

Clinical features depend on type of nail invasion (Table 89-4). The possibility of mold onychomycosis should be suspected when proximal subungual onychomycosis (PSO) is associated with periungual inflammation, or when white superficial onychomycosis is severe and involves the entire nail plate (Fig. 89-11). Nondermatophytic onychomycoses are becoming more frequent worldwide and represent a clinical problem, because they usually respond poorly to systemic treatment.

TABLE 89-4
Clinical Presentations of Onychomycosis (See Chapter 188)

Distal subungual onychomycosis[a]	*Trichophyton rubrum*, *Trichophyton interdigitale*	Onycholysis associated with subungual hyperkeratosis, patchy or linear yellow discoloration
Proximal subungual onychomycosis	*T. rubrum*[b]	Proximal leukonychia with normal nail plate surface
	Fusarium sp. *Aspergillus* sp. *Scopulariopsis* sp.	Associated with periungual inflammation and purulent discharge
White superficial onychomycosis	*Trichophyton interdigitale*[a]	Multiple superficial areas of friable opaque leukonychia
	Fusarium sp. *Aspergillus* sp.	Involvement more diffuse and deeper

[a]Associated with tinea pedis.
[b]Possible marker of human immunodeficiency virus infection.

ONYCHOMYCOSIS AT A GLANCE

- Fifteen percent of the general population and 40% of individuals older than 60 years are affected.
- Clinical presentation reflects the route of nail invasion.
- Dermatophytes account for 85% of cases, nondermatophyte fungi for 15%.
- Infection with human immunodeficiency virus should be suspected with proximal subungual onychomycosis (PSO) due to *Trichophyton rubrum*.
- Mold fungal infection should be suspected when PSO is associated with acute periungual inflammation or when white superficial onychomycosis involves most of the nail plate.
- *Candida* sp. is the causative agents only in immunosuppressed individuals.
- Toenails are involved in most cases; tinea pedis is usually associated.
- The cure rate for toenail onychomycosis is approximately 80% with the use of systemic antifungals, but recurrences are frequent (up to 20%). Mold infections respond poorly to systemic treatment.

ENVIRONMENTAL NAIL DISORDERS

NAIL FRAGILITY[62]

(Box 89-3)

With nail fragility, the nails are brittle and show distal lamellar splitting (onychoschizia) (Fig. 89-12). Several fingernails are usually affected. The nail plate margin is irregular due to distal splitting. Idiopathic nail fragility usually affects middle-aged women who are exposed to water and chemicals that dehydrate the nail plate. Aging also is associated with increased nail fragility. The risk of nail fragility from trauma is increased by manicures, onychotillomania, and certain occupations, especially those that involve frequent exposure to water and chemicals. Fragile nails can be a feature of several dermatologic disorders, such as lichen planus, alopecia areata, psoriasis, and onychomycosis. In addition, nutritional deficiency, peripheral neuropathies, peripheral vascular disease, and use of certain medications increase the risk of nail fragility. Management includes protection of the hands by the use of cotton gloves under rubber gloves and frequent application of topical moisturizers.[61] Oral biotin, 5 mg/day, can be helpful.[63]

BOX 89-3 CAUSES OF NAIL FRAGILITY

- Idiopathic
  - Aging
  - Exposure to water and chemicals
- Traumatic
  - Occupational injury
  - Manicure
  - Onychotillomania
- Dermatologic diseases
  - Lichen planus
  - Alopecia areata
  - Psoriasis
  - Onychomycosis
- Systemic conditions
  - Use of certain drugs
  - Peripheral vascular diseases
  - Peripheral neuropathies
  - Nutritional deficiencies

CHRONIC PARONYCHIA[64–66]

Chronic paronychia is an inflammatory disorder that almost exclusively involves the fingernails of adult women. Mechanical or chemical traumas damage the cuticle and permit penetration of irritant and allergenic environmental substances under the proximal

Figure 89-11 White superficial onychomycosis due to *Fusarium* sp. Note diffuse and "deep" nail invasion.

Figure 89-12 Onychoschizia lamellina: lamellar exfoliation of the distal nail plate.

CHRONIC PARONYCHIA AT A GLANCE

- Occurs most commonly in food handlers and housecleaners.
- Associated with mechanical or chemical cuticle damage.
- Characterized by eczematous inflammation of the proximal nail fold and matrix.
- Secondary colonization by bacteria and yeasts usually occurs.
- First, second, and third digits of the dominant hand are most often affected.
- Management includes protective measures, topical and/or systemic steroids, and topical antimicrobials.
- Systemic antifungals are not effective.

nail fold, causing an inflammatory reaction of the nail folds and matrix. Secondary colonization with *Candida* sp. and/or bacteria occurs in most cases, causing self-limited episodes of painful acute inflammation (see Chapter 189). Chronic paronychia most commonly affects the first, second, and third fingers of the dominant hand. Clinically, the proximal and lateral nail folds show mild erythema and swelling, and the cuticle is absent. The nail plate may show superficial abnormalities and green discoloration due to *Pseudomonas* invasion. Hand protection from the environmental hazards is mandatory for remission of chronic paronychia, which can be considered cured only when the cuticle has regrowth. Systemic antifungals are not effective. Chronic paronychia should be treated as contact dermatitis, with topical steroids or tacrolimus associated with topical antiseptics to prevent secondary microbial colonization.

IDIOPATHIC ONYCHOLYSIS[65]

IDIOPATHIC ONYCHOLYSIS AT A GLANCE

- Occurs in homemakers and those in certain occupations.
- Caused by mechanical or chemical damage.
- Follows asymptomatic and slowly progressive nail plate detachment.
- Management includes taking protective measures, trimming the onycholytic nail plate, and applying topical antiseptics.

BOX 89-4 ONYCHOLYSIS

- Primary
  - Idiopathic
  - Fingernails: women (mechanical/chemical damage)
- Trauma
  - Fingernails: occupational injury
  - Toenails: podiatric abnormalities, improper shoes
- Secondary
  - Vesiculobullous disorders
    - Contact dermatitis
    - Pompholyx
    - Herpes simplex
  - Nail bed hyperkeratosis
    - Onychomycosis
    - Psoriasis
  - Nail bed tumors
    - Drugs (often hemorrhagic)

Idiopathic onycholysis usually affects the fingernails of women and is a consequence of mechanical and chemical damage of the nail bed isthmus (Box 89-4). The detached nail plate is white due to the presence of air and frequently presents areas of green–brown discoloration due to bacterial colonization (Fig. 89-13). The use of sharp tools to clean the nail plate free margin produces roller coaster onycholysis (manicure onycholysis). Traumatic onycholysis of the fingernails is usually occupational and is more commonly observed in butchers, slaughterhouse workers, chicken processing workers, and workers lifting heavy bags. Traumatic onycholysis of the toenails most frequently affects the big toe, often bilaterally. It is usually a consequence of anatomic abnormalities (overlapping of the second toe on the first toe) or poorly fitting shoes. Subungual hematoma is frequently associated. Secondary onycholysis is seen in several dermatologic disorders. When only one nail is affected, it is important

Figure 89-13 Idiopathic onycholysis: note areas of green discoloration of the onycholytic space due to *Pseudomonas* colonization.

to explore the nail bed after cutting the onycholytic nail to rule out a nail tumor. Patients with idiopathic onycholysis should be instructed to keep the nail dry, trim the onycholytic nail plate, and wear cotton gloves under rubber gloves. Application of topical 4% thymol in chloroform solution on the exposed nail bed can accelerate cure.

NAIL TUMORS[67]

Tumors of the nail usually affect one digit and are associated with symptoms that depend on tumor localization: nail plate furrows or grooves are due to tumors in the proximal nail fold, while onycholysis or subungual nodule are a consequence of nail bed tumor. The nail plate may be altered both in its shape and thickness and in color.

BENIGN TUMORS

FIBROMA/FIBROKERATOMA. Fibroma/fibrokeratoma appears as a nodular or filiform growth that often has a keratotic surface. Most fibromas originate in the proximal nail fold and extend to the nail plate surface, where the tumor presents as a longitudinal furrow or groove. Subungual lesions are uncommon. Tuberous sclerosis should be considered, especially if multiple lesions are present (see Chapter 140).

SUBUNGUAL EXOSTOSIS.[68] Subungual exostosis appears as a subungual hard nodule that detaches and lifts the nail plate. The toenails of young adults are usually affected, and a history of trauma is not unusual. Radiography confirms the diagnosis.

MYXOID CYST.[69] Myxoid cyst appears as a nodule of the proximal nail fold associated with a longitudinal groove in the correspondent nail plate. Because the cyst often drains spontaneously, the shape of the groove is irregular. Myxoid cysts usually affect the fingernails of middle-aged women and are associated with osteoarthritis of the interphalangeal joints.

GLOMUS TUMOR. Glomus tumor may hardly be seen, appearing as a small red patch under the nail plate and usually affecting the hand. The minimal clinical appearance is disproportionate to the intense pain, which is usually accentuated by cold and radiates to the limb. Due to the small size of the tumor, preoperative assessment with MRI or high-variable frequency ultrasound is advisable to improve the out come of surgery.

ONYCHOMATRICOMA.[70] Onychomatricoma is a rare benign fibroepithelial tumor that originates from the nail matrix and produces typical clinical features: the whole or part of the nail is thickened, overcurved, with a yellow–white discoloration and multiple longitudinal tunnels (hollows) that end in the distal nail producing a beehive appearance of the free margin.

BOX 89-5 CLINICAL SIGNS THAT REQUIRE HISTOLOGIC EVALUATION OF LONGITUDINAL MELANONYCHIA

- Periungual pigmentation
- Adult age
- Change in color/width of the band
- Hyperpigmented lines within the band
- Proximal portion of the band wider than distal
- Thumb, index finger, or toe involvement
- Blurred margins

NAIL MATRIX NEVI.[71,72] Nail matrix nevi produce a band of LM and usually appear in childhood. The color and width of the band are variable, and modification of the pigmentation (fading or darkening) with time is common (eFigs. 89-13.1 and 89-13.2 in online edition). Pigmentation of the periungual tissues (Hutchinson's sing) is commonly associated with congenital nevi. Clinical management of nail matrix nevi in children is often problematic as lesions frequently show signs (Box 89-5) that are indicative for nail melanoma in adults.[73,74] Excision of the lesions that show rapid increase in size is probably the best option, to exclude the possibility of a melanoma, which is rare but can occur.

MALIGNANT TUMORS

SQUAMOUS CELL CARCINOMA. (See Chapter 114). *In situ* squamous cell carcinoma (Bowen's disease) usually manifests in fingernails, with a lesion that clinically, closely resembles a wart. Associated melanonychia or paronychia may be a diagnostic clue (Fig. 89-14).

Figure 89-14 Bowen's disease. Verrucous lesion of the nail bed, associated with onycholysis and melanonychia.

Figure 89-15 Subungual squamous cell carcinoma: ulcerated subungual nodule.

Human papillomavirus (HPV) 56 has been detected in tumoral cells of cases of Bowen's diseases associated with LM, indicating that the virus may be involved in the carcinogenesis of these cases.[75] Squamous cell carcinoma presents as a slowly growing subungual nodule that eventually ulcerates (Fig. 89-15) or a warty periungual growth. The underlying bone is commonly involved. It is more common in the fingernails and after the fifth decade of life, and the diagnosis is often delayed, since the tumor simulates other benign nail lesions and is frequently not recognized until it ulcerates.[76] Oncogenic HPV may be isolated from fingernail lesions. Surgical excision with Mohs surgery is the best treatment for squamous cell carcinoma without bone involvement.

MELANOMA.[77–79] (See Chapter 124)

MELANOMA AT A GLANCE

- Involvement of nails is rare (0.7%–3.5% of melanomas).
- Thumb or hallux is most often affected.
- Longitudinal melanonychia and Hutchinson sign are classic.
- Lesion is amelanotic in 25% of cases.
- Only 15% of patients survive 5 years or longer.

Nail melanoma is an uncommon form of acral melanoma that arises within the nail matrix or bed. The incidence for acral melanomas is similar worldwide, but the proportion is higher in dark-skinned individuals. It represents about 2% of cutaneous melanomas in Caucasians, and up to 25% in Africans and 10% in Japanese. Nail melanoma most commonly affects the thumb or great toe of middle-aged or elderly patients and is usually an acral lentiginous melanoma. Melanoma of the nail matrix presents as a band of LM, usually dark in color and with irregular border. Periungual brown–black pigmentation (Hutchinson nail sign) indicates superficial spreading of the tumor and is a diagnostic clue (Fig. 89-16). Although dermoscopy is increasingly utilized in the evaluation of nail pigmentation, the experience in this field is still limited and there are no data showing that dermoscopy is superior to clinical evaluation in early detection of nail melanoma. Recent evidence indicate that dermoscopy should not be considered a substitute for pathology in the differential diagnosis of doubtful cases of LM and an excisional biopsy is recommended in all cases of LM showing suspicious features (Box 89-5).[74]

Figure 89-16 Nail melanoma: note Hutchinson's sign of the hyponychium.

Up to 33% of subungual melanomas are amelanotic, and they are often misdiagnosed as pyogenic granuloma or squamous cell carcinoma, because the tumor appears as a nail bed growth that first detaches the nail plate and then destroys the epithelium with erosion and bleeding. The low survival rate of patients with nail melanoma is related mainly to the delay in diagnosis.

NAIL PSORIASIS

(See Chapter 18)

NAIL PSORIASIS AT A GLANCE

- Present in up to 50% of patients with skin psoriasis and up to 83% of those with psoriatic arthritis.
- Isolated nail psoriasis is not rare.
- Nail matrix and nail bed are most commonly affected.
- Most often precipitated or worsened by trauma.
- Most common signs are onycholysis, salmon patches, subungual hyperkeratosis, and irregular pitting.
- Fingernails and/or toenails may be affected. Several nails are involved in most cases.
- Treatment is often unsatisfactory.

Up to 50% of patients with psoriasis have concurrent nail psoriasis, which can occur in the absence of skin lesions. Up to 30% of patients with skin psoriasis also have psoriatic arthritis and of these, approximately 80% have nail disease. It has been recently understood that the close proximity of the nail unit to the distal phalanx and the joint has important functional and pathological consequences.[80] The fibers of the extensor tendon of the digit insert to the periosteum and then are directed to the nail matrix, which they envelop and link to the bone. The collateral ligaments of the digit anchor the lateral sides of the nail to the interphalangeal joint. Thus, any acute inflammatory process affecting the interphalangeal joint necessarily affects the nail and vice versa.

Psoriasis limited to the nails can be easily diagnosed when it produces typical signs, usually detectable only in the fingernails: psoriatic pitting, onycholysis with erythematous border and salmon patches of the nail bed.[81] Psoriatic pits are large, deep, and irregular (see Fig. 89-4), and represent psoriatic involvement of the proximal nail matrix. Onycholysis is actually the most common manifestation of nail psoriasis and may affect both fingernails and toenails. In fingernails the presence of an erythematous border along the onycholytic area is diagnostic for nail psoriasis (Fig. 89-17). In toenails, onycholysis is usually combined with subungual hyperkeratosis and may closely resemble onychomycosis (Fig. 89-18). Salmon patches (oil drop sign) appear as yellow–red areas of discoloration in the center of the nail or bordering an onycholytic area. Rarely, nail psoriasis may produce severe nail plate abnormalities such as trachyonychia or crumbling. Other common but rather aspecific signs include splinter hemorrhages and paronychia.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of nail psoriasis is summarized in Box 89-6.

Pathology of nail clipping can be helpful for diagnosis and to rule out onychomycosis.[82] When typical symptoms are not present, diagnosis of nail psoriasis may rely on videodermoscopy of the hyponychium (magnification 40×), which shows dilated, tortuous, elongated, and irregularly distributed capillaries, a finding typical of nail psoriasis (eFig. 89-18.1 in online edition). The capillary density positively correlates with disease severity and decreases with the response to treatment.[83]

Figure 89-17 Nail psoriasis: onycholysis surrounded by an erythematous border and salmon patches of the nail bed.

Figure 89-18 Psoriasis of the toenails producing subungual hyperkeratosis and onycholysis.

TREATMENT

Treatment of psoriasis affecting only the nails is often unsatisfactory and should be limited to patients who experience functional impairment or severe cosmetic problems. It is important to instruct patients to avoid trauma and to refer the patient to a rheumatologist if digital pain is described.

Systemic treatments for skin and joint psoriasis are generally effective for nail psoriasis (methotrexate, cyclosporine A). Since the advent of biologic therapies for severe skin and joint psoriasis, their effects on nails symptoms has been investigated and infliximab 5 mg/kg appears to be the most effective to date. Statistically significant mean percent improvement in the Nail Psoriasis Severity Index (NAPSI) score over placebo was obtained at both week 10 and week 24.[84] Phototherapy is not effective.

Intralesional steroids (triamcinolone acetonide 2.5–5.0 mg/mL in saline) are the best treatment for nail

BOX 89-6 DIFFERENTIAL DIAGNOSIS OF NAIL PSORIASIS

- Onycholysis
  - Onychomycosis (usually associated with subungual hyperkeratosis): up to 21% of psoriatic nails have secondary onychomycosis
  - Idiopathic onycholysis (fingernails): usually seen with other nail changes
  - Trauma (toenails): psoriasis usually affects several nails, not just the great toenails
- Pitting
  - Eczema: often has periungual scaling and Beau's lines
  - Alopecia areata: different morphology of pits

matrix psoriasis limited to a few fingernails, for which they can be injected in the proximal nail fold every 4–8 weeks. Acitretin at low dosages (0.2–0.3 mg/kg/day) for 4 to 6 months is an effective option in severe nail psoriasis.[85] In nail bed psoriasis, topical treatment with calcipotriol, combination of calcipotriol and betamethasone, or tazarotene may be effective after removal of the detached nail plate.[86–88]

PUSTULAR PSORIASIS

(See Chapters 18 and 21)

The diagnosis of Hallopeau' acrodermatitis is suggested by a clinical history of relapsing periungual and subungual pustules with onycholysis (Fig. 89-19). The patient is most commonly seen when the acute episode has subsided; at this time the affected digit shows onycholysis with nail bed and periungual erythema and scaling. Low-dose acitretin (0.3 mg/kg/day) may be useful.

Figure 89-19 Hallopeau acrodermatitis continua.

LICHEN PLANUS[81]

(See Chapter 26)

NAIL LICHEN PLANUS AT A GLANCE

- Nail lichen planus is seen in approximately 10% of patients with skin lichen planus.
- Nail involvement is not associated with oral, skin, or scalp lesions in most cases.
- Nail matrix lichen planus produces nail thinning, with longitudinal fissuring, dorsal pterygium, and trachyonychia.
- Nail bed lichen planus is frequent, but clinical signs are not specific (onycholysis and mild subungual hyperkeratosis).
- Several nails are involved in most cases. Scarring of the nail matrix with dorsal pterygium is a possible sequela.
- Diagnosis should be confirmed by nail biopsy, and systemic treatment is necessary to avoid scarring.

Nail lichen planus is not rare, and nail lesions may occur in the absence of cutaneous or mucosal involvement. Nail localization of lichen planus should be taken seriously, because it may destroy the nails. Therefore, it is important to diagnose and treat the disease as soon as possible. Although lichen planus often affects both the nail matrix and the nail bed, clinical suspicion should be aroused by nail matrix signs, particularly nail thinning with longitudinal ridging and fissuring (Fig. 89-20). Dorsal nail pterygium formation is not common. It results from nail matrix destruction and appears as a V-shaped extension of the skin of the proximal nail fold that adheres to the nail bed. Idiopathic atrophy of the nails is a rare variety of nail matrix lichen planus characterized by acute and progressive painless nail destruction leading to diffuse nail atrophy with and without pterygium. Onycholysis is quite frequent in both fingernails and toenails. Severe toenail involvement causes features that resemble yellow nail syndrome, with thickened, yellow–brown toenails. More rarely, nail lichen planus may present with erosive lesions of the nail bed and periungual tissues. Other possible clinical presentations include trachyonychia and nail plate thickening.

DIFFERENTIAL DIAGNOSIS

(Box 89-7)

In patients with brittle nails, the nail abnormalities are milder. The nails are thin and ridged, but fissuring at multiple sites is not observed. Onychoschizia is frequently associated. Trauma that produces damage to the matrix in an area wider than 3 mm causes permanent thinning and fissuring. Only one nail is

Figure 89-20 Nail matrix lichen planus: note longitudinal ridging and fissuring of the nail plate.

BOX 89-7 DIFFERENTIAL DIAGNOSIS OF LICHEN PLANUS

- Longitudinal fissuring
  - Brittle nails
  - Trauma (single fissure)
  - Systemic amyloidosis
  - Lichen striatus
  - Graft-versus-host disease
- Pterygium
  - Trauma
  - Bullous diseases
  - Digital ischemia
  - Dyskeratosis congenita
  - Graft-versus-host disease

usually affected, and it may show a single fissure. Nail abnormalities may be the first sign of systemic amyloidosis, with nail thinning, ridging, and fissuring closely resembling mild nail matrix lichen planus. In amyloidosis, nail bed hemorrhages are common. Diagnosis depends on nail biopsy. Lichen striatus may manifest as nail thinning and fissuring limited to one or two adjacent digits. Skin changes that course from the affected nail in a linear configuration are typical. Inherited (EB) and acquired (e.g., bullous pemphigoid) bullous diseases can produce pterygium. Skin and mucosal lesions are usually present. Digital ischemia is distinguished in that the digit is cold and shows skin signs of impaired vascular skin supply.

TREATMENT

Nail matrix lichen planus requires oral or intramuscular treatment with systemic steroids, which induce remission of the disease in 2/3 of the cases (Figs. 89-21 and 89-22). Intralesional (vs. systemic) corticosteroid injections should be considered in patients with involvement of fewer than three digits. Relapses are not uncommon, but usually respond to treatment.

Figure 89-21 Nail matrix lichen planus before and after treatment with systemic steroids.

Figure 89-22 Nail matrix lichen planus before and after treatment with systemic steroids.

Dorsal pterygium is not reversible and when it is the sole manifestation, should not be treated. Solitary nail lichen planus presenting as trachyonychia does not lead to nail scarring and therefore does not necessarily require treatment.

PARAKERATOSIS PUSTULOSA

Parakeratosis pustulosa is a rather common condition that occurs only in children. The disease is limited to one nail in most cases (usually the thumb or index finger) with a clinical picture that closely resembles that of psoriasis. Characteristics are distal onycholysis, fingertip desquamation, and mild subungual hyperkeratosis. Spontaneous regression usually occurs after puberty.

TRACHYONYCHIA (TWENTY-NAIL DYSTROPHY)

TRACHYONYCHIA (TWENTY-NAIL DYSTROPHY) AT A GLANCE

- Idiopathic but likely reflects alopecia areata, psoriasis, dermatitis, or lichen planus of the nail. More common in children.
- Characterized by nail roughness due to excessive longitudinal ridging (sandpaper nails).
- Several nails are involved in most cases; involvement of 20 nails is not necessary for diagnosis.
- Nail changes often regress spontaneously.
- Treatment is not required.

Figure 89-23 Trachyonychia.

Trachyonychia (twenty-nail dystrophy) is a nail sign that can be caused by several inflammatory disorders that produce a mild disturbance of nail matrix keratinization. These include alopecia areata, psoriasis, lichen planus, and eczema. The nail is rough and opaque due to excessive longitudinal ridging (Fig. 89-23). The disease occurs most commonly in children. Trachyonychia does not produce nail scarring, even in cases due to lichen planus.

DARIER DISEASE[1]

(See Chapter 51)

The nail abnormalities noted in Darier disease are diagnostic but are not seen in all patients). Key features are longitudinal erythronychia, longitudinal leukonychia associated with distal nail plate nicking (V shaped), and subungual hyperkeratotic papules.

ALOPECIA AREATA

(See Chapter 88)

Nail involvement is seen in approximately 20% of adults and 50% of children with alopecia areata and is most common in male patients with severe involvement. Geometric pitting is most typical. Pits are small, superficial, and regularly distributed in a geometric pattern along longitudinal and transverse lines. Trachyonychia is quite common in children affected by alopecia totalis or universalis. Other nail abnormalities include punctate leukonychia, mottled lunulae, and acute onycholysis. Nail abnormalities may improve with systemic steroid treatment or spontaneously; they respond poorly to application of topical medications.

ATOPIC DERMATITIS

(See Chapter 14)

Nail abnormalities associated with atopic dermatitis are nonspecific in most cases. Manifestations are most commonly Beau's lines, irregular pitting, and chronic paronychia. Onycholysis and subungual hyperkeratosis are seen in severe cases, especially those triggered by occupational exposure.

YELLOW NAIL SYNDROME

YELLOW NAIL SYNDROME AT A GLANCE

- In the typical syndrome, nail changes are associated with respiratory disorders and lymphedema.
- Arrested nail growth is diagnostic.
- Nails are overcurved and thickened, the cuticle is absent, and nail color varies from pale yellow to green. Onycholysis is often associated.
- Most or all nails are usually involved.

Yellow nail syndrome may or may not be associated with a systemic disorder and is occasionally familial.[88,89] However, it is important to refer patients to a pneumologist to exclude respiratory tract involvement. Other conditions that may be associated with yellow-nail syndrome include rheumatoid arthritis and internal malignancies. The history is the most important clue to diagnosis, because patients always claim that their nails have stopped growing (Fig. 89-24).

The nail changes may benefit from treatment with high oral dosages of vitamin E. Spontaneous improvement is possible. Topical vitamin E and systemic antifungal medications (itraconazole, fluconazole) do not appear to be effective.[89–91]

NAIL SIGNS OF SYSTEMIC DISEASES

(Table 89-5)

In systemic diseases, nail manifestations usually involve most or all nails. The diagnosis is suggested by clinical history, morphology, and distribution of

Figure 89-24 Yellow nail syndrome.

TABLE 89-5
Nail Signs of Systemic Disease

Beau's lines/onychomadesis	See Box 89-1
Koilonychia	Sideropenic anemia
Proximal splinter hemorrhages	Bacterial endocarditis Trichinosis Antiphospholipid syndrome Altitude sickness
Periungual erythema	Collagen disorders Infection with human immunodeficiency virus or hepatitis C virus
Lichenoid nail changes with hemorrhages	Systemic amyloidosis
Apparent leukonychia Half-and-half nails Terry's nails Banded nails (Muehrcke's lines)	 Renal disorders Hepatic disorders Systemic chemotherapy Hypoalbuminemia
Clubbing	See Box 89-8
Melanonychia	See Boxes 89-2 and 89-5

the nail abnormalities. Beau's lines located at the same level in all digits or onychomadesis occurring simultaneously in all digits is strongly diagnostic for nail matrix damage from a systemic cause.

Examination and capillaroscopy of the proximal nail fold are very important for the diagnosis of connective tissue diseases. Patients with scleroderma and dermatomyositis show enlarged capillary loops with reduced capillary density and avascular areas. In systemic lupus, erythematous, periungual erythema and telangiectasia are typical; although periungual vessels can be tortuous, the capillary density tends to be normal. Cuticular hyperkeratosis and hemorrhages are seen in systemic lupus erythematous and dermatomyositis. Pterygium inversum unguium is typical of scleroderma; in this condition the nail plate adheres to the fingertip skin, which makes nail trimming very painful.

The diagnosis of systemic amyloidosis can be suggested by nail symptoms, which sometimes precedes skin and mucosal changes. The nails are thinned, longitudinally fissured, and show subungual hemorrhages.

Mild leukonychia is often seen in normal individuals and therefore does not represent a specific sign of systemic disorders. Clinical patterns include half-and-half nails (leukonychia affects the proximal half of the nail bed), Terry's nails (leukonychia affects the entire nail bed except for its 2-mm distal margin), and Muehrcke's lines (narrow paired transverse bands parallel to the lunula).

Clubbing may or may not be associated with cyanosis (Box 89-8). In clubbing the angle between the proximal nail fold and nail plate is greater than 180 degrees. The digit has a bulbous appearance, and the nail plate is enlarged and excessively curved.

Melanonychia can be associated with a variety of systemic disorders and conditions, particularly human immunodeficiency virus infection, adrenal disease, pregnancy, and certain drugs (Box 89-9).

BOX 89-8 CAUSES OF CLUBBING

- Cardiovascular disorders
  - Aortic aneurysm[a]
  - Congenital/acquired cardiovascular disease[b]
- Bronchopulmonary conditions[c]
  - Intrathoracic neoplasms
  - Chronic intrathoracic suppurative disorders
- Gastrointestinal disorders
  - Inflammatory bowel disease
  - Gastrointestinal neoplasms
  - Hepatic disorders
  - Multiple polyposis
  - Bacillary dysentery
  - Amoebic dysentery
- Chronic methemoglobinemia

[a]Unilateral.
[b]Associated with cyanosis.
[c]Associated with hypertrophic osteopathy.

DRUG-INDUCED NAIL ABNORMALITIES[92]

A few nail abnormalities are highly likely to have resulted from administration of medication (see

BOX 89-9 DRUG-INDUCED NAIL CHANGES

- Chemotherapy
  - Beau's lines
  - Onychomadesis
  - Muehrcke's lines
  - Hemorrhagic onycholysis
  - Pyogenic granulomas
  - Melanonychia
- Antiretrovirals
  - Azathioprine
    - Melanonychia
  - Indinavir
    - Pyogenic granuloma

  - Digital ischemia
- Bleomycin
  - Digital ischemia
- Psoralen plus ultraviolet A phototherapy
  - Photo-onycholysis
  - Melanonychia
- Retinoids
  - Nail fragility
  - Pyogenic granuloma
  - Paronychia

Figure 89-25 Hemorrhagic onycholysis due to taxanes

Box 89-9). Pyogenic granulomas involving several nails are an occasional side effect of treatment with retinoids, indinavir, and antiepidermal growth factor receptor chemotherapeutic agents, often leading to drug discontinuation. Retinoids have also been associated with nail fragility and paronychia. Taxanes (docetaxel and paclitaxel) frequently induce painful onycholysis with subungual hemorrhage and abscess formation (Fig. 89-25). The nail lesions resemble a subungual infection and are reversible after drug discontinuation. Both β blockers and bleomycin may lead to digital ischemia. Therapy with psoralen plus ultraviolet A light has been associated with photo-onycholysis and melanonychia. Photo-onycholysis has recently been seen after photodynamic therapy.[93] and can rarely follow the intake of tetracycline derivatives, psoralens, and fluoroquinolones. It may be associated with a photosensitivity reaction in the skin and typically affects the central part of the nail plate of one or more fingernails (Fig. 89-26). Onycholysis is painful and often hemorrhagic.[94]

TRAUMATIC NAIL DISORDERS

NAIL BITING

Nail biting is common in children and may encourage spreading of subungual warts (Fig. 89-27). When nail biting is associated with picking and chewing of the cuticle and periungual skin, the nail plate often shows superficial abnormalities and melanonychia due to melanocyte activation.

Figure 89-26 Photo-onycholysis: note the presence of nail bed hemorrhages.

HABIT TIC DEFORMITY (ONYCHODYSTROPHIA MEDIANA CANALIFORMIS)

In habit tic deformity the thumb shows a central longitudinal furrow with multiple transverse parallel lines (Fig. 89-28). The nail deformity is due to the nervous tic of pushing back the cuticle and the proximal nail fold of the thumb with the index finger.

SUBUNGUAL HEMATOMA

Subungual hematoma may be caused by a single acute trauma or by repeated microtraumas (see Chapter 99). Nail hematomas last several months because part of the blood is incorporated into the nail plate. Very dark lesions require differentiation from melanotic pigmentation. Dermoscopy shows rounded red–black globules (eFig. 89-28.1 in online edition).[74] Acute hematomas require immediate drainage to avoid matrix compression.

ONYCHOLYSIS

Traumatic onycholysis of the great toenails is frequent in athletes, in women wearing high-heeled shoes,

Figure 89-27 Subungual warts in a nail biter.

Figure 89-28 Longitudinal furrow of the nail plate due to habit tic.

and in individuals with podiatric abnormalities. Nail detachment is not associated with nail bed hyperkeratosis.

ONYCHOGRYPHOSIS

Onychogryphosis is common in the elderly and neglected individuals .The nail is thickened, distorted, opaque, and yellow–brown, and tends to have an oyster shell appearance.

PINCER NAILS

Pincer nails is a painful abnormality that usually affects the toenails and may be associated with subungual exostosis. The distal nail plate is overcurved and compresses the subungual soft tissues (Fig. 89-29).

INGROWING TOENAILS

Ingrowing toenails most commonly affect young adults with congenital malalignment of the great toenails. Improper nail cutting may lead to embedding of a nail edge, causing inflammation and granulation tissue formation. Hyperhidrosis is frequently associated. The aim of treatment for ingrowing toenails is to extract the nail edge that is ingrowing and prevent further penetration of nail fragments into the lateral

Figure 89-29 Pincer nails.

Figure 89-30 Retronychia: proximal ingrowing of the nail plate.

folds. To accomplish this, the lateral nail plate can be lifted by using a cotton pack or by inserting a gutter splint along the lateral nail margin.[95] The width of the nail plate can also be reduced by surgical or chemical (phenolization) removal of the lateral nail matrix.[96,97]

RETRONYCHIA

Retronychia describes the ingrowth of the proximal nail plate into the proximal nail fold associated with multiple generations of nail plate misaligned beneath the proximal nail.[98] It involves 1 or both the first toenails and starts as an onychomadesis (posttraumatic) not followed by nail shedding. The persistence of the partially detached plate under the proximal nail fold, associated with the growth of new nail plates underneath it, results in inflammation with pain and granulation tissue formation (Fig. 89-30). Nail plate avulsion leads to a slow regrowth of a normal nail.

PART 4 Disorders Due to the Environment

Disorders Due to Ultraviolet Radiation

Chapter 90 :: Fundamentals of Cutaneous Photobiology and Photoimmunology

:: Irene E. Kochevar, Charles R. Taylor, & Jean Krutmann

FUNDAMENTALS OF CUTANEOUS PHOTOBIOLOGY AND PHOTOIMMUNOLOGY AT A GLANCE

- When radiation enters the skin, it is scattered or absorbed. Only light absorbed by molecules (chromophores) in the skin can cause a photobiologic response.
- Electromagnetic radiation can be conceptualized either as a wave or as packets of energy called *photons*.
- An action spectrum indicates which wavelengths produce a photobiologic response most effectively and is plotted as the reciprocal of the minimum effective fluence versus wavelength.
- The most erythemogenic wavelengths present in sunlight are in the ultraviolet B (UVB) range. Ultraviolet A (UVA) is roughly 1000-fold less effective than UVB.
- Prostaglandins and nitric oxide appear to be the major mediators for UVB erythema.
- When certain drugs and dyes absorb UV/visible light, inflammation ensues. This is called *photosensitization*.
- Photosensitivity responses are usually mediated by reactive oxygen species.
- Blocked by sunscreen use, cutaneous vitamin D production is mediated by wavelengths from 295–300 nm. Optimal vitamin D blood levels are essential for good bone health and increasingly associated with a myriad of other potential health benefits.
- Ultraviolet radiation is immunosuppressive. Local and systemic immunosuppressions are recognized.
- Pyrimidine dimers, reactive oxygen species and urocanic acid initiate UV-induced immunosuppression.
- Interleukin-10 (IL-10), tumor necrosis factor (TNF)-α, platelet-activating factor, platelet-activating factor-like lipids and other molecules mediate photoimmunosuppression.
- The major cellular players in UV immunosuppression are Langerhans cells, keratinocytes, macrophages, and T cells.
- UV radiation impairs T helper 1-mediated cellular immune response.

Knowledge of the interaction of sunlight with the skin is fundamental to understanding the pathogenesis, diagnosis, and treatment of more than 100 cutaneous disorders. Whenever ultraviolet (UV) or visible radiation is used to diagnose or treat a skin condition, important principles of photophysics involving absorption and emission of light underlie the success of the therapy. Sunscreen recommendations rely on an understanding of solar UV radiation and the ways in which the causative wavelengths can be minimized. Skin cancer is an epidemic clinical problem, whose pathophysiology necessitates comprehension of the photophysical, photochemical, and photobiologic events described in this chapter.

Almost every ancient civilization worshipped a god of the sun whose healing powers were believed to be broad reaching. Even today, sun exposure is widely felt to induce a sense of well-being. In addition, sunlight is important for the synthesis of vitamin D_3 and the setting of internal clocks. On the negative side, sunlight causes deleterious acute and chronic inflammatory skin reactions, skin cancer, and photoaging, and can elicit adverse reactions to certain drugs (see Chapters 91, 92, 109, 112). Although the sun is a major source of the UV and visible radiation that interacts with human skin, UV and/or visible radiation are also emitted from common sources such as fluorescent lights, incandescent bulbs, photocopy machines, and phototherapy lamps. Tanning salons are another familiar example. Thus, UV and visible radiation are a constant part of the human environment and play a role in health, disease, and therapy. Photodermatology is the study of this interaction between human skin and UV and visible radiation. To understand the responses of skin to UV and visible radiation, it is essential to be acquainted with the principles governing the interaction of these wavebands with biomolecules in the skin.

When UV and visible light photons reach the skin surface the energy of the radiation is transformed into an observable response as shown schematically in Figure 90-1. First, the radiation must penetrate to the appropriate level in the skin where it is absorbed by molecules in the skin, termed *chromophores*. Photochemical reactions then convert the chromophores into new molecules, the photoproducts. These photoproduct molecules stimulate cellular signal transduction pathways leading to biochemical changes that culminate in cellular effects, such as the proliferation, secretion of cytokines, and apoptosis that are responsible for the observed acute skin responses.

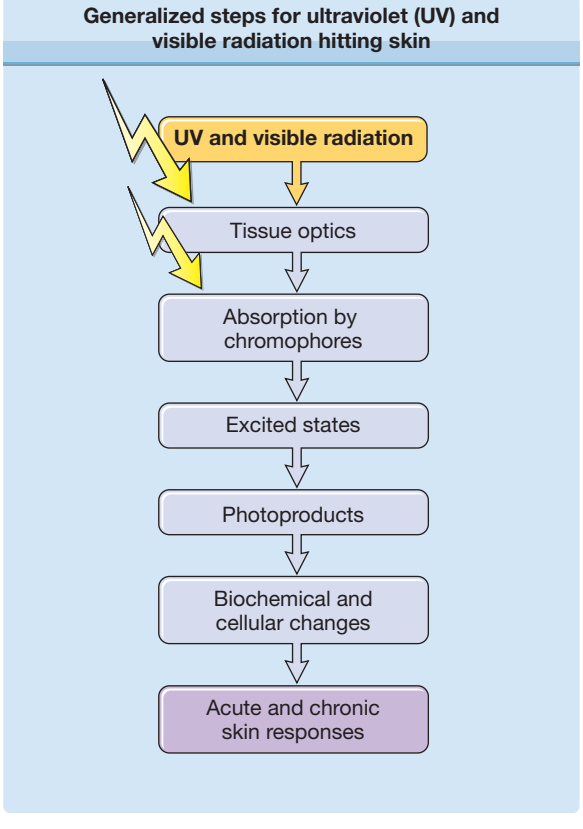

Figure 90-1 Generalized steps from ultraviolet (UV) and visible radiation hitting the skin to observation of clinical responses.

ULTRAVIOLET AND VISIBLE RADIATION

UV radiation and visible light are portions of the electromagnetic (EM) spectrum, which includes a wide range of wavelengths, from high-energy X-rays to low-energy microwaves and radio waves (Table 90-1; Fig. 90-2). The UV waveband is of special interest because dozens of skin disorders are aggravated by these wavelengths and, many popular therapies, such as UVB phototherapy (see Chapter 237) and psoralen and ultraviolet A light (PUVA) photochemotherapy (see Chapter 238), use sources emitting UV radiation. Visible light encompasses those wavelengths perceived as color by the human eye and is also frequently used in therapies, such as blue-light amino levulinic acid–photodynamic therapy (PDT; see Chapter 238), and is emitted by several lasers intended to target cutaneous chromophores (see Chapter 239).

ULTRAVIOLET RADIATION

For medical photobiology, the UV range (200–400 nm) is subdivided into UVA, UVB, and UVC (see Table 90-1 and Fig. 90-2). A division was made at 290 nm because wavelengths from the sun shorter than 290 nm are absorbed by ozone in the stratosphere and do not reach the earth's surface at sea level. Wavelengths in the range of 200 to 290 nm are referred to as *UVC* or *germicidal radiation*. These wavelengths are strongly absorbed by DNA and therefore can be lethal to viable cells of the epidermis or to bacteria. UVC lamps emit at 254 nm and are used for air and water purification. Care must be taken to avoid exposure of eyes and skin to UVC radiation because of the danger of UV keratitis and mutation.

The range 290 to 320 nm is known as *UVB* and is often referred to as *mid-UV* or *sunburn spectrum*. It includes the biologically most active wavelengths

TABLE 90-1
Electromagnetic Radiation According to Wavelength

Waveband	Wavelength Range (nm)
X-ray	0.1–10
Vacuum ultraviolet	10–200
Ultraviolet C	200–290
Ultraviolet B	290–320
Ultraviolet A (UVA)	320–400
UVA I	340–400
UVA II	320–340
Visible	400–760
Violet	400
Blue	470
Green	530
Yellow	600
Red	700
Near infrared	760–1000
Far infrared	1000–100,000
Microwaves and radio waves	$>10^6$

reaching the earth's surface. The UVB constitutes only approximately 5% of the UV and 0.5% of total radiation reaching the earth's surface; the exact amount varies markedly with the time of day, season, cloud conditions, and other factors. Ordinary window glass blocks UVB. Most sunscreens efficiently reflect or absorb these wavelengths, and the sun protection factor (SPF) is primarily based on testing against this waveband. However, it is important to note that different wavelengths within these subdivisions can elicit greatly varying biologic responses. For example, consider the response of skin to two wavelengths in the UVB range, 297 and 313 nm. Radiation at 297 nm is nearly 100 times more erythemogenic than 313-nm radiation[1] and more effectively causes DNA damage and photocarcinogenesis.[2] An example relevant to phototherapy is the great efficacy of certain UVB wavelengths for treatment of full UVB spectrum.[3,4] Narrowband UVB (311 nm) and excimer laser (308 nm) are used to treat psoriasis because these wavelengths are more effective than other portions of the UVB spectrum.[3,4]

Long-wave UV or UVA (320–400 nm) is sometimes referred to as *black light* because it is not visible to the human eye but causes certain substances to emit visible fluorescence. Approximately 95% of the UV radiation reaching the earth's surface is UVA. As described for UVB radiation, the response of skin to UVA is not constant across all wavelengths from 320 to 400 nm.[3] In fact, UVA has been divided into UVA I (340–400 nm) and UVA II (320–340 nm) because the latter band is more damaging to unsensitized skin than the longer wavelengths. Although most sunscreens offer their greatest protection against UVB wavelengths, those products said to be "broad-spectrum" indeed have considerable ability to protect against UVA wavelengths, although no widely used formal measure equivalent to the SPF rating yet exists. Generally, the higher the SPF, for example, 45 or greater, the more likely one is going to find some UVA protection in that preparation. Newer sunscreen agents enhance protection against damaging UVA rays (see Chapter 223). Because of its predominance in the UV radiation reaching the earth's surface, protection against UVA is quite important for minimizing adverse cutaneous effects such as photoaging and carcinogenesis.

VISIBLE RADIATION

The visible spectrum (400–760 nm) is defined by the wavelengths that are perceived as color by the retina.

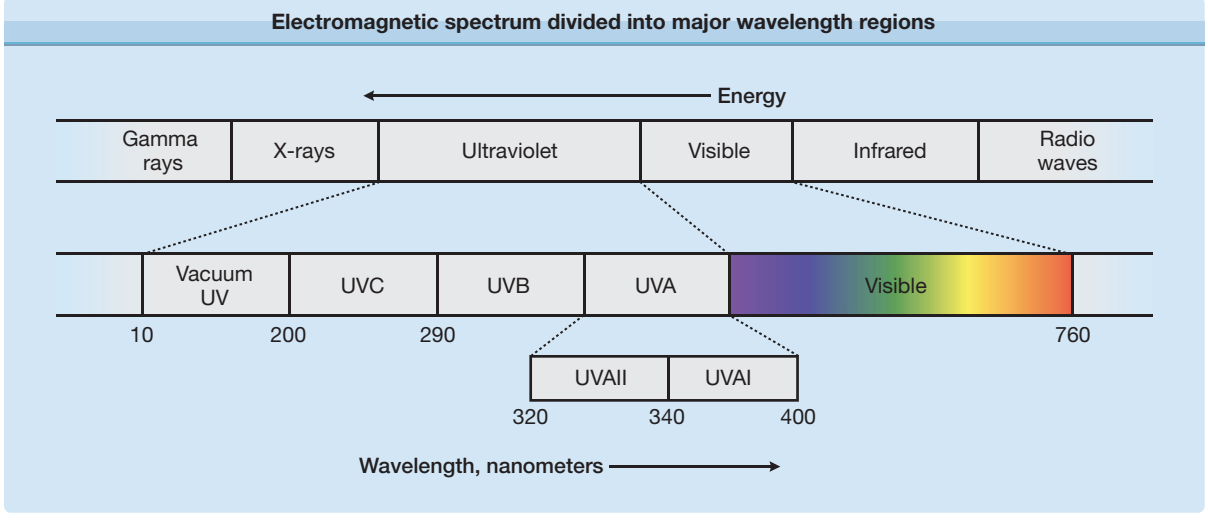

Figure 90-2 Electromagnetic spectrum divided into major wavelength regions. The lower band emphasizes the ultraviolet (UV) and visible bands that are important for photobiologic responses in human skin.

Specific colors are associated with different wavelengths, as shown in Fig. 90-2. Skin responses to visible light generally require photosensitization. For example, in PDT, dyes absorbing long wavelength visible light (red) are used (see Chapter 92). Because they take advantage of the absorption spectra of endogenous chromophores, intense pulsed visible light sources such as lasers are used to treat vascular, pigmented and other lesions without application of a photosensitizing dye (see Chapter 239).

OTHER WAVEBANDS OF ELECTROMAGNETIC RADIATION

X-rays and γ rays occupy the short wavelength (high energy) end of the EM spectrum, and infrared radiation (IR) is found at longer wavelengths (lower energy) than visible radiation (see Table 90-1). X-ray and γ rays ionize molecules (remove electrons) indiscriminately and are known as *ionizing radiation*, the subject of radiobiology (see Chapter 240). In radiation therapy of tumors, these wavelengths kill tumor cells by ionizing water molecules and producing free radicals that damage DNA. IR has lower energy than visible light. It is subdivided into IR-A (760–1,440 nm), IR-B (1,440–3,000 nm), and IR-C (3,000 nm–1 mm). IR-A penetrates into the dermis and causes skin damage whereas IR-B and IR-C are felt as heat. Recent studies suggest that IR-A wavelengths might also be therapeutic.[5]

PROPERTIES OF ELECTROMAGNETIC RADIATION

Certain principles are better illustrated by conceptualizing EM radiation as waves, whereas others are better understood by thinking of it as packets of energy called *photons*. These two descriptions are complementary.

When considering EM radiation as a wave, it is described as oscillating electric and magnetic fields at right angles to each other and to the direction of propagation. Consequently, it may be described either by its frequency (number of oscillations per second) or by its wavelength (distance traveled per oscillation). Frequency and wavelength have an inverse relationship, which is expressed as: $\nu = c/\lambda$, where ν = frequency (number of oscillations per second), c = speed of light (3×10^8 m/s), and λ = wavelength in meters.

EM radiation also may be described as a stream of discrete packets of energy known as *quanta* or *photons*. The amount of energy in a photon (quantum) is directly proportional to the frequency of the radiation and inversely proportional to its wavelength, as expressed by Planck's law: $E = hc/\lambda$, where E = the energy of the photon in joules (J), h = Planck's constant (6.626×10^{-34} J/s), c = speed of light, and λ = wavelength in meters. This relationship shows that the energy of the photon increases when the wavelength is shorter and decreases when the wavelength is longer. For example, a 300-nm UVB photon has twice the energy of a 600-nm yellow photon.

SOURCES OF ULTRAVIOLET AND VISIBLE RADIATION

SUNLIGHT

The shortest wavelength of the solar spectrum reaching the earth's surface at sea level is approximately 290 nm, although slightly shorter wavelengths are detected at high altitudes. Depending on the geographic location and the season, it has been estimated that sunlight produces between 2 and 6 mW/cm^2 of UV radiation between 290 and 400 nm. Filtering of wavelengths less than 290 nm by ozone is a very important process because the shorter UVC wavelengths are highly damaging to animals and plants. Because the transmission of solar UVC and UVB through the atmosphere varies exponentially with ozone concentration, small changes in the ozone layer may result in hazardous increases in UV irradiance at the earth's surface.[6] For example, calculations of the effects of ozone depletion predicted a doubling of skin cancer incidence by 2,100 AD even if the Montreal Protocol restrictions on ozone-depleting substances were followed.[7]

The UV Index developed by the National Weather Service and the US Environmental Protection Agency represents an attempt to quantify the risks attendant with solar radiation at a given time and place. Among other factors, the effects of altitude, latitude, season, and clouds are considered. The scale goes up to 15, and any UV Index greater than 10 is considered a high-risk day for possible overexposure in that locale.

ARTIFICIAL SOURCES OF ULTRAVIOLET AND VISIBLE RADIATION

Skin is exposed to UV and visible radiation from a wide variety of sources in daily life and from a different set of light sources for therapy and diagnosis. Specific information should be obtained from the manufacturer before using a new light source.

INCANDESCENT SOURCES. Incandescent light sources include conventional electric light bulbs, flood lamps, and some quartz iodide bulbs. In these lamps, an electric current passing through a metal filament heats the filament, causing it to emit mostly visible and IR. Only the occasional patient with solar urticaria, chronic actinic dermatitis, or some porphyrias is bothered by the output of ordinary incandescent sources. Tungsten-halogen incandescent lamps, often used as flood lamps, emit UVA and visible radiation. Some quartz iodide incandescent lamps produce significant UVA and some UVB emission.

ARC SOURCES. Arc sources include xenon lamps, medium- and high-pressure mercury (hot quartz) lamps, fluorescent lamps, and halide lamps. In arc lamps, electrons are driven through a gas by a potential difference between two electrodes. The gaseous

molecules are ionized and subsequently release EM radiation. Radiation is emitted preferentially at specific wavelengths (emission lines) as well as in a continuum, that is, all wavelengths are emitted rather than just specific wavelengths. The wavelengths and relative power at each wavelength depend on the gas used, the arc temperature, the pressure within the lamp, and the lamp wall material.

Xenon arc lamps emit both UV and visible radiation and are now the most common sources used in solar simulators. Photoprovocation testing for polymorphic eruption is often done with such sources using filters to limit the wavelengths. Xenon arcs are also used in some phototherapy and photobiologic research applications. In a xenon lamp, xenon gas under 20–40 atmospheres (atm) of pressure produces intense visible and UV radiation. At these pressures, the xenon spectrum becomes a continuum.

The wavelengths emitted by mercury arc lamps are strongly influenced by the pressure of the gas within the envelope. Low-pressure mercury germicidal lamps emit 85% of the radiant energy at 254 nm. Because the operating temperature is low, they are also known as *cold quartz lamps*. With increasing pressure (1 atm), the primary 254-nm emission is absorbed by other mercury atoms within the lamp and reemitted at longer wavelengths (297, 302, 313, 334, and 365 nm, and visible wavelengths). With further pressure increases (2–100 atm), these spectral lines broaden and decrease relative to the intensity of the continuous spectral background. In medical practice, medium- and high-pressure mercury (hot quartz) lamps are generally used as sources of UVB, although their spectral power distribution is mainly in the UVA and visible range.

The commonly used UVB sunlamps (see Chapter 237) and UVA lamps for PUVA therapy (see Chapter 238) are fluorescent lamps. They are, in essence, modified low-pressure mercury arc lamps. The inner surface of the glass tube is coated with a phosphor, which absorbs the 254-nm radiation and reemits the energy at longer wavelengths. The chemical composition of the phosphor determines which wavelengths are reemitted. In general, fluorescent lamps have a relatively wide, bell-shaped emission spectra, with emission lines of mercury superimposed, and are referred to as *broadband light sources*.

Fluorescent sunlamps (type FS) emit mainly in the UVB range (Fig. 90-3). They are often referred to as *UVB lamps*, even though they emit a portion of UVA radiation, because the therapeutically significant radiation is in the UVB range (Table 90-2). A fluorescent lamp with a major emission peak at 311 nm (Philips TL01) was developed for use in phototherapy (see Fig. 90-3).[8,9] This lamp is an efficient source for psoriasis phototherapy because, compared to a conventional UVB lamp, the energy emitted almost entirely overlaps with the action spectrum for clearance of psoriasis.[3] Interestingly, this lamp has also been successfully used for the treatment of vitiligo, atopic dermatitis, and polymorphic light eruption, all of whose action spectra are unknown and may possibly differ from that for psoriasis.

High-intensity, UVA-emitting fluorescent lamps are most often used in PUVA therapy of psoriasis, vitiligo,

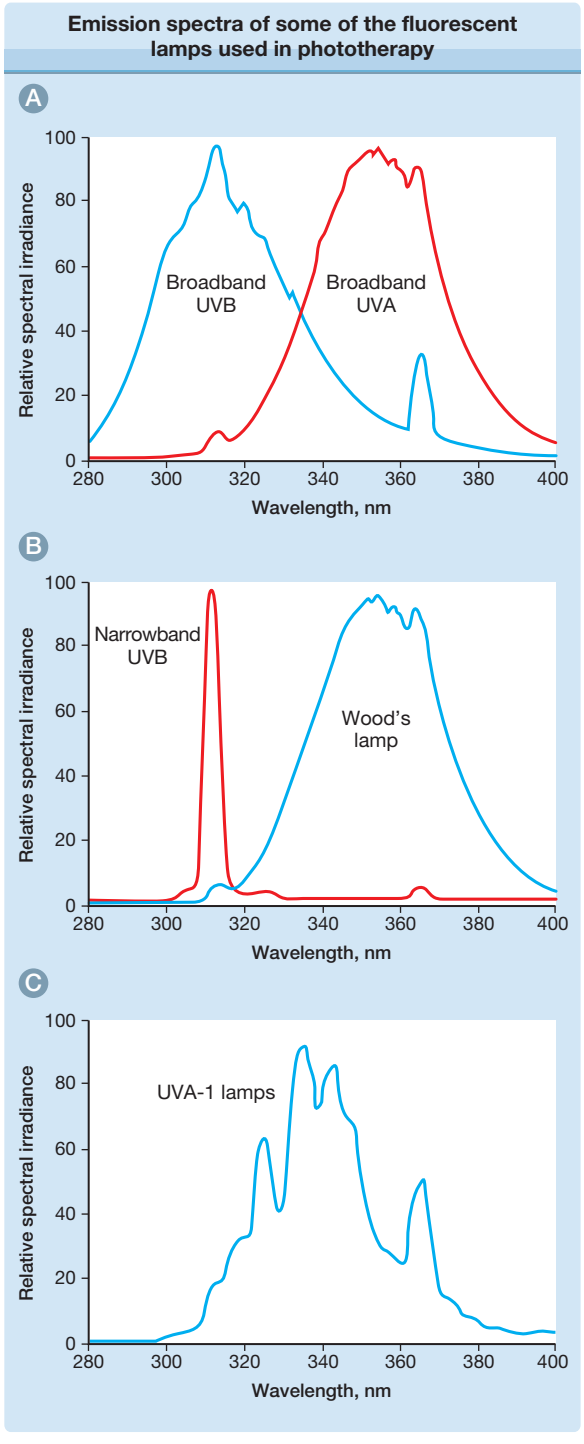

Figure 90-3 Emission spectra of some of the fluorescent lamps used in phototherapy. **A.** Broadband ultraviolet B (UVB) fluorescent lamps and UVA (black light) fluorescent lamps. **B.** Narrowband (Phillips TL01) fluorescent lamp with a maximum at 311 nm and a fluorescent lamp with a Wood's glass filter. **C.** UVA I halide lamps (Sellamed 24,000 bed system). Emission spectra were measured with a Luzchem model SPR-4001 spectroradiometer.

TABLE 90-2
Approximate Spectral Power Distribution of UVB and UVA Radiation Expressed as Percentage of Total Emission in the UV Waveband in Common Phototherapy Sources

	% UVB	% UVA
Broadband UVB (Westinghouse Sunlamp)	60	40
Narrowband UVB[a] (Phillips Fluorescent UVB, TL01, 311 nm)	80	20
Broadband UVA (Houva Lite; Black Light by Sylvania, Westinghouse, and General Electric; Sylvania Puva Life Line; Dermalight Metal)	2	98
UVA I[b] (Dermalight UltrA1, Dr. K. Hönle Medizintechnik GmbH)	0	100
Wood's light[c] (RA Fisher; Spectronics)	0	100
Halide lamps[d] (Dermalight Systems, Dr. K. Hönle Medizintechnik GmbH)	0	100

[a]Most (~95% of the UVB emission of the typical narrowband UVB source is centered around 311 nm).
[b]This UVA emission is above 340 nm.
[c]The filter used (so-called *Wood's filter*) is glass with nickel oxide phosphor. Consequently, UVB is screened. A moderate amount of visible light is produced.
[d]The actual amount depends on the model purchased and the filters used (glass vs. quartz). Some models allow the operator to change the filters readily and thus increase the amount of UVB to >50% of the irradiance.

and other skin diseases. The most efficient UVA source for PUVA therapy would maximize the emission of 320- to 360-nm radiation for photoactivation of psoralen molecules, while minimizing the UVB emission. Table 90-2 shows the percentage of total emission that is in the 320–360-nm range from several UVA-emitting light sources that are used in phototherapy units.

Wood's lamps are small, low-pressure, UVA-emitting fluorescent lamps with a UVA-transmitting, visible-absorbing glass envelope. They are useful in clinical practice because, after UVA absorption, the fluorescent emission from normal and abnormal components of skin, hair, teeth, and urine may be diagnostic (e.g., in porphyria, vitiligo, and fungal infection).

Halide lamps emit a high-intensity continuum in the UVB and especially the UVA range. With appropriate filters, this lamp is used increasingly as a UVB, as well as a UVA, source for phototherapy (in particular, UVA I therapy) and photochemotherapy. The metal halide lamp usually consists of a high-pressure mercury lamp with metal halides as additives. The continuous range of wavelengths emitted from halide lamps differentiates them from medium-pressure mercury arc lamps that emit in narrow wavelength ranges. Approximately 20% of the emission spectrum can be UVA radiation.

LASERS. (See Chapter 239.) Lasers produce intense beams of monochromatic (single wavelength) radiation. The laser operates by exciting molecules to a metastable excited state from which photon emission is stimulated by a subsequent photon incident on the excited molecule. The emitted photon and the stimulating photon are then each capable of stimulating emission of yet other excited molecules, eventually producing an avalanche of photons of the same wavelength, phase, and direction of propagation. Different lasers emit UV, visible, or infrared wavelengths and may operate as either continuous or pulsed sources.

ULTRAVIOLET AND VISIBLE RADIATION DOSIMETRY

To treat patients with the appropriate amount and wavelengths of UV or visible radiation, it is important to become acquainted with how the radiation is quantified and related to the exposure time. The basic unit of EM energy is the joule (J). Power is the rate of energy flow, joules per second (J/s), usually expressed as watts (W). The rate at which the radiant energy is delivered to a surface, such as skin, is expressed as the power delivered per unit area of surface (power/area; W/cm^2). This quantity is called *irradiance*. The total radiant energy delivered per unit area of skin surface over a period of time is called the *exposure dose* or *fluence* and is the product of irradiance and time:

$$\text{Irradiance } (w/cm^2) \times \text{time (s)} = \text{Exposure dose or fluence } (J/cm^2)$$

For most responses to UV and visible radiation, it is the fluence at particular wavelengths that determines the magnitude of the response. The irradiance generally does not affect the response using conventional light sources.

The irradiance delivered by a source as a function of wavelength is called the *spectral irradiance* and is expressed as units of irradiance per nanometer [$(W/cm^2)/nm$]. A spectroradiometer is used to measure the spectral irradiance of a light source. When measuring a light source's irradiance over a given spectral region, a detector weighted to the wavelengths of interest is most useful. For example, a broadband radiometric measurement of wavelengths less than 315 nm provides a rough indication of the erythemally effective wavelengths emitted by a source of UV radiation.

There is, however, no substitute for knowing the full spectral irradiance delivered by a source, as determined by a spectroradiometer. For example, in phototesting, only the wavelengths of interest should be

used. To assess endogenous UVA sensitivity, the UVB portion of a source's emission, if present, must be filtered out so that the more erythemogenic UVB wavelengths do not lead to a falsely lower determination of erythema threshold in the UVA range.

OPTICAL PROPERTIES OF SKIN

When UV and visible radiation strike the skin, part is remitted (reflected and scattered), part is absorbed by chromophores in various layers, and part is transmitted inward to successive layers of cells until the energy of the incident beam has been dissipated (Figs. 90-4 and 90-5). The two major processes limiting the penetration of UV and visible radiation into skin, absorption and scattering, vary with wavelength.[10]

UV wavelengths less than 320 nm are readily absorbed by proteins, DNA, and other components of epidermal cells. Along with scattering, this absorption accounts for the low penetration of these wavelengths into skin (see Fig. 90-4). For example, approximately 10% of 300-nm radiation and 50% of 350-nm radiation reaches the dermal–epidermal junction in fair skin. Between 5% and 10% of incident light is reflected by the outer surface of the stratum corneum. This surface or so-called *specular reflectance* is relatively constant for all visible wavelengths and accounts for the surface appearance of skin, which is especially glossy if the surface is smooth, wet, or oily. In contrast, if the surface is irregular, the light is scattered and the skin appears dull or "rough." Moisturizers applied to the skin reduce this rough appearance by smoothing out the many air–surface interface irregularities and making the skin look shinier.

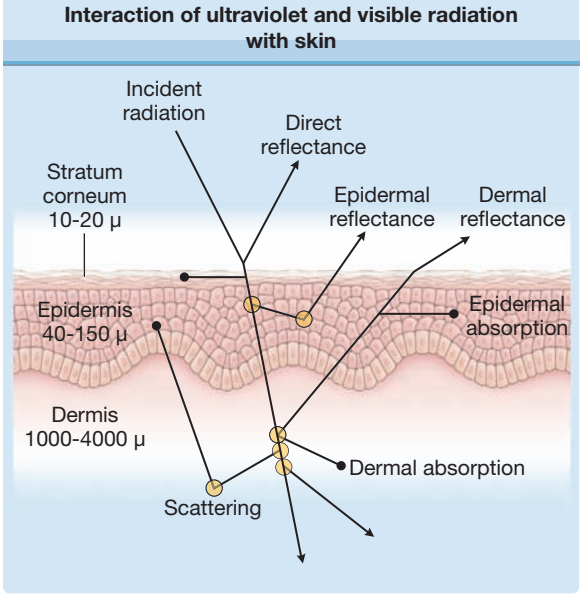

Figure 90-4 The interaction of ultraviolet and visible radiation with skin. The incident radiation is reflected from the surface, scattered (*circles*), and absorbed (*black dots*) as it travels through the skin.

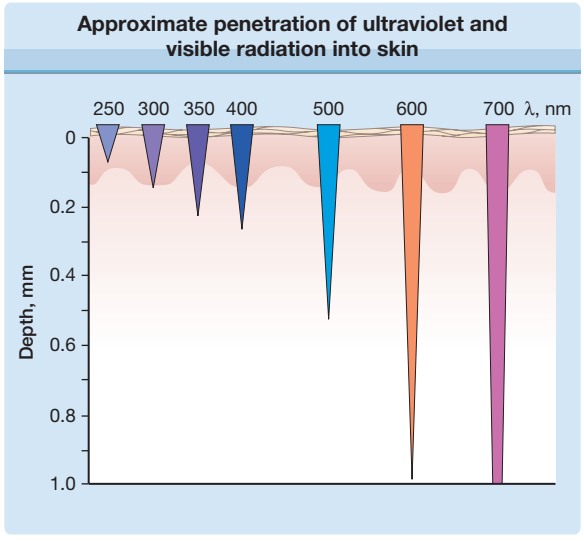

Figure 90-5 Illustration of the approximate penetration of ultraviolet and visible radiation into skin. λ = wavelength.

Scattering includes any process that deflects the path of optical radiation. For example, skin with scales, as in psoriasis, scatters more light than does normal skin. During phototherapy, application of emollients to the psoriatic plaques helps reduce the scattering of UV radiation and allows more of the effective wavelengths to penetrate into the viable tissue.

Melanin, which absorbs relatively uniformly over the visible wavelengths and is normally present only in the epidermis, acts largely as a neutral density filter to diminish remittance from the dermis. The greater overall melanin content in darker skin absorbs more visible light and therefore causes the skin to appear darker as there is less light remitted back to the observer. Blood (hemoglobin) within the dermis absorbs the shorter (blue) visible wavelengths, diminishing these spectral regions, and giving a reddish hue to our perception of the total remittance. Abnormal location and quantity of these or other pigments account for the appearance of the skin in pathologic conditions (e.g., melasma with extra pigment in the epidermis and/or dermis, vitiligo with an absence of epidermal melanin).

ABSORPTION OF ULTRAVIOLET AND VISIBLE RADIATION BY MOLECULES IN SKIN

When a photon is taken up by a chromophore, it is said that absorption has occurred. The specific wavelengths absorbed by each molecule (called an *absorption spectrum*) are characteristic of the structure of the molecule (i.e., the arrangement of the nuclei and electrons). Only radiation that is absorbed by the chromophores can initiate biologic responses.

The absorption spectrum of a compound is a plot of the probability of absorption of photons of a specific wavelength on the *Y*-axis against wavelength on the

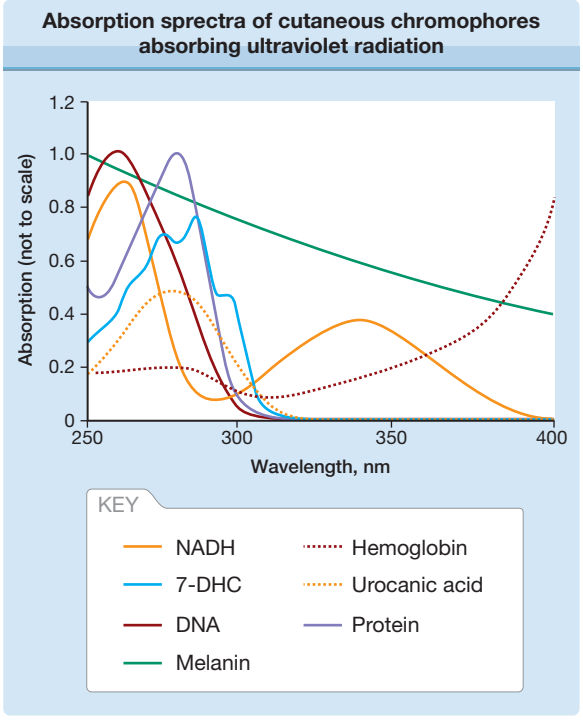

Figure 90-6 Absorption spectra of cutaneous chromophores absorbing ultraviolet radiation. Note that the relative amounts of ultraviolet radiation absorbed by these chromophores in skin depend on the heights of the absorption peaks as shown in this figure, the amount of each chromophore in skin, and the penetration of each wavelength into skin. 7-DHC = 7-dihydrocholesterol; NADH = reduced nicotinamide adenine dinucleotide.

X-axis (Fig. 90-6). The wavelengths that have the highest probability of absorption are called *absorption maxima*, λ_{max}, (e.g., DNA, λ_{max} = 260 nm; porphyrins, λ_{max} = 400–410 nm). Many of the biomolecules that absorb in the UVB spectrum actually have absorption maxima at shorter wavelengths in the UVC range (see Fig. 90-6). These include the purine and pyrimidine bases in DNA and RNA (λ_{max} ~260 nm) and 7-dehydrocholesterol (λ_{max} = 285 nm). Many endogenous cutaneous chromophores absorb UVA or a combination of UVA and visible radiation, including hemoglobin (λ_{max} = 410 nm) and bilirubin (λ_{max} = 450 nm). Melanin absorbs throughout the UV, visible, and near IR spectra without a distinct absorption maximum wavelength. The absorption spectra of few chromophores extend into the IR-A waveband, an exception being cytochrome c oxidase, which is last enzyme in the mitochondrial respiratory electron transport chain.

PHOTOCHEMICAL REACTIONS LEADING TO SKIN RESPONSES

After absorbing the energy of a photon, the chromophore is in an "excited state," which exists for only a very short time before reacting with nearby molecules. The products of these reactions initiate signal transduction processes that lead to the observed responses in skin.

EXCITED STATE MOLECULES

Normally, molecules are in the so-called *ground state* and have a certain distribution of electrons in space around the nuclei of their atoms. For each molecule, a series of electronic states with higher energies and different distributions of electrons also exist; these are called *excited states*. When a molecule in the ground state absorbs the energy of a UV or visible photon, the molecule is promoted to an excited electronic state (Fig. 90-7). According to quantum mechanics, only certain energy gaps are allowed to exist between electronic states. Consequently, a molecule can absorb photons only with certain energies; this results in a unique absorption spectrum for each molecule.

A molecule exists in this first excited state formed for a very brief period. It is called a *singlet excited state* and exists for a few nanoseconds. The molecule may return to the ground state by emitting light (fluorescence) or releasing the energy as heat by a process called *internal conversion* (see Fig. 90-7). Alternatively, the singlet excited state may undergo a chemical reaction to form a photoproduct, or it may convert into another excited state with lower energy, the triplet excited state, by a process called *intersystem crossing* (see Fig. 90-7). Singlet and triplet excited states differ in the spins of a pair of electrons in an orbital. The ground state is almost always a singlet state. The triplet excited state may exist for a longer time (i.e., a few microseconds). It may emit light (phosphorescence), undergo a chemical reaction, or return to the singlet ground state by intersystem crossing (see Fig. 90-7).

These excited state processes are responsible for the effectiveness of light for diagnosis and therapy. For example, fluorescence occurs every time a Wood's light is used. UVA emitted from this lamp causes autofluorescence of dermal collagen fibers. To the examining physician, this fluorescence is viewed through

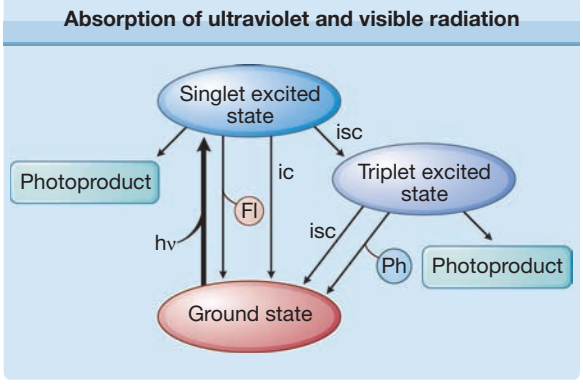

Figure 90-7 Absorption of ultraviolet and visible radiation (hν) by molecules and the dissipation of the absorbed energy by fluorescence (Fl), internal conversion (ic), intersystem crossing (isc), phosphorescence (Ph), and photochemistry to form photoproducts.

the overlying epidermis. Thus, any epidermal lesions such as lentigines tend to have their borders accentuated by contrast because the fluorescence is observed most brightly around the lesion. The heat generated by internal conversion is responsible for the effects of pulsed lasers (see Chapter 239).

PHOTOPRODUCTS

During a photochemical reaction, the excited state molecule is transformed into a new, stable molecule called the *photoproduct*. Photoproducts in DNA are important for UVB-induced responses in skin. The photoproduct molecule may be produced entirely by rearrangement of the bonds in the chromophore, for example, the formation of previtamin D3 from 7-dehydrocholesterol or in DNA of a four-membered ring structure called a *cyclobutyl pyrimidine dimer (CPD)* from adjacent thymines or cytosines. These DNA photoproducts lead to mutations and development of nonmelanoma skin cancers (see Chapter 112). Alternatively, the chromophore may form covalent bonds with another molecule in the cell, for example, the formation of covalent adducts between psoralen and DNA. The phototherapy of diseases such as psoriasis makes use of this photochemical reaction (see Chapter 238). In addition, many skin responses to UV and visible light are initiated when the excited state chromophore transfers its energy to oxygen to form singlet oxygen or transfers an electron to form superoxide anion. These forms of oxygen react with cellular molecules, which often initiates intracellular signal transduction leading to the inflammation seen in sunburn and drug phototoxicity.

Photochemical reactions vary in efficiency. Not every chromophore molecule that absorbs a photon undergoes a photochemical reaction because the excited states may fluoresce or follow other pathways (see Fig. 90-7). The term *quantum yield* indicates the likelihood that one of these processes occurs. For example, the quantum yield for forming a certain photoproduct is:

$$\text{Photoproduct quantum yield} = \frac{\text{Number of photoproduct molecules formed}}{\text{Number of photons absorbed}}$$

PHOTOSENSITIZATION

When certain drugs (e.g., tetracyclines, fluoroquinolones, psoralens) and dyes absorb UV and/or visible radiation, delayed erythema or inflammation is observed (see Chapter 92). This phenomenon is called *photosensitization*, and the dyes and drugs are called *photosensitizers*. Photosensitization requires the presence of oxygen in most cases and the initial photoproducts are reactive oxygen species (ROS). ROS are small molecules and free radicals including singlet oxygen, hydrogen peroxide, superoxide anion and hydroxyl radical. These ROS oxidize unsaturated lipids in membranes, certain amino acids in proteins (histidine, methionine, tryptophan, cysteine), and guanine in nucleic acids. The oxidized products initiate signal transduction processes leading to inflammatory mediators, for example, prostaglandin E_2 (PGE_2) and tumor necrosis factor (TNF)-α, that produce the inflammation observed as erythema.

A photosensitizer molecule in an excited triplet state can transfer its energy to an oxygen molecule, thereby generating the ROS called singlet oxygen ($^1O_2$). Singlet oxygen is relatively long-lived for a singlet state (<4 microseconds) and reacts with other cellular molecules to generate additional ROS. The skin photosensitization produced by PDT drugs and by protoporphyrin IX, the porphyrin that accumulates to abnormally high levels in red blood cells of patients with erythropoietic protoporphyria (EPP), involves initial formation of singlet oxygen. Oxidation of membrane lipids is believed to initiate the signal transduction processes, leading the wheal and flare response observed in EPP photosensitivity. Singlet oxygen is also involved in the phototoxicity mechanisms for some phototoxic drugs. However, the observed skin phototoxicity responses often differ from that seen in EPP photosensitivity, possibly because of the presence of the photosensitizing agents in different tissue locations (e.g., epidermis, dermis, or vasculature). The photosensitizers may also be in different locations in the cells (i.e., nucleus, mitochondria, or cell membranes), which would influence the photoproducts formed and the subsequent cutaneous effect observed. Endogenous UVA-absorbing chromophores generate singlet oxygen in keratinocytes and fibroblasts and in skin.[11]

Endogenous chromophores and some exogenous photosensitizers generate other ROS.[12] For example, hydrogen peroxide and superoxide anion are produced after photosensitized and direct photon damage to mitochondria. The UVB or UVA radiation also activates ROS-producing enzymes such as nicotinamide adenine dinucleotide phosphate (NADPH) oxidase in keratinocytes and fibroblasts.[13,14] The UVA-induced responses in normal skin and in photosensitivity conditions are generally dependent on production of ROS. Recent studies suggest that ROS are important in the development of many UVB-initiated responses. Antioxidants act by quenching (i.e., chemically reacting with and removing) ROS and other free radicals before they can damage cellular molecules.

ACUTE RESPONSES TO UV RADIATION

Sunburn and tanning are the most obvious responses elicited by exposure of skin to a single dose of UV radiation. Many other responses are less visually apparent, but have important physiologic effects including formation of vitamin D3, altered immune responses, production of antimicrobial peptides and disruption of the epidermal barrier function. In addition, the cumulative effect of repetitive exposures gives rise to chronic skin changes including skin cancer development and photoaging. All of these responses result from a complex burst of UV-induced activity in the epidermis and dermis involving cytokines, neuropeptides, prostaglandins, ROS, and altered expression of at least 600 proteins.[11,15–17]

This section centers on three different parts: (1) UV-induced inflammation (sunburn), (2) vitamin D synthesis, and (3) altered immune responses. Two other acute responses to UV, (1) tanning (melanogenesis) and (2) abnormal acute responses to UV, are described in Chapters 72 and 91, respectively.

ACUTE INFLAMMATION—SUNBURN

Erythema is the most visually apparent indicator of UV-induced skin inflammation. Increased blood flow in the superficial and deep vascular plexus is responsible for the appearance of erythema and also may increase skin temperature. Two other classical signs of inflammation, swelling caused by increased vasopermeabilty and pain caused by released mediators on nerve endings, may also occur. Both UVB and UVA radiations elicit inflammation although the initiating photochemistry, cell signaling processes, and biochemical pathway processes involved are not identical. Erythema has been used as the endpoint for measuring the relative effects of different wavelengths in the UVB and UVA, usually expressed as an action spectrum.

ACTION SPECTRA. An action spectrum indicates which wavelengths most effectively produce a skin response. It is used to understand the basic science of a photobiologic as well as a therapeutic response because phototherapy is most efficient when the emission of the lamp matches the action spectrum for the beneficial response. An action spectrum is most accurately plotted as the reciprocal of the number of incident photons required to produce a given effect (*Y*-axis) against wavelength (*X*-axis). Conventionally in dermatology, the reciprocal of the minimum fluence (exposure dose) to produce the response is plotted versus wavelength. In an ideal case, the action spectrum corresponds to the absorption spectrum for the chromophore and can be used to identify the chromophore for a given photobiologic reaction. For example, an action spectrum for wheal formation in a patient with EPP showed a maximum at 400 nm, close to the maximum of protoporphyrin IX, which supports biochemical evidence for this porphyrin as the chromophore.[18] Another example involves the action spectrum for the clearance of psoriasis, which was found to peak around 313 nm.[3] This insight has led to the development of so-called "narrowband" UVB sources with peak output at 311 nm, and the use of the excimer 308-nm laser for the efficacious treatment of psoriasis. Absorption in this range suggests that DNA is a punitive chromophore, but given the different depths of penetration of the two wavelengths into skin and the varying clinical responses, it is possible the relevant chromophore for the therapeutic effect of UVB on psoriasis is not exclusively DNA. Moreover, in some cases, the action spectrum for a response may not directly correlate to the absorption spectrum of the responsible chromophore because the wavelengths actually reaching the chromophore are distorted by absorption and scattering of light by tissue above the level of the chromophore.

The action spectrum for erythema indicates that the most effective wavelengths present in sunlight are in the UVB range.[1,19] UVA is roughly 1,000-fold less effective than UVB. The time in the sun required to produce sunburn is strongly influenced by many factors including skin pigmentation, season, geographical location, cloud cover and time of day. The relative contributions of UVB and UVA radiation from the sun to a sunburn response are not constant because the UVB to UVA ratio in the solar spectrum varies with the time of day, the season and other factors.

UVB-INDUCED INFLAMMATION

Erythema is usually apparent 3–5 hours after UVB exposure, reaches a maximum intensity at 12–24 hours and generally resolves by 72 hours. However, when the UVB dose is high, erythema appears sooner, reaches a maximum at a later time and is more persistent, and the response is more likely to include pain or swelling. The minimal erythema dose or MED is the fluence that elicits minimal erythema at 24 hours. The UVB MED for fair skin (Fitzpatrick type I–II) using fluorescent UVB bulbs is about 30 mJ/cm^2 (300 J/m^2). Many biochemical and cellular events occur before the erythema is evident including increased blood flow, endothelial cell activation and elevated inflammatory mediator levels.[20,21]

HISTOLOGY—UVB. The extent and time course of the histological changes observed after UVB varies with the magnitude of the exposure dose.[22,23] Dyskeratotic cells, so-called "sunburn cells," may appear in the epidermis as soon as 30 minutes after a 3 MED exposure. Sunburn cells are apoptotic keratinocytes that show condensed nuclear chromatin and eosinophilic cytoplasm. They increase in number with a maximum at about 24 hours and eventually (by 72 hours) form a band at the stratum corneum. Intercellular edema occurs early and may persist to 72 hours.

Dermal changes include early (30 minutes) and persistent (up to 72 hours) endothelial cell swelling, perivenular edema and degranulated mast cells.[22] Neutrophils appear perivascularly shortly after UVB and the influx peaks at about 14 hours. A later mononuclear (macrophage) infiltrate persistes at least 48 hours.

MECHANISM—UVB. Absorption of UVB photons by chromophores in skin leads to the production of inflammatory mediators and cytokines that characterize the sunburn response. The action spectrum for erythema closely correlates with the absorption spectrum of DNA suggesting that DNA is one of the important chromophores and that DNA photoproducts initiate at least partially the biochemical pathways leading to UV-induced inflammation.[1,24] A role for DNA photoproducts is further supported by the observation that xeroderma pigmentosum patients, who have low ability to repair DNA, demonstrate prolonged UVB-induced erythema that can be reduced by treatment with a DNA repair enzyme.[25] The biochemical pathways linking the DNA photoproducts with inflammatory mediators are still unclear. However, an action

spectrum for TNF-α followed the DNA absorption spectrum suggesting formation of this proinflammatory cytokine is initiated by DNA photoproducts.[26]

In addition to DNA, other UVB-absorbing chromophores initiate formation of inflammatory mediators.[27,28] A UVB-induced photoproduct of tryptophan initiates signaling events leading to expression of cyclooxygenase-2 (COX-2), which catalyzes formation of prostaglandins, which are associated with erythema.[29] UVB exposure rapidly generates ROS that oxidize membrane lipids leading to proinflammatory cytokines.[27,28,30] The role of ROS is supported by the ability of topical antioxidants to modulate UVB-induced erythema.[12,31]

INFLAMMATORY MEDIATORS—UVB. Prostaglandins and nitric oxide appear to be the major mediators for UVB-induced inflammation. Early studies showed that PGE_2 levels in suction blister fluid increased before the appearance of erythema and continued to rise at least until 24 hours.[22] More recently, numerous proinflammatory and anti-inflammatory eicosanoids were identified in suction blister fluid over a 72 hours period after UVB exposure.[15] Prostaglandins with vasodilatation activity (PGE_2, $PGF_{2\alpha}$, and PGE_3) appeared at 24–48 hours, and the species with leukocyte chemoattractant activity [11-, 12-, and 8-monohydroxy-eicosatetraenoic acid (HETE)] were present to later times (4–72 hours). Interestingly, an anti-inflammatory species, 15-HETE, was maximally present at 72 hours. The first UVB-induced step in the formation of these eicosanoids is a rapid (<30 minutes) increase in the activity of phospholipase A_2, which liberates arachidonic acid from cell membranes. Arachidonic acid is then acted on by cyclooxygenases and lipoxygenases to produce the eicosanoids. Inhibiting cyclooxygenases with indomethacin applied after UVB suppressed erythema.[21,32]

A role for nitric oxide in UVB-induced inflammation was established using NG-nitro-L-arginine methyl ester (L-NAME), a specific inhibitor of nitric oxide synthase, which suppressed erythema.[21,33] Interestingly, L-NAME effectively suppressed erythema even when injected 48 hours after UVB indicating that nitric oxide was continuously synthesized. Histamine, however, which can trigger an inflammatory response, does not appear to be a major contributor to the UVB-induced sunburn[34] even though it rises after UVB.[22]

Several proinflammatory cytokines, including TNF-α, IL-1, IL-6, and IL-8, are elevated after UVB exposure of human skin.[35–38] The IL-1-like activity was detected by 1 hour after UVB[36] and TNF-α was elevated by 4 hours, maximal at 15 hours, and then declined.[35] Cytokines may play several roles in UVB-induced inflammation including recruiting leukocytes from the vasculature by acting as chemoattractants and as inducers of endothelial cell adhesion molecules that facilitate movement of cells across the capillary walls.

UVA-INDUCED INFLAMMATION

Sunburn elicited by UVA has been much less thoroughly examined than UVB-induced erythema even though the amount of UVA in sunlight vastly exceeds (~19-fold) the UVB portion. UVB and UVA contribute significantly to the effects of chronic sun (and tanning bed) exposure. Erythema is usually present at the end of the UVA exposure using clinical or laboratory light sources. This immediate response may fade or merge into a delayed erythema with a maximum between 6 and 15 hours depending on the fluence, irradiance and spectrum of the light source.[20,39] The UVA MED in fair skin is generally 30–75 J/cm^2.[20,23,40]

HISTOLOGY—UVA. In contrast to UVB-induced erythema, the major histological changes after UVA exposure occur in the dermis. Most notably, the sunburn cells that characterize UVB-exposed epidermis are not apparent after UVA.[23,39] Epidermal intercellular edema was present for at least 48 hours, and LCs decreased over 48 hours. In the dermis, neutrophils peaked at 3 hours, earlier than after UVB, and remained present for at least 48 hours. A lymphocytic infiltrate was also apparent throughout the dermis at all times after irradiation.[39]

MECHANISMS—UVA. The differences in time course and histology between UVB and UVA-induced responses suggest that different mechanisms are involved. The erythema action spectrum supports this concept; the slope of the curve decreases at wavelengths longer than about 330 nm and a small shoulder is seen at about 360 nm.[1,19] In addition, UVA-induced erythema was suppressed when the skin oxygen level was reduced whereas the UVB erythema was not affected.[40] Although several UVA chromophores are present in skin (Fig. 90-6), the identity of the light absorber for UVA sunburn is still unidentified.

ROS play a significant role in UVA-induced inflammation, as suggested by the oxygen dependence of UVA erythema.[40] Singlet oxygen and other ROS are detected by spectroscopy when skin is exposed to UVA.[11,41] These reactive species are responsible for activating phospholipase A_2, which releases arachidonic acid from membrane lipids and makes it available for enzymatic conversion into proinflammatory eicosanoids. ROS also initiate intracellular signal transduction pathways that activate the synthesis of proinflammatory cytokines. In addition, UVA has been shown to liberate nitric oxide very rapidly from storage forms in skin.[42]

INFLAMMATORY MEDIATORS—UVA. Exposure of skin to UVA increased the levels of proinflammatory prostaglandins as measured in suction blister fluid.[43] A study in keratinocytes indicated that increased prostaglandin levels were caused by UVA-induced activation of PLA_2.[44] In vivo UVA stimulated an increase in the levels of PGD_2, PGE_2, and 6-keto-$PGF_{1\alpha}$ at 5–9 hours, which returned to normal by 24 hours.[43] Histamine also increased by 9–15 hours and returned to baseline by 24 hours. UVB, but not UVA, stimulated production of TNF-α from keratinocytes and in human skin.[45,46]

VITAMIN D PHOTOBIOLOGY

In 1928, Adolf Windaus garnered the Nobel prize in chemistry for his studies on the constitution of sterols and their connection with vitamins.[47] The fat-soluble substance under his investigation was vitamin D; however, the story of vitamin D and rickets, its deficiency, actually dates back to antiquity based on careful study of writings and paintings. Conducting dietary studies with cod-liver oil on dogs in 1919, Mellanby first concluded that rickets stems from the absence of an "accessory food factor."[48] Three years later McCollum et al found that heated, oxidized cod-liver oil could cure rickets in rats.[49] They named the new factor vitamin D because it was the fourth vitamin discovered.

Concurrently, an entirely different remedy for rickets appeared in the form of UV light. By the late nineteenth and early twentieth centuries, lack of fresh air and sunshine or lack of exercise was implicated in the etiology or rickets.[50] In 1921, Hess and Unger observed that seasonal incidence of rickets seemed to parallel seasonal variations of sunlight.[51] Chick independently observed that sunlight would cure rickets just as well as cod-liver oil.[52] In 1919, Huldschinsky reasoned that artificial sunlight might well do the same as natural sunlight.[53] Controlling for dietary intake and ambient UV exposure, he irradiated severely rachitic children with a UV-emitting quartz-mercury lamp and observed remarkable clinical and radiographic improvement, including fresh calcium deposition.

From cottonseed oil in 1925, Hess and his team isolated sitosterol, which was inactive against rickets in rats until it was irradiated by UV light.[54] The discovery that irradiation of food, in particular of whole milk, could impart antirachitic potency led to tremendous advances in public health, producing a rapid decline in the prevalence of rickets in children. With amazing foresight, Hess hypothesized that cholesterol in skin is activated by UV-irradiation and rendered antirachitic. The complete photochemical and thermal reaction steps in the vitamin D pathway were finally elucidated in 1955 by Velluz.[55] The exact sequence of steps leading to the cutaneous photoproduction of cholecalciferol was reported in a comprehensive paper by Holick in 1980.[56]

FUNCTIONS OF VITAMIN D. Vitamin D regulates calcium and phosphorus metabolism.[56] Its major role is to increase the flow of calcium into the bloodstream, by promoting absorption of calcium and phosphorus from the intestines, and reabsorption of calcium in the kidneys, thus enabling normal mineralization of bone and muscle function. It affects serum alkaline phosphatase level. Vitamin D also inhibits the proliferation of T-cells and the maturation of dendritic cells (DCs) along with affecting keratinocyte function.

Vitamin D deficiency results in impaired bone mineralization that leads to bone softening diseases, rickets in children and osteomalacia in adults, and possibly contributes to osteoporosis.[57] Deficiency can arise from inadequate intake coupled with inadequate sunlight exposure, disorders that limit its absorption, or conditions that impair conversion of vitamin D into active metabolites, such as liver or kidney diseases. Most vulnerable to low vitamin D levels are elders, individuals living at high latitudes with long winters, obese persons, and all individuals with dark skin pigmentation living at high latitudes.[58–65]

Toxicity from excess vitamin D may manifest itself as hypercalciuria or hypercalcemia, the latter causing muscle weakness, apathy, headache, confusion, anorexia, irritability, nausea, vomiting, and bone pain, and potentially leading to complications such as kidney stones and kidney failure. Chronic toxicity effects include the aforementioned symptoms along with constipation, anorexia, abdominal cramps, polydipsia, polyuria, backache, and hyperlipidemia. Findings may also include calcinosis, followed by hypertension and cardiac arrhythmias (due to shortened refractory period). Although information about the effects of high doses of vitamin D is limited, 10,000 IU daily is a safe upper limit for adult intake.[66] Chronic toxic dose is more than 50,000 IU/day in adults.

There are two major sources of vitamin D, one is diet and the other is skin. When obtained exogenously from food or supplements, vitamin D is absorbed in the small intestine. Natural food sources rich in vitamin D include certain oily fish such as salmon, mackerel, tuna, herring, catfish, cod, sardines and eel, butter, margarine, yogurt, liver, liver oil, and egg yolks, but at least in the United States, most dietary vitamin D comes from the fortification of food like cereal, milk, and orange juice.[67] Fortified milk, for example, typically provides 100 IU per 8 oz glass, or only a quarter of the estimated adequate daily intake for adults. To get the recommended daily allowance, most Americans have to take supplemental vitamin D either alone, or with calcium or in a multivitamin.

BIOCHEMICAL PATHWAY. (Fig. 90-8.) As a result of UVB exposure on the skin, provitamin D3 (7-dehydrocholesterol, a precursor of cholesterol) is rapidly converted to previtamin D3, which spontaneously isomerizes to vitamin D3, entering the circulation on a binding protein and joining dietary D2 (or ergocalciferol) and D3 (cholecalciferol) absorbed from the gut.[56] Once reaching the liver, these undergo passive hydroxylation in the endoplasmic reticulum of the hepatocytes, a process that requires NADPH, O_2 and Mg^{2+}. The product 25-hydroxyvitamin D_3 [25(OH)D_3 (calcidiol)] is stored in the hepatocytes until it is needed when it can be released into the plasma to make its way to the proximal tubules of the kidneys, where it is acted upon by 25(OH)D-1-α-hydroxylase, an enzyme whose activity is increased by parathyroid hormone and low PO_4^{2-}. People with kidney disease may not be able to convert vitamin D to its active form. Following this conversion, 1,25-hydroxyvitamin D_3 [1,25$(OH)_2D_3$ (calcitriol)] is released into the circulation, and by binding to a carrier protein in the plasma, vitamin D-binding protein (VDBP), it is transported to various target organs.

ACTION SPECTRUM FOR VITAMIN D FORMATION IN SKIN. Action spectra studies show that wavelengths the most effective at bringing about the

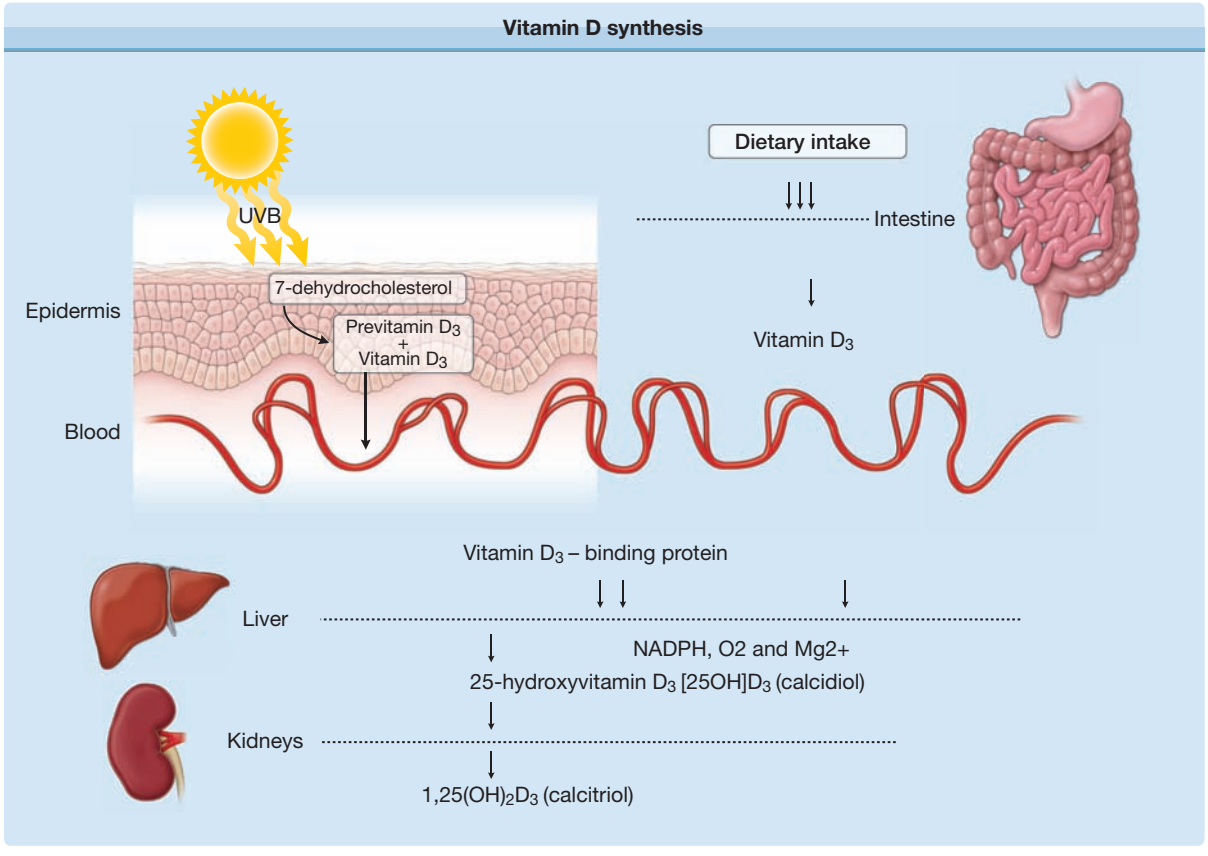

Figure 90-8 Vitamin D synthesis: Vitamin D is synthesized in the epidermis in response to UVB and is also absorbed from the intestine. It is then transported on a binding protein to the liver, where it undergoes 25-hydroxylation. This metabolite calcidiol is the major circulating form of Vitamin D. The final step occurs mainly in the proximal tubules of the kidneys, where it is acted upon by 25(OH)D-1-α-hydroxylase, an enzyme whose activity is increased by parathyroid hormone and low PO_4^{2-}. This l-α-hydroxylation is also believed to occur peripherally such as in the skin, where Vitamin D promotes differentiation.

photosynthesis of cutaneous vitamin D lie in the range of 295 nm to 315 nm, which ironically are some of the same wavelengths most responsible for photocarcinogenesis.[68] Optimal synthesis occurs in a very narrow band of UVB spectra between 295–300 nm with peak isomerization at 297 nm.[68,69] With a UV Index of at least 3, which occurs daily in the tropics and almost never at high latitudes, adequate amounts of vitamin D_3 can be made in the skin after 10–15 minutes of sun exposure at least two times per week to the face, arms, hands, or back without sunscreen. In Boston, sunlight exposure from November through February is inadequate to result in significant cutaneous vitamin D production.[65] The available flux of UVB for the synthesis of vitamin D depends on all the factors that determine the UV Index, including time of day, cloud cover, smog, shade, reflection from nearby water, sand or snow, latitude, altitude, and season of the year. Of course, individual factors such as age (vitamin D production decreases when older[70]), body mass index, clothing worn, amount of skin exposed also have an effect.[71] Individuals with higher skin melanin content require more time in sunlight to produce the same amount of vitamin D as individuals with lower melanin content.

According to Holick, human beings make at least 10,000–25,000 units of vitamin D upon full body exposure to the sun at one minimal erythemal dose.[72,73] Vitamin D production in the skin occurs within minutes and is already maximized before your skin turns pink. Exposure to sunlight for extended periods of time does not normally cause vitamin D toxicity. Within 20 minutes of sun exposure in fair-skinned individuals (1–3 hours for pigmented skin) the concentration of vitamin D precursors produced in the skin reaches an equilibrium, and excess vitamin D simply degrades as fast as it is generated.

OPTIMAL LEVELS OF VITAMIN D. Ninety years after its discovery, vitamin D has become a subject of intense interest to dermatologists in part due to the fact that its deficiency is being increasingly recognized and that its deficiency may well have important health consequences beyond those related to bone health. As dermatologists counsel patients to employ sunscreens in order to minimize subsequent risk of skin cancer, they should be aware that sun protection recommendations may impede the efficacy of vitamin D photosynthesis in the skin.[74] Several studies have all shown that most people, even those living in year-round sunny locations such as Florida and Australia have low vitamin D levels.[75–79] In addition, other studies have demonstrated that minimal or even moderate UVB exposures may

not be sufficient to maintain 25-hydroxy vitamin D [25(OH)D] levels at the now widely quoted "sufficient level" of 30 ng/mL.[75,80] Consequently, relying solely on ambient exposure appears not to be sufficient as a means to obtain adequate vitamin D. Nearly all randomized trials that have proven the beneficial effects of increased vitamin D have achieved that increase by oral supplementation. It seems most likely that skin cancer prevention recommendations in the form of sunscreen use and judicious use of protective clothing did not cause the problem of low vitamin D levels and equally unlikely that urging unprotected ambient exposure will not fully solve this year-round problem either unless dietary vitamin D supplementation is recommended.

Low levels of vitamin D are clearly associated with falls and fractures in the elderly.[81–86] As to whether vitamin D supplementation can reduce these complications, there is controversy with reports showing a benefit while others do not. Capturing more attention as of late is the mounting evidence that vitamin D plays a role in preventing colorectal cancer and to a lesser extent cancers of the breast and prostate.[87–92] Other malignancies have been associated with vitamin D insufficiency in observational studies. Moreover, multiple other health problems have been shown to be inversely correlated in frequency with vitamin D levels in some studies. Examples include diabetes mellitus,[93,94] multiple sclerosis,[95] hypertension,[96] myocardial infarction,[97] cardiovascular,[98] seasonal affective disorder,[99] chronic pain,[100] peripheral artery disease,[101] cognitive impairment, which includes memory loss,[102] and infections,[103,104] among others. There is an association between low vitamin D levels and Parkinson's disease.[105] Current evidence is simply insufficient to infer a causal relationship in any of these conditions.

What is an optimal level of vitamin D? Risk of cardiovascular events in the Framingham Offspring cohort study suggested levels as low as about 20–25 ng/mL.[106] The national representative National Health and Nutrition Examination Survey data suggested that overall mortality was minimized at levels of about 30–40 ng/mL.[101] Given concerns about potential confounding factors, we cannot be certain about these estimates of optimal levels, but the preponderance of published evidence would support values of 25–40 ng/mL.[107] Thirty ng/mL (75 nmol/L) is a common estimate given current knowledge.[108]

Clinicians can measure individual levels and recommend supplementation accordingly. Common guidelines include 400–1,000 IU daily with or without calcium or in a multivitamin, 10,000 IU weekly or every 10 days, or 50,000 IU every month. After correction of their vitamin D status with oral vitamin D, patients should have a repeat test of their 25(OH)D level to confirm that they are in the normal range. Such measurement is necessary since there is great variation in the increment of 25(OH)D achieved from a given dose of vitamin D supplement. If a patient remains persistently low, despite several attempts at correction with oral vitamin D, there may be malabsorption and referral to a gastroenterologist is in order. A trial of UVB light therapy may be considered to improve vitamin D status. For patients with 25(OH)D levels less than 15 ng/mL, one usually prescribes oral supplements of 50,000 IU vitamin D weekly for 8 weeks and then switches to standard maintenance doses. Efficacy of vitamin D supplementation is dependent on body mass index (BMI).[57] Overweight and obese patients with hypovitaminosis D require higher doses of vitamin D to achieve vitamin D repletion compared to individuals with normal body weight.

In short, we can conclude that vitamin D supplementation appears to enhance musculoskeletal health and may possibly reduce mortality in some groups. We have evidence that vitamin D may have an influence on cancer, cardiovascular disease, autoimmune disease, and infection, but this evidence, although suggestive, is quite variable in strength and does not allow the conclusion that any of these associations are proven. These are subjects of ongoing investigation.

PHOTOIMMUNOLOGY

Skin cancer is caused largely by direct damage to DNA, leading to specific gene mutations. However, for the development of clinically apparent skin cancer, a second UVB-induced mechanism is required, namely, UVB-induced immunosuppression.[109,110] The connection between sun exposure and skin cancer was realized first in the beginning of the last century when physicians observed skin tumors that grew preferentially at sites that had been extensively sun exposed. This was followed in the 1970s by a seminal study by Kripke,[111] who discovered a connection between immunosuppression and photocarcinogenesis. In a series of experiments, she demonstrated that UV-induced tumors, which had been transplanted onto syngeneic recipient mice, were rejected if the recipient mice had not been exposed to UVB. This result implies that UV-induced tumors have a highly antigenic phenotype[111] and can be rejected by a functioning immune system. Treatment with known immunosuppressive drugs, or—this was the novel finding—with low doses of UVB, led to failure of tumor rejection.[112,113] Both aspects (i.e., the strong antigenicity of UV-induced tumors and the immunosuppression by UVB) have triggered vigorous research activities in the field now termed *photoimmunology*. Numerous studies tried to clarify the cellular and molecular mechanisms.[114] These have turned out to be highly complex (see Fig. 90-9). Results sometimes appear contradictory, likely due to use of various experimental approaches and model systems.

MODEL SYSTEMS FOR ULTRAVIOLET B-INDUCED IMMUNOSUPPRESSION

The standard model for studying UVB-induced immunosuppression is the delayed-type hypersensitivity (DTH) to antigens and the contact hypersensitivity reaction (CHS). The ability of UVB irradiation to block either induction or elicitation of allergic sensitization can then be quantified; typically a hapten such as dinitrofluorobenzene or oxazolone is applied to the skin as the stimulus and intensity of the subsequent immune response is measured as tissue swelling. DTH responses have become the model of choice to study

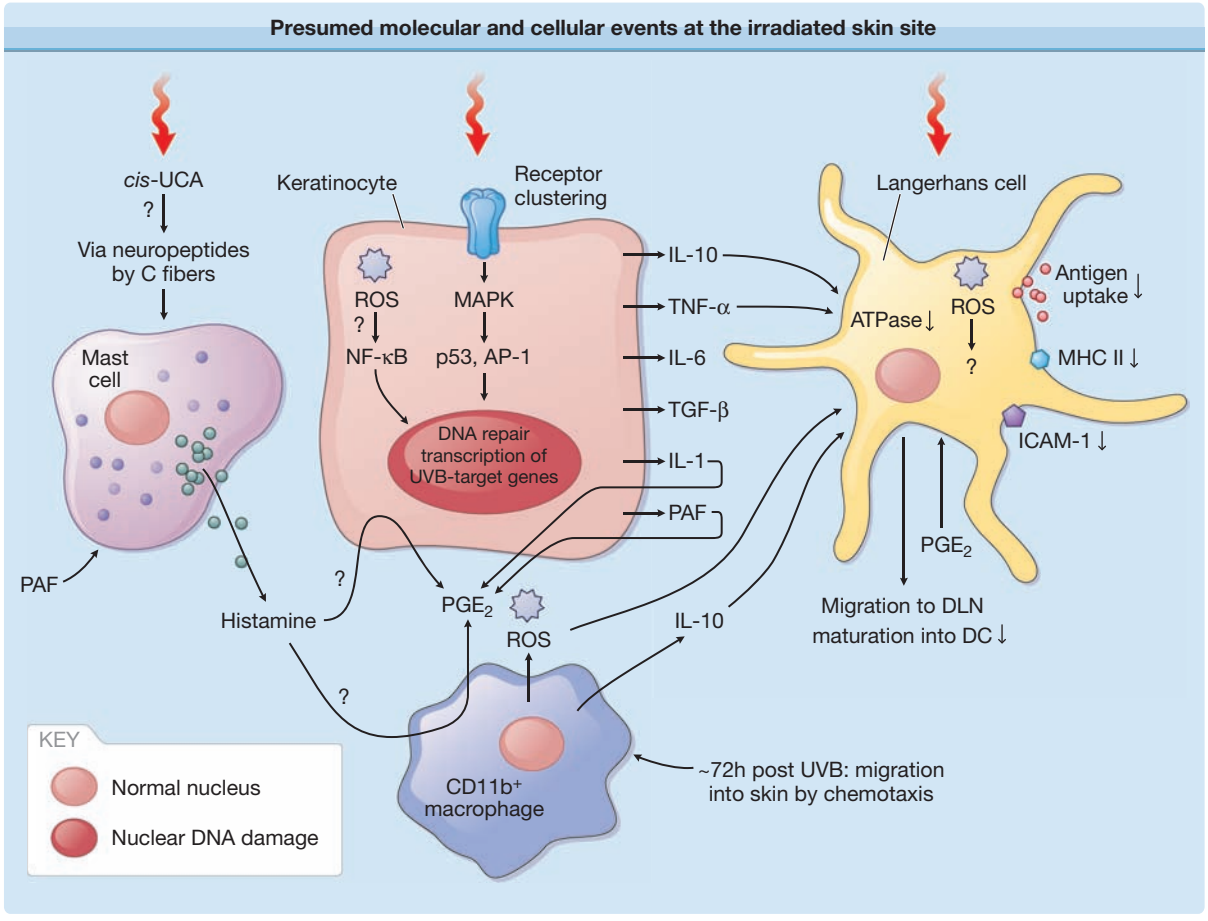

Figure 90-9 Ultraviolet B (UVB) radiation-induced immunosuppression: Illustration of the presumed molecular and cellular events at the irradiated skin site. ATPase = adenosine triphosphatase; DC = dendritic cell; DLN = draining lymph node; IL = interleukin; ICAM = intercellular adhesion molecule; MAPK = mitogen-activated protein kinase; MHC = major histocompatibility complex; NF-κB = nuclear factor κB; PAF = platelet-activating factor; PGE_2 = prostaglandin E_2; ROS = reactive oxygen species; TGF = transforming growth factor; TNF = tumor necrosis factor; UCA = urocanic acid.

the immunosuppressive effects of UVB radiation, as the tumor-associated antigens of UVB-induced tumors are only poorly characterized and testing DTH responses is less time-consuming and less laborious than examining photocarcinogenesis. UVB radiation has also been shown to affect immune responses involved in the pathogenesis of viral, parasitic, fungal, and bacterial infections. UVB-mediated immunosuppression is of two types: (1) local immunosuppression in which the immune response to antigens applied at the irradiated site is abrogated, and (2) systemic immunosuppression in which the immune response to antigens applied to unexposed sites is impaired (Fig. 90-10).[115] However, some mice are more susceptible to UVB-induced immunosuppression than others, with the genetic loci for lipopolysaccharide, *Lps*, and tumor necrosis factor, *Tnf*, strongly influencing the response.[116]

MOLECULAR TARGETS IN PHOTOIMMUNOSUPPRESSION

DNA is a chromophore for UVB radiation and can be a direct target (see Fig. 90-6). UVB radiation generates a variety of photoproducts, most commonly CPDs[6–4] and photoproducts. Pyrimidine dimer formation is a direct cause of UV-induced immunosuppression (Fig. 90-9). The cells of the opossum *Monodelphis domestica* contain endogenous photoreactivating enzymes, which are capable of repairing CPDs, and UVB does not induce immunosuppression in these animals on exposure to photoreactivating light immediately after irradiation.[117] Also in mice, a correlation between CPDs and UVB-induced systemic immunosuppression exists.[118]

UVB irradiation leads to CPDs in antigen-presenting cells (APCs) and impairment of their antigen-presenting capacity. The damage persists for several days, and the damaged cells migrate from the skin to lymph nodes. Treatment at the site of UVB irradiation with liposomes containing the DNA repair enzyme T4 endonuclease V prevents the impairment in antigen presentation.[119] The role of DNA damage in UVB-induced immunosuppression was also confirmed in human skin, in which topical application of photolyase-containing liposomes to UVB-exposed sites prevents UVB-induced immunosuppression.[120]

In addition to direct DNA damage, the generation of ROS is likely to be involved in photoimmunosuppression (see Fig. 90-9). Accordingly, topical application of a polyphenolic fraction isolated from green tea before

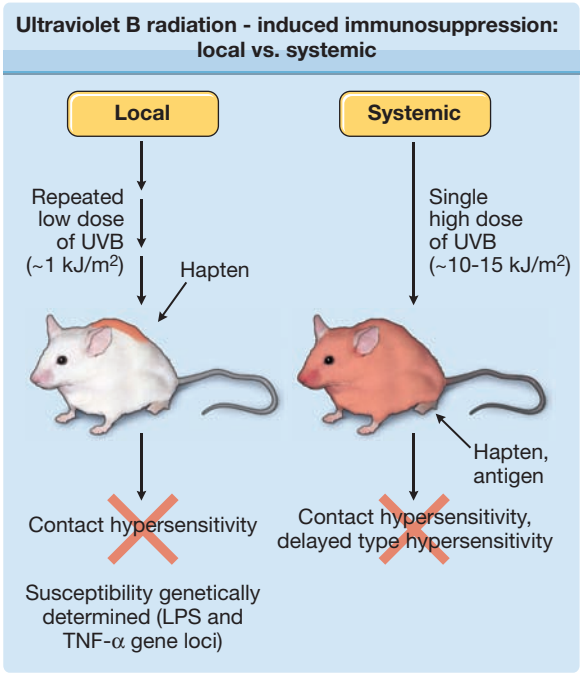

Figure 90-10 Ultraviolet B (UVB) radiation-induced immunosuppression: local versus systemic. TNF = tumor necrosis factor.

and after UVB irradiation to mouse skin protects against UV-induced immunosuppression,[121] an effect most likely mediated by the antioxidant epigallocatechin-3-gallate, the component of extract that has the ability to reduce oxidative stress, inflammatory responses, and skin cancer. It should be noted that such secondary plant metabolites affect cell signaling, however, so that protection against UVB-induced events may not exclusively be explained by antioxidant effects.

The cell membrane of immunocompetent skin cells is another target for UV radiation. An important function of the cell membrane is to transfer signals from outside into the cell via membrane receptors. UVB exposure leads to clustering and internalization of cell surface receptors for epidermal growth factor, TNF, and IL-1 in the absence of the respective ligands. Clustering results in strong activation of stress-induced c-Jun NH_2-terminal kinases, which are members of the mitogen-activated protein kinase family[122] (see Fig. 90-9). Conceivably, such aberrant receptor clustering may subvert signaling pathways normally used by growth factors and cytokines, eventually contributing to the immunological response. The chromophore for these UVB-induced membrane alterations is cytoplasmic tryptophan. The resulting tryptophan photoproduct(s) bind to the transcription factor arylhydrocarbon receptor (AhR), which in its inactive form is part of a cytoplasmic complex including c-src and the heat shock protein Hsp90. Upon binding of the tryptophan photoproduct to the AhR, the complex dissociates and the AhR translocates into the nucleus whereas c-src translocates to the cell membrane where it subsequently causes the previously mentioned cell membrane/surface receptor activation.[29]

UVB radiation can lead to lipid peroxidation, including cell membrane lipids. Phosphatidylcholine, an important membrane lipid, can be oxidized to platelet-activating factor(PAF)-like lipids that bind to PAF receptors and activate cytokine synthesis. A role of UVB-induced PAF formation in photoimmunosuppression is suggested by the observation that comparable immunosuppression can be induced in mice when they are irradiated with UVB, injected with carbamyl-PAF, or injected with phosphatidylcholine that had been exposed to UVB under atmospheric oxygen. The immunosuppressive properties of all three treatments were equally blocked by specific PAF receptor antagonists, indicating that UVB-induced PAF-like lipids can trigger the PAF receptor in a way similar to PAF. In turn, PAF receptor activation stimulates a variety of downstream effects, including the activation of mitogen-activated protein kinase pathway and synthesis of immunosuppressive cytokines (see Fig. 90-9).[123] Interestingly, UVB radiation-induced immunosuppression as well as formation of PAF were enhanced in mice, which were unable to take up the osmolyte taurine. Thus, similar to nucelotide excision repair, taurine uptake is critically involved in protection of the skin against UVB radiation-induced immunosuppression.[124]

An extracellular chromophore that mediates UVB-induced immunosuppression is UCA (see Fig. 90-6).[125] UV radiation isomerizes *trans*-UCA to *cis*-UCA dose-dependently until a balanced photostationary state is reached. A number of independent studies confirmed the importance for *cis*-UCA in UVB-induced immunosuppression, although the exact mechanism of action is not clear at present.

CELLULAR EVENTS INVOLVED IN PHOTOIMMUNOSUPPRESSION

UVB radiation of keratinocytes alters their expression of surface molecules and induces the synthesis and secretion of a whole set of immunomodulatory soluble factors, including IL-1, IL-6, IL-8, TNF-α, and PGE_2 (see Fig. 90-9).[126] Evidence for keratinocyte-derived soluble factors with immunosuppressive function came from experiments showing that either serum factors from UVB-exposed mice or supernatants from UVB-irradiated murine epidermal cells suppressed hypersensitivity reactions in mice. Subsequently, it was found that TNF-α and IL-10, two potent immunosuppressive cytokines, are produced by UVB-irradiated keratinocytes as well.[125,128] IL-10 is also released by $CD11b^+$ macrophages in human skin.[129] Injection of TNF-α mimics UVB-induced alterations on Langerhans cells (LCs). The administration of a neutralizing antibody to TNF-α before irradiation abrogates partially UVB-induced accumulation of DCs in draining lymph nodes (DLNs) and suppression of contact hypersensitivity. The release of TNF-α is of special importance for local immunosuppression, and, as mentioned above, the *Tnfa* gene locus contributes to UVB susceptibility.

IL-10 is a T-helper cell type 2 (Th2) cytokine and abrogates the production of Th1 cytokines, in particular, interferon-γ (IFN-γ). UVB-induced IL-10 production

by keratinocytes in murine or macrophages in human skin[130] shifts the immune response from a Th1 to a Th2 type. This can explain why Th1-mediated cellular immune reactions are impaired by UV radiation.

The interactions between the different cytokines are not fully understood, but IL-10 certainly is a major player. For instance, anti-IL-10 antibodies neutralize the suppressive effects of supernatants from UVB-irradiated keratinocytes on DTH in mice.[127] The main mechanism of IL-10 is probably inhibiting the antigen-presenting capacity of LCs. In parallel, UV-exposed keratinocytes release PAF and PAF-like lipids, which trigger the PAF receptor, as described in Section "Molecular Targets in Photoimmunosuppression."[29] Presumably, PAF and its receptor enhance the production of COX-2, PGE_2, IL-4, and IL-10. IL-10 production can be reversed by IL-12. Incidentally, IL-12 can restore UV-impaired CHS.[130] Injection of mice with IL-12 after UVB exposure prevented UVB-induced immunosuppression and suppressed partially UVB-induced tolerance obtained by resensitization 14 days after the UV irradiation. This IL-12 effect is most likely linked to the capacity of this cytokine to enhance the repair of UVB radiation-induced DNA photoproducts, which form the molecular basis for IL-10 production by irradiated keratinocytes.

CELLULAR MEDIATORS OF PHOTOIMMUNOSUPPRESSION: LANGERHANS CELLS, MACROPHAGES, AND T CELLS

LCs, 2%–5% of epidermal cells, are a DC subset that originates from bone marrow precursors and populates the epidermis. They are the "professional" skin-specific APCs and ingest antigen locally in the skin, but lack costimulatory capacity. After antigen uptake, LCs migrate to the DLN, where they mature to potent stimulators for antigen-specific T cells, expressing high levels of major histocompatibility complex molecules and costimulatory molecules B7.1 and B7.2 and intercellular adhesion molecule-1 on their cell surface (see Chapter 10).

In the 1980s, it was demonstrated that epidermal LCs play a pivotal role in the induction and regulation of CHS reactions. LC density is an important factor for the induction of CHS responses, and UV radiation leads to the disappearance of LC from irradiated sites.[131] In these studies, mice were sensitized with the hapten dinitrofluorobenzene either on skin with typical amounts of LC or on LC-deficient skin. A significantly impaired CHS response was observed when the mice were sensitized on LC-deficient skin. The capacity to deplete LCs temporarily from the skin appears to be an important feature of UVB irradiation. Moreover, UV exposure results in reduced surface expression of costimulatory molecules Ia, B7.1, B7.2, and intercellular adhesion molecule-1 (see Fig. 90-9).[132,133] The depletion of these molecules might account for or contribute to immunosuppression. The loss of LCs in the skin is accompanied by an increase in DCs in the DLN. [134] Fluorescein isothiocyanate+ Ia+ CPD+ cells in the DLNs were found after painting the skin with fluorescein isothiocyanate and irradiating subsequently with UV. This demonstrates that LCs indeed leave the skin after UV exposure. UVB possibly induces LC migration in the absence of exogenous antigen, although the migratory effect is enhanced by sensitization with antigen. The ultimate fate of chronically irradiated LCs remains to be examined. UVB-induced LC migration was also observed in human skin in vivo.[135]

In addition to reducing the number of LCs in the skin, UVB radiation affects LC function by impairing the antigen-presenting capacity in DTH and CHS. UVB-irradiated LCs activate preferentially $CD4^+$ Th2 cells.[136] In contrast, they do not activate $CD4^+$ T cells of the Th1 subset, but induce clonal anergy.[137] Another cellular player in UV-induced immunosuppression is $CD11b^+$ macrophages, which infiltrate UVB-irradiated human skin (see Fig. 90-9). These cells produce IL-10, and their deletion by antibodies makes UV-irradiated mice permissive again for CHS.[138]

In addition to immunologic unresponsiveness to haptens applied after irradiation, UVB exposure-induced hapten-specific tolerance (i.e., resensitization with the same hapten at later time points) likewise fails.[139] In adoptive transfer experiments, it was shown that UVB induces T-suppressor cells. Elmets et al[140] prepared single cell suspension of the spleen and lymph nodes from UVB-exposed and hapten-treated mice, injecting the cell suspension into naive mice. When the recipient mice were sensitized and challenged with the same hapten that was used for the donor mice, they showed significantly impaired CHS responses.

The phenotype of the regulatory T cells and their mechanism of action are not well understood (Fig. 90-11). Results obtained so far are difficult to compare. Different experimental setups yielded partly contradictory results. There is evidence to suggest that $CD8^+$ T cells are important mediators of UVB-induced immunosuppression in the local immunosuppression.[141] In addition, T cells (not defined by CD4 or CD8) that express cytotoxic T lymphocyte antigen (CTLA)-4 on their surface transfer UV-induced tolerance.[142] CTLA-4 appeared to be of functional relevance, because in vivo injection of anti-CTLA-4 antibodies blocked transfer of suppression. The physiologic function of CTLA-4 is to end immune responses by shutting down activated T cells, so CTLA-4 is an important molecule in immune regulation. On stimulation with antigen-bearing DCs, $CTLA\text{-}4^+$ T cells secrete high levels of IL-10, transforming growth factor-β, and IFN-γ, but low levels of IL-2 and no IL-4. Other studies showed that $CD4^+$ T cells from UV-exposed mice are capable to suppress CHS when injected into untreated recipient mice.[143] These $CD4^+$ T cells produce IL-10, but no IL-4 and IFN-γ on APC coculture and inhibit IL-12 production by APCs.

Apart from $CD4^+$ regulatory T cells, natural killer T cells with regulatory capacities were found in UVB-induced systemic immunosuppression (see Fig. 90-10). In particular, $CD3^+$, $CD4^+$, and $DX5^+$ CD1-restricted natural killer T cells have been described, which secrete IL-4 and can adoptively transfer suppression of tumor rejection as well as DTH responses.[134]

ULTRAVIOLET RADIATION EFFECTS ON INNATE IMMUNITY

In the skin, in addition to slow but specific adaptive immune responses, the more primitive innate immune response can be generated as well. Essential components of the innate immune response are neutrophils, eosinophils, natural killer cells, mast cells, cytokines, complement, and, in particular, amtimicrobial peptides and proteins. It is important to note that the immunosuppressive properties of UV radiation refer exclusively to the adaptive immune response. In contrast, UV radiation has been shown to induce rather than suppress the innate immune response by increasing the production of the antimicrobial peptides human β-defensin (HBD)-2, -3, ribonuclease 7 and psoriasin in human keratinocytes and skin in vitro and in vivo.[144] This may explain why T-cell-mediated immune reactions are suppressed on UV exposure but not host defense reactions against bacterial attacks.

PHOTOIMMUNOLOGY: CONCLUDING REMARKS

UV radiation is a permanent environmental threat, and adaptive responses against its damaging effects have been developed in all living organisms. From a theoretic point of view, it is therefore tempting to speculate that photoimmunosuppression serves a physiologic role as an adaptive response of the skin to UV-induced modifications of proteins and an immunologic response to so-called *neoantigens* and, as a consequence, chronic inflammation. Under these conditions, the higher risk of skin cancer that appears to accompany UV-induced immunosuppression appears of less significance in evolutionary terms, as skin cancers occur principally in late life, after the reproductive period. From a practical point of view, however, photocarcinogenesis poses a serious health problem. Accordingly, modern approaches to prevent UV-induced immunosuppression include broad-spectrum UV filters, liposomally encapsulated DNA repair enzymes, antioxidants, and osmolytes.[145]

Chapter 91 :: Abnormal Responses to Ultraviolet Radiation: Idiopathic, Probably Immunologic, and Photoexacerbated

:: Travis W. Vandergriff & Paul R. Bergstresser

ABNORMAL RESPONSES TO ULTRAVIOLET RADIATION: IDIOPATHIC, PRESUMED IMMUNOLOGIC, AND PHOTOEXACERBATED

Abnormal responses to ultraviolet radiation (UVR) exposure divide into four categories (Table 91-1): (1) acquired idiopathic, presumed immunologic; (2) DNA repair defect disorders; (3) chemical and drug photosensitivity, including the porphyrias; and (4) photoexacerbated dermatoses not caused directly by UVR. The first and last categories and an approach to assessing photosensitivity are covered in this chapter. The other categories are covered in other chapters in this book. Diagnosis of photodistributed eruptions is discussed in Box 91-1 and Figure 91-1, and the entities are discussed in the following sections.

ACQUIRED IDIOPATHIC, PROBABLY IMMUNOLOGIC PHOTODERMATOSES

POLYMORPHIC (POLYMORPHOUS) LIGHT ERUPTION

EPIDEMIOLOGY. Polymorphic light eruption (PMLE) is common worldwide, but thought to occur more frequently in temperate latitudes and rarely in equatorial latitudes. However, a large-scale cross-sectional study has revealed no latitudinal gradient

BOX 91-1 DIFFERENTIAL DIAGNOSIS OF POLYMORPHIC LIGHT ERUPTION

USUAL ACUTE FORM

- Photoexacerbated dermatoses such as atopic or seborrheic dermatitis or acne
- Solar urticaria
- Erythropoietic protoporphyria
- Xeroderma pigmentosum

RARE PERSISTENT FORM

- Jessner lymphocytic infiltrate

POLYMORPHIC LIGHT ERUPTION AT A GLANCE

- A common acquired sunlight-induced disorder typically presenting in the spring.
- Clinical presentation: a pruritic, erythematous, symmetrically distributed, papulovesicular eruption, usually on exposed areas, within hours of exposure to ultraviolet radiation, most commonly sunlight, with full resolution in days to several weeks.
- Histopathology: epidermal spongiosis with a superficial and deep dermal, perivascular, mainly mononuclear cell infiltrate and papillary dermal edema.
- Genetics: most likely a genetically determined delayed-type hypersensitivity reaction against UVR-induced cutaneous antigen(s).
- Therapy: responds to broad-spectrum sunscreen use, oral or topical steroids, and prophylactic low-dose immunosuppressive phototherapy.

TABLE 91-1 Abnormal Responses to Ultraviolet Irradiation

- Acquired idiopathic, presumed immunologic photodermatoses
- Polymorphic light eruption
- Actinic prurigo
- Hydroa vacciniforme
- Chronic actinic dermatitis
- Solar urticaria
- DNA repair defect disorders
- Xeroderma pigmentosum
- Cockayne syndrome
- Trichothiodystrophy
- Bloom syndrome
- Rothmund–Thomson syndrome (probable)
- Chemical and drug photosensitivities
- Exogenous
- Systemic
- Topical
- Endogenous
- The porphyrias
- Photoexacerbated dermatoses

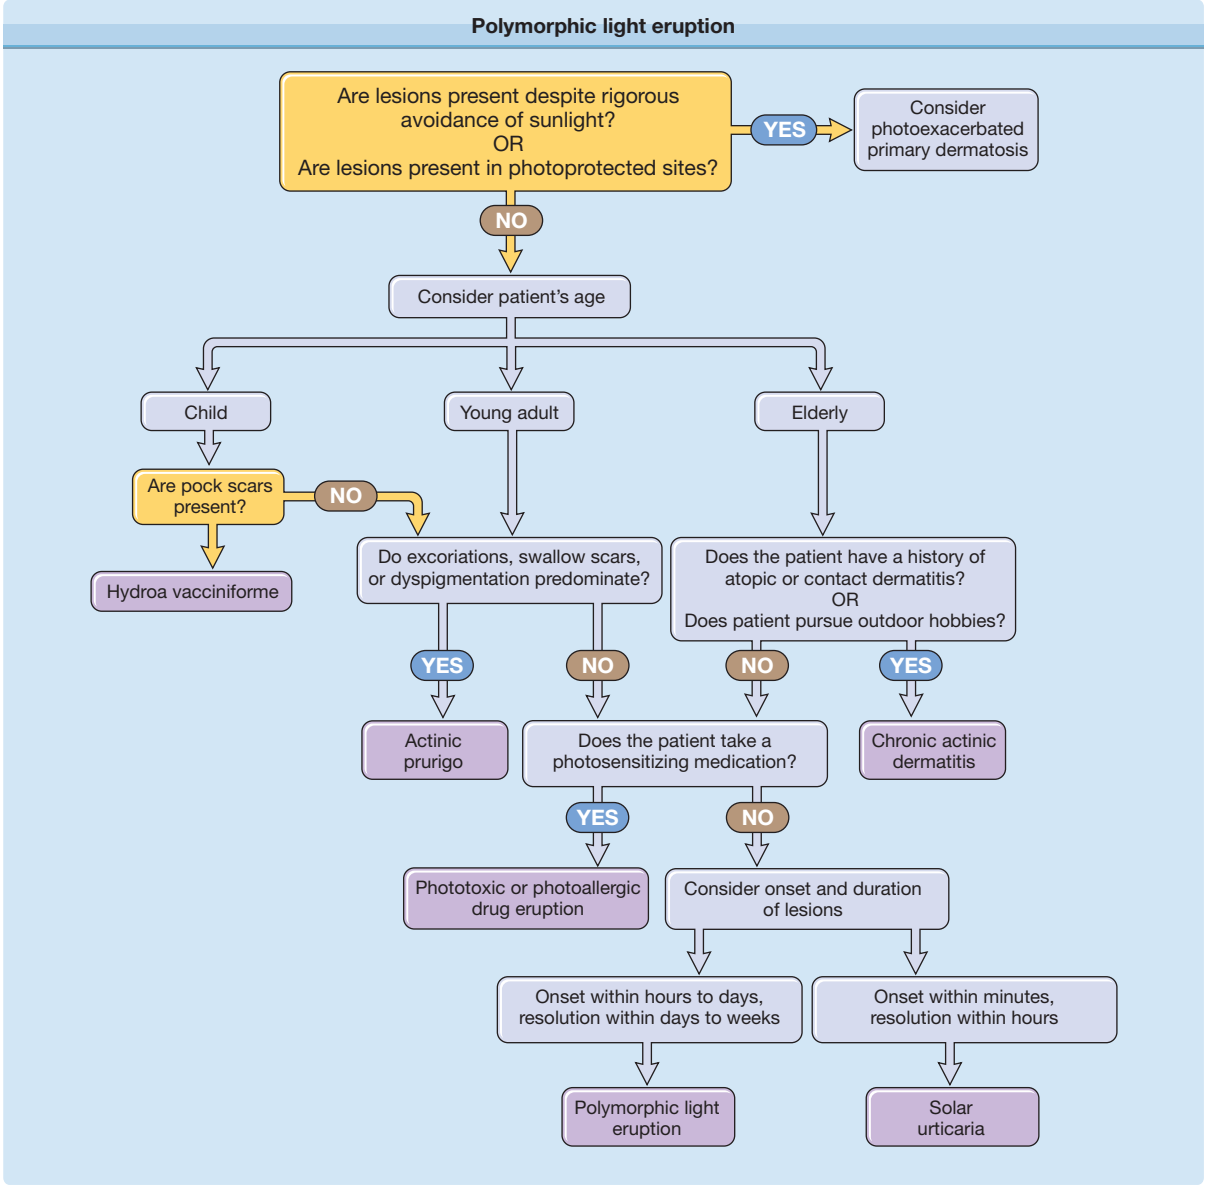

Figure 91-1 Diagnostic algorithm for abnormal responses to ultraviolet radiation.

in Europe.[1] This study estimated an overall suspected lifetime prevalence of 18% among Europeans. Previous reports indicate a prevalence of 10%–15% among North Americans[2] and southern Britons,[3] and 5% among southern Australians.[3] Women are affected more than twice as frequently as men.[1] Fitzpatrick skin type also influences the risk of developing PMLE, with the highest prevalence in people with skin type I and the lowest prevalence in people with skin type IV or higher.[1]

ETIOLOGY AND PATHOGENESIS.

A delayed-type hypersensitivity (DTH) response to a sunlight-induced cutaneous photoantigen was first suggested as the cause of PMLE in 1942, based on the delay between UVR exposure and onset of the eruption, as well as on its lesional histologic features.[4] In normal skin, UVR is known to induce a transient state of immunosuppression by depleting epidermal Langerhans cells and by promoting the release of immunosuppressive cytokines, including IL-4 and IL-10. In patients with PMLE, the immunosuppression normally associated with UVR is diminished substantially. It is thought that this creates an environment in which hypersensitivity responses to one or more photoinduced neoantigens is permissible. The notion that PMLE represents a DTH response is supported by histopathologic, molecular, and epidemiologic data.

Histopathologic examination of biopsy specimens from lesions of PMLE induced by solar-simulated radiation demonstrates the consistent appearance within hours of a T-cell dominated perivascular infiltrate that peaks by 72 hours. $CD4^+$ T cells are most numerous in early lesions, whereas by 72 hours $CD8^+$ T cells predominate, perhaps abolishing the response.[5] Increased

numbers of epidermal Langerhans cells and dermal macrophages are also present. Additionally, it has been demonstrated that neutrophil infiltration into the skin following UVB irradiation is deficient, leading to impaired IL-4 and IL-10 release.[6] Whereas a Th2 cytokine milieu is favored in normal skin following irradiation, a Th1 cytokine profile is favored in patients with PMLE.[7]

Molecular studies have revealed increased intercellular adhesion molecule-1 expression on keratinocytes overlying the perivascular infiltrate in PMLE,[8] as has been noted in DTH reactions but not in irritant contact dermatitis or after the UVB (290–320 nm) irradiation of normal skin.[9]

More recently, the induction of allergic contact sensitivity to dinitrochlorobenzene after solar-simulated irradiation of sensitization sites has been shown to occur more easily in PMLE patients than in normal individuals,[10,11] which suggests that sensitization to a putative UVR-induced cutaneous antigen may also be easier during disease-inducing exposure. On the other hand, elicitation of allergic contact responses to dinitrochlorobenzene in previously sensitized PMLE patients and normal individuals were equally suppressed by irradiation,[12] which explain the frequent development of immunologic tolerance, often called *hardening* or *desensitization*, as summer progresses or during prophylactic phototherapy. In fact, normalization in the depletion of epidermal Langerhans cells in response to UVR has been observed in patients with PMLE after undergoing therapeutic hardening.[13]

Finally, epidemiologic studies also point to hypersensitivity in patients with PMLE. The prevalence of PMLE is much lower in patients with skin cancer, suggesting that UVR-induced immunosuppression that may allow the persistence of malignant cells also inhibits hypersensitivity to photoantigens.[14] Also, PMLE is quite uncommon in iatrogenically immunosuppressed transplant recipients, occurring in only 2% of this population.[15]

The photoinduced neoantigens that initiate PMLE have not been identified, but several molecules may play roles, even in a single patient. The altered molecule(s) itself may hypothetically become antigenic directly by UVR, or secondarily through UVR-induced free radicals that modify nonantigenic peptides in such a way that they become antigenic. Of course, both mechanisms may even take place simultaneously.

UVA radiation (320–400 nm) usually seems more effective than UVB (290–320 nm)[12,16] at initiating PMLE. In one study, UVA irradiation elicited the eruption successfully in 56% of patients exposed to UVA or UVB daily for 4–8 days, in 17% of those exposed to UVB, and in 27% of those exposed to both.[17] However, other reports have suggested that UVB radiation may be implicated in up to 57% of patients. Therefore, it could broadly be said that approximately 50% of PMLE patients seem sensitive to UVB radiation and 75% to UVA, including in each case approximately 25% who are sensitive to both. Even visible light may be responsible on rare occasions.[18] As a result, paradoxically, patients may note that the use of sunscreens, which tend preferentially to remove UVB while transmitting some UVA and all visible light, may even have a PMLE-enhancing effect if exposure times are lengthened. There is most likely genetic predisposition to PMLE,[19] but the intensity of initial UVR exposure may also be important in such predisposed individuals.

CLINICAL FEATURES

History. PMLE usually has onset within the first three decades of life and affects females two to three times more often than males. It occurs in all skin types and racial groups, but is more common in Caucasians. A positive family history is present in about a fifth of patients.[19]

The typical PMLE eruption (Fig. 91-2) occurs each spring or on sunny vacations after the first substantial UVR exposure following a prolonged period with little exposure. It can also occur after recreational sunbed use or, very rarely, after exposure to visible light,[18] and it often abates with continuing exposure. It is rare in winter except after extended outdoor recreational activities. Sufficient exposure may also occur through window glass. The threshold required to trigger PMLE varies from patient to patient and is usually from 30 minutes to several hours, although it may occur several days into a vacation. Lesions appear in hours to days following exposure, but usually in not less than 30 minutes. Patients may note itching as the first sign of an impending PMLE eruption. Once UVR exposure ceases, all lesions gradually resolve fully without scarring over one to several days, occasionally taking a week or two. In any given patient, PMLE outbreaks always tend to affect the same exposed sites. The distribution is generally symmetric. Only some of the exposed skin is usually affected, particularly skin that is habitually covered, and large areas may be spared. An apparent extreme example of PMLE is juvenile spring eruption,[20] which tends to affect boys in the

Figure 91-2 Polymorphic light eruption. Papular lesions of exposed sites.

Figure 91-3 Polymorphic light eruption. Papulovesicular lesions on the arm.

spring and is characterized by pruritic papules and vesicles on their ear helices, although typical PMLE sometimes coexists. Systemic symptoms in PMLE are rare, but malaise and nausea may occur.

Cutaneous Lesions. PMLE has many morphologic forms, all probably with similar pathogenesis and prognosis. The term "polymorphous" describes the variability in lesion morphology observed among different patients with the eruption. In fact, the lesions are usually quite monomorphous in an individual patient. Papular, papulovesicular (Fig. 91-3), plaque (Fig. 91-4), vesiculobullous, insect bite-like, and erythema multiforme-like forms have been described, and pruritus alone may even occur, albeit rarely.[21] The papular form, characterized by large or small separate or confluent erythematous and edematous papules that generally tend to form clusters, is most common. Papulovesicular and plaque variants occur less frequently, and the other forms are rare. An eczematous form has been claimed but probably refers to mild chronic actinic dermatitis or photoexacerbated seborrheic or atopic dermatitis.

Figure 91-4 Polymorphic light eruption. Variably sized itchy plaques on the cheek.

Small papular PMLE, generally sparing the face and occurring after several days of continuing exposure, has been designated *benign summer light eruption* in Europe.[22]

LABORATORY TESTS

Histology. The histologic features of PMLE are characteristic but not pathognomonic,[23] and they vary with clinical presentation. There is generally a moderate to dense perivascular infiltrate in the upper and mid dermis in all forms. The infiltrate consists predominantly of T cells, with neutrophils and infrequent eosinophils. Other common features are papillary, dermal and perivascular edema with endothelial cell swelling. Epidermal change, not always present, may include variable spongiosis and occasional dyskeratosis, exocytosis, and basal cell vacuolization.

Blood Tests. Assessment for circulating antinuclear antibodies (ANA) and extractable nuclear antibodies (ENA) is advisable to exclude subacute cutaneous or other form of cutaneous lupus erythematosus (LE), and, if there is uncertainty, red blood cell protoporphyrins should be assessed to exclude erythropoietic protoporphyria (EPP). Approximately 11% of patients with PMLE have been found to have a positive ANA, with the vast majority having insignificant titers of less than 1:160.[24] An even smaller fraction (less than 1%) of patients with PMLE have anti-Ro antibodies.[24] Clinical correlation is necessary in these patients to exclude the possibility of cutaneous LE.

Phototesting. Cutaneous phototesting with a monochromator confirms photosensitivity in up to half of cases,[25] but usually does not differentiate PMLE from other photodermatoses. However, provocation testing with a solar simulator or other broadband source, sometimes repeated over 2 or 3 successive days, may induce the eruption, allowing a subsequent skin biopsy. This is most appropriate when the history and clinical features are not diagnostic.

DIFFERENTIAL DIAGNOSIS. (See Box 91-1)

COMPLICATIONS.

A very few patients with PMLE may develop LE, as there is a higher than normal prevalence of prior PMLE in patients with LE.[26] However, the presence of autoantibodies does not portend development of LE. Patients with PMLE may also experience significant disease-related psychosocial morbidity. The rate of both anxiety and depression in patients with PMLE are twice that of the general population, and these rates are similar to those observed in patients with psoriasis and atopic dermatitis.[27]

PROGNOSIS AND CLINICAL COURSE.

Over 7 years, 57% of 114 patients reported steadily diminishing sun sensitivity, including 11% in whom the condition cleared.[28]

PREVENTION.

PMLE may often be avoided by moderating sunlight exposure, wearing protective clothing,

and applying broad-spectrum high-protection-factor sunscreens regularly. Sunscreens with UVA and UVB protection may prevent PMLE eruptions in photoprovocable patients,[29] but sunscreens without UVA protection are generally ineffective. Prophylactic phototherapy each spring or before sunny vacations tends to prevent attacks.

TREATMENT. The first goal in treating PMLE is to prevent it. As noted above, one should advise restricting midday sunlight exposure and employing frequent applications of broad-spectrum, high-protection sunscreens. If this is not fully effective, patients who have outbreaks only infrequently, such as on vacations, usually respond well to short courses of oral steroids that are prescribed and taken with them to use in the event of an eruption.[30] If PMLE does develop, approximately 20–30 mg prednisone taken at the first sign of pruritus and then each morning until the eruption clears usually provides relief within several days, and recurrences are then uncommon during the same vacation. This treatment, if well tolerated, may be repeated safely every few months.

More severely affected individuals who experience repeated attacks of PMLE throughout the summer may require prophylactic courses of low-dose photochemotherapy (psoralen and UVA radiation: PUVA) in the spring. This appears to be more effective than broadband UVB radiation, controlling symptoms in up to 90% compared to approximately 60% of cases.[31] Narrowband (311-nm) UVB phototherapy, effective in 70%–80% of cases, is now probably the treatment of choice, because of ease of administration.[32] Prophylactic PUVA or UVB irradiation may sometimes trigger the eruption, particularly in severely affected patients, in which case a brief course of oral steroid therapy is indicated.

Various other therapies have also been tried but appear largely ineffective. These include hydroxychloroquine,[33] which is perhaps occasionally useful; β-carotene,[34] which is rarely effective; nicotinamide,[35] which is usually ineffective; and ω-3 polyunsaturated fatty acids, which are perhaps of moderate assistance in some patients.[36]

A small percentage of patients remain who are unsuitable for, unable to tolerate, or not helped by any of these measures. For these patients, when severely affected, oral immunosuppressive therapy, usually intermittent, with azathioprine or cyclosporine can be helpful.[37,38]

ACTINIC PRURIGO

EPIDEMIOLOGY. Actinic prurigo (AP) occurs throughout much of the world. Native North and South Americans are particularly affected. The disease is estimated to occur in 2% of the Canadian Inuit population.[39] In Mexico, AP is seen most commonly in the indigenous and Mestizo populations living at altitudes greater than 1,000 m.[40] Less commonly, inhabitants of Europe, United States, Australia, and Japan are reported to develop AP.

ACTINIC PRURIGO AT A GLANCE

- A rare, persistent, pruritic and excoriated papular or nodular eruption of sun-exposed and, to a lesser extent, nonexposed skin.
- Beginning in childhood, it may remit at puberty, exacerbate most often in summer, and fade in winter.
- A persistent variant of the sometimes coexistent polymorphic light eruption.
- Similar to the hereditary or familial variant of PMLE that affects native North and South Americans predominantly but which is usually more severe, persisting into adulthood.
- Prevention through avoidance of sunlight is the first line therapy; thalidomide or other immunosuppressive agents may be required.

PATHOGENESIS. AP appears to be UVR-induced in that it is more severe in spring and summer and often demonstrates abnormal skin phototest responses to UVB and/or UVA radiation.[41] UVA is implicated more often than UVB.[42] The cytokine TNF-α is overexpressed by keratinocytes in lesions of AP, creating a proinflammatory environment.[40] Sunlight exposure and solar simulating irradiation may sometimes induce an eruption resembling PMLE in patients with AP, and many patients have close relatives with PMLE.[19] A dermal, perivascular mononuclear cell infiltrate similar to that of PMLE may be seen in early lesions.

Therefore, AP may be a slowly evolving, excoriated variant of PMLE, and thus also a DTH reaction. The human leukocyte antigen (HLA) DRB1*0407 (DR4) is found in 60%–70% of patients with AP but in only 4%–8% of normal DR4 positive controls.[42] Additionally, HLA DRB1*0401 is found in approximately 20% of affected individuals.[42] These immunogenetic features may well be responsible for modulating conventional PMLE into AP. In addition, in some patients, AP appears to transform into PMLE and, in others, PMLE appears to transform into AP,[43] all of which suggests a relationship between the two disorders. The cutaneous UVR chromophores responsible for the eruption are not known, but they are likely to be diverse.

CLINICAL FEATURES

History. AP occurs more commonly in females, with a female to male ratio of about 2:1.[42] The eruption has its onset in childhood, usually present by age 10 years.[41] A positive family history of either AP or PMLE is present in about a fifth of patients.[19] The eruption is often present all year round, but it is commonly worse in summer. Very rarely it is worse in winter or both spring and

Figure 91-5 Actinic prurigo. Papules and nodules on the legs of a 15-year-old girl.

fall, with immunologic tolerance presumably developing during the summer. Exacerbations tend to begin gradually during sunny weather in general rather than after specific sun exposure, although PMLE-like outbreaks may also occur.

Cutaneous Lesions. The primary lesion of AP is a pruritic papule or nodule that occurs singly or in clusters (Fig. 91-5). Papules and nodules are often excoriated and crusted, and plaques may assume a lichenified or eczematous appearance. Vesicles are not seen unless superinfection is present.[42] Sun-exposed areas are most often affected, particularly the forehead, chin, cheeks, ears, and forearms. There is a gradual fading toward habitually covered skin, and the sacral area and buttocks may be mildly affected. Lower lip cheilitis and conjunctivitis are also possible, particularly in Native Americans[44] (Figs. 91-6, and 91-7). Healed facial lesions may leave dyspigmentation and sall pitted or linear scars.

LABORATORY TESTS

Histology. Early papular lesions show changes similar to those of PMLE, namely, mild acanthosis, exocytosis, and spongiosis in the epidermis and a moderate lymphohistiocytic superficial and middermal perivascular infiltrate.[23] A dense dermal lymphoid infiltrate and lymphoid follicles may be seen in lesions from the lip.[40] In persistent lesions, however, excoriations, more acanthosis, variable lichenification, and a dense mononuclear cell infiltrate produce a nonspecific appearance.

Figure 91-6 Cheilitis of actinic prurigo seen in a Mexican landscape gardener.

Blood Tests. Assessment of ANA and ENA should be undertaken to exclude subacute cutaneous or other forms of cutaneous LE. The finding of HLA type DRB1*0401 (DR4) or DRB1*0407, especially the latter, supports the diagnosis of AP.

Phototesting. Cutaneous phototesting with a monochromator confirms light sensitivity in up to half of cases,[41] but, as in PMLE, does not differentiate other photodermatoses. Most patients with positive monochromator testing have reduced minimal erythema doses (MED) in the UVA spectrum or in the combined UVA/UVB spectra.[42] Provocation testing with a solar simulator or other broadband sources induces typical lesions of AP in about two-thirds of patients.[42]

DIFFERENTIAL DIAGNOSIS. (See Box 91-2)

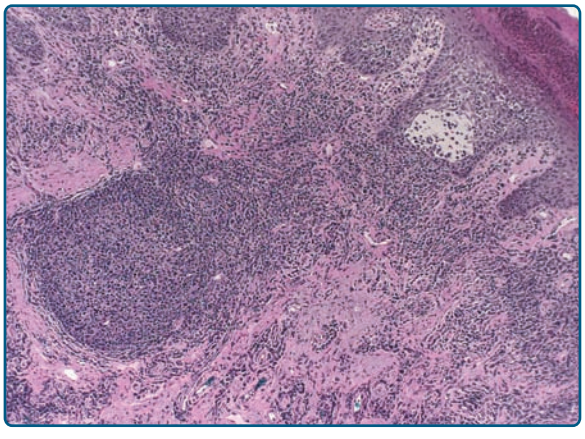

Figure 91-7 Lip biopsy from a patient with actinic prurigo shows a dense lymphohistiocytic infiltrate as well as a lymphoid follicle in the lamina propria.

BOX 91-2 DIFFERENTIAL DIAGNOSIS OF ACTINIC PRURIGO

Most Likely

- Polymorphic light eruption
- Atopic eczema
- Photoexacerbated atopic or seborrheic eczema
- Insect bites
- Prurigo nodularis

Always Rule Out

- Scabies

COMPLICATIONS. Mild scarring, especially on the face, and hypopigmentation may result from excoriations associated with AP. Additionally, two cases of primary cutaneous B-cell lymphoma arising on the face in patients with AP have been reported.[45]

PROGNOSIS AND CLINICAL COURSE. AP commonly arises in childhood and often improves or resolves in adolescence, although persistence into adult life is possible. Persistent cases may assume features of PMLE in adulthood. More rarely, the disorder arises in adulthood and persists indefinitely.[46]

PREVENTION. Prevention begins by restricting midday sunlight exposure and the compulsive use of broad-spectrum sunscreens.[46] In addition, topical calcineurin inhibitors tacrolimus and pimecrolimus may be effective in preventing recurrences in patients with previously documented disease. Of course, there is no known way to prevent its initial onset.

TREATMENT. In less severe cases of AP, sufficient relief may be achieved by restricting sun exposure and by using broad-spectrum, high-protection-factor sunscreens alone.[47] Higher potency topical corticosteroids may be used to relieve the inflammation and pruritus associated with the disease. Phototherapy with narrowband UVB or PUVA may occasionally help,[48] perhaps more reliably if the skin is cleared first with oral steroids. Topical tacrolimus or pimecrolimus may also help, again if the skin is cleared first. The treatment of choice in more severe or recalcitrant cases is thalidomide, with initial doses of 50–100 mg daily, preferably given intermittently. Responses to thalidomide are evident in most patients within several weeks. The most serious complication associated with thalidomide is teratogenicity, so pregnancy must be rigorously avoided. Other potential adverse effects are typically mild, including drowsiness, headache, constipation, and weight gain. An increased risk of thromboembolism and dose-related peripheral (mostly sensory) neuropathy are other potential adverse effects of thalidomide. In cases where thalidomide is unavailable or otherwise not appropriate, oral immunosuppressive therapy with azathioprine or cyclosporine may also be considered.

HYDROA VACCINIFORME

HYDROA VACCINIFORME AT A GLANCE

- A rare, chronic, scarring photodermatosis sometimes associated with Epstein–Barr virus infection
- Characterized by recurrent sunlight-induced crops of papulovesicles and vesicles, most commonly on the face and dorsa of the hands.
- Onset commonly in childhood, remitting most often at puberty.
- May be a scarring variant of polymorphic light eruption.
- Focal intraepidermal vesiculation, reticular keratinocyte degeneration, epidermal and upper dermal necrosis, and sometimes ulceration are virtually pathognomonic histologic changes.
- Avoidance of ultraviolet radiation, including the use of broad-spectrum high-protection-factor sunscreens, is the only established therapy.
- Prophylactic immunosuppressive phototherapy, administered with great care to avoid induction of new lesions, may help.

EPIDEMIOLOGY. Hydroa vacciniforme (HV) occurs in North America, Europe, Japan, and very likely elsewhere. However, its rarity and lack of universally acknowledged diagnostic criteria may make the diagnosis difficult to establish.

ETIOLOGY AND PATHOGENESIS. The pathogenesis of HV is not known. No chromophores have been identified, and although UVB minimal erythemal dose responses are normal in most patients, some have increased UVA sensitivity.[49] Blood, urine, and stool porphyrin concentrations are normal, as are all other laboratory tests. Nevertheless, its clear relationship to sunlight exposure, its distribution, and its early clinical appearances are all similar to that of PMLE, which suggests a relationship. On the other hand, fully developed HV eruptions are more severe than those found in PMLE, are associated with permanent scarring, and are unresponsive to treatments ordinarily effective in PMLE, apart perhaps from sunscreens and occasionally prophylactic phototherapy. Reports from Asia and Mexico have linked HV to chronic Epstein–Barr virus (EBV) infection,[50,51] although a relationship

between EBV and HV in all populations has not been established. Japanese reports indicate that EBV nucleic acids are found in the cutaneous lesions of HV in 85%–95% of patients but not in lesional skin of control patients.[51,52] A recent report from France has now provided substantial evidence that EBV infection persists in adult patients with HV and that it plays an important pathogenic role.[53]

CLINICAL FINDINGS

History. HV commonly develops in early childhood and resolves spontaneously by puberty, although, in some patients, it is lifelong. There is male predominance for severe forms, whereas milder disease is more common in females.[49,54] Familial incidence is exceptional. One estimate of the prevalence of HV is 0.34 cases per 100,000 with an approximately equal sex ratio; males had a later onset and longer duration of the disorder than females.[54]

HV eruptions typically occur in summer,[41] often with an intense burning or stinging sensation followed by the appearance of individual or confluent papules and then vesicles, all within hours of sunlight exposure (Fig. 91-8). This is followed by umbilication, crusting, and progression to permanent pock scarring within weeks. The eruption affects the cheeks and, to a lesser extent, other areas of the face as well as the backs of the hands and outer aspects of the arms. The distribution tends to be symmetrical.

Cutaneous Lesions. HV is characterized by initial erythema, sometimes with swelling, followed by symmetrically scattered, usually tender papules within 24 hours; vesiculation, occasionally confluent and hemorrhagic (Fig. 91-9); umbilication; then crusting and detachment of the lesions with permanent, depressed, hypopigmented scars within weeks. These scars are invariably present. Oral ulcers and eye signs also occur rarely.[55,56]

Figure 91-8 Hydroa vacciniforme. Vesicular, bullous, and crusted facial lesions, which are precursors of vacciniform scars.

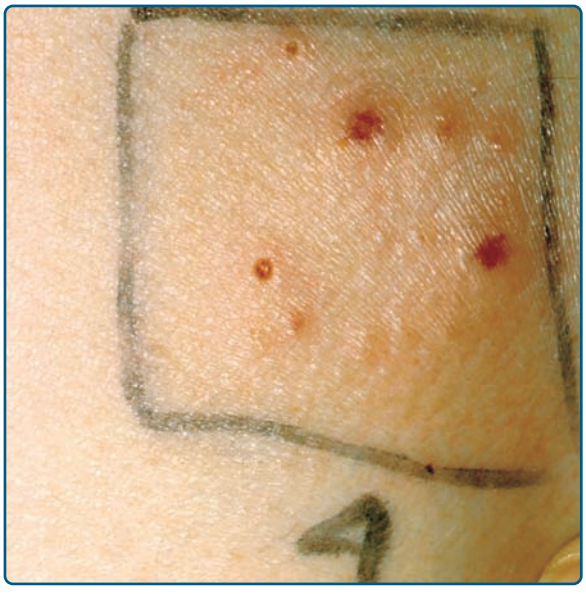

Figure 91-9 Typical hydroa vacciniforme lesions provoked by repeated ultraviolet A irradiation.

LABORATORY TESTS

Histology. Early histologic changes include intraepidermal vesicle formation with subsequent focal epidermal keratinocyte necrosis and spongiosis. There is a dermal perivascular neutrophil and lymphocyte infiltrate.[23] Older lesions show necrosis, ulceration, and scarring. Vasculitic features have been reported.[49]

Blood Tests. Blood, urine, and stool porphyrin concentrations should be assessed to exclude cutaneous porphyria, and an ANA and ENA to exclude the small possibility of cutaneous LE.

Phototesting. Phototesting may show increased sensitivity to short-wavelength UVA in some patients, but phototesting usually does not discriminate HV from other photodermatoses. Simulated solar irradiation may also induce erythema at reduced doses or occasionally provoke the typical vesiculation of HV (see Fig. 91-7).

Other Tests. Viral studies for herpes infection or other viral disorders should be undertaken if photoexacerbation or photoinduction of these other disorders seems at all possible.

DIFFERENTIAL DIAGNOSIS.

(See Box 91-3). There are reports of severe HV-like eruptions occurring in patients with chronic EBV infection and other associated disorders such as hypersensitivity to mosquito bites and the hemophagocytic syndrome. HV-like eruptions are distinguished from true HV by the development of lesions in both exposed and sun-protected skin and by the presence of systemic symptoms such as fever, hepatosplenomegaly, and wasting.[51,57]

BOX 91-3 DIFFERENTIAL DIAGNOSIS OF HYDROA VACCINIFORME

- Photoexacerbated viral dermatoses such as herpes simplex
- Erythropoietic protoporphyria
- Polymorphic light eruption
- Subacute cutaneous lupus
- Xeroderma pigmentosum

The distinction between an HV-like eruption and true HV is important because patients with a severe HV-like eruption may rarely go on to develop potentially fatal hematologic malignancy.[56–59] Finally, a recent quality-of-life study indicates that HV causes embarrassment and self-consciousness among children with the disease.[60] The negative impact of HV on quality of life exceeds previously reported indices for atopic dermatitis and psoriasis.[60]

COMPLICATIONS. Pock scarring is an inevitable sequela of HV. Cases of severe HV-like eruption may progress to lymphoproliferative disease.

PROGNOSIS AND CLINICAL COURSE. HV often resolves in adolescence but may occasionally persist into adult life.

PREVENTION. Sun avoidance and sunscreen use, as well as prophylactic phototherapy annually in spring, tend to prevent HV in some patients.

TREATMENT. Treatment of HV consists of restricting sunlight exposure and use of high-protection-factor broad-spectrum sunscreens. Occasionally, antimalarials appear to have helped, but their true value has not been established. As with PMLE, prophylactic phototherapy with narrowband UVB or PUVA, particularly the latter, may be helpful but must be administered with care to avoid disease exacerbation.[49,53,61] If conservative measures are ineffective, however, as often occurs, topical or intermittent oral steroids, topical calcineurin inhibitors, or even oral immunosuppressive medication may be tried if clinically appropriate, though these agents too are usually ineffective. In patients with chronic EBV infection, antiviral therapy with acyclovir and valacyclovir was reported in a small series of patients to reduce the frequency and severity of eruptions.[62]

CHRONIC ACTINIC DERMATITIS

EPIDEMIOLOGY. Chronic actinic dermatitis (CAD) has regularly been diagnosed in Europe, North America, Africa, Australia, New Zealand, Japan, and India. The disorder therefore appears to have worldwide distribution, affecting all skin types, although it is perhaps more common in temperate regions.

CHRONIC ACTINIC DERMATITIS AT A GLANCE

- A rare acquired persistent eczematous eruption of exposed skin, sometimes having pseudolymphomatous features.
- Commonly affects older men, but sometimes young atopic patients and rarely patients with hydroa vacciniforme or human immunodeficiency virus infection.
- Histologic features are eczematous, but pseudolymphomatous forms may be virtually indistinguishable from cutaneous T-cell lymphoma.
- Ordinarily induced by small amounts of ultraviolet B radiation, often with ultraviolet A radiation, and sometimes even visible light; in rare cases, induced by UVA radiation or visible light alone.
- Persistent light reaction, actinic reticuloid, photosensitive eczema, and photosensitivity dermatitis are all considered clinical variants.
- Very likely due to a delayed-type hypersensitivity reaction against an endogenous photoinduced epidermal antigen(s).
- Therapy consists of strict avoidance of ultraviolet radiation, along with topical and intermittent oral steroids, topical calcineurin inhibitors, or prolonged low-dose immunosuppressive phototherapy. Oral immunosuppression with cyclosporine or azathioprine is often required.

ETIOLOGY AND PATHOGENESIS. Studies of the clinical, histologic, and immunohistochemical features of CAD all show it to resemble the DTH reaction of allergic contact dermatitis,[73–75] even in its severe pseudolymphomatous form (formerly called *actinic reticuloid*), in which the clinical and histologic features duplicate those seen in long-standing allergic contact dermatitis.[76] It is therefore highly probable that CAD is an allergic reaction. In addition to hypersensitivity to cutaneous photoantigens, patients with CAD often have concomitant allergic contact dermatitis to airborne or other ubiquitous allergens, including plant compounds, fragrances, and medicaments.[77] Commonly implicated allergens include sesquiterpene lactone from plants of the Compositae family and sunscreens. A recent study indicates that sesquiterpene lactone remains the most common allergen in patients with CAD, with positive and clinically relevant photopatch testing to this allergen documented in approximately 20% of patients.[78]

TABLE 91-2
Original Criteria for the Eczematous Photosensitivity Disorders

- Persistent light reaction[62]: Eczema of predominantly light-exposed skin sensitive to UVB ± UVA following acute photoallergic contact dermatitis
- Actinic reticuloid[63]: Infiltrated papules and plaques of mainly light-exposed skin with lymphoma-like histologic features and sensitivity to UVB + UVA ± visible light; negative results on photopatch testing
- Photosensitive eczema[64]: Morphologic and histologic eczema of mainly light-exposed skin with photosensitivity only to UVB; negative results on photopatch tests
- Photosensitivity dermatitis[65]: Morphologic and histologic eczema of mainly light-exposed skin with photosensitivity to UVB ± UVA; positive results on photopatch testing in some of the patients
- Chronic actinic dermatitis[66]: Syndrome encompassing photosensitive eczema, photosensitivity dermatitis, and actinic reticuloid; persistent light reaction also now included

UVA = ultraviolet A radiation; UVB = ultraviolet B radiation.

In addition, cc has emerged as an increasingly common antigen in CAD[78] as has balsam of Peru.[79]

When CAD occurs in the absence of an obvious epicutaneous contact allergen, the relevant novel antigen must be either directly radiation-induced or formed indirectly as a result of secondary oxidative metabolism. Important support for the latter possibility comes from the fact that albumin can become antigenic in vitro through photooxidation of its histidine moieties.[80] There is no evidence for a genetic susceptibility to CAD; however, one stimulus for the acquisition of skin reactivity may be concurrent allergic contact dermatitis to recognized exogenous sensitizers or photosensitizers,[81,82] often airborne, which may predispose by altering cutaneous immunity, and thus permitting immunological recognition of an endogenous photoantigen. Long-standing endogenous eczema,[68,69,83,84] drug-induced photosensitivity,[85] human immunodeficiency virus infection,[86] and possibly PMLE[75] may also play similar roles. On the other hand, in addition or instead, chronic photodamage in frequently sun-exposed elderly outdoor enthusiasts, those who most often develop CAD,[75] may impair normal UVR-induced skin immunosuppression sufficiently for endogenous UVR-induced photoantigens to be recognized, as apparently also occurs for genetic reasons in PMLE.[19] Clearly, there is much work left to be done to identify the immunologic mechanisms that account for CAD.

Determining the action spectrum for CAD should theoretically help identify the postulated antigens, and the action spectra for CAD have been shown to resemble that of sunburn in many patients.[87] However, the eruption in CAD is eczematous, and much lower doses of UVR are required to evoke CAD than to produce erythema. In any event, the UVR chromophore for some patients may be the same as that of sunburn, namely DNA,[87] with UVR-damaged DNA serving directly as an antigen in CAD. In other patients with CAD, however, the photoallergen must be different, because these patients react only to UVA radiation,[88] and some patients react only to visible light.[89]

In summary, CAD appears to be an allergic contact dermatitis-like reaction against UVR-altered DNA or similar or associated molecules, perhaps as a result of enhanced immune reactivity due to concomitant airborne contact dermatitis or a reduced immunosuppressive capacity in photodamaged skin. The eruption occurs most often in patients with long-standing exposure to sunlight and airborne contact allergies.

CLINICAL FEATURES

History. CAD may arise de novo in apparently normal skin or in the skin of patients with previous endogenous eczema, photoallergic or allergic contact dermatitis, or rarely PMLE.[75,90] Concurrent allergic contact sensitivity to plant allergens, fragrances, or sunscreens is common.[82] The condition usually affects middle-aged or elderly men,[75] as CAD is rarely seen in patients under 50 years of age, except for those with prior atopic eczema.[83,84] The disorder is worse in summer, developing within minutes to hours after sunlight exposure and producing a pruritic confluent erythematous eruption that occasionally remits over several days with scaling, if exposure ceases and if the reaction is mild. However, severely affected patients frequently do not even recognize that exacerbations are related to sunlight exposure, especially when affected all year round.

Cutaneous Lesions. The lesions of CAD are eczematous, patchy or confluent, and acute, subacute, or chronic (Figs. 91-10 and 91-11). In severe cases, lichenification is common. Less commonly, scattered or widespread erythematous, shiny, infiltrated pseudolymphomatous papules or plaques are present on a background of erythematous, eczematous,

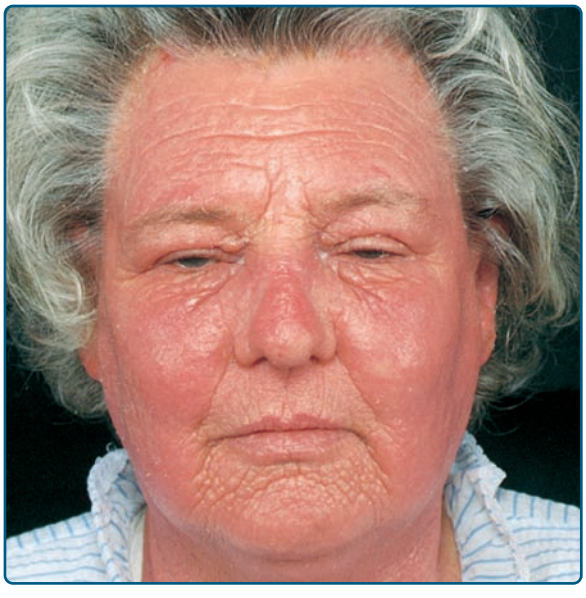

Figure 91-10 Chronic actinic dermatitis. Infiltrated eczematous eruption on the face.

Figure 91-11 Chronic actinic dermatitis. **A, B.** Severe light-induced eczema of the face and neck. **C, D.** Patient in full remission after low-dose psoralen plus ultraviolet A irradiation over weeks, with initial high-dose oral steroid cover to prevent initial exacerbation.

or normal skin.[75] Habitually exposed areas are most often affected, commonly with sharp cutoff at lines of clothing. There is sparing of deep skin creases, upper eyelids, finger webs, and skin behind the earlobes. In severe disease, eczema of the palms and soles may also be found. Eyebrows, eyelashes, and scalp hair may be stubbly or altogether lost from constant rubbing and scratching. Erythroderma, usually but not always accentuated on exposed sites, supervenes rarely. Variable, sometimes geographic, sparing of exposed areas of the face or elsewhere, as well as irregular hyperpigmentation and hypopigmentation, sometimes vitiligo-like,[91] may also occasionally be found.

LABORATORY TESTS

Histology. Histologic features include epidermal spongiosis and acanthosis, sometimes with hyperplasia. There is usually a predominantly perivascular lymphocytic cellular infiltrate confined to the upper dermis that in milder cases may resemble chronic eczema.[23] Severe CAD, however, may mimic cutaneous T-cell lymphoma (CTCL), on occasion being virtually indistinguishable. Features mimicking CTCL include epidermal Pautrier-like microabscesses and deep, dense epidermotropic mononuclear cell infiltration, sometimes with atypia. Typically, there is no marked increase in mitoses. T-cell receptor gene rearrangement studies should be undertaken if there is suspicion of CTCL. However, T-cell receptor clonality may also be observed in benign dermatoses.

Blood Tests. Assessment of the ANA and ENA is advisable in all patients to exclude the unlikely possibility of cutaneous LE. In severe or erythrodermic CAD, there may be large numbers of circulating $CD8^+$ Sézary cells without other suggestions of malignancy.[92,93] Human immunodeficiency virus status should be assessed if there is suspicion that this may be a predisposing factor.[86] Serum IgE may be elevated,

with higher levels of IgE correlating with more severe disease.[79]

Phototesting. Phototesting is essential, if available, to confirm the diagnosis of CAD. Almost invariably one finds low erythemal thresholds and eczematous or pseudolymphomatous responses after irradiation with UVB, usually with UVA, and rarely with visible wavelengths.[75] A small number of patients react only to UVA,[88] and fewer still only to visible light,[89] in which case, drug photosensitivity must be excluded. Testing should be done on uninvolved skin of the back with no topical or systemic steroid therapy for at least the preceding few days to avoid false-negative results.[94] Monochromatic and broad-spectrum sources both induce abnormal responses, with the former determining the action spectrum for disease induction and the latter tending to demonstrate acute eczema.

Patch and Photopatch Testing. Patch and photopatch testing is also essential in suspected CAD, because contact sensitivity to airborne allergens such as Compositae oleoresins, phosphorus sesquisulfide, and colophony alone may resemble CAD or even coexist. In addition, occasional secondary contact or photocontact sensitivity to sunscreens or other topical therapies may complicate the clinical picture further. Positive results with photopatch testing are found in approximately 80% of patients.[78,79]

DIFFERENTIAL DIAGNOSIS. (See Box 91-4)

COMPLICATIONS.

A relationship to CTCL seems likely to be coincidental, especially because results of T-cell receptor, immunoglobulin gene rearrangement, and other studies are negative in CAD.[92,95,96] In addition, CAD gradually resolves in many patients, there is no higher incidence of malignancies, and life expectancies are thought to be normal.[97] However, CTCL itself may present very rarely with severe CAD-like photosensitivity, and careful investigation to exclude CTCL is necessary when the disease suspected.[98]

PROGNOSIS AND CLINICAL COURSE.

Once established, CAD usually persists for years before resolving gradually.[98]

TREATMENT.

Treatment of CAD is often difficult and not fully effective. Rigorous avoidance of UVR and exacerbating contact allergens is essential, along with regular application of high protection-factor broad-spectrum topical sunscreens of low irritancy and allergenic potential. Strong topical steroids such as clobetasol propionate are also often needed and frequently produce marked symptomatic relief without adverse effects, even after long-term use, if confined to affected skin. Occasional oral steroid use is often helpful for disease flares. In more resistant disease, the topical calcineurin inhibitors—tacrolimus and pimecrolimus—sometimes produce good results if tolerated.[99,100] For refractory CAD, however, oral immunosuppressive therapy is almost always necessary and generally helpful if tolerated. Azathioprine 1.5–2.5 mg/kg/day often produces remission in months,[101] after which it may be reduced in dosage, or perhaps discontinued in the winter. Cyclosporine 3.5 to 5.0 mg/kg/day is usually rapidly effective,[102] but is more likely to produce adverse effects, which sometimes necessitate withdrawal. Mycophenolate mofetil is less often useful. Finally, long-term low-dose phototherapy with PUVA, usually several times weekly initially followed by maintenance exposures about every 3 weeks may be helpful,[103] generally accompanied initially by oral and topical steroid therapy to avoid disease flares.

PREVENTION.

The risk of CAD can probably be reduced by moderating outdoor pursuits, especially those associated with plant allergen exposure such as gardening, even more so for individuals who already have a tendency to develop eczematous eruptions in exposed areas. Avoidance of UVR is critical, and patients should be aware that indoor lighting may also be a source of UVA exposure. Compact fluorescent lamps even emit UVR at wavelengths as low as 254 nm, and some patients with CAD appear to be susceptible to disease flares after exposure to such lamps.[104]

BOX 91-4 DIFFERENTIAL DIAGNOSIS OF CHRONIC ACTINIC DERMATITIS

- Photoexacerbated atopic or seborrheic eczema
- Drug or chemical photosensitivity
- Cutaneous T-cell lymphoma
- Eczematized actinic prurigo

SOLAR URTICARIA

EPIDEMIOLOGY.

Solar urticaria (SU) has been reported in Asia, Europe, and the United States, and, thus, probably occurs worldwide. Perhaps 3 per 100,000 are affected.[105] Ultraviolet and visible radiation are causes of this form of urticaria, but SU accounts for less than 0.1% of all cases of chronic urticaria.[106]

ETIOLOGY AND PATHOGENESIS.

Primary SU is an immediate type I hypersensitivity response against a cutaneous or circulating photoallergen(s) generated from a precursor at the time of irradiation. Both circulating photoallergens and relevant IgE antibodies have been demonstrated. This has been termed primary SU, for which no genetic basis has been identified. Very rarely, SU may occur in association with drug photosensitivity, such as chlorpromazine and coal tar,[106] cutaneous porphyria, or LE. This has been termed secondary SU.

Two types of primary SU have been proposed, both involving immunoglobulin E-mediated hypersensitivity against a neoantigen that is photoinduced. In type 1, the photoallergen is the chromophore, which is generated only in patients with SU. Type 2 is mediated by circulating antibodies found only in patients and

SOLAR URTICARIA AT A GLANCE

- An uncommon sunlight-induced whealing disorder that occurs more often in females.
- Rarely is secondary to phototoxic drug use or with cutaneous porphyria.
- Onset within 5 to 10 minutes of sunlight exposure. Resolves in an hour or two; may be disabling and, rarely, life threatening.
- An immediate type I hypersensitivity response against a cutaneous or circulating photoallergen(s).
- Clinical and histologic features are those of urticaria.
- Phototesting may confirm the diagnosis and identify the action spectrum.
- Sensitivity may be to ultraviolet B, ultraviolet A, visible light, and/or any combination, but most commonly to ultraviolet A and visible light.
- Sunlight avoidance prevents solar urticaria, and high protection-factor broad-spectrum sunscreens and antihistamines may help.
- When necessary, phototherapy, plasmapheresis, or oral immunosuppressive drugs may be helpful in management.

directed against a common chromophore-generated antigen.[106] The wide range of inducing wavelengths is attributed to the unique action spectra of different photoallergens (chromophores). Patients with type 1 SU appear to have photoallergens of molecular mass 25–34 kilodaltons (kDa) and action spectra within the visible region, whereas type 2 SU has photoallergens of 25–1,000 kDa and variable action spectra.[107] The range of eliciting wavelengths can narrow or broaden over months or even years, suggesting that the relevant choromophores may vary over time.

Exposure to visible or UVA irradiation before, during, or after the urticaria-inducing irradiation inhibits whealing in some patients, possibly by inactivation of the initial photoproduct or the inhibition of subsequent reactions.[108,109]

CLINICAL FEATURES

History. Primary SU is slightly more common in females and may arise at any age, although most patients develop the disease in childhood or young adulthood.[106] The first episode typically occurs after prolonged sunlight exposure or occasionally following tanning bed use. It also seems to be associated with other photosensitive skin disorders more often than expected.[110] Typically, 5–10 minutes or, rarely, 20–30 minutes of exposure leads to itching and erythema, followed by patchy or confluent urticarial whealing, with gradual resolution within 2 hours. Rarely, patients report itching alone, and the onset of symptoms may be delayed for up to several hours.[111] A rare variant termed "fixed solar urticaria" has been reported and is characterized by urticarial lesions that are induced repeatedly in the same location.[112] In patients with mild disease, or in those who quickly recognize their SU onset and avoid further exposure, whealing may not be reported, even if it may be elicited during phototesting. Patients having extensive whealing may also describe headache, nausea, bronchospasm, and syncope, which rarely may be life threatening. Angioedema and anaphylaxis are exceedingly rare but have been reported. Secondary SU should be excluded by ruling out drug photosensitivity, cutaneous porphyria, and LE.

Cutaneous Lesions. SU usually affects all exposed skin with an initial macular erythema, followed by whealing and a surrounding patchy erythematous flare (Fig. 91-12), often with clear demarcation at lines of clothing. Rarely, there is sparing of the face and hands, perhaps as a result of UVR-induced tolerance. In some patients, specific sites may be affected repeatedly.

LABORATORY TESTS

Histology. There is dermal vasodilation, edema, and predominantly perivascular neutrophil and eosinophil infiltration at 5 minutes and at 2 hours, but not 24, hours.[23] Endothelial cell swelling occurs early on, with mononuclear cell infiltration later following higher irradiation doses. Extensive eosinophil granule major basic protein deposition is also present in the dermis at 2 and 24 hours, which suggests eosinophil degranulation.[113] Histologic features do not distinguish SU from other causes of urticaria.

Figure 91-12 Solar urticaria. Pruritic wheals with a surrounding patchy flare occurring within 15 minutes of sun exposure after irradiation of the patient's back through a template.

Blood Tests. Tests for an ANA and ENA should be employed to exclude cutaneous LE, as should the blood, urine, and stool porphyrins to exclude cutaneous porphyria.

Phototesting. Phototesting with a monochromator, broad-spectrum source, or sunlight allows confirmation of the diagnosis of SU and identification of the inducing wavelengths. However, negative phototest results do not exclude the disorder, because the ease of SU induction, particularly when mild, may vary. If no monochromator is available, appropriately filtered broadband sources can be used, and minimal urticarial dose estimation may help in assessing treatment efficacy. Patients with SU may have a biphasic response to phototesting whereby wheals develop in response to one action spectrum but are inhibited by another action spectrum.[114] Most commonly, shorter wavelengths induce wheals on phototesting while longer wavelengths may inhibit wheal formation.[114]

DIFFERENTIAL DIAGNOSIS. (See Box 91-5)

COMPLICATIONS.

Severe primary SU may lead to anaphylactic shock, which is rarely fatal. The rare secondary SU related to drug or chemical photosensitivity, cutaneous porphyria, or cutaneous lupus may be associated with the complications of the primary conditions.

COURSE AND PROGNOSIS.

SU often persists indefinitely, sometimes with deterioration but also sometimes with improvement, with the probability of clinical resolution at 5, 10, and 15 years of 12%, 26%, and 46%, respectively.[105,106]

TREATMENT.

Restricting sun exposure and using high protection-factor broad-spectrum sunscreens and appropriate clothing may be helpful in preventing SU. Sunscreens with UVA and UVB protection effectively increase the minimal urticarial dose on phototesting.[115] Antihistamines have been demonstrated to suppress wheal and itch formation in patients with SU, and, when combined with sunscreens, the increase in UV tolerance may be remarkable.[115] Phototherapy may be helpful in those patients who commonly develop SU tolerance as summer advances and also sometimes in those with persistent disease. Unfortunately, phototherapy usually needs to be continued to maintain its effect, and, consequently, carries the usual risks of long-term phototherapy. In addition, phototherapy should be undertaken with caution early on to avoid the risk of anaphylaxis, particularly in severely affected individuals.[113] Multiple UVA exposures with increasing doses during the same day (so-called *rush hardening*) have helped some patients.[116] Others with recalcitrant disease have been reported to respond to plasma exchange, or plasmapheresis, particularly if they are found to have circulating SU-associated serum factors; these remissions may be long-lived.[117,118] Intravenous immunoglobulin has also been helpful on occasion,[119] as has oral cyclosporine. Partial improvement has recently been reported with omalizumab, a monoclonal antibody directed against IgE.[120]

BOX 91-5 DIFFERENTIAL DIAGNOSIS OF SOLAR URTICARIA (SU)

- Polymorphic light eruption[a]
- Subacute cutaneous lupus[a,b]
- Photoexacerbated dermatoses such as atopic or seborrheic eczema
- Erythropoietic protoporphyria[b]
- Hepatic porphyrias[b]
- Drug or chemical photosensitivity[b]

[a]Rarely may coexist with SU.
[b]A rare cause of secondary SU.

PHOTOEXACERBATED DERMATOSES

Several dermatoses that are not caused by UVR may be worsened by it (Table 91-3). Mechanisms of this phenomenon, termed photoexacerbation, have rarely been studied. The initial condition may be severely worsened even if it was originally only mild or subclinical.[121,122] These disorders are relatively common and account for a significant percentage of all photodermatoses. Such conditions, especially the eczemas, psoriasis, and acne, improve with UVR exposure in most patients, perhaps because cutaneous reactivity is reduced, but in a small proportion of individuals, it is instead aggravated. If photoexacerbation does occur, the new eruption generally develops or worsens initially at sites typical of the basic disorder (Fig. 91-13), followed at times by extension to other areas. In photoexacerbated

TABLE 91-3
Selection of Diseases Sometimes Exacerbated by Ultraviolet Irradiation

- Acne
- Atopic eczema
- Carcinoid syndrome
- Cutaneous T-cell lymphoma
- Dermatomyositis
- Disseminated superficial actinic porokeratosis
- Erythema multiforme
- Familial benign chronic pemphigus (Hailey–Hailey disease)
- Keratosis follicularis (Darier disease)
- Lichen planus
- Lupus erythematosus
- Pellagra
- Pemphigus foliaceus (erythematosus)
- Pityriasis rubra pilaris
- Psoriasis
- Reticulate erythematous mucinosis syndrome
- Rosacea
- Seborrheic eczema
- Transient acantholytic dermatosis (Grover disease)
- Viral infections

Figure 91-13 Photo-exacerbated seborrheic dermatitis, affecting the face only at sites of predilection for the seborrheic eruption.

seborrheic eczema, however, an unpleasant sensation at the exposed sites may be the first or only feature. Treatment consists of minimizing UVR exposure, protection with suitable clothing, application of high protection-factor broad-spectrum sunscreens, and careful treatment of the underlying disorder. Taking these steps alone, frequently, if perhaps surprisingly, even may abort the photosensitivity.[121] If these actions are inadequate, low-dose phototherapy, as for PMLE, can sometimes help, for example, in seborrheic or atopic eczema and psoriasis, but its use is contraindicated in cutaneous LE or dermatomyositis, in which aggravation of the systemic disease is a risk. Photoexacerbated acne commonly requires treatment with oral isotretinoin.

Individual diseases for which photoexacerbation may occur are discussed in more detail in the online sections of this chapter include the disorders many of the disorders in Table 91-3.

APPROACH TO THE PATIENT WITH ABNORMAL SKIN PHOTOSENSITIVITY

CLINICAL FEATURES

Patients with abnormal photosensitivity present in three ways: (1) sporadic or (2) persistent eruptions in sunlight-exposed areas, or, infrequently, (3) erythroderma. When sporadic, the patient usually considers sunlight exposure to be responsible; when persistent, the physician often must identify the association. However, careful history taking is essential, first to confirm that sunlight exposure is responsible and then to make a diagnosis. Information of considerable importance are age at disease onset, gender, family history, previous sunlight sensitivity, occupation, leisure pursuits, and systemic and topical drug (or chemical) use. Additional relevant details include distribution of lesions, effects of season, exposure times required for induction, time between exposure and the appearance of lesions, duration of the eruption after exposure ceases, effects of sunlight received through window glass (implicating UVA and visible light), presence of systemic symptoms, and patient-assessed morphologies (progression of the disease before the clinic visit).

In terms of age and sex, young woman are more likely to develop PMLE; women or girls more commonly develop AP; children of either gender may have HV, xeroderma pigmentosum (XP), or EPP; elderly men or younger individuals with a history of eczema most often develop CAD.

A family history of sunlight sensitivity may be present in patients with PMLE, AP, XP, and the porphyrias. CAD is more common in outdoor enthusiasts exposed to both sunlight and airborne allergens, although exacerbations of disease, despite sunscreen use, invoke the possibility of sunscreen allergy. On the other hand, exacerbations with sunscreens may even occur in the absence of allergy in PMLE. An eruption appearing in minutes and remitting within 2 hours suggests SU or occasionally photosensitivity to drugs, such as amiodarone. Onset within 20 minutes to several hours, with resolution over days suggests PMLE, HV, EPP, cutaneous LE or other photoexacerbated dermatoses, or other drug photosensitivities, such as to thiazides. Systemic malaise is uncommon in PMLE, HV, and SU. Development of lesions after exposure through window glass suggests an inducing spectrum that includes UVA, although it may occur in virtually all of the photodermatoses.

The eruption described by patients with PMLE is generally that of small or large, elevated, pruritic, red or skin-colored, and often clumped spots of blisters, sometimes confluent, that usually involve several, but not all exposed sites. In HV, blistering with scar formation occurs, and in SU, elevated pruritic wheals are often confluent. In EPP and amiodarone drug photosensitivity, a marked burning sensation, without visible change, has been reported. In EPP, relatively lengthy exposure may lead to firm, colorless or pink, diffuse swelling, rarely with scattered blisters. In most drug photosensitivity reactions and in XP, an exaggerated sunburn-like reaction is possible, which is often maximal in XP at 2–3 days. Finally, in photoexacerbated dermatoses, the eruption resembles that of the primary disorder.

Photosensitivity eruptions are usually present on some, and occasionally all, of the forehead, nose, upper cheeks, tip of the chin, rims of the pinnae, back and sides of the neck, upper chest, backs of the hands and feet, and extensor aspects of the limbs. Covered areas may also be involved, but to a lesser extent. On the other hand, portions of the face protected by hair or customarily shown in shadow such as upper eyelids, finger webs, skin creases and skin under the nose, lower lip, chin, and earlobes are frequently unaffected, except when there is associated airborne contact dermatitis.

Excoriated papules suggest AP, whereas eczematous lesions, or very rarely light-associated erythroderma, suggest CAD or photoexacerbated atopic or seborrheic eczema. Finally, skin fragility, bulla formation, and atrophic superficial scarring suggest hepatic porphyria or pseudoporphyria, especially if there has been drug or excessive alcohol intake.

Clinical appraisal along with the history usually results in a diagnosis, although for complete certainty, several of the studies listed below may be appropriate.

LABORATORY STUDIES

If the diagnosis is not certain, appropriate additional studies include an assessment of the ANA and ENA. If present at significant titers, cutaneous LE should be considered. In addition, examination of blood, urine, and stools for porphyrins should be considered.

Biopsies may be helpful. Lesional histologic features are characteristic in several photodermatoses, especially PMLE, HV and CAD. However, with the exception of HV, histopathologic changes in photodermatoses are rarely entirely diagnostic. These are reviewed in the preceding disease descriptions.

Phototesting of normal back skin with a monochromator in CAD and SU often produces the papules or wheals of the condition itself, frequently at low irradiation doses, and this also may identify the action spectrum. Phototesting also helps to confirm XP through the delayed development of erythema over 2–3 days, with an abnormally low-dose threshold, often eventuating in blister formation (Table 91-4). In eczematous photosensitivity, patch and photopatch testing are also essential to identify relevant allergens. Finally, special techniques such as the assessment of DNA excision repair or of RNA synthesis recovery rate in cultured fibroblasts after UVR exposure are essential for the diagnoses of certain genophotodermatoses.

PHOTOTESTING. Techniques of phototesting vary greatly from country to country and from center to center. Although it is the investigational technique of choice for photodermatoses when the diagnosis is uncertain or when details of the inducting action spectrum are required, it remains primarily a research tool employed in a limited number of clinical centers. The cost of the equipment and its infrequent use in most clinical practices means that patients should be referred for consultation to such centers whenever indicated.

Phototesting falls into two categories: (1) Monochromatic phototesting, usually of the upper back with selected wavelengths and selected doses to identify the action spectrum for the disorder and (2) photoprovocation with a broad-spectrum source to induce the eruption for its clinical appearance and subsequent biopsy if indicated. Table 91-4 lists the disorders for which monochromatic testing may be helpful.

For precise characterization of the wavelength dependency of a disorder, monochromatic testing, preferably with a xenon arc irradiation monochromator, should be employed. For photoprovocation, the favored device is a solar simulator, usually a xenon arc-filtered source that produces a spectrum that resembles the terrestrial sunlight spectrum at noon on a midsummer's day in temperate regions of the world. Keep in mind that the terrestrial spectrum at noon in June varies considerably between Iceland and Kenya, as it also does between high elevations and sea level. Several suitable protocols have also been described for using simple broad-spectrum metal halide or fluorescent light sources with filters if necessary. In some parts of the world, sunlight with filters has also been used, although this method is generally too unpredictable for clinical use.[148,149]

The mainstay of phototesting is a monochromator. It is composed of a high-pressure xenon arc source that emits radiation along a pathway incorporating a diffraction grating angled to produce the required waveband at the exit slit. Such equipment needs regular calibration of output and wavelength. Because even large centers cannot always afford such equipment, lesser alternatives have been created, for example, metal halide or fluorescent light sources of sufficient output intensity. With such sources, the UVB, UVA, and visible light components of patient photosensitivity can be studied, based on deviation from normal erythemal reactions throughout the UVR spectrum.

Monochromatic phototesting is preferably performed on unaffected skin of the upper back, lateral

TABLE 91-4
Usual Monochromatic Phototest Responses in Idiopathic, Probably Immunologic Photodermatoses

Disease	Action Spectrum	Frequency of Abnormal Findings
Polymorphic light eruption	UVA more often than UVB	Only sometimes
Actinic prurigo	UVA more often than UVB	Only sometimes
Hydroa vacciniforme	More often UVA	Only sometimes
Chronic actinic dermatitis	UVB ± UVA ± visible light	Virtually always
Solar urticaria	UVB, UVA, or visible, or combination	Usual
Xeroderma pigmentosum	UVB	Usual
Photoexacerbated dermatoses	UVB, UVA, or combination	Rare

UVA = ultraviolet A radiation; UVB = ultraviolet B radiation.

to the paravertebral groove whereas lesion induction, except when done relatively easily with the monochromator, as in SU and CAD, is best undertaken using broadband sources with output directed over larger areas of skin known to be susceptible to the eruption. PMLE, AP, and HV are conditions in which repeated irradiation with UVA- or UVB-emitting or combined sources is often required to reproduce the disease.

It is important that the use of potent topical and systemic steroids be avoided when possible for at least several days before phototesting to prevent false-negative results. It is not certain how much the other oral immunosuppressive agents affect testing, but they should be stopped whenever possible, as well. False-positive results may also occur in patients with widespread disease, and the eruption should first be well controlled whenever possible, if necessary by keeping the patient in a reduced-light environment. However, it is often difficult to fulfill these requirements if the eruption is active, and in such circumstances, testing may need to be undertaken with knowledge of its limitations.

All phototesting should be undertaken at carefully standardized sequential doses (often a geometric series) and wavelengths, and the results read at consistent times after exposure in carefully controlled conditions of light and temperature. Furthermore, because testing involves UVR exposure, potentially noxious to both skin and eyes, the patient and the investigator should be protected with appropriate clothing, shielding and goggles.

PHOTOPATCH TESTING. (See Chapter 92.) Photopatch testing is an established investigational tool designed to identify photoallergic contact dermatitis, although it can also be employed to help identify phototoxic agents. It is essentially a more complex version of patch testing, and it is used in patients with exposed-site eczema, whether or not they also have another photodermatoses, to determine whether photoallergy is also present.

The methodology of photopatch testing has received less attention than allergen testing or phototesting, as it resides between the two specialty areas of photodermatology and contact dermatology. However, consensus methodology is now available.[150]

Using this approach, test materials (usually sunscreens, topical nonsteroidal and anti-inflammatory agents, and other possible causative agents) are applied in duplicate for 24–48 hours to normal skin. One set of test sites is then uncovered and irradiated with a broad-spectrum UVA source, usually at 5 J/cm^2 from fluorescent PUVA lamps, and the results read 24 and 48 hours later. Strongly positive reactions at sites exposed to both chemical agent and UVA, with no reactions at the covered control sites, confirms a diagnosis of photoallergy. Occasionally, however, contact irritation or contact allergy occurs in both sites, making a diagnosis of photoallergy uncertain. One should also be alert to the possibility that all irradiated sites may become positive, suggesting that underlying widespread UVA photosensitivity is responsible. Furthermore, the identification of potential photoallergens is still primitive, often with separation of phototoxicity from photoallergy uncertain. Once again, testing for photoallergy is best conducted in regional centers or by physicians with appropriate experience.

The current authors (Travis W. Vandergriff and Paul R. Bergstresser) are grateful to the authors of this chapter in the previous edition for leaving behind an outstanding framework that we employed as our starting point for this updated edition. Special thanks go to John L. M. Hawk and James Ferguson.

Chapter 92 :: Abnormal Responses to Ultraviolet Radiation: Photosensitivity Induced by Exogenous Agents

:: Henry W. Lim

ABNORMAL RESPONSES TO ULTRAVIOLET RADIATION AT A GLANCE

- Photosensitivity is broadly divided into phototoxicity and photoallergy, caused by topical or systemic agents that absorb ultraviolet A (UVA) energy.
- Phototoxicity occurs in anyone exposed to sufficient phototoxic agent and UV radiation and usually manifests as an exaggerated sunburn reaction.
- Photoallergy is an immune reaction to a UVA-modified chemical, commonly topical sunscreen agents and antimicrobials in the United States and the United Kingdom and topical nonsteroidal anti-inflammatory agents in Europe. It presents as eczematous eruption on sun-exposed areas.
- History taking is an important part of the evaluation; phototesting and photopatch testing are sometimes helpful.
- Differential diagnosis includes contact allergic or contact irritant dermatitis, airborne contact dermatitis, and other photodermatoses.
- Management consists of identification and avoidance of the precipitating agent, photoprotection, and symptomatic therapy.

Photosensitivity may be caused by exogenous or endogenous agents. It occurs when a compound, classically one with unsaturated double bonds in a six-carbon ring, absorbs radiation energy in its action spectrum, usually ultraviolet A (UVA) wavelengths. Exogenous photosensitizers can be agents administered systemically or applied topically. Well-characterized examples of photosensitivity induced by endogenous photosensitizers are the cutaneous porphyrias, which are associated with enzymatic defects in heme biosynthetic pathways that result in elevated levels of porphyrins, known phototoxic agents (see Chapter 132).

Photosensitivity induced by exogenous agents can be divided into phototoxicity and photoallergy. Phototoxicity is the result of direct tissue injury caused by the phototoxic agent and radiation. It can occur in all individuals exposed to adequate doses of the agent and the activating wavelengths of radiation (Table 92-1). In contrast, photoallergy is a type IV delayed hypersensitivity response to a molecule that has been modified by absorption of photons. It has a sensitization phase, occurs only in sensitized individuals, and requires only a minimal concentration of the photoallergen (see Table 92-1).

INCIDENCE

Over 350 medications in the United States have been reported to cause photosensitivity.[1] Only a small number of them, however, induce reactions frequently or have been well studied (Tables 92-2, 92-3, 92-4, and 92-5). In evaluations performed at photodermatology centers in New York City, Melbourne, Singapore, and Detroit, photosensitivity induced by a systemic drug was documented in 5% to 15% of the referred patients.[2–5] In studies performed in the United States, United Kingdom, Europe, and Australia, the percentage of photopatch-tested patients who had clinically relevant reactions leading to a diagnosis of photoallergic contact dermatitis ranged from 1.4% to 12.0%, with the value in most series being around 10%.[2,5–11]

PHOTOTOXICITY

PATHOPHYSIOLOGY

Several pathways eventuate in the development of phototoxic tissue damage, and for many phototoxic agents more than one pathway is responsible.

PHOTODYNAMIC PROCESSES. On absorption of radiation energy by the photosensitizer (P) at its ground state, formation of an excited (usually triplet) state (^3P) molecule occurs. The excited state molecule may then participate in oxygen-dependent processes (i.e., photodynamic processes) via two major pathways, type I and type II reactions, both of which result in cytotoxic injury.[12]

The type I reaction involves transfer of an electron or a hydrogen atom to the excited state photosensitizer (^3P), which results in the formation of free radicals [Eq. (92-1)]. These may then participate in an oxidation–reduction reaction that results in peroxide formation and subsequent cell damage [Eqs. (92-2) and (92-3)].

$$^3P + RH \rightarrow PH\cdot + R\cdot \quad (92\text{-}1)$$

$$PH\cdot + PH\cdot \rightarrow P + PH_2 \quad (92\text{-}2)$$

$$PH_2 + O_2 \rightarrow P + H_2O_2 \quad (92\text{-}3)$$

TABLE 92-1
Characteristics of Phototoxicity and Photoallergy

	Phototoxicity	Photoallergy
Clinical presentation	Exaggerated sunburn reaction: erythema, edema, vesicles, and bullae; burning, stinging; frequently resolves with hyperpigmentation	Eczematous lesions; usually pruritic
Histologic features	Eosinophilic keratinocytes, epidermal necrosis, dermal edema, sparse dermal infiltrate of lymphocytes, macrophages, and neutrophils	Spongiotic dermatitis, dermal lymphohistiocytic infiltrate
Pathophysiology	Direct tissue injury	Type IV delayed hypersensitivity response
Occurrence after first exposure	Yes	No
Onset after exposure	Minutes to hours	24 to 48 hours
Dose of agent needed for reaction	Large	Small
Cross-reactivity with other agents	None	Common
Diagnosis Topical agent Systemic agent	 Clinical Clinical + phototests	 Photopatch tests Clinical + phototests; possibly photopatch tests

Alternatively, interaction of ^3P with ground state oxygen could result in the formation of superoxide anion (O_2^{-}), which, in turn, can be converted into highly reactive and cytotoxic hydroxyl radicals (OH·).

The type II reaction is also known as an *energy transfer process*. Transfer of energy to ground state oxygen results in the formation of singlet oxygen ($^1O_2$), which is highly reactive and has a lifetime of 50 ns [Eq. (92-4)]:

$$^3P + 0_2 \rightarrow P + {}^1O_2 \qquad (92\text{-}4)$$

Cytotoxic injury occurs upon singlet oxygen-induced oxidation of amino acids and unsaturated fatty acids; interaction with the latter results in the formation of hydroperoxides, which initiate lipid and protein oxidation.

Phototoxicities induced by porphyrins,[12] quinolones,[13] nonsteroidal anti-inflammatory agents, tetracyclines, amitriptyline, imipramine, sulfonylureas, hydrochlorothiazide, furosemide, and chlorpromazine[14] are examples of photodynamic phototoxic reactions.

TABLE 92-2
Topical Phototoxic and Photosensitizing Agents

Agent	Exposure
Fluorescein	Used topically to visualize the anterior surface of the eye
Fluorouracil[a]	Topical treatment of actinic keratoses
Furocoumarins	Occur naturally in plants (especially Compositae species), including fruits and vegetables (lime, lemon, celery, fig, parsley, and parsnip); used in topical photochemotherapy
Retinoids[a]	For treatment of acne and photoaging
Rose Bengal	Used in ophthalmologic examinations
Tar	Used as topical therapeutic agent; found in roofing materials

[a]Induces exaggerated UV response due to skin irritancy.

GENERATION OF PHOTOPRODUCTS. Exposure to radiation may result in the generation of stable photoproducts that are responsible for tissue injury. Phototoxic products have been demonstrated on irradiation of phenothiazines, chlorpromazine, tetracyclines, quinolones, and nonsteroidal anti-inflammatory agents.[15]

BINDING TO SUBSTRATE. Another mechanism of phototoxicity is radiation-mediated binding of the photosensitizer to its biologic substrate. A photoaddition reaction occurs when the excited state molecule covalently binds to a ground state molecule. An example is the covalent binding of 8-methoxypsoralen to pyrimidine bases of the DNA molecules, which results in the formation of a cross-link between the DNA strands.

INFLAMMATORY MEDIATORS. Mediators of inflammation and inflammatory cells participate in phototoxic tissue injury. Biologically active products of complement activation, mast cell-derived mediators, eicosanoids, proteases, and polymorphonuclear leukocytes contribute to the development of phototoxicity induced by porphyrins, demeclocycline, and chlorpromazine.[16]

APOPTOSIS. Photodynamic therapy (PDT) involves the use of a photosensitizer and electromagnetic

TABLE 92-3
Systemic Phototoxic Agents

Class	Generic Name (Common US Trade Names)[a]
Antifungal	Griseofulvin (Fulvicin, Grifulvin V, Gris-PEG)[b] Voriconazole (Vfend)
Antimalarials	Chloroquine (Aralen) Quinine[b]
Antimicrobials	Sulfonamides Tetracyclines Demeclocycline (Declomycin)[c] Doxycycline (Adoxa, Doryx, Monodox, Periostat, Vibra-Tabs, Vibramycin)[c] Minocycline (Arestin, Dynacin, Minocin) Tetracycline (Helidac, Sumycin) Trimethoprim (Bactrim, Polytrim, Primsol, Septra) Quinolones Ciprofloxacin (Cipro) Enoxacin (Penetrex)[b] Gemifloxacin (Factive) Lomefloxacin (Maxaquin)[b,c] Moxifloxacin (Avelox) Nalidixic acid (NegGram)[b,c] Norfloxacin (Chibroxin, Noroxin) Ofloxacin (Floxin, Ocuflox) Sparfloxacin (Zagam)[c]
Cardiac drugs	Amiodarone (Cordarone, Pacerone)[c] Quinidine (Quinaglute, Quinidex)[b]
Diuretics	Furosemide (Lasix)[c] Thiazides Bendroflumethiazide (Corzide) Chlorothiazide (Aldoclor, Diuril)[c] Hydrochlorothiazide (Accuretic, Aldactazide, Aldoril, Atacand, Avalide, Capozide, Diovan, Dyazide, Hyzaar, Inderide, Lopressor, Lotensin, Maxzide, Micardis, Microzide, Moduretic, Prinzide, Teveten HCT, Uniretic, Vaseretic, Zestoretic, Ziac)[c]
Dyes	Fluorescein (AK-Fluor, Fluorescite) Methylene blue
Furocoumarins	Psoralens 5-Methoxypsoralen[c] 8-Methoxypsoralen (Oxsoralen-Ultra)[c]
Hypoglycemics	Sulfonylureas Acetohexamide (Dymelor) Chlorpropamide (Diabinese) Glipizide (Glucotrol, Metaglip) Glyburide (DiaBeta, Glucovance, Glynase PresTab, Micronase) Tolazamide (Tolinase) Tolbutamide (Orinase)[c]
Immunosuppressant	Azathioprine (Azasan, Imuran)
Nonsteroidal anti-inflammatory drugs	Acetic acid derivative Diclofenac (Arthrotec, Cataflam, Voltaren) Alkanone derivative Nabumetone (Relafen)[c] Anthranilic acid derivative Mefenamic acid (Ponstel) Cyclooxygenase-2 inhibitor Celecoxib (Celebrex) Enolic acid derivative Piroxicam (Feldene)[b,c] Propionic acid derivatives Ibuprofen (Advil, Motrin, Nuprin, Vicoprofen) Ketoprofen (Orudis, Oruvail) Naproxen (Aleve, Naprelan, Naprosyn)[c] Oxaprozin (Daypro) Tiaprofenic acid Salicylic acid derivative Diflunisal (Dolobid)
Oncologic drugs	Dacarbazine (DTIC-Dome) Docetaxel (Taxotere) Fluorouracil (Adrucil) Methotrexate (Rheumatrex)[d] Paclitaxel (Taxol) Vinblastine (Velban)
Photodynamic therapy agents	Porfimer (Photofrin)[c] Verteporfin (Visudyne)[c]
Psychotropic drugs	Alprazolam (Xanax) Chlordiazepoxide (Librax, Librium, Limbitrol) Clozapine (Fazaclo) Phenothiazines Chlorpromazine (Thorazine)[c] Perphenazine (Triavil, Trilafon) Prochlorperazine (Compazine)[c] Thioridazine (Mellaril) Trifluoperazine (Stelazine) Tricyclics Amitriptyline (Elavil, Limbitrol, Triavil) Desipramine (Norpramin) Imipramine (Tofranil)
Other	Dapsone Flutamide (Eulexin) Hypericin (St John's wort) Pyridoxine (vitamin B_6) Ranitidine (Zantac)

[a]Although it is the policy not to use trade names in this book, exceptions are made in cases in which we consider this information highly useful.
[b]Also reported as a systemic photoallergen.
[c]Commonly reported.
[d]Induces erythema on previously UV-exposed sites.

Antimicrobials	Quinolone Enoxacin (Penetrex)
Cardiac medication	Quinidine (Quinaglute, Quinidex)
Nonsteroidal anti-inflammatory drugs	Ketoprofen (Orudis, Oruvail) Piroxicam (Feldene)
Vitamin	Pyridoxine hydrochloride (vitamin B_6)

[a]Although it is the policy not to use trade names in this book, exceptions are made in cases in which we consider this information highly useful.

radiation in the presence of oxygen to treat premalignant and malignant skin conditions. In addition to generating reactive oxygen species, which results in cytotoxicity, PDT also is a potent inducer of apoptosis.[12]

CLINICAL MANIFESTATIONS

ACUTE PHOTOTOXICITY. (See Table 92-1.) Acute phototoxicity occurs within hours of exposure to the phototoxic agent and UV radiation. Symptoms are drug-dose and UV-dose dependent—usually asymptomatic, but at sufficient doses, the patient complains of a burning and stinging sensation on exposed areas, such as forehead, nose, V area of the neck, and dorsa of the hands (Fig. 92-1). Erythema and edema may appear within hours of exposure; in severe cases, vesicles and bullae may develop accompanied by pruritus. Protected areas, such as nasolabial folds, postauricular and submental areas, and areas covered by clothing, are spared. A notable exception to these kinetics is psoralen-induced phototoxicity, in which often the acute response first appears after 24 hours, and peaks at 48–72 hours, which is the rationale for administering psoralen plus UVA (PUVA) photochemotherapy doses 48–72 hours apart. The phototoxic response resolves with a varying degree of hyperpigmentation, which may last for months. At lower drug/UV doses, gradual tanning only, without preceding sunburn-like reaction, can be seen.

PHOTO-ONYCHOLYSIS. Separation of the distal nail from the nail bed, usually painful, is a manifestation of acute phototoxicity, with the nail plate serving as a lens to focus UV energy on the nail bed. It has been reported with doxycycline and other tetracyclines, fluoroquinolones, psoralens, benoxaprofen, clorazepate dipotassium, olanzapine, aripiprazole, indapamide, and quinine (Fig. 92-2).[17]

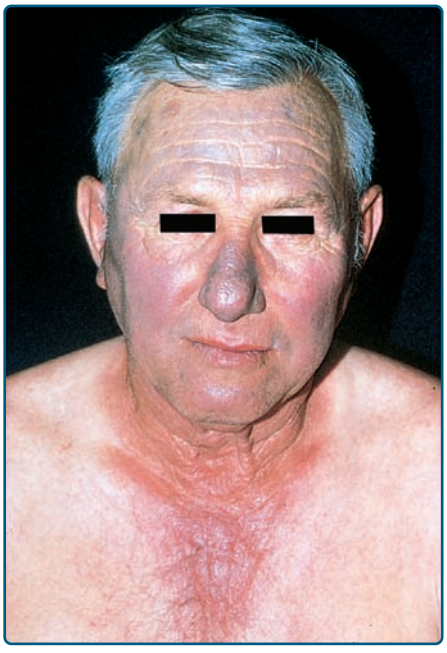

Figure 92-1 Amiodarone-induced phototoxicity. Note the erythema and slate-gray pigmentation (nose, forehead) on the sun-exposed area.

SLATE-GRAY PIGMENTATION. Asymptomatic blue–gray pigmentation on sun-exposed areas has been associated with exposure to several agents.[18,19] One percent to ten percent of patients taking amiodarone develop this side effect (Fig. 92-1). Chlorpromazine and clozapine can induce a similar change. The tricyclic antidepressants imipramine and, less commonly, desipramine have also been reported to cause slate-gray pigmentation. A drug metabolite–melanin complex has been postulated to be the cause of this alteration. Minocycline can induce blue–gray pigmentation on the face (Fig. 92-3), frequently on sites of acne scars, although similar pigmentation on forearms and shins can also occur. Chronic exposure to diltiazem, a benzothiazepine calcium channel blocker, has resulted in photodistributed, reticulated, slate-gray pigmentation. Slate-gray pigmentation seen in argyria involves the nail lunulae, mucous membranes, and sclerae. A photochemical reaction, in which silver granules are deposited in the dermis, results in these pigmentary alterations.

Figure 92-2 Distal onycholysis in a patient receiving psoralen plus ultraviolet A therapy.

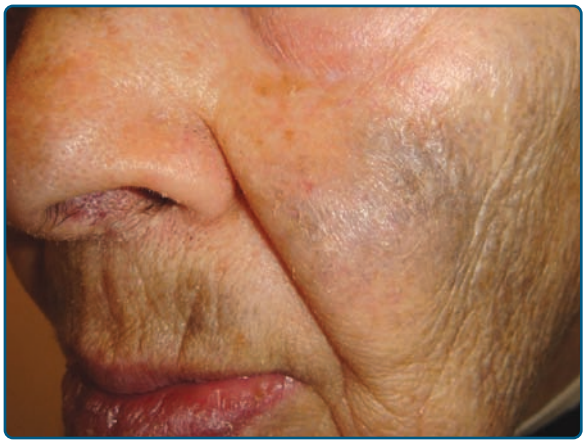

Figure 92-3 Minocycline-induced blue–gray pigmentation on cheeks and upper lip.

LICHENOID ERUPTION. Lichenoid eruption has been reported as a form of phototoxicity, but is controversial.

PSEUDOPORPHYRIA. The development of porphyria cutanea tarda-like cutaneous changes of skin fragility, vesicles, and subepidermal blisters is associated with several phototoxic agents (Fig. 92-4). Although histologic and immunofluorescence findings are similar to those of porphyria cutanea tarda, the porphyrin profile is normal or in the upper range of normal in these patients. Naproxen is the most commonly reported causative agent. Other drugs incriminated include amiodarone, β-lactam antibiotics, celecoxib, ciprofloxacin, cyclosporine, diflunisal, etretinate, furosemide, imatinib, nabumetone, nalidixic acid, narrowband UVB, oral contraceptives, oxaprozin, ketoprofen, mefenamic acid, the tetracyclines, tiaprofenic acid, torsemide, and voriconazole.[20,21]

ACCELERATED PHOTO-INDUCED CHANGES. This has been uniquely described with voriconazole, a broad spectrum antifungal agent. Immunosuppressed patients receiving voriconazole for >12 weeks can develop photosensitivity, pseudoporphyria, photoaging, lentigines, premature dermatoheliosis; in addition, squamous cell carcinoma and melanoma have been described in this group of patients who were on voriconazole for >12 months.[21]

PHOTODISTRIBUTED TELANGIECTASIA. Telangiectasia on sun-exposed areas has been reported with calcium channel blockers, including nifedipine, amlodipine, felodipine, and diltiazem, with the

Figure 92-4 Pseudoporphyria. Note subtle erosions on dorsum of hand and at the base of the index finger, and crusting on the knuckle.

antibiotic cefotaxime, and with antidepressant venlafaxine. In some of these patients, provocation with UVA resulted in the development of telangiectasia.[22]

PERSISTENCE OF PHOTOSENSITIVITY AND EVOLUTION TO CHRONIC ACTINIC DERMATITIS. Although phototoxicity usually resolves after discontinuation of the causative agent, there are reports of persistence of photosensitivity for many years after the cessation of exposure, which results in the development of chronic actinic dermatitis (Fig. 92-5). The condition presents with pruritus and lichenification and excoriation on sun-exposed sites; it has been reported with thiazides, quinidine, quinine, and amiodarone.[23]

CHRONIC EFFECTS. Cutaneous effects of long-term, repeated phototoxic tissue injury are best exemplified by the manifestations in patients who have received long-term PUVA photochemotherapy, which is known to affect DNA. These effects include premature aging of the skin, lentigines, squamous cell and basal cell carcinomas, and melanoma. These are discussed in greater detail in Chapter 238.

PHOTOTOXIC AGENTS

TOPICAL AGENTS. Table 92-2 lists the major topical phototoxic and photosensitizing agents. It should be noted that fluorouracil and retinoids induce exaggerated UV response due to their irritant effect on the skin. Therapeutic or occupational exposures to these agents are the common route of contact.

Furocoumarins. Topical exposures to furocoumarins may occur in individuals in certain occupations (bartenders, salad chefs, gardeners) and in patients receiving topical photochemotherapy with psoralens.

Tar. Crude coal tar, although no longer commonly used in dermatologic therapy, is well documented to produce a burning and stinging sensation on exposure to UVA ("tar smarts"). In addition to phototoxicity, occupational exposure to tar is associated with increased risk of nonmelanoma skin cancers.

Figure 92-5 Chronic actinic dermatitis. Note the lichenification and hyperpigmentation on sun-exposed areas, and sparing of skin folds.

SYSTEMIC AGENTS. Table 92-3 lists the major systemic phototoxic agents.[24–28] They commonly produce an exaggerated sunburn reaction but, like most phototoxins, may also induce an eczematous photoallergic response in a small percentage of users, especially after topical exposure. As a rule, the action spectra are in the UVA range; notable exceptions are the porphyrins, fluorescein, and other dyes, whose action spectra are in the visible light range.

HISTOPATHOLOGY

Acute phototoxicity is characterized by individual necrotic keratinocytes and, in severe cases, epidermal necrosis (see Table 92-1). There may be epidermal spongiosis, dermal edema, and a mild infiltrate consisting of neutrophils, lymphocytes, and macrophages. Slate-gray pigmentation is associated with increased dermal melanin and dermal deposits of the drug or its metabolite.[18,19] Histologic features of lichenoid eruptions are similar to those of idiopathic lichen planus; however, there may be a greater degree of spongiosis and dermal eosinophilic and plasma cell infiltrates, and a larger number of necrotic keratinocytes and cytoid bodies. In pseudoporphyria, as in porphyria cutanea tarda, there is dermal–epidermal separation at the lamina lucida and deposits of immunoglobulins at the dermal–epidermal junction and surrounding blood vessel walls.[20,21]

MANAGEMENT

Identification and avoidance of the causative phototoxic agent are the most important steps in management.

Beyond this or if the agent cannot be removed, sun avoidance is essential. Because the action spectrum for most agents is in the UVA range, high sun protection factor, broad-spectrum sunscreens containing efficient UVA filters should be used (see Chapter 223). Acute phototoxicity can be managed with topical corticosteroids and compresses; systemic corticosteroids should be reserved for only the most severely affected patients. Management of patients with slate-gray pigmentation, lichenoid eruption, pseudoporphyria, and photodistributed telangiectasia is symptomatic only, and patients should be advised that it will take months after the discontinuation of the offending agent for the condition to resolve. Patients with nonsteroidal anti-inflammatory drug-induced (NSAID-induced) pseudoporphyria who require NSAIDs should be switched to a different class of agents or to those that are less photosensitizing, such as indomethacin or sulindac.[29]

PHOTOALLERGY

PATHOPHYSIOLOGY

Photoallergy is a type IV delayed hypersensitivity response requiring the presence of both photoallergen and the activating wavelengths of radiation, which for most agents are in the UVA range.[30] After the absorption of UV energy, a photoallergen may be converted to an excited state molecule, which subsequently reverts to ground state by releasing the energy. In this process, the molecule may conjugate with a carrier protein to form a complete antigen. This is thought to be the mechanism of photoallergy induced by halogenated salicylanilides, chlorpromazine, and *para*-aminobenzoic acid (PABA). Alternatively, a photoallergen may form a stable photoproduct on exposure to radiation, which in turn may conjugate with a carrier protein to form a complete antigen. Sulfanilamide and chlorpromazine have both been shown to participate in this reaction.

Once the complete antigen is formed, the mechanism of photoallergy is identical to that of contact allergy. The antigen is taken up and processed by Langerhans cells, which then migrate to regional lymph nodes to present the antigen to T lymphocytes. Cutaneous lesions develop when the activated T lymphocytes circulate to the exposed site to initiate an inflammatory response.

CLINICAL MANIFESTATIONS

In sensitized individuals, exposure to the photoallergen and sunlight results in the development of a pruritic, eczematous eruption within 24 to 48 hours after exposure (see Table 92-1). Although the morphology is clinically indistinguishable from that of allergic contact dermatitis, the distribution of the eruption in photoallergy is predominantly confined to sun-exposed areas; however, in severe cases, it may spread to the covered areas, albeit at a lower intensity. Unlike the lesions in phototoxicity in fair-skinned individuals, those in photoallergy usually resolve without significant postinflammatory hyperpigmentation. Lichenoid eruption has also been reported.

Currently, in the United States, United Kingdom, and France, UV filters in sunscreen products (especially benzophenone-3) and antimicrobial agents are the most common cause of photoallergy, whereas NSAIDs are the leading topical photoallergens in Europe.[10,11,30–32] Although there have been reports of systemic agents inducing a photoallergic response, the evidence of such response remains unclear.[30]

As with phototoxicity, persistence of photosensitivity and evolution to chronic actinic dermatitis (see Chapter 91) have been reported after exposure to photoallergens, including chlorpromazine, dioxopromethazine, halogenated salicylanilides, ketoprofen, musk ambrette, olaquindox, and quinidine.[33,34] The mechanism is not completely understood. One possible explanation is that UV radiation alters the carrier protein that originally binds the photoallergen; this results in the formation of a neoantigen that stimulates the immune system over the long term. This hypothesis is supported by the observation that the histidine moiety in albumin can undergo oxidation in the presence of salicylanilide, which binds to albumin.

PHOTOALLERGENS

TOPICAL AGENTS. Topical exposure is the most common route of sensitization to photoallergens.[30,35] Table 92-4 lists the common groups of photoallergens.

SYSTEMIC AGENTS. Photoallergy caused by systemic agents is much less frequent, and not as well documented, than that induced by topical agents. All but one of these photoallergenic agents (pyridoxine) are also phototoxic and have been discussed previously in this chapter (see Section "Systemic Agents" under Section "Phototoxic Agents" and Table 92-3).

HISTOPATHOLOGY

The histologic features of photoallergy are similar to those of allergic contact dermatitis. There is epidermal spongiosis associated with infiltrate of mononuclear cells in the dermis (see Table 92-1).

MANAGEMENT

Management is identical to that of phototoxicity: identification and avoidance of the photoallergen, sun-protective measures, and symptomatic therapy.

EVALUATION OF PATIENTS WITH PHOTOTOXICITY AND PHOTOALLERGY

The evaluation of patients with phototoxicity and photoallergy is similar to the evaluation of patients

with other photosensitivity disorders and is described in greater detail in Chapter. A history of exposure to known photosensitizers is most important. It is also helpful to ascertain whether window glass-filtered sunlight can induce the cutaneous eruption, because UVB is filtered out by window glass. Distribution of the cutaneous eruption is a helpful clue to the type of photosensitizer responsible. Widespread eruption suggests systemic photosensitizers, whereas topical photosensitizers produce lesions only in areas that have been exposed to both sensitizers and radiation. Vesicular and bullous eruptions are most commonly associated with phototoxicity, whereas eczematous eruptions strongly suggest photoallergy; usually, the former is associated with a burning sensation, the latter with pruritus. Skin biopsy findings may also be helpful in differentiating these two conditions: necrotic keratinocytes are commonly seen in phototoxicity, whereas spongiotic dermatitis is associated with photoallergy (see Table 92-1).

Phototests and photopatch tests are an integral part of the evaluation of photosensitivity when history and physical examination alone are insufficient to determine the responsible agent. Approximately 10% of patients who undergo photopatch testing have clinically relevant positive results, which leads to the diagnosis of photoallergic contact dermatitis.[2,11]

The procedures for phototesting and photopatch testing are generally as follows, although there are variations in testing methods.[5,10] On day 1, exposure to UVB and UVA to determine minimal erythema dose (MED) is carried out, and duplicate sets of photoallergens are applied symmetrically to another site on the back and covered by an opaque tape. On day 2, the MEDs are determined. One of the duplicate set of photoallergens is exposed to 10 J/cm^2 of UVA or 50% of the MED to UVA, whichever is lower. After irradiation, the exposed site is covered again with an opaque tape. On day 3, both irradiated and nonirradiated test sites are uncovered, and the reactions are graded. On day 5 or day 8, the irradiated and nonirradiated sites are evaluated for delayed reactions. Reaction only at an irradiated site indicates photoallergy. Reaction of equal intensity at both irradiated and covered sites indicates allergic contact dermatitis. Reaction at both sites, but with higher intensity at the irradiated site, signifies both photoallergy and allergic contact dermatitis. Well-defined erythema that resolves promptly indicates an irritant dermatitis.

DIFFERENTIAL DIAGNOSIS OF PHOTOTOXICITY AND PHOTOALLERGY

Airborne allergic contact dermatitis is characterized by involvement of skinfolds on exposed areas, such as the nasolabial folds, and the eyelids that receive minimal direct sunlight. It also involves exposed areas that are relatively sun protected, such as the postauricular areas and area under the chin. Allergic contact dermatitis and irritant contact dermatitis occur at sites of contact, in both sun-exposed and in sun-protected areas.

Other photodermatoses can be differentiated from phototoxicity and photoallergy by their characteristic time course and morphology and lack of a compatible exposure history. Polymorphous light eruption manifests itself within a few hours of sun exposure as pruritic papules, plaques, and, uncommonly, vesicles on sun-exposed sites and resolves in a few days. Chronic actinic dermatitis presents as chronically lichenified plaques on sun-exposed areas. Lesions of solar urticaria appear within minutes of sun exposure as mildly pruritic urticaria and resolve within a few hours.

OTHER EXOGENOUS AGENT-INDUCED PHOTODERMATOSES AND PHOTOEXACERBATED DERMATOSES

PORPHYRIA CUTANEA TARDA

(See Chapter 132)

Ingestion of wheat treated with hexachlorobenzene (HCB) as a preservative resulted in an outbreak of a porphyria cutanea tarda-like syndrome in Turkey in the 1950s.[36] Inhibition of the enzyme uroporphyrinogen decarboxylase by HCB was thought to be responsible for the clinical manifestations. However, a study of adults highly exposed to HCB in Catalonia, Spain, and of children from the same area, did not show any increase in prevalence of porphyria cutanea tarda or increased urinary concentrations of porphyrins.[37]

LUPUS ERYTHEMATOSUS

(See Chapter 155)

Drug-induced systemic lupus erythematosus present with purpura, erythema nodosum, urticarial and necrotizing vasculitis, and/or photosensitivity. It is most commonly associated with exposure to hydralazine, procainamide, isoniazid, and minocycline; antinuclear antibody (ANA) test is positive and antihistone antibodies are characteristically present.[38]

Drug-induced subacute cutaneous lupus erythematosus (SCLE) presents with similar cutaneous lesions as idiopathic SCLE, although blisters and targetoid lesions may occur, and lower extremities may be involved. Antinuclear antibody and anti-Ro/SSA antibodies are frequently present, while antihistone antibodies are usually absent. Drugs associated with this condition include calcium channel blockers, angiotensin-converting enzyme inhibitors, thiazide diuretics, terbinafine and tumor necrosis factor(TNF)-α antagonists.[38]

Drug-induced discoid lupus erythematosus is very rare; it has been reported with exposure to fluorouracil and TNF-α antagonists.

Identification and avoidance of the precipitating agent is the treatment of drug-induced lupus erythematosus.

Skin Changes Due to Other Physical and Chemical Factors

Chapter 93 :: Thermoregulation

:: Dean L. Kellogg, Jr.

HUMAN THERMOREGULATION AT A GLANCE

- Thermoregulatory reflexes involve changes in skin blood flow and sweating that act to preserve thermal balance with an internal temperature of approximately 37°C (98.6°F).
- Thermal balance is determined by metabolic heat production; evaporative heat loss; heat gain or loss through radiant, convective, and conductive mechanisms; and useful mechanical work done.
- Dermal papillary loops, arteriovenous anastomoses, and sweat glands are the major skin effectors of thermoregulation.
- Heat stress evokes large increases in skin blood flow and sweating through cholinergic cotransmitter and nitric oxide-dependent mechanisms to facilitate heat dissipation.
- Local skin heating causes a local vasodilation through antidromic neurotransmitter release from afferent skin nerves and increased nitric oxide generation.
- Cold stress evokes reduced skin blood flow through noradrenergic cotransmitter mechanisms to facilitate heat conservation.
- Local skin cooling causes a local vasoconstriction through noradrenergic and afferent neural mechanisms as well as nonneural mechanisms.

THE ROLE OF SKIN IN HUMAN THERMOREGULATION

Human beings are homeotherms: we maintain our internal, or core temperature of the body within a narrow range despite thermal stresses. Thermal stress can arise from variations in environmental temperature or from the human body itself, as with heat generation by skeletal muscle during dynamic exercise. When thermal stresses arise from the environment, changes in skin temperature occur prior to any change in internal temperature. When thermal stresses arise from the body itself as with exercise, changes in core temperature occur prior to any change in skin temperature. In either case, thermal gradients are established between the skin and the body core. If skin temperature is lower than core temperature, heat will be lost from the body unless skin blood vessels constrict. If skin temperature is greater than core temperature, the body will gain heat, unless skin vessels dilate and sweat glands produce perspiration. The skin is thus a crucial component of human thermoregulation.

Human thermoregulation is achieved through an integration of several physiological processes. These integrated processes make up thermoregulatory reflexes that maintain a stable internal temperature at a "set point" of 37°C (98.6°F) despite thermal stresses. The set point is not invariant and may fluctuate as much as 0.5°C–1.0°C (0.9°F–1.8°F) according to circadian rhythms and during the menstrual cycle in females. The thermoregulatory reflexes designed to preserve internal temperature at the set point are coordinated by thermally sensitive neurons in the anterior hypothalamic–preoptic area and spinal cord, which respond to the changes in internal and skin temperatures. For example, cold-sensitive neurons in the anterior hypothalamic–preoptic area and spinal cord integrate afferent sensory inputs and activate heat-conserving mechanisms that include cutaneous vasoconstriction and increased metabolic heat production (shivering). Conversely, the stimulation of heat-sensitive neurons in the anterior hypothalamic–preoptic area and spinal cord integrate afferent sensory inputs and activate heat-dissipating mechanisms that include cutaneous vasodilation and sweat production.

HEAT TRANSFER

To maintain thermal balance, heat gained or lost by the body must equal heat dissipated from, or produced

by the body. This concept can be mathematically expressed as:

$$\Delta S = M - E \pm R \pm C \pm K - W$$

where

- ΔS = change in heat storage by the body
- M = metabolic heat production and is defined as the rate of transformation of chemical energy into heat and mechanical work
- E = evaporative heat loss and is defined as the rate of heat loss by evaporation of water from skin and surfaces of the respiratory tract. E is dependant on (1) rate of sweat secretion, (2) water vapor pressure of the environment, and (3) the area of evaporative surface.
- R = radiant heat gain or loss and is defined as heat exchange by emission and absorption of electromagnetic (infrared) radiation. This component accounts for 50%–60% of the heat loss in a thermally comfortable (thermoneutral) individual, but can easily become a net heat gain as when one is in direct sunlight.
- C = convective heat gain or loss and is defined as heat exchange due to forced movement of a fluid, either liquid or gas. This component is responsible for the transfer of heat to the skin through skin blood flow and transfer from the skin to the environment by air or water movement. Within the body, the cardiovascular system is the major mediator of convective heat transfer. C is dependent on (1) body surface area, (2) temperature differences, and (3) fluid (or air) movement.
- K = conductive heat gain or loss and is defined as heat transfer by flow down a temperature gradient, as between tissues and blood, between blood and skin, and between skin and the environment. This is usually combined with convective heat transfer.
- W = useful mechanical work

The sum of R, C, and K is determined by the temperature gradient between the skin and the environment. If ΔS is zero, the body is in heat balance. This "thermoneutral" condition is characterized as having low skin blood flow of approximately 5% of cardiac output. Sweating does not occur during thermoneutrality.

If $\Delta S < 0$, the body is losing heat, core temperature is falling, and thermoregulatory reflexes are evoked to conserve heat. Thermal stability is maintained through reduction of skin blood flow that can approach zero during maximal vasoconstriction. Reduction in skin blood flow increases the thermal insulation between the body and the environment by minimizing losses through conductive (K), convective (C), and radiant (R) mechanisms. If heat loss continues despite low skin blood flow, metabolic generation of heat (M) through the shivering of skeletal muscle is initiated to restore and maintain core temperature. Brown adipose tissue can also be a source of metabolic heat generation through nonshivering thermogenesis.[1] Although originally thought to be important only in human neonates where brown adipose tissue is 2%–5% of body weight, some brown adipocytes persist into adulthood.[2] These adipocytes can directly generate heat (M) to maintain core temperature.[3] If, despite all these mechanisms, ΔS remains negative, core temperature will fall and life-threatening hypothermia may result.

If $\Delta S > 0$, the body is gaining heat and core temperature is rising. Under this circumstance of heat stress, thermal stability is maintained by increases in skin blood flow to facilitate heat loss through K, C, and even R losses. If heat gain continues despite these mechanisms, sweating is evoked to increase heat loss through evaporation (E) of perspiration. If ΔS remains positive, blood flow is diverted from skeletal muscle and gastrointestinal beds, providing for dramatic increases in skin blood flow. Sweat rate will also increase until maximal levels are achieved. If, despite maximal skin blood flow and maximal stimulation of sweating, ΔS remains positive, core temperature will rise and life-threatening hyperthermia, i.e., heat stroke, will occur.

THERMOREGULATION AND THE SKIN

ANATOMIC CONSIDERATIONS

The critical role of the skin in human thermoregulation is well understood: thermoregulation is achieved through variations in blood flow and sweat production so as to maintain thermal stability.[4] Without these variations, thermal stability cannot be maintained resulting in risk of hypothermia or hyperthermia (see Chapters 94 and 95). Under normothermic conditions, skin blood flow ranges from 30–40 mL/min/100 g of skin in resting humans. However, the cutaneous vasculature is exceedingly compliant so that skin blood flow can vary from nearly zero during cold stress periods with maximal vasoconstriction to 8 L/min over the body's surface during maximal vasodilation in heat stress.[5]

Blood vessels in the skin are arranged in several plexuses in superficial and deep layers parallel to the skin surface. Most vessels are in the superficial layer and consist of high-resistance terminal arterioles, papillary loops, and postcapillary venules. Papillary loops are true capillaries. Blood flow through the loops is controlled by highly innervated arterioles. The loops are located near the dermal–epidermal junction, a region characterized by a maximal thermal gradient because of its proximity to the skin surface. Since the papillary loops also have a large surface area, blood flow through these vessels is a major determinant of heat exchange through vasodilation during heat stress and vasoconstriction during cold stress.

While papillary loops are found in both glabrous (palms, plantar aspect of feet, and lips) and nonglabrous skin (most of the body's surface, including the limbs, head, and trunk), arteriovenous anastomoses (AVAs) are found mainly in glabrous skin. They represent direct connections between arterioles and venules that bypass the high-resistance arterioles and capillaries of the papillary loops. AVAs have thick muscular walls with rich noradrenergic innervation and lie deep

to papillary loops.[6] Because of their deeper location in the dermis and smaller surface area, AVAs are less efficient in heat transfer than papillary loops. While AVAs dilate in response to heat stress and constrict during mild-to-moderate cold stress, their major role is to mediate local vasodilation during prolonged cold exposure. AVA vasodilation delivers warm blood to maintain tissue temperature and thus tissue viability through "cold-induced vasodilation."[7]

Sweat glands also play a major role in human thermoregulation (see Chapter 83). The critical thermoregulatory role of the eccrine sweat glands that are found over most of the body surface is well known. Clearly, the main function of eccrine sweat glands is to increase heat loss through the evaporation of sweat. The density of these glands varies from 700 glands per cm^2 in planar and plantar skin to 64 glands per cm^2 on the back[8]; these glands may hypertrophy with repeated heat exposure.[9] Each gland is made up of a secretory coil found in the dermis with a duct that extends through the dermis and epidermis to the surface of the skin. Sweat is secreted as an isotonic fluid by the coils. NaCl is reabsorbed within the ducts so sweat that is finally delivered to the surface is hypotonic.[10] Each liter of sweat evaporated is capable of removing 580 kcal from the body. Although apocrine sweat glands have been dismissed as "atavistic scent glands," this has recently been questioned.[11] Apocrine glands are usually associated with hair follicles and are most developed on the scalp, face, upper back, and chest. It has been proposed that sebum from apocrine glands acts as a surfactant at high temperatures and, thus, facilitates dispersion of eccrine sweat over the skin's surface. At low temperatures, sebum may function to repel water from the skin and, thus, reduce heat loss.

CUTANEOUS THERMOREGULATORY MECHANISMS

Cutaneous circulation is a major effector of human thermoregulation.[4] During heat stress, elevated internal temperature and skin temperature lead to cutaneous vasodilation through neural mechanisms and the local effect of higher temperatures on the skin vessels themselves. During the periods of cold stress, reduced temperatures mediate a cutaneous vasoconstriction through neural as well as local vascular effects. Under normothermic conditions, skin blood flow averages approximately 5% of cardiac output; however, the absolute amount of blood in the skin can vary from nearly zero during periods of maximal vasoconstriction in severe cold stress to as much as 60% of cardiac output in severe heat stress.[5]

SWEATING

Heat dissipation through the secretion and evaporation of eccrine sweat is critical to maintaining thermal stability in hot environments or during heat stress induced by strenuous dynamic exercise. Indeed, when environmental temperature exceeds blood temperature, the evaporation of sweat is the sole mechanism for heat dispersal. Sweat secretion is controlled primarily by sympathetic cholinergic nerves that release acetylcholine (Ach) to activate muscarinic receptors on the glands. Sweat secretion can be augmented by local production of nitric oxide near sweat glands.[12] Stimulated glands produce an isotonic fluid that becomes progressively hypotonic as the Na^+ is reabsorbed in the sweat gland duct by active ion transfer (see Chapter 84).

NEURAL CONTROL MECHANISMS OF THE CUTANEOUS VASCULATURE

In glabrous skin, cutaneous arterioles are innervated by sympathetic vasoconstrictor nerves that release norepinephrine and other cotransmitters.[7,13–16] All thermoregulatory reflex changes in blood flow in these areas are caused by changes in noradrenergic vasoconstrictor activity and the effects of local temperature on the skin blood vessels themselves (Fig. 93-1).[4,7,17]

In nonglabrous skin, changes in skin blood flow are mediated by two branches of the sympathetic nervous system: (1) noradrenergic vasoconstrictor nerves as found in glabrous skin and (2) a cholinergic active vasodilator system.[4,7,17] These dual sympathetic neural control mechanisms are the major effectors of thermoregulatory responses. Vessels in nonglabrous skin also respond to the effects of local temperature changes (Fig. 93-2).[4,7,17]

In normothermia, cutaneous arterioles are under little neural tone. During cold stress, reduction of skin temperature and/or internal temperature cause a thermoregulatory reflex-mediated reduction in skin blood flow to conserve body heat. Enhanced noradrenergic vasoconstrictor tone mediates an arteriolar vasoconstriction and, thus, decreases skin blood flow.

Conversely, during heat stress, thermoregulatory reflexes that facilitate body cooling are affected. As internal temperature continues to rise over a threshold value of approximately 37°C (98.6°F), a cutaneous vasodilation begins. At this threshold, active vasodilator tone to the cutaneous arterioles is enhanced. At rest, sweating also begins at the same internal temperature threshold. Vasodilator tone increases as internal temperature increases. Enhanced vasodilator activity decreases smooth muscle tone, leading to an arteriolar vasodilation, and, thus, an increase in skin blood flow, especially through the papillary loops. High skin blood flow delivers heat to the body surface where it is dissipated to the environment in conjunction with the evaporation of sweat. Overall, the active vasodilator system is responsible for 80%–95% of the elevation in skin blood flow that accompanies heat stress. A small, but significant portion of the vasodilation is mediated by the direct vasodilator effects of local heat on the cutaneous vessels.[18]

Dual vasoconstrictor nerves and vasodilator nerves in skin were first suggested in 1931 by Lewis and Pickering[19] and confirmed by Grant and Holling.[20] They measured skin temperature as an index of blood flow in the human forearm and found that large increases in response to heat stress could be abolished by sympathectomy or nerve blockade. They noted that while sympathectomy or nerve blockade caused only a slight

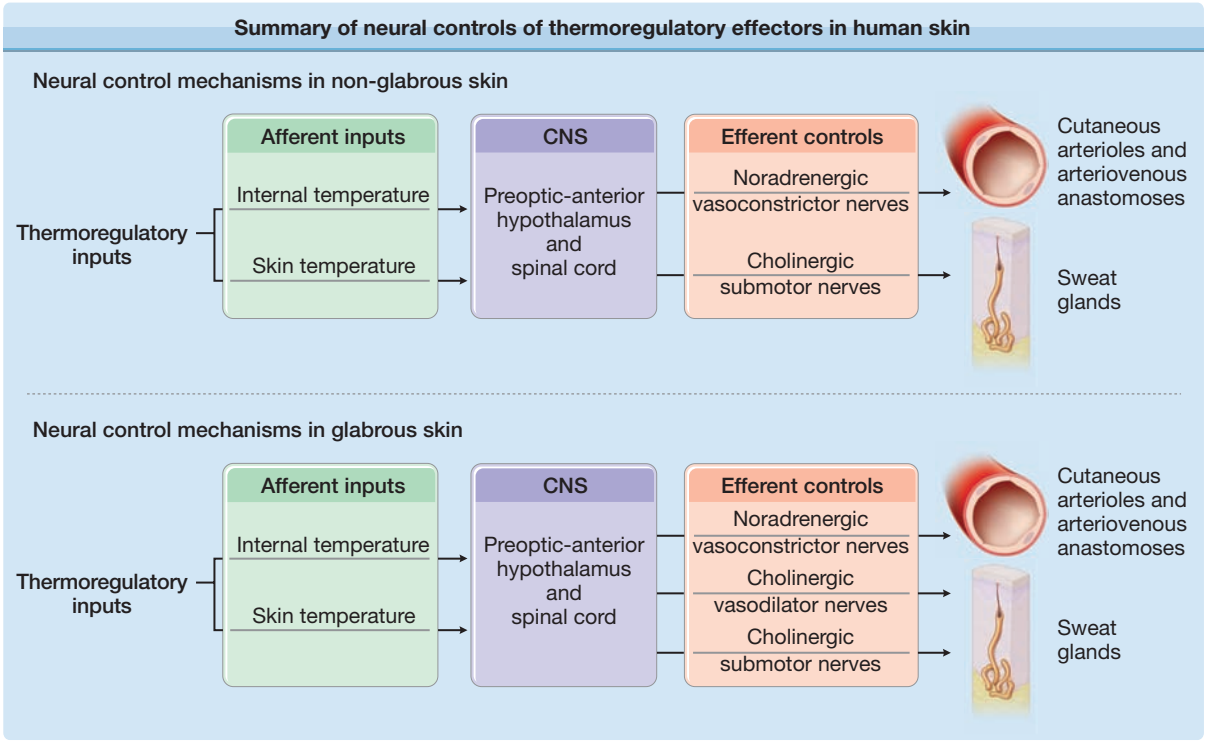

Figure 93-1 Summary of neural controls of thermoregulatory effectors in human skin: Thermoregulatory reflexes are mediated by the afferent inputs of internal and skin temperature. These afferent inputs are integrated in the preoptic anterior hypothalamus and spinal cord areas of the central nervous system. Efferent control of blood vessels and sweat glands in glabrous skin is mediated by noradrenergic vasoconstrictor nerves and cholinergic sudomotor nerves, respectively. In nonglabrous skin regions, efferent control of blood vessels is effected through a system of dual sympathetic innervation, noradrenergic active vasoconstrictor nerves and cholinergic active vasodilator nerves. Sweat glands also receive cholinergic sympathetic innervation; however, whether cholinergic active vasodilator nerves and cholinergic sudomotor nerves are one and the same is not known.

cutaneous vasodilation during normothermia, heat stress elicited a much greater increase in skin blood flow. In addition, nerve blockade during established heat stress abolished any cutaneous vasodilation. These results suggested that cutaneous vessels in nonglabrous skin are innervated by sympathetic active vasodilator as well as sympathetic vasoconstrictor nerves. In the 1950s, their findings were confirmed by Edholm et al[21] and by Roddie et al.[22] In addition, it has been shown that bretylium tosylate (a prejunctional noradrenergic neuronal blocking agent) abolishes the cutaneous vasoconstriction induced by cold stress, but does not alter the vasodilator responses induced by heat stress.[23] This confirmed that dual efferent neural systems control the cutaneous arterioles: a noradrenergic vasoconstrictor system and a nonadrenergic active vasodilator system.

FACTORS THAT ALTER RESPONSES TO HEAT AND COLD

Thermoregulatory responses undergo physiological acclimatization after repeated thermal challenges over a prolonged (2-week) time period. After repeated exposure to a hot environment, sweat glands hypertrophy to produce more sweat and cutaneous active vasodilation begins at lower internal and skin temperatures to facilitate long-term thermal stability by favoring earlier and greater heat dissipation.[87] Humans also acclimate to cold environments after repeated exposure by increasing metabolic heat generation (in part through increased amounts of brown adipose tissue) and habituating to cold. These adaptations are less effective in promoting thermal stability than adaptations to heat.[88]

Acute and chronic dermatological disorders can impair thermoregulation. For example, sunburn compromises sweat production, thus impairing evaporative cooling and reducing heat tolerance. At the same time, the inflammatory vasodilation that accompanies sunburn can compete against thermoregulatory reflex vasoconstriction during cold exposure. This will compromise the ability to reduce skin blood flow to conserve body heat, thus reducing cold tolerance.[87] Other inflammatory skin conditions, of which erythroderma is the most extreme, have the same effect.

Medications can alter thermal tolerance, especially during heat exposure. Numerous medications have anticholinergic effects. Since the cutaneous active vasodilator system and sweat glands are both controlled by cholinergic sympathetic nerves, it is not surprising that such agents have deleterious thermoregulatory consequences. Examples of commonly used medications that can compromise heat stress responses include first generation antihistamines, H_2-receptor antagonists, and tricyclic antidepressants. These systemic agents

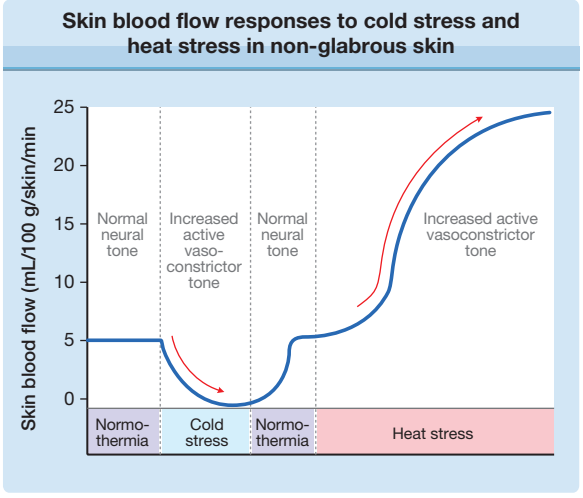

Figure 93-2 Skin blood flow responses to cold stress and heat stress in nonglabrous skin: under normothermic conditions, skin blood flow is relatively low (approximately 5% of cardiac output) and skin vessels receive relatively minor neural inputs from active vasoconstrictor and vasodilator nerves. During cold stress, reductions of skin and internal temperatures lead to reflex increases in sympathetic noradrenergic vasoconstrictor nerve activity. Increased vasoconstrictor system tone reduces skin blood flow, thus increasing thermal insulation and conserving body heat. During heat stress, increasing skin and internal temperatures lead to reflex increases in sympathetic cholinergic active vasodilator nerve and cholinergic sudomotor activity. Increased activity of the vasodilator system leads to potentially dramatic increases in skin blood flow that can reach 60% of cardiac output. High skin blood flow delivers heat to the skin surface where it is removed to the environment primarily through evaporation of sweat.

(and many others) can reduce sweat secretion, attenuate cutaneous active vasodilation, and increase the risk of thermoregulatory failure.[17]

Aging also modifies thermoregulatory reflexes. Relative to younger subjects, in healthy older persons, noradrenergic mechanisms are more important than cotransmitter mechanisms in vasoconstricting skin during cold stress.[89] During heat stress, older subjects show a delay in the onset and reduced magnitude of cutaneous vasodilation.[90] These alterations in cutaneous responses to thermoregulatory challenges contribute to increased morbidity and mortality during thermal stresses in older persons.

Chapter 94 :: Cold Injuries

:: Gérald E. Piérard, Pascale Quatresooz, & Claudine Piérard-Franchimont

COLD INJURIES AT A GLANCE

- Skin is important for maintaining core body temperature within a narrow physiologic range.
- Cold weather, wind, humidity, dampness, and altitude combine to inflict skin damage.
- Nonfreezing and freezing conditions can both produce cold injuries.
- Frostbite occurs after exposure to intensely cold air, liquids, or metals. Several degrees of frostbite are recognized.
- Winter xerosis and acrocyanosis are common consequences of prolonged exposure to cold.
- Erythrocyanosis tends to occur over skin areas with thick adipose tissue, whereas chilblain is more frequently seen in lean persons.
- Cold urticaria is rare and occurs at the sites of localized cooling.
- Primary erythromelalgia is a rare neuropathic disorder to which there is a genetic predisposition.

The human capacity for physiologic adaptation to cold is minimal. This deficiency may cause problems, because seasonal changes in the outdoor environment are quite prominent, even in the temperate zones of the world. In this context, skin is important in thermoregulation, and cutaneous blood flow and the resulting skin temperature may vary widely to help preserve the core body temperature.[1–3] Physiologic, behavioral, and environmental factors modulate skin responses to cold exposure.

PHYSIOLOGIC RESPONSE TO COLD

Core body temperature is maintained within a narrow range by thermoregulatory mechanisms that rely largely on control of the cutaneous blood flow. Arteriovenous anastomoses are abundant in acral areas, and they regulate the volume of blood that passes through the skin. When the skin is cooled, there is usually an immediate acute reduction in the amount of blood that flows to the surface. These events alter skin temperature, heat loss, and color. Skin reactivity and the anatomic pattern of blood supply differ in the skin of newborns, adults, and older people. For instance, a reticulate appearance of cooled skin is a common finding in young infants (Fig. 94-1).

The parallel arrangement of large arteries and veins in the limbs allows countercurrent exchange of heat. Vasoconstriction due to cold results in shunting of blood from the superficial to the deep venous system, and heat is transferred from arteries to veins. Thus, the blood going to the acral part of the limbs is precooled, and less heat is lost to the environment. With such thermoregulation, the body can maintain a constant core temperature of approximately 37°C (98.6°F) over a range of external temperatures between 15°C and 54°C (59°F and 129.2°F).

Normally, the skin is to some extent adapted to a cooler environment than the 37°C (98.6°F) of internal organs. Given the presence of many cold-adapted enzymes, the skin may even function more effectively when slightly cooled. In the case of adipose tissue, mild long-term exposure to cooling may lead to progressively better insulation. Habitually cold-exposed skin also develops a more efficient system for shunting blood away from the surface. These adaptive mechanisms are most flexible during the first years of life. Tissues in the aged are less able to develop new shunts.

Figure 94-1 Reticulate appearance of cooled skin in the newborn due to the anatomic pattern of the blood supply and factors influencing flow such as arteriolar vasoconstriction and the increased viscosity of cooled blood.

The effect of swimming in cold water after extreme heating—for example, after using a sauna[4]—is somewhat comparable to accidental cold water immersion. Well-being depends substantially on the degree of subcutaneous insulation, so that overweight persons, as well as those who are well clothed, can survive prolonged accidental cold-water exposure.[5]

Viscosity of fluids generally increases as temperature decreases. However, blood is a non-Newtonian fluid that exhibits thixotropy, i.e., it becomes less viscous with increasing flow velocity, independent of temperature. This effect is strongly influenced by hematocrit and by packing of erythrocytes. Macrophages also can block capillaries when they develop pseudopods as a result of reduced flow. The combination of slow flow and leukocyte conformational changes is, in part, a physiologic process that enables these cells to migrate through the endothelial lining.[6] Other factors affecting blood viscosity include increased platelet adhesiveness, changes in concentrations of proteins, and the presence of abnormal proteins. Fibrinogen level is particularly important.

THERMOREGULATION AND HUNTING REACTION

Local and systemic thermoregulation is complex. A group of neurons in the hypothalamus responds directly to temperature. When the temperature decreases, the rate of discharges decreases. From this temperature-sensitive area, signals radiate to various other portions of the hypothalamus to control either heat production or heat loss. Stimuli that influence the autonomic nervous system, such as painful stimuli, mental stress, arousal stimuli, and deep breaths, can all produce cutaneous vasoconstriction in warm subjects but vasodilation in cold subjects.[7,8]

Cold exposure produces an initial massive cutaneous vasoconstriction, which results in a fall in skin temperature. This change serves to maintain core temperature, but at the expense of the skin. Conversely, cold-induced vasodilation represents a protective mechanism to prevent skin necrosis. This physiologic reflex, known as the *hunting reaction of Lewis*, involves transient cyclic vasodilation caused by the opening of arteriovenous anastomoses.[9,10]

A chilling effect is produced by applications of dedicated hydrogel pads or cushions previously stored in a refrigerator.[11,12] This biothermal procedure is commonly used during laser therapy. It also serves to achieve a sustained removal of heat from the skin and its underlying tissues. It produces discrete skin hemodynamic changes and may relieve pain.

COLD, WIND, HUMIDITY, AND ALTITUDE

Outdoor work and winter sports are common risk situations for cold damages. A cold environment can be a threat to the skin, leading to a subsequent fall in core body temperature. Many physiologic, behavioral, and environmental factors predispose to the global effects of cold injuries. Marked increases in convective, conductive, or radiant heat loss are responsible for the immediate effects of cold exposure. For instance, touching cold metal objects considerably increases conductive cooling (Fig. 94-2). Other predisposing factors increasing heat loss and/or decreasing heat production and insulation from clothing make people especially susceptible to cold.[13]

There is ample evidence that the effect of low temperature on skin biology is, in part, a function of environmental humidity, wind speed, and altitude. In this respect, the wind chill index is indicative of the convective heat loss. Wind chill affects the gradients of temperature and water content across the stratum corneum, which result in an imbalance in condition between outer and deeper epidermal layers.[14] High altitude, which reduces the oxygen supply to tissues, also contributes to increase the skin damage induced by cold.[15]

Transepidermal water loss (TEWL) plays a prominent role in evaporative thermal loss. The skin temperature and the relative and absolute environmental humidity are key factors affecting cold injuries. The ambient humidity indicates the mass of water vapor present in a unit volume of the atmosphere. An accurate representation of the amount of moisture in the air as a function of temperature is given by the calculation of the dew point,[11,16] which is defined as the temperature of the air at which the gaseous moisture begins to condense, that is, the temperature at which relative humidity reaches 100%.

Poor clothing insulation is a common reason for cold injuries. The insulation is insufficient when clothing is too light, wet, tight, permeable to wind, or inadequate to cover the cold sensitive body parts. Individual factors predisposing to cold injuries are physical injuries, leanness, low physical fitness level, fatigue, dehydration, previous cold injuries, sickness, trauma, poor peripheral circulation, the wearing of tight constrictive clothing, and old age.[13] Newborns, the elderly, and individuals with impaired mental faculties remain the most vulnerable. Injury is often increased by alcohol, smoking, and psychotropic drug use.

Figure 94-2 Bullous frostbite following contact with a cold steel sheet.

Severe cold injuries have historically influenced the outcome of battles and wars.[17,18] Peacetime military operations also impose risks.[19–22] However, cold injuries are becoming more prevalent among the general population.[21] Many cases are associated with alcohol consumption, homelessness in urban centers, and car breakdown. Frostbite also prevails among winter sport enthusiasts such as cross-country skiers and backpackers who get lost or trapped in a snowstorm.[2,22–26] Accidental exposure to liquefied gas is another cause of severe cold injuries.[27]

Adaptation to cold protects one from responding inappropriately, and a moderate degree of exposure to cooling might be health promoting by stimulating a responsive and protective vasculature. In contrast, individuals who have experienced severe cold injury may have a profoundly delayed or abolished hunting reaction in the affected limbs.[28] They are rendered more susceptible to recurrent cold injury with pain, hyperesthesia, or paresthesia.[29] Some of these individuals also have coldness of the skin, which is very persistent and probably related to a functional imbalance in the sympathetic nervous system that results from increased α-adrenergic receptor density or affinity for norepinephrine.[30] In addition, altered vascular structure may reduce vasocompliance after cold exposure. There may also be impairment of normal vascular reflexes to various stimuli, including deep inspiration, venous occlusion, neck cooling, and ipsilateral skin cooling.[30]

CLASSIFICATION OF SKIN COLD INJURIES

Freezing and nonfreezing injuries can be distinguished according to the severity and duration of chilling. However, the damage caused depends on many variables other than the actual temperature. Recognition is generally easy at a clinical level, but awareness of potential uncommon underlying disorders is important. Treatment, both physical and pharmacologic, is aimed at keeping the body warm and maintaining vasodilation.

Frostbite is the consequence of extreme and prolonged freezing conditions. In addition, the whole body may cool down so much that life-threatening hypothermia may ensue. This is an important concern for people who enjoy cold weather sports, particularly in mountains and circumpolar regions. Prompt recognition and treatment are of paramount importance, because many hypothermia victims can recover from very low body temperatures. Treatment in an adequate medical facility can make the difference between full recovery and lifelong problems. Even if the victim appears to be dead from exposure to cold, resuscitative efforts should be started and continued until the proper core body temperature is reached.[31]

Figure 94-3 Hemorrhagic bulla and necrosis of the skin induced by freezing a wart with liquid nitrogen.

Figure 94-4 Facial redness in a person exposed to cold winters in a temperate climate.

Extreme and often conductive heat loss at a given body site freezes the tissues and results in localized blistering and necrosis (Fig. 94-3). Several cutaneous disorders also occur when the tissue temperature is maintained just above freezing for long periods. These conditions include chilblains, cold urticaria, cold panniculitis, erythrocyanosis, and acrocyanosis, among others. These disorders may be a consequence of impaired blood flow, reduced sensory perception, or a change in the physical properties of the tissues, such as in adipose tissue.

Minor but long-term cold exposure combined with environmental desiccation may have profound effects on the biology of the epidermis, leading, for example, to winter xerosis.[32,33] Persistent erythema of the face and the hands is not a rare finding (Fig. 94-4).

FROSTBITE

Frostbite occurs when tissue freezes after exposure to extremely cold air, liquids, or metals. The clinical effects of accidental injury that leads to the death of tissues are similar to those caused by cryosurgery.[34] The components of tissue that may lead to damage when frozen are water, with formation of ice crystals at 0°C (32°F), and lipids such as fat globules or cell membrane constituents.

Contrasting with damaging cryoinjuries, cryopreservation is used to preserve or "to freeze" in vitro most of the biomolecules present in tissues.[35] Any metabolic activity is blocked in these circumstances. Cryoscopy is a diagnostic procedure applicable in vivo.[36] It relies on an acute but short icing of the stratum corneum in order to disclose some structures exhibiting different capacities of thermal conductivity.

The rate of freezing determines the site of injury at the cellular level.[37] Extracellular formation of ice occurs most commonly with slow freezing, whereas fast freezing tends to produce intracellular ice. The formation of ice crystals in the extracellular space alters the osmotic properties of the tissues and disturbs the flow of water and electrolytes across the cell membranes. Thawing may be as damaging as the freezing itself, and repeated freeze and thaw cycles, as may occur in accidental injury, compound the damage, making more water available, which rapidly leads to intracellular flooding. The rewarming rate is also important. In slow rewarming, ice crystals become larger and more destructive. Cells are also exposed to a high concentration of electrolytes for a longer period than with rapid rewarming.

As the body cools, there is a reflex constriction of the arteries and veins in the extremities.[31] This results in increased venous pressure, decreased capillary perfusion, and sludging. Cooling also creates a leftward shift in the oxygen dissociation curve, and hemoglobin gives up its oxygen less readily. These two conditions result in hypoxia and damage to the capillaries and surrounding tissue. Oxygen tension is further decreased by thrombus formation in the microvasculature, which results in arteriovenous shunting. Arterial and arteriolar constriction, mediated by sympathetic outflow, initiates and probably maintains circulatory impairment. In addition, segmental vascular necrosis occurs in areas of erythrostasis, which suggests that ultimate damage may depend more on insufficient clearance of toxic substances than on initial vasoconstriction.

Cell types vary in their susceptibility to cold injury. Melanocytes are very sensitive to cold, and irreversible damage may occur at –4°C to –7°C (24.8°F–19.4°F). This sensitivity explains the hypopigmentation that often follows cryotherapy. In addition, it appears that black persons are more susceptible to frostbite than whites. Nerve axons are also easily damaged by cold,

TABLE 94-1

Arteriovenous shunting
Segmental vascular necrosis
Massive thrombosis

and nerve injury may occur with axonal degeneration of large myelinated fibers. Autonomic fibers are also affected, and this may account for the abnormal sweating and cold sensitivity that follow nonfreezing cold injury.[38,39] Nerve sheaths are quite resistant to cold, as are bone and cartilage.[28] Desolidification of lipids in adipose tissue and disruption of endothelial cells lining blood vessels and lymphatics, with secondary disturbances of permeability and blood flow, are other consequences of severe cold. In the overall assessment, there are marked similarities in the pathologic processes to those seen in thermal burns and in ischemia-perfusion injuries.

Three stages of cooling are recognized. The first is massive vasoconstriction, which causes a rapid fall in skin temperature. In a second step, the hunting reaction follows with a cyclic rise and fall in skin temperature. If cold exposure continues, the third stage of freezing occurs as the skin temperature falls to approach ambient temperature. The events that ensue in freezing and nonfreezing cold injuries are similar.[17,40] Consequences of cold injuries and their classification are presented in Tables 94-1 and 94-2, respectively.

Frostbite commonly affects fingers, toes, ears, nose, and cheek.[41,42] The clinical presentation of frostbite falls into three categories corresponding to mild frostbite or frostnip, superficial frostbite, and deep frostbite with tissue loss.

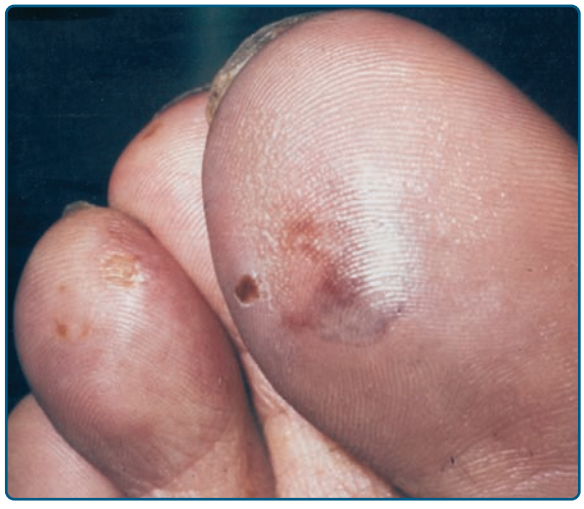

Figure 94-5 Frostnip.

Frostnip involves only the skin and causes no irreversible damage. There is a sensation of severe cold progressing to numbness followed by pain. Erythema is usually present on the cheeks, ears, nose, fingers, and toes (Fig. 94-5). There is no edema or bleb formation. Frostnip is the only form of frostbite that can be treated safely in the field with first aid measures.

Superficial frostbite involves the skin and immediately subcutaneous tissues. It includes the previously described signs but with the pain subsiding to feelings of warmth. This is a sign of severe involvement. The skin has a waxy appearance, but deeper tissues remain soft and resilient. Clear blebs form, accompanied by edema and erythema within 24–36 hours after thawing. Lesions may become eroded (Fig. 94-6).

Deep frostbite extends to the deep subcutaneous tissue. The injured skin becomes white or bluish white with a variable degree of anesthesia. Most often the affected skin becomes deceptively pain free, and the discomfort of feeling cold vanishes. The tissue is

Figure 94-6 Superficial frostbite.

Figure 94-7 Deep frostbite after rewarming. Large blisters have formed. Note cyanosis of toes as a sign of developing necrosis. This cold injury occurred in a homeless person who was found on the street after heavy alcohol consumption and overnight snowfall.

Figure 94-8 Dry gangrene of all fingers in a mountain climber 5 weeks after being caught in a snowstorm.

totally numb, indurated with immobility of joints and extremities. Muscles may be paralyzed. Nerves, large blood vessels, and even bone may be damaged. Large blisters form 1 to 2 days after rewarming, and they can be classified according to depth, as in heat-induced burns (Fig. 94-7). Frostbite blister fluid contains high amounts of prostaglandins, including prostaglandin $F_{2\alpha}$ and thromboxane A_2. These mediators may contribute to increased vasoconstriction, platelet aggregation, leukocyte adhesiveness, and ultimately progressive tissue injury. The blister fluid begins to be resorbed within 5 to 10 days, which leads to the formation of hard, black gangrene. Weeks later, a line of demarcation occurs, and the tissues distal to the line undergo autoamputation (Fig. 94-8).

PREVENTION

Prevention is key to protecting individuals from the effects of cold weather; and frostbite, frostnip, and hypothermia always should be taken seriously. Prognostic factors[25,43–46] are listed in Table 94-3. Wearing protective clothing, warm hat, earflaps and scarf together with preventive behavior such as turning bare areas away from the wind are the most important procedures for preventing frostbite. Nonmedicated waterless ointments are traditionally used for protection against facial frostbite, but their benefit is undocumented. The thermal insulation they provide is indeed minimal.[41,42] The use of protective emollients seems to cause a false sensation of safety, which leads to an increased risk of frostbite, probably through neglect of other, more efficient protective measures.[47,48] In less extreme conditions, however, some specific topical formulations bring beneficial effects.[49] The most effective products are those reducing TEWL and perspiration because these biological functions cause emission of body thermal energy and thus cool the skin.

MANAGEMENT

The first consideration in frostbite treatment is to be aware that the victim may be suffering from hypothermia.[25,31,50,51] Because of the difficulty in assessing the depth of frostbite injury, conservative waiting after the frostbite episode is often encouraged in an attempt to delineate the extent of tissue loss. Beyond this, the main principles are to avoid trauma, friction, pressure, massaging with snow, and refreezing. Slow rewarming increases tissue damage, and therefore rapid rewarming is the keystone of treatment.[20] It should be performed in a

TABLE 94-3
Prognostic Signs of Frostbite

Good prognostic signs	Large, clear blebs extending to the tips of the digits Rapid return of sensation Rapid return of normal (warm) temperature to the injured area Rapid capillary filling time after pressure blanching Pink skin after rewarming
Poor prognostic signs	Hard, white, cold, insensitive skin Cold and cyanotic skin without blebs after rewarming Dark hemorrhagic blebs Early evidence of mummification Constitutional signs of tissue necrosis, such as fever and tachycardia Cyanotic or dark red skin persisting after pressure Freeze–thaw–refreeze injury

water bath no warmer than 40°C–42°C (104°F to 107.6°F) until the most distal parts of the body are flushed. Large amounts of analgesics may be required. The damaged part should be elevated, and blisters should be left intact. Surgical debridement is often best delayed until 1 to 3 months after demarcation. However, triple-phase bone scans, magnetic resonance imaging, and magnetic resonance angiography can be used to predict ultimate tissue loss and to assess the possibility of earlier surgical intervention.[40,52,53]

There is no uniformly accepted protocol for other measures allegedly beneficial in the treatment of frostbite injury.[51] Intra-arterial reserpine and sympathectomy have been used to reverse vasospasm, which may contribute to tissue loss. Their role is controversial, although some patients have benefited from this therapy. To counteract vasoconstriction caused by local release of inflammatory mediators, the use of topical aloe vera, which inhibits thromboxane synthetase, and systemic ibuprofen, which inhibits cyclooxygenase, have been advocated. Oxpentifylline has been presented as an advanced therapy.[54] In addition, several adjunctive therapies, including vasodilators, thrombolysis, and hyperbaric oxygen, are sometimes useful.[55] Tetanus toxoid should be given in the case of open wounds. Surgery and amputation remain the ultimate strategies to help the victims.[56]

SEQUELAE

Sequelae of frostbite include permanent hypersensitivity to cold and, less often, hyperhidrosis.[38] Squamous cell carcinoma is a rare outcome, usually occurring on the heel 20–30 years later.[57] Epiphyseal plate damage or premature fusion may occur in children. Premature fusion can result in shortened digits, joint deviation, and dystrophic nails. In addition, frostbite arthritis, resembling osteoarthritis, may occur weeks to years later.

NONFREEZING COLD INJURY AND DAMPNESS

Nonfreezing cold injury occurs when tissues are cooled to temperatures between approximately 15°C (59°F) and their freezing point for prolonged periods. This type of injury, which is exacerbated by dampness, has claimed numerous casualties in warfare. Nonfreezing cold injury may be followed by cold sensitivity and hyperhidrosis, which may persist for years.

During World War I, trench foot was identified as a separate entity. Wet conditions at temperatures above freezing and limb dependency due to immobility and constrictive footwear were important pathogenic factors. Three stages were described. Stage I consisted of initial erythema, edema, and tenderness. Stage II followed within 24 hours with paresthesia, marked edema, numbness, and sometimes blisters. Stage III corresponded with progression to a usually superficial gangrene. Immersion foot, similar to trench foot, was described in shipwreck survivors during World War II.

Tropical immersion foot was described during the Pacific campaign in World War II. Occurring after exposure to the warm, wet conditions of jungle warfare, this condition differed from classic trench foot and immersion foot in that it caused less tissue destruction, numbness, and anesthesia and was followed by more rapid complete recovery. The role of temperature in tropical immersion foot is unclear and may not be important.[58] As with trench foot and immersion foot, prevention is most important.

Another specific condition known as *pulling-boat hands* was described, characterized by the presence of erythematous macules and plaques on the dorsum of the hands and fingers of sailors aboard rowboats.[59] Small vesicles developed later, accompanied by itching, burning, and tenderness. These individuals were exposed to long periods of high humidity, cool air, and wind, an ideal setting for the development of nonfreezing cold injury. In addition, hours of vigorous rowing daily produced repetitive hand trauma.

WINTER XEROSIS

Many individuals present with dryness of the skin, particularly on the lower extremities, during wintertime. The hands, forearms, cheeks, lips, and trunk also may be affected. Itching, a dry appearance, chapping, and cracking of the stratum corneum are more or less prominent. The condition is markedly influenced by cold environments, especially in combination with low humidity.[38,39] Predisposing factors include atopic dermatitis, ichthyosis, and increasing age. Excessive washing exacerbates winter xerosis. Indeed, irritant dermatitis of the hands worsens in a cold and dry environment.[60] Emollients and improvement in the environmental temperature and humidity are helpful in controlling this condition.

ACROCYANOSIS

Acrocyanosis is a bilateral dusky mottled discoloration of the hands, feet, and sometimes the face. It is persistent and accentuated by cold exposure. When the temperature is very low, the skin may be bright red. Trophic changes and pain do not occur, and pulses are present. This condition must be distinguished from Raynaud phenomenon (see Chapter 170), which is clearly episodic, often segmental, and painful, as well as from obstructive arterial disease (see Chapter 173).

Acrocyanosis is genetically determined and usually starts in adolescence. Chronic vasospasm of small cutaneous arterioles or venules with a secondary dilatation of the capillaries and subpapillary venous plexus has been postulated. Stasis in the papillary loops with aneurysmal dilatation at the tips redistributes blood flow to the subpapillary venous plexus. The blood flow may be compromised by altered erythrocyte flexibility, increased platelet adhesiveness, and other plasma viscosity factors. Cold agglutinins may exacerbate the acrocyanosis manifestations.[61,62] The "puffy hand

syndrome" is defined by the presence of hand edema superposed on acrocyanosis.[63]

Tissues are less sclerotic in acrocyanosis than in Raynaud phenomenon. They contain twisted collagen fibrils and large pericytes. In cases developing for the first time late in life, an underlying myeloproliferative disorder should be excluded. Remittent necrotizing acrocyanosis is associated with enhanced susceptibility to cooling and pain, as well as ulceration and gangrene of the fingers. Arteriolar occlusion by thrombi or intimal proliferation may occur. Cold pain should be distinguished from cold allodynia and cold hyperalgesia.

There is no effective treatment for acrocyanosis. Supportive measures to keep the skin warm are helpful.

ERYTHROCYANOSIS

Erythrocyanosis is a dusky cyanotic discoloration, worse in winter, which occurs over areas with a thick layer of subcutaneous fat (Fig. 94-9). The condition is seen most often on the lower legs and thighs of adolescent girls and middle-aged women. Nodular lesions similar to chilblains may occur and have been described in women with severe erythrocyanosis and paraplegia. Keratosis pilaris, angiokeratomas, and telangiectasia are commonly associated. Spontaneous improvement often occurs after a few years. However, the disease may persist with long-standing edema and fibrosis.

The wearing of warm clothes and weight reduction are important to decrease the insulating effect of the subcutaneous fat, which is responsible for a chronically low skin temperature. The outcome remains unpredictable.

CHILBLAINS

Chilblains, also called *pernio* or *perniosis* (Fig. 94-10), are localized inflammatory lesions caused by continued exposure to cold above the freezing point.[64,65] Dampness and wind that increase thermal conductivity and convection play a part. Absolute temperature is less important than the cooling of nonadapted tissue. The condition shows a genetic predisposition. It has been described most often in temperate regions, where winters are occasionally cold and damp. Chilblains are seen less often in very cold climates, where well-heated houses and warm clothing are available. Both acrocyanosis and chilblains appear to be more common in children, women, and persons with low body mass index. Spontaneous remission is common when spring arrives, and relapse is frequent during the following winters. However, chilblains do not always occur at the time of maximum cold.

Chilblains develop acutely as single or multiple, burning, erythematous, or purplish swellings (see Fig. 94–10A and C). Patients may complain of itching, burning, or pain. In severe cases, blisters (see Fig. 94-10B), pustules, and ulceration may occur. Characteristic locations include the proximal fingers and toes, plantar surfaces of the toes, heels, nose, and ears, but other sites like the calves and thighs can be affected[66,67] (see Fig. 94-10C). Lesions usually resolve in 1 to 3 weeks but may become chronic in elderly people with venous stasis. Tight garments such as gloves, stockings, and shoes are especially to be avoided in cases in which there is also peripheral vascular disease. A papular form of chilblains resembles erythema multiforme and occurs at all times of the year, usually in crops on the sides of the fingers,[68] often superimposed on a background of acrocyanosis.

Figure 94-9 Erythrocyanosis of plump upper arms of a woman.

Figure 94-10 Chilblains are common at such sites as the hands and feet when they are exposed to both cooling and tight garments. **A.** Chilblains on the toes. **B.** Chilblains on the dorsum of the foot. Children and the elderly are most commonly affected, perhaps, because they take less care to protect themselves from cooling. **C.** Equestrian chilblains from horse riding on a cold morning with inadequate clothing.

A peculiar clinical presentation may occur in young women riding horses for several hours daily during winter.[69,70] Indurated red-to-violet tender plaques develop on the lateral calves and thighs (see Fig. 94-10C). The condition is quite similar to the nodular perniotic lesions described in adolescent girls with erythrocyanosis. For prophylaxis, experienced riders usually wear baggy breeches that provide insulation and are not tight enough to compromise the circulation.

Perniotic lesions have been described in association with myeloproliferative disorders,[71] probably as a consequence of blood flow changes, presence of cold agglutinins, and altered inflammatory response on cooling.

Idiopathic perniosis is characterized histologically by edema of the papillary dermis and by the presence of superficial and deep perivascular lymphocytic infiltrates. Necrotic keratinocytes and lymphocytic vasculitis also have been reported. Thickening of blood vessel walls with intimal proliferation may lead to obliteration of the vascular lumen.[72–74]

Chilblain lupus is a distinct disease and is similar to discoid lupus erythematosus.[75,76] Lupus pernio is a variant of sarcoidosis (see Chapter 152) and is unrelated to cold injuries.

The unfamiliarity of physicians with chilblains sometimes gives rise to unnecessary hospital admissions with expensive laboratory and radiologic evaluations and, at times, hazardous therapy. The most important point in management is prophylaxis through the use of adequate, loose, insulating clothing and appropriate warm housing and workplace. Maintaining the blood circulation by avoiding immobility is also helpful. A short course of ultraviolet light therapy at the beginning of winter was a recommendation but has been challenged.[77] Once chilblains occur, treatment is symptomatic with rest, warmth, and topical antipruritics. Calcium channel-inhibiting drugs may be effective in the treatment of severe recurrent perniosis,[78] although they may cause headache and flushing that are troubling to some patients. In cases of crippling severity, thyrocalcitonin and hemodilution may be helpful.

COLD URTICARIA AND POLYMORPHOUS COLD ERUPTION

Acquired cold urticaria is a form of physical urticaria (Fig. 94-11). Lesions occur at sites of localized cooling, usually when the area is rewarmed. The disease is recognized by wheal and flare-type reactions and/or angioedema. The condition may be idiopathic or associated with some serologic abnormality.[79–83] It accounts for approximately 2% of cases of urticaria (see Chapter 38).

Most cases fall into the group of essential cold urticaria. They can be subdivided into a rare familial type and an acquired form. Immunoglobulin E and, more rarely, immunoglobulin M have been implicated in the pathogenesis. The antigen is likely a normal metabolite produced on exposure to cold. Histamine is one of the most important mediators, but leukotrienes, platelet-activating factor, and others have been incriminated. In this disease, exposure to cold causes prolonged

Figure 94-11 Cold urticaria induced by the application of ice to the skin.

edematous papules and plaques, often with headache, fever, arthralgia, and leukocytosis. Swelling of the oral mucosa and esophagus may occur on ingestion of cold liquids. A rather distinctive combination of cold urticaria and dermographism or cholinergic urticaria is not uncommon. Alarming signs resembling those of histamine shock may lead to loss of consciousness. Death while swimming in cold water has been reported.

Familial cold urticaria is a rare autosomal dominant condition with onset at an early age.[84,85] A mutation in the gene responsible for the cold-induced autoinflammatory syndrome-1 (CIAS1) has been identified.[85] Urticaria develops when the patient is exposed to generalized cooling, particularly chilling wind, rather than local cold application. The delayed type of familial cold urticaria is characterized by localized angioedema developing 9 to 18 hours after cold exposure.

Cold urticaria may occur in 3%–4% of patients with cryoglobulinemia, and it also may be associated with cold agglutinins, cryofibrinogens, and cold hemolysins. Cold urticaria has been reported in cases of infectious mononucleosis in association with either cryoglobulins or cold agglutinins, but such occurrences are rare. Cold urticaria may also be a sign of the Muckle–Wells syndrome that associates urticaria, deafness and amyloidosis.[86] In this rare genetic disorder recurrent bouts of urticaria, fever, chills and malaise may occur from birth and persist throughout life. *Helicobacter pylori* has been suggested as a causative agent in some cases of acquired cold urticaria.[87]

Diagnosis of cold urticaria is confirmed by a cold challenge induced by an ice cube wrapped in a plastic bag placed on the skin of the forearm for periods varying from 30 seconds to 10 minutes (see Fig. 94-11). Wheals form on rewarming. Sometimes water at 7°C (44.6°F) is more effective, presumably because it causes less severe vasoconstriction. Peltier effect-based temperature challenge appears to be an improved method for diagnosis.[88] The Peltier effect relies on using two different heat-transferring metals to generate a precise skin surface temperature, sufficiently cold, to induce lesions. The temperature is regulated by a microprocessor control unit monitoring the actual temperature at the test site.

Cold erythema seems to be a related disorder with erythema and pain but without urticaria. Familial polymorphous cold eruption is a rare autosomal dominant disease characterized by childhood onset of nonpruritic,

erythematous patches often accompanied by influenza-like symptoms and leukocytosis after generalized exposure to cold. Results of the ice cube test are negative. The pathogenesis remains unknown. The disease frequently has been referred to as *familial cold urticaria*, although the skin lesions are not urticarial.[89]

Avoiding cold wind exposure and swimming in cold water are important preventive measures. Antihistamines reduce clinical signs and symptoms. Desensitization to cold is possible by immersing one arm into water at 15°C (59°F) for 5 minutes daily.

COLD PANNICULITIS AND RELATED ENTITIES

Cold injuries may affect the subcutaneous tissue in different ways. The freezing injury in deep frostbite results in tissue gangrene. Nonfreezing injuries also can alter the hypodermis. Among them, cold panniculitis is more common in children than in adults. It affects the cheeks and legs most commonly. Tender erythematous subcutaneous nodules appear 1 to 3 days after exposure and subside spontaneously within 2 to 3 weeks. Ice cube challenge to the child's skin for 10 minutes results in the development of an erythematous plaque 12 to 18 hours later.

A perivascular mixed infiltrate with neutrophils, lymphocytes, and histiocytes is present at the dermal–subcutaneous junction after 24 hours, followed by a well-developed panniculitis at 48 to 72 hours. Some adipocytes are necrotic and rupture to form cystic spaces. The reaction subsides completely in 2 weeks. Infants have a higher content of saturated fatty acids in adipose tissue than do adults, and this may result in solidification at higher (less cold) temperatures.[90,91] Cold panniculitis should be distinguished from other related disorders, including erythrocyanosis with nodules, sclerema neonatorum, and subcutaneous fat necrosis of the newborn.

SCLEREMA NEONATORUM AND SUBCUTANEOUS FAT NECROSIS OF THE NEWBORN

(See Chapters 70 and 107)

Sclerema neonatorum and subcutaneous fat necrosis of the newborn are distinct disorders involving the subcutaneous fat of the newborn. As noted in the prior paragraph, infant fat differs from adult fat in that it has a higher saturated–unsaturated fatty acid ratio, which results in solidification at a higher temperature. Prematurity and immaturity of enzyme systems may result in a relative inability to desaturate fatty acids, which alters the ratio further. Sepsis, dehydration, chilling, infection, and other stresses also may inhibit the enzyme system. Thus, infants in general, and premature or otherwise compromised newborns in particular, are susceptible to such disorders.

Sclerema neonatorum is a rare disorder characterized by diffuse, rapidly spreading hardening of the skin and subcutaneous tissue in infants.[92] It starts on the buttocks and trunk, usually in the first week of life. Palms, soles, and scrotum are spared. Fifty percent of affected infants are premature. They have difficulty feeding and are lethargic, and many are otherwise debilitated. Septicemia is frequent, and the prognosis is poor. Cold exposure does not seem to be important in the etiology of sclerema neonatorum; however, similar clinical findings have been seen in cases of primary cold injury.[93] Histologically, the subcutaneous layer is greatly thickened by enlarged fat cells and wide, fibrous bands. There is no fat necrosis, and many of the fat cells contain fine needle-like clefts.[94]

Treatment of sclerema neonatorum involves correcting dehydration and electrolyte imbalance and treating septicemia if present. The value of systemic glucocorticoids is controversial. Successful treatment with exchange transfusions has been reported.[95]

Subcutaneous fat necrosis of the newborn is characterized by discrete red to violaceous mobile plaques and nodules that usually appear within a few days of birth. The back, thighs, and cheeks are most commonly affected. Fat necrosis and crystallization are the hallmarks of the disease. There may be a granulomatous inflammatory response with foci of calcification. In most cases, the condition is benign and self-limited, although it has been associated with hypercalcemia and death.[96]

As in sclerema neonatorum, there is no clear etiologic relationship to cold, and the cause is likely multifactorial. It has been postulated that an underlying defect in fat composition, poor nutrition, and various physical stresses such as hypothermia may be important.

ERYTHROMELALGIA

Erythromelalgia or erythermalgia is a rare chronic cutaneous disorder characterized by erythema, burning discomfort, and warmth of the extremities.[97,98] Primary erythromelalgia is an autosomal dominant neuropathic disorder involving a mutation in a voltage-gated sodium channel subunit.[99–106] Vasoconstriction apparently precedes reactive hyperemia, similar to that seen in Raynaud phenomenon. An early-onset type and an adult-onset type have been recognized. When the extremity is lowered or heat is applied, the pain is intensified. The application of cold or elevation of the extremity has the opposite effect of decreasing the pain. Idiopathic erythromelalgia may involve increased thermoregulatory arteriovenous shunt flow. Secondary erythromelalgia is associated commonly with myeloproliferative syndrome-related thrombocythemia and is mostly evident in the adult-onset type.

Treatment for adults with erythromelalgia includes a single daily dose of acetylsalicylic acid (aspirin), but children who have no associated underlying disorder obtain little to no relief from the drug. Other drugs including mexiletine[107] and venlafaxine[108] may also help. Pain may be decreased by topical amitriptyline combined with ketamine.[109] Lidocaine in patches[110] or

administered intravenously in combination with oral mexiletine[111] may also alleviate pain. Sympathectomy in the upper extremities is another option for treating refractory primary erythromelalgia.[112]

Chapter 95 :: Thermal Injuries

:: Robert L. Sheridan

THERMAL INJURIES AT A GLANCE

- Burns are common; most are small and managed in the outpatient setting.
- Serious burns require inpatient care, ideally in a verified burn center.
- Large burns are managed in four general phases:
  - Initial evaluation and resuscitation.
  - Wound excision and biologic closure.
  - Definitive wound closure.
  - Rehabilitation and reconstruction.
- Styles of outpatient burn care are variable, but proper patient selection and monitored wound healing are essential.
- Long-term outcome quality tends to be very good in patients surviving large burns.

EPIDEMIOLOGY

The very young and very old are at increased risk of domestic burns.[1,2] Active young adults in industrial jobs are at modest increased risk. In developed countries, about 70% of pediatric burns are caused by hot liquid. Flame injuries are more common in older children and young working adults. Scalding and flame injuries each account for approximately half of burn injuries in the elderly, with kitchen and bathing accidents being predominant. Approximately 20% of burns in younger children involve abuse or neglect.

ETIOLOGY AND PATHOGENESIS

The development of an envelope of cornified skin was a crucial component of the adaptation of aquatic sea animals to the land environment. The vapor and fluid barrier created by the epidermal layer facilitates the maintenance of fluid and electrolyte homeostasis within very narrow limits. The dermis provides strength and flexibility, and the reactive dermal vasculature facilitates control of internal body temperature within very narrow limits. The appendages provide lubrication and prevent desiccation. All of these critical functions are lost when substantial areas of the skin are burned.

There is both a local and a systemic response to the burn wound.[3,4] The local response consists of coagulation of tissue with progressive thrombosis of surrounding vessels in the zone of stasis over the first 12–48 postinjury hours. An ability to truncate this secondary microvascular injury and its associated tissue loss is a major area of ongoing investigation. In larger burns, a systemic response develops that is driven initially by release of mediators from the injured tissue, with a secondary diffuse loss of capillary integrity and accelerated

transeschar fluid losses. This systemic response is subsequently fueled by by-products of bacterial overgrowth within the devitalized eschar.

Burn wounds are initially clean but are rapidly colonized by endogenous and exogenous bacteria.[5] As bacteria multiply within the eschar over the days following injury, proteases result in eschar liquefaction and separation. This leaves a bed of granulation tissue or healing burn, depending on the depth of the original injury. In patients with large wounds involving 40% or more of the body surface, the infectious challenge generally cannot be localized by the immune system, leading to systemic infection. This explains the rare survival of patients managed in an expectant fashion with burns of this size.

The systemic response to injury is characterized clinically by fever, a hyperdynamic circulatory state, increased metabolic rate, and muscle catabolism.[6] This stereotypical response to injury has been retained by all mammalian species. It is effected by a complex cascade of mediators, including changes in hypothalamic function resulting in increases in glucagon, cortisol, and catecholamine secretions; deficient gastrointestinal barrier function with translocation of bacteria and their by-products into the systemic circulation; bacterial contamination of the burn wound with systemic release of bacteria and bacterial by-products; and some element of enhanced heat loss via transeschar evaporation. It is likely that this response has significant survival value, but control of some of the adverse aspects of this response, particularly muscle catabolism, is an active area of ongoing investigation.[7,8]

BOX 95-1 ESSENTIALS OF BURN MANAGEMENT

- Burn size, extent, depth, and circumferential components influence decisions regarding outpatient care, hospitalization or transfer.
- Burn extent is best estimated using the Lund–Browder diagram that compensates for the changes in body proportions with age (see eFig. 95-4.1 in online edition). An alternative is a "rule-of-nines" for adults and children (see eFig 95-5.1 in online edition).
- In the adult rule-of-nines, the head and neck is given 9%, each lower extremity is given 18%, each upper extremity is given 9%, and the anterior and posterior torso are each given 18%.
- In the pediatric rule-of-nines, the head and neck is given 18%, each lower extremity is given 15%, each upper extremity is given 10%, and the anterior and posterior torso are each given 16%.
- For scattered or irregular burns, the entire palmar surface of the patient's hand represents approximately 1% of the body surface over all ages.

CLINICAL FINDINGS

(See Box 95-1)

Burns are classified by depth:

- First degree: Red, dry, and painful and are often deeper than they appear, sloughing the next day (Fig. 95-1A).
- Second degree: Red, wet, and very painful with enormous variability in their depth, ability to heal, and propensity to hypertrophic scar formation (see Fig. 95-1B).

Figure 95-1 Burn depth is classified as first, second, third, or fourth degree. **A.** First-degree burns are red, dry and painful and are often deeper than they appear, sloughing the next day. **B.** Second-degree burns are red, wet and very painful. There is an enormous variability in their depth, ability to heal, and propensity to hypertrophic scar formation. **C.** Third-degree burns are leathery, dry, insensate, and waxy. **D.** Fourth-degree burns involve underlying bone and/or muscle.

- Third degree: Leathery, dry, insensate, and waxy (see Fig. 95-1C).
- Fourth degree: Involve underlying subcutaneous tissue, tendon, or bone (see Fig. 95-1D).

Circumferential burns require special monitoring and possible surgical decompression. If across the torso, they will interfere with ventilation. If they involve an extremity, limb-threatening ischemia may occur during resuscitation.

LIGHTNING STRIKES

Although lightning strikes carry large amounts of energy, measured in millions of volts, human injuries are rare, with only about 50 people so injured annually in the United States and a fatality rate of only about 10%. Injury can rarely occur from direct strike, and is usually fatal. More commonly, people are injured by current flow around the skin envelope, or side flash, when a nearby object is struck. Destructive burns are unusual. Serious injury is more often the result of associated blunt trauma or occasional cardiac arrest. In most survivors, lingering symptoms are nonfocal, neurologic in nature, often preceded by an immediate but transient loss of consciousness.[9] The most common physical finding in those injured by side flash is an evanescent serpiginous cutaneous erythema, as noted in Figure 95-2.

Figure 95-2 (**A** and **B**) An evanescent serpiginous cutaneous erythema is characteristic of lightning injury.

TABLE 95-1
Burn Wound Complications

Common Outpatient Burn Complications
- Wound sepsis, usually streptococcal cellulitis
- Excessive pain and anxiety
- Underestimation of burn depth

Common Inpatient Burn Complications
- Wound sepsis, often invasive
- Septic shock and organ failures
- Inadequately controlled pain and anxiety
- Compartment syndromes
- Ocular exposure
- Respiratory failure
- Gut failure
- Pancreatitis
- Cholecystitis
- Urosepsis
- Donor site infection
- Soft-tissue contractures

COMPLICATIONS

In the outpatient setting, patient selection should ensure that major complications are few (Table 95-1). The most common issues that arise are wound sepsis, excessive pain and anxiety, and underestimation of burn depth.[10] The most common wound infection in this setting is streptococcal cellulitis, which presents initially with surrounding erythema that progresses to lymphangitis and systemic toxicity (Fig. 95-3). These patients often need admission for antibiotics, observation, and sometimes surgery. In some situations, adequate pain and anxiety management is very difficult in the outpatient setting, especially around dressing changes. This can be addressed with judicious medication and sometimes carefully monitored membrane dressings. Some patients will require admission. It is common for burn depth to be underestimated initially, with areas of full-thickness injury not appreciated for several days. These patients may require admission for surgery.

As burns increase in size and depth, the local injury is accompanied by an increasing degree of systemic derangement. Classically, this response has two phases. An initial "ebb" phase of reduced perfusion and metabolic rate, which lasts 24–48 hours, is followed by a "flow" phase of protein catabolism and a hyperdynamic circulation.[11] This later phase lasts until well after wound closure. Management of this physiology is an essential part of inpatient burn care. Those with large burns are susceptible to a host of other complications

Figure 95-3 The most common wound infection in this setting is streptococcal cellulitis, which presents initially with surrounding erythema that progresses to lymphangitis and systemic toxicity.

Figure 95-4 Some burn patterns are very suggestive of possible abuse. Here is illustrated flexor sparing in an immersion injury.

related to sepsis and organ failure. Careful monitoring and early intervention are essential to successful outcomes (Table 95-1).

PROGNOSIS AND CLINICAL COURSE

PATIENT EVALUATION AND TREATMENT PLANNING

In both outpatient and inpatient settings, a careful evaluation of the patient is essential for treatment planning. Patient evaluation is organized into a primary and a secondary survey, following the guidelines of the American College of Surgeons Committee on Trauma and the Advanced Burn Life Support Course of the American Burn Association. As in trauma, the primary survey begins with an assessment, and control if necessary, of the airway. Deeper burns of the face and neck can result in progressive airway edema. Occasionally, a child will aspirate hot liquids resulting in very severe upper airway edema mandating urgent intubation.

A burn-specific survey evaluates the issues uniquely associated with burn injury (eTable 95-1.1 in online edition). This may take just a few seconds if the burn is small, but will be much more time consuming in the more seriously injured.[12] In those with small injuries, essentials include a detailed determination of the mechanism of injury, a screen for associated trauma, consideration of the possibility of abuse (Fig. 95-4), and a detailed assessment of the burn wound. Delayed presentation for care, confusing stories, sharply demarcated margins, immersion patterns, and contact injuries are physical findings suggesting for abuse or neglect.[13] All such children should be admitted for evaluation.

After the patient has been evaluated, the burn wound should be examined for size, extent, depth, and circumferential components.[14] Burn extent is best estimated using a chart based on the Lund–Browder diagram that compensates for the changes in body proportions with age (eFig. 95-4.1 in online edition). An alternative is a modified "rule-of-nines," in which the head and neck is given 18% (instead of the adult 9%), each lower extremity is given 15% (instead of the adult 18%), each upper extremity is given 10% (instead of the adult 9%), and the anterior and posterior torso are each given 16% (instead of the adult 18%). For scattered or irregular burns, the entire palmar surface of the patient's hand represents approximately 1% of the body surface over all ages.

Burn depth is classified as first, second, third, or fourth degree (Fig. 95-1A–D). First-degree burns are red, dry and painful and are often deeper than they appear, sloughing the next day. Second-degree burns are red, wet and very painful. There is an enormous variability in their depth, ability to heal, and propensity to hypertrophic scar formation. Third-degree burns are leathery, dry, insensate, and waxy. Fourth-degree burns involve underlying subcutaneous tissue, tendon, or bone.

Near or completely circumferential burns should be identified for special monitoring, as they may need to be decompressed in the hours following injury to avoid ischemia (extremities) or failure of ventilation (torso).

The majority of burns can be successfully managed in the outpatient setting. However, poorly provided outpatient burn care can be frustrating and painful for patients and providers. The key is careful patient selection (eTable 95-1.2 in online edition) and a detailed care plan, especially an inpatient care plan (eTable 95-1.3 in online edition).

PATIENT OUTCOMES

Burn wounds and grafts typically develop some degree of hypertrophic scarring.[15] This involves a gradual increase in vascularity and collagen deposition in the months following healing. Some wounds will demonstrate significant contracture formation, with important functional and esthetic consequences (Fig. 95-5). Many patients will have bothersome pruritus and sometimes temporary neuropathic pain if burns are deep. A

Figure 95-5 Hypertrophic scarring and contracture formation can become difficult problems after serious burns (**A**), but are often amenable to surgical improvement (**B**).

long-term follow-up plan, consisting of scar management strategies, rehabilitation, reconstructive surgery, and emotional support will facilitate optimal outcomes. This care is best provided in a multidisciplinary burn clinic, ideally part of a comprehensive burn program. With such supports in place, the long-term outcome for most patients is surprisingly good. When managed in a comprehensive follow-up program, even those who have suffered devastating burns tend to become happy and productive again.[16,17]

TREATMENT

OUTPATIENT BURNS

Practice patterns vary widely, but certain characteristics are universal.[18] The wound should be kept generally clean and regularly inspected for infection. Desiccated exudates and topical medications should be periodically cleansed. Burns selected for outpatient management tend to be small and superficial with a corresponding low risk of infection, so clean rather than sterile technique is reasonable. If topical agents rather than membrane dressings are used, wounds may be cleansed with lukewarm tap water and a bland soap. Soaking adherent dressings prior to removal will decrease the pain associated with daily wound care. The wound is gently cleansed with a gauze or clean washcloth, inspected for any sign of infection, patted dry with a clean towel and redressed. It is important to instruct each patient to return promptly if they notice erythema, swelling, increased tenderness, lymphangitis, odor, or drainage so that infectious complications can be addressed early. Most small burns are adequately managed with a daily cleansing and dressing change. In some cases, a membrane dressing is applied once it is clear that early surgery is not needed, early infection is unlikely, and wounds are superficial. Pain and anxiety can be an issue for many. Some will benefit from an oral narcotic given 30–60 minutes prior to a planned dressing change. If dressings are occlusive, pain between dressing changes tends to be modest.

Increasing pain and anxiety associated with dressing changes; inability to keep scheduled follow-up appointments; delayed healing; signs of infection or a wound, which appears deeper than appreciated at the time of the initial examination, should prompt early return and specialty evaluation. Wounds selected for outpatient management are usually fairly superficial and heal within two weeks, but patients with mid and deep dermal injuries may have a deeper component with resulting scarring that may benefit from specialty evaluation. Finally, wounds of the face, ears, hands, genitals, and feet have functional and cosmetic importance out of proportion to their wound size. In some cases, early specialty evaluation may be prudent, as initial care can have an impact on long-term outcome.[19]

INPATIENT BURNS

A system of burn center verification has evolved to ensure that the patients requiring care of more

serious injuries receive coordinated efforts by experienced providers. Burn center referral criteria can be found at www.ameriburn.org (eTable 95-1.4 in online edition). Care of severe burns can be divided into phases, each with important objectives (eTable 95-1.3 in online edition).[20] Critical care is an important component, especially in the first three phases. Verified burn programs are required to have embedded burn intensive care units.

TOPICAL MEDICATIONS AND MEMBRANES

There is an increasingly confusing array of wound medications and membranes available for burn wounds. Wound medications and membranes provide three benefits: (1) pain control, (2) prevention of wound desiccation, and (3) reduction of wound colonization.

Topical wound medications range from aqueous solutions through antibiotic-containing ointments and debriding enzymes. Most topical agents in outpatient use have a viscous carrier that prevents wound desiccation and a more or less broad antibacterial spectrum that reduces wound colonization. A gauze wrap minimizes soiling of clothing and protects the wound from trauma. Silver sulfadiazine is in common use because it is painless on application and has a broad spectrum of antibacterial activity. Superficial burns are commonly treated with a clear, viscous antibacterial ointment containing low concentrations of various antibiotics. Wounds around the eyes can be treated with topical ophthalmic antibiotic ointments. Significant ear burns should be treated with mafenide acetate, as it is the only agent that will penetrate the relatively avascular cartilage.

Wound membranes provide transient physiologic wound closure while the underlying wound heals.[21] Physiologic closure implies a degree of protection from mechanical trauma, vapor transmission characteristics similar to skin, and a physical barrier to bacteria. The major benefit of wound membranes is that, when successful, they minimize wound manipulations. These membranes help create a moist wound environment with a low bacterial density and are generally intended for use on selected clean superficial wounds and donor sites. Occlusive synthetic membranes must be used with caution if wounds are not clearly clean and superficial, as submembrane infection can occur, deepening underlying wounds and causing systemic infection and toxicity.

PREVENTION

There have been a plethora of burn prevention efforts, which have met with mixed success. They can be based on (1) public education, (2) legislation, or (3) engineering.[22] Public education campaigns depend for their success on an educated literate community. The "stop, drop, and roll" campaign in elementary schools is an excellent example. Legislation is often more effective. Examples include safe factory set points for home water-heaters and flammability standards for children's bedclothes. Engineering solutions are perhaps the most effective. Examples are common in industry, and include physical isolation of high-power lines and "child-proof" cigarette lighters. Often all the three are combined, a current example being the fire-safe cigarette. A self-extinguishing cigarette has been engineered and, in some places, its sale is mandated after public education influenced the legislative process.

Chapter 96 :: Skin Problems in Amputees

:: Calum C. Lyon & Michael H. Beck

SKIN PROBLEMS OF AMPUTEES AT A GLANCE

- Skin problems under limb prosthesis result from:
  - Trauma.
  - Heat.
  - Pressure.
  - Occlusion and maceration.
- Physical trauma, disturbances of tissue fluid dynamics may cause other distinctive skin changes.
- Microclimate under prosthesis promotes bacterial and fungal infections.
- Irritant and allergic contact dermatitis occurs due to materials applied to skin, worn, or used in construction of the prosthesis.
- Koebner phenomenon may occur in skin under prosthesis.
- Management: most important are basic hygiene measures.
- Early medical intervention and collaboration with prosthetist are essential to address problems.

TECHNICAL BACKGROUND: LIMB PROSTHESES

In most centers, artificial limbs are constructed in a modular fashion.[1] The stump is placed in a thermoplastic socket that is then fitted into the main body of the limb. The bulk of the prosthesis comprises a metal frame with articulations and an outer casing of acrylic resin or carbon composite material. Before fitting the limb, many patients place their stump in a liner designed to reduce friction on the skin. This may be an expanded plastic cup, a silicon/mineral oil sleeve, or a cotton or nylon sock. The prosthetic limb, once fitted, is held in position by one of a range of suspension elements. In above-knee (Fig. 96-1) or proximal arm amputations, this is usually a fabric belt arrangement worn around the waist or shoulders, respectively. Below-knee amputees require a different system using either a butyl rubber sleeve or corset to hold the appliance firmly onto the thigh (Fig. 96-2). Many patients with above-knee amputations now use a suction socket device that provides sufficient suspension by holding the prosthesis in place through negative pressure without the need for additional belts (see Fig. 96-1).

Limb prostheses are the subject of continual technological development particularly in the field of bionics. Myoelectric devices, for example, rely on skin contact with electrodes to detect neuromuscular signals that can be converted to artificial limb movement. Neuroprosthetic devices involve implantation of electrodes into neural tissue usually through the skin, for example, cochlear implants. Such devices are under development for prosthetic limbs. These devices thus have the potential for causing skin problems.

DERMATOLOGIC PROBLEMS IN AMPUTEES

The skin of an amputation stump is not designed to withstand the physical insults it encounters within a prosthetic limb. For example, although some adaptation to friction or pressure occurs, some skin problems are inevitable. If these dermatoses cannot be prevented or rapidly resolved by prosthesis adjustment or medical intervention, they can incapacitate the patient, particularly those who have lower limb, weight-bearing prostheses. As a result, patients may suffer social isolation,

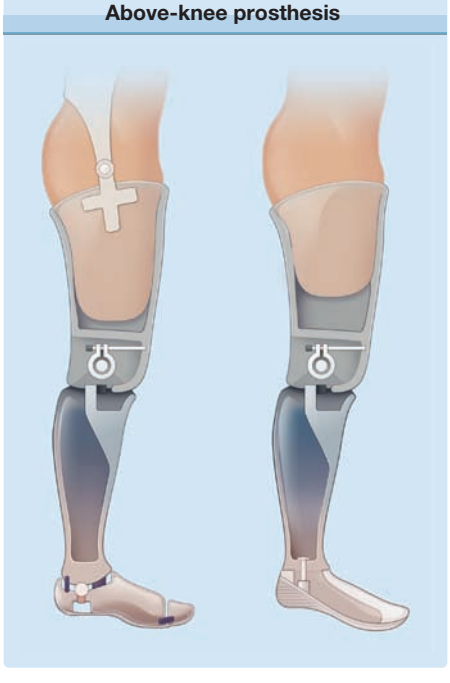

Figure 96-1 Above-knee prosthesis. Suction-socket prosthesis.

Figure 96-2 Below-knee prosthesis. Patellar tendon-bearing cuff suspension.

emotional distress, or even financial deprivation if they are unable to work.

Skin problems may occur because of allergy or chemical irritation to materials in contact with the skin, as well as from trauma and occlusion. Examples of physical stresses on the skin include shearing and friction from elements in the socket and pressure on load-bearing areas, especially on the tibial tuberosity in below-knee amputations and the ischial tuberosity, adductor region, or groin in above-knee amputations. In all cases, the occlusion results in increased humidity from trapped perspiration, increasing the likelihood of irritation, allergy, and infection.

The common skin disorders in amputation stumps can be classified into diseases related to the reasons for the amputation, physical effects of a prosthesis, infection, contact dermatitis, and other cutaneous disorders.

EPIDEMIOLOGY

The great majority of artificial limb wearers are amputees, although a small proportion are people with congenital limb malformations. Lower limb amputees are the most numerous and are also the group at greatest risk of skin problems. Traumatic amputations are possibly more likely to be associated with a dermatosis[2] although the commonest problems encountered are the same as for all amputees.[3] Modern limb prostheses allow many of today's amputees to lead an active life with good mobility. Nevertheless, as many as 73% of one cohort of lower limb amputees reported at least one skin disorder.[2] In a further group of 745 lower leg amputees, 40.7% had at least one skin problem. Further analysis identified four factors independently associated with dermatologic disorders, namely transtibial amputation, employment status, type of walking aid used, and peripheral vascular disease.[4] A more recent questionnaire-based study of 805 lower limb amputees[5] suggests that the factors more likely to be associated with skin problems are, smoking, younger age, female sex, washing the stump frequently and the use of antibacterial soaps. Overall one-third of amputees, either upper or lower limb, experiences a skin problem that significantly interferes with the normal use of the artificial limb.[6]

DERMATOSES RELATED TO THE REASONS FOR AMPUTATION

Several disorders resulting in the need for amputation can have a significant impact on skin integrity. In general, younger patients require artificial limbs because of traumatic amputations, congenital abnormalities, or malignancy, whereas in the older age group, arterial disease and vascular complications of diabetes mellitus predominate. Amputations after trauma or severe vasculitis may be associated with scarring that makes for a suboptimal prosthesis fit (Fig. 96-3). Stump dermatoses appear to be more likely in patients following traumatic amputations. Koc et al[2] found a skin problem in nearly three quarters of amputees most of whom had lost a limb as a consequence of mine explosions. The nature of current conflicts means that, presently, such amputations are unfortunately common amongst both service personnel and civilians. Vasculitis resulting in amputation may be ongoing and cause problems in the skin of amputation stumps (Fig. 96-4). However, it is diabetes mellitus that is particularly associated with protracted skin problems (Chapter 151) as a result of impaired wound healing, susceptibility to infection, abnormal sensory nerve function, and disruption of normal tissue fluid balance.[7] Diabetic amputees as a group require more frequent clinical review to prevent complications. Treatment of the diabetic amputee not only requires good control of the blood glucose level but possibly a change of the stump environment through adjustment or redesign of the artificial limb. The diabetic amputee highlights the need for close links with a prosthetics department, which allow rapid referral of patients for assessment.

Figure 96-4 Patient with vasculitis resulting in ischemia (**A**) that required amputation (**B–C**). This recurred on the amputation stump (**D**) but fortunately responded to systemic therapy.

PHYSICAL DERMATOSES

The physical effects of wearing a prosthesis are the most common causes of skin problems.[6,8] These can be divided into those resulting from repeated direct trauma and those secondary to disturbance of tissue fluid dynamics.

DIRECT PHYSICAL TRAUMA

Ulceration. Ulceration and callus formation are seen where there is chronic pressure or repeated frictional forces on stump skin. Ulceration may also be caused by infection or poor cutaneous nutrition, particularly secondary to diabetes mellitus (Figs. 96-5 and 96-6). Stump ulcers should be treated early as malignancy may develop in long-standing ulceration.[9] With repeated infection and ulceration, an amputation scar on the distal stump skin can erode further. In some cases, the skin may become completely adherent to bone and develop thick, callus-like hyperkeratosis (Fig. 96-7), which may necessitate revision of the distal bony surface. Ulceration or other injuries incurred while putting on artificial limb components may be particularly associated with poor manual dexterity consequent on neurological disorders or arthritic changes.[10,11] Incorrect use of some appliance components can also result in injury.[12] Patient selection and access to follow-up advice is therefore important in reducing such injuries. Apparently spontaneous ulceration at unexpected sites is occasionally seen (Fig. 96-8). In every instance, the cause of the ulceration must be determined to resolve a chronic process that can become totally disabling. However, a recent study

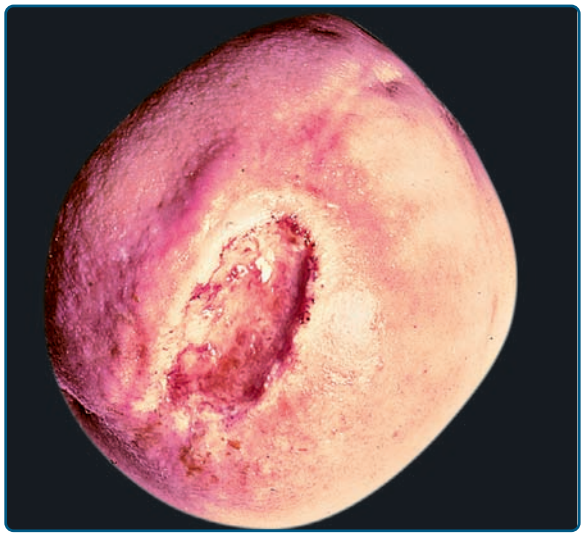

Figure 96-5 Chronic ulcer of stump skin.

examining 102 patients over 4 years suggests that the majority of patients with delayed wound healing or secondary ulcers will experience healing despite continuing to use their prosthesis, provided they are carefully monitored.[13]

Physical Dermatitis. In some patients, eczema may be caused by a poorly fitted or misaligned prosthesis or by edema and congestion of the terminal portion of the stump; only with alleviation of these problems does the condition clear.

Epidermoid Cysts and Follicular Keratoses. Epidermoid cysts and follicular keratoses are two ends of a spectrum of the same disorder. Repeated pressure and friction from the prosthesis appears to cause

Figure 96-6 Ulceration associated with infection in a diabetic man with an amputation for ischemia.

Figure 96-7 Chronic ulceration resulting in thick hyperkeratosis and scab formation adherent to the underlying bone.

invagination of keratin around hair follicles, which then results in a foreign-body reaction. Follicular keratoses are therefore the earliest changes.[14] These are very common, often multiple, and distributed at sites of weight bearing such as the anterior tibial area, popliteal fossa, and the adductor or inguinal areas of the thigh (Fig. 96-9A). Fortunately, they cause little trouble in many cases, but they can become inflamed and painful particularly if the patient picks at them to extract

Figure 96-8 Ulceration in a patient receiving nicorandil for angina. The ulcer appeared spontaneously and not at a site of friction. It resolved slowly over 3 months after nicorandil was stopped suggesting the drug may have been involved.

Figure 96-9 Epidermoid cysts in different stages. **A.** Early follicular keratoses in the popliteal fossa of a man with below-knee amputation. **B.** Hemorrhagic and inflamed large epidermoid abscess in a man with an above-knee prosthesis. Note the follicular hyperkeratosis. **C.** Inflamed epidermoid cysts in the groin of a man with an above-knee prosthesis.

the keratin plug or if they become infected. Inflamed follicular keratoses can have an acneiform appearance, leading some to suggest that they represent a form of acne mechanica. When the continued pressure and friction causes the keratin to extend deeper into the dermis, larger cystic lesions, 1–3 cm in diameter, form; these are commonly termed *posttraumatic epidermoid cysts*. Meulenbelt et al[15] described a case of follicular keratoses of a transfemoral amputation stump in a patient who did wear an appliance at all. These lesions recurred after resection and were associated with retention of vellus hairs. This raises the possibility that, in some individuals, mechanisms other than just friction may be involved. Deeper cysts can be very tender when compressed by the prosthesis. Some cysts have an obvious punctum and patients may express keratinous material from them. Large cysts can be so painful that the patient can no longer wear a weight-bearing prosthesis each day (see Fig. 96-9B and 96-9C). Distention of the overlying epidermis can occur, followed by spontaneous rupture. A serous, purulent, or hemorrhagic fluid is then discharged. The resulting sinus is difficult to occlude and the discharge continues as long as the prosthesis is worn. Intercommunicating sinuses can appear and spontaneous ruptures may occur. In advanced cases, a granulomatous reaction occurs around the cyst with considerable capillary dilation, vascularization, and a heavy inflammatory infiltrate progressing to abscess formation (see Fig. 96-9B).

Management of this condition can be difficult. Clearly, prevention is the ideal but is not always possible despite regular prosthetic assessments. The fit of the prosthesis is the single most important method of preventing cyst formation. The problem can sometimes be improved or successfully eliminated by proper fitting and aligning of the prosthesis and continued adjustment by the prosthetist. Rough surfaces in areas of increased contact pressure in the socket, particularly the suction socket, tend to catch the skin, increasing the shearing forces. For this reason, the lining of the socket should be kept smooth. With the idea of inserting a buffer between the skin and the socket, protective devices such as liners and stump socks are used. Various synthetic films and adhesives, such as Teflon, have been found satisfactory as liners. They allow for a smooth, gliding action of the prosthetic socket wall or brim against the skin. Applying a vapor-permeable adhesive membrane to the skin before fitting the appliance can

also help reduce frictional trauma. Topical glucocorticoids can be used at night to reduce inflammation and provide symptomatic relief. Intralesional injection of glucocorticoids into the cysts and their channels also results in temporary improvement.

Surgical intervention is useful in cases with a few lesions that are not infected. Lesions can be surgically incised and drained. In other instances, removal of the prosthesis is sufficient to cause the lesion to involute, provided that the cyst has not become too large. However, spontaneous rupture, incision, and drainage, and even spontaneous resorption of the lesion are of only temporary benefit. When the prosthesis is worn again, these cysts can recur so that surgical excision is not always the treatment of choice, especially in continually rubbed areas.

In selected cases, systemic retinoid therapy may be appropriate to minimize hyperkeratosis. One author found oral isotretinoin to be effective in a patient described as having acne mechanica.[16]

DISTURBANCES OF TISSUE FLUID DYNAMICS

Edema. Amputation of a lower extremity greatly disturbs the normal pattern of blood and lymph channels, as well as the relationship of pressure both inside the vessels and in the surrounding tissues of the stump. An important feature of care during convalescence after amputation is the reduction of edema and stabilization of new circulatory patterns in the stump. Swelling can be partially prevented by gradual compression of the stump tissues with an elastic bandage or "shrinker" sock before fitting the prosthesis and socket.

When an amputee begins to wear a suction-socket prosthesis, the skin must adapt to an entirely new environment. The patient can expect edema, reactive hyperemia for days or weeks, a reddish-brown pigmentation resulting from capillary hemorrhage, and, occasionally, serous exudation and crusting of the skin of the distal portion of the stump. These changes are relatively innocuous, usually short lived, and do not usually require therapy.

The extent to which edema may persist or recur in the healed stump depends on many factors.[17] Edematous portions of the skin of the distal part of the stump may become pinched and strangulated within the socket (Fig. 96-10). Such areas may ulcerate if they catch in the spring-valve opening and become gangrenous as a result of the impaired blood supply. Therapy includes eliminating all mechanical factors contributing to the edema, such as choking by the socket, poor fitting, and misalignment. Excessive negative pressure in a suction-socket prosthesis also contributes to circulatory congestion and edema. Treatment should be directed toward better support of the distal soft tissues. Occasional use of an oral diuretic sometimes allows the edema to resolve.

Verrucous Hyperplasia. *Verrucous hyperplasia* refers to a reactive hyperplastic condition, characterized morphologically by numerous, coalescent warty papules (Fig. 96-11). It occurs when the chronic pressure effects of a poor prosthetic fit disrupt vascular and lymphatic channels, resulting in chronic tissue edema. The same appearance is seen around longstanding leg ulcers where there is an element of lymphedema (see Chapter 174). Histologic examination can show evidence of pseudoepitheliomatous hyperplasia, although the condition itself is benign and potentially reversible. However, in neglected cases, malignant change can occasionally occur (see Fig. 96-11C). Bacterial infection may play a role in the development of pseudoverrucous hyperplasia, as secondary mixed flora infections are common because of the poor superficial blood flow and the convoluted surface (Fig. 96-12). External compression is the best method of treatment, in combination with topical control of bacterial infection. In below-knee amputees, the distal part of the stump is edematous; the stump dangles freely in the socket or has no distal support or partial end-bearing. When the stump end is supported in the socket by a temporary cushion or platform, compression gradually reduces and slowly clears the verrucous condition. The greater the compression on the distal stump, the more immediate and lasting is the improvement. The use of compression bandaging, shrinker socks and other pads, and partial end-bearing all have a definite place in therapy and can be skillfully applied by the prosthetist. Short courses of oral diuretics may be indicated to reduce edema of the stump. The medication can be gradually decreased when the stump and its skin return to normal.

Figure 96-10 Dependent edema/early verrucous hyperplasia in a man with multiple amputations after severe peripheral vasculitis and necrosis.

Acroangiodermatitis. Acroangiodermatitis occurs when the chronic pressure changes result in vessel proliferation in the upper- and middermis. There is also extravasation of red blood cells and these features combine to give a purplish hue to the papules and plaques that appear on a background of edematous skin. The appearance may mimic Kaposi sarcoma.[18] Some authors suggest that acroangiodermatitis occurs in above-knee amputees who use a suction socket prosthesis that exerts negative pressure.[19] However, there are reports of acroangiodermatitis in below-knee amputees,[20] and the same condition is seen in chronic venous insufficiency and in the patients with arteriovenous

Figure 96-11 Verrucous hyperplasia of the distal stump skin. **A.** Before compression therapy. **B.** Total resolution after compression therapy. **C.** Malignant degeneration into squamous cell carcinoma.

shunts (acroangiodermatitis of Mali). Management of this condition is the same as for stump edema and verrucous hyperplasia.

BACTERIAL AND FUNGAL INFECTIONS

The bacterial flora of amputation stumps have been examined in small groups of patients,[21,22] and the most common species encountered are *Staphylococcus epidermidis*, *S. aureus*, and *Streptococcus* sp. (see Chapter 176). The moist, occluded environment under a prosthesis is ideal for fungal and bacterial growth so that minor skin infections occur fairly frequently. In one study, *S. aureus* folliculitis or *Trichophyton rubrum* infection was identified in 3% of the study population.[6] Infections are more common during hot weather and in those amputees who pay insufficient attention to stump hygiene, partly because in these situations the skin becomes macerated more readily and follicular infections become more likely. Although folliculitis (Fig. 96-13) and furuncles are more common, superficial infections of the skin itself may also occur (see Chapter 176). Superficial dermatophyte and candidal infection (see Chapters 188 and 189) are also common and may be difficult to eradicate because of the ideal environment for fungal growth within a prosthesis.

The diagnosis of infection is usually obvious when the rash extends onto skin not covered by the prosthesis. Underneath the prosthesis, any superficial infection may present as a nonspecific scaling erythema indistinguishable from that caused, for example, by chronic irritation. All stump rashes should be swabbed and scraped for bacterial and fungal culture.

In the management of bacterial infections, oral antibacterial therapy should be directed by bacterial culture and sensitivity. Topical antiseptics or antibacterials can be used but some antiseptic preparations can cause irritation and there is also the potential for sensitization.

Figure 96-12 This man developed postinfectious purpura fulminans after varicella-zoster infection as a child in the 1960s and lost both legs as a consequence. He presented with infected verrucous hyperplasia having lived a reclusive life in a cabin in the woods wearing an old-fashioned unadjusted aluminum prosthesis for many years. The infection was treated with new hygiene measures, and he was fitted with a modern modular prosthesis. The skin rapidly resolved, although some of the verrucous hyperplasia changes persisted.

Figure 96-13 Folliculitis of stump skin showing the typical distribution in the occluded area.

Superficial fungal infections respond to appropriate topical therapy (see Chapters 188 and 189) but can be hard to completely eradicate because of the favorable conditions for fungal growth. In this situation, systemic antifungal therapy is useful.

CONTACT DERMATITIS

(See Chapters 13 and 48)

The clinical presentations of irritant and allergic contact dermatitis affecting amputation stumps are indistinguishable (Fig. 96-14), ranging from dry, scaling erythema to weeping dermatitis.[6] Indeed, the morphologic features may be the same as nonspecific eczematization where no irritant, allergic, or infectious cause is found, and where there is no history of eczema or atopy. Consequently, a careful history and examination is essential if one is to identify irritant or allergic causes (Table 96-1). This includes accurate timing of the onset of dermatitis in relation to changes in the patient's appliance routine or the composition of the prosthesis. The distribution of rash typically matches the site of the contactant. To identify a primary irritant or allergen, it is particularly important for the dermatologist to observe the patient removing and refitting their limb, making note of its construction and any medicaments or other agents such as cleansers, talcs, and creams that the patient uses. These products may contain allergens such as fragrances or preservatives. Colored stump socks may contain potentially allergenic nylon dyes.

Knowledge of the materials used in prosthesis manufacture is also necessary when considering potential sensitizers and irritants. This is best achieved by liaison with the local prosthetist, as different construction techniques may be used in different areas. In general,

Figure 96-14 Allergic contact dermatitis to formaldehyde-releasing biocides in a lubricating "baby oil." Note the nonspecific, dry, eczematous appearance.

TABLE 96-1
Causes of Dermatitis on Amputation Stump

- Traumatic
- Irritant
  - Soaps and washing materials
  - Topical applications, including medicaments
  - Solvents in glues and resins used to make prosthesis
- Allergic
  - Active ingredients, perfume, and excipients of topically applied materials (e.g., deodorizers, cleansers, topical medicaments, and moisturizers)
  - Acrylic, epoxy, polyester, and formaldehyde resins
  - Resin hardeners
  - Other plastic additives (e.g., *para*-tertiary butylphenol catechol)
  - Nickel
  - Rubber accelerators and antioxidants
  - Chromate (leather)
  - Nylon dyes

modern modular prostheses are fabricated with sockets, liners, and casings that may contain acrylic resins, carbon composites, and thermoplastics. Epoxy and, occasionally, polyester resins are still used by some manufacturers. Acrylate-based thread sealants are commonly used in socket bolts and metalwork. Butyl or black rubber material may be used to conceal access points to the metal frame. Rubber materials can also be found in some suction socket valves (Fig. 96-15). Accelerators used in the manufacture of natural or synthetic rubbers are potential allergens, for example, dialkyl thiourea used in chloroprene rubber.[23] Suspension elements often include chrome-tanned leather and sometimes have metal fastenings, rivets, or screws containing nickel. Glues containing *para*-tertiary butylphenol formaldehyde resins are often used.

Repairs or adjustments to prostheses can introduce new irritants and allergens. For example, sockets sometimes have additional leather linings cemented to points of friction or pressure.

Irritant dermatitis (see eFig. 96-15.1 in online edition) can be due to occluded contact with volatile solvents in glues or resins and from fragrances and detergents in topical medicaments or lubricants. Soaps and other washing materials used to clean appliances can cause irritation if they are not removed by proper washing (see Table 96-1). Burns from a malfunctioning electrode used in a myoelectric prosthesis have been reported.[24]

Contact allergy should always be considered as a cause of inflammatory and dermatitic disorders affecting the stump, especially if there is secondary spread (see Table 96-1). In addition to standard series patch testing, the authors recommend an extra series of allergens to include components of plastic, including acrylic, epoxy, and polyester resin systems, as well as an azo dye series. It is important to test with pieces of the prostheses and all materials applied to the stump skin including emollients, cleansers, powders, medicaments, and cosmetics. In our experience, the most common relevant allergens are nickel, acrylates, rubber, chromate (in leather), *para*-tertiary butylphenol formaldehyde resin, and components of topical applications.[6]

OTHER CUTANEOUS DISORDERS

Common skin diseases, for example, eczema (see eFig. 96-15.2 in online edition) and psoriasis (see eFig. 96-15.3 in online edition), may affect amputation stumps. Those

Figure 96-15 Allergic contact dermatitis to rubber materials in a suction socket from an arm prosthesis. **A.** The prosthesis fitted. **B.** The dermatitis is worst around the areas where the pressure is released on removing the limb.

diseases that exhibit the Koebner phenomenon, especially psoriasis or lichen planus, have been reported on amputation stumps with little involvement of other areas of skin. Treatment should always take into account the implications of an occluded environment.

Hyperhidrosis can be a problem in some patients resulting in maceration of the skin increasing the risk of erosions and even ulceration. Standard topical antiperspirants can be irritating under occlusion and one novel approach is to use intradermal botulinum toxin A.[25]

Benign keratoses, warts, nevi, and a variety of cutaneous papillomas may occur on stump skin and occasionally cause discomfort when a prosthesis is worn. Malignancies have also been described and squamous cell carcinoma (Marjolin's ulcer)[9] may develop in nonhealing chronic stump ulcers or verrucous hyperplasia (see Fig. 96-11). The patients who have amputations for lymphangiomas may develop the Stewart–Treves syndrome and metastatic lymphangiosarcoma (see Chapter 128). There is a risk that such malignancies may not be recognized as an ulcer might be wrongly blamed entirely on trauma from a poorly fitting prosthesis. A biopsy of persistently ulcerated areas should be undertaken.

Treatment of these benign and malignant tumors is the same as when they occur elsewhere on the skin. Healing after tumor excision may take weeks, during which time the artificial limb may not be worn.

GENERAL MANAGEMENT CONSIDERATIONS

Many of the more common skin problems can be prevented or controlled by adherence to an appropriate hygiene and skin-care regimen in conjunction with regular prosthetics reviews, which ensure that the prosthesis remains appropriate and correctly adjusted. To this end, it is important that good communication exists between the dermatologist and prosthetist, which permits rapid referral of patients before skin disorders become established.

As a general routine, the stump skin should be washed at night rather than in the morning because newly washed skin is hydrated and swollen, thereby increasing the likelihood of friction and shearing trauma. Nonperfumed soap should be used to minimize contact with potential sensitizers and fully removed with tepid water and gentle rubbing with a nonabrasive towel.

Antibacterial soaps and washes can reduce the possibility of infection in addition to their cleansing action. However, these antiseptic preparations can cause irritation or allergy in a small number of cases and patients should be warned about this. If a stump sock is worn, it should be changed daily and washed and rinsed fully as soon as it is taken off, before perspiration is allowed to dry within it. Silicone liners should be washed every day.

Chapter 97 :: Skin Problems in Ostomates

:: Calum C. Lyon & Michael H. Beck

SKIN PROBLEMS IN STOMA PATIENTS AT A GLANCE

- Peristomal skin is chronically occluded and subject to pressure, shearing forces, and fecal/urine soiling. Some skin problems are therefore inevitable.
- Two-thirds of ostomates develop dermatological problems. Irritant reactions, common skin diseases, and infections are the most common.
- The occlusion under a stoma appliance can result in unusual clinical appearances of common dermatoses. All rashes should be swabbed to exclude primary or secondary infection.
- Allergic contact dermatitis is relatively uncommon. Nonetheless patients should be advised to minimize exposure to potential allergens especially fragrances and preservatives.
- Some dermatoses are commoner than expected around stomas, particularly psoriasis, pyoderma gangrenosum, and lichen sclerosus.
- Liaison with stoma nurses (ET therapists) and surgeons is essential to provide an effective service for patients with peristomal dermatoses.

SKIN PROBLEMS IN PATIENTS WITH ABDOMINAL STOMAS (OSTOMATES)

A stoma is a surgically created opening onto the skin of part of the gastrointestinal or urinary tract in order to drain the effluent from that viscus. The most frequently performed stomas are ileostomies, colostomies, and ileal conduits (urostomies or urinary diversion). The commonest indications for stoma surgery are inflammatory bowel disease, malignancy and neurological problems. A patient with a stoma is usually termed an "ostomist" or "ostomate."

EPIDEMIOLOGY

There are estimated to be more than 1.4 million ostomates in the United States and 100,000 in the United Kingdom and Ireland. Some stomas are temporary, with surgical anastomosis delayed, pending resolution of the acute disorder. Temporary stomas are often "loop stomas" where a loop of bowel is brought to the skin surface and part of the wall removed to allow preferential drainage into a stoma pouch in order to relieve a distal problem, for example, perianal ulceration. Such stomas are more frequently associated with skin problems secondary to leaks.[1] Many stomas formed for malignant indications can be seen as palliative procedures.

A stoma appliance is essentially a device for collecting stoma effluent with a high degree of comfort and security until it can be disposed of. There continues to be promising advances in the design of stoma bags. Essentially, the device is a pouch or bag held in place over the stoma by an adhesive skin barrier made solely or partly from hydrocolloid. Many ileostomists and urostomists use two-piece appliances where the barrier remains on the skin for 2–4 days and is detachable; disposable bags are changed as necessary. Appliances with convexity on the surface next to the skin are available for patients with short or buried stomas (Fig. 97-1). Useful recent innovations include softer convex appliance that apply less pressure on the skin and collars or sleeves that fit snugly around the stoma before applying the bag thereby reducing the chance of leaks of effluent or intestinal mucus under the barrier.

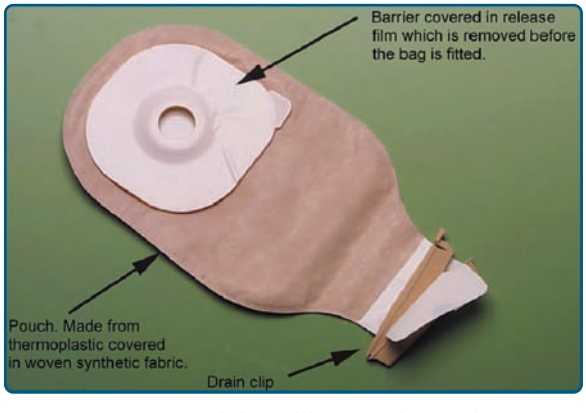

Figure 97-1 A typical drainable stoma bag with a convex barrier.

Figure 97-2 Peristomal dermatitis due to fecal irritation. The skin beneath the stoma was chronically exposed to feces because a bag with too large an aperture was used.

As many as two-thirds of ostomates experience skin problems that interfere with the normal use of their stoma appliance,[2,3] and such dermatoses are the commonest reasons for a visit to outpatient stoma services.[4,5] The majority of these problems are irritant reactions, usually dermatitis secondary to leaks from the stoma; however, there are also a number of other well-defined irritant reactions. Common coincidental dermatoses, particularly psoriasis and constitutional eczema, account for around 15% of the diseases seen.[2,6] An approach to diagnosing peristomal dermatoses is given in eFigure 97-1.1 in online edition.

IRRITANT REACTIONS

DERMATITIS. Dermatitis most frequently results from the chronic leakage of effluent onto the skin because the patient is using an inappropriately shaped appliance or one with too large a hole for their stoma. The most common cause is the remodeling of the stoma and abdominal wall that occurs in the months after surgery, whereby a stoma usually becomes a little shorter and thinner, resulting in leaks unless a correctly fitting appliance is selected (Figs. 97-2–97-6). Leaks will also occur when patients gain a lot of weight after surgery and the effective length of their stoma diminishes because it becomes buried by subcutaneous fat.[7] Irregular scarring after surgery or retraction of the stoma, may also be associated with chronic leakage. Such irregularities can be corrected with topically applied pastes. One effective alternative is to use collagen fillers (Porcine collagen Permacol™)[8] to recontour the skin surface. Short stomas (<2 cm long), loop ileostomies and stomas formed as emergency procedures are more likely to be associated with skin problems.[1,9] Chronically irritated skin can become markedly hyperkeratotic and acanthotic

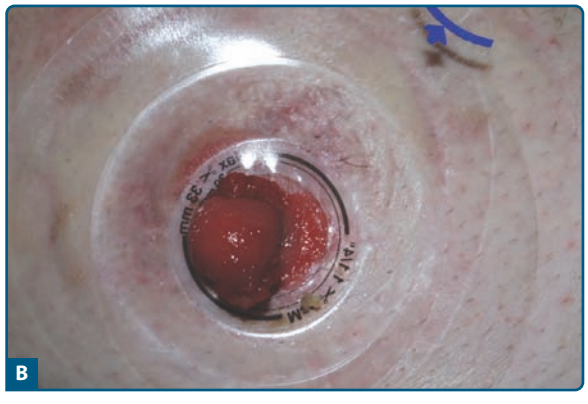
Figure 97-3 Irritant contact dermatitis circumferentially around an ileostomy because the bag aperture was cut too big thereby allowing soiling of the skin around this short stoma.

Figure 97-5 A short ileostomy where recurrent soiling has led to irritation and hypertrophic changes due to massive hyperkeratosis and acanthosis similar to chronic papillomatous dermatitis.

(Fig. 97-7). These problems can be prevented and resolved by careful postsurgical follow-up by the enterostomal therapist (ET; stoma nurse specialist) to ensure that the correct appliance is being used. Severe, acute irritant dermatitis can be effectively treated with a short course of topical corticosteroid while longer term appliance modifications are being undertaken (Table 97-1).

Anxieties about possible leaks and odors can lead to excessively frequent bag changing, which may cause an irritant dermatitis by stripping the skin. Patients may, for the same reasons, wear waist belts too tightly thereby causing pressure damage even ulcers (eFig. 97-7.1 in online edition) and occasionally necrosis. Whatever the cause of skin inflammation, a vicious cycle can develop when the damaged skin prevents proper bag adhesion necessitating more frequent bag changes.[12] Careful counseling is usually necessary in order to reassure the patient regarding leaks.

Approximately 15% of ostomates with skin problems suffer from a chronic or recurrent dermatitis for which no irritant, allergic, or infective cause can be found, and where primary skin disease is ruled out.[2] In the absence of a primary treatable cause, the use of topical corticosteroid lotions is appropriate. Most patients



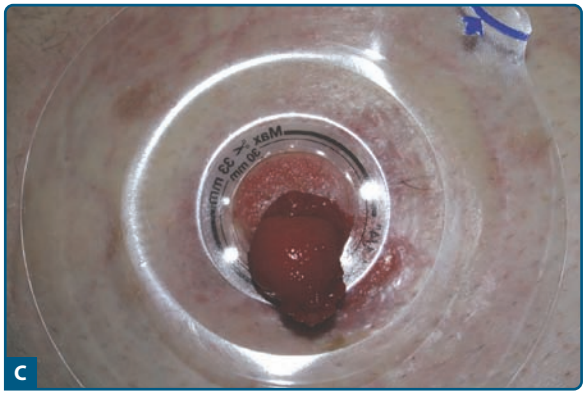


Figure 97-4 **A.** Eroded irritant dermatitis in two places around an ileostomy. **B** and **C.** show the release film from the bag in the two positions that the patient was accustomed to place the appliance, accounting for the fecal soiling and the dermatitis seen.

Figure 97-6 Irritant contact dermatitis from leaks occurring when reclining at night resulting in a cycle of poor bag adhesion and further leaks. Patient was unable to sleep sitting up and the rash did not respond to barriers or steroid tape. It eventually responded to applications of beclomethasone via a metered dose inhaler allowing proper bag adhesion and less leakage.

require only occasional short courses for a maximum of 4 weeks' duration (Table 97-1). A small number of patients require intermittent applications longer term. Provided that the frequency of application is no more than once every 10 days, steroid atrophy of the skin appears to be unusual.

In ileostomy patients with short bowel, the output may be very high and corrosive due to the enzyme and bile salt content. In this situation, some leaks are inevitable, despite the use of proprietary barrier preparations or soothing lotions. Where the irritation has resulted in an eroded dermatitis, sucralfate powder applied at every stoma bag change can be very effective. In addition to forming a sticky barrier, the preparation is thought to promote healing.[13] Surgical scars and even large striae (eFig. 97-7.2 in online edition) can lead to ulcerations and bag failures, which may respond to topical carmellose sodium or sucralfate powders. Wound dehiscence can cause severe difficulties for bag adhesion (eFig. 97-7.3 in online edition) and

TABLE 97-1
Topical Corticosteroid Treatment of Inflammatory Peristomal conditions

1. Good adhesion between the appliance and the skin is essential. Ointments, creams, and greasy lotions will cause a bag to lift so that most patients will not use them.
2. One approach tolerated by some patients is to use dressings such as thin hydrocolloid or vapor-permeable membranes placed over the cream preparation and before applying a stoma bag.
3. Another approach is to apply a cream preparation for 1–3 hours per day before wiping off and applying a stoma bag. While the cream is in place, a nonadhesive bag can be worn, held in place with a waist belt, provided that the patient is sedentary during this time.
4. A number of alternative vehicles for delivering topical corticosteroid are available although none is ideal nor designed for stoma use.
   a. Adhesive tapes impregnated with fludroxycortide 4 mcg/cm^2.
   b. Scalp lotions (oil-free; 40% isopropyl alcohol) betamethasone valerate 0.1%, clobetasol propionate 0.05%. These will sting on broken skin and can be applied to the bag adhesive and allowed to dry before applying to the stoma.[10]
   c. Scalp gels flucinolone acetonide 0.025%. This preparation contains propylene glycol that may impair bag adhesion a little.
   d. Steroid asthma inhalers beclomethasone dipropionate 250-µg/metered dose. Several activations are used to the affected area (Fig. 97-6)
   e. Carmellose sodium oral pastes are especially useful in ulcerative conditions such as mild pyoderma gangrenosum, e.g., triamcinolone acetonide 0.1% in carmellose sodium paste (this product needs to be compounded).
   f. Alternative nongreasy steroid sprays are available in some regions.[11]
5. With each of these preparations, the steroid is under occlusion and, therefore, effectively more potent. Skin atrophy and absorption, particularly in children must be considered. The authors limit initial courses to a maximum of 4 weeks and thereafter one to two times per week if needed.

Figure 97-7 **A.** Ulcerated hyperkeratotic dermatitis due to leaks. **B.** Three weeks after leakage was reduced using a combination of convex barrier and filler pastes around the stoma.

presents particular challenges for nursing management where the dermatologist may be called upon for advice as part of the multidisciplinary team.[14]

CHRONIC PAPILLOMATOUS DERMATITIS. This term refers to clinical appearance of warty excrescences around urostomies resulting from leaks and pooling of urine on the peristomal skin (eFig. 97-7.4 in online edition). Recurrent urinary tract infections appear to increase the likelihood of chronic papillomatous dermatitis (CPD) probably due to the presence of ammonia from urea-splitting bacteria. Histologically, there is massive hyperkeratosis and acanthosis. Pseudoepitheliomatous hyperplasia may also be a feature but is not universal. The histology is therefore not specific and comparable to that of other irritant reactions. Verrucous lesions with similar appearances are occasionally seen affecting ileostomies[15] (Fig. 97-5). In severe cases, the lesions can encroach on the stoma and cause stenosis (Fig. 97-8). When the leaking of urine is caused by a receding stoma, CPD will resolve rapidly if a convex-backed appliance is used to increase the effective length of the urostomy and thereby stop leaks. Acetic acid soaks (10% domestic vinegar in water)[16] at each bag change are effective in some cases (eFig. 97-8.1 in online edition). Larger excrescences may be shaved off under local anesthetic to allow a bag with a smaller aperture to be used. In severe cases, surgical revision of the stoma may be required.

GRANULOMAS. The term *granuloma* is commonly used for a range of papular lesions, which are almost all secondary to irritation. The authors have only seen the condition affecting ileostomies or colostomies and not urostomies. They may affect the stoma itself (inflammatory colonic or ileal polyps) or the mucocutaneous junction, or may be found more widely,

Figure 97-8 Chronic papillomatous dermatitis affecting a urostomy in a patient who is using a bag with too large an aperture. The red area is stoma and is becoming stenosed by the warty papules. The brown pigmentation is a typical finding in long-standing urostomies in all races. (Courtesy of Anita Eriksson, Karolinska Institute, Stockholm, Sweden.)

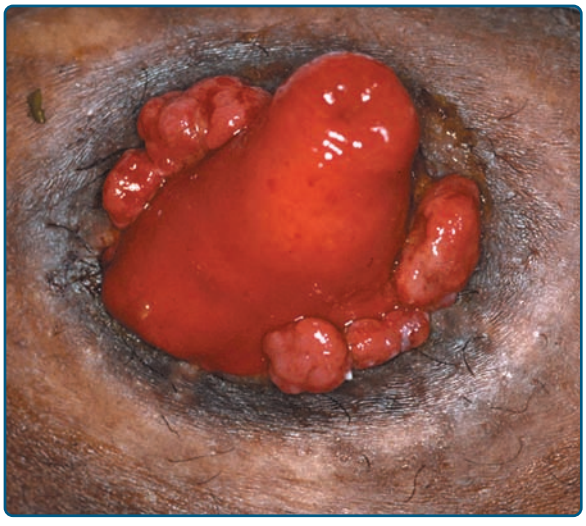

Figure 97-9 Granulomas around a colostomy. The patient has cut the bag aperture larger to accommodate the original lesion, and the area thus exposed is seen as a ring of postinflammatory hyperpigmentation in which new lesions developed.

extending onto the peristomal skin (Fig. 97-9). The latter is more frequent in patients with colostomies, and in this situation, the papules may become very extensive. This occurs when the patient enlarges the stoma bag aperture to accommodate a papule, thereby exposing normal skin to fecal irritation, which precipitates further lesions and prompts the patient to enlarge the aperture still further (eFig. 97-9.1 in online edition). Histologically, the lesions contain a chronic inflammatory infiltrate, granulation tissue, and sometimes metaplastic bowel mucosa where the metaplasia is probably a response to fecal irritation. Comparable lesions occur around ileostomies (eFig. 97-9.2 in online edition) but are generally flatter and may even present as sheets of cherry-red granulation tissue. These lesions are sometimes caused by seeding mucosa at the time of surgery.[17] The majority, however, probably represent mucosal metaplasia as a consequence of persistent fecal contact with the skin. In long-standing ileostomies (greater than 10 years), there is a small risk of malignant change *analogous to* Barrett esophagus.[18] A biopsy to rule out malignant change should be considered for unusual lesions particularly ulcerative changes in existing granulomas around ileostomies.

Asymptomatic, solitary lesions can be left. Where they are painful[19] or bleed easily leading to poor stoma bag adhesion, they can be destroyed by cautery (thermal or silver nitrate) or by cryotherapy, using a liquid nitrogen spray. Larger and proliferating lesions especially around colostomies are best removed by shave and cautery under local anesthetic and an appliance with a correctly sized aperture fitted in order to prevent massive proliferation. Laser ablation is increasingly regarded as a first-line treatment being less painful and possibly more effective.[20]

PSORIASIS. Psoriasis is a common cause of peristomal skin disease because it may appear in irritated

or traumatized skin (Koebner's phenomenon) and because it is associated with inflammatory bowel disease (Chapter 18). Peristomal psoriasis presents as a glazed erythema similar to flexural psoriasis (eFig. 97-9.3 in online edition) and can be treated in the same way with topical corticosteroids although, at the peristomal site, a nongreasy base should be selected (Table 97-1). The diagnosis is usually unmistakable being part of more generalized involvement (eFig. 97-9.4 in online edition) but localized peristomal involvement is described.[21] Resolution of psoriasis under hydrocolloid occlusion has been described,[22] which is of relevance to stoma patients because 50% of cases of peristomal psoriasis will resolve if a bag is selected with a thicker, hydrocolloid-only barrier. Where the patient can tolerate the stoma being temporarily unprotected from leaks, ultraviolet (UV) phototherapy is effective as for psoriasis elsewhere. The mucous membranes of the stoma should be protected from UV light. Although irritating topical psoriasis treatments are not usually tolerated, some patients have had success with creams containing hydrocortisone 1% and coal tar 3%, the application being left on the skin for 1 hour each day (Table 97-1, Point 3). Superficial X-ray (Grenz-ray) therapy has been used in recalcitrant cases.

INFECTIONS. The most frequent peristomal skin infection is staphylococcal folliculitis, usually, but not exclusively, in those individuals with hairy abdomens who shave regularly to help the bags stick (eFig. 97-9.5 in online edition). It responds to oral antibiotics and to a reduction in shaving frequency to no more than once per week. Although antiseptic washes can be a useful additional therapeutic measure, they can cause irritant reactions if the skin is not correctly rinsed before being occluded by the stoma bag. Localized skin infections, usually staphylococcal or streptococcal, can produce a rash indistinguishable from irritant dermatitis or primary skin disease such as psoriasis or eczema. Furthermore, preexisting psoriasis or eczema can become secondarily infected under occlusion (eFig. 97-9.6 in online edition). Therefore, all peristomal rashes should be swabbed for microbiological investigation and appropriate antibiotics prescribed based on microbiological sensitivities. In tropical climates, cutaneous fungal infections are common, whereas in more temperate regions, *Candida albicans* is an occasional problem and dermatophyte infection is rare. Viral warts are occasionally seen and can present as verrucous lesions solely affecting the stoma itself (eFig. 97-9.7 in online edition). Despite the body site and the presence of skin trauma herpes zoster is surprisingly uncommon around stomas. Nonetheless viral infections should be considered in the differential diagnosis of vesicular eruptions and where there are peristomal erosions because vesicles and bullae are typically deroofed by removing stoma bags and, therefore, are not commonly observed (eFig. 97-9.8 in online edition).

PYODERMA GANGRENOSUM. This rare, inflammatory, ulcerative neutrophilic dermatosis (see Chapter 33) is more common in peristomal skin than would be expected from its frequency in the general population.[23,24] Clearly, this is partly due to its strong association with inflammatory bowel disease. There is some evidence, however, that the increased use of convex-backed appliances may contribute to the incidence via the pathergic effect of increased pressure on the skin. We have seen a decline in incidence of peristomal PG in the last 5 years associated with reduced use of deeply convex appliances and the introduction of softer convex materials. Although some cases of pyoderma gangrenosum (PG) are associated with active inflammatory bowel disease,[25] the association is not universal; indeed, peristomal PG occurs in ostomates who have no history of inflammatory bowel disease.[26] Peristomal PG presents as a painful papule or pustule, often hemorrhagic, which then ulcerates and is usually very painful (eFigs. 97-9.8 and 97-9.9 in online edition). The pain and the ulceration can have profound effects on the patient's ability to wear a bag and, therefore, on their quality of life. The ulcers heal with cribriform scarring (eFigs. 97-9.10 and 97-9.11 in online edition) that can itself impair bag adhesion so that rapid, effective treatment of PG is essential.

Management is similar to that for PG elsewhere (Chapter 33) although small, superficial, and solitary ulcers respond very rapidly to topical therapy alone (eFig. 97-9.12 in online edition). Because of the problems with greasy preparations causing lifting of stoma bags, alternative vehicles are usually necessary (Table 97-1). There are no randomized controlled trials of treatment for this rare condition and some current evidence has recently been reviewed.[27] The author's approach is detailed in Table 97-2.

CONTACT ALLERGY

Modern stoma bags are made largely from food-grade materials and those with a low potential for sensitization. Nonetheless, there are case reports of sensitivities to individual ingredients including Gantrez® (GAF

TABLE 97-2
Management of Peristomal Pyoderma Gangrenosum

- The majority of smaller and superficial PG ulcers respond to potent or superpotent topical corticosteroid in a suitable base (Table 97-1).[23,28]
- Larger, deeper, or multiple lesions and those not responding to steroid alone may require topical tacrolimus 0.3% in carmellose sodium paste.[29,30] Fludroxycortide impregnated tape used in conjunction with topical tacrolimus may hasten improvement; it also serves to reduce the overgranulation typically seen when topical tacrolimus is associated with rapid healing of a PG ulcer.[30]
- Systemic treatment may be indicated from the outset for very multiple, circumferential or rapidly progressing PG as well as for where topical therapy has failed. These agents are as described for PG elsewhere (Chapter 33). Those specifically reported for peristomal PG include cyclosporin, mycophenolate mofetil,[31] infliximab,[32] and adalimumab.[33]
- With all treatments the first sign of improvement is reduction of pain and tenderness usually seen within 48 hours with effective therapies.

Corporation. Wayne NJ) resins and acrylate adhesive systems (eFig. 97-9.13 in online edition). Furthermore, there is a potential for contact allergy from deodorizers and topically applied preparations. These case reports of peristomal allergic contact dermatitis have recently been the subject of a literature review.[34] Despite the fact that contact allergy is a relatively uncommon cause of peristomal dermatitis most patients and many health professionals regard contact hypersensitivity to their appliance as the likely cause of a peristomal rash. Patch testing is indicated in patients with persisting problems where infection, irritation, and constitutional skin disease has been ruled out.[35] We have patch tested well over 100 such patients and relevant positive allergic reactions were found in only three cases of topically applied materials including fragrance in a deodorizer and biocides in wet wipes.

OTHER CONDITIONS

In theory, almost any of the multitude of skin disorders might affect a stoma. In clinical practice, the common disorders (e.g., psoriasis predominate and others) are more common than expected (e.g., PG). Some less common peristomal dermatoses are worthy of note either because they present practical difficulties such as pemphigoid and nicorandil ulceration, or in the case of lichen sclerosus because they have an unusual predilection for this site. The authors have managed five patients with pemphigoid affecting the skin around stomas (eFig. 97-9.14 in online edition); in all cases, the principal problems are pain and the failure of stoma bag adhesion (eFig. 97-9.15 in online edition). This necessitates a low threshold for rapidly effective systemic therapy (Chapter 56) otherwise the patient is rendered immobile in order to reduce the effect of a leaking stoma. Cecchi et al have summarized the clinical features and therapy of their own plus five previously published cases.[36]

Nicorandil, a potassium channel activator with nitrate activity is used in the management of angina. It has been associated with mouth ulceration as well as perianal,[37] peristomal and even small bowel ulceration.[38] It presents as rather indolent ulcers with minimal inflammation clinically or histologically. In a patient with pericolostomy ulcers that has had the stoma formed because of intractable perianal ulcers, for example, the diagnosis is usually straightforward. There are, however, a range of differential diagnoses for nonspecific ulceration including simple trauma such as one sees in patients with parastomal hernias that cause stretching and tearing of the skin. The diagnosis should be considered in patients receiving nicorandil with otherwise unexplained ulceration around a stoma. In most cases, the ulceration resolves within a month or two of stopping the drug (eFig. 97-9.16 in online edition).

Lichen sclerosus affecting peristomal skin is an enigmatic condition as it can present in the absence of genital involvement and affect any type of stoma.[39–41] In the authors' experience of six cases (eFig. 97-9.17 in online edition), the condition is painful and readily ulcerates. Topical corticosteroid therapy may be ineffective and intralesional steroid may be required (eFig. 97-9.17 in online edition). Stoma surgery is avoided if at all possible in patients with inherited conditions that are associated with skin fragility or blistering. These conditions together with the more severe congenital ichthyoses can cause significant difficulties with proper stoma bag adhesion.

Benign tumours, particularly seborrheic keratoses, sometimes cause problems if they become inflamed or infected under the occlusion of a stoma appliance. In these circumstances, ablative treatment with simple curettage and cautery is effective.

Other conditions occasionally seen around stomas include Crohn disease, metstatic ulcerative colitis,[42] basal cell carcinoma,[43] squamous carcinoma,[44] and metastatic adenocarcinoma.[45]

Chapter 98 :: Corns and Calluses

:: Thomas M. DeLauro & Nicole M. DeLauro

CORNS AND CALLUSES AT A GLANCE

- Corns and calluses result from prolonged application of forces to the skin and produce painful symptoms.
- Every weight-bearing human being is vulnerable.
- Lesions occur in predictable pedal locations.
- Corns and calluses show changes within the epidermis, dermis, and adipose layer.
- There are no associated systemic abnormalities.
- Treatments are available and vary in aggressiveness.

EPIDEMIOLOGY

Every human being, with the exception of the non-weight-bearing infant, is vulnerable to the development of corns and calluses, because the skin is subjected to regular mechanical stress. The prevalence of corns and calluses can be readily appreciated by the number of nonprescription products aimed at reducing or preventing them—a billion-dollar market annually.

The earliest known discussion of these lesions can be found in the writings of Cleopatra, who authored a textbook on cosmetics.[1] Corns and calluses have plagued humankind since antiquity, affecting those at all socioeconomic levels.

Certain foot types and regions are prone to mechanically induced skin thickening, regardless of race, gender, or age.

ETIOLOGY AND PATHOGENESIS

Corns and calluses result from the prolonged application of excessive mechanical shear or friction forces to the skin. In theory, these forces induce hyperkeratinization, which leads to a thickening of the stratum corneum, although the precise mechanism by which this occurs remains unknown. If the abnormal forces are distributed over a broad area (i.e., more than 1 cm^2), a callus develops. In contrast, a corn will form if the same forces are applied to a focused location, with the lamellae of the stratum corneum becoming impacted to form a hard central core known as the *radix* or *nucleus* (Fig. 98-1).

Mechanical keratoses are not determined genetically. Heredity does play a role, however, in configuring the individual's skeletal architecture. A family history of bony abnormality or ligamentous laxity predisposes the person to the presence of sites of increased cutaneous friction or shear. The prevalence of these lesions has also proven to be significantly higher in females, certain ethnic groups, and mentally ill patients.[2,3]

CLINICAL FINDINGS

HISTORY

Corns and calluses produce painful symptoms often described as burning, especially when the affected area is weight bearing and/or shoes are worn. This discomfort is thought to result from microtearing of the thickened, inflexible skin.

CUTANEOUS LESIONS

Corns [clavi or helomata (singular: clavus or heloma)] and calluses [tylomata (singular: tyloma)] are, respectively, keratotic papules and plaques that occur in areas that are subject to sustained excessive mechanical shear or friction forces.

RELATED PHYSICAL FINDINGS

The lesions occur in predictable pedal locations, corresponding to a structural deformity or biomechanical fault. Crookedness of the lesser toes leads to prominence of the proximal and/or distal interphalangeal joints. Keratoses can therefore form either dorsal to those joints, between the toes, at the distal end of the toe, or on the lateral aspect of the fifth toe and/or

Figure 98-1 A simple corn beneath the fifth metatarsal head. Note the white central radix or nucleus, which has been partially pared. This radix must be pared to provide comfort.

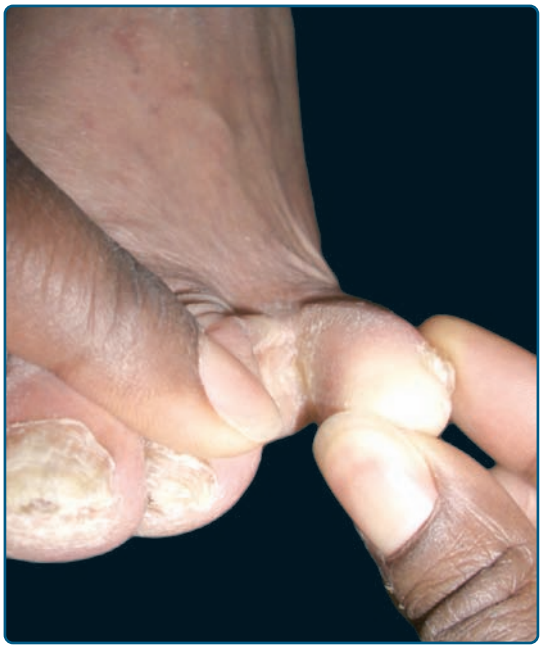

Figure 98-2 A soft corn (also known as a *heloma molle*) located deep within the fourth interdigital space.

Figure 98-3 A large callus beneath the fifth metatarsal head in a postpoliomyelitis patient whose foot is now in rigid adductovarus.

toenail (lateral toenail corn, also known as *Durlacher's corn*; see eFig. 98-1.1 in online edition). Interdigital corns can be hard when they are adjacent to the interphalangeal joint(s) (see eFig. 98-1.2 in online edition) or soft when deep within the fourth interdigital space. The softness of latter last corn results from trapped perspiration, which leads to maceration of the keratotic tissue (Fig. 98-2).

In patients with bunions (hallux valgus), a callus usually forms at the medioplantar aspect of the hallux. During gait, the individual rolls off that portion of the great toe because of its incorrect position. The skin is subsequently pinched to form a "pinch callus" (see eFig. 98-2.1 in online edition). In addition, the first metatarsal often does not bear its fair share of the weight-bearing load. Weight is therefore transferred laterally to the second metatarsal head, which usually leads to the development of an additional corn or callus beneath that bone.

Other favored locations for lesser metatarsal head keratosis include the following:

- Beneath the first and fifth metatarsal heads in cavus foot types
- Beneath the fifth metatarsal head alone in persons with tailor's bunions (bunionette)
- Erratic locations (e.g., beneath the third and fifth metatarsal heads, isolated third or fourth metatarsal head, second and fourth metatarsal heads) in individuals with structural abnormalities such as brachymetatarsia or dislocated metatarsophalangeal joints, as in rheumatoid arthritis or neuroarthropathy (Fig. 98-3)
- Beneath the second through fourth metatarsal heads when multiple hammertoes, hallux valgus, or an equinus deformity coexists (Fig. 98-4)

Another variant of corn is that referred to as *heloma miliare* or *seed corn*. This title is derived from the clinical appearance of these corns: multiple guttate keratoses that are easily pared. When seamed nylon hosiery was fashionable, this garment was considered the causative factor. However, patients still present with seed corns even though they have never worn seamed stockings.

Figure 98-4 A large callus beneath the second metatarsal head in a patient with concomitant hallux valgus. Usually, the hallux valgus segment causes a lateral shift in weight bearing to the second metatarsal.

HISTOPATHOLOGY

In contrast to nonmechanically induced keratoses, corns and calluses exhibit changes within the epidermis, dermis, and adipose layer. Corns demonstrate a parakeratotic plug within the stratum corneum, with a pressure-related loss of the stratum granulosum as well as atrophy of the stratum malpighii. The dermis displays significant fibrosis, dilated eccrine ducts and blood vessels, hypertrophied nerves, and scar tissue replacement of subcutaneous fat. Overall, the histologic changes in calluses are less pronounced, and include a thickened stratum corneum but intact stratum granulosum.[4]

Because corns and calluses are the result of mechanical friction and shear alone, there are no associated hematologic, chemical, serologic, or immunohistochemical abnormalities.

BOX 98-1 DIFFERENTIAL DIAGNOSIS OF CORNS AND CALLUSES

Most Likely (Secondary to Structural Deformity)

Deformity	Corn or Callus Location
Pronation	Medioplantar heel
Pes planus foot type	Medioplantar heel
Charcot neuroarthropathy	Midsole
Cavus foot type	Submetatarsal heads 1 and 5
Tailor's bunion	Submetatarsal head 5
Hallux valgus	Submetatarsal head 2 Medioplantar hallux
Brachymetatarsia	Submetatarsal heads 3, 5
Dislocations as in rheumatoid arthritis and other structural abnormalities	Submetatarsal heads 3, 4 Submetatarsal heads 2, 4
Transmetatarsal amputation without tendo-Achilles lengthening	Stump of amputation

Consider

- Multiple guttate keratoses
  - Heloma miliare
- Painful corns
  - Intractable plantar keratoses
- Neurofibrous or neurovascular corn
- Porokeratosis plantaris discreta

Always Rule Out

- Lesions not associated with bony prominences
  - Verruca
  - Genokeratoses
  - Cutaneous neoplasms
  - Neuroborreliosis

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

(See Box 98-1)

PROGNOSIS AND CLINICAL COURSE

If left untreated, corns and calluses result in painful ambulation and also in subhelomal bursitis and blistering that can rupture to the surface. Because of the close proximity of some corns to joints and bone, septic arthritis and/or osteomyelitis can ensue. The mechanical forces that cause corns and calluses can also rupture portions of the subcutaneous vascular plexus, which leads to hemorrhage into keratotic tissue. In healthy patients, such findings are of minor significance, but in other cases (e.g., in diabetic patients and patients with connective tissue disease), they may herald extensive skin ulceration or vasculitis.

The need for lower extremity amputation is a dominant fear in most diabetic patients. Such amputations are most often preceded by a history of foot ulceration (see Chapter 151). Although a number of comorbidities contribute to the development of ulceration (e.g., peripheral vascular disease, neuropathy, and limited joint mobility), minor trauma via repetitive pressure is the pivotal precipitating event. As markers of repetitive friction and shear, corns and calluses in the diabetic foot are of special significance. Simple débridement of these hyperkeratotic lesions decreases peak plantar pressures by as much as 26%.[5] In a retrospective review of more than 200 diabetic foot ulcerations, patients who had their corns and calluses pared frequently experienced a statistically significant decrease in the incidence of foot ulceration, hospitalization, and surgical intervention.[6] Hemorrhage within a corn or callus is an especially ominous sign, indicating subcutaneous breakdown with a strong potential for ulceration. Therefore, ulcer care should include paring of calluses. The use of proper footwear by the diabetic as well as the nondiabetic patient may also play a role in not only preventing but also reducing the development of callosities. Shoes should be correctly sized to accommodate the width and length of the patient's foot, and the heel should be elevated minimally, if at all, to prevent pathology and pain.[7,8]

TREATMENT

(See Box 98-2)

PREVENTION

Corns and calluses can be prevented only by reducing or eliminating the mechanical forces that created

BOX 98-2 TREATMENT

	PHYSICAL		TOPICAL		SURGICAL
First line	Paring Padding	Central radix of corn requires débridement	Keratolytics[a]	40% salicylic acid or 40% urea cream used as directed	
Second line	Injections[b]	4% alcohol mixed with local anesthetic	Lipid extract with garlic[c]		Osseous and/or soft-tissue procedures[d]
Under investigation	Injections[e]	Botulinum toxin to reduce digital contractures and thereby reduce the increased local skin pressures that lead to hyperkeratosis[13]			

[a]Keratolytics are to be used with caution. Their use is contraindicated in patients with comorbid peripheral neuropathy or arterial disease.
[b]Injections are useful for soft corns and intractable plantar keratoses. Typically up to seven injections may be required, with darkening and thrombosis of the lesion heralding a cure.[9,10]
[c]Newer modality under research. Side effects include blistering, redness, burning, and hyperpigmentation.[11]
[d]Osseous procedures are designed to redistribute weight-bearing pressures, whereas soft-tissue procedures (i.e., adipofasciocutaneous flaps[12]) are used to eliminate cicatrix (fifth digit) secondary to the use of medicated padding.
[e]Newer modality under research. Efficacy undetermined.

them. Usually, this is a daunting, if not impossible, task. Repetitive occupational motions are often unavoidable, patients are commonly reluctant to alter shoe styles, and osseous architecture is predetermined through heredity.

Chapter 99 :: Sports Dermatology

:: Dirk M. Elston

SPORTS DERMATOLOGY AT A GLANCE

- Forty percent of all athletes develop skin problems.
- Infections are highly prevalent.
- Community-acquired methicillin-resistant *Staphylococcus aureus* (CAMRSA) has emerged as the most important pathogen among athletes.
- MRSA typically presents as an abscess or folliculitis.
- The most important intervention for a CAMRSA abscess is drainage.
- Control of MRSA outbreaks requires treatment of fomites and skin colonization.
- Infections with *Pseudomonas*, *Vibrio*, and atypical mycobacteria are frequently associated with water sports.
- Heat and cold injury remain important problems in athletes.

EPIDEMIOLOGY

Skin problems are common among athletes.[1,2] During an 8-week survey of university athletes, 40% reported skin problems.[3] In a study of mountain biking injuries, skin lesions accounted for 75% of all injuries.[4] Skin lesions account for 35% of all in-line skating injuries.[5] Skin infections are more prevalent in athletes than in the general population.[6] Skin-related complaints are especially common in warm, humid climates. During the 1993 Central American and Caribbean Games, held in Puerto Rico, one out of every hundred athletes had a skin-related complaint severe enough to require medical care.[7] Similarly, sports that involve repeated immersion in water are associated with an increased incidence of skin injury and infection.[8] Winter sports often involve short periods of repetitive injury resulting in a high frequency of injuries.[9]

Table 99-1 lists some unique sports-associated skin conditions that are worthy of mention but are not discussed further in this chapter (Figs. 99-1 and 99-2).

PYOGENIC SKIN INFECTIONS

EPIDEMIOLOGY

Cutaneous community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA) has emerged as the most important pathogen among athletes.[10–13] Athletes at risk include weight lifters, wrestlers, and members of competitive sports teams.[14–16] During an outbreak of MRSA in a college football team, linemen had the highest attack rate (18%). Preexisting cuts or abrasions and sharing bars of soap were important risk factors associated with infection. Nasal carriage was associated with sharing towels, living on campus, having a locker near a teammate.[17] Cosmetic body shaving has also been identified as a risk factor for MRSA infection.[18] Data

TABLE 99-1
Sports-Associated Skin Conditions

Bikini bottom: bacterial folliculitis on the buttocks of swimmers
Jazz ballet bottom: buttock cleft abscess
Jogger's nipples: painful, swollen, eroded or hyperkeratotic nipples
Karate cicatrices: linear scars on the dorsal aspects of the hands
Mogul skier's palm: traumatic hypothenar ecchymosis
Painful piezogenic pedal papules: transdermal fat herniations
Ping-pong patches: traumatic ecchymotic patches
Pool palms: smooth, shiny, tender palms secondary to rough pool surfaces
Pulling-boat hands: pernio-like condition produced by friction and damp cold
Rower's rump: lichenification
Runner's nail: multiple Beau's lines or periodic shedding of the nail plate (see Fig. 99-1)
Runner's rump: ecchymoses of the superior gluteal cleft
Stingray hickey: bite ecchymosis
Stretcher's scrotum: scrotal hematoma
Swimmer's shine: facial oiliness seen in swimmers
Swimmer's shoulder: abrasion of the shoulder by the beard during crawl stroke
Talon noir (black heel): intradermal hemorrhage
Tennis toe: subungual hematoma with or without subungual hyperkeratosis or nail dystrophy (jogger's toe, hiker's toe, skier's toe are similar) (see Fig. 99-2)
Turf toe: metatarsophalangeal joint sprain

Figure 99-1 Runner's nail. In this case there are multiple Beau's lines with onychoschizia.

from an outbreak of MRSA abscesses among members of a professional football team (St. Louis Rams) indicates that most infections developed at turf-abrasion sites. Infection was significantly associated with the lineman or linebacker position as well as a higher body mass index. MRSA was cultured from whirlpools and taping gel as well as from 35 of the 84 nasal swabs from players and staff.[19] In competitive male athletes, abscesses generally occur at sites of minor abrasions. In weightlifters, abscesses favor the axillae. Abscesses among female athletes favor the thighs and buttocks. Folliculitis and abscesses noted during an outbreak of MRSA in a saturation diving facility involved the nose, external ear canal, necks, back, extremities, and buttocks.[20]

Figure 99-2 Tennis toe. Subungual hemorrhage seen in runners and basketball and tennis players that produces anxiety because of fear of melanoma. It can be easily differentiated from melanoma by dermoscopy.

ETIOLOGY AND PATHOGENESIS

MRSA isolates usually contain the type IV staphylococcal chromosomal cassette (SCC)*mec* coding for methicillin resistance, as well as the Panton-Valentine leukocidin virulence factor. There is a high risk of colonization in close contacts of individuals with MRSA, and those who are colonized commonly progress to clinical infection.[21,22] Sharing of towels and higher body mass index are independent risk factors for MRSA infection.[23]

CLINICAL FINDINGS

MRSA infection in athletes typically presents as folliculitis or spontaneous abscess (see Chapters 176 and 177). Abscesses may begin as furuncles but rapidly evolve to fluctuance with surrounding cellulitis.

TREATMENT

Like other abscesses, MRSA abscesses respond to drainage. Surveillance data from Baltimore, Atlanta, and Minnesota including 1,647 cases of CAMRSA infection show that therapy to which the strain was resistant was not associated with adverse patient-reported outcomes if the abscess was incised and drained.[24] Other data also suggest that many MRSA abscesses respond to drainage alone.[25,26] Failure to drain MRSA abscesses may have catastrophic results, even if effective antibiotic therapy is prescribed. In one report, bilateral blindness resulted.[27]

Although the SCC*mec* type IV gene cassette present in most *MRSA* strains codes only for methicillin resistance, an isolate from a Japanese athlete also contained a transmissible plasmid coding for multiple-drug resistance.[28] Other MRSA isolates have emerged that are resistant to multiple antibiotics. Some MRSA isolates from Taipei carry a distinct SCC*mec* cassette (type VT) that codes for resistance to multiple antibiotics.[29] While drainage will cure many MRSA abscesses, some athletes will require antibiotic therapy. Of the inexpensive oral agents available to treat MRSA infections, sulfa drugs consistently show the best mean inhibitory concentrations. Tetracyclines are good alternative agents, although only about 80% of MRSA will be sensitive in many locations. Lincosamide resistance is increasing.[30–32] Inducible resistance, related to the *erm* gene, results in strains that test clindamycin-susceptible in vitro, but may be resistant in vivo. A D-test can be used to determine the presence of inducible resistance. In the D-test, clindaymcin and erythromycin disks are placed close together on a culture plate. If inducible lincosamide resistance is present, the zone of inhibition around the clindamycin disk is flattened on the side towards the erythromycin disk, resembling a capital letter D. Rates of inducible lincosamide

resistance vary from 8% in Houston to 94% in Chicago.[33–37] In some areas in the United States, MRSA strains were less likely than methicillin-sensitive strains to demonstrate inducible resistance.[38] In contrast, some locations in Asia report that 100% of tested MRSA strains demonstrate the *ermB* gene.[39]

Some serious MRSA infections will require the use of linezolid, vancomycin, fluoroquinolones, daptomycin, quinupristin/dalfopristin, or newer generation carbapenems. Fluoroquinolones and linezolid, have the advantage of oral administration. In some groups of severely ill patients, linezolid has proved superior to vancomycin.[40–42] Daptomycin has been used effectively in serious MRSA infections, but resistance has been reported, and disk diffusion testing may not predict clinical outcome.[43,44] A new cephalosporin, ceftobiprole medocaril appears to offer a good balance of efficacy and tolerability.[45]

PREVENTION

Nasal colonization correlates poorly with cutaneous MRSA infection, suggesting that other sites of carriage and close physical contact with carriers are important in disease transmission.[46] Cutaneous carriage and fomites are important in the spread of MRSA infection among athletes, and preventive measures directed only at nasal decolonization are frequently ineffective.[47,48] Topical antiseptics such as chlorhexidine, povidone iodine, quaternary ammonium compounds, triclosan, and Dakin's solution play an important role in management.[49] Chlorhexidine gluconate is widely used and generally has good activity against staphylococci. Some MRSA isolates are less sensitive to chlorhexidine than methicillin-sensitive *Staphylococcus aureus* (MSSA) isolates.[50,51] Some chlorhexidine-resistant isolates also exhibit resistance to quaternary ammonium compounds. Resistance can be overcome by using disinfectants containing both alcohol and chlorhexidine.[52] Seventy percent ethanol alone is an effective agent for fomite sterilization if contact can be maintained for 3 minutes.[53] Povidone iodine has shown good activity against both MRSA and MSSA isolates.[81] Triclosan-based products are readily available as "no-wash" hand sterilizers. Some triclosan resistance has been documented, and some MRSA isolates are less sensitive than MSSA isolates.[54,55] Mupirocin is commonly used to treat staphylococcal nasal carriage, but resistant strains have emerged.[56] In one double-blind, placebo-controlled trial, successful nasal eradication was only 44%.[57]

OTHER PYOGENIC SKIN INFECTIONS AMONG ATHLETES

Group A streptococcal infections may also spread rapidly among athletes. Pyoderma with a nephritogenic *Streptococcus* can cause epidermic glomerulonephritis. *Streptococci* also produce erysipelas and lymphangitis (see Chapters 177 and 178).

Pseudomonas infections are commonly associated with water. *Pseudomonas* folliculitis, green nails, and *Pseudomonas* webspace infection are the most common (see Chapter 180 and online edition).

VIRAL SKIN INFECTIONS

Herpes simplex virus (see Chapter 193) can be transmitted by skin-to-skin contact during any contact sport. Herpes gladiatorum is recognized as a major problem among wrestlers. Attack rates as high as 34% have been reported. Ocular involvement is a serious complication. Wrestlers with active infections are barred from participation. The use of abrasive shirts may contribute to the spread of herpes simplex virus infection among wrestlers. They should be avoided. Oral antiviral drugs such as acyclovir, valacyclovir, and famciclovir can be used to shorten the course of an outbreak. It is likely that all three of these drugs can prevent outbreaks of herpes gladiatorum when given as long-term or periodic prophylaxis.

FUNGAL INFECTIONS

(See Chapter 188)

Cutaneous fungal infections are more common among athletes than in the general population, and are particularly common among swimmers and soccer players.[58,59] Tinea facei and tinea capitis are particularly common among wrestlers and others who engage in close contact sports.[60,61] During an outbreak of *Trichophyton tonsurans* tinea in Japan, 52% of the patients were Judo participants and 39% were wrestlers.[62] Asymptomatic carriage and poor compliance with eradication regimens is common in this setting and contributes to the spread of the disease.[63–65] Many of the implicated strains were recently imported to Japan, spread first through martial arts, then to the community at large.[66] Tinea pedis may be spread by floors around swimming pools. Prevalence among runners increases with age, and asymptomatic carriers are common. Periodic prophylactic treatment of carriers with topical agents to prevent clinical disease may be possible, and oral prophylaxis with 100 mg of fluconazole daily for 3 days twice during the season has been shown to be effective in reducing the incidence of fungal infections among high-school wrestlers. In one study, the incidence rate of tinea gladiatorum dropped from 67.4% to 3.5% as a result of intervention.[67]

TRANSMISSION OF BLOOD-BORNE PATHOGENS

There is growing concern about possible transmission of blood-borne pathogens during contact sports. Minor cuts and abrasions are both a source of contamination and a portal of entry for human immunodeficiency virus and hepatitis viruses. Lacerations can be covered with self-adherent biosynthetic dressings to prevent blood transmission from minor wounds during contact sports.

HEAT AND COLD INJURY

Heat injury is a common cause of morbidity during sports. The skin serves as the major organ of thermal regulation. Regular exercise modifies the responsiveness of cutaneous vessels, increasing cutaneous perfusion during periods of activity.[68] The duration of exercise can be safely increased in hot environments if a volume of fluid at least equal to that lost in sweat is ingested within 60 minutes prior to and during exercise.[69] Uniforms promote heat retention, and adequate skin surface must be exposed during exercise in order to reduce the risk of heat stress injury. Evaporative cooling from forearm skin is more efficient than that from the upper trunk; therefore, short sleeve uniforms are helpful in hot climates.[70] Clothing should be lightweight and have high water permeability in order to facilitate evaporative cooling. At high humidity, evaporative cooling from skin is inefficient and the risk of heat stress increases. Spraying of water on the skin during exercise can reduce skin temperature, but results in vasoconstriction and does not reduce core body temperature.[71] Cooling vests can improve athletic performance in hot weather.[72,73] Harlequin syndrome is a disorder of the sympathetic nervous system with diminished sweating and flushing in response to exercise.[74]

Younger athletes have a greater skin surface area, which places them at greater risk for hypothermia in cold environments. Skin injury, such as frostbite and perniosis, are seen in sports enthusiasts who engage in cold weather sports. Frostbite is a common problem among joggers, and may involve the face, hands, feet and penis. The decreased oxygen tension at high altitudes contributes to peripheral vasoconstriction, decreasing peripheral blood flow and increasing the risk of frostbite.[75] Clothing must remain dry in order to retain its insulating properties. Frequent changes of socks and periodic breaks in a warm environment are important safeguards. If frostbite occurs, rapid rewarming should be accomplished as soon as the individual is in a safe environment with no risk of refreezing.

SKIN INJURIES

Skin and soft tissue injuries are common among athletes.[76,77] New treatments, including hydroactive wound dressings, have advanced the treatment of superficial wounds. Application of a hydroactive dressing can provide a protective barrier that can allow an athlete to return to training. Cold gel application has been shown to provide effective symptomatic relief for sports-related soft tissue injuries.

FRICTION BLISTERS

Friction blisters occur as a result of midepidermal necrosis (Fig. 99-3). Proper fitting of footwear and the use of gloves and chalk can reduce the incidence of blistering. Heat, sweating, and maceration increase the risk of blistering. Antiperspirants have been used in an attempt to reduce the incidence of blistering, but results have been mixed, and they may cause irritant dermatitis. Attempts to reduce the incidence of irritant dermatitis through the addition of emollients reduce the efficacy of the antiperspirant. In a study of cross-country hikers, use of a 20% solution of aluminum chloride hexahydrate in anhydrous alcohol reduced the rate of blister formation from 48%–21%, but the incidence of irritant dermatitis was high and noncompliance with the treatment regimen was common. The use of closed-cell neoprene insoles, acrylic socks, or thin polyester socks combined with thick wool or polypropylene socks that maintain their bulk can reduce the incidence of blisters. The use of mesh-top footwear can decrease the risk of blistering by providing a cooler, dryer environment without the use of antiperspirants. A unique form of friction dermatitis occurs in Sumo wrestlers.[78]

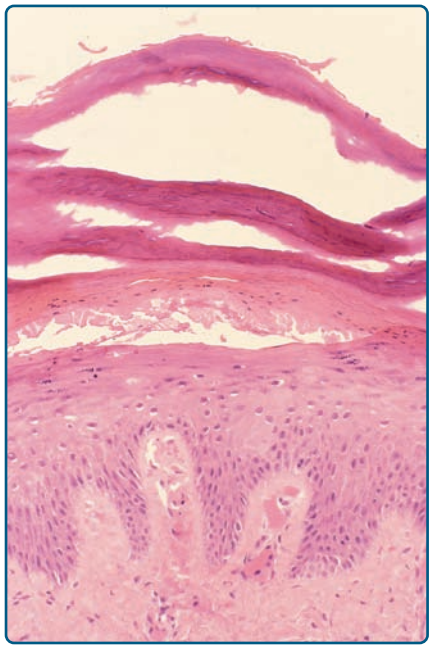

Figure 99-3 Friction blisters are a manifestation of intraepidermal necrosis.

LIME BURNS

The use of calcium oxide (quicklime) or calcium hydroxide (slaked lime) instead of calcium carbonate (chalk) to line sports fields may result in chemical burns, especially in wet weather. Second- and third-degree burns may occur. Lime use may also result in severe inhalation and ocular injury.

ATHLETE'S NODULES

Collagenous "surfer's nodules" are a well-described complication of surfboarding. Boxers, marbles players, and football players are also prone to collagenous nodules. Surgical excision may be required.

ACTINIC DAMAGE

(See Chapters 90 and 113)

Actinic irradiation can cause burns and a risk of skin cancer in later life. Even relatively short periods of exposure during sports are associated with an increased risk of basal cell carcinoma. Sweating alters hydration of the stratum corneum and lowers the minimal erythema dose of ultraviolet (UVB) light by as much as 40.9% after just 15 minutes of jogging. Actinic exposures are particularly high during nautical and mountain sports and participation in water sports and marathons are independent risk factors for both melanoma and nonmelanoma skin cancer.[79–82] Athletes should be advised to reduce UV exposure by choosing training schedules with lower sun exposure, wearing UV-protective clothing, and using water-resistant sunscreens.

ALLERGIC CONTACT DERMATITIS

(See Chapter 13)

Rubber allergens are the most common cause of sports-associated allergic contact dermatitis (Fig. 99-4).[83] Rubber adhesives and rubber chemicals in the box toe and cushioning materials can cause dermatitis from footwear. Contact dermatitis can also result from equipment, swimming-pool chemicals, athletic tape, epoxy resins associated with golf clubs or bowling balls, and topical creams and sprays.[84–86] Wetsuit dermatitis is usually related to thioureas but may also be caused by *p*-tert-butylphenol formaldehyde resin and zinc diethyldithiocarbamate.[87] Clothing dermatitis in athletes may relate to fabric softener, textile finishes, dyes, or designs applied to the fabric. Textile dye penetration of skin is more closely related to the degree of sweating rather than the duration of contact between fabric and skin.[88] Dermatitis under soccer shin guards more commonly represents irritant dermatitis related to sweating and friction rather than allergic contact dermatitis.[89]

Figure 99-4 Athletic shoe allergic contact dermatitis.

BITES AND STINGS

Unexpected bites and stings are frequent while playing sports and may result in both local injury and anaphylaxis (see Chapter 210).

SKIN PROBLEMS RELATED TO WATER SPORTS

Skin eruptions account for almost half of all illnesses related to recreational water. Monitoring of water for fecal coliforms has been practiced for years and has proved to be a better predictor of the risk of skin disease than of the risk of gastrointestinal disease. Contamination by storm runoff results in a predominance of organisms linked to skin infections. Water and activity can rapidly reduce the effect of many sunscreens, although some newer formulations retain their efficacy better under these conditions.[90]

Exposure to the rough surfaces of diving boards can result in a chronic plantar dermatosis. The fingers can also be affected. Some individuals with this disorder have a history of atopic dermatitis, psoriasis, or juvenile plantar dermatosis. The rough interior of swimming pools can result in "pool palms." The skin appears taut, shiny, and erythematous with loss of dermatoglyphics (Fig. 99-5). Green hair is related to the presence of copper in pool water. Copper pipes or algicides may be the source of the high copper levels. Acidic pH, fluoridation of water, and swimming pool chlorination all contribute to the release of copper into pool water. Green hair has been treated with penicillamine shampoo, hot vegetable oil, hydrogen peroxide, edetic acid, and 1-hydroxyethyl diphosphonic acid.

Swimming pool water may be treated with chlorine, bromine, or ozone ionization. All three methods are acceptable, although the use of bromine with ozone may be associated with a slightly lower risk of cutaneous reactions.

Figure 99-5 Finger dermatitis in this diver paralleled the intensity of her training. It resolved during breaks from training.

SWIMMER'S ITCH

(See Chapter 209)

Swimmer's itch is related to avian schistosome cercariae.[91] Newly created bodies of water, such as recently abandoned quarries, are associated with a lower incidence of swimmer's itch. Administration of praziquantel to ducks inhabiting a lake can reduce the incidence of swimmer's itch. Chemical control or mechanical removal of snails can also be effective. The rash heals spontaneously in 2–3 weeks. Topical steroids and antihistamines may be beneficial. Topical antipenetrants have been evaluated, but an ointment based on IR3535 (ethyl butylacetylaminopropionate) failed to prevent an outbreak of cercarial dermatitis during swimming races across Lake Annecy in France.

SEA BATHER'S ERUPTION

(See Chapter 209 and online edition)

OTHER SKIN PROBLEMS RELATED TO OCEAN SPORTS

(See also Chapter 209)

Jellyfish stings result in immediate pain and may produce delayed immune-mediated reactions. *Cyanea* and *Chrysaora* sea nettles are the most common causes of jellyfish dermatitis. *Chrysaora* jellies are especially common off Atlantic beaches. *Physalia physalis*, the Portuguese man-of-war, is common in the southeastern United States and the Gulf of Mexico. *Physalia utriculus*, the blue bottle jellyfish, is native to the Pacific. Stings of *Chironex fleckeri*, the Pacific box jellyfish or sea wasp, may result in shock or death. Victims of any marine envenomation should immediately be removed from the water. Administration of antivenin can prevent cardiovascular collapse. Verapamil shows little effect in experimental animals and may negate some of the beneficial effect of antivenin. Unlike verapamil, $MgSO_4$ has been shown to prevent cardiovascular collapse in test animals. First aid includes mechanical removal of tentacles by seawater and sand. Most northern sea nettle nematocysts are inactivated in alkaline conditions, and most man-of-war nematocysts are inactivated in acidic conditions; however, the use of either acid or alkaline solutions can be complicated by the release of venom in some species. Application of ice can provide analgesia. Most marine venoms are inactivated by heat, and hot water immersion [40°C–41°C (104°F–105.8°F)] generally results in better pain relief. Jellyfish sting inhibitors can be added to sunscreen lotions. *Haloclava producta*, the "ghost anemone," is responsible for summer outbreaks of dermatitis off the coast of Long Island, New York.

Stingray injury usually occurs when a swimmer accidentally steps on a ray. Roughly 750 stingray stings are reported each year off the US coast. Stings are associated with severe pain, hyperhidrosis, hypotension, muscle cramps, and dysrhythmia. Tissue necrosis can be extensive, and surgical exploration is commonly required. Hot water immersion is effective in the control of acute pain but may not prevent skin necrosis. Lionfish are most common in the subtropical waters of the Pacific but are increasingly being reported off the coast of the United States. Stings cause pain, swelling, redness, bleeding, and mild systemic symptoms. Hot water immersion generally produces pain relief. Surgical exploration may be prudent for injuries involving the hands.

Corals, especially fire coral, can produce contact dermatitis in divers. Their stinging cells produce a powerful irritant that can produce severe local reactions, including reactions that resemble full-thickness burns. Contact with seaweed has been implicated in vesiculobullous reactions. Algal organisms in seaweed can cause "stinging seaweed dermatitis" and pustular folliculitis.

Mycobacterium marinum can cause epidemics of swimming pool granuloma (see Chapter 184). Mycobacterial infections are also commonly acquired in brackish coastal waters. Marine *Vibrio* infections (see Chapter 180) also occur with exposure to brackish coastal waters. Necrotizing fasciitis and sepsis may occur. Culture of specimens from wounds contaminated with seawater has a greater yield if thiosulfate-citrate-bile-sucrose agar is used, and the cultures are incubated both at room temperature and at 30°C (86°F).

Decompression injury may affect the skin of divers. Livedo reticularis is commonly noted. In a porcine model of decompression injury, vascular congestion and vasculitis were common findings in skin biopsy specimens.

HISTAMINE-MEDIATED REACTIONS

Exercise-associated urticarial reactions include cholinergic urticaria, solar urticaria, symptomatic dermatographism, pressure-induced urticaria, cold urticaria, aquagenic urticaria, latex-induced contact urticaria, and exercise-induced anaphylaxis. These entities are discussed in Chapter 38.

ACNEIFORM LESIONS

Acne mechanica is common among athletes, occurring under chinstraps, helmets, and shoulder pads. The lesions may respond better to keratolytics than to antibacterial agents. Severe acne may be a sign of anabolic steroid use.[92] The use of these drugs is widespread among athletes of all ages. Some studies suggest that healthcare providers provide illegal androgens to up to 48.1% of abusers, and physicians are involved in illegal prescription of anabolic steroids in 32.1% of cases.[93] There is an alarming trend to combine anabolic steroids with human growth hormone, insulin, and insulinotropic milk protein-fortified drinks to potentiate the effect of each agent.[94] Although the standard in drug testing is immunoassay screening followed by gas chromatography–mass spectrometry of urine samples to provide confirmation, newer technology may allow reliable detection of anabolic steroids in hair.

DERMATOLOGIC PROBLEMS OF SPECIAL ATHLETES

Patients with preexisting dermatoses may experience koebnerization or pathergy following cutaneous injuries related to sports.[95] Athletes with atopic eczema may experience bouts of pruritus with exercise. However, there is evidence that the sweating and vascular response improve with athletic training and that athletics may not interfere with treatment of atopic dermatitis.[96,97] Application of an emollient after showering and short periods of rest can inhibit sweat-induced itching in atopic athletes, and regular moderate exercise does not cause deterioration in the condition of their skin.[98]

The athlete treated with oral retinoids also faces special problems. Arthralgia, staphylococcal colonization, photosensitization, and fatigue may result in lost training time or lost seasons. Retinoids cause disruption of epidermal integrity and skin fragility. Greater trochanter enthesopathy (pain at the site of tendon insertion) may be a complication of short-term oral retinoid therapy in athletes.[99] When possible, retinoid treatment should be planned between seasons.

Chapter 100 :: Decubitus (Pressure) Ulcers

:: Jennifer G. Powers, Lillian Odo, & Tania J. Phillips

PRESSURE ULCERS[1,2] AT A GLANCE

- Commonly known as *decubitus ulcers*, *pressure sores*, and *bedsores*.
- Affect approximately 0.5% to 2.2% of the population.
- Tend to occur over bony prominences, more common from the waist down.
- Etiologic factors include pressure, shearing, frictional forces, and moisture.
- Related risk factors are prolonged immobilization, sensory deficit, impaired consciousness, circulatory disturbance, poor nutrition, and chronic diseases.
- Staged according to the degree of tissue damage observed (I to IV); pathologic findings depend on the stage of evolution.
- No specific laboratory findings. The diagnosis is made clinically.

EPIDEMIOLOGY

Estimates are that between 1.5 and 3 million people in the United States have pressure ulcers. Hospital stays with pressure ulcers listed as a diagnosis increased by nearly 80% in the United States between 1993 and 2006. These chronic wounds cost approximately $5 billion annually to treat, and Center for Medicaid and Medicare Services (CMS) no longer reimburses for additional costs arising from nosocomial stage III or IV pressure ulcers.[1–6]

The prevalence and incidence of pressure ulcers varies with the clinical setting. In acute care, the incidence ranges from 0.4% to 38%; in long-term care, from 2.2% to 23.9%; and in home care, from 0% to 17%. Most pressure ulcers develop during the first few weeks of hospitalization. The prevalence of pressure ulcers in acute care settings is approximately 15%, in long-term care settings from 2.3% to 28%, and in home care from 0% to 29%.[1–4]

Pressure ulcers are more common in the elderly, especially those over the age of 70, in patients who have had surgery for hip fracture, and in patients with spinal cord injury. A multicenter study of 3,233 elderly admitted from the emergency demonstrated a pressure-ulcer incidence (mostly stage II) of 6.2% on hospital day 3, with significant associations to advanced age, male gender, dry skin, urinary and fecal incontinence, difficulty turning in bed, and poor nutritional status.[7]

The majority of pressure ulcers occur on the lower part of the body, 65% in the pelvic area and 30% on the lower limbs, though other locations include the scalp in infants with neurological injury or the face from endotracheal tubes during long surgeries or intensive care unit (ICU) stays.[1–4]

ETIOLOGY AND PATHOGENESIS

The main etiologic factors contributing to pressure ulcer development include pressure, shearing forces, friction, and moisture.

Pressure or force per unit area is considered to be the most important factor in pressure ulcer formation. Normal tissue pressure is between 12 and 32 mm Hg. Pressures higher than this upper limit can compromise tissue circulation and oxygenation. When a patient lies immobile on a hospital bed, pressures as high as 150 mm Hg can be generated, especially over bony prominences. At pressures of 70 mm Hg or more, there is an inverse time–pressure curve with rapid pressure ulcer formation.[2] Sitting positions can also generate elevated pressure over precise body surfaces. The duration as well as degree of pressure is important. If pressure is relieved regularly, tissue recovery can occur, whereas constant pressure can lead to tissue death (Fig. 100-1). Often, damage occurs deep at the bone–muscle interface, in which the limited cutaneous injuries may be only the "tip of the iceberg" of deeper, more extensive damage (eFig. 100-1.1 in online edition). Patients who are immobile should therefore be turned regularly to prevent pressure ulceration. The pathophysiology of pressure ulcer formation is summarized in eFigure 100-1.2 in online edition, and common sites of pressure ulcers are shown in Figure 100-2.

Figure 100-1 Pressure ulcer, stage IV. (From Wolff K and Johnson RA. Fitzpatrick's Color Atlas, 2009.)

Shear force results from the motion of bone and subcutaneous tissues relative to the skin when the skin is fixed (e.g., when the upper body of a supine patient is raised to an angle above 30° and the skin remains in contact with the bed). Shearing forces are parallel to the tissue surface, and the subsequent sliding pressure is transmitted to deeper tissues, which can become angulated and occlude the blood vessels (Fig. 100-3A). Spinal cord injury patients develop such shearing forces with muscle spasms, which may be controlled with muscle relaxants.[8]

Friction is the force that resists the relative motion between two surfaces that are in contact. This causes damage to the superficial layers of the skin (e.g., when a patient is dragged across the bedsheets) (Fig. 100-3B).

A moist environment from urinary or fecal incontinence, perspiration, or excessive wound drainage can cause maceration of the skin, which increases the risk of pressure ulcer formation fivefold (Fig. 100-4). Other risk factors for pressure ulcer development include prolonged immobilization, sensory deficit, circulatory disturbances, poor nutrition, acute illness, advanced age, and a previous history of pressure ulcers as well as fecal and urinary incontinence, hip fractures, smoking, and dry skin. Concomitant use of medications such as corticosteroids, which can impair healing; sedatives and analgesics, which can impair consciousness; and drugs that can cause alterations in cutaneous blood flow, such as antihypertensive medications, can also increase pressure ulcer risk, and such drugs should be used with care (Table 100-1).

CLINICAL FINDINGS

(See eFig. 100-4.1 in online edition)

HISTORY

History taking and physical examination for pressure ulcer patients should incorporate a risk assessment scale.

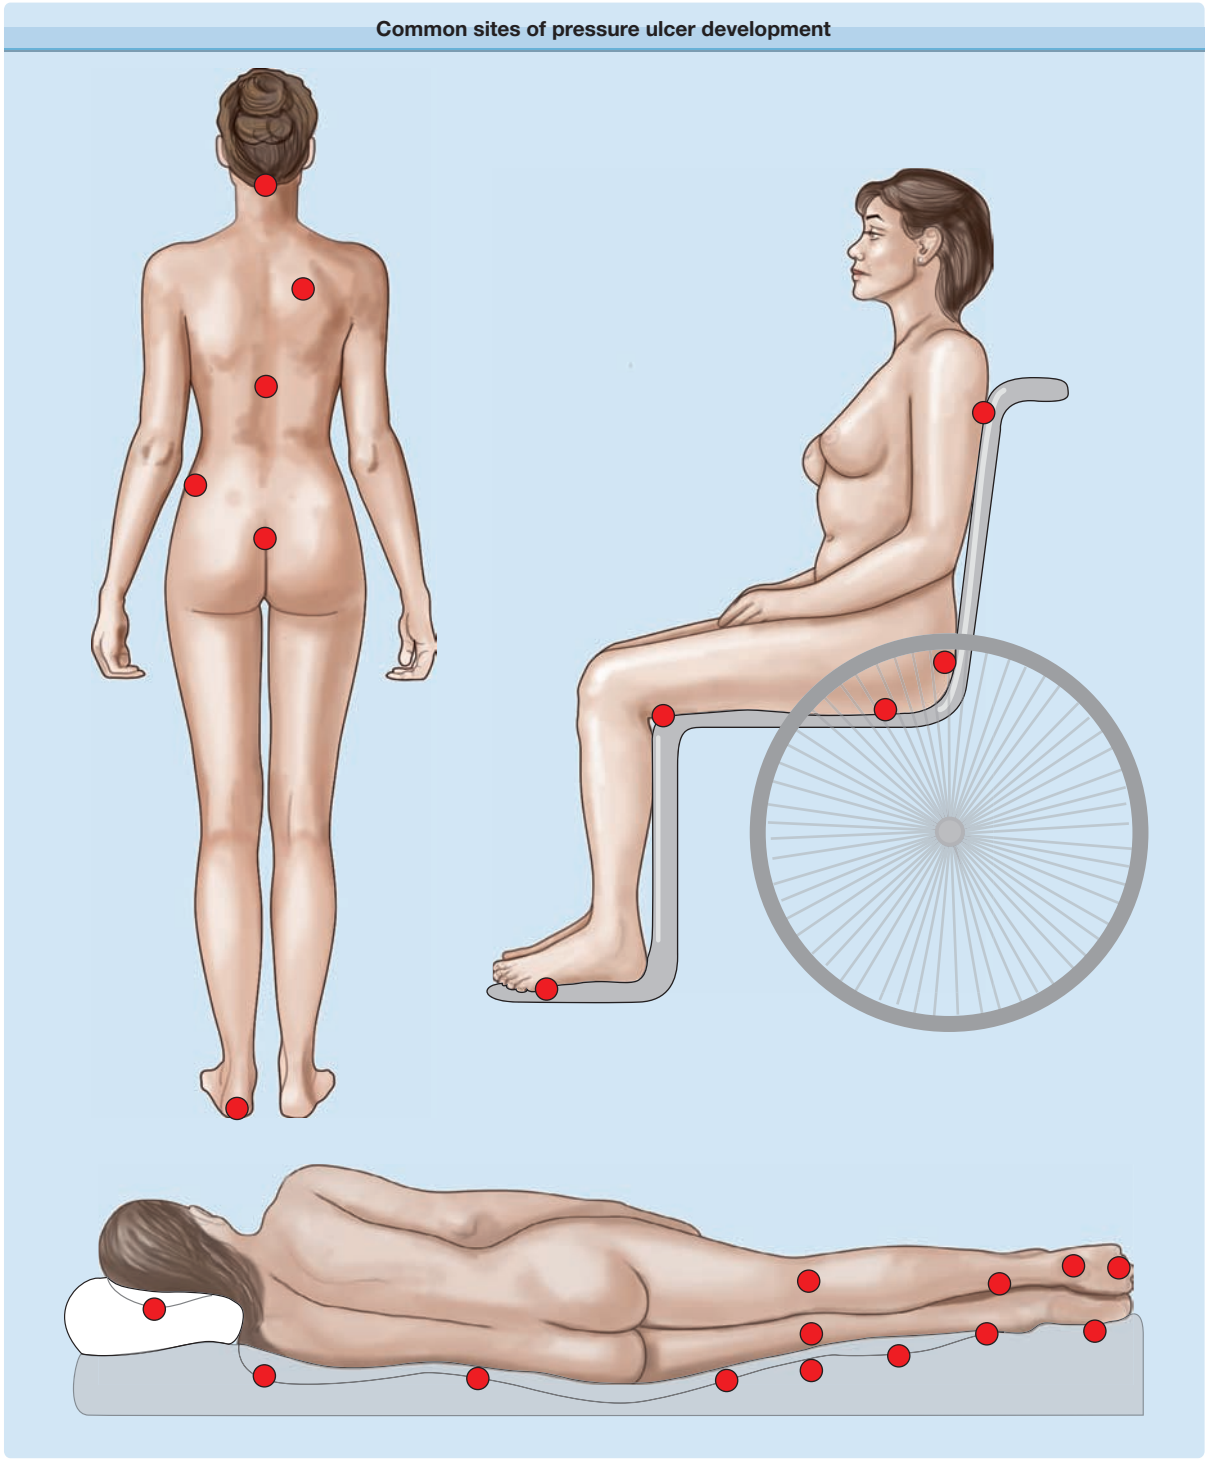

Figure 100-2 Common sites of pressure ulcer development. (From *Preventing Pressure Ulcers: A Patient's Guide*. Washington, DC, US Department of Health and Human Services, USGPO 617-025/68298, 1992.)

A number of risk assessment tools have been devised in an attempt to identify persons at risk for pressure ulcers. The Braden, Waterlow, and Norton scales have been extensively tested for reliability and validity and have been recommended by the Agency for Healthcare Research and Quality for predicting the risk of developing pressure sores. Currently, best practices in acute care, long-term care, and home-health care dictate that such risk assessments be performed initially at admission and at subsequent precise intervals. Components of these scales assess the following risk factors: mobility, activity level, nutritional status, mental status, incontinence/moisture conditions, general physical condition, skin appearance, medication use, friction and shear, weight, age, predisposing diseases, and prolonged pressure (eTable 100-1.1 in online edition).

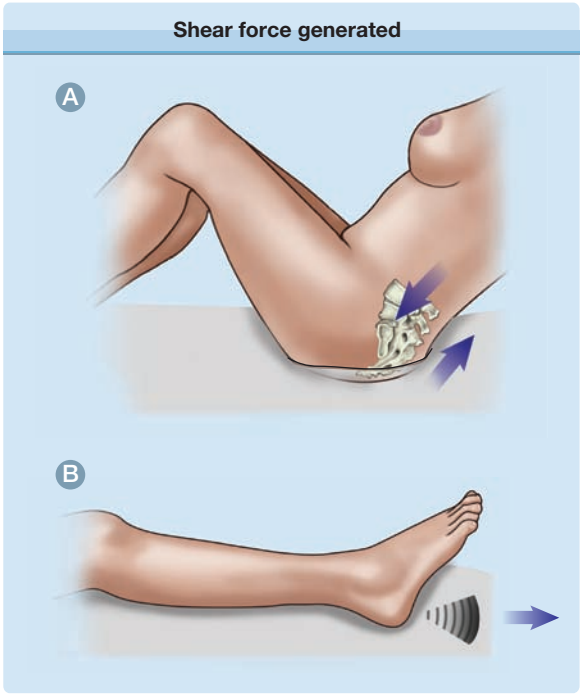

Figure 100-3 Shear force generated when a patient slides down a bed, for example, in the sacral region (**A**) or on the heels (**B**). (From Grey JE, Harding KG, Enoch S: Pressure ulcers. *BMJ* **332**:472, 2006, with permission of Blackwell Publishing.)

CUTANEOUS LESIONS

Staging is an assessment system that classifies pressure ulcers based on anatomic depth of soft-tissue damage. Pressure ulcers often progress from lower to higher stages, and any small pressure ulcer should be considered as the possible "tip of an iceberg." Table 100-2 shows the clinical appearance of pressure lesions and ulcers and their histopathologic correlates as defined by the National Pressure Ulcer Advisory Panel (NPUAP). Palpation is important to assist visual evaluation. Ulcers that initially appear superficial can end up being classified as stage III or IV after débridement reveals their true depth. The epidermis may be hypertrophic at the ulcer margin with varying degrees of pigmentation.[10]

There are several staging systems for classifying pressure ulcers. The most commonly used include the NPUAP, Shea, and Yarkony et al systems. In February 2007, the NPUAP redefined the stages of pressure ulcers established in 1989 by preserving the four original stages and adding two new stages of deep tissue injury and unstageable pressure ulcers. The unstageable category was created to avoid unnecessary removal of slough or eschar simply for the purpose of staging, which might hinder ulcer healing (Fig. 100-5). eTable 100-2.1 in online edition compares these four classification systems.[2,10–13]

TABLE 100-1
Major Risk Factors for Developing Pressure Ulcers

Alteration in Sensation or Response to Discomfort
■ Degenerative neurologic disease
■ Cerebrovascular disease
■ Central nervous system injury
■ Depression
■ Drugs that adversely affect alertness
Alteration in Mobility
■ Neurologic disease or injury
■ Fractures
■ Pain
■ Use of restraints
Significant Changes in Weight (≥5% in 30 days or ≥10% in previous 180 days)
■ Protein–calorie undernutrition
■ Edema
Incontinence
■ Bowel and bladder

Figure 100-4 Pressure ulcer, stage III, complicated by fecal incontinence.

RELATED PHYSICAL FINDINGS

All pressure ulcer patients should undergo a full physical examination to identify systemic disease contributing to wound development, such as anemia, chronic cardiac or respiratory disease, and neurologic disorders.

Tenderness, erythema, edema and warmth of surrounding skin, exudate, and foul odor are symptoms and signs of infection. Fever and declining mental or physical status should raise suspicion of bacteremia or osteomyelitis.

Spasticity secondary to inflammation and infection may trigger muscle contractures and joint deformity

TABLE 100-2
Comparison of Clinical and Histologic Findings by Ulcer Stage

Classification/Stage[9]	Clinical Findings	Histopathologic Description
Stage I 	Nonblanchable erythema of intact skin	Epidermis appears normal. Striking red blood cell engorgement of capillaries and venules, mainly in papillary dermis with platelet thrombi and hemorrhage. Degeneration of sweat glands and subcutaneous fat is often seen.
Stage II 	Partial-thickness skin loss involving epidermis, dermis, or both	Epidermis is lost. Dermal papillae are often identifiable. Acute inflammation of papillary and reticular dermis is found. In addition to a perivascular lymphocytic infiltrate, neutrophils are seen. Necrotic changes in the appendages and fat are more pronounced.
Stage III 	Full-thickness skin loss involving damage to or necrosis of subcutaneous tissue that may extend down to, but not through, underlying fascia.	Hemorrhagic crust containing acute inflammatory cells or a thin zone of coagulation necrosis on the surface. Diffusely fibrotic dermis. Loss of appendageal structures.
Stage IV 	Full-thickness skin loss with extensive necrosis of or damage to muscle, bone, or supporting structures.	Full-thickness destruction of skin. The tissue appears basophilic with obliteration of cellular detail, although the general dermal architecture is preserved. Inflammatory infiltrate is often not seen.

NPUAP = National Pressure Ulcer Advisory Panel.

that can limit motion, which complicates positioning. Weakness and signs of anemia and dehydration can be found secondary to profound loss of fluid and protein from these open, draining wounds.

LABORATORY TESTS

The diagnosis is made clinically. However, anemia, leukocytosis, hypoproteinemia, hypoalbuminemia, elevated ESR, or reduced serum iron levels may be present. It is important to exclude other diseases that can cause skin ulcers, including calciphylaxis, vasculitis, and connective tissue diseases.

SPECIAL TESTS

BIOPSY. Histologic analysis may be helpful to diagnose the pressure ulcer stage when clinical findings are insufficient to determine depth and exclude other diseases that can present with skin ulcers such as collagen vascular diseases. In long-standing pressure ulcers, squamous cell carcinoma can develop (Marjolin's ulcer). Histologic findings in pressure ulcers are described in Table 100-2.

IMAGING STUDIES. Radiology is most useful to identify complications, particularly of deep pressure sores. Plain radiographs can identify ectopic bone, air in the ulcer cavity, and sclerotic or destructive changes in the underlying bony prominence. Ectopic bone can cause a pressure sore by altering the patient's posture and locally increasing pressure over soft tissue.[14] When there is clinical uncertainty about the size or extent of a pressure ulcer, sinography can be performed. Direct magnification radiography of sacral areas is useful when plain radiographs leave doubt about the condition of the bony cortex adjacent to a pressure sore. If the cortex is intact, osteomyelitis is unlikely.

Computed tomographic scanning is useful to determine the extent of a pressure ulcer and its anatomic relation to surrounding structures. It is helpful in assessing large, complicated lesions with associated sinus tracts or extensive undermined margins. Computed tomography is the only radiographic modality that can define the external margin of the lesion.

Magnetic resonance imaging (MRI) is helpful in determining the depth and extent of soft-tissue involvement underlying decubitus ulcers. It can also be a useful tool for identifying osteomyelitis, fluid collections, abscesses, and sinus tracts.[15,16] The gold standard for the diagnosis of osteomyelitis is histologic/microbiologic analysis of surgical biopsy specimens, but MRI is accurate in the diagnosis of osteomyelitis (sensitivity, 98%; specificity 89%) and associated soft-tissue abnormalities. It also can delineate the extent of infection to assist in guiding limited surgical resection and preserving viable tissue.[14]

TREATMENT

Therapy should be individualized for each patient and involves more than simple wound management. Pressure ulcers are frequently a clinical sign of underlying medical conditions which should be treated to facilitate healing. Treatment takes great coordination by inpatient facilities such as nursing homes, where caretakers often use the NPUAP-designed PUSH (Pressure Ulcer Scale for Healing) tool or the Bates–Jensen Wound Assessment Tool (BWAT) to document wound healing.[23,24] Photography can also be an important means of documenting improvement and should include dimensions, date, and wound location.[25] Few controlled trials have evaluated specific treatment modalities for pressure ulcers, but reasonable interventions include use of basic support surfaces, repositioning the patient, optimizing nutritional status, and moisturizing sacral skin with expectations of some improvement within 2 weeks.[26] The general principles of therapy for pressure ulcers are as follows.

TABLE 100-3
Complications of Pressure Ulcers

- Local infections
- Bacteremia
- Osteomyelitis
- Sinus tracts
- Malignancies
- Necrotizing fasciitis

  - Hypoproteinemia
  - Anemia
- Postsurgical complications
  - Hematoma
  - Seroma
  - Wound dehiscence
  - Abscess
- Amyloidosis and others
- Death

RELIEF OF PRESSURE, SHEAR, AND FRICTIONAL FORCES

POSITIONING. Positioning techniques are critical in the management of tissue loads.

While in bed, patients should be positioned to avoid pressure over existing ulcers or over bony prominences, especially the trochanter. Pillows or foam wedges can be used to raise a pressure ulcer off its support surface or to prevent direct contact between bony prominences, such as knees or ankles. It is important to limit the amount of time the head of the bed is elevated and to maintain the head of the bed at the lowest possible level of elevation tolerable to reduce shearing forces at sacral tissues. Immobilized patients are usually placed in a 30° oblique position to the left or right, which should be alternated every 2 hours at a minimum. International best practices have validated this approach though controlled studies are still needed.

The patient and caregivers must learn appropriate transfer or mobilization techniques to avoid friction. The patient should be lifted rather than dragged across the bedsheets, using lifting devices such as a trapeze or bed linen.[27] Repositioning should be done as frequently as warranted by the patient's condition.

Moisture from urinary or fecal incontinence, perspiration, or wound drainage should be minimized, and the skin should be kept clean. Absorbing underpads or briefs, diapers, and occasionally urinary catheters or rectal tubes may be required to help manage incontinence. Skin barrier creams can help protect the skin from maceration.

Patients, who are sitting, may select a pressure-relieving cushion based on specific needs. Donut-type devices should be avoided because they result in venous congestion and may worsen ulcers. Patients should be encouraged to reposition themselves frequently.

SUPPORT SURFACES. Support surfaces can be used on top of or instead of standard mattresses. They distribute pressure over a large surface area, and the type of support surface used will depend on the patient's needs and abilities. Support surfaces are typically divided into static and dynamic, the latter powered by electricity (eTable 100-3.1 in online edition).

Static support surfaces are recommended for patients who can assume several positions without bearing weight on an ulcer. These include specialized foam mattresses and mattresses with various fillings. They may also be overlays used atop of a base mattress.

"Low-tech" foam mattresses are the most commonly used material for pressure reduction, given their ease of use, affordability, and evidence base. A Cochrane Systematic Review examined five trials comparing foam alternatives with standard hospital mattresses, demonstrating a relative risk reduction of 60% in pressure ulcer incidence with the use of foam mattresses.[28] Foam slabs should be 3–4 inches thick to effectively reduce pressure. A trial with 70 intensive care unit patients in France showed 85% risk reduction in heel ulcers in patients using a total foam body support system compared to control groups receiving standard pressure ulcer protocol including a water mattress.[29]

Other "low-tech" pressure supports include static supports filled with air, water, gel, silicone, polyvinyl, heel elevators, and sheepskins. Most of them permit a high degree of immersion, allowing the body to sink into the surface as it conforms to the bony prominences. This increases the surface pressure distribution area and lowers the interface pressure by transferring the pressure to adjacent areas. Unfortunately, many of the water-filled and bead-filled mattresses that demonstrated success in clinical trials are no longer available. A Cochrane Systematic Review of two trials examining the effects of sheepskins showed relative risk of 0.42 for pressure ulcer development compared to standard low-tech support surfaces.[28]

Patients who cannot tolerate frequent turning, immobile patients, those with large or multiple ulcers, and patients with unresponsive ulcers may require dynamic support surfaces, which are electrically powered. These provide cyclical, alternating pressure relief, and include air-fluidized, low-air-loss, and/or alternating-air beds.

Air-fluidized beds contain microspheric silicon-coated beads encased in an air-permeable fabric (polyester or Gore-Tex). The beads are suspended by pressurized streams of warmed air, which allows patients to "float" and decreases pressure through the principle of immersion while simultaneously reducing shear. Feces and body fluids flow freely through the sheet; thus, the skin is kept dry.

Low-air-loss systems use a series of connected, air-filled cushions that are inflated to specific pressures. Some have alternating and pulsating pressure features. A prospective, randomized trial demonstrated that the use of low-air-loss beds resulted in threefold faster wound healing than use of a foam mattress.[30] Unlike with air-fluidized beds, urine and feces do not pass through the fabric of low-air-loss beds.

Alternating-pressure systems distribute pressure by shifting the body weight to different surface contact areas. The air is pumped into the chambers at periodic intervals to inflate and deflate them in opposite phases, which thereby changes the location of contact pressure. Though alternating-pressure systems have not been proven more efficacious than low-tech supports, a cost effectiveness analysis by the UK National Health Service associated them with 80% probability of being cost saving due to shorter hospital stays and delay in ulceration.[28,31]

Other pressure supports that may be of modest benefit include kinetic turning beds, operating table overlays, and seat cushions. Kinetic turning beds are primary used in ICU settings for pulmonary concerns. Operating table overlays may decrease postoperative pressure ulcer incidence and should be employed with high-risk patients undergoing long procedures.

WOUND MANAGEMENT

CLEANSING. Cleansing should be performed gently to minimize mechanical and chemical trauma to healing tissues. Normal saline is preferred because it

is most physiologic in relation to the wound. Safe and effective irrigation pressures for ulcers range from 4 to 15 psi; higher pressures than this may cause trauma and drive bacteria into the wound tissue. Certain skin cleansers and antiseptics such as povidone iodine, sodium hypochlorite solution, hydrogen peroxide, acetic acid, and liquid detergents should be avoided, because these agents are cytotoxic and may retard epithelialization.

DÉBRIDEMENT. Ulcers with devitalized, necrotic tissue should be débrided, because necrotic tissue supports the growth of pathogenic organisms. Mechanical débridement techniques include application of moistened saline or wet-to-moist dressings, hydrotherapy (whirlpool), wound irrigation, and application of dextranomers. Wet-to-dry dressings changed every 4 to 6 hours are painful and are nonselective for necrotic tissue. Whirlpool devices can be considered for pressure ulcers with thick exudate, slough, or necrotic tissue. For wound irrigation, a large 35-mL syringe and 19-gauge angiocatheter can be used to provide adequate pressure.[1]

Sharp débridement involves the use of a scalpel, scissors, or other sharp instrument to remove devitalized tissue and is generally indicated in cases in which there is eschar. For smaller ulcers, local anesthesia can be used, whereas larger stage III or IV ulcers may require extensive surgical débridement under general anesthesia. Enzymatic débridement can be used in patients who cannot tolerate surgery. Topical agents such as sutilains, collagenase, fibrinolysin, and deoxyribonuclease can be used. Papain was removed from the market due to hypersensitivity reactions.[32] Dressings should be changed once to several times daily. Contact dermatitis can sometimes occur, and these agents should not be used if tendon is exposed.[2]

Autolytic débridement involves the use of synthetic dressings to cover the wound, which allows digestion of necrotic tissue by enzymes normally present in wound fluids.

In addition to traditional débridement methods, the use of sterile fly larvae (maggots) to clean necrotic tissue is gaining popularity and appears to be safe and effective.

DRESSING PRODUCTS. Dressings can help protect the wound from the environment, reduce or prevent wound infection, stimulate autolytic débridement, reduce wound pain, and stimulate the development of granulation tissue. It has been demonstrated experimentally that wounds maintained in a moist environment heal 40% faster than air-exposed wounds. Control of moisture and drainage from the wound helps provide an optimum wound environment for healing. There are several types of dressings, each one of which has specific properties, advantages, and disadvantages (eTable 100-3.2 in online edition). Higher stage ulcers usually require more absorptive dressings to maintain a moist environment. A variety of specialized dressings may be helpful for pressure ulcer management, including a bilayer matrix wound dressing, pig-derived acellular small intestine submucosa, and natural latex biomembrane. Both the NPUAP and the EPUAP (European Pressure Ulcer Advisory Panel) state in their international pressure ulcer guidelines that gauze dressings should be avoided in clean, open pressure ulcers since they may stick to wounds, causing pain with dressing changes.[24] In fact, a systematic review of 29 studies demonstrated hydrocolloid dressings to be superior to gauze in terms of pressure ulcer healing, pain associated with dressing change, absorption capacity, side effects, and cost.[33]

Intact skin surrounding the ulcer should always be assessed for signs of inflammation and infection. Irritation of surrounding skin may result from epidermal skin stripping during dressing changes or maceration secondary to contact with feces, urine, or wound drainage. Periwound skin must be adequately moisturized but neither macerated nor eroded.[28] A randomized clinical trial of 331 patients over a 30-day period demonstrated pressure ulcer incidence was 7.32% in a group of patients treated twice daily over high-risk sites with Mepentol, a hyperoxygenated fatty acid preparation, compared with 17.37% in the placebo group treated with a generic greasy product. In addition, Mepentol, comprised of such compounds as oleic acid, linoleic acid, arachidonic acid, and eicosenoic acid was found to be cost effective.[34] Creams or gels containing metronidazole, balsam of Peru, trypsin, and recombinant human platelet-derived growth factor are also available.

BACTERIAL COLONIZATION AND INFECTION MANAGEMENT

Ulcer cleansing and débridement are important to control microbial burden in pressure sores. Systemic antibiotic therapy is not recommended for contamination or minor localized infections but is indicated when bacteremia, cellulitis, or osteomyelitis is present.

Topical antibiotics are used to prevent or treat wound infection, reduce bacterial load, or reduce odor and signs of inflammation. Topical antibiotics such as neomycin and bacitracin are common allergens and can cause contact dermatitis and, rarely, anaphylaxis. Topical formulations of antibiotics that are used systemically (e.g., gentamicin) should be avoided because bacterial resistance may develop. However, the Agency for Healthcare Research and Quality guideline recommends a short 2-week course of topical antibiotics for a clean ulcer that is not healing or that is producing a moderate amount of exudate despite appropriate care.[35] The use of topical metronidazole 1% solution or 0.75% or 0.80% gel has gained popularity in reduction of wound odor, though randomized controlled trials are still needed to prove efficacy.[36]

PAIN MANAGEMENT

Pain management requires a combination of conservative measures, medications, and appropriate wound care. Muscle relaxants and physical and occupational therapy may be helpful to decrease muscle spasm in the area of ulceration. Transcutaneous electrical nerve

TABLE 100-4
Preventive Measures

Maintain personal hygiene. Consider topical lotions containing fatty acids.
Try to assure adequate nutrition and hydration.
Evaluate and manage urinary and fecal incontinence.
Position to alleviate pressure over bony prominences and shearing forces over heels and elbows, base of head, and ears.
Try to reposition every 2 h when in bed and every hour when in a chair; if alert and capable, the patient should be taught to shift his or her weight every 15 min while in a chair.
Use appropriate positioning devices and foam padding; do not use donut-shaped devices. Consider dynamic supports in high-risk patients.
Try to avoid placing the patient on his or her trochanters or directly on the wound.
Maintain the lowest head elevation possible (no greater than 30°)
Use lifting devices such as draw sheets or a trapeze.
Try to prevent contractures.
Do not massage reddened areas over bony prominences.

Modified from American Medical Directors Association: *Clinical Practice Guideline: Pressure Ulcers*. Columbia, MD, American Medical Directors Association, 2008. © 2008 American Medical Directors Association.

stimulation may help relieve acute and chronic pain. The use of topical anesthetics such as lidocaine-prilocaine cream on wounds 30 minutes before débridement significantly reduces pain associated with wound care procedures. An opiate diamorphine gel was also shown to significantly reduce pain with dressing changes in a small randomized controlled trial of patients with stage II and III ulcers.[37]

Nonopioid analgesics (aspirin, other nonsteroidal anti-inflammatory drugs) are first-line systemic therapy, followed by stronger medications such as opioids. Adjuvant medications such as tricyclic antidepressants can be used to enhance analgesia.[37] They can also improve depression in some chronic pain states and have sedative, sleep-enhancing qualities.

PREVENTION

Preventive actions can decrease the patient's risk of developing pressure ulcers. These steps can also keep pressure ulcers from getting worse. Preventive measures are listed in Table 100-4.

Chapter 101 :: Body Art

:: Anne Laumann

BODY ART AT A GLANCE

- Tattoos are common: 24% of the US 18- to 50-year-olds in 2004, equal numbers of men and women.
- Tattooing medical complications are rare: mainly related to pigment ingredients, but include viral, bacterial, fungal, and transfusion-transmitted diseases.
- Tattoo social associations and difficulties are significant.
- Piercing: soft earlobes 37% and body piercing excluding the soft earlobe 14% of the US 18- to 50-year-olds in 2004, mainly women; 46% of women aged 16–24 in the United Kingdom in 2005. Body piercing fashion started in the late 1980s.
- Piercing medical complications are common: metal-induced contact allergic dermatitis, broken teeth, anesthetic risks, and infections of all types.
- The relationship of body art to hepatitis is unclear.

DEFINITIONS

Body art is art made on, with, or consisting of, the human body. The most common forms of body art are tattoos, body piercings, and body painting, but other types include scarification, branding, tongue splitting, subdermal and extraocular implants. *Tattooing* is the practice of producing an indelible mark or figure on the human body by inserting pigment under the skin using needles or other sharp instruments.[1] *Body piercing* refers to the cosmetic piercing of body parts for the implantation of objects such as rings, studs, or pins.[2] *Body painting* is the application of paint on to the skin and includes face painting, the application of *mehndi* and temporary tattoos. *Scarification* is a means of permanently marking the skin by cutting alone, without the use of pigments. This includes the deliberate formation of keloids. When purposeful third-degree burns are used to induce a scar, the procedure is called branding.[3] *Tongue splitting* is the bisection of the tongue from the tip toward the back for about 3–5 cm leading to an appearance similar to the tongue of a lizard.[4,5] *Subdermal implantation* is the placing of a foreign body under the skin so that none of the object remains outside of the body. A three-dimensional effect is seen on the surface. Materials used are silicone, Teflon, or metal.[6]

Extraocular implantation is the placing of sterile nonpyrogenic platinum jewelry inside the interpalpebral conjunctiva of the eye.[7]

TATTOOING

EPIDEMIOLOGY AND BACKGROUND

The word "tattoo" is said to come from Captain Cook after he saw markings on the bodies of the Polynesian people during his 1769 South Pacific voyage. "Ta-Tu" means "to mark" in Tahitian and is associated with the sound made by the Tahitian tattoo instrument.[8] However, tattoos have probably been performed since the beginning of humanity. The famous Ice Man dating from 3300 BC found in the mountains of Europe was covered in tattoos, and they are seen on Egyptian mummies dating from 2000 BC. Tattoos were a sign of nobility, bravery and beauty. They are forbidden in the Old Testament in both Leviticus and Deuteronomy and in the Koran. Despite this, the practice has persisted and has been popular in Europe and America. During the Depression, the prevalence of tattooing declined as incomes shrank. Nondecorative tattoos were used to identify slaves, criminals and internees in prisoner of war and concentration camps during the Second World War. Military personnel often had tattoos with patriotic designs, together with hearts and the names of loved ones. With the advent of peace, the popularity of tattoos decreased, although they were still seen in close-knit group situations. They became associated with marginalized groups, signaling time spent in jail, "punk" status, membership in a motorcycle gang or a traveling circus. In recent times, images have become increasingly eclectic and the practice has become mainstream.[9]

Studies performed in 2008,[10] 2006,[11] and 2004[12] found that 14% of 18- to 64-year-olds in the United States have tattoos, including approximately 30% of those under the age of 40. They are equally common among men and women and are seen in all ethnic groups. They are still found more commonly in those with a military association and in those of low educational and socioeconomic backgrounds. They are associated with the abuse of alcohol, the taking of illicit drugs and having spent significant time in prison.[13] They are inversely associated with having a religious affiliation and having never drunk alcohol. Most tattoos are done in a dedicated studio, but approximately a quarter of people with tattoos have had at least one tattoo done elsewhere.

PROCESS

A handheld device, powered by low-voltage direct current, holds solid needles placed singly or in groups of up to fourteen on an oscillating bar (Fig. 101-1). The needles are dipped into colored inks and then moved across the skin in the desired pattern, penetrating rapidly and vertically 0.5–2.0 mm into the skin, depositing the pigment into the dermis. A thin layer of petroleum jelly is applied to the skin prior to and during the procedure to minimize blood loss and prevent spatter. After the tattoo is finished, the area is cleaned with a mixture of alcohol and water, and more ointment is applied. Sometimes, the ink is spread over an area of skin and the needles made to penetrate through it to carry the particles into the skin. Amateur tattooers often do it this way using handheld needles wound round with thread to prevent too deep penetration. Other instruments used may be pencils, pens, and straight pins.

Figure 101-1 Tattooing with a handheld electric tattoo machine.

Figure 101-2 Four days after the application of this tattoo, much of the inserted pigment is extruding.

Figure 101-4 This Tattoo is 35 years old and the image has blurred. From the top down: Mom in heart, a wreath, an eagle, a peace arrow, God Bless America.

Much of the pigment is extruded through the epidermis during the first 10 days (Fig. 101-2). The final location of the pigment is in the mid-to-lower dermis (Fig. 101-3), but the pigment in amateur tattoos tends to be more superficially and more variably placed. The particles are membrane bound (in secondary lysosomes) within fibroblasts, macrophages and occasionally mast cells around blood vessels. They may also be seen around hair follicles and sebaceous glands. Many of the pigment conglomerations are too large to traverse the vessel walls and leave the area of original deposition, but with time pigment diffusion from the site may lead to blurring of the visible design as well as pigment deposition in the draining lymph nodes (Fig. 101-4).[14,15]

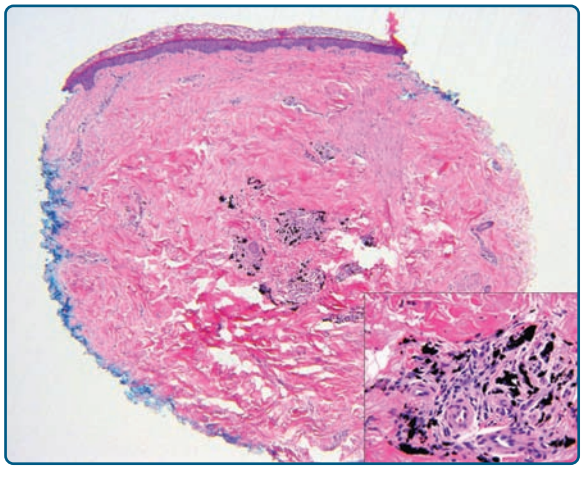

Figure 101-3 Tattoo pigment is seen in the reticular dermis. The particles are within fibroblasts, macrophages, and occasional mast cells around blood vessels.

PIGMENTS

Tattoo pigment composition, as obtained from the manufacturer, and possibly further mixed by the artist, is complex, usually nonsterile, unregulated, variable and changing. In recent times, industrial organic pigments, including azo and polycyclic compounds, sandalwood and brazilwood, as well as aluminum, cadmium, calcium, copper, iron, phosphorus, silica, and sulfur have been identified.[16] In addition, titanium dioxide and barium sulfate are often used to lighten the color. The 1976 Food, Drug and Cosmetic Act limited the content of lead and mercury in cosmetics for application to the skin so that now these two elements are rarely found.[17–19] The pigment in amateur tattoos is usually black and carbon based, often deriving from India ink, charcoal, soot, or mascara[20] (Table 101-1).

COMPLICATIONS

Medical complications are unusual in developed countries. Clearly, there is a real risk of contracting a contagious disease, but most recent reports are anecdotal. These include reports of verrucae, molluscum contagiosum, and atypical mycobacterial infections in the area of the tattoo, methicillin-resistant staphylococcal infections spreading from the area of the tattoo and bacterial endocarditis within a week of tattoo application.[21–26] There has been more than one report of cutaneous leishmaniasis in a tattoo site among HIV-infected individuals with visceral leishmaniasis.[27] Inoculation leprosy is common in parts of the world where leprosy is endemic.[28,29] (See Table 101-2.)

There have been outbreaks of hepatitis B traced to tattoo parlors in the past, but currently there is a

TABLE 101-1
Tattoo Pigments

Red	Mercuric sulfide (cinnabar); cadmium selenide; ferric hydrate (sienna); sandalwood; brazilwood; aromatic azo compounds including naphthol-AS; quinacridone
Green	Chromium oxide; lead chromate; copper or aluminum phthalocyanine; malachite (contains copper); ferrocyanides and ferricyanides
Purple	Manganese ammonium pyrophosphate; aluminum salts; quinacridone; dioxazine/carbazole
Blue	Cobalt aluminum oxide; chromium oxide; copper phthalocyanine
Yellow	Cadmium sulfide; curcuma (from the ginger plant family); chrome yellow (lead chromate mixed with lead sulfide)
Black	India ink; ferrous oxide; magnetite (Fe_3O_4); carbon; logwood (a heartwood extract from *Haematoxylum campechianum* found in Central America and the West Indies)
Brown	Iron oxides
White	Zinc oxide; titanium dioxide; lead carbonate; barium sulfate

controversy as to how often hepatitis C in the United States is transmitted this way. During the same time that the prevalence of tattoos has increased, the absolute numbers of reported acute hepatitis B and C cases have fallen. The numbers were at a nadir for hepatitis B in 2007 (1.5/100,000), in contrast to a high of 11.5/100,000 in 1985; for hepatitis C, the numbers are stable at 0.3/100,000 since 2003, from a high of 2.4/100,000 in 1992.[30] Most hepatitis C infection is asymptomatic. The sources of approximately 65% of the cases of hepatitis C are unidentified. Cross-sectional data from a number of population groups, for example, veterans,[31] attendees in an orthopedic practice,[32] hospital outpatients,[33] have been inconsistent in identifying tattoos as an independent risk factor for the presence of Hepatitis C. Variables such as getting the procedure in a dedicated studio or in a penitentiary[34,35] may be relevant and the confusion may relate to the fact that, in some people, tattoos are a marker for other unconventional or socially disapproved behaviors.[36,37] The American Association of Blood Banks recommends that blood for donation not be taken from anyone within a year of a tattoo or a body piercing, unless applied by a state-regulated entity with sterile needles and ink that have not been reused.[38] In 2005, the Canadian Blood Services decreased the deferral period from 12 to 6 months. Donor deferral rates were assessed before and after the change. Remote tattooing was associated with increased hepatitis C risk, but this did not hold true for recent tattooing nor piercing. There was no measurable adverse effect on safety and a positive but less than expected effect on blood availability.[39]

Many, but not all, of the pigment-based reactions are in the red areas of tattoos (Fig. 101-5). Now that cinnabar, vermilion or other pigments containing mercuric sulfide, are rarely used, other culprits have been identified. These include cadmium selenide and quinacridone.[40] Reactions may be photosensitive and histology may be pseudolymphomatous, lichenoid,[41] or granulomatous, either (1) foreign body type with numerous giant cells containing pigment or (2) hypersensitivity type with dense aggregates of epithelioid cells, a thin peripheral ring of lymphocytes and few giant cells.[42] Hypersensitivity reactions may be localized or generalized,[43] but standard epicutaneous patch testing is not often helpful, presumably related to the dermal placement or the rapid decomposition of the tattoo antigen.[44] The social implications of tattooing are protean and may alert the onlooker to other risk-taking behaviors.[45]

TABLE 101-2
Known Infectious Complications of Tattooing

Bacterial	Viral
■ Impetigo	■ Warts
■ Ecthyma	■ Molluscum contagiosum
■ Furunculosis	■ Herpes simplex
■ Erysipelas	■ Herpes zoster
■ Tuberculosis cutis	■ Vaccinia
■ Atypical mycobacterial infection	■ Rubella
■ Syphilis	■ Viral hepatitis
■ Leprosy	■ HIV possible but no case reports
■ Endocarditis (rare)	

TATTOO REMOVAL

Most people are proud of their tattoos, but approximately 17% desire removal. In addition, 5% opt for and 8% are considering further tattooing to cover a disliked or faded image. Often these people have obtained their tattoos at a young age and want them

Figure 101-5 Red tattoo reaction.

TABLE 101-3
Tattoo Removal Methods

Excision with primary closure or grafting	For grafting, to avoid donor site scars, techniques may be used that enzymatically separate the excised epidermis from the underlying, excised, pigment-containing dermis and grafting this epidermis to the original tattoo site.[48]
Mechanical dermabrasion	May use a handheld mechanical unit or sterile sandpaper to abrade the skin to the reticular dermis. Rotating (up to thousands of rpm) wire brushes, diamond fraises, or serrated wheels attached to compact electric machines are available.
Salabrasion	First described by Aetius, a Greek physician in 543AD, tap water dipped in salt is rubbed vigorously to abrade the skin overlying the tattoo.
Chemical extraction using a remover paste	The remover paste, made with deionized water, zinc oxide, magnesium oxide, calcium oxide, triethanolamine, isopropanol, and benzoic acid[49] is applied. A superficial microtattoo process is used to puncture the skin over the tattoo and the paste is reapplied. Inflammation ensues and the pigment is extruded.[50]
Cryosurgery	Salt/ice (–20°C) or dimethyl ether/propane (–50°C) mixtures, solid carbon dioxide (–79°C), nitrous oxide (–70°C), or liquid nitrogen (–196°C) may be used.
Application of caustic chemicals	These include phenol, trichloroacetic acid, tannic acid, or oxalic acid with silver nitrate.[51]
Argon and carbon dioxide lasers	These were the early tattoo removal lasers but nowadays mainly used for the removal of tattoo granulomas as healing times are prolonged. Significant thermal damage and hypertrophic scarring often ensue.
Q-switched lasers	These produce nanosecond pulses similar to the Tr[a] of the target pigment. Each pulse has a very high peak power. Surface cooling may be used to prevent epidermal damage.

[a]Tr is the thermal relaxation time, the time it takes for the target chromophore to lose 50% of its incident heat without conducting heat to the surrounding tissue.

removed or changed to enhance self-esteem, or for social, domestic, and family reasons.[46,47] Many tattoo removal methods have been documented (Table 101-3), but most are only partially effective, and leave scarring and pigmentary changes (Fig. 101-6). With the advent of the theory of thermal relaxation, lasers with very short (nanosecond) high-energy pulses have been designed, which are less likely to heat the surrounding tissue leaving scars (Table 101-4). On the horizon, are lasers (titanium:sapphire) with picosecond pulse durations which may be even more effective but potentially more destructive to surrounding tissue. The laser energy photoacoustically explodes the pigment particles. Some of these may be allergenic or carcinogenic. Macrophages engulf the fragments so that they are removed via the draining lymphatics, and some may be extruded through the epidermis. Lightening may take several weeks. In general, proximally placed and old tattoos are easier to remove than distally placed and more recent ones.[20]

Removal of tattoos in dark-skinned individuals is difficult. A long wavelength laser (Q-switched Nd:YAG) may be used together with skin freezing to cause lightening of the epidermis so that the laser light not only penetrates deeply enough but also bypasses the melanin in the epidermis to avoid a permanent pigment change. Red, white, and flesh-tone tattoos, which often contain ferric and/or titanium oxides, may darken with laser treatment related to chemical reduction by the laser beam (See Chapter 239).

Figure 101-6 Scarring related to tattoo removal by acid 50 years previously.

TEMPORARY TATTOOS

Traditional henna tattooing, practiced throughout Africa, the Middle East, and India (mehndi) for thousands of years, very rarely causes hypersensitivity reactions. Henna is made from the leaves of the plant *Lawsonia inermis*, a member of the Loosestrife family, and is a reddish brown color. Recently, the application of temporary tattoos has become popular in the developed world. Some of these are made with "black henna," which contains up to 16% *para*-phenylenediamine (PPD) used as a darkening agent. Concentrations of PPD as high as this commonly cause sensitization and lead to contact allergic dermatitis (see Chapter 13).

TABLE 101-4
Use of Lasers for Tattoo Removal

Q-Switched[a] Laser	Wavelength (nm)	Pulse Duration (ns)	Fluence (J/cm^2)	Used for This Color
Nd:YAG	1,064	10	6–12	Black, blue
Frequency-doubled Nd:YAG	532	10	2–12	Red, orange, purple
Ruby	694	~ 25	8–10	Black, blue, green
Alexandrite	755	50–100	4.5–8	Black, blue, green

[a]A Q-switch is an electro-optical device that concentrates laser energy into a single, intense nanosecond pulse.

BODY PIERCING

EPIDEMIOLOGY AND BACKGROUND

Body piercing has been practiced in almost every society and on every continent, not only for beautification but also for ritual, religious and status reasons. Usually, only the ears, mouth, and nose were pierced, although penile piercing was described in detail in the Kama Sutra (4th century BC). More recently there have been many myths propagated by the promoters of body art in order to stimulate interest in the practice.[52] For instance, it is a myth that a nipple piercing could support the weight of a Roman centurion's toga. In the United States, piercing of the soft earlobes has been common in women since the 1960s, but the body piercing fashion appears to have taken off in the late 1980s.

A US cross-sectional study of 18- to 50-year-olds in 2004 found that 19% of men and 49% of women had soft earlobe piercings and 8% of men and 21% of women had body piercings in other parts of the body. Of 18- to 29-year-olds, 32% had body piercings, not including the soft earlobe.[12] Similarly, a 2005 UK study found that 46% of 16- to 24-year-old females and 13% of males had body piercings other than the soft earlobes.[53] Other studies in teens and young adults have shown body piercing outside the earlobe in 27%–51%.[54,55] Women are more likely to have body piercings than men, and more than 50% of those with body piercings have more than one. Most piercings are done in tattoo or dedicated shops, but soft earlobe piercings are often done in department or specialty stores. Important behavioral and social associations in the young include some cultural normative attributes, for example, being of Hispanic or South Asian heritage, but they also include the participation in a number of risk-taking behaviors such as being a drinker, having used illicit drugs, having spent time in jail, having limited religious affiliation, and having early and multiple sex partners. It may also be a marker for depression.[56,57]

PROCESS

A hollow 12–16 gauge needle is passed through the body part and body jewelry is inserted in the hole. A piercing gun is often used for soft earlobe piercings,

TABLE 101-5
Complications Related to Infection of Piercings

Complication	Reported Organisms
Loss of ear cartilage	*Staphylococcus aureus* *Pseudomonas aeruginosa*
Endocarditis: usually superimposed on a known underlying cardiac abnormality, but occasional reports without prior cardiac abnormality	Skin piercing: *Staphylococcus aureus* Group A β-hemolytic *Streptococcus* *Staphylococcus epidermidis* Mucosal piercing: *Streptococcus viridans* *Neisseria mucosa* *Haemophilus aphrophilus* *Haemophilus parainfluenzae*
Septic arthritis	Group A β-hemolytic *Streptococcus*
Osteomyelitis	*Staphylococcus aureus*
Toxic shock syndrome	*Staphylococcus aureus*
Lymphadenitis	*Lactobacillus*
Cephalic tetanus	*Clostridium tetani*
Acute glomerulonephritis (may lead to acute renal failure)	Group A β-hemolytic *Streptococcus*
Ludwig's angina	Oral piercing: *Streptococcus viridans* *Neisseria mucosa* *Haemophilus aphrophilus* *Haemophilus parainfluenzae*
Fournier gangrene	Male genital piercing: Group A *Streptococcus* and mixed Gram-negative bacilli and anaerobic organisms
Brain abscess	Tongue piercing resulting in a mixed infection: *Streptococcus viridans* *Peptostreptococcus micros* *Actinomyces* species *Eikenella corrodens*
Lupus vulgaris	*Mycobacterium tuberculosis* inoculation at time of nose piercing (India)

but these are difficult to sterilize, can lead to crush injuries, and, if used in a cartilaginous area, to loosening of the perichondrium. Swelling occurs immediately so that the jewelry inserted has to be long and fine enough to allow for this. It should be made of titanium, niobium, ≥14-karat yellow gold, or stainless steel in order to avoid the induction of nickel and/or cobalt delayed type hypersensitivity. Postoperative healing times, from 2 weeks for clitoris to 9 months for navel piercings, vary with the site. There are two types of bead closures. The captive bead ring is held closed by pressure. The bead screw is similar to any other screw mechanism and is often part of hoops, barbells, and circular barbells.

COMPLICATIONS

These vary with the site on the body of the piercing as well as with the place the procedure is done, for example, at home or in a commercial studio. Bleeding may occur during or immediately following the procedure, and bacterial, fungal, or viral diseases may be transmitted, especially if nonsterile instruments are used[58] (Table 101-5). However, most infection comes from the subject's own flora often related to poor hygienic practices during the healing period leading to localized infection (erythema, edema, purulent drainage). Rates as high as 35% after ear cartilage piercings have been reported, sometimes leading to loss of ear cartilage and, rarely, endocarditis (Fig. 101-7).[59,60] Other high-risk areas include the navel, with its propensity for movement, and any intraoral site.[61] Jewelry may be left in place to facilitate drainage and prevent sac formation. In addition, local hygiene should include compresses, a topical antibiotic, and, if necessary, an oral antibiotic. If pseudomonas is suspected a fluoroquinolone, which will also cover most species of *Staphylococcus* and *Streptococcus*, including many β-lactam-resistant strains, is a good choice. Importantly, viral hepatitis may be transmitted through the piercing needle. This includes hepatitis C and less often hepatitis B and D, although this uncommonly occurs in modern America,[62] where disposable or sterilized piercing equipment is used.[63] Transmission of HIV is another risk that has not been proven to occur.

Other complications are protean (Table 101-6). In view of the high and increasing prevalence of nickel

Figure 101-7 Early upper ear cartilage infection following the insertion of metal jewelry.

TABLE 101-6
Noninfectious Complications Related to Piercings

Bleeding
- Usually at time of or immediately after procedure. This may lead to significant blood loss.

Avulsion Injuries
- Earlobe tear, urethral rupture, splitting of urinary stream, rejection of jewelry near the eyebrow, navel, or nipple.

Scarring
- May lead to phimosis or strictures.
- Keloid formation.
- Cyst related to tract closure.

Neurological Damage
- Loss of taste, increased salivary flow, clitoral numbness.

Anesthetic Risks
- Interference with free access to the airway[a], postoperative laryngospasm, pressure on area during surgery, electrosurgical burns, problems with catheterization.

Intraoral
- Aspiration of jewelry ball.
- Broken teeth and gingival recession.
- Speech impairment.
- Loss of taste.
- Increased salivary flow.
- Embedding of jewelry in tongue.

Nipples
- Galactorrhea related to hyperprolactinemia due to nipple stimulation.

Penis
- Priapism related to entrapment of penis in a scrotal-piercing hole.
- Paraphimosis related to inability to replace the prepuce over jewelry in the glans.
- Glanular hypospadias.
- Split urinary stream.

Jewelry-induced Contact Allergy
- Nickel and cobalt are the most likely allergens (Type IV delayed hypersensitivity)
  - In the US
    - 12% jewelry allergy in those without piercings
    - 31% in those with piercings: 48% in those with three piercings
- Gold and palladium rarely cause delayed reactions which may be of granulomatous (sarcoidal) type.[64]

[a]To avoid problems, remove tongue, lip, or cheek jewelry before anesthesia and insert a nonreactive thread to preserve tract patency.

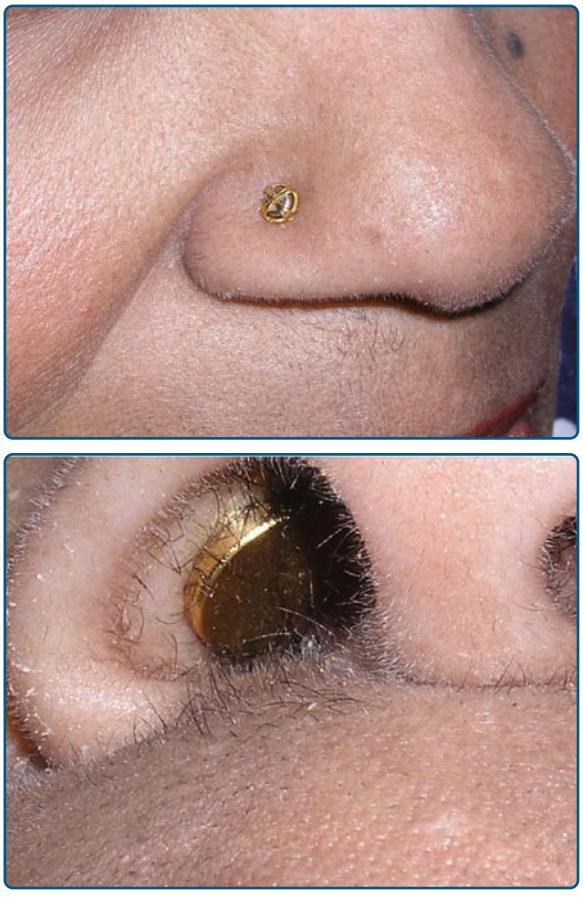

Figure 101-8 Magnetic jewelry avoids a piercing but still can be inhaled accidentally or become embedded in the tissue.

allergy, European nations implemented legislation to limit the release of nickel from objects intended to be in prolonged contact with the skin. This legislation was first passed in Denmark in 1976 and went into full effect in 1992. The European Union (EU) adopted the EU Nickel Directive in 1994. It went into full effect in all EU nations in 2001. Nickel content of piercing post assemblies was initially set at ≤0.05%. In 2004, this was changed to ≤0.2 μg/cm^2/week of nickel release, and it appears that the incidence of new sensitization is falling.[65]

Piercing tracts are not necessarily permanent as they may close if the jewelry is removed. This is common with tongue piercings as the epithelium in the depths of the tract is thin and possibly missing.[66] Replacement of tongue jewelry prior to anesthesia can be done with a fine inert flexible catheter.

MAGNETIC JEWELRY

This is occasionally used to avoid piercing (Fig. 101-8). Aspiration of the magnetic back of the jewelry is a possible complication.

Neurocutaneous and Psychocutaneous Aspects of Skin Disease

PART 5

Neurocutaneous and Psychocutaneous Skin Disease

Chapter 102 :: Neurobiology of the Skin

:: Martin Steinhoff & Thomas A. Luger

NEUROBIOLOGY OF SKIN AT A GLANCE

- In an interactive network, cutaneous nerves communicate with various skin cells, the endocrine system, and the immune system.
- Neurocutaneous interactions influence a variety of physiological and pathophysiological functions such as thermoregulation, cell growth, inflammation, host defense, apoptosis, pruritus, pain, metastasis, and wound healing.
- Primary afferent as well as autonomic nerves release neuromediators and activate specific receptors on many target skin cells.
- Cutaneous cells express a variety of specific receptors tightly controlled by upregulatory or downregulatory signals, peptidases, or neighboring receptors.
- Many mediators (peptides, proteases, cytokines, kinins, prostanoids, opioids, cannabinoids, neurotrophins, etc.) are critically involved in physiological and pathophysiological conditions in the skin by activating neuronal receptors.
- The spinal cord and CNS modulate transmitted signals from the peripheral nerves with respect to the perception of pain or itch, and—vice versa—modulate skin function.
- New pathways are being defined for the treatment of various skin diseases in which the neuro-immuno-endocrine axis is implicated.

THE NERVOUS SYSTEM AND SKIN

This chapter discusses the structural basis and the specific molecules involved in the interactions between the skin and different portions of the nervous system.

The peripheral nervous system provides essential information to the rest of body during injury of "danger signals" such as parasites, UV radiation, toxins, allergens, pH changes, or "stress". This information can be modulated at various levels including the brain, spinal cord, dorsal root ganglia (DRG), peripheral sensory nerve endings, autonomic nerves and neurons, etc; and through specialized structures like Pacini bodies or specialized cells such as Merkel cells. This closely woven group of structures and their molecules are ultimately and critically involved in normal

cutaneous biology and skin diseases (eTable 102-0.1 in online edition). In conjunction with the spinal cord and the brain, peripheral sensory nerves have afferent functions; their endings detect physical stimuli such as touch, heat or cold, and chemical mediators into the skin from nerve endings and also have efferent functions in the skin. (eFig. 102-0.1 in online edition). These sensory nerves critically contribute to skin development before birth and to protection and homeostasis after birth. In addition, autonomic nerves modulate both physiological and pathophysiological functions as part of the stress response to external or endogenous stimuli, and form a vital link communicating with the vascular, endocrine, and immune systems (eTable 102-0.1 in online edition).

PERIPHERAL NERVES

Sensory as well as autonomic (in the skin predominantly cholinergic sympathetic) nerves influence a variety of physiologic and pathophysiologic functions of the skin such as embryogenesis, vasoconstriction, vasodilation, body temperature, erector pili movement, regulation of the function of the pilosebaceous unit, sensing physical, chemical and biological stimuli on the skin surface; modulating epidermal barrier function, cell secretion, cell growth and differentiation, cell nutrition and apoptosis, nerve growth, inflammation, immune defense, and wound healing, respectively (eTable 102-0.1 in online edition).

In unstimulated cutaneous nerves, neuromediators are stored in cytoplasmic vesicles. On direct or indirect activation through physical, mechanical, electrical, chemical or biologic or endogenous inflammatory processes lipids, cytokines or neurotrophins (NT), a significant increase of regulatory neuropeptides, or oxygen products can be detected at the site of inflammation within seconds to hours. Thus, mediators derived from sensory or autonomic nerves may play an important regulatory role in the skin under many physiologic and pathophysiologic conditions. However, in addition to neuroimmunomodulation in the periphery, a subtle and complex communication network also exists between the spinal cord, the central nervous system (CNS), and the immunoendocrine system that also modulates skin function. In addition, neuropeptides and NTs can be upregulated and released by nonneuronal cells under certain circumstances that may amplify or counterregulate the neurogenic stimulus. While certain neuropeptides [e.g., substance P (SP)] exert clear-cut proinflammatory effects during inflammation, others such as calcitonin-gene-related protein (CGRP) may be acutely released to induce vasodilatation (proinflammatory), but in addition counterregulate inflammatory responses like antigen presentation and immunosuppression in order to reestablish skin homeostasis at the later stage of inflammation.

The skin expresses a variety of receptors for these neuromediators, such as G protein-coupled receptors, ion channels and certain cytokine receptors (see Tables 102-1 and 102-2). This neuromediator–receptor interaction is controlled by endopeptidases [neutral endopeptidase (NEP), angiotensin-converting enzyme (ACE), endothelin-converting enzyme (ECE)], which terminate neuropeptide-induced inflammatory or immune responses.[1–3] A close multidirectional interaction between neuromediators, high-affinity receptors, and regulatory peptidases is critical to maintain or reestablish tissue integrity and regulating pathophysiologic conditions in the skin. Ion channels are promiscuous and can be activated by physical stimuli (heat, cold), chemicals (e.g., capsaicin, menthol, protons) as well as lipid metabolites like prostaglandins. Activation of ion channels by cannabinoids (CB) has been also recently described.

From this background, it is clear that a better cellular and molecular understanding of the complex skin–nervous system interactions opens an avenue for future therapeutic approaches to skin disease.

Taken as a whole, present information clearly indicates a crucial role for the neuronal skin network in influencing a variety of physiologic and pathophysiologic functions such as host defense, inflammation, pruritus, pain, burning, wound healing, and probably cancer (e.g., by modulating angiogenesis).

BRAIN–SKIN AXIS

The CNS proper is connected to skin either directly via efferent nerves or CNS-derived mediators, or indirectly via the adrenal glands or immune cells.[1] Cutaneous nerves also respond to internal stimuli from the circulation (e.g., pH changes, osmotic changes, bradykinin, cytokines) or the skin itself and to emotions (internal trigger factors).[2] Under normal circumstances, the sensory and the autonomic nervous systems modulate important biologic functions such as body temperature, blood flow, and cell growth. Mechanically induced nerve impulses transmit information such as pressure to the CNS. Chemical- or heat-responsive afferent nerve fibers are involved in recognizing dangerous signals. Thus, normally the innervated skin is a crucial barrier in protecting the body from danger from the external environment. This is also supported by the finding that not only the dermis but also the epidermis is highly innervated.[4] Interactions between the central and peripheral nervous system have been implicated to play a role in thermoregulation,[1,5] the pathophysiology of various skin diseases such as psoriasis,[6–8] atopic dermatitis,[9] acne,[10] wound healing,[11] as well as hair loss and regrowth.[12–14]

SPINAL CORD

Our knowledge about the involvement of the spinal cord in regulating specific chronic pain sensations in human skin, its role in modulating pruritus, or modulating inflammatory stimuli transduced from the periphery to the brain is very limited. We know that μ-opioids such as morphine can induce pruritus while being analgesic when injected intrathecally. In contrast, κ-opioids exert antipruritic effects, probably by the inhibition of the μ-opioid receptor. These results strongly indicate a role of opioids in the regulation of

TABLE 102-1
Role of Nerves in Inflammation, Immunomodulation, Pruritus and Pain

Pruritogenic Stimuli (In Alphabetic Order)	Receptors	Sources, Receptors by which Expressed	Comments
Acetylcholine (ACh)	Nicotinergic (nAChR) and muscarinergic (mAChR) ACh receptors	Autonomic cholinergic nerves, keratinocytes, lymphocytes, melanocytes, dermal fibroblasts, endothelial cells	Mediates itch in atopic dermatitis; mAChR3 is probably involved in itch.
Calcitonin gene-related peptide (CGRP)	CGRP receptors	Sensory nerve fibers	Expressed on central terminals; sensitizes receptive endings. Associated with increased pain transmission, prolongation of itch latency after substance P injection (inhibitory effect on itching). Involved in itchy skin diseases. Regulates antigen presentation on Langerhans cells; involved in drug-induced adverse reactions, atopic dermatitis and contact dermatitis. Downregulates NF-κB
Cannabinoids	CB1, CB2 receptors	Nerves, keratinocytes, immune cells	Involved in antinociception (peripheral and central), anti-fibrotic; anti-inflammatory (contact dermatitis); regulates cell growth, differentiation, apoptosis. Involved in thermoregulation.
Corticotropin-releasing hormone (CRH) and proopiomelanocortin (POMC)	CRH receptors (CRHR1, CRH-R2)	CRH-R1: keratinocytes, mast cells CRH-R2: bone marrow mast cells	Induces release of histamine, cytokines, TNF-α, VEGF from mast cells. CRH-like immunoreactivity seen on sensory nerves (rat).
Cytokines	Cytokine receptors (e.g., IL-2, IL-31)	Leukocytes, keratinocytes, endothelial cells, nerves	T cells release IL-31 during inflammation and activate monocytes and keratinocytes via the IL-31 receptor (IL-31R). IL-31R is upregulated in atopic dermatitis and prurigo.
Endocannabinoids	Cannabinoid receptors (CB1, CB2)	Nerves, immune cells, keratinocytes, hair follicles	Antipruritic in the periphery.
Endothelins (ETs)	Endothelin receptors (ET_A, ET_B)	Endothelium, mast cells	Induces burning itch. Degraded by chymase via ET_A-receptor activation.
TRP channels and agonists (heat, cold, acidosis, osmolar changes, capsaicin, menthol, camphor, eicosanoids, bradykinin, prostaglandins, various neurotrophins; aldehydes, formalin, nicotine, etc.)	Activation of transient receptor potential vanilloid 1 (TRPV1) sensitization of TRPV1 via activation of specific receptors (see in this table)	TRPV1 is expressed on sensory neurons, mast cells, epidermal and hair follicle keratinocytes, Langerhans cells, smooth muscle, and sebocytes TRPV2 expressed by sensory nerves and murine macrophages TRPV3 and TRPV4: expressed by sensory nerves and keratinocytes. TRPV6: keratinocytes. TRPA1: expressed by sensory nerves and keratinocytes	Short-term TRPV1 activation: induces pain and itch, depletes neuropeptides from sensory neurons. Long-term antipruritic effect of TRPV1 agonists (e.g., capsaicin): Suspend interplay between sensory neurons and mast cells. Affects epidermal and hair follicle proliferation, differentiation, apoptosis, and cytokine release. Increased expression in epidermal keratinocytes of prurigo nodularis patients. TRPV2: role in antigen presentation in mice. TRPV3 and TRPV4: role in sensory and keratinocyte function. TRPA1: role in pain, hypernociception, vasoregulation, barrier function. TRPV6: keratinocyte differentiation
Gastrin-releasing peptide	Activates GRPR	GRP: sensory nerves. GRPR: superficial dorsal horn of spinal cord	GRP mediates itch but not pain (histamine dependent and independent).

(continued)

TABLE 102-1
Role of Nerves in Inflammation, Immunomodulation, Pruritus and Pain (Continued)

Pruritogenic Stimuli (In Alphabetic Order)	Receptors	Sources, Receptors by which Expressed	Comments
Histamine	Histamine receptors (H_1R to H_4R)	Sensory fibers	In humans, histamine induces itch by stimulating specific sensory fibers, whereas H_1 (and to a lesser extent H_2) antagonists reduce itch in numerous clinical trials. In mice, H_3 antagonists induce scratching behavior, whereas H_1 and H_4 antagonists effectively suppress pruritus.
Proteases, kallikreins, tryptase, trypsins, cathepsins, (MMP1)	Partly proteinase-activated receptors (PARs), tryptic enzymes	Keratinocytes, endothelial cells, mast cells, platelets	Massive itch behavior in mice overexpressing epidermal kallikrein-7. Potential role of other kallikreins. Chymase degrades pruritic and antipruritic peptides. Tryptase, trypsin and cathepsin S induce inflammation and itch by a neurogenic mechanism via PAR-2. Microbial proteases may induce itch and inflammation via PAR-2. PAR1 and PAR4 involved in pain.
Kinins	Bradykinin receptors (B1R, B2R)	Endothelial cells, immunocytes	Bradykinin induces pain rather than pruritus. B2R antagonists reduce itch.
Leukotriene B_4	Leukotriene receptors	Sensory nerves fibers, keratinocytes	Leukotriene B_4 induces itch and is also involved in the substance P- and nociceptin-mediated induction of itch.
Neurokinin A (NKA) and substance P (SP)	Tachykinin (neurokinin) receptors (NKRs)	Sensory nerve fibers	NKA: upregulates keratinocyte nerve growth factor expression. SP: at low (physiologically relevant) concentrations, primes mast cells. Mediates release of TNF-α, histamine, leukotriene B_4, and prostaglandins from mast cells (agents involved in pruritus and burning).
Nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), neurotrophins (NT-3, NT-4)	Specific receptors TrkA: NGF TrkB: NT-4, BDNF TrkC: NT-3	Keratinocytes, mast cells, fibroblasts, eosinophils	NGF levels enhanced in atopic dermatitis. Induces tryptase release from mast cells. Inducible by histamine. TrkA: enhanced in keratinocytes during inflammation. NT-4: enhanced in atopic dermatitis and induces sprouting of sensory nerves. BDNF: increases eosinophil chemotaxis levels in atopic dermatitis and inhibits apoptosis. Neurotrophins sensitize receptive nerve endings and upregulate neuronal neuropeptides and TRPV1.
Opioids	μ, κ, δ opioid receptors (partly receptor-independent cell activation)	Nerves, keratinocytes	Antipruritic effect of μ-opioid antagonists (central effect) and κ-opioid agonists (spinal cord level). Opioid agonists do not provoke itch on injection or intradermal application. μ-Opioid receptor upregulated in atopic dermatitis.
Pituitary adenylate cyclase-activating polypeptide (PACAP) and vasoactive intestinal peptide (VIP)	VPAC receptors	Autonomic and sensory nerve fibers, lymphocytes, dermal endothelial cells, Merkel cells	PACAP: involved in flush, vasodilation, pain, neurodegeneration. Induces release of histamine from mast cells. VIP: Histamine release from mast cells, allodynia (no allodynia in atopic dermatitis) intensifies ACh-induced itch in atopic dermatitis patients (together with ACh).
Prostaglandins	Prostanoid (P) receptors	Sensory nerve fibers, keratinocytes	Prostaglandin E_2 induces itch sensitization in humans but not in mice. Prostaglandin D_2 reduces immunoglobulin E-mediated scratching in mice. Thromboxane A2 induces itch in mice.

ATP = adenosine triphosphate; IL = interleukin; TNF-α = tumor necrosis factor-α; VEGF = vascular endothelial growth factor.

TABLE 102-2
Role of Nerves in Inflammation

Neuromediator	Receptor	Source	Target Cells/Function
Acetylcholine	Nicotinergic and muscarinergic acetylcholine receptors	Autonomic cholinergic nerves, keratinocytes, lymphocytes, melanocytes	Innervation of sweat glands and arteriovenous anastomoses; keratinocyte and lymphocyte differentiation, proliferation, adhesion, migration. α_7-Nicotinergic receptor modulates keratinocyte function, modulates skin microcirculation; involved in atopic dermatitis.
Adenosine, ATP	Purinergic receptors	Nerves, keratinocytes, endothelial cells, immune cells	Involved in pain and hypernociception; neuronal cell death; involved in vasoregulation and immune response (cytokine release, cell adhesion molecules).
Catecholamine, noradrenaline	Adrenergic receptors	Autonomic adrenergic nerves, keratinocytes, melanocytes	Innervation of blood vessels, erector pili muscles; pain transmission; regulation of activity in natural killer cells and monocytes; induction of apoptosis in lymphocytes. Regulate dendritic cell function. β-Adrenergic-induced inhibition of keratinocyte migration.
CGRP			Involved in sweating.
Galanin and galanin-like peptides	Galanin receptors (GPCRs)	Sensory nerves	Inhibit inflammatory edema by reduction of microvascular blood flow via Gal3R.
Substance P	Tachykinin (neurokinin) receptor	Sensory nerve fibers, keratinocytes (inducible)	Mediation of skin edema, pruritus; upregulation of cell adhesion molecule expression on keratinocytes and endothelial cells; induction of release of IL-8, TNF-α, histamine, tryptase, leukotriene B_4, prostaglandin D_2; regulation of sebaceous glands; involved in inflammatory pain, contact dermatitis, immunomodulation, tumorigenesis and metastasis. Released by proteinase-activated receptor 2 (PAR-2) agonists.
Neurokinin A	Tachykinin (neurokinin) receptor	Sensory nerve fibers	Upregulation of keratinocyte nerve growth factor expression.
Vasoactive intestinal peptide	VPAC receptors	Sensory nerve fibers, Merkel cells	Sweat secretion, vasodilation; proliferation, migration of keratinocytes; histamine release from mast cells. Downregulation of VPAC2 receptor in mast cells in atopic dermatitis.
Pituitary adenylate cyclase-activating polypeptide	VPAC receptors	Autonomic and sensory nerve fibers, lymphocytes, dermal endothelial cells	Vasodilatation, immunomodulation; effect on T cells and macrophages; modulation of mast cell function; inhibition of antigen-induced apoptosis of mature T lymphocytes; downregulation of proinflammatory cytokines and chemokines in T cells; upregulation of cytokines and cell adhesion molecules in dermal microvascular endothelial cells; nociception.
Calcitonin gene-related peptide (CGRP)	CGRP receptors	Sensory nerve fibers	Keratinocyte and endothelial cell proliferation; stimulation of cytokine production. Increased CGRP nerves in atopic dermatitis and nummular eczema; released by PAR-2 stimulation.
Pro-opiomelanocortin (POMC)	Melanocortin receptors	Melanocytes, keratinocytes, endothelial cells, Langerhans cells, mast cells, fibroblasts, monocytes, macrophages	Antagonism of effects of proinflammatory cytokines (IL-17α, IL-1β, IL-6, TNF-α, endotoxins); upregulation of IL-10; induction of release of histamine from mast cells; inhibition of nuclear factor κ B. Thioredoxin regulates *POMC* genes. MSH-induced exocytosis from melanosomes. Melanocortin 1 receptor expressed on human keratinocytes. Antioxidative and cytoprotective.

IL = interleukin; MSH = melanocyte-stimulating hormone; TNF-α = tumor necrosis factor-α.

pain and pruritus on the spinal cord level. Moreover, gastrin-releasing peptide (bombesin) released to the central nerve endings in the spinal cord activates the gastrin-releasing peptide receptor (GRPR) on postsynaptic spinal neurons, thereby regulating selectively itch transduction but not pain.[15,16] Together, these data implicate the spinal cord as an important regulator of skin–nervous system interactions as observed during inflammation, pruritic diseases, and pain, and may be a target for future therapies.

ANATOMY AND PHYSIOLOGY OF THE SKIN NERVOUS SYSTEM

SENSORY NERVES

Most nerve fibers are found in the middermis and the papillary dermis. Region-specific differences can be observed with respect to the mucocutaneous border, glabrous skin, and hairy skin.[17] In the epidermis, sensory nerves are linked to keratinocytes, melanocytes, Langerhans cells (LC), and Merkel cells. Cutaneous nerve fibers are principally sensory, with an additional complement of autonomic nerve fibers.[18,19] In contrast to sensory nerves, autonomic nerves never innervate the epidermis in mammals. Sensory nerves innervate the epidermis and dermis as well as the subcutaneous fatty tissue[20–22] (see eFig. 102-0.1 in online edition).

Sensory nerves are categorized into two groups: (1) the epidermal and (2) the dermal skin nerve organs. The epidermal skin nerve organs consist of free nerve endings or nerve organs (e.g., Merkel cells). In the dermis, there are free sensory nerve endings, the hair nervous network (Pinkus discs), and the encapsulated endings [Ruffini, Meissner, Krause, and Vater–Pacini (vibration) corpuscles, and mucocutaneous end organ]. These can be subdivided into four groups: (1) A-α fibers (12–22 nm) are highly myelinated, show a fast conduction velocity (70–120 m/second), and are associated with muscular spindles and tendon organs. (2) A-β fibers are moderately myelinated (6–12 µm) and innervate touch receptors. (3) A-δ fibers have a thin myelin sheath (1–5 µm), show an intermediate conduction velocity (4–30 m/second), and are generally polymodal. (4) The slow-conducting C fibers (0.5–2.0 m/second) are unmyelinated and thin (0.2–1.5 µm) (nociceptors). A-β and A-δ fibers are mostly mechanically sensitive afferents (type I) localized on hairy and glabrous skin and show a long latency to heat. A subpopulation of A-δ fibers on hairy skin are mechanically insensitive (type II). A-δ fibers constitute approximately 80% of primary sensory nerves sprouting from DRG, whereas C fibers make up approximately 20% of the primary afferents.[23,24]

C-fibers are either polymodal nociceptors, which can respond to chemical (c^+), temperature changes (h^+) or mechanical (m^+) stimuli, or more specialized, which only respond to a combination ($C\text{-}c^+h^+m^-$) or a single stimulus ($C\text{-}c^-h^-m^+$). Among human peripheral nerves, 45% of the cutaneous afferent nerves belong to a subtype of sensory nerves that are both mechano- and heat-responsive C-fibers ($C\text{-}c^-m^+h^+$).[25] However, 13% of these nerves are only mechanosensitive ($C\text{-}m^+$), 6% only heat sensitive ($C\text{-}h^+$), 24% are neither heat nor mechanoresponsive ($C\text{-}m^-h^-$), and approximately 12% are of sympathetic (cholinergic) origin. Fifty-eight percent of $C\text{-}m^+h^+$ respond to mustard oil, whereas 30% of $C\text{-}m^+$ or ($C\text{-}m^-h^-$) do so indicating the existence of chemosensitive fibers among the other subtypes.[25]

Sensory nerves percept cutaneous stimuli such as warmth, cold, or touch. The nerves for warmth are predominantly unmyelinated C-fibers, a subpopulation of A-δ fibers respond to gentle cooling, whereas selective C-fibers become activated during noxious cold. Many subtypes of cells respond to touch and play an important role in mechanically induced pain. Thus, our body system has designed less selective as well as highly specialized nociceptors in order to guarantee body integrity and survival.[26]

A specific receptor distribution on these different sensory nerve subtypes appears to be important for the various functions (temperature, chemical, mechanical) and the sensations, which may derive thereof (prickling, stinging, burning, pain, itch). For example, mechanoreceptors exclusively express the T-type calcium channel Ca(v)3.2 in the dorsal root ganglion of D-hair receptors. The sodium channels Nav1.8 (SNS/PN3) and Nav1.9 (SNS/SNS2) are expressed by both peptidergic as well as nonpeptidergic $IB4^+$ (isolectin B4 from Griffonia simplicifolia) neurons and have been shown to be critically involved in certain subtypes of pain.[27] Only certain small-diameter primary afferents express the transient receptor potential vanilloid-1 (TRPV1) receptor which is critically involved in heat sensation.[28] Only nonpeptidergic (poor peptidergic) sensory fibers express the purinergic P2×3 receptor. Exogenous factors like trauma, UV-radiation, temperature changes, microbial agents, toxins, or allergens, as well as endogenous inflammatory triggers such as pH changes or stress hormone responses are able to stimulate the activation and/or sensitization of certain sensory nerves. The cellular events that transmit a stimulus (e.g., UV radiation) to a certain response (burning pain) via activation of a certain pathway (activation of pain fibers but not itch fibers and vice versa) are only poorly understood.[29,30]

AUTONOMIC NERVES

Compared to sensory nerves, autonomic nerves represent only a minority of cutaneous nerve fibers. In human skin, autonomic nerve fibers are derived almost completely from sympathetic (cholinergic) and rarely from parasympathetic (also cholinergic) neurons.[31] The distribution of autonomic nerves is restricted to the dermis, where they innervate blood vessels, arteriovenous anastomoses, lymphatic vessels, erector pili muscles, eccrine glands, apocrine glands, and hair follicles.[32]

Postganglionic autonomic nerves in the skin predominantly generate acetylcholine, although observations have revealed an additional role for neuropeptides. For example, neuropeptide Y (NPY)

and atrial natriuretic peptide[33] are expressed solely by autonomic nerve fibers.[34]

The cutaneous autonomic nervous system adjusts sweat gland function, thereby regulating body temperature, and modulates water and electrolyte balance in various organs. Under pathophysiologic conditions, autonomic nerves are involved in hyperhidrosis or hypohidrosis, congenital sensory neuropathy type IV, progressive segmental hypohidrosis, diabetic neuropathy, syringomyelia, lepra, and dysfunction after sympathectomy.[35–38]

Autonomic nerves exert their effects mainly by releasing classical neurotransmitters (noradrenaline, acetylcholine) or—to a lesser extent—certain neuropeptides like vasoactive intestinal peptide (VIP). In contrast, primary afferent (sensory) nerves release different classes of molecules such as neuropeptides, prostanoids, or nitric oxide (NO).[1]

Autonomic nerve fibers are crucially involved in the regulation of vascular effects in the skin. Sympathetic nerve fibers release noradrenalin and/or NPY to innervate arterioles, arteriovenous anastomoses, and venous sinusoids, which results in vasoconstriction, whereas parasympathetic nerves mediate vasodilation through activation of venous sinusoids by the release of acetylcholine and vasoactive intestinal peptide (VIP)/peptide histidine methionine[39–42] (eTable 102-0.1 and Table 102-1 in online edition). Of note, C-fiber nociceptors can develop responsiveness to adrenergic neurotransmitters by upregulating the corresponding receptors during trauma or inflammation. Thus, the sensory and the autonomic nervous systems communicate and interact in disease on the molecular level.

Small arteries, arterioles, and the arteriovenous anastomoses are richly supplied with noradrenergic nerves.[43] Previous studies suggested that this system is cholinergic and involves a cotransmitter, possibly VIP.[44] Cholinergic sympathetic nerves are also known to stimulate eccrine sweat glands via muscarinic receptors,[31] whereas higher concentrations of acetylcholine induce an axon-reflex flare mediated via nicotinic receptors. In the vasoconstrictor system, the transmitter appears to be norepinephrine along with one or more cotransmitters. The best-characterized sympathetic cotransmitters that participate in the regulation of blood flow include adenosine triphosphate[45] and NPY.[46]

Interestingly, even without intact sensory or autonomic function the skin reveals a nonneurogenic vasodilator and nonneurogenic vasoconstriction response. The mechanisms for the nonneurogenic vasodilator and vasoconstrictor components of the response to direct cooling are poorly understood but may involve several pathways including cholinergic stimulation, NO and neuropeptides.[5,47]

BIOCHEMISTRY AND CELL BIOLOGY OF THE CUTANEOUS NERVOUS SYSTEM

As outlined above, many subtypes of nerve fibers exist to cover the multiple functions of the skin nervous system to maintain or reestablish body integrity. This chapter focuses on the role of neuropeptides, TRP channels, and cytokines in the skin (Table 102-1).

SKIN NEUROPEPTIDES AND NEUROPEPTIDE RECEPTORS

Classically, neuropeptides range from as few as 4 to more than 40 amino acids. Because they are released by nerve endings and modulate various biologic functions, they were originally defined as neuropeptides. Later, these molecules were also found to be generated by nonneuronal cells (e.g., epithelial cells and immune cells). Therefore, the designation *regulatory peptide* may be more appropriate.[48] These peptides mainly activate members of the G protein-coupled receptor superfamily with seven transmembrane domains. To date more than 20 neuropeptides, including SP, neurokinin A (NKA), neurotensin, CGRP, VIP, pituitary adenylate cyclase-activating polypeptide (PACAP), peptide histidine-isoleucinamide, NPY, somatostatin (SST), dynorphin, β-endorphin, enkephalin, galanin, secretoneurin, melanocyte-stimulating hormone (MSH), thyroid-stimulating hormone (TSH), or corticotropin-releasing hormone (CRH), have been detected in the skin.[1,2,49] Table 102-1 lists the neuropeptides, ion channels, and other molecules like NO involved in pruritus, pain, and inflammation. eFigure 102-0.1 in online edition and Fig. 102-1 depict the basic concepts and knowledge concerning these neuropeptides.

Various neuropeptides are produced and released by a subpopulation of unmyelinated afferent neurons (C fibers) known as *C-polymodal nociceptors*. In addition, it has been shown that cutaneous cells themselves, such as keratinocytes, microvascular endothelial cells, Merkel cells, fibroblasts, and leukocytes, are capable of releasing regulatory peptides under physiologic or pathophysiologic circumstances.

In the skin, nerves are necessarily closely linked to the vascular system. Dermal blood vessels are tightly associated with sensory and autonomic nerve fibers, they also synthesize neuropeptides and they express receptors for neuropeptides. Arterial sections of arteriovenous anastomoses, precapillary sphincters of metarterioles, arteries, and capillaries appear to be the most intensely innervated regions. Large increases in skin blood flow provide the necessary augmentation of convective heat loss during environmental heat exposure and/or exercise, and the reflex cutaneous vasoconstriction is key to preventing excessive heat dissipation during cold exposure. Sensory nerves are important for vasodilation and neuropeptides from sympathetic neurons such as NPY mediate vasoconstriction, which supports an important role for neuropeptides in thermoregulation, blood flow during inflammation or tumorigenesis, as well as activation of endothelial cells and smooth muscle cells. Both endothelial cells and smooth muscle cells respond to neuronal modulation in inflammatory diseases such as atopic dermatitis and rosacea and during host defense, neovascularization, and wound healing. Sensory as well as autonomic nerves modulate the function of sweat glands, sebaceous glands, apocrine glands, and

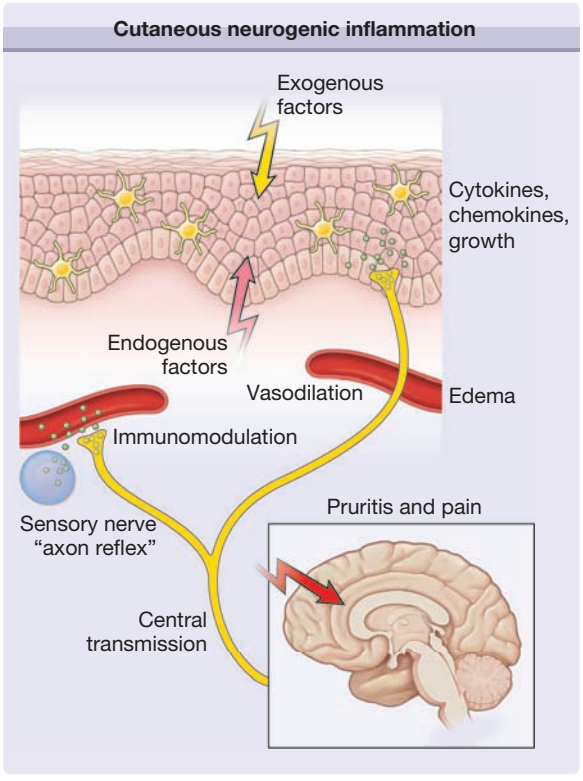

Figure 102-1 Cutaneous neurogenic inflammation. Exogenous trigger factors (heat, scratching, irritants, allergens, ultraviolet light, microbiologic agents) or endogenous trigger factors (pH changes, cytokines, kinins, histamine, proteases, neurotransmitters, hormones, stress) may directly or indirectly stimulate nerve endings from primary afferent neurons. Signals are transmitted to the central nervous system and thereby affect regions involved in pruritus, pain, somatosensory reactions (scratching), and probably emotional responses. In addition, peripheral nerve endings stimulate neighboring afferent nerve fibers in the dermis and epidermis in a process known as *axon reflex*. Stimulated release of neuropeptides results in vascular responses (triple response of Lewis, erythema by vasodilation, and edema by plasma extravasation), modulation of immunocyte function (e.g., mediator release from mast cells), and regulation of mediator release (cytokines, chemokines, growth factors) from keratinocytes and Langerhans cells.

the pilosebaceous unit. In the following, we emphasize the biological role of certain neuromediators and neurohormones in more detail.

CYTOKINES AND CHEMOKINES FROM A NEURONAL PERSPECTIVE

Cytokines are capable of inducing pruritus, and, conversely, cytokine inhibitors have been demonstrated to reduce neurogenic inflammation, pain, and pruritus. Thus, cytokines and chemokines may communicate with sensory nerves via high-affinity receptors[269–274] (see eFig. 102-0.1 in online edition and Table 102-1).

"Neurophilic" cytokines include IL-1, IL-6, IL-8, and IL-31.[48,52] Of note, transgenic mice overexpressing IL-31 released by T cells and macrophages developed a chronic inflammatory skin disease characterized by a T-cell infiltrate and pruritus, similar to atopic dermatitis in humans. IL-31 activates the IL-31 receptor (IL-31R), a heterodimeric receptor composed of the IL-31R A subunit and the oncostatin M receptor subunit. Whether IL-31 exerts its pruritic effects via direct activation of IL-31R on sensory nerves or indirectly (e.g., via keratinocytes) is currently unknown. The finding that keratinocytes express IL-31R suggests that IL-31 may induce pruritus through the induction of a yet unknown keratinocyte-derived mediator that subsequently activates unmyelinated C fibers in the skin. Therefore, one may speculate that IL-31 is upregulated in pruritic forms of cutaneous inflammation.[275,276] These findings were confirmed in mice: the expression of cutaneous IL-31 messenger RNA was significantly higher in NC/Nga mice with scratching behavior than in NC/Nga mice without scratching behavior.[277] Therefore, IL-31 may participate in causing an itch sensation and promoting scratching behavior.[278,279] In addition, IL-31 may be also a link in the communication between eosinophils and keratinocytes in pruritic inflammatory skin diseases.[280–282] Primary cutaneous amyloidosis (PCA) is an itchy skin disorder associated with amyloid deposits in the superficial dermis. A gene mutation has been recently described in PCA, a pruritic skin disorder associated with amyloid deposits in the superficial dermis.[283] Together, IL-31 may serve as a link between the immune and neural systems by regulating inflammation as well as itch. For this reason, IL-31 and the IL-31R are promising targets for the treatment of inflammatory and itchy dermatoses such as atopic dermatitis, urticaria, and other genetically associated pruritic diseases. Various antagonists such as the OSMR-L-GPL fusion protein are currently under investigation.[284]

ROLE OF THE NERVOUS SYSTEM IN SKIN PATHOPHYSIOLOGY

A number of human clinical diseases or symptoms, appear to have a significant neurogenic component, including atopic dermatitis, prurigo, pruritus-associated diseases, psoriasis, rosacea, urticaria, herpes zoster, or inflammatory arthritis (see Table 102-0.1).[1] The peripheral nervous system also modulates inflammatory responses or symptoms in other organs, such as eye inflammation, asthma, inflammatory bowel syndrome, and transmits pain. Moreover, neuronal mediators play a role during wound healing by regulating growth, proliferation, and angiogenesis.

The ability of neuropeptides to activate human mast cells and induce urticaria has been appreciated for a number of years.[285] For example, chronic idiopathic urticaria and, to a lesser extent, pressure urticaria showed enhanced SP- and CGRP-induced wheal-and-flare reactions (see Fig. 102-1). Certain transient receptor potential ion channels are expressed by sensory nerves as well as by mast cells that can be activated by trigger factors of urticaria like heat, cold, pressure, or food ingredients.

A neurogenic component in the pathophysiology of psoriasis is suggested based on clinical obser-

vation (e.g., stress induction) and is supported by experimental studies.[286–289] Data suggest a role for NGF as a mediator of inflammatory responses in psoriasis, although its significance remains to be established.[290]

In acute as well as lichenified lesions of atopic dermatitis, increased staining of cutaneous nerves or concentrations of neuropeptides has been observed.[80,139,291–297] Also, characteristics of the triple response (erythema, wheal, flare) of neurogenic inflammation as well as pruritus have been observed after injection of neuropeptides into human skin.[298,299] The lesions of patients with atopic dermatitis show enhanced concentrations of mast cell tryptase, a ligand for the proteinase-activated receptor-2 (PAR-2), which is upregulated in atopic dermatitis and mediates pruritus, inflammation, and upregulation of intercellular cell adhesion molecule 1 or nuclear factor κB.[300–303] A role for proopiomelanocortin peptides in the pathogenesis of atopic dermatitis is supported by the in vitro observation that α-MSH modulates immunoglobulin E production and the finding of increased levels of proopiomelanocortin peptides in the skin of patients with atopic dermatitis.[304,305] Some studies also suggest that NTs such as NGF or NT-3 may participate in the pathophysiology of atopic dermatitis (Table 102-2).[306]

Neuropeptides such as CGRP, PACAP, or α-MSH, are obviously involved in the regulation of epidermal antigen presentation.[307–310] Also, pretreatment of the skin with capsaicin enhances contact hypersensitivity (CHS) at the site of treatment. It has been suggested that capsaicin-sensitive neurons modulate this reaction via the release of neuropeptides.[114,311] Studies also indicate that SP agonists can prevent impaired CHS and tolerance after UVB irradiation.[191] CGRP significantly inhibited antigen presentation to antigen-specific T cells.[114,312] The effect of CGRP on murine LCs is probably mediated by a specific CGRP receptor, which leads to intracellular increase in cyclic adenosine monophosphate.[113] Accordingly, IL-10 can be upregulated by CGRP.[313] α-MSH is one of the most powerful neurohormones in terms of its ability to modify CHS reactions.[314–316] PACAP is also able to inhibit CHS reactions.[310]

The skin nervous system also plays a crucial role during wound healing and impaired wound healing processes. Released neuropeptides participate in inflammation, cell proliferation, cytokine, and growth factor production, and neovascularization.[317,318] Of note, delayed wound healing occurred in animal models after surgical resection of cutaneous nerves.[319–323] For instance, decreased concentrations of SP, SST, and CGRP were observed in wounds in rats[324]; elevated levels can be observed in other wound models.[321,324] CGRP promotes proliferation and migration of human keratinocytes[325–327] and stimulates proliferation of human dermal endothelial cells.[328] VIP has both inhibitory and stimulatory effects on the proliferation of keratinocytes.[325,326,329] Angiotensin II appears to influence tissue repair via activation of the angiotensin I receptor in fibroblasts, which leads to collagen remodeling, collagen gel contraction, and upregulation of collagen-binding integrins in vitro.[330] NGF induces human skin and lung fibroblast migration but not proliferation.[331] In a mouse model, it could be observed that NGF accelerated the rate of wound healing.[332] These findings have encouraged successful treatment of leg ulcers in humans with topical NGF.[333,334] Parathyroid hormone-related protein expression is temporarily upregulated in migratory keratinocytes, myofibroblasts, and infiltrating macrophages in guinea pig skin, although topical application of a parathyroid hormone-related protein agonist did not change the healing rate or morphology in these wounds.[335,336]

NEP expression appears to be both increased and redistributed in the wound environment during wound healing, which indicates a role for neuropeptide-degrading enzymes in this process.[337] In normal skin, NEP immunoreactivity was restricted to the basal layer, whereas during wound healing, NEP was also detected in the suprabasal layer of human skin. Future studies using transgenic and knockout animals, in which certain components of the neurologic system are overexpressed or deleted by homologous recombination, may make it possible to examine the role of the cutaneous nervous system in normal and delayed wound healing.[338]

Pruritus is one of the most frequent symptoms of skin diseases and derives from stimulation of sensory nerve endings, spinal cord modulation, or dysfunction of certain areas in the CNS (see Table 102-0.1).[48,65,222,339] Polymodal C fibers, stimulated by chemicals or heat, transmit signals to the spinal cord and CNS, which results in itching. Accordingly, both the peripheral cutaneous system and the CNS coordinate the sensation of itch, which leads to the autonomic reflex of scratching. Histamine is the best-studied, albeit definitely not the only, mediator of pruritus. New histamine receptors (e.g., histamine receptor-3, histamine receptor-4) have now been cloned; their role in human itch is poorly understood.[212] Another important mediator of pruritus in patients with atopic dermatitis may be IL-31 (see Table 102-1, eFig. 102-0.1 in online edition).[275,279,340,341] In notalgia paresthetica, a neuropathy characterized by pruritus, pain, and hyperalgesia, immunostaining for several neuropeptides revealed that affected areas had a significant increase in intradermal nerve fibers as well as epidermal dendritic cells, which suggests that sensory nerve fibers are involved in the pathogenesis of this disease. Agents such as capsaicin that deplete neuropeptides from sensory neurons have been shown to have a therapeutic effect in diseases associated with pruritus and pain. Other neuromediators such as opioids seem to be involved in the pathophysiology of cholestatic pruritus.[342,343] Cholestatic pruritus can be significantly reduced by application of an antagonist to 5-hydroxytryptamine.[344] Like opioids, endogenous CB appear to be implicated in itching.[48,65,261,345] Under inflammatory conditions,[346] CB are capable of activating and sensitizing the TRPV1 receptor.[347,348] Cannabinoid receptors also induce release of analgesic β-endorphin from murine keratinocytes.[149] Aprepitant, a selective NK1R antagonist, which has been recently demonstrated to be beneficial for the treatment of pruritus and prurigo,[75] may also be beneficial for the treatment of other pruritic skin diseases.

SUMMARY AND PERSPECTIVES

In many ways, the nervous system modulates (and eventually "manipulates") the function of the skin, which under physiological conditions leads to control of skin homeostasis. However, under pathophysiological conditions, neuromediators can either aggravate (proinflammatory) or ameliorate (anti-inflammatory) disease development. The bidirectional interaction of the skin with the peripheral nervous system as well as the CNS plays a crucial role in skin homeostasis and disease states, as seen for inflammation, pain, or pruritus. Recent discoveries have increased our knowledge about the molecular mechanisms regulating the function of neuromediators, their receptors, and controlling enzymes. The development of modern techniques including proteomics, genomics, metabolics, and molecular imaging of neuronal structures offer exciting insights into the complex network between skin, nerves, and immune system during inflammation, tumorigenesis, pruritus, or chronic pain. Various applications like TRPV1 channel agonists/antagonists or neuropeptide receptor antagonists are currently in clinical or preclinical trials for the treatment of various skin diseases including atopic dermatitis, rosacea, viral infection, pruritus, or pain. Using novel technical approaches and understanding new pathways of neuro-immuno-endocrine communication, it will be possible to learn how neuromedicine can contribute to treat skin diseases and symptoms such as inflammation, cancer, pigmentation disorders, allergic reactions, endocrine disregulation, painful skin diseases, or pruritic diseases.

Chapter 103 :: Pathophysiology and Clinical Aspects of Pruritus

:: Gil Yosipovitch & Tejesh S. Patel

PRURITUS AT A GLANCE

- Pruritus is the predominant symptom of skin disease.
- May originate in the skin or nervous system.
- Clinical classification of itch includes:
  - pruritus on diseased (inflamed) skin
  - pruritus on nondiseased (noninflamed) skin
  - pruritus presenting with severe chronic secondary scratch lesions
- Chronic itch consists of multidimensional phenomena including sensory, emotional, and cognitive components.
- Central and peripheral mediators in humans include histamine, proteinases, opiates, substance P, nerve growth factor, interleukins, and prostaglandins.
- Treatment should address the multifactorial nature of pruritus including central pathways and peripheral mediators.

INTRODUCTION

Pruritus (itching) is the predominant symptom of skin disease and can best be defined as a sensation that leads to a desire to scratch. All human beings experience this sensation in the course of their lifetime; therefore, it is important to make a distinction between acute itch, which is of a limited period of time ranging from seconds to a week such as the itch related to acute insect bite reaction, and chronic itch, which lasts for months and is the focus of this chapter.[1] Chronic itch is a multidimensional phenomenon consisting of sensory, emotional, and cognitive components. In most cases, chronic itch results from interaction of the brain-skin axis. Although itch and pain are separate and distinct sensations, itch has many similarities to pain.[2,3] Both itch and pain are unpleasant sensory experiences, follow similar neural pathways, and can severely impair patients' quality of life. However, the behavioral response patterns differ—pain elicits a reflex withdrawal, whereas itch leads to a scratch reflex.

The limited understanding of itch results from the subjective nature of itching, the absence of specific and sensitive investigational methods to study the neuropathophysiology and molecular basis of itch in humans, the lack of convincing animal models and incomplete knowledge of pharmacologic mediators of pruritus. However, significant progress has been made in the past decade with the discovery of new neural pathways (both histaminergic and nonhistaminergic) as well as novel receptors in humans and animals. The concept that itch is transmitted to the central nervous system (CNS) and processed in the brain should lead to new approaches to antipruritic therapy.[4]

EPIDEMIOLOGY

Itch is a symptom rather than a specific disease entity; therefore, epidemiologic data for itch are limited. Nevertheless, itch has been found to be the dominant skin complaint among all age groups.[5] In a large cross-sectional study in Norway, the prevalence of pruritus was approximately 8% among adults.[6] Itch is a primary symptom in a diverse range of skin diseases as well as in systemic diseases. The prevalence of pruritus in different dermatologic and systemic diseases is outlined in Tables 103-1 and 103-2.

TABLE 103-1
Prevalence of Itch in Skin Disorders and Infectious Skin Diseases

Cause	Estimated Prevalence of Pruritus
Skin disease	
Atopic dermatitis	100%
Contact dermatitis	Unknown
Poison ivy	Unknown
Elderly idiopathic xerosis	30%–60%[7]
Urticaria	97%
Extensive psoriasis	80%
Pityriasis rosea	Unknown
Seborrheic dermatitis	Unknown
Neurodermatitis: lichen simplex chronicus, prurigo nodularis, lichen amyloidosis	Unknown
Burns	67%–87%[8]
Pityriasis rubra pilaris	Unknown
Dermatitis herpetiformis	Unknown
Acne	50%–70%[9,10]
Linear immunoglobulin A disease	Unknown
Bullous pemphigoid	Unknown
Collagen disease	
Dermatomyositis	38%
Sjögren syndrome	Unknown
Scleroderma	45%[11]
Infection	
Varicella	Unknown
HIV disease	HIV-associated folliculitis in 25%–50% of HIV patients; nonspecific pruritic eruption in 11%–46% of HIV patients
Onchocerciasis	5%–67%[12]
Scabies	100% (except Norwegian scabies)[13]
Superficial fungal infections	Unknown

HIV = human immunodeficiency virus.
Adapted from Yosipovitch G: Epidemiology of itching in skin disease. In: *Itch: Basic Mechanisms and Therapy*, edited by G Yosipovitch et al: New York, Marcel Dekker, 2004, with permission.

ETIOLOGY AND PATHOGENESIS

Pruritus may originate in the skin or in the CNS. There is no single, definitive classification of pruritus. The International Forum for the Study of Itch (IFSI) has proposed a classification that distinguishes three clinical groups of patients as follows[14]:

Group I: Pruritus on diseased (inflamed) skin
Group II: Pruritus on nondiseased (noninflamed) skin
Group III: Pruritus presenting with severe chronic secondary scratch lesions, such as prurigo nodularis

The first group includes underlying dermatological diseases, while the second and third group includes patients with systemic diseases including diseases of pregnancy and drug-induced pruritus as well as neuropathic and psychiatric diseases. In some patients, more than one cause may account for pruritus (category "mixed") while in others no underlying disease can be identified (category "others").[14] It is also important to differentiate acute itch from chronic itch because therapies that provide transient itch relief often do not address the pathological processes underlying chronic itch.[1] Moreover, the biologic function of nerve fibers most probably differs in chronic itch than acute itch.

ITCH–SCRATCH CYCLE

Itch and scratching are interwoven together in both acute and chronic itch conditions. Phylogenetically,

TABLE 103-2
Prevalence of Pruritus in Systemic Disease

Disease	Estimated Prevalence of Pruritus
■ Chronic renal failure, end stage	25%–85%
■ Hepatic	
■ Cholestatic jaundice	20%–25%
■ Primary biliary cirrhosis	100%
■ Hepatitis C	4%
■ Cholestasis of pregnancy	Unknown
■ Hematopoietic	
■ Polycythemia vera	48%
■ Iron deficiency anemia	Unknown
■ Multiple myeloma	Unknown
■ Mastocytosis	Unknown
■ Hodgkin lymphoma	30%
■ Non-Hodgkin lymphoma	Unknown
■ Endocrine	
■ Hyperthyroidism	60%
■ Hypothyroidism	Unknown
■ Carcinoid syndrome	Unknown
■ Diabetes	11%
■ Anorexia nervosa	58%

itch is probably a mechanism for animals to remove parasites residing in the hairy skin. Scratching is also a behavioral response. A study in humans has shown that repetitive scratching activates the prefrontal cortex in particular, an area of the brain implicated in goal-directed and habit-learning systems.[15] It is thus possible that activity induced by scratching in the prefrontal cortex may serve to drive the compulsion to continue scratching and could also account for the highly rewarding aspects of scratching. Furthermore, the hedonic experience of scratching may be associated with release of endogenous opioids. Repetitive scratching in chronic conditions such as atopic dermatitis and psoriasis further damages the skin and causes secretion of neuropeptides and opiates that may further augment the vicious itch-scratch cycle (Fig. 103-1).

ALLOKNESIS: "ITCHY SKIN"

Alloknesis is a phenomenon in which a normally innocuous stimulus induces itch. For example, application of a fine brush to an itchy site induces itch. Alloknesis is analogous to the better-known allodynia (defined as pain due to stimuli, which does not normally provoke pain). This type of itch is mediated by mechanical mechanoreceptor units as well as an ongoing activity of afferent C nerve fibers and is considered a central neural sensitization response. Alloknesis is common in chronic atopic dermatitis; sweating or slight mechanical stimulation associated with wearing wool exacerbates itch. The exact role of central sensitization in pruritus associated with specific diseases is unknown.[3]

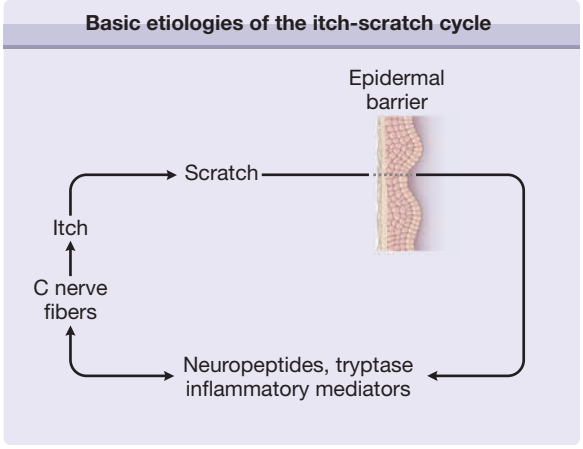

Figure 103-1 Basic etiologies of the itch-scratch cycle.

ITCH TRANSMISSION IN THE SKIN

The only peripheral tissues from which itch can be evoked are skin, mucous membranes, and cornea. Interestingly, the nerves in the deeper layer of the reticular dermis and subcutaneous fat do not transmit itch and inflammatory skin diseases affecting these areas, such as panniculitis, cause pain but not itch. Removal of the epidermis abolishes perception of pruritus, suggesting that pruritus receptor units are located predominantly within this layer.[16] We suspect that the epidermis acts as a receptor for itch, but a specific receptor has not yet been identified. Light microscope and ultrastructural studies of human skin have shown the existence of intraepidermal nerve fibers with "free" nonspecialized nerve endings extending to the stratum granulosum.[17] Many epidermal nerve fibers stain positively for neuropeptides implicated in itch transmission. It has recently been shown that Mrgprs, a family of G protein-coupled receptors expressed exclusively in peripheral sensory neurons, function as itch receptors.[18]

Keratinocytes express a variety of neural mediators and receptors, all of which appear to be involved in the itch sensation.[19] Mediators include opioids, proteases, substance P (SP), nerve growth factor (NGF), and neurotrophin 4 whereas receptors include μ- and κ-opioid receptors, proteinase activated receptor-2 (PAR-2), vanilloid receptors, tropomyosin-related kinase A (TRKA), transient receptor potential vanilloid (TRPV) ion channels, gastrin releasing peptide receptor, and cannabinoid receptors 1 and 2. Keratinocytes also have voltage-gated adenosine triphosphate channels and adenosine receptors similar to C nerve fibers. Because these channels have a role in pain,[20] these findings suggest that keratinocytes may act as itch receptors.

DEDICATED ITCH-TRANSMITTING C NERVE FIBERS

Significant advances in our understanding of itch neurophysiology have been achieved in the past decade.

Microneurography has helped to disprove the historic concept that pruritus and pain are simply responses of the same neurons to mild versus intense stimuli, respectively. Studies using electric field stimulation coupled with microneurography have identified individual histamine-sensitive C nerve fibers that transmit itch.[21] The C nerve fibers have exceptionally slow conduction velocity, unusually wide innervation territories, and represent no more than 5% of total C fibers. These neurons are sensitive to pruritogenic and thermal stimuli as well as capsaicin, but not mechanical stimuli. The co-responsiveness of this subset of C neurons to temperature change as well as pruritic stimuli is of interest because raising the temperature of skin lowers the threshold of receptors to pruritic stimuli[22] and most pruritic patients complain of aggravation of pruritus in a warm environment. In chronic itch, spontaneous activity in these C fibers occurs.[23] In contrast, the vast majority of C fibers are sensitive to mechanical and heat stimuli and are entirely insensitive to histamine.[24]

The existence of a subset of dedicated itch-transmitting C neurons receives further support from studies of spinal-cord pathways. Itch-transmitting primary afferent C neurons synapse with secondary transmission neurons that cross over to the contralateral spinothalamic tract and ascend to the thalamus. In the cat, microneurography identified lamina 1 neurons in the lateral spinothalamic tract that selectively responded to histamine, suggesting a central dedicated nerve pathway for itch.[25] Other C nerve fibers transmit itch as well. Mechanically induced itch is commonly observed clinically; for example, itch associated with contact with wool cannot be explained by histamine-sensitive nerve fibers. Moreover, in patients with chronic pruritus, electrical or painful stimuli can also induce itch.[26–28] Oral antihistamines are ineffective in the treatment of most types of itch, suggesting that nonhistamine-mediated fibers also play an important role. A separate nonhistaminergic itch processing pathway activated by cowhage (Mucuna pruriens) was discovered in peripheral nerve fibers of humans as well as in the spinothalamic tract in primates.[29,30] The active ingredient inducing itch by cowhage has been found to be a cystine protease which acts through PAR-2 and PAR-4.[31] Therefore, two parallel subpopulations of primary afferent C-fibers and spinothalamic tract neurons transmit itch in humans. Both of these pathways are most probably not itch specific since they also transmit burning sensations and respond to the algogen, capsaicin. In addition, gastrin-releasing peptide (GRP) receptor positive neurons were recently found to constitute a dedicated neuronal pathway for itch in the spinal cord of mice.[32] The role of these neurons and their interaction with both histaminergic and nonhistaminergic pathways in humans remains to be elucidated.

The perceived sensation of pruritus can vary greatly in quality. Patients may experience sensations of burning or pricking but the neurophysiologic and psychologic correlates of these differences have not yet been elucidated. Information obtained from itch questionnaires based on previously developed pain questionnaires has enabled us to better understand the different characteristics of itch.[7,33–35]

THE CENTRAL PROCESSING OF ITCH

The central processing of itch has been demonstrated using the neuroimaging techniques of positron emission tomography and functional magnetic resonance imaging in healthy humans and patients with atopic dematitis. In these studies, histamine-induced itch activated various brain areas implicated in sensory and motor function as well as emotion—reflective of the multidimensional aspects of this distressing symptom. A recent study showed that that the central processing of itch in atopic dermatitis is different from that of healthy subjects. The anterior and posterior cingulate cortex as well as the dorsal lateral prefrontal cortex, which are involved in emotions, reward, and memory of negative experiences were significantly activated in patients with atopic eczema but not in healthy subjects.[36] The activation of the precuneus, which is located in close proximity to the posterior cingulate cortex seems unique in itch and has rarely been reported in pain imaging. The precuneus is involved in episodic memory retrieval and could be associated with the affective components involved in itch.[36,37]

CLINICAL FINDINGS

HISTORY

It is of prime importance to determine whether the cause is related to a primary skin disease or systemic disease. Diseases such as skin dryness or scabies may exhibit few primary skin lesions; therefore, careful history and laboratory evaluation can be particularly important. It is important to differentiate between generalized pruritus and localized itch. Careful history, including a full drug history, and physical examination including lymph nodes, are the starting points. The history should take into account the multidimensional nature of itching and should include details of quality, distribution, and timing. Any patient referred with generalized pruritus in the setting of other family members with pruritus should be assumed to have scabies until proved otherwise—skin signs may be clinically inapparent, perhaps confined to a few small nodules on the genitalia. In addition, patients with localized pruritus, especially in a dermatomal distribution, that present with other sensory complaints such as a burning sensation, loss of sensation or increased pain should be evaluated carefully for neuropathic itch. Figure 103-2 is an algorithm showing the approach to a patient with pruritus.

CUTANEOUS LESIONS

Secondary skin lesions characteristic of pruritus include excoriations, lichenification, and hyper- or hypopigmentation. Lichenification results from continuous

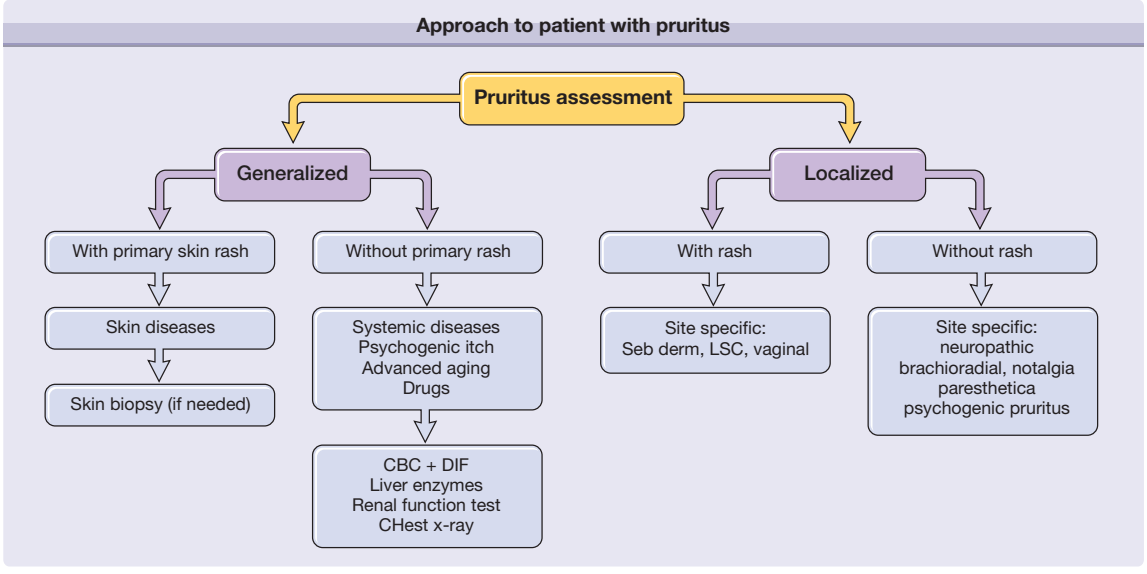

Figure 103-2 Approach to a patient with pruritus. CBC = complete blood cell count; DIF = differential; LSC = lichen simplex chronicus; Seb derm = seborrheic dermatitis.

rubbing or scratching and consists of well-developed, thickened plaques with marked accentuation of skin creases (see Chapter 14). Post-inflammatory hyperpigmentation or hypopigmentation is common in patients with skin phototypes 4 through 6 (see Chapter 75). Lichenified plaques are most commonly distributed in areas the patient can easily scratch or rub (i.e., nape of neck, below the elbow, ankle, buttock, and genitalia). The butterfly sign consists of normal-appearing skin in the middle of the back outlined by a butterfly pattern of contrasting hyperpigmentation in areas subjected to persistent scratching, resulting from the patient's inability to reach the middle of the back. Shiny fingernails may result from prolonged rubbing. Prurigo nodules are excoriated papules that form nodules in patients with chronic pruritus (see Chapter 15). In many cases, this type of itch is accompanied by a painful, burning sensation suggestive of a neuropathic component. Prurigo nodules are frequently associated with emotional stress and obsessive-compulsive disorder; however, they can be also be a manifestation of itch in patients with atopic dermatitis or chronic renal failure. Such nodules are usually distributed over extensor aspects of the limbs.

Some pruritic states have specific clinical patterns. Despite severe pruritus, chronic urticaria usually does not show secondary skin lesions associated with scratching. Neuropathic itch in disease entities, such as postherpetic neuralgia, brachioradial pruritus, and notalgia paresthetica, is typically associated with pain and burning sensation. Atopic dermatitis may also be associated with burning sensation after scratching.[89]

LABORATORY TESTS AND SPECIAL TESTS

Laboratory tests to be considered in the evaluation of generalized pruritus are outlined in Box 103-1. Secondary laboratory considerations may include stool examination for ova and parasites, screening for hepatitis B or C, plasma protein electrophoresis, and immunoelectrophoresis. A computed tomography scan of the chest and abdomen may be justifiable to help rule out lymphoma. A skin biopsy is not warranted and only useful to exclude clinically inapparent cutaneous mastocytosis, bullous pemphigoid or cutaneous T cell lymphoma.

DIFFERENTIAL DIAGNOSIS

(Box 103-2)

COMPLICATIONS

Pruritus can significantly impair patients' quality of life and have an effect on prognosis. Patients with chronic pruritus often have difficulty sleeping, difficulty concentrating, decreased sexual desire and sexual function, agitation, and depression.[7,90] In addition, eczematous

BOX 103-1 RECOMMENDED LABORATORY TESTS FOR INVESTIGATION OF PATIENTS WITH GENERALIZED PRURITUS

- Recommended
  - Complete blood cell count with differential
  - Chemistry profile: urea, creatinine, liver enzymes
  - Thyroid function tests
  - Chest radiograph
- Optoinal
  - Stool Examination for parasites
  - Human immunodeficiency virus testing with other associated symptoms and signs

BOX 103-2 DIFFERENTIAL DIAGNOSIS OF GENERALIZED PRURITUS WITHOUT PRIMARY SKIN DISEASE

- Chronic renal disease
- Cholestasis
- Hyperthyroidism
- Pruritus in hematologic disease and lymphoreticular malignancy
  - Hodgkin disease and non-Hodgkin lymphoma
  - Polycythemia vera
  - Myeloid and lymphatic leukemia
  - Myelodysplasia
  - Mastocytosis
- Solid malignant tumors (paraneoplastic manifestation)
- Human immunodeficiency virus-associated pruritus
- Itching in advanced age
- Aquagenic pruritus
- Itching as a manifestation of psychiatric disease
  - Delusions of parasitosis
  - Itch associated with obsessive-compulsive disorder
  - Itch associated with fibromyalgia and depression
  - Pruritus of anorexia nervosa
- Neuropathic itch
  - Postcerebrovascular accident pruritus
  - Multiple sclerosis-associated pruritus
  - Pruritus of Creutzfeldt–Jakob disease ("prion pruritus")
- Drug-induced pruritus
  - Opiate-associated pruritus
  - Hydroxyethyl starch-induced pruritus

lesions resulting from scratching can become secondarily infected, particularly in patients with atopic dermatitis. Moreover, in a large multinational study in hemodialysis patients, pruritus was associated with a 17% higher mortality risk.[91]

CLINICAL COURSE

Generalized pruritus can wax and wane. Changes in the clinical presentation may be associated with seasonal changes, such as exacerbation of atopic dermatitis in the winter, or changes between dry and humid environments. Pruritus associated with underlying internal disease is often multifactorial, involving both systemic and external factors, including ambient temperature and humidity. Chronic itch associated with skin disease may also include central neural sensitization.[28,36]

ITCH CAUSED BY SKIN DISORDERS

PRURITUS IN ATOPIC DERMATITIS. (See Chapter 14.) Pruritus in atopic dermatitis remains a controversial area and the molecular basis of pruritus in atopic dermatitis remains largely unexplained.[92] Whether itch precedes skin lesions or vice versa is also an unresolved issue. What is certain is that a vicious itch-scratch cycle (see Fig. 103-1) exists in atopic patients, in which scratch damage enhances pruritus. Itching is particularly acute in response to punctate stimuli such as wool fibers. Alloknesis (see Section "Alloknesis: Itchy Skin") is a prominent feature of the itch of atopic dermatitis and explains the bouts of intense itching associated with sweating, sudden changes in temperature, dressing, undressing, and direct contact with wool.

A central (neurogenic) component to the itch of atopic dermatitis is suggested by the poor response to low sedation H_1 antihistamines.[93] The intensity of itch in atopic dermatitis has been related to mental factors, and itch may be induced by cognitive stress, such as anxiety, as well as depression.[94–97] Of note, itch intensity and disease severity were significantly correlated with brain activity in the anterior cingulate cortex as well as the insula in atopic dermatitis patients.[36] Opioid peptides may serve as central and peripheral mediators because opioid antagonists acting at these levels are effective in some patients.[98] Interestingly, there is a significant downregulation of μ-opioid receptor expression in the epidermis of atopic dermatitis patients.[99] Nocturnal scratching is a major problem in atopic dermatitis, occurs during superficial sleep, and occupies 10%–20% of the total sleeping time, leading to tiredness and irritability.

PSORIASIS. Itch in psoriasis is a significant but underrecognized problem in dermatology. Several studies have demonstrated that itch is a principal symptom of psoriasis.[100–104] Among psoriasis patients, 77% experience pruritus on a daily basis.[90] Dermatologists emphasize observable criteria of psoriasis, such as visible lesions; however, itching frequently occurs in areas of the body where no psoriasis plaques are visible. Scalp itching, in particular, is specific to psoriasis and may require different therapies than pruritus in other areas of the body.[103,105]

NEUROPATHIC ITCH

POSTHERPETIC NEURALGIA. Postherpetic neuralgia commonly has neuropathic pain; and often, associated neuropathic itch in 30%–58% of such patients. Pruritus commonly accompanies both acute zoster and postherpetic neuralgia, particularly lesions affecting the head, face, and neck.[106,107]

BRACHIORADIAL PRURITUS. Brachioradial pruritus, a localized pruritus, is becoming increasingly common. Patients, usually fair skinned, affluent, and middle aged, habitually indulge in golf, tennis, sailing, or other leisure outdoor activities in sunny climates.[108,109] They develop persistent pruritus of the outer surface of the upper arm, elbow, and forearm, associated with clinical evidence of chronic sun damage and xerosis. The itch is often accompanied by a

burning sensation. The itch may gradually become more widespread. The pathophysiology is believed to involve compression of spinal nerve roots in C4–C6 and in rare cases it has been associated with spinal nerve tumors.[110] Of note, exposure to UV light has been an eliciting factor.[111] (See Chapter 90.)

NOTALGIA PARESTHETICA. Notalgia paresthetica is a chronic localized itch, affecting mainly the interscapular area especially the T2–T6 dermatomes, but occasionally with a more widespread distribution, involving the shoulders, back, and upper chest. The sensation perceived by the patient is part itch, part paraesthesia. There are no specific cutaneous signs, apart from those attributed to scratching and rubbing. Amyloid deposition in skin biopsies is a secondary event. The current view on etiology is that it is a neuropathic itch due to nerve entrapment of the posterior rami of spinal nerves arising at T2–T6.[112,113]

SYSTEMIC ITCH

PRURITUS OF CHRONIC KIDNEY DISEASE. (See Chapter 150.) Pruritus is one of the most distressing symptoms of chronic kidney disease (CKD). It affects 42% of patients on hemodialysis as reported by the Dialysis Outcomes and Practice Pattern Study (DOPPS).[91] The DOPPS report and a large study in Japan showed that CKD-associated itch induces depression, sleep disturbance and increased mortality.[91,114] Scratching is common and patients may be heavily excoriated or the skin may appear lichenified or present with prurigo nodules. The back is invariably affected, and the arm bearing the arteriovenous fistula is also a common site in dialysis patients. Patients with CKD associated-pruritus often have dry skin, but correction of this by emollients usually provides minimal relief.

The pathophysiology of CKD-associated pruritus remains poorly understood. Current understanding points towards central roles for the immune and opioidergic systems. It is postulated that the itch associated with CKD is a manifestation of an immune system derangement that results in a proinflammatory state. In line with this theory, immunomodulators such as ultraviolet B light,[115] tacrolimus[116] and thalidomide[117] have been shown to alleviate CKD-associated pruritus. An imbalance of the endogenous opioidergic system has also received recent attention in terms of the pathophysiology of CKD-associated pruritus.[118] An increased ratio of serum β-endorphin to dynorphin A has been reported in HD patients compared with healthy controls, and the ratio increased with the increased intensity of itch.[119] Moreover, a kappa-receptor agonist, nalfurafine, was shown to significantly decrease itch intensity and excoriations in HD patients.[120,121] Other proposed etiologic factors may include elevated calcium levels, release of pruritogenic cytokines during hemodialysis, damage to C nerve fibers, proliferation of sensory nerve endings in skin, increased numbers of dermal mast cells, elevated plasma histamine levels, secondary hyperparathyroidism and abnormal levels of divalent cations.[118,122,123] Secondary hyperparathyroidism, though common in patients with renal failure, is a rare cause of renal pruritus. The proliferation of nerve endings in skin is most likely a response to incessant scratching and rubbing, rather than the primary cause of pruritus. Elevation of histamine levels, with or without increased population density of dermal mast cells, is also unlikely to be important because antihistamines are rarely effective.

PRURITUS OF CHOLESTASIS. (See Chapter 150.) Pruritus of cholestasis is highly distressing. The unique feature of cholestatic pruritus is that the itch initially starts and is most intense in the palms and soles, which is usually not reported in other diseases and later becomes more generalized. Of note, intractable itch in chronic liver disease may be an indication for liver transplantation even in the absence fulminant liver failure.[124] Both peripheral and central mechanisms are important. Cholestatic pruritus is associated with high plasma levels of bile salts; however, there is little or no evidence of a correlation between skin or serum concentrations of bile salts and itching[125] although administration of cholestyramine, which lowers bile salt levels, does provide some relief. Patients also have elevated plasma opioid levels,[126] and pruritus has been shown to improve with treatment with opioid antagonists including naloxone, naltrexone, and butorphanol.[127–129] In addition, animal models of cholestasis are associated with elevated levels of opioid peptides and scratching, relieved by naloxone.[130,131] Thus, combination of both bile salt-lowering and opioid-directed strategies appear reasonable in the management of pruritus of cholestasis.

Furthermore, recent studies have shown that patients with cholestatic pruritus have elevated serum levels of autotoxin and its substrate lysophosphatidic acid (LPA) a signaling phospholipid. The activity of autotaxin in cholestatic patients' sera correlated with the intensity of pruritus. LPA and autotaxin may therefore be potential targets in the treatment of cholestatic pruritus.[132]

PRURITUS OF ENDOCRINE DISEASE. (See Chapter 151.) Generalized intractable itching is a recognized feature of thyrotoxicosis and may be a presenting symptom.[133] This may be due to increased blood flow, which raises the skin temperature, which, in turn, reduces the threshold to itching.[22] Hypothyroidism is less frequently associated with itch. Generalized itching is not a feature of diabetes mellitus.[134] However, anogenital itching is a common presenting feature, and is due to mucocutaneous candidiasis. Localized itching of the scalp and lower extremities in the form of lichen simplex chronicus can also be a manifestation of diabetic neuropathy,[135] which may respond to topical capsaicin treatment.[136] In addition, truncal pruritus of unknown origin has been recently reported to be associated to diabetes and diabetic neuropathy.[137]

PRURITUS IN HEMATOLOGIC DISEASE AND LYMPHORETICULAR MALIGNANCY. (See Chapters 144 and 145.) Itch is common in hematologic

disorders. In widespread cutaneous T-cell lymphoma, and erythrodermic forms of cutaneous T-cell lymphoma including Sézary syndrome (T-cell leukemia), intractable itch is difficult to manage. In polycythemia vera, it occurs in approximately 50% of patients, is often precipitated by contact with water ("bath itch"), and is associated with raised blood histamine levels.[138,139] In other lymphoproliferative diseases, itch can also be precipitated by contact with water. In Hodgkin disease, it may be a presenting symptom and occurs in between 15%–19% of patients.[124,140] It can a be a presenting sign in non-Hodgkins lymphoma also. Of note, recent data has shown functional abnormalities of mast cells in patients with myeloproliferative disease with an increased release of pruritogenic factors, such as histamine, leukotrienes, and IL-31, when compared to normal mast cells.[141] In cutaneous mastocytosis (see Chapter 149), itching occurs locally following rubbing the skin, although it can be widespread in severely affected patients, when it is usually associated with systemic symptoms. Itching may occur in patients with myeloid and lymphatic leukemia and myelodysplasia.

PARANEOPLASTIC PRURITUS. (See Chapter 153). Chronic itch could be a presenting sign of both hematologic malignancies as well as solid tumors. It may occasionally be present years before the tumor becomes clinically detectable. It could also be present as part of a primary epidermal or dermal skin disease associated with malignancy such as eruptive seborrheic keratosis, malignant acanthosis nigricans, erythroderma, transient acantholytic dermatosis (Grover disease) and dermatomyositis.[142] Traditionally, the onset of pruritus in a middle-aged or elderly patient with an otherwise normal-looking skin prompts a thorough investigation for underlying systemic causes, including internal neoplasia, although the latter is an uncommon cause. Full investigation for a causative solid tumor is probably not worthwhile in the absence of other skin or systemic findings suggestive of malignancy even if resources are available.[143,144]

PRURITUS OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION. (See Chapter 198.) Itch is an early symptom of human immunodeficiency virus (HIV) disease and may be associated with skin disease or a result of systemic disease (e.g., hepatic, renal, adverse drug reactions, lymphoma, and systemic and skin infections including *Staphylococcus aureus* and *Pityrosporum*). However, it may occur as a primary symptom of HIV.[145] The most common example is eosinophilic folliculitis. Other common types of itch in HIV are insect bite hypersensitivity reaction, pruritic papules other than eosinophilic folliculitis, and itch associated with skin xerosis and lichenoid dermatitis, as well as exacerbation of seborrheic dermatitis and psoriasis.

PSYCHOGENIC ITCH

(See Chapter 104)

The prevalence of pruritus among psychiatric inpatients is as high as 42% and appears related to psychosocial stress.[146,147] Patients with depression, fibromyalgia, and other somatoform disorders can suffer from severe itch that responds well to selective serotonin reuptake inhibitors (SSRIs). Of importance, delusions of parasitosis is one of the more challenging types of itch that dermatologists encounter. The patient holds a false belief that they are infested with parasites, although careful inspection reveals no supporting clinical findings. The patient often brings "evidence" in the form of collected fragments, although on examination the material proves to be nonspecific debris. The patients often refuse to see a psychiatrist. Delusions of parasitosis is classically treated with typical antipsychotic agents; pimozide is most commonly used by dermatologists. Olanzapine (5 mg/day) is another option to treat this severe type of psychogenic itch. Localized pruritus in the form of prurigo nodularis or anogenital pruritus could be a manifestation of obsessive-compulsive disorders and anxiety.

MISCELLANEOUS TYPES OF ITCH

ADVANCED AGE AND ITCH. Itch is the most common dermatologic symptom among people over 65 years of age.[148,149] At least 50% of persons aged 70 years or older suffer from prolonged bouts of troublesome pruritus. Idiopathic itch in the elderly, sometimes referred to inappropriately as *senile pruritus*, is common and presents a diagnostic and therapeutic challenge. Itch in senescent skin can result from a variety of causes including dry skin, inflammatory skin diseases such as low-grade eczema and scabies, as well as underlying systemic disease, especially cholestasis and renal failure. Several drugs can induce pruritus without a rash including opioids and angiotensin converting enzyme inhibitors. However, in many instances, no cause is found. Although dry skin is probably the most common associated factor, it may not be the cause of pruritus; many elderly patients have senescent skin without xerosis. Other factors may play important roles, such as age-related changes in nerve fibers and loss of input from pain fibers leading to central disinhibition of itch. Additional skin changes in elderly patients that may contribute to itch include decreased skin surface lipids, decreased clearance of transepidermally absorbed materials from the dermis, decreased sweat and sebum production, and diminished barrier repair.[150]

ITCH ASSOCIATED WITH BURNS AND SCARS. (See Chapters 66 and 95.) Burn scars are common in both children and adults and are associated with significant pruritus. The reported prevalence rates of mild to severe itching were as high as 87%, 70% and 67% at 3, 12, and 24 months post burn respectively.[8] Compared to healthy skin, burn-graft skin displays significantly elevated SP nerve fibers as well as significantly elevated thresholds for pinprick, warming, touch, and vibration.[151] Keloids are frequently associated with itch at the periphery of the keloid lesion and less frequently pain in the center of the keloid.[152] These

findings probably result from entrapment of small nerve fibers.

AQUAGENIC PRURITUS. Originally described by Shelley[153] and subsequently characterized by Greaves et al,[154] aquagenic pruritus is a rare, intractable pruritus of unknown etiology found mainly in the middle-aged and elderly.[155] Characteristically, local itching without visible skin signs is provoked by contact with water. Notably, aquagenic pruritus can be associated with lymphoproliferative disorders such as polycythemia vera.[139,156]

TREATMENT OF PRURITUS

Unfortunately, there are no general-purpose antipruritic drugs. Treatment of pruritus depends on identifying and removing the cause, whether systemic or cutaneous. False hopes of highly effective treatment for those patients in whom no cause can be found should not be raised. Recently, a kappa opioid receptor agonist, nalfurafine, was officially approved in Japan for clinical use as an antipruritic for CKD-associated pruritus. The antipruritic effects of this drug on other forms of itch still need to be elucidated. It is important to obtain a detailed history, including the precise quality, timing, and distribution of the itch, so that more focused therapy can be instituted. The sensation of itching is heightened if the skin is warm,[22,157] therefore measures should be taken to cool the skin down, including tepid showering, light clothes, and air conditioning where appropriate. Cooling lotions, such as calamine lotion or menthol 1%, may help. Of note a subset of chronic itch patients report that hot showers alleviate their itch for several hours.[35,90]

A general therapeutic ladder for generalized pruritus is presented in Fig. 103-3.

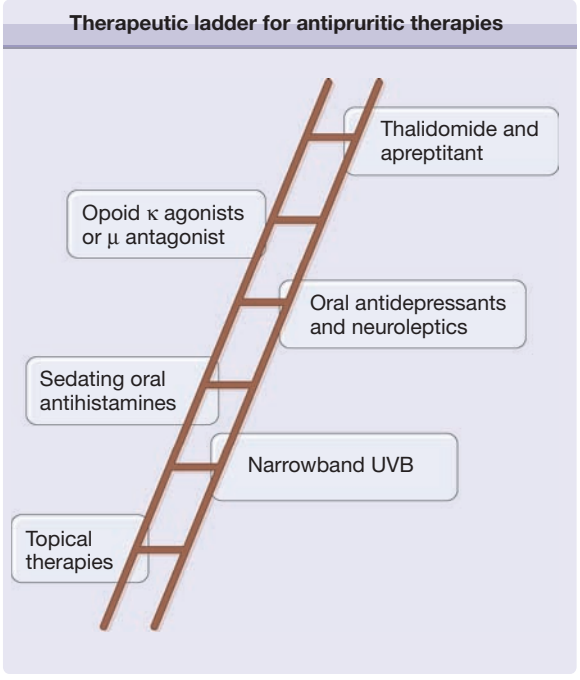

Figure 103-3 Therapeutic ladder for antipruritic therapies. UVB = ultraviolet B.

TOPICAL ANTIPRURITIC TREATMENTS

There is a lack of controlled studies for most topical antipruritic treatments. Many topical agents are claimed to be effective for pruritus; however, few claims are supported by more than anecdotal evidence. Although capable of relieving pruritus due to inflammatory skin disease, corticosteroids are not intrinsically antipruritic. Antihistamines are only antipruritic if the pruritus is caused by histamine, as in urticaria. However, a number of pharmacologic mechanisms offer promising avenues for treatment of itch. A summary of topical antipruritic treatments is given in Table 103-3.

BARRIER CREAMS AND COMBINATION THERAPIES. Emollients and barrier repair creams often reduce pruritus through improved barrier function. They help the stratum corneum to retain water and provide an exogenous barrier to prevent transepidermal water loss. Such barrier creams are often effective treatments for itch associated with dry skin and atopic dermatitis; however, the mechanism of their antipruritic effects are not fully understood. Restoration of the barrier minimizes fissuring and reduces exposure of C nerve fibers. Atopic dermatitis patients treated with ceramide-dominant emollients demonstrate improved transepidermal water loss and overall severity of skin disease. Lipids, occlusives, and humectants also reduce damage to skin by decreasing contact between skin proteins, lipids, and surfactants. Acidifying the stratum corneum may also reduce itch. High pH solutions increase the swelling of the stratum corneum, change lipid rigidity, and increase secretion of serine proteases, suggesting that neutral or acidic pH solutions are less damaging.[158]

TOPICAL SALICYLATES. Clinical trials have shown that applying a topical salicylic acid solution to the skin relieves itch. Topical salicylic acid is a common keratolytic agent and may also increase hydration and soften the stratum corneum by decreasing its pH (see Chapter 222). Topical aspirin significantly reduced pruritus in patients with lichen simplex chronicus—a form of localized itch[85]; however, oral salicylates do not relieve pruritus except in polycythemia vera.

TOPICAL IMMUNOMODULATORS. (See Chapter 221.) Although topical immunomodulators, such as tacrolimus and pimecrolimus, are used primarily for atopic dermatitis, these medications are promising antipruritic treatments in other dermatologic diseases as well. Other pruritic dermatoses treated successfully with topical calcineurin inhibitors include chronic irritative hand dermatitis, seborrheic dermatitis, graft-versus-host disease, lichen sclerosus, anogenital pruritus and prurigo nodularis. Tacrolimus and pimecrolimus have both been shown to directly affect C nerve fibers.[159,160]

TABLE 103-3
Topical Antipruritic Treatments

Medication	Dose	Indication	Notes
Barrier repair creams	N/A	Atopic dermatitis, dry skin	—
Salicylic acid	2%–6%	Lichen simplex chronicus	Stinging
Tacrolimus	0.03%–0.1% ointment	Atopic eczema, contact dermatitis	Stinging, burning sensation
Pimecrolimus	1% cream	Atopic eczema, contact dermatitis	Stinging, burning sensation
Menthol	1% cream	Patients who respond well to cold showers	Skin irritation
Capsaicin	0.025%–0.1% cream	Neuropathic itch (notalgia paresthetica, postherpetic itch), uremic itch, psoriasis, atopic dermatitis	Poor compliance due to transient burning sensation
Pramoxine	1.0%–2.5%	Facial eczema, atopic eczema	Particularly effective for pruritus of face
Polidocanol	5% urea + 3% polidocanol (Lauromacrogol)	Atopic dermatitis, contact dermatitis, psoriasis, uremic pruritus	—
Doxepin	5% cream	Atopic dermatitis	Drowsiness in 25% of patients; allergic contact dermatitis
Cannabinoids		Atopic dermatitis, uremic pruritus	Combine with a barrier cream

COOLANTS AND COUNTER-IRRITANTS. A distinct subset of sensory neurons may directly sense changes in temperature via receptors of TRP ion channels on cutaneous nerve endings. These include vanilloid receptors, such as TRPV1, which respond to warmth and capsaicin. These receptors act synergistically with other receptors involved in itch, such as PAR-2 and SP receptor (Neurokinin 1). These receptors are targets for treatment of itch. Other receptors from the same family include cold receptors, such as TRPM8. Menthol has been used as a symptomatic topical treatment for pruritus for centuries and relieves itch in some patients by activating nerve fibers that transmit a cool sensation. Menthol may reduce itch via TRPM8 receptors in keratinocytes and nerve fibers.[161,162] Menthol 1% cream is popular with patients who have pruritic skin; however, higher concentrations can induce skin irritation.[163] Those patients who report that cold showers and ice relieve their itch tend to respond extremely well to treatment with menthol.

CAPSAICIN. Topical capsaicin, the active compound in the chili pepper, causes release of neuropeptides, including SP, from C nerve fibers. The exact mechanism is not fully understood; however, prolonged application of capsaicin to the skin depletes stores of SP, desensitizes neurons, and abolishes pruritus at the site of application. Capsaicin activates the vanilloid receptor TRPV1, which is abundant in the epidermal layer of the skin.[17] Several reports have supported capsaicin's value for localized, chronic pruritic disorders, particularly those of neuropathic origin, including brachioradial pruritus, notalgia paresthetica, postherpetic itch as well as pruritus associated with CKD, psoriasis and atopic dermatitis.[164,165] Unfortunately, compliance is poor because initial application causes an intense, transient burning sensation at application sites; however, this usually resolves after using the medication for a few days or with application of a topical anesthetic.[107]

TOPICAL ANESTHETICS

Pramoxine. Pramoxine is a topical anesthetic that reduces itch, especially when applied to facial areas, by blocking the transmission of nerve impulses. Double-blind studies have shown that pramoxine inhibits histamine-induced itch in humans and CKD-associated pruritus.[166,167]

Polidocanol. Polidocanol is a nonionic surfactant with both local anesthetic properties and moisturizing effects. In an open-label study, a combination of 5% urea and 3% polidocanol (Lauromacrogol) was found to significantly reduce pruritus in patients with atopic dermatitis, contact dermatitis, and psoriasis.[168]

TOPICAL ANTIHISTAMINES. Doxepin is a tricyclic antidepressant with potent H_1- and H_2-antihistamine properties and significant atropine-like (anticholinergic) side effects. Doxepin 5% cream has been shown to relieve pruritus in patients with atopic dermatitis in a large placebo-controlled, double-blind study.[169] However, percutaneous absorption of doxepin, causing drowsiness, occurs in approximately 25% of patients, limiting its usefulness. Allergic contact dermatitis is also a recognized adverse effect.

TOPICAL CANNABINOIDS. Uncontrolled trials have shown that topical cannabinoids combined with

a barrier cream have an antipruritic effect in patients with atopic dermatitis and uremic pruritus.[170]

FUTURE TOPICAL THERAPIES. Although none are currently available, topical drugs that inhibit serine proteases may be an additional mechanism for future antipruritic therapies. Drugs that act in a similar manner to prostaglandin (PG) D_2 are currently being tested in humans and may also have a potential therapeutic role in itch.

SYSTEMIC ANTIPRURITIC TREATMENTS

ANTIHISTAMINES. (See Chapter 229.) Pruritus due to histamine is mediated exclusively via H_1 receptors; H_2 antihistamines are ineffective in relieving pruritus. First-generation (classic) H_1 antihistamines have marked sedative and atropine-like (anticholinergic) actions. Second generation (minimal- or low-sedation) H_1 antihistamines have lower lipophilicity and consequently are associated with less drowsiness and other unwanted side effects. Sedative (first-generation) antihistamines are useful in severe chronic urticaria with or without angioedema because they suppress pruritus and alleviate associated anxiety. Hydroxyzine is especially valuable in this context along with doxepin. Second-generation H_1 antihistamines are suitable in the daytime for relief of pruritus due to urticaria; however, the role of these nonsedating antihistamines is limited in other pruritic disorders. A summary of systemic antipruritic treatments is given in Table 103-4.

OPIATE ANTAGONISTS AND AGONIST–ANTAGONISTS. As previously mentioned, μ-opioid receptor agonists can cause generalized pruritus.[67,69–71] μ-Opioid antagonists, such as naloxone and naltrexone, have been used for the treatment of pruritus associated with cholestasis, uremia, and dermatologic diseases. The efficacy of such opioid antagonists is supported by data from controlled clinical trials.[64,127,129,171–173] Naltrexone was effective in the treatment of some cases of severe, intractable pruritus.[174] However, such μ-antagonists are associated with significant side effects including hepatotoxicity, nausea and vomiting, difficulty sleeping, and reversal of analgesia, among others. κ-Receptor agonists also inhibit μ-receptor effects. In animal models, κ-opioid receptor agonists inhibit pruritus and scratching induced by SP or histamine.[68,69] The novel κ agonist, nalfurafine (TRK-820), has been shown to be effective in treatment of severe uremic pruritus.[121] Thus, κ agonists are a promising treatment for severe itch.[120]

Butorphanol is a commercially available opioid agonist-antagonist analgesic with both κ-agonist activity and μ-antagonist activity. Previous studies have found that epidural butorphanol was effective in relieving pruritus associated with epidural morphine.[175,176] Intranasal butorphanol is an effective treatment for many patients with chronic, severe, and intractable pruritus due to systemic diseases and inflammatory skin diseases.[177]

ANTIDEPRESSANTS. The oral antidepressant and selective noropinephrine re-uptake inhibitor, mirtazapine, has been shown to relieve itch in some patients.[178,179] Unlike other SSRIs, mirtazapine is a central presynaptic α_2 noradrenergic inhibitor and specific serotonergic antidepressant. Mirtazapine is a safe medication without serious side effects and may be an effective alternative for the treatment of nocturnal pruritus.[179] It has been shown to be effective when used to treat systemic pruritus as well as pruritus of inflammatory skin diseases and in particular nocturnal itch using a low dose of 15 mg at night. A recent open-labeled study showed paroxetine and fluvoxamine, both selective serotonin reuptake inhibitors, to be efficient in the treatment of chronic itch.[180]

THALIDOMIDE. (See Chapter 235.) Thalidomide has shown antipruritic efficacy in treatment of inflammatory skin diseases, such as prurigo nodularis, actinic prurigo, eczema, and idiopathic elderly pruritus. It is especially useful in pruritus associated with multiple myeloma and lymphoproliferative disease. Thalidomide has been used for years as an immunomodulatory agent whose spectrum of activity is not fully characterized. The antipruritic activity could be related to several mechanisms, including inhibition of TNF-α synthesis. Although TNF-α does not have any direct pruritogenic effect, it is elevated in many pruritic dermatoses. Thalidomide may also act directly as a peripheral and central nerve depressant. The major adverse effects of thalidomide are peripheral neuropathy and teratogenicity.

NEUROLEPTICS. Gabapentin is a structural analog of the neurotransmitter γ-aminobutyric acid and has been used as an anticonvulsant; however, its mechanism of action in the CNS is poorly understood. Studies have shown that gabapentin is effective for treatment of brachioradial pruritus, multiple sclerosis-induced itch, other types of neuropathic itch as well as uremic itch. Gabapentin appears to alter sensation and pruritus associated with itch related to nerve damage in dermatologic and systemic disease. Gabapentin may inhibit central itch pathways, as it does in pain. Pregabalin is a neuropathic pain medication that has a similar structure and function to gabapentin with fewer side effects and can reduce neuropathic itch or alter the sensation of itch in systemic diseases.[113,181]

SUBSTANCE P ANTAGONIST. Aprepitant, an oral drug that antagonizes the effect of SP on neurokinin type 1 receptor has recently been shown to be effective against pruritus associated with the Sézary syndrome in a case series of 3 patients.[182]

NONPHARMACOLOGIC TREATMENTS FOR ITCH

PHOTOTHERAPY. (See Chapter 237.) Phototherapy has been used for more than three decades to treat different types of itch. Reports have suggested that narrow band UVB may be as effective for treatment

TABLE 103-4
Nonclassical Systemic Antipruritic Treatments

Medication	Dose	Indication	Notes
Doxepin	25–100 mg PO qd	Chronic urticaria	Drowsiness, dry mouth; abrupt withdrawal may cause confusion; should not be coadministered with other antidepressants
Hydroxyzine	25–100 mg PO qd	Nocturnal pruritus, atopic dermatitis, chronic urticaria	Drowsiness, dry mouth; abrupt withdrawal may cause confusion
Naloxone	0.002 µg/kg/min increased gradually up to 0.2 µg/kg/min over 24 h	Cholestatic pruritus, uremic pruritus	Hepatotoxicity, nausea and vomiting, difficulty sleeping, reversal of analgesia
Naltrexone	12.5–50 mg PO qd	Cholestatic pruritus, uremic pruritus	Hepatotoxicity, nausea and vomiting, difficulty sleeping, reversal of analgesia; contraindicated in patients with liver dysfunction
Nalfurafine	2.5–5 µg PO qd	Useful in CKD-associated pruritus	May cause insomnia, approved in Japan only
Butorphanol (intranasal)	1–4 mg inhaled qhs	Intractable pruritus due to systemic and some inflammatory skin disease	Drowsiness, dizziness, nausea and vomiting
Mirtazapine	7.5–15 mg PO qhs	Systemic and inflammatory skin disease	Drowsiness, increased weight and appetite, dry mouth
Paroxetine	10–40 mg PO qd	Generalized pruritus	Insomnia, sexual dysfunction
Thalidomide	100 mg PO qd	Pruritus in multiple myeloma and lymphoproliferative disease	Teratogenic, peripheral neuropathy, drowsiness, expensive
Gabapentin	300–3,600 mg PO qd	Neuropathic itch	Drowsiness, constipation
Pregabalin	75–300 mg PO qd	Neuropathic itch	Drowsiness and weight gain
Aprepitant	80 mg PO qd	Purigo nodularis, recalcitrant atopic dermatitis, pruritus associated with malignancy and epidermal growth factor inhibitors	Alopecia, nausea

of pruritus as broadband UVB or psoralen and UVA light. Phototherapy decreases the population density of mast cells by inducing apoptosis, causes peripheral nerve dysfunction, and reduces divalent cations in the skin. Phototherapy is an effective treatment for itch associated with atopic dermatitis, psoriasis, and CKD. Remissions may last for as long as 18 months.

CUTANEOUS FIELD STIMULATION AND ACUPUNCTURE. Cutaneous field stimulation (CFS) is a new technique that electrically stimulates afferent fibers, including nociceptive C fibers. CFS has similarities to transcutaneous electrical nerve stimulation, which activates large myelinated nerve fibers; however, CFS more specifically targets unmyelinated C nerve fibers. CFS may act through endogenous central inhibitory mechanisms that are normally activated by scratching.[183] In patients with localized itching, CFS significantly reduces patient-reported itch and causes degeneration of epidermal nerve fibers.[184] However, CFS is only practical for localized disease. In addition, acupuncture at the correct points showed a significant reduction in type I hypersensitivity itch in both healthy volunteers and patients with atopic eczema.[185,186]

BEHAVIORAL THERAPY TARGETING THE CENTRAL NERVOUS SYSTEM. Stress and other psychogenic factors are important in chronic itch.[187,188] Atopic dermatitis patients have been shown to demonstrate an abnormal sympathetic and parasympathetic response to itch and mental stres.[189] Studies have shown that behavioral modification therapy reduces both itching and scratching.[190] Other possible behavioral interventions include stress reduction and biofeedback.[188] Stress reduction using holistic approaches such as meditation, yoga and mindfulness may have adjunctive role in reducing itch intensity.

Chapter 104 :: Psychocutaneous Skin Disease

:: Evan Rieder & Francisco A. Tausk

PSYCHOCUTANEOUS DISEASES AT A GLANCE

- **Primarily Psychiatric Disorders**
  - **Delusional:** Delusions of Parasitosis, Body Dysmorphic Disorder.
  - **Factitial:** Dermatitis Artefacta, Dermatitis Para-Artefacta (Trichotillomania, Skin Picking), Malingering.
  - **Somatoform:** Body Dysmorphic Disorder, Atypical Pain/burning, Hypochondriasis, Somatization.
  - **Obsessive Compulsive Disorders.**
- Affecting approximately 5% of dermatology patients.
- Variable degree of insight, mostly poor.
- Mostly self-induced lesions.
- Poor prognosis if untreated.
- Quality of life severely deteriorated.

Scientific advances are shedding new light on the understanding and treatment of long-recognized conditions located at the interface of dermatology and psychiatry. Both arising from ectoderm, the skin and the nervous system are connected by more than just their common origins. The skin is one of the major avenues by which humans perceive the world, and, in turn, are perceived by it. When these perceptions go awry, great distress may result. When the skin is markedly affected by a primary dermatologic condition, psychological sequelae in the form of comorbidity often follow, greatly impacting patient quality of life.

The central nervous system (CNS) can influence the health of other organ systems, including the skin. Psychophysiologic mechanisms for this interaction range from the stress responses mediated by neuroadrenal connections and associated changes in immunologic function, to the systemic and local action of various neuropeptides and neurohormones.[1,2]

ROLE OF THE DERMATOLOGIST

Between 20% and 40% of patients seeking treatment for skin complaints have some type of psychiatric or psychological problem causing or complicating the presenting symptoms.[3,4] A large number of these patients lack insight into the possible psychogenic origin of their symptoms and are often reluctant to accept any kind of psychiatric referral. Therefore, in the absence of a psychiatry liaison clinic in the dermatologic setting,[4] the dermatologist must be familiar with the most common of these diagnoses, their clinical manifestations (both psychological and dermatologic), and the basic principles of treatment. When approaching these issues, it is important to explore psychiatric, and particularly psychotic, symptoms as well as compliance with medications. Collateral informants such as family members can be quite helpful if the patient grants permission. Lastly, the effects of patient symptoms on familial and social life can be of much assistance in understanding the issues to be addressed.

CLASSIFICATION OF PSYCHOCUTANEOUS DISEASES

Following the original description of C. Koblenzer,[5] psychocutaneous diseases can be classified on the basis of their primary etiology as:

- *Primary psychogenic* disorders, which can present with a variety of symptoms and behaviors, usually characterized by self-injury, that can lead to perceived or actual dermatologic conditions, or
- *Primary dermatologic* disorders that can be either triggered or amplified by contextual causes (e.g., life stresses or interpersonal relationships) that may lead to psychiatric comorbidities such as, anxiety, depression, and distress through their impact on physical appearance and well being. In some instances, the psychiatric comorbidities are not merely the result of the detrimental aspects of skin, but are associated to the pathophysiology of the dermatological disease itself. An example of the latter is the association of psoriasis with depression, in which both conditions share common inflammatory pathways.

The classification can guide in implementing an effective treatment approach including dermatologic, psychiatric, and contextual aspects of the disease aimed to interrupt the circular reinforcement of pathology. In this chapter, we focus on the description of the most frequent *primary psychogenic disorders* that present to the dermatologist, and require acknowledgement and treatment.

BOX 104-1 CLASSIFICATION OF THE PRIMARY PSYCHOCUTANEOUS DISEASES[6]

DELUSIONAL	Delusion of parasitosis
	Body odor delusion
	Hypochondriacal syndrome
	Body dysmorphic disorders (BDD[a])—somatic form
FACTITIOUS	Dermatitis para-artefacta syndrome
	Dermatitis artefacta syndrome
	Malingering
SOMATOFORM	BDD
	Cutaneous dysesthesias
	Somatization syndrome
COMPULSIVE	Compulsive washing
	Lichen simplex chronicus
	BDD

[a]BDD is classified by the DSM-IV as a somatoform disorder, although some patients may be classified as having obsessive-compulsive disorders (OCD) and others as delusional.

PRIMARY PSYCHOGENIC DISORDERS

Frequently, these diseases are manifested by self-inflicted dermatosis. The most significant difference between them is the degree of insight or conscious perception of autoinjury. The classification of these disorders as *delusional, factitial, somatoform, or compulsive* is adapted for the clinical dermatological practice, following the one described in *Clinical Management in Psychodermatology*[6] with the understanding that in many instances, disorders may span through various categories (Box 104-1), and may differ conceptually from the DSM-IV (*Diagnostic and Statistical Manual of Mental Disorders*, published by the American Psychiatric Association), which is directed towards the psychiatric practitioners[7] and clinical studies.

DELUSIONAL DISORDERS

DELUSION OF PARASITOSIS

Subjects with delusional disorders present with somatic complaints, no insight into the involved psychological issues, and encapsulated monosymptomatic delusions. Delusions are fixed, false beliefs that are not endorsed by the larger cultural, ethnic, or religious community. Patients' unshakeable beliefs frequently coexist with a fairly intact character and personality structure. The most frequent form of this condition seen by dermatologists is *delusion of parasitosis*[8] in which patients manifest the belief of being infested with parasites. Because this is frequently the only overt manifestation of the subject's psychosis, these patients most often present to dermatologists and entomologists rather than to psychiatrists. Although we will describe below the more common form of *delusions of parasitosis*, there are other more rare forms of delusions such as hypochondriacal, where patients believes that they are afflicted by a particular disease (such as AIDS, cancer, etc.), or delusions of body odor. In many instances, patients with body dysmorphic disorder (BDD) may have the unshakeable delusional conviction that they have a severe physical disfigurement.

EPIDEMIOLOGY. This disease predominates in middle aged to elderly females with premorbid social isolation. In approximately 12% of patients, the delusion of infestation is shared or at least endorsed by a family member (*folie a deux*).[9,10]

CLINICAL FINDINGS. Patients with delusional parasitosis frequently present to the clinician in an anxious, ruminative, overwhelmed state, with a history of visits to multiple physicians without satisfaction. In addition to proffering a long and detailed history that includes visual or tactile hallucinations of the organisms, the patient also frequently provides "evidence" of the parasitic infection in the form of clothing lint, skin crusts, or other debris, the so-called "matchbox sign"[11] (these items are collected in a matchbox to be presented to the physicians), which is

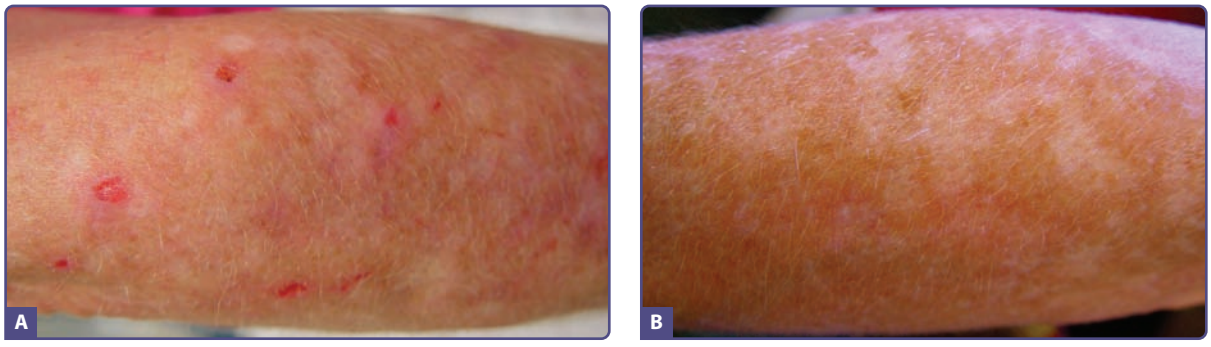

Figure 104-1 Delusions of parasitosis. **A.** Excoriations secondary to the attempt to provide an exit route for the parasites. **B.** After 2 months of treatment with aripiprazole.

delusionally misinterpreted as entire organisms, body parts, larvae, or ova. Skin manifestations can be quite variable, if present. Lesions ranging from mild excoriations (Fig. 104-1A) to large ulcers may reflect patients' unsuccessful attempts at treating the perceived infestation.[12] Because this is a monosymptomatic delusional disorder, some patients have a well-organized train of thought and normal outward appearance and behavior, resulting in the conviction by those surrounding them that the subject has a true infestation. The delusion becomes apparent to the physician when the subject is approached.

DIFFERENTIAL DIAGNOSIS. Actual infestation and underlying skin or systemic disorders must be ruled out (see Box 104-2). Subsequently, the differential diagnosis of psychosis must be considered, distinguishing between the primary psychiatric conditions that manifest with delusions of infestation. True monosymptomatic hypochondriasis represents a form of delusional disorder characterized by a discrete, circumscribed delusional belief with possible associated hallucinations without clear syndromic changes in affect or personality.[7] On the contrary, patients with uni- or bipolar depressive psychosis will describe predominantly classic changes in mood, motivations, sleep, and appetite. Schizophrenic patients may have a history of previous psychotic episodes and often show deterioration in global functioning, impaired social relatedness, thought disorder, paranoid traits, and more bizarre and extensive delusions and hallucinations. In arriving at the diagnosis, it is critical that the clinician differentiate true delusions of parasitosis from formication, which involves the cutaneous sensation of crawling, biting and stinging, but lacks the fixed unshakeable conception that the skin sensations are induced by parasites.

PROGNOSIS AND CLINICAL COURSE. Although often regarded as chronic, unremitting, and difficult to treat, these patients have an improved recovery rate following appropriate pharmacologic therapy.

TREATMENT. The critical tenet of treatment is to keep the patient engaged. Empathetic listening, statements of concern, and examinations of the material that patients brings in help to establish rapport. Because these patients will frequently reject psychiatric referrals,[13] various authors have suggested means of increasing trust, thus paving the road towards psychiatric evaluation.[13,14] It is critical that the dermatologist avoids confronting the patient directly, and exhibits interest in the chief complaint patiently. After a few visits, the physician may carefully introduce the notion that the parasites may not be present, or that the patient is so distressed by this condition, that the prescription of psychotropic medication could be warranted. Targeted therapy is undertaken with antipsychotic medications (Fig. 104-1B).[15] Pimozide has been used historically as the drug of choice,[16,17] although it is now being replaced by atypical antipsychotics, which are associated with a more favorable side effect profile (eBox 104-2.1 in online edition).[14,18] The clinician needs to be aware of the need for monitoring for metabolic syndrome characterized by abdominal obesity, insulin resistance and impaired glucose tolerance, disturbance in lipid metabolism, hypertension, and weight gain.

BOX 104-2 DIFFERENTIAL DIAGNOSIS OF DELUSIONS OF PARASITOSIS

DERMATOLOGIC	SYSTEMIC	PSYCHIATRIC
Chronic folliculitis	Dementia	Cocaine use
Insect bite reactions	Malignancy (brain)	Amphetamine use
Dermatitis artefacta	Cerebrovascular disease	Psychotic-spectrum illness
Dermatitis para-artefacta	Vitamin B12 deficiency	Affective disorders

In many instances, the psychotropic medication needs to be introduced by the dermatologist, and only when the patient begins to respond favorably is it possible to obtain a referral to a psychiatrist.

FACTITIOUS DISORDERS

This group of syndromes is characterized by self-inflicted dermatological disease; they are mostly differentiated based on the degree of insight or consciousness of their behavior.

DERMATITIS ARTEFACTA

Dermatitis artefacta is a form of factitious disorder in which patients intentionally feign symptoms and produce signs of disease in an attempt to assume the patient role.[6] Unlike patients with malingering who engage in similar behavior for external or "secondary gain" (such as monetary reward or relief from occupational or other social responsibilities), the factitious patient seeks the "primary gain" of the emotional and psychological benefits that accrue to those who are "ill." Patients with borderline personality disorder also frequently exhibit self-mutilatory behavior[19] as do patients who consume cocaine or methamphetamine. However, their reasons for self-mutilation are variable, and are not usually consistent with efforts for primary or secondary gain. Occasionally, a psychologically disturbed adult will induce skin lesions in their children.[20]

EPIDEMIOLOGY. Predominating in females, the age of onset varies significantly from adolescence through adulthood.[21] Comorbid depressive and personality disorders may also be seen coexisting with this rare syndrome.[6]

CLINICAL FINDINGS. Although it has long been observed that patients with dermatitis artefacta may present with lesions in virtually all areas of the body that can mimic most dermatoses, some common elements may hint at this diagnosis. Lesions are often in areas readily accessible to the patient, and may have geometric patterns or angulated borders surrounded by completely healthy skin. Morphology is often bizarre and does not conform to typical presentations of known dermatoses (Figs. 104-2 and 104-3). Patients are often unable to provide a clear history of the initial appearance or evolution of the process, typically deny any role in the production of the lesions, and may self-induce the lesions in a dissociated state.[22] Characteristically, the histopathology is unrevealing.

DIFFERENTIAL DIAGNOSIS. As in all cases of factitious disease, the clinician must rule out possible disease entities that are consistent with the history and clinical findings. Unusual presentations of common illnesses and rare conditions must be entertained. However, exhaustive searches for primary skin pathology without supporting clinical evidence may compound the problem and actually perpetuate the patient's factitious behavior. Occlusive dressings (e.g., an Unna boot) or other means of preventing manipulation by the patient lead to healing of the lesions and are often helpful strategies in clarifying the diagnosis.

Figure 104-2 Dermatitis artefacta. Linear, sharply bordered ulcer.

TREATMENT. A supportive, nonconfrontational, empathic approach to the patient is indicated initially. Immediate confrontation regarding the suspicion that the patient's lesions are self-induced can be counterproductive in that the patient often flees from treatment. Frequent visits and symptomatic topical treatments are initially useful.[23] However, the clinician must be careful not to collude in the patient's abnormal illness behavior. Ultimately, the recognition of the patient's role in the production of the lesions must be broached. The goal is to establish a trusting relationship such that the patient will accept a psychiatric referral. Antidepressants (eBox 104-2.2 in online edition) and low-dose atypical antipsychotics (eBox 104-2.1 in online edition) have been reported to be useful adjunctive therapies.[24,25] In the case of inflicted lesions in a child protective services or equivalent agencies must be alerted immediately to safeguard the welfare of the child.

Figure 104-3 Dermatitis artefacta. Part of the nasal cartilage has been manually destroyed.

COURSE AND PROGNOSIS. These are fundamentally determined by the underlying psychopathology. In those patients with severely disturbed personalities, the recurrent self-defeating and destructive behaviors are likely to continue.

DERMATITIS PARA-ARTEFACTA SYNDROME

These are a group of factitious diseases, where problems of *impulse control* play a significant role; the patients are conscious or semiconscious of manipulating their skin, but are unable to stop this behavior.

Trichotillomania is an impulse control disorder,[7] characterized by repetitive pulling of hair, resulting in alopecia. Strict criteria also include a build up of tension before hair pulling or when resisting an urge to do so, pleasure or relief after pulling out the hair, and significant functional impairment and distress in the patient.

EPIDEMIOLOGY. Prevalence rates are estimated to be between 0.5% and 3.5% with a mean age of onset between 10 and 13 years. Despite its current classification, there are marked similarities with obsessive-compulsive disorder (OCD), which may have important treatment implications.[26–28] Comorbid psychiatric disorders are depression, anxiety, and OCD.

CLINICAL FINDINGS. Trichotillomania presents clinically with nonscarring alopecia, most commonly with hairs broken at different lengths, normal overall hair density (Fig. 104-4), and a negative pull test[29]; occasionally, repeated trauma may result in some scarring. Body areas involved typically include the scalp, eyelashes, eyebrows, and pubic hair, with a majority of patients pulling hair from more than one site. Rarely, this is followed by the ingestion of the hair, leading to the potentially dangerous complication of trichobezoar.[30] Awareness of the behavior is partial to complete in a vast majority of patients, and frequently occurs while patients are engaged in isolated, sedentary activities. Attempts to resist the behavior and to disguise its cosmetic sequelae are common. Typical histopathologic findings that may be helpful in confirming the diagnosis in questionable cases include catagen and telogen hairs, pigment casts, and traumatized hair bulbs without significant inflammation or scarring.[31] Perifollicular hemorrhage near the hair bulb is diagnostic.

Figure 104-4 Trichotillomania. Hairs broken off at different lengths.

DIFFERENTIAL DIAGNOSIS. When patients do not have awareness of pulling their own hair and present with alopecia, other etiologies of hair loss must be ruled out.

TREATMENT. Because of trichotillomania's similarities to OCD, the use of selective serotonin reuptake inhibitors (SSRIs) and clomipramine, as well as combinations with atypical antipsychotics have received much attention (eBoxes 104-2.1 and 104-2.2 in online edition).[28,32–37] However, psychopharmacologic data have been conflicting, and the best-designed studies have not demonstrated superiority of psychotropics over nonpharmacologic interventions. Nonpharmacologic treatment of trichotillomania relies heavily upon behavioral therapies, especially habit reversal, which entails engaging the patient in a behavior incompatible with hair pulling when the urge appears. The addition of cognitive-behavioral or insight-oriented psychotherapy have good results; hypnotherapy may also be very useful, particularly in children.[38]

PROGNOSIS AND CLINICAL COURSE. Trichotillomania is a chronic disorder and data on long-term success of pharmacologic and psychotherapeutic interventions are inconclusive. Though children typically have a benign course, adult-onset trichotillomania is often associated with other psychiatric conditions and sustained improvement has yet to be shown convincingly.

SKIN PICKING (NEUROTIC EXCORIATIONS)

This is also a condition in which patients induce skin lesions through repetitive, compulsive excoriation of their skin. However, unlike patients with dermatitis artefacta syndrome, these patients admit their role in the production of the lesions.

EPIDEMIOLOGY. This is the most common psycho-cutaneous disorder, reported in up to 2% of dermatology clinic patients[39] with a predominance in middle-aged females, and are frequently associated with compulsivity–impulsivity spectrum and mood disorders.[40,41]

Figure 104-5 Dermatitis para-artefacta: skin picking on the breast of a 16-year-old girl.

CLINICAL FINDINGS. Patients with skin picking often describe significant itch leading to persistent scratching, which is frequently antedated by considerable psychological stressors. The development of this disorder has also been noted to be associated with the marked limitation in activity seen in illness or senescence.[42] The repeated excoriation can lead to the development of an "itch–scratch cycle," perpetuating the behavior. Patients present with multiple excoriations in various stages of evolution and healing, with postinflammatory hyperpigmentation and frequent scarring (Fig. 104-5). The distribution of the lesions reflects their self-inflicted nature with most being on the extensor surfaces of the extremities, upper back, and face, sparing unreachable areas such as the central mid-upper back. Frequently, patients develop excoriations overlying preexisting dermatosis, such as folliculitis and acne; excessive manipulation of the latter leads to the condition known as "acne excorieé". These patients often spend many hours each day in front of the mirror injuring the skin with instruments such as tweezers. The trauma often results in temporary relief of anxiety. Prurigo nodularis can be considered an extreme variant of this entity, characterized by severely pruritic nodules varying from a few millimeters to 1–2 cm in diameter, preferentially located on the extremities (Fig. 104-6) (see also Chapter 15).

DIFFERENTIAL DIAGNOSIS. The clinician must evaluate the patient for causes of pruritus (see Chapter 103) and rule out possible internal diseases including neoplasms, in particular, lymphomas. The differential for the underlying psychiatric disorder,[43] if present, must include depressive and anxiety disorders and, more rarely, excoriations secondary to delusions of parasitosis.

Figure 104-6 Prurigo nodularis.

TREATMENT. Work-up for pruritus should be instituted in those patients that present significant itch. In the absence of organic cause, these patients may improve with phototherapy. Additional treatment should be directed at underlying psychopathology when identifiable. Antidepressants, helpful in both depressive and anxiety disorders including OCD,[44] are very useful. Subsequent addition of low-dose atypical antipsychotics has been found effective. Supportive psychotherapeutic approaches and behavioral interventions as those used to treat self-injurious behaviors in Tourette's syndrome may be helpful.[45]

COURSE AND PROGNOSIS. This can be a chronic condition whose prognosis depends on the underlying psychiatric illness.[46] With appropriate therapy, patients with affective and anxiety disorders may have excellent outcomes, with a symptom-free, normally functioning state.

MALINGERING

Malingerers intentionally induce skin lesions in order to obtain secondary gains, often workman's compensation or disability. Since there is no patient motivation for therapy, treatment is not possible.[6,47]

SOMATOFORM DISORDERS

This is a group of heterogeneous disorders where the patients complain of a variety of symptoms that cannot

be objectively verified by the physician, but they share similar psychiatric underlying problematics.

BODY DYSMORPHIC DISORDER

BDD is a chronic condition characterized by an excessive preoccupation or concern with a presumed defect in physical appearance despite normal or minimally objective anomalous findings.[48] Also known as *dysmorphophobia*,[49,50] this is a psychological experience that also results in functional impairment, poor quality of life, and low treatment response.

The nosological classification of BDD revolves around the intensity with which patients hold on to their abnormal beliefs. Those with unshakeable convictions are currently diagnosed as having a delusional disorder.[7] However, there appears to be a continuum of intensity and insight from preoccupations, through overvalued ideas to clear delusions.[51] Those patients that retain a certain degree of insight evidence characteristics more similar to the obsessive–compulsive spectrum of disorders,[51,52] a finding that has significant potential treatment implications. BDD patients have obsessive thoughts about their "flaws" and engage in compulsive behaviors related to how they perceive their appearance, similar to behavior seen in obsessive–compulsive disorder.[53]

EPIDEMIOLOGY. The prevalence of BDD, is estimated to be from 0.7% to 2.4% in the general population to 12% in dermatology clinic patients, often in association with mood disorders such as major depressive disorder (MDD) (37%), social phobia (33%) and OCD (26%).[54,55] Improvement of MDD and BDD seems to be closely related, with the improvement of each disorder significantly predicting the remission of the other. Improvement of OCD significantly predicts remission of BDD, but not vice versa. Approximately 80% of patients report a history of suicidal ideation and 24%–28% have attempted suicide.[56–58]

CLINICAL FINDINGS. Patients present with intensely articulated distress about various body parts. Most patients also develop ideas of reference in which they think or are convinced that others notice and comment upon the presumed defect. Time-consuming, compulsive behaviors often accompany the worrisome thoughts, including repeated examination in mirrors, covering up defects, and asking others for reassurance. Consultations with other physicians and past operations on the perceived defect are common. Marked restriction in social and occupational functioning is seen in up to 98% of individuals, and 30% of patients have been described as housebound.[59] Thoughts and attempts of suicide are frequent. Thus, current or past suicidal ideation should be routinely assessed by the practitioner. Particular monitoring may be needed with younger patients as antidepressant action may increase impulsivity and likelihood of suicidal attempts.[58]

TREATMENT. Many patients with BDD will seek dermatologic or surgical treatment over the course of their illness. Evidence suggests that if patients receive such treatment they do not improve, are usually disappointed with the results, and may even experience an exacerbation of their symptoms. It is strongly recommended that cosmetic lines of treatment be avoided. BDD is a severe and complex disorder that often requires multimodal treatment using cognitive behavioral therapy (including exposure response prevention) and medication.[60,61]

Pharmacologic trials show a good response to SSRIs (see eBox 104-2.2 in online edition), improving insight while decreasing distress, compulsions, and frequency and intensity of obsessions about perceived defects. Interestingly, SSRIs appear equally effective for delusional as well as nondelusional patients. Efficacy usually requires 12–16 weeks of relatively high dosages. Issues of compliance require close monitoring, since they are a frequent cause of treatment failure. A significant proportion of patients who fail one adequate SSRI trial respond favorably to a second SSRI, suggesting that serial trials of similarly acting agents should be administered in initially refractory cases. Lack of clear success has been noted with other agents such as antipsychotics, tricyclic antidepressants (TSA) (other than clomipramine), benzodiazepines, and anticonvulsants.[62–67] Similar to patients with OCD, cognitive-behavioral therapy is strongly recommended.

PROGNOSIS AND CLINICAL COURSE. BDD is a chronic illness without clear evidence for spontaneous remission without treatment. Pharmacotherapy with appropriate medications may lead to improvement in a considerable number of patients. However, effective doses of SSRIs are usually beyond those approved by the FDA; the data also indicate high recurrence rates with discontinuation of treatment.[64] Thus patients may require long-term treatment, including adjunctive insight oriented psychotherapy.[57,60]

SOMATIZATION DISORDER

These patients present to the physician with multiple significant physical complaints and the belief that their symptoms are due mostly to exposure to environmental causes. This disorder includes Gulf War syndrome, multiple chemical sensitivity syndrome, amalgam related syndrome, chemical or detergent allergies, "sick building syndrome," food intolerances, and "candida hypersensitivity syndrome," among many others. There is no medical proof of a direct causal relationship between exposure and the extent of complaints. The widespread dissemination of information through the Internet as well as the insistence of self-proclaimed experts reinforces the patients' misinterpreted beliefs.

HYPOCHONDRIACAL DISORDERS

Typically these patients express the conviction or fear of suffering from a serious illness (such as AIDS, venereal diseases or cancer) despite the lack of medical evidence.

CUTANEOUS DYSESTHESIAS (ATYPICAL CHRONIC PAIN/BURN SYNDROME)

Occasionally, patients will present to dermatologists with complaints of burning, pain, or dysesthesias in the skin or mucus membranes for which no identifiable pathology can be found. This can be a frustrating situation for patient and clinician alike. A psychiatric approach to these patients may offer a means of understanding the complex factors underlying this syndrome, such as comorbid affective disorders, personality vulnerabilities, behavioral problems, and life circumstances that may perpetuate the pain cycle and maintain the patient in an illness role.

There is a significantly increased rate of depression in patients with chronic pain syndromes and a clear relationship between lifetime depression and the development of medically unexplained symptoms, including pain.[68] Depression not only worsens the experience of pain by psychologically magnifying negative perceptions, but may also interfere with the function of descending monoaminergic neurons that dampen nociceptive transmission.[69,70] Other complicating factors include anxiety, which is also commonly seen in patients with chronic pain.[68] Personality disorders influence all aspects of patients' lives and may make the burden of a chronic condition more challenging. At times, family or social environments may unwittingly play a role in undermining the chronic pain patient's rehabilitation by rewarding illness behaviors with well-meaning, yet oversolicitous, attention. Pain states can further be complicated if the patient develops an inappropriate pattern of using prescribed analgesics. For all of these reasons, the best course of action for patients presenting with poorly explained chronic pain is to refer them to a multidisciplinary pain center for thorough evaluation and treatment. The presence of burn syndrome may occasionally respond to the administration of gabapentin (see eBox 104-2.2 in online edition). Milnacipran, an SNRI approved for fibromyalgia (eBox 104-2.2 in online edition), also may be effective for chronic pain/burn/dysesthesia syndrome. Extreme forms of chronic dysesthesia can resolve with the administration of antipsychotic medication, suggesting that it represents a form of delusion.

PSYCHOGENIC PRURITUS

Psychogenic pruritus and itch in general are discussed in Chapter 103.

OBSESSIVE-COMPULSIVE DISORDERS (OCD)

These include dermatological findings that are the result of disorders such as compulsive washing (xerosis, eczema) or rubbing (lichen simplex chronicus). OCD is also related to BDD as well as some factitious conditions such as trichotillomania or skin picking (see above).

PSYCHOTROPIC MEDICATIONS USED IN DERMATOLOGY

Dermatologists who elect to treat psychocutaneous disorders routinely use a number of different classes of psychotropic medications. Knowledge of the drugs and their actions, indications, side effects, therapeutic doses, and potential drug interactions is critical.[71] These drugs are classified according to their clinical utility (e.g., antidepressants or antipsychotics) and further identified by their chemical structure and/or mechanism of action. All of the drugs discussed in this section exert their clinical effects through modulation of neurotransmitter function in the CNS by altering presynaptic reuptake of the transmitters, blocking their pre- and/or postsynaptic receptor binding, stimulating those receptors, or some combination thereof. The most appropriately used in each of the following three major classes are discussed: antipsychotics, antidepressants, and anxiolytics.

For a detailed discussion of these drugs, their side effects, and precautions, see online edition of the book.

NONPHARMACOLOGIC TREATMENTS FOR PSYCHOCUTANEOUS DISORDERS

The dermatologist should request a consultation with a psychiatrist or a liaison clinic during the treatment of patients with psychocutaneous disorders as soon as it is amenable to the patient. Although dermatologists are becoming more comfortable with the use of certain psychotropic medications, they generally do not have the time or the training to use effectively nonpharmacologic modalities. Therefore, it is sufficient that the practicing dermatologist be aware that a variety of adjunctive, stress-reducing approaches are available, including hypnosis, biofeedback, progressive muscle relaxation, and psychotherapy (Box 104-3). Although no modality has been demonstrated to be superior to another, certain types of therapies may be more effective for a given condition. Diagnosis should drive choice of therapy.

BOX 104-3 NONPHARMACOLOGICAL TREATMENTS

- Cognitive-behavioral therapy
- Insight-oriented psychotherapy
- Hypnosis
- Mindfulness-based cognitive therapy
- Biofeedback
- Family therapy

Chapter 105 :: Cutaneous Manifestations of Drug Abuse

:: Haley Naik & Richard Allen Johnson

MUCOCUTANEOUS MANIFESTATIONS OF DRUG ABUSE AT A GLANCE

- The morphology and arrangement of skin lesions can identify persons with former and current drug dependency.
- Skin lesions associated with drug use can be related directly to the drug itself, mode of drug delivery, and/or adulterants or infectious agents mixed with the drug.
- Drug addiction-related bacterial infections predominantly involve the skin and soft tissue. Culture-guided antibiotic therapy is essential because infection with unusual organisms, antibiotic-resistant strains, and polymicrobes is more common.
- Behavioral effects of drug use can lead to the transmission of sexually transmitted diseases and blood-borne pathogens including *Treponema pallidum*, hepatitis B virus, hepatitis C virus, human immunodeficiency virus, and human T-lymphotropic viruses 1 and 2.

INTRODUCTION

Drug abuse and addiction can be suspected or diagnosed on the basis of mucosal and cutaneous findings. The administration of drugs may cause cutaneous stigmata and eruptions predominantly through local or systemic, toxic or hypersensitivity-induced effects as a result of the drug itself, adulterants, infectious agents, or the mode of drug delivery.

DEFINITIONS

Illicit drug use is a maladaptive pattern involving self-administration of prescribed or recreational drugs. *Chipping* is a lay term used to describe a pattern of drug use in which the user is not physically dependent, but rather sustains "controlled use" of a drug. A certain percentage of users will progress to *drug dependence*, a physical and/or psychological need for the effects of a chemical in order to avoid withdrawal symptoms associated with abstinence (Box 105-1). Drug dependence often leads to *drug abuse*, an intense desire to recurrently obtain increasing amounts of one or more chemical substances to the exclusion of all other activities, resulting in

BOX 105-1 CRITERIA FOR DRUG DEPENDENCE

The presence of three or more of the following, occurring any time in the same 12-month period:

- Tolerance
- Withdrawal symptoms
- Sustained intent or unsuccessful efforts to abate drug use
- Administration of drug in higher doses and longer duration than initially intended
- Significant time devoted to obtaining the drug or recovering from its effects
- Relinquishment or reduction of social, occupational or recreational activities because of drug abuse
- Continued drug use despite awareness of the presence of a persistent or recurrent physical or psychological problem caused or exacerbated by the drug

Adapted from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders IV-TR*, 4th edition. Washington DC, American Psychiatric Press, 2000.

BOX 105-2 CRITERIA FOR DRUG ABUSE

The presence of one or more of the following, occurring within a 12-month period:

- Recurrent substance use resulting in a failure to fulfill major role obligations at work school, or home
- Recurrent substance use in physically hazardous situations
- Recurrent substance-related legal problems
- Continued substance use despite having persistent or recurrent substance-related social or interpersonal problems

Adapted from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders IV-TR*, 4th edition. Washington DC, American Psychiatric Press, 2000.

clinically significant physical, emotional or social distress (Box 105-2). *Tolerance* defines a physiologic state in which progressive increases in the dose of a drug are needed to achieve the effects previously experienced at smaller doses. Some drugs chiefly induce physical dependence, while cause predominantly psychological dependence.[1]

The National Institute of Drug Abuse (NIDA) (http://www.drugabuse.gov/)[2] considers the following agents to be drugs of abuse in the United States:

- Alcohol
- Club drugs
- Cocaine
- Heroin
- Inhalants
- Lysergic acid diethylamide (LSD)
- Marijuana
- 3,4-Methylenedioxymethamphetamine (MDMA, Ecstasy)
- Methamphetamine
- Phencyclidine (PCP)
- Prescription medications
- Steroids (anabolic)
- Tobacco

Betel is widely used in South Asia, Southeast Asia and the South Pacific.

EPIDEMIOLOGY

In 2004, the United Nations' World Drug Report estimated that between 3% and 5% of the global population used illicit drugs.[3] In 2008, the National Survey on Drug Use and Health in the United States estimated that:

- 20.1 million Americans aged 12 or older (8% of that population) were currently using illicit drugs including marijuana/hashish, cocaine, crack, heroin, hallucinogens, inhalants or prescription-type psychotherapeutics.
- Marijuana was the most commonly used illicit drug (15.2 million past month users).
- The most commonly injected drugs were heroin and cocaine.
- Almost 2 million current cocaine users, comprising 0.7% of the population, were estimated.[4]
- The actual number of individuals who use heroin is difficult to determine because there has been a growing tendency to sniff, snort or smoke rather than to inject heroin intravenously or subcutaneously.
- An estimated 70.9 million Americans (28.4%) aged 12 or older were current users of tobacco in any form.
- Of Americans aged 12 and older, 51.6% had consumed alcohol at least once in the 30 days prior to being surveyed; 23.3% reported drinking heavily (>5 drinks on >5 occasions).

The drugs most commonly associated with emergency department visits in 2001 included cocaine, marijuana, benzodiazepines and heroin, in that order (Fig. 105-1).

PATHOGENESIS

Studies in concordant twins have shown a strong influence of genetic inheritance on the susceptibility to drug use.[5] The potential of a drug to cause addiction varies. The processes by which genes regulate physical reactions to addictive drugs have not been clearly elucidated. Repeated exposure to cocaine causes a change at the level of gene expression that leads to altered levels of the specific brain protein called *cyclin-dependent kinase-5*. This protein regulates the action of dopamine, which potentiates the euphoric effects of cocaine and other drugs.[6] Narcotics disable the neurons that normally inhibit the release of dopamine while amphetamines and cocaine increase dopamine signaling, either by directly stimulating its release, or by blocking its absorption. Environmental factors such as history of sexual abuse during childhood, severe family dysfunction with drug abusing, detached or mentally ill parents, poor social skills, and drug-using peers are also clearly important.

The mechanisms of addiction, tolerance and dependence are complex. Addictive drugs flood the synapses of the mesolimbic system, especially the nucleus accumbens, with excessive amounts of dopamine, augmenting the hedonic tone and producing a euphoric state. The subsequent pleasurable reactions of the frontal cortex, amygdala, and hippocampus are exaggerated. The association of drug use and euphoria in these brain areas is reinforced with each exposure until the user no longer controls behavior, at which point addiction has resulted.[7] Chronic users have sustained activation of the cAMP response element-binding (CREB) protein, a trigger for the production of dynorphin and other proteins that shut off dopamine release, preventing the individual from finding pleasure in usually enjoyable activities and requiring subsequent fixes with higher doses of drug to overcome the effects of

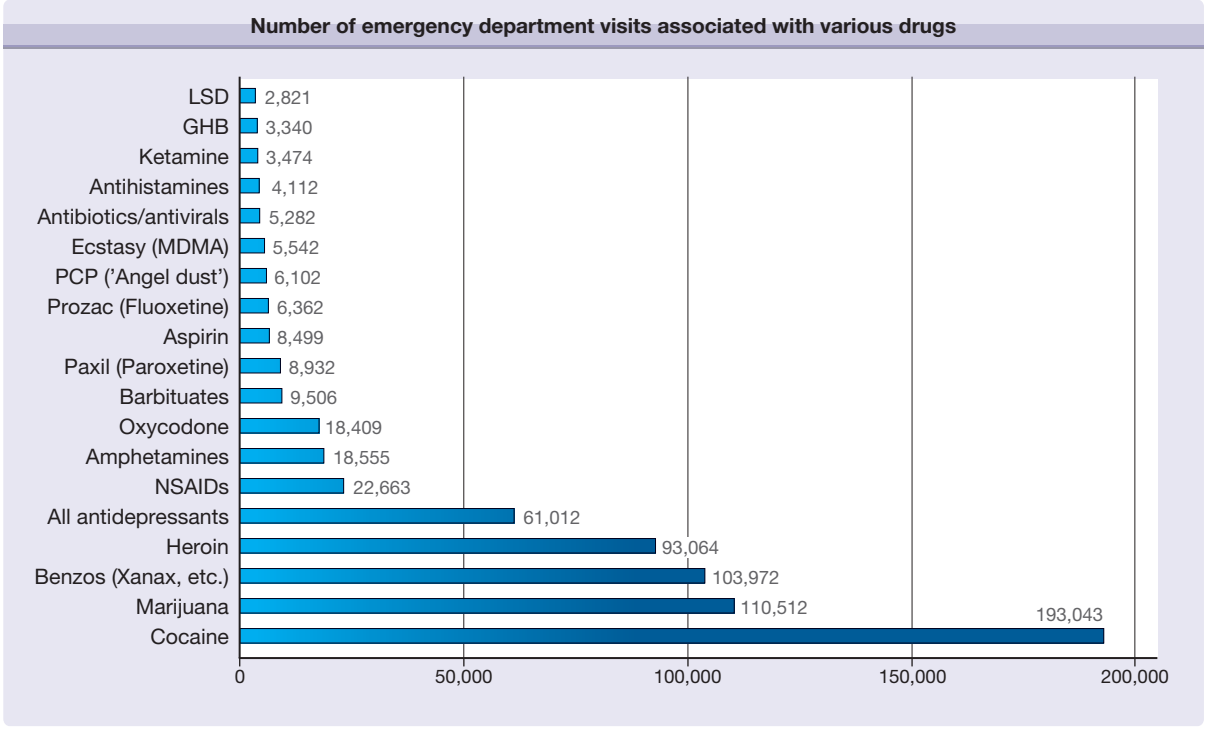

Figure 105-1 Number of emergency department visits associated with various drugs. Cocaine, marijuana and benzodiazepines were the most common drugs associated with emergency department visits in 2001. Data from the United States Substance Abuse and Mental Health Services Administration, 2001, http://thedea.org/statistics.html.[158]

tolerance. Addictive drugs also inhibit or excite neuronal activity in various areas of the nervous system. To compensate for these alterations, neuroadaptation develops with either formation of new neuroreceptor sites or diminished synthesis and sensitivity of neurotransmitters and neuroreceptor sites. Discontinuation of the drug reverses the neuroadaptation process and results in an exaggerated neural response that produces withdrawal symptoms.

CLINICAL FINDINGS ASSOCIATED WITH COMMONLY USED DRUGS

ALCOHOL

Ethyl alcohol, or ethanol, is the intoxicating ingredient found in alcoholic beverages. It is a central nervous system depressant that impairs brain function and motor skills and is rapidly absorbed from the stomach and small intestine into the bloodstream. Heavy use can increase the risk of liver disease, stroke and certain cancers.

Direct liver toxicity of alcohol can cause hepatomegaly, jaundice, shrunken liver in the setting of cirrhosis, and hypoalbuminemia leading to Muehrcke lines and Terry nails (see Chapter 89). Hyperestrogenemia can lead to gynecomastia, palmar erythema, spider angiomata, and testicular atrophy. Portal hypertension secondary to alcohol-induced liver cirrhosis can lead to an enlarged spleen, ascites, variceal bleeding, hemorrhoidal bleeding and caput medusae. Dupuytren contractures due to fibroblastic proliferation and disorderly collagen deposition may be seen in 66% of alcohol abusers. Asterixis and confusion are seen in patients with hepatic encephalopathy. Alcohol withdrawal delirium, also known as delirium tremens, is characterized by tachycardia, hypertension, body temperature elevation and delirium. Ataxia, confusion and lateral gaze palsy are indications of Wernicke encephalopathy. Wernicke encephalopathy followed by anterograde and retrograde amnesia along with confabulation characterize Korsakoff syndrome.

CLUB DRUGS

Club drugs include γ-hydroxybutyric acid (GHB, date rape drug), flunitrazepam (Rohypnol®, roofies), ketamine, MDMA, and LSD (Table 105-1). These drugs tend to be used by teenagers and young adults in social settings. In 2008, NIDA showed that among 12th graders, 1.3% had abused flunitrazepam, 1.2% had abused GHB and 1.5% had abused ketamine at least once in the year prior to their being surveyed.[8] GHB is sedating and can cause coma and seizures. It is being used increasingly by bodybuilders, who believe that it helps to metabolize fat and build muscle. Flunitrazepam is also sedating and can incapacitate users and cause amnesia; when combined with alcohol, this drug can be lethal. Ketamine distorts perception and produces feelings of detachment from the environment and self.

TABLE 105-1
Drugs: Street Names and Routes of Administration

Drug	Street Names[a]	Route of Administration
Alcohol	Booze Brew Juice	Ingestion
Anabolic steroids	Gym candy Juice Pumpers Stackers	Ingestion Injection
Betel	Bunga (Tagalog) Cau (Vietnamese) Jambe (Javanese) Kunya (Burmese) Paan (Sanskrit) Supadi (Nepali) Shupari (Bengali)	Chewed
Tobacco	Bogie, cancer stick, cigs (cigarettes) Chaw, snuff, chew (smokeless tobacco)	Chewed Smoke inhalation
Club Drugs		
GHB	Fantasy G Georgia Home Boy Liquid ecstasy Soap	Ingestion
Flunitrazepam	Roofies	Ingestion
Ketamine	Jet Special K Vitamin K	Ingestion
Cocaine	Blow Coke Crack Flake Snow	Nasal inhalation Injection Transdermal application
Heroin	H Junk Ska Smack	Injection Smoke inhalation
Inhalants	Poppers Snappers Whippets	Inhalation
Club Drugs

COCAINE

Cocaine (benzoylmethylecgonine) is an alkaloid extracted from the leaves of the coca plant *Erythroxylon coca*.[9–15] It is a powerful sympathomimetic, vasoconstrictor, local anesthetic, and stimulant. Cocaine hydrochloride is a powder that can be can be nasally inhaled or injected intravenously or subcutaneously, also known as "skin popping" (Fig. 105-2). Crack cocaine or "crack," the freebase rock crystal form of cocaine hydrochloride, is smoked (Table 105-1). *Freebase* refers to the pure basic form of an amine, as

Figure 105-2 Skin popping scars. Multiple white angular atrophic scars on the dorsal forearms and hands.

opposed to its salt form. The amine is usually a natural alkaloid product.

Cocaine can produce intense vasoconstrictive effects by directly stimulating the central nervous system and increasing peripheral catecholamines. The vasospastic action of cocaine is greatest at one hour after use and can be associated with ischemia, infarction and hemorrhagic injuries of most organ systems including the skin.[16–18] The ischemic effects of cocaine in the skin can lead to acute multifocal skin necrosis,[19] chronic skin ulcers,[20] cutaneous fibrosis,[21] blackened hyperkeratotic "crack hands"[22] and claw-like "parrot beak" curvature of the nails. These changes are commonly found in association with pernio and some atrophy of the distal portions of the digital pulp secondary to ischemia. At skin-popping sites, there may be central pallor surrounded by ecchymosis due to the vasoconstrictive properties of cocaine acting locally at the injection site with hemorrhage occurring in the surrounding tissue. *Skin popping* is a method of drug administration whereby a substance is injected subcutaneously or intradermally, but not intravenously and not typically intramuscularly. Individuals with vasomotor instability are more susceptible to these types of reactions.[23]

Inadvertent or deliberate direct intraarterial injection of cocaine can cause severe tissue ischemia and necrosis via direct vasoconstriction. Individuals experience an initial intense burning pain, followed by cyanosis and marked edema. Compartment syndrome may also result. In the most severe cases necrosis leads to amputation.[24,25] Skin popping also puts one at risk for developing secondary amyloidosis.

Cocaine-induced vasospasm may cause major internal organ injury including acute myocardial ischemia, cerebrovascular accidents, renal infarction[26] and splenic infarction.[18,27] Vasoconstriction of mesenteric vessels and the direct toxic effect of cocaine on gastrointestinal mucosa can result in acute abdominal crises (known as *crack belly*) secondary to perforations, intestinal ischemia and infarction.[28,29]

Various vasculitic and vasculopathic processes have been associated with cocaine use including pseudovasculitis,[30] urticarial vasculitis,[31] Churg–Strauss vasculitis,[32] Raynaud phenomenon,[33,34] Henoch–Schonlein purpura, necrotizing vasculitis[35,36] and Buerger disease (see Chapters 163, 164, and 173).[37,38]

The local anesthetic properties of cocaine make it difficult for individuals to feel traumatic injury. This leaves users prone to repetitive trauma from the irritant properties of the drug itself and implements of drug delivery, thus exposing them to an increased risk of infection.[39] Missing a vein and injecting into the surrounding tissue creates a niche environment in which bacteria can thrive.[40] Repeated needlesticks increase the likelihood of cutaneous infection and transmission of blood-borne viruses.[41]

Mucosal manifestations of ischemia secondary to cocaine inhalation or smoking include dental caries,[42] gingival recession,[43] oral blisters[44] and nasal and palatal perforation.[45] Insufflating (snorting) cocaine may lead to recurrent epistaxis, intranasal crusting, rhinitis and chronic sinusitis.[42,46] Inhalation utensils themselves can act as vectors for viruses and may induce "snorter's warts." Nasal septum perforation reduces nasal support and results in a broad, flat nose or "saddle nose deformity."[46–49] Nasal septum perforation typically occurs prior to development of palatal perforation. Cocaine burns of the upper airway are associated with hoarseness, dysphonia, odynophagia, dysphagia and stridor.[23,26,50–53] Crack cocaine smoke has a direct toxic effect on the corneal epithelium of the eye. Repeated exposure to the alkaloid smoke may cause an irritant effect leading to excessive eye rubbing and subsequent infectious complications, and chemical burns.[51]

Drug reactions including acute generalized exanthematous pustulosis[54] and Stevens–Johnson syndrome [55] have also been reported.

The stimulant properties of cocaine are associated with increased metabolism and dramatic weight loss.[56] Psychiatric conditions, most commonly delusions of parasitosis and subsequent formication are experienced approximately 20% of the time in cocaine users (also known as *coke bugs*)[57] (see Chapter 104). Recent reports have emerged of febrile agranulocytosis and often vasculitis with prominent involvement of the ear lobes secondary to cocaine adulterated with levamisole, an anthelmintic medication used in veterinary medicine to control parasites in livestock.[58,59]

HEROIN

Natural and semisynthetic derivatives of the opium poppy are known as opiates. Biologically natural opiates include morphine and codeine, while semisynthetic opiates such as heroin and hydromorphone are derived from biologically active opiates. Diacetylmorphine, or heroin, crosses the blood–brain barrier and binds opioid receptors in the brain, resulting in its euphoric, analgesic and anxiolytic effects. Heroin

is the most common parenterally injected illicit drug, either by intravenous or subcutaneous (*skin popping*) administration. Heroin may also be inhaled. With a peak "rush" at 7–8 seconds, it is the fastest-acting and via smoking most potent opiate, accounting for up to 90% of opiate use in the United States.

Scarring is the primary cutaneous stigma of injection drug use. The antecubital fossa is the usual starting point of intravenous drug use, followed sequentially by the upper arms, hands, neck, feet, legs, groin and digits.[60] Linear cord-like scars along a vascular distribution (*track-marks*), are formed after repeated injections along a superficial vein, resulting in venous thrombosis and subsequent fibrosis.[61] (Fig. 105-3) Skin popping scars are irregular round hypopigmented or hyperpigmented, atrophic or hypertrophic scars or keloids.[62] (see Fig. 105-2) *Soot tattoos* or *shooting tattoos* result from soot deposition or the introduction of foreign materials in the dermis after "cooking" of the drug and/or flaming of needles (Fig. 105-4).[63]

Diluting or "cutting" heroin to retail "street strength" is a common practice. Common diluents for white powder heroin include quinine, lactose, lidocaine, caffeine, lemon juice, inositol, dextrose, sucrose, procaine, starch, magnesium silicate and mannitol.[64] Diluents may cause lymphatic destruction, foreign body granulomas, cutaneous nodules, ulcerations, panniculitis and dermal sclerosis secondary to irritation and dermal inflammatory processes (Fig. 105-5).[65–67] The subsequent vascularized granulation tissue in and around chronic ulcers may be used as a site for drug injection.[20] (see eFig. 105-5.1 in online edition) *Black tar heroin* is a dark, gummy form of heroin that is less refined and cheaper than the white powder variant. It is mixed with a variety of diluents including dextrose, burnt cornstarch, instant coffee and dirt.[68] The mixture may

Figure 105-3 Track marks formed after repeated intravenous drug injections. (**A**) Inflammatory tracks of the dorsal hand, (**B**) inflammatory tracks with associated ulcers, nodules and abscesses on the hands and forearms, and (**C**) fibrotic tracks on the dorsal forearms.

Figure 105-4 "Soot tattoo." Soot tattoos result from the deposition of soot and other foreign materials in the dermis. Foreign materials may be introduced via adulterated drugs and/or introduction of needles with adherent soot after flaming for sterilization.

also contain dust and pathogens introduced during the process of manufacturing or storage.[64,66] Irritant substances can also cause sterile chemical cellulites and abscesses.

Cutaneous infections are common in injection drug users (Table 105-1). Skin popping and black tar heroin use are associated with cutaneous necrosis and necrotizing ulcers.[69–72] An increase in *Clostridial* infections including wound botulism due to *Clostridium botulinum*, tetanus due to *Clostridium tetani*, and rapidly progressive myonecrosis with a fulminant shock syndrome due to *Clostridium sordellii* have been observed with the use of black tar heroin in California.[73–76]

Fungi have been cultured from confiscated heroin specimens.[77] Systemic candidosis characterized by painful nodules and pustules on the scalp and hair-bearing areas, chorioretinitis or uveitis, and costochondritis has been described in individuals injecting brown heroin diluted with lemon juice.[78]

Figure 105-5 Foreign body response and cellulitis. Angular ulcerations, firm erythematous nodules, and warm tender induration at the site of subcutaneous and intravenous injection of adulterated heroin.

Inhaling smoke and then exhaling it into another individual's mouth (known as *shotgunning*) is associated with efficient transmission of respiratory pathogens. [79]

Opiates induce histamine release that results in subsequent pruritus that starts almost immediately after heroin injection and can last 10 minutes to 24 hours.[80] Urticaria, severe angioedema and bronchospasm have also been reported with heroin use.[80]

Rare morbilliform eruptions, fixed drug eruptions and a case of toxic epidermal necrolysis have also been reported.[62,64,81] Adulterants are thought to be responsible for most of these reactions.

Secondary systemic amyloidosis is an important cause of renal disease in heroin users. Its pathogenesis is thought to be associated with chronic antigenic stimulation and prolonged inflammation secondary to cutaneous infections. Patients were observed to progress to end stage renal disease over several months to 3 years.[82]

3,4-METHYLENEDIOXYMETHAMPHETAMINE

3,4-methylenedioxymethamphetamine (MDMA, ecstasy), along with lysergic acid diethylamide (LSD) and hallucinogenic mushrooms, is one of the most commonly used illicit hallucinogens (Table 105-1). More than 7 million persons have tried MDMA at least once in their lifetime. MDMA is a synthetic stimulant with psychoactive properties that acts both by causing a massive synaptic release of serotonin, and to a lesser extent dopamine and norepinephrine, as well as inhibiting the reuptake transporters within the synapse. Its short-term effects include inducing euphoria, a sense of enhanced intimacy with others, and diminished anxiety and depression. Adverse health effects can include nausea, chills, sweating, teeth clenching, muscle cramping, and blurred vision. MDMA is usually ingested, but may be injected or inhaled with effects lasting for 3–6 hours. It is frequently used in combination with alcohol, cannabis, amphetamine or cocaine, resulting in unpredictable effects.[83]

MDMA is associated with xerostomia and is therefore often coupled with soft drinks, which may lead to dental caries. The neurotransmitter release associated with MDMA induces bruxism, trismus and teeth grinding that can wear down tooth enamel. Direct application of MDMA to the gums may cause necrotizing gingivitis and widespread perioral and intraoral swelling. MDMA can also interfere with systemic temperature regulation that can, rarely, be lethal.

METHAMPHETAMINE

Methamphetamine is a very addictive synthetic stimulant that affects the brain and central nervous system through the release of dopamine, norepinephrine, and serotonin. By concurrently blocking reuptake of these neurotransmitters, sensations of euphoria, lowered inhibitions, feelings of invincibility, and hyperactivity are produced.[84] Metamphetamine a white, odorless,

bitter-tasting powder that can be ingested orally, snorted or injected. It may also be smoked in its rock "crystal" form.[85] Short-term effects include feelings of euphoria, decreased fatigue associated with difficult life situations, headache, difficulty concentrating, diminished appetite, abdominal pain, vomiting, diarrhea, disordered sleep, paranoid or aggressive behavior, and psychosis. Long-term use of methamphetamine use is associated with anorexia, neurotoxicity, neurodegeneration, and clinical depression that may lead to homicidal and suicidal ideation and action.[85]

An increased rate of skin and soft tissue infections have been reported in methamphetamine users, including increased rates of methicillin-resistant *Staphylococcus aureus* (MRSA) infections in noninjection drug users. Methamphetamine use is associated with formication that can lead to subsequent skin picking, skin breakdown, and portals of infection (see eFig. 105-5.2 in online edition). Use of methamphetamine and other sexually stimulating drugs can also increase direct skin-to-skin sexual contact and transmission of MRSA[86] (Table 105-1).

Methamphetamine users are at risk for developing *meth mouth*, or oral decay characterized by poor oral hygiene, xerostomia and rampant caries typically on the smooth surfaces of teeth, and excessive tooth wear.[87] Methamphetamine use has also been associated with psychosis and subsequent self-injurious behavior including genital mutilation.[88]

SEDATIVES

Sedatives as a class of drugs includes benzodiazepines, hydroxybutyrate, flunitrazepam and cannabis. Cutaneous manifestations and reactions to this group of drugs is quite rare, however drug reactions have been rarely associated with benzodiazepines, including type IV morbilliform drug hypersensitivity eruptions,[89] acute generalized exanthematous pustulosis to tetrazepam[90] and erythema multiforme to clonazepam.[91]

ANABOLIC STEROIDS

Most anabolic steroids are synthetic substances similar to the male sex hormone testosterone. They may be ingested or injected, and are used especially by athletes to build muscle and enhance athletic performance. In 2000, approximately 3.6% of male and 0.9% of female twelfth graders in the United States had used anabolic steroids. Their abuse is most commonly associated with acne vulgaris, striae formation and alterations in hair growth.

Anabolic steroids induce sebaceous gland enlargement and the development of comedones through abnormal follicular keratinization.[92,93] Steroid-associated acne is characteristically distributed on the face, shoulders, chest and back.[93] It can progress to acne conglobata and fulminans secondary to the brisk immune response to *Propionibacterium acnes* in individuals who have never even had acne.[94] Steroid-associated acne does not always respond to routine therapy and may persist for weeks to months following discontinuation of the drugs (see Chapter 80).[93,95]

Anabolic steroid use is also associated with alterations in hair growth, including hirsutism and androgenic alopecia, both of which are often more noticeable in women and may not be reversible with discontinuation of the drug.[93,96,97] Males can develop testicular atrophy, gynecomastia and infertility. Women may experience menstrual changes, male-pattern alopecia, and deepening of the voice. Teenagers risk permanently stunted height and accelerated pubertal changes.

Steroid use is associated with striae formation secondary to dramatic hypertrophy of muscle tissue.[98] Gingival enlargement has also been observed in those using anabolic steroids for greater than one year. Systemic effects of steroid abuse include hepatic damage, jaundice, hypertension and dyslipidemia.

Bacterial abscesses may occur at steroid injection sites secondary to nonsterile injection techniques.[93,96] Repeated injection into the same site can result in inflammation and oil-induced granuloma formation.[99] Soft tissue pseudotumors[100] and rhabdomyolysis[101] have also been reported in injectors.

In addition to causing de novo conditions, anabolic steroid use is also associated with exacerbation of existing acne and psoriasis.[93] Case reports have described exacerbation of angiolipomas[102] and latent acute hereditary coproporphyria as well.[103]

TOBACCO

Through the use of tobacco, nicotine is one of the most heavily used addictive drugs in the United States. Cigarette smoking accounts for 90% of lung cancer cases in the US. Tobacco is an agricultural product processed from the leaves of plants in the genus *Nicotiana*, which can be smoked or chewed (more precisely, placed between gingival and buccal mucosa) to allow nicotine absorption via oral mucosa. Nicotine in the tobacco leaves is responsible for the vasoconstrictive effects of smoking via increased vasopressin secretion and stimulation of the sympathetic nervous system, thereby causing peripheral vasoconstriction.[104–108] Smoking a single cigarette can produce cutaneous vasoconstriction for up to 90 minutes.[109] Smoking decreases tissue oxygenation via vasoconstriction and by increasing carboxyhemoglobin, thereby limiting the blood's oxygen carrying capacity.[110] Smoking also increases platelet aggregation[111] and blood viscosity,[112] and decreases prostacyclin formation.[113] This combination of mechanisms also leads to impaired postoperative wound healing in smokers.[114,115] The tar in cigarettes increases a smoker's risk of lung cancer, emphysema, and bronchial disorders. The carbon monoxide in smoke increases the chance of cardiovascular diseases.

Although the mechanism is unknown, smoking tobacco has also been linked with premature aging and rhytid formation. Elastin from photoprotecting skin in smokers is thick and fragmented, resembling that of sun-damaged skin but involving the reticular rather than the papillary dermis. Chronic dermal ischemia of as well as

Figure 105-6 The "nicotine sign." The orange hue of tobacco can lead to yellow–orange discoloration of the fingertips and fingernails in chronic cigarette smokers. Clubbing of the distal digits indicates the presence of chronic lung disease.

the decreased collagen synthesis likely play roles in the damaging elastic fibers.[116] Increased plasma neutrophil elastase activity secondary to smoking may contribute to abnormal elastin.[117] Smoking also causes a yellow–brown discoloration of the fingers and fingernails of digits habitually holding the cigarette (Fig. 105-6).[118]

Cigarette smoking and chewing tobacco use are associated with a number of mucosal conditions. *Leukokeratosis nicotinica palati* (nicotine stomatitis, smoker's palate) is characterized by uniform keratosis of the hard palate with multiple tiny umbilicated erythematous papules representing the inflamed orifices of minor salivary glands.[119] This benign oral lesion is seen exclusively in smokers and is caused by the tars and heat in tobacco smoke. Resolution is usually complete within 2 weeks of smoking cessation. All forms of tobacco use play a significant causative role in the development of leukoplakia.[120] *Leukokeratosis nicotinica glossae* (also known as tongue) is a homogeneous leukoplakia affecting the anterior two-thirds of the dorsal tongue.[121] Acute necrotizing ulcerative gingivitis "trench mouth," Vincent disease is caused by bacteria but is not communicable. Smokers tend to have fewer oral aphthous ulcers than nonsmokers due to decreased mucosal blood flow resulting from the vasoconstrictive effect of nicotine. Yellow discoloration of teeth secondary to tar deposition is also commonly observed.

Oral verrucous carcinoma, black hairy tongue, oral melanosis and oral warty dyskeratoma have been linked to tobacco use, but the connection is not as strong as in the aforementioned conditions.[122,123]

All forms of tobacco are associated with an increased risk of oral cancer.[124–127] Cigarette smoke may act as a direct carcinogen or via systemic absorption.[128,129] Smokers are also at an increased risk of developing squamous cell carcinomas at sites other than the oral mucosa, likely because of the immunosuppressive effects of smoking.[130–132] Immune dysregulation associated with smoking is thought to be the reason that smokers with melanomas present with more advanced lesions and have a poorer disease prognosis.[133,134]

Thromboangiitis obliterans (Buerger disease) is an obstructive vascular disease that is indisputably associated with heavy cigarette smoking in young men. Cutaneous manifestations include blanching, cyanosis, burning, tingling, ulceration, necrosis, and gangrene (see Chapter 170).

Cigarette smoking has been shown to exacerbate and possibly induce palmoplantar pustulosis.[135,136]

Both allergic and irritant contact dermatitis characterized by itching and burning, have been documented to nicotine patches.[137] Allergic contact dermatitis to the tobacco leaf has also been reported in tobacco harvesters and factory workers.[138,139]

BETEL

Betel (*Piper betle*) belongs to the *Piperaceae* family; its leaf has an important social and cultural role in South Asia, Southeast Asia and the South Pacific. Betel leaves are chewed with the areca nut (also known as *betel nut*), calcium hydroxide, Acacia catechu bark, and occasionally tobacco in a wrapped package known as "betel quid." Betel leaves are used as a stimulant, antiseptic and breath freshener. The areca nut contains the alkaloid and stimulant arecoline which promotes salivation and stains saliva and teeth dark red to rust-colored. Calcium hydroxide keeps the active ingredients alkaline, thereby enabling its sublingual absorption and entry into the bloodstream.

Continuous chewing of betel quid maintains constant moisture at the oral commissures which, when coupled with continuous friction of opposing surfaces, causes maceration, erosion and fissures. These lesions can be mistaken for angular cheilitis, candidiasis or vitamin-deficiency associated perleche.[140] The mixture is usually kept between the teeth and lip and may thus cause burning and erosions of the buccal mucosa.[140] *Chewer's mucosa* results from the direct chemical action of the quid and/or traumatic effect of chewing, and is characterized by a brownish–red discoloration of the buccal mucosa with an irregular desquamative epithelial surface. These mucous membrane findings are not thought to be malignant or premalignant.[141] Oral lichenoid lesions regress with decrease in frequency, duration or change in site of placement of the quid.[142]

Oral submucous fibrosis is directly related to betel quid chewing and affects the buccal mucosa, lips, retromolar areas, soft palate and occasionally the pharynx and esophagus.[143] It is characterized by prodromal oral dysesthesia aggravated by spicy foods, followed by early blanching mottled mucosal lesions and subsequent late development of palpable vertical fibrous bands in the buccal mucosa and around the mouth opening requiring surgical release for sufficient opening of the mouth.[144] Trismus, dysphagia, xerostomia, rhinolalia and tongue stiffening present late in the disease course. Mucosal petechiae, leukoplakia and epithelial dysplasia are also seen.[145,146] The most serious complication of oral submucous fibrosis is the development of oral carcinoma, which can be seen in up to 10% of users and is typically localized to the buccal tongue and labial mucosa.[147] Of all oral cancers in Taiwan, as many as 86.2% of cases have been reported to be in betel quid chewers.[148]

POLYSUBSTANCE ABUSE

Polysubstance abuse, the concurrent use of several drugs with different pharmacologic effects, is becoming increasingly common. The diversity of reported drug use combinations suggests that achieving some perceptible change in state may be the primary motivator driving this practice. One drug may be used to enhance the effects of another, as with the combined use of benzodiazepines and methadone or cocaine and heroin (*speedballs*). Polysubstance abuse can cause adverse health consequences, such as pulmonary disease, reproductive dysfunction and immunosuppression in chronic cocaine and psychostimulant abuse. It may also exacerbate preexisting conditions such as hypertension and cardiac disease. The concurrent use of some drugs, including cocaine and opiates, is frequently associated with deleterious behavior such as needle sharing by injection drug users.

COMPLICATIONS

In addition to the local reactions and systemic effects of specific drugs themselves complications of drug use must also be considered.

Injection drug use is associated with inoculation and transmission of infectious agents leading to local skin and soft tissue infections and abscesses, as well as the subsequent hematogenous spread of microbes. Gram-positive cocci including *Staphylococcus aureus*, group A β-hemolytic streptococcus and other streptococci are the most commonly observed microbial agents.[149–151] Anaerobes are the second most common group of bacteria to be isolated, while Gram-negative bacteria are less commonly isolated. The source of the pathogens is variable, but most originate from the flora of the skin and oropharynx secondary to needle-licking practices and use of saliva to clean or moisten skin and injection implements.[149] Abscesses and cellulitis occur in 22%–65% of drug users[152] (Fig. 105-7). Irritant substances including the drug or its diluents may cause sterile chemical cellulitis and abscesses. Systemic infections including bacteremia, endocarditis, osteoarthritis, and systemic candidosis may result. Systemic candidosis is the most common systemic fungal infection in injection drug users (Table 105-2).

Direct intra-arterial injection of drugs may cause severe ischemia and necrosis. Early intense burning is noted in the injected area, followed by marked edema, compartment syndrome, cyanosis, and livedoid patches of the affected limb within a few hours. Distal necrosis may occur in the most severe cases, and has been seen with the use of drugs such as cocaine, heroin, pentazocine, diazepam, amphetamine and others[25,153,154] The local cytotoxicity of a drug may cause a chemical endarteritis resulting in vasospasm and thrombosis.

The behavioral effects of injection drug use has been associated with an increased risk of sexually transmitted diseases as well as blood-borne diseases transmitted through unsterilized needles including hepatitis B virus (HBV), hepatitis C virus (HCV), human immunodeficiency virus (HIV) and human T-lymphotropic virus (HTLV) (Table 105-2).

Figure 105-7 Cellulitis at the site of repeated drug injection. Tender warm erythema and induration surrounding a chronic ulceration at the site of routine drug injection. Secondary infections at injection sites can be caused by introduction of pathogens via unsterilized needles, adulterated drugs, and at sites of compromised skin integrity. *S. aureus* infectious endocarditis occurred following bacteremia from this site.

The repeated trauma of venipuncture, local infections and the irritant drugs and adulterants can lead to superficial and deep venous thrombosis. Chronic venous insufficiency can result from vein trauma, necrotic ulcers at sites of past subcutaneous injection, vein thrombosis and blockage of the lymphatic system.[155,156]

Other noninfectious diseases associated with drug use include psychiatric disease, accidental injury due to altered mental status and trauma due to criminal violence or domestic abuse.

TABLE 105-2
Common Infectious Agents Associated with Drug Abuse and Addiction

Class	Infectious Agent
Bacterial	*Staphylococcus aureus* *Streptococcal* species *Pseudomonas aeruginosa* *Clostridium botulinum* *Eikenella corrodens* Anaerobes Unusual organisms
Fungal	Dermatophytes *Candida* *Aspergillus* *Mucor*
Viral	Herpatic viruses Human T-cell lymphotropic virus Human immunodeficiency virus Hepatitis B virus Hepatitis C virus
Sexually transmitted	*Chlamydia trachomatis* *Neisseria gonorrhoeae* Human immunodeficiency virus Human papilloma viruses *Molluscum contagiosum* *Treponema pallidum*

TABLE 105-3
Drug Detection in Body Fluids and Hair

Substance	Blood/Saliva	Urine	Hair
Alcohol	12–24 hours	6–24 hours	Up to 90 days
Amphetamines (except meth)	12 hours	1–3 days	Up to 90 days
Methamphetamine	1–3 days	3–5 days	Up to 90 days
MDMA (Ecstasy)	25 hours	24 hours	Up to 90 days
Benzodiazepines	6–48 hours	Therapeutic use: 0–7 days Chronic use (>1 year) 4–6 weeks	Up to 90 days
Cannabis	2–3 days, up to 2 weeks in heavy users	3–7 days, up to >30 days after heavy use and/or in users with high body fat	Up to 90 days
Cocaine	2–5 days	2–5 days with exceptions for certain kidney disorders	Up to 90 days
Codeine		2–3 days	
Cotinine (break-down product of nicotine)	2–4 days	2–4 days	Up to 90 days
Morphine	1–3 days	2–4 days	Up to 90 days
Heroin	1–2 days	3–4 days	Up to 90 days
LSD	0–3 hours	24–72 hours (tests for LSD are very uncommon)	Up to 3 days
Methadone	24 hours	3 days	Up to 90 days
PCP	1–3 days	3–7 days for single use; up to 30 days in chronic users	Up to 90 days

DIAGNOSIS

While mucocutaneous findings can be suggestive of drug use drug testing is needed to identify the agents used. Bodily fluids including saliva, blood, urine and hair can be used in drug detection. Urinalysis for qualitative detection of psychoactive substances and their metabolites is often the fastest way to determine ingestion of a substance (Table 105-3).

Systemic conditions secondary to the effects of substance abuse should also be part of the evaluation of these patients. Cutaneous infections at sites of trauma, ulcers, or necrosis should be swabbed or biopsied for culture to identify and treat causative organisms. Thorough evaluation and imaging may be required to rule out injury to or involvement of vital organs and bony structures. In injection drug users, thorough cardiac evaluation and examination of mucocutaneous and acral surfaces should be undertaken to access for embolic phenomenon. Evaluation for transmitted infections such as HIV, hepatitis and sexually transmitted diseases may be required.

DIFFERENTIAL DIAGNOSIS

It is imperative to rule out primary infectious causes of ulcers, nodules, skin and subcutaneous infections in suspected drug users. Inflammatory and vasculopathic processes such as pyoderma gangrenosum, livedoid vasculopathy and medium vessel vasculitides must be considered in the setting of ulcers and nodules. Evidence of distal vascular compromise can be seen in pernio, thromboembolic phenomenon and Raynaud phenomenon. The edematous phase of scleroderma, eosinophilic fasciitis and secondary lymphatic obstruction are rare entities to consider the setting of distal extremity swelling. Infectious and noninfectious granulomatous diseases [including tuberculosis, leishmaniasis, granulomatosis with polyangiitis (Wegener's) and sarcoidosis] can present with nasopalatal infiltration and perforation. Patients with pruritus and formication may require evaluation for infestation, metabolic or psychiatric etiologies of their symptoms.

TREATMENT

A detailed discussion of the treatment of drug abuse and dependence is beyond the scope of this chapter, but it is essential to recognize that these are chronic illnesses that require long-term strategies. Combined medical and behavioral therapy are important elements of a therapeutic process comprising detoxification, treatment and relapse prevention. Amelioration of withdrawal symptoms is key to initiation of therapy. A multidisciplinary approach including addiction

counseling, social work support and management of associated infectious, vascular, cardiac and hepatic complications is critical to comprehensive care.

Potential therapies for opiate dependence include drug detoxification (office-based, inpatient or ultra rapid under anesthesia), agonist maintenance (injectable diacetylmorphine, methadone, levomethadyl or buprenorphine), antagonist maintenance (naltrexone) and pharmacologic treatment of withdrawal symptoms (clonidine, lofexidine or guanfacine).

Treatment options for tobacco addiction include nicotine replacement therapies (patch, spray, gum and lozenges). Bupropion and varenicline have been approved by the Food and Drug Administration for management of nicotine addiction. Behavioral interventions include group and individual therapies, and telephone quitlines.

Outpatient and residential treatment centers can provide environments in which individuals can participate in therapeutic communities and benefit from behavioral therapy and peer support. Alternative therapies including acupuncture may also prove useful in combination with medical and behavioral therapeutic interventions. Although relapses are common, successful outcomes are accomplishable, indicating the importance of candid, supportive, nonjudgmental, care-facilitating discussions in patients whose drug use has been revealed through skin examination.

The transmission of infectious disease via injection drug use can be addressed by encouraging physicians to prescribe sterile injection equipment, setting up injection rooms staffed by healthcare personnel who can provide advice on safe injection techniques and instituting strictly supervised heroin, diamorphine or buprenorphine prescription programs for long-term injectors.[157] This may help reduce the risk of life-threatening infection from nonsterilized drugs, prevent overdose from drugs of unknown purity, break the link between drug use and criminal activity to acquire drugs and decrease the number of injections in public places.

Chapter 106 :: Skin Signs of Physical Abuse

:: Howard B. Pride

ABUSE AT A GLANCE

- Child abuse, elder abuse, and domestic violence are common.
- Abuse is a problem of all socioeconomic classes and races.
- Bruising on soft padded areas of the body and patterned bruising that are multiple and in different stages of healing are suspicious of abuse.
- Burns that are bilateral and uniform are suspicious of abuse.
- Law mandates the reporting of all suspected cases of child abuse and, in some states, elder abuse.

CHILD ABUSE

Child abuse is an uncomfortable topic for most practitioners and is a source of anxiety, anger, and confusion among those who care for children. True incidence statistics are difficult to determine, but each year in the United States, of the approximately three million children referred to child protective services, approximately one million are determined to be the victims of abuse and neglect (or about 12 cases per 1,000 children) and approximately 1,500 die from abuse or neglect.[1] Clearly, those whose practices involve the dermatologic care of children encounter real or suspected child abuse. Practitioners must have some basic knowledge of abuse and its evaluation to appropriately manage these cases.

Because many forms of physical abuse have external manifestations, the skin examination may serve as the first clue that abuse is taking place. Conversely, a broad knowledge of skin diseases provides a unique

TABLE 106-1
Conditions Mistaken for Abusive Bruising

- True petechiae and purpura
  - Disorders of coagulation
  - Ehlers–Danlos syndrome
    - Infections
    - Rocky Mountain spotted fever
    - Meningococcal infections
    - Group A streptococcal infections
- Palpable purpura of vasculitis
- Valsalva petechiae
- Lichen sclerosus
- Folk remedies
  - Cao gio: rubbing vigorously with a hard object such as a coin
  - Cupping: suction mark left by the cooling of a warm metal cup
- Nodular lesions mimicking deep bruises
  - Neuroblastoma
  - Vascular malformations
  - Dermatomyositis-associated nodules
  - Erythema nodosum
  - Discolorations that look like bruises
  - Phytophotodermatitis
  - Maculae coeruleae from lice infestation
  - Mongolian spots
  - Dye from blue jeans
- Inflammatory conditions that mimic bruising
  - Urticaria/angioedema/urticarial vasculitis
  - Pernio
- Conditions that mimic whip marks
  - Incontinentia pigmenti
  - Striae
  - Phytophotodermatitis

insight into those diagnoses that may mimic various forms of child abuse (Tables 106-1 and 106-2). The literature is rich in examples in which an astute clinician averted the disastrous results of a false claim of abuse by correctly diagnosing a dermatologic condition.

True abuse must be reported and a thorough evaluation conducted. It is essential that practitioners develop a relationship with the institution or individual in their area who is best able to manage these difficult cases. Ideally there should be an abuse team consisting of a dermatologist, pediatrician, social worker, medical photographer, and, when needed, pediatric subspecialists such as orthopedists, hematologists, psychologists, and gynecologists. The need for specialization in this field is highlighted by the institution in the United States of pediatric subspecialty board certification in child abuse, beginning in 2010. It is most helpful if one's relationship is forged with the abuse team before an abuse incident and a set protocol for dealing with alleged or suspected abuse is established in the practitioner's office. Local emergency phone numbers for reporting abuse can be obtained from the Child Welfare Information Gateway or Childhelp National Headquarters (Table 106-3).

Child abuse spans all ages with 32% of abused children being younger that 4 years of age, 24% being 4–7 years of age, and 19% being 8–11 years of age. Typical children who suffer abuse have emotional or behavioral problems, have special medical needs, have several siblings, live in single-parent households, or live at or below the poverty level. Abuse is approximately

two times more common in Pacific Islanders, American Indians, Native Alaskans, and African American children compared to the average American population. Perpetrators tend to have emotional or psychological problems, have frequently been victims of abuse themselves, abuse drugs or alcohol, are perpetrators of spousal abuse or have a history of marital discord, have marginal parental skills or knowledge, and have poor self-esteem. Parents are the perpetrator 80% of the time.[2] Although these profiles are helpful, it is important to remember that any child may be the victim of abuse.

THE BATTERED CHILD

Bruising is the result of blunt trauma, delivered either accidentally or intentionally. Active children, particularly toddlers, are prone to multiple bruises, and the identification of abusive injury is fraught with difficulty. The size, shape, color, and feel of a bruise varies on the basis of anatomic site, the degree of force used, the firmness of the object delivering the force, and the underlying health of the injured individual. Great care and attention to detail must be exercised when evaluating these children who likely have been brought to the office for some other complaint. The history should include as much detail as possible and inconsistencies in the parent's story clearly documented in the medical record (eTable 106-3.1 in online edition).[3] It is essential to perform a total body, skin, and mucous membrane examination. It is also important to note the child's behavior and parent–child interactions.

The color of all bruises should be noted and clearly documented. This may aid in determining the age of a bruise and may point out inconsistencies in the caretaker's history. Multiple bruises of differing colors may indicate ongoing trauma rather than one isolated incident. Caution must be exercised in dogmatically, stating the time of injury based on bruise characteristics because color depends on the intensity, depth, and location of the injury. There is good evidence that a bruise with any yellow color must be older than 18 hours, but a bruise may be red, blue, or purple/black throughout its life span, from beginning to resolution. Bruises of identical age and cause on the same person may not appear as the same color and may not change at the same rate.[4] It is most prudent to document color without alluding to a specific age of a bruise in the medical record. Faint bruised might be more easily visualized with the use of a Wood's lamp.

Although there are no absolute differentiating features, certain aspects of an intentionally inflicted bruise may suggest abuse. Because young children tend to explore in a forward direction, accidents are more frequent on the distal arms and legs, knees, elbows, and forehead. Soft, padded, posterior, and protected areas of the body are far less likely to be accidentally injured. Bruises on the abdomen, buttocks (Fig. 106-1), thighs, genitalia, ear lobes, and cheeks are uncommon, so marks in these areas should raise concern.

Inflicted bruises often leave patterned imprints of a hand, whip, or hard object. Linear purpura, with a small triangle at the base (Fig. 106-2) representing the interdigital and finger web spaces, occurs after a slap injury. Grab or pinch marks can be recognized by their location on soft padded areas and their unusual patterning. Circumferential purpura or hemosiderin pigmentation (Fig. 106-3) suggests a ligature injury, which would be difficult to explain as accidental. Bite marks (Fig. 106-4) are always inflicted, although they are sometimes from siblings or other children. The shape and size of the marks can identify an adult mouth versus a bite from a child. It is helpful to include a ruled measuring scale in any photographs to help forensic identification at a later date.

The head is the most common target of physical abuse (see eFig. 106-4.1 in online edition). Black eyes are common accidental injuries but are more suspicious if they are bilateral or are unaccompanied by evidence of trauma to the nose or superior orbital ridge. Subconjunctival hemorrhages can be seen in 0.5%–13.0% of typical newborns, but a large subconjunctival hemorrhage beyond 1 and 2 weeks of life is suspicious of abuse. Petechiae in the periorbital region

Figure 106-1 Purpura and erosions on the soft, padded areas of the buttock and thighs, representing very obvious abuse. (Used with permission from Paul Bellino, MD.)

Figure 106-2 Linear purpura representing the interdigital spaces from a hand slap. Note the inferior triangular shape that corresponds to the finger web space. (Used with permission from Paul Bellino, MD.)

have been seen in children with abuse related retinal hemorrhages. Accidental bruising or other injuries to the oral mucous membranes are unusual and should be considered as suspect (see eFig. 106-4.2 in online edition).

Any bruises in a young infant who is not yet pulling to a stand should raise concerns of abuse or of an unsafe environment (see eFig. 106-4.3 in online edition). A shaken infant may have bruising on the hands because he or she is liable to be flailing during the shaking incident (see eFig. 106-4.4 in online edition). Concern should be raised whenever the history of an accident is inconsistent with the developmental level of the child.

INFLICTED BURNS

The most common agent involved in childhood burns, both accidental and inflicted, is hot liquid. Accidents such as inadvertently stepping into a hot tub or pulling a hot liquid off a table counter or stove leave irregular or geographic burn patterns that lack symmetry. By contrast, inflicted scalds tend to be symmetric, with sharply demarcated edges and an absence or paucity of splash marks. In one study, all the children whose bathtub burns were inflicted had associated features of abuse, including bruises, fractures, or evidence of neglect.[5] Stocking and glove burns result when the feet or hands are forcibly held under hot water. The uniformity of the burn indicates that the child was not able to reflexively withdraw from the scalding water as would happen with accidental immersion. A common pattern of inflicted immersion burn involves the buttocks, low back, and thighs. The child is flexed at the waist and dipped into the hot water, frequently as a punishment for a toilet training accident. The resultant pattern may give "zebra stripes" on the abdomen due to sparing of the flexural skin that is protected from the scald when bent forward. A "donut hole" pattern of sparing might be seen on the buttock if the child is pushed forcibly to the bottom of the tub that is cooler than the scalding water.[6] Inflicted splash burns are much more difficult to differentiate from accidents. A careful history is needed to detect inconsistencies between the proposed injury and the physical examination. When doubt exists, it is mandatory that child protective services be contacted.

An inflicted contact burn can be recognized by the pattern that duplicates the object creating the injury (see eFig. 106-4.5 in online edition). Accidental contact burns tend to be smaller, less severe, less patterned, and of irregular depth. When a child is held against a hot object, the depth is more uniform, the pattern is more clearly defined, and the burn is more severe. Irons, curling irons, hot plates, and cigarettes are objects commonly used to inflict burns.[7] Some burns may, in fact, be accidental but represent inadequate supervision and neglect. This situation is also harmful to children and needs to be reported to the appropriate agencies.

Figure 106-4 Human bite marks. (Used with permission from Paul Bellino, MD.)

SEXUAL ABUSE

It is estimated that more than 300,000 children suffer from sexual abuse each year in the United States. The lifetime risk of sexual abuse is approximately 25%–40% for girls and approximately 10% for males. *Sexual abuse* is defined by the American Academy of Pediatrics as the engaging of a child in sexual activities that the child cannot comprehend, for which the child is developmentally unprepared, and cannot give informed consent and violate the social taboos of society.[8] This broad definition includes inappropriate touching, genital penetration, fondling, and sexual kissing, but also includes noncontact activities such as exhibitionism, voyeurism, and the involvement of a child in verbal sexual propositions or the making of pornographic pictures or movies. Clearly, many forms of sexual abuse leave no physical examination findings.

Girls are more likely than boys to suffer sexual abuse and the risk rises in preadolescence (Fig. 106-5). Most abuse is at the hands of someone known to the child

Figure 106-5 Sexual abuse. Perianal wound in a 3-year-old girl after anal penetration. (Used with permission from Dr. Francesca Navratil, Zurich, Switzerland.)

and only 10% is carried out by strangers. Victims and perpetrators span all racial, religious, and socioeconomic spectrums but risk factors for sexual abuse include the presence of a stepfather, single-parent families, children whose mothers are extensively out of the home, a history of parental violence, parents who have suffered abuse themselves, parental substance abuse, and low household income level.

Most victims of sexual abuse have no physical findings.[9,10] Pregnancy, positive cultures for sexually transmitted diseases, presence of sperm or acid phosphatase, acute genital or anal injuries without plausible explanation, and marked hymeneal opening enlargement with associated hymeneal disruption are very definitive signs of abuse. However, it is very seldom that such signs are present. The American Academy of Pediatrics Committee on Child Abuse and Neglect recommends that certain findings are consistent with, but not diagnostic of, abuse. These include chafing, abrasions or bruising of the inner thighs and genitalia, scarring, tears or distortion of the hymen, a decreased amount or absent hymeneal tissue, scarring of the fossa navicularis, injury to or scarring of the posterior fourchette, scarring or tears of the labia minora, and enlargement of the hymeneal opening, even without disruption of the hymen.[8]

The child's spoken word is the most valuable piece of evidence in establishing sexual abuse. All historical information must be very well documented and preserved with the same care as any piece of forensic evidence. It is immensely important to enlist the help of an experienced abuse team in obtaining the history and completing an appropriately thorough physical examination with the aid of colposcopic observations.

The skin examination's greatest contribution may be in correctly diagnosing those dermatoses that may look similar to sexual abuse but are not. Irritant dermatitis, atopic dermatitis, psoriasis, seborrheic dermatitis, pinworms, candidiasis, scabies, and other common dermatoses tend to cluster in the diaper region and should be easily diagnosed with a critical eye. Other conditions that have been reported as mimickers of sexual abuse are listed in Table 106-4.

TABLE 106-4
Conditions Mistaken for Sexual Abuse

- Lichen sclerosus
- Crohn disease
- Localized vulvar pemphigoid
- Langerhans cell histiocytosis
- Perianal streptococcal dermatitis
- Hemangiomas
- Urethral prolapse
- Entities that look like condylomata acuminata
  - Focal epithelial hyperplasia
  - Darier disease
  - Lymphangioma circumscriptum
  - Pigmented vulvar hamartomas
  - Pseudoverrucous papules
  - Epidermal nevus and inflammatory linear verrucous epidermal nevus
- Entities that look like herpes simplex
  - Localized varicella/zoster
  - Allergic contact dermatitis

Genital warts pose a particularly difficult problem for practitioners. They certainly can be sexually transmitted to children, and the possibility of sexual abuse needs to be discussed with parents. However, there is much evidence that genital warts can be acquired perinatally from an infected mother, through autoinoculation from warts on other parts of the body or through nonsexual contact with caretakers.[11] Children younger than 3 years of age at the onset of warts are least likely to have acquired their warts from sexual contact, whereas children with onset after 5 years of age have a much greater risk of having suffered sexual abuse. The ages in between represent a gray zone. Other signs of abuse will seldom be present to aid in the diagnosis, and human papillomavirus typing is not helpful. History provides the most valuable insight into the correct diagnosis; again, it is imperative that an abuse team be involved. At the author's institution, all children with perianal or genital warts are referred, in a nonaccusatory and nonjudgmental fashion, to the hospital's abuse social worker and pediatrician as routine protocol.[12]

ELDER ABUSE

Elder abuse is one of the fastest growing forms of abuse. Although statistics vary, the National Center on Elder Abuse in Washington, DC, estimates that 1 to 2 million Americans 65 years of age or older are victims of various forms of abuse each year. Abuse may affect a range of 2%–10% of the elderly population. Those older than age 80 years are two to three times more likely to suffer abuse, and the American population in this age range continues to increase each year. For every case of reported elder abuse, at least another five cases go undetected.[13] All segments of society are affected. Although there is inherent inaccuracy in these statistics, it is readily apparent that elder abuse is common enough for a busy dermatologist to encounter a few abused patients every week.

TABLE 106-5
Types of Elder Abuse

- Neglect: 55%
- Physical abuse: 15%
- Financial and material abuse: 12%
- Emotional or psychological abuse: 8%
- Sexual abuse: 1%
- Unspecified forms of abuse: 9%

The US National Academy of Sciences has defined *elder abuse* as:

> *(a) intentional actions that cause harm or create a serious risk of harm (whether or not harm is intended) to a vulnerable elder by a caregiver or other person who stands in a trust relationship to the elder, or (b) failure by a caregiver to satisfy the elder's basic needs or to protect the elder from harm.*

Acts of commission and omission are thus included in the definition. Types of abuse and their respective incidence rates are listed in Table 106-5. More than one type of abuse can occur simultaneously.[14,15]

Abuse most often occurs at the hands of caregivers or family members who have frequent close contact with patients and often may live with them. Historically, adult children of the abused patient have been the most common perpetrators, but most recent data show that spouses now account for the majority of abuse cases. Men are more likely to abuse than women. The abuser is often financially dependent on the victim, and they are usually in a shared living situation. However, financial abuse is more common among those who live alone. Risk factors for abuse are listed in Table 106-6. Note that the risk factors have far more to do with the caretaker than the abused patient. In particular, the level of debility or health status of the patient does not predict abuse.

Physical abuse is defined as the intentional application of any force that causes bodily injury, pain, or impairment to an elderly individual. It may include acts such as hitting, beating, shaking, kicking, slapping, pushing, pinching, burning, overly aggressive force-feeding, and the improper use of physical or chemical restraints. The signs discussed in Section "Child Abuse" above apply to elder abuse as well and include multiple bruises or fractures in different stages of healing, bruises in normally well-protected areas such as the inner thighs, odd-shaped injuries such as from pinching or slapping, belt marks or patterned bruising (see eFig. 106-5.1 in online edition), unusual welts or puncture wounds, cigarette burns, rope marks that might indicate restraints, bed sores, strangely patterned alopecia, attempts to hide part of the body, and signs of malnutrition or dehydration. Because many of these signs, particularly multiple bruises, can occur normally in elderly individuals, detection of abuse can be very challenging. Unexplained repetitive injuries or explanations by caretakers that do not match the pattern of injury are concerning. Caretakers who act withdrawn, infantilize the patient, or insist on providing the medical history should alert the clinician.

TABLE 106-6
Risk Factors for Elder Abuse

- Older age
- Lack of access to resources
- Low income
- Social isolation
- Minority status
- Low level of education
- Functional impairment
- Substance abuse by elder or caregiver
- Previous history of family violence
- History of psychological problems
- Caregiver stress
- Cognitive impairment

It is important to interview by directing questions to the patient rather than the caregiver, and it is prudent to try to arrange a time to confer with and examine the patient alone. Repetitive follow-up visits help develop a rapport with the patient and allow serial observation of past and ongoing injuries. The assurance of confidentiality facilitates garnering sensitive information.

Once abuse is suspected, most states mandate that physicians contact the appropriate authorities. Information on a particular state's laws can be obtained from the National Center on Elder Abuse (see Table 106-3). The nearest medical center's social service department is well equipped to offer guidance, but the agencies listed in Table 106-3 are also helpful resources. Treatment, support, and counseling may be needed for the perpetrator as well.

DOMESTIC VIOLENCE

Domestic violence is a pattern of coercive behaviors that may include repeated battering, psychological abuse, sexual abuse, social isolation, deprivation, and intimidation perpetrated by someone who is or was involved in an intimate relationship with the victim. Conservative estimates say that in the United States approximately 1 million people suffer domestic violence each year, but the actual number likely approaches 4 million. Women comprise approximately 90%–95% of all victims, and men 95% of all perpetrators. Forty percent to 60% of men who abuse their partner or spouse are also abusing their children. In the United States, approximately one in three women suffers a least one physical assault during her life, and 1,500 women are murdered by their husbands or boyfriends each year.[16,17] Domestic violence is a devastatingly common problem.

The profiles of domestic abuse are similar to child and elder abuse. Women ages 19–29 years are the most common victims, with other risk factors being low income, mental health issues, alcohol or substance abuse by the victim or the perpetrator, pregnancy, large age difference between partners, separated or divorced status, and a family history or personal past history of abuse and violence. Women with educational or occupational levels above that of their partners may be at

higher risk. Abusers are typically underachievers with occupational status below their educational level.[16,17]

Whenever possible, the patient should be interviewed alone, without the partner's presence. A thorough examination should be done with a nurse chaperone, but not the partner, in the room. Repeat visits may be used to document new or progressing skin findings and to build trust with the patient. Statements such as "Because domestic violence is such a prevalent problem, we have begun to ask about it routinely" may open the door to more discussion regarding difficulties at home. Literature and posters in the clinic setting with information and hotline numbers for abuse victims indicate the common reality of abuse and may facilitate disclosures.

For various reasons, a victim may not want to reveal abuse. Implausible explanations for an injury or a delay in seeking medical attention may be clues of abuse. Signs of depression, excessive use of sedatives, chronic pain disorders, or vague stress-related symptoms may be subtle signs of abuse.[17]

Physical examination findings are the same as outlined for child and elder abuse. The distribution of injuries tends to be central, and the perpetrator may choose to injure hidden areas, such as the breast or genitals, to deter detection. Unlike infants or debilitated adults, blows to a young adult may be to areas suggesting a defensive posture and might include purpura, sprains, dislocations, and fractures to the wrist or forearms, palms, and soles.

The social service department at the local medical center is a good resource for information and help on domestic violence. The National Domestic Violence hotline (800–799-7233) is a 24-hour resource for women who need to find a local shelter. Other helpful organizations can be contacted (see Table 106-3).

PART 6 Skin Changes across the Span of Life

From Birth to Old Age

Chapter 107 :: Neonatal, Pediatric, and Adolescent Dermatology

:: Mary Wu Chang

NEONATAL, PEDIATRIC, AND ADOLESCENT DERMATOLOGY AT A GLANCE

- Many dermatologic diseases exhibit different manifestations in newborns, infants, and children.
- Some dermatoses are encountered only in neonates and infants and therefore require special attention.
- Obtaining a history and methods of clinical examination in infants and children differ from the approaches chosen for adults. In adolescents, different skills are required to enhance compliance.
- Many outpatient procedures in pediatric dermatology can be done easily with appropriate planning and age appropriate techniques. Necessary biopsies should not be avoided simply because of a patient's young age.
- The infant has increased risk for systemic toxicity from topically applied substances; the risk is even greater in premature infants. Children with disorders of barrier function are at high risk of excess percutaneous absorption and toxicity as well.
- Drug labeling for pediatric patients is different from that in adults and most therapeutic agents are prescribed off-label.

Just as dermatology cannot be separated from internal medicine, pediatric dermatology is inseparable from general pediatrics. Since most dermatologists have experience and training in internal medicine but less exposure to pediatrics and neonatology, an introduction to the special issues that can arise in pediatric dermatology is presented herein. As it is impossible to discuss all of pediatric dermatology in one chapter, the focus is instead on certain methods, diseases, and issues divided by three age divisions: neonates and infants, children, and adolescents. Topics of special importance such as pediatric medication use and biopsy pitfalls are discussed. Methods to enhance success in outpatient procedures in pediatric dermatology are also reviewed.

TABLE 107-1
Ten Helpful Tips in Pediatric Dermatology

1. The child is the patient, not the parents.
2. Biopsy when indicated, regardless of age. (Refer if necessary)
3. Be aware of the family situation: Does the child live in two homes? Are the parents going through a divorce?
4. Be aware of the parents' perception of the child: Was there difficulty in conceiving? Prematurity? Significant early illness?
5. A team approach with the pediatrician, neonatologist, or family physician is most efficient. Psychiatrist comanagement may be indicated (e.g., isotretinoin issues or trichotillomania).
6. Chronic illness in one person affects the entire family (e.g., severe atopic dermatitis).
7. Guide parents and patients to appropriate Internet resources, but always review materials for accuracy beforehand.
8. Obtain consent from parents, and assent from children, for procedures and photos.
9. An adolescent's confidentiality must be maintained unless there is a danger of harm to the patient, or others. Consider interviewing patient alone without parents for a portion of the visit. Consider a chaperone in the office for full skin exams.
10. Remember the aphorism, "To cure sometimes, to relieve often, to comfort always."

Successful care of the pediatric patient is best achieved via comanagement with the neonatalogist, pediatrician, or primary care physician. In addition, an understanding of the parental or family situation is important. For example, children living in two households (due to divorced parents) may do best with two sets of medications, one in each home, to enhance compliance. Table 107-1 reviews ten helpful tips in practicing pediatric dermatology. As an example, if Internet access exists, patients or parents will likely search online for medical information before or after the office encounter. Parents and patients should be warned that medical information on the Internet is often inaccurate.[1] It is wise to direct them to specific Internet Web sites, support groups, or pamphlets, but these resources should be reviewed before recommending them.

Lastly, the aphorism, "To cure sometimes, to relieve often, to comfort always," should always be kept in mind when delivering pediatric care. Parents often have higher expectations, and a heightened level of worry and concern for their children and the office visit cannot be rushed.

NEONATES AND INFANTS

The neonatal period is defined as the first 30 days of life. Neonatal skin diseases evolve much more rapidly than adult skin diseases, and some conditions that initially appear to be serious turn out to be trivial, whereas in others, the opposite is true. Infancy is defined as beginning after the first 30 days of life.

NEONATAL SKIN

After birth, the neonate's skin undergoes a series of changes in adaptation to the extrauterine environment. In utero, the skin of the fetus is protected by the vernix caseosa and is immersed in amniotic fluid. After birth, the vernix is wiped off, and the skin is exposed and adapts to the dry ambient air. For example, desquamation of the upper layers of the stratum corneum occurs normally in all infants and is believed to be a normal adaptive process.

Research regarding the maturation of the neonatal stratum corneum in neonates has produced varying results, and the question of when full barrier function is achieved is not fully answered. Barrier stabilization appears to be a dynamic process, one dependent upon a balance between different biologic and environmental parameters. Postnatal life is believed to accelerate stratum corneum maturation in premature and term infants. Parameters such as skin thickness, skin pH, and stratum corneum hydration indicate that neonatal skin is continuously adjusting to the extrauterine environment, in contrast to the adult skin, which remains in a steady state.[2]

In vivo studies of human skin show that infant stratum corneum and epidermis is thinner than adult skin and has higher transepidermal water loss (TEWL) rates, but infant stratum corneum has higher water content. Infant corneocytes and granular cells are smaller than adult corneocytes suggesting a more rapid cell turnover than in adults.[3]

Infants have an increased risk for systemic toxicity from topically applied substances. This is due in large part to the great surface area–body mass ratio in the infant. In addition, the infant's metabolism, excretion, distribution, and protein binding of substances can be significantly different from those of an adult and add to increased risk of toxicity.[4]

The postmature infant (>40 weeks' gestation) typically has dry and cracked or peeling skin noted soon after birth (Fig. 107-1). Shedding of the dry peeling skin of postdates infants occurs spontaneously in the first month of life, leaving normal, healthy skin. Topical care should include moisturizers and avoidance of overbathing.

Premature infants, particularly those born before 34 weeks of gestation, have markedly decreased epidermal barrier function and an even greater surface area–body mass ratio than term infants. In addition, the immature organs of the premature infant may affect the metabolism, excretion, distribution, and protein binding of chemical agents. Local or systemic toxicity can occur in the premature infant not only from topical medications, but also soaps, lotions, or other cleansing solutions.[4,5]

Increased skin fragility is a hallmark of prematurity (gestational age less than 37 weeks). Epidermal and dermal injury may lead to significant cutaneous pain even with routine handling and nursing care. The premature infant is at risk for infection and sepsis from skin-associated organisms entering through breaks in the thin and fragile skin and via iatrogenic portals of entry. Sweating

Figure 107-1 The feet of a postmature newborn. The dry, hyperlinear, and scaly skin is typical of a postdates baby. There are also pustules of transient neonatal pustular melanosis.

in the premature infant is functionally reduced and contributes to poor thermal regulation. Heat regulation is dysfunctional due to a thin subcutaneous fat layer for insulation, poor autonomic control of cutaneous vessels, and a large surface–body ratio. In the nursery, the premature infant is usually placed in a temperature and humidity-controlled isolette until the infant matures and temperature and fluid regulation stabilizes.

In the 1990s researchers reported application of petrolatum-based emollient therapy to be beneficial in hospitalized preterm infants, decreasing transepidermal water loss.[6] Subsequently, various emollients and regimens have been tested in infants of variable prematurity and birthweight. Improved skin integrity consistently improved in these studies, however, a threefold increase in the incidence of systemic candidiasis was reported after emollient therapy was implemented in extremely low birthweight (≤1,000 g) premature infants in one neonatal intensive care unit.[7] Another outbreak of systemic candidiasis occurred in very low birthweight neonates (≤1,500 g) in a different neonatal intensive care unit.[8] A 2004 Cochrane review concluded that prophylactic application of topical ointments increased the risk for nosocomial infection and advised against their routine use in preterm infants. In contrast, randomized, controlled studies in impoverished Bangledeshi preterm neonates have demonstrated decreased mortality rates when sunflower seed oil or Aquaphor ointment was applied by massage, compared to premature infants not receiving massage or emollients.[9] Until prospective, controlled trials are performed, neonates receiving petrolatum-based emollient therapy should be carefully monitored for infections, particularly those infants with birthweights less than 1,500 g.

Once at home, bathing once or twice a week in plain water is sufficient for most infants; if bathing is more frequent, moisturization with unscented, simple emollients is recommended. The face, hands, and diaper area may be cleansed daily using a small amount of a mild, unscented, pH-neutral cleanser. Well-meaning parents often bathe their infants too frequently and use a multitude of products on their infant's skin. In addition to irritation and asteatosis, these practices may increase the risk of allergic contact dermatitis in infants. It has been estimated that the average newborn is exposed to approximately 10 skin care products in the first month of life, leading to exposure to more than 50 different chemicals ranging from mildly toxic to toxic.[10] Parents should be taught that "less is best."[11]

EXAMINATION TECHNIQUES

A complete history includes gestational and birth history as well as family history. Exposures during pregnancy, including medications, illicit drugs, and infectious diseases such as varicella and sexually transmitted diseases, should be reviewed. Obstetric data, including placental appearance and cultures, can be invaluable. In examining an infant, the most important element is thoroughness. Whether the infant is examined in the lap of the parent or on the examination table, all surfaces, including the creases and valleys of body folds and the diaper region (including the genitalia), deserve close examination. A vascular stain, vasoconstricted macule, or erosion can be the presenting sign of a hemangioma.[12] A stray hair may later strangulate an appendage and should be removed. Infants with digital tourniquet (pseudoainhum) and clitoral tourniquet have been described.[13,14] Congenital lesions of all classifications (e.g., pigmented, vascular, aplasias) warrant closer inspection to rule out associated findings. Midline lesions on the face, scalp, or spine may have central nervous system (CNS) connections and should not be biopsied without proper evaluation (see Table 107.7). The diaper area has its own unique set of problems and deserves examination at every visit.

The infant is vulnerable and completely dependent on the caretakers. The social support system and family structure must be considered when implementing a medical plan. There are times when the parents' desire for treatment may not be in the best interest of the patient.

Medical and surgical decision making for the infant is based primarily on function rather than cosmesis. For example, extraction of a natal tooth is indicated if breast-feeding is impaired; whether or not the tooth is a component of a genetic syndrome is a separate issue.

DISEASES OF NEONATES AND INFANTS

TRANSIENT DERMATOSES OF THE NEONATE.

Skin conditions encountered in newborns that tend to resolve by 30 days of age are considered to be transient. They are very common and many are expected in newborns.

Caput Succedaneum and Cephalohematoma. Caput succedaneum is subcutaneous edema over the presenting part of the head and is a common occurrence in newborns. Cephalohematoma is a subperiosteal collection of blood and is less common. Both lesions are due to shearing forces on the scalp skin and skull during labor.

Caput succedaneum is soft to palpation, and borders are ill-defined. Cephalohematoma is bounded by the suture lines of the skull and often feels fluctuant. If purpura is extensive, it can lead to hyperbilirubinemia. Congenital lymphedema or lymphatic malformations (such as in Turner syndrome) can mimic caput succedaneum. Both caput succedaneum and cephalohematoma resolve spontaneously; however, caput usually fades in 7–10 days, whereas cephalohematoma slowly resolves over several weeks.

Milia. Milia are multiple pinpoint- to 1-mm papules representing benign, superficial keratin cysts. They are seen most commonly on the nose of infants and may be present in the oral cavity as well, where they are called *Epstein's pearls*. They are expected findings in the newborn and resolve spontaneously within a few weeks of life.

Sebaceous Gland Hyperplasia. At least 50% of normal newborns have sebaceous gland hyperplasia (Fig. 107-2). Tiny (<1-mm) yellow macules or papules are seen at the opening of each pilosebaceous follicle over the nose and cheeks of term newborns. It is a benign condition that clears spontaneously by 4–6 months of age.

Erythema Toxicum Neonatorum. Erythema toxicum neonatorum (ETN) is an idiopathic, common condition seen in up to 75% of term newborns. It is rarely seen in premature infants. Blotchy erythematous macules 1–3 cm in diameter with a 1–4-mm central vesicle or pustule are seen in ETN (Fig. 107-3). They usually begin at 24–48 hours of age, but delayed eruption as late as 10 days of age has been documented.[15] These follicular-based lesions can be located anywhere but tend to spare the palms and soles. A smear of the central vesicle or pustule contents will reveal numerous eosinophils on Wright-stained preparations. A peripheral blood eosinophilia of up to 20% may be associated, particularly in infants, with numerous lesions. Transient neonatal pustular melanosis (TNPM) lesions conrail neutrophils rather than eosinophils, and individual lesions heal with residual pigmentation, which is not seen in ETN. Bacterial infections, *Pityrosporum* folliculitis, and congenital candidiasis also may mimic ETN. Bacterial and fungal culture of lesions and Gram staining will help differentiate among these entities. ETN is benign and clears spontaneously by 2–3 weeks of age without residua.

Figure 107-2 Sebaceous hyperplasia on the nose of a 1-day-old infant.

Figure 107-3 Erythema toxicum neonatorum. Erythematous macules, some with a tiny central papule or pustule, on the arm of a 1-day-old newborn.

Transient Neonatal Pustular Melanosis. TNPM is an idiopathic pustular eruption of the newborn that heals with tiny brown-pigmented macules (Fig. 107-4). It is less common than ETN and is more prevalent among newborns with darkly pigmented skin. Lesions are usually present at birth or shortly thereafter, but may appear as late as 3 weeks of age, as superficial vesicles and pustules, with ruptured lesions evident as collarettes of scale. Pigmented macules are also often present at birth or develop at the sites of resolving pustules or vesicles within hours or during the first day of life; occasionally babies are born with the tiny melanocytic macules, suggesting in utero vesiculation. Lesions can occur anywhere but are common on the forehead and mandibular area. The palms and soles may be involved. Smear of the vesicle or

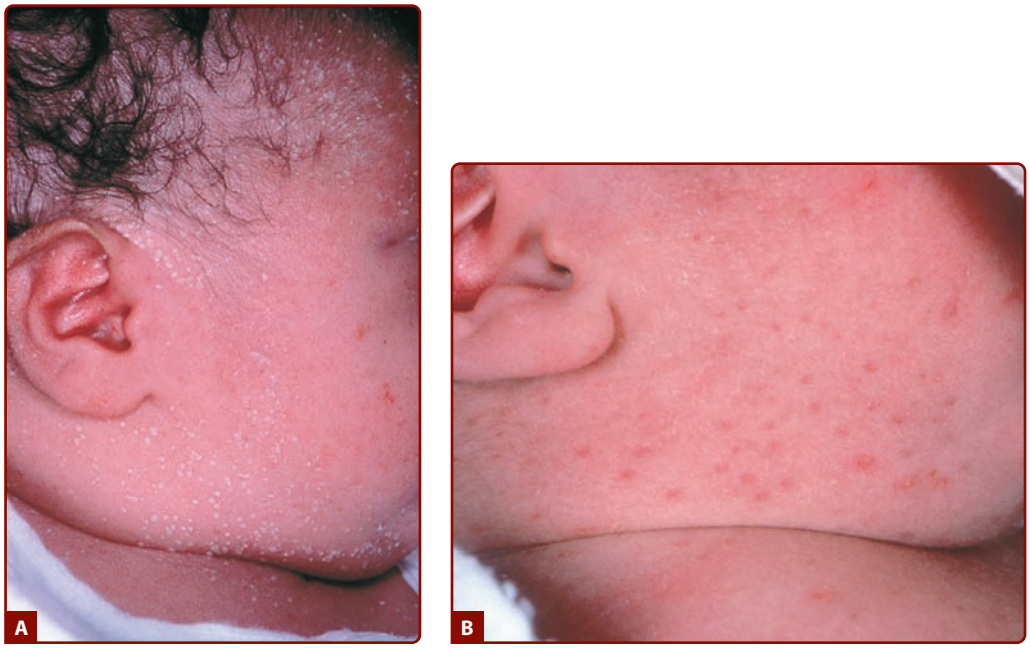

Figure 107-4 Transient neonatal pustular melanosis. **A.** A newborn with congenital, thin-walled pustules that rupture easily. **B.** Hyperpigmented macules appeared by 10 hours of age.

pustule contents will reveal a predominance of neutrophils with occasional eosinophils on Wright-stained preparations.[16]

Miliaria rubra is frequently confused with ETN and TNPM. The erythema around miliaria rubra is small in area (1–2 mm versus 20–30 mm in ETN). The central pustule of TNPM may mimic congenital candidiasis, *Pityrosporum* folliculitis, or bacterial folliculitis lesions. Herpes simplex should be considered if lesions are vesicular. A Gram-stained slide of the pustules of ETN or TNPM will not show organisms. A Wright-stained slide usually will show a predominance of neutrophils. TNPM is a harmless condition that requires no treatment. The pustules usually disappear within 5–7 days of age, leaving residual pigmented macules that resolve over 3 weeks to 3 months.

Mottling. Mottling is a blotchy or lace-like pattern of dusky erythema over the extremities and trunk of neonates that occurs with exposure to cold air. Virtually all babies demonstrate mottling at some time during the newborn period due to immaturity of the autonomic control of the cutaneous vascular plexus. This physiologic mottling disappears on rewarming, differentiating it from cutis marmorata telangiectatica congenita and livedo reticularis. Normal mottling resolves spontaneously by 6 months of age.

Harlequin Color Change. Harlequin color change is a rare vascular phenomenon occurring in low-birthweight infants. When the infant is placed on one side, an erythematous flush with a sharp demarcation at the midline develops on the dependent side, and the upper half of the body becomes pale. The color change usually subsides within a few seconds of placing the baby in the supine position but may persist for as long as 20 minutes. The exact mechanism of this unusual phenomenon is not known, but it may be due to immaturity of autonomic vasomotor control. Harlequin color change is seldom seen after 10 days of age.

Sucking Blisters. Sucking blisters may be present at birth as the result of intrauterine sucking, but are more commonly seen during the first weeks of life. Sucking blisters are usually solitary, intact oval or linear blisters, erosions, or drying crusts, arising on noninflamed skin of the dorsal-radial aspect of forearms, wrists, or fingers or on the upper lip. They resolve within a few days. If the affected extremity is brought up to the infant's mouth, the infant will often commence sucking at the site, confirming the diagnosis. Herpesvirus infection is often considered when sucking blisters are encountered, but lesions of *Herpes simplex* infection are grouped vesicles occurring on an erythematous base or punched out, hemorrhagic erosions.

Benign Cephalic Pustulosis. Neonatal acneiform facial lesions usually develop within the first 30 days of life and are estimated to occur in 50% of newborns (Fig. 107-5). This benign eruption appears to be hormonally mediated (see Chapter 80) and has been attributed to overgrowth of *Malassezia* sp., and termed "benign neonatal cephalic pustulosis."[17] Most cases resolve spontaneously, but the eruption can be treated topically with ketoconazole, benzoyl peroxide, or erythromycin. True neonatal acne is probably much less common than benign cephalic pustulosis and can be distinguished by the presence of comedonal lesions. Similarly, infantile acne usually shows true comedones, sometimes with papules, pustules, and even cysts. An example of infantile acne is seen in Figure 107-6.

Figure 107-5 Benign cephalic pustulosis. Tiny papulopustules on the cheeks of a 3-week-old infant.

HAIR LOSS IN THE INFANT[18]

Telogen Effluvium. Telogen effluvium occurs frequently in newborns and is often overlooked. The hair loss may be gradual or sudden, and may occur as soon as the first few days of life, with the telogen hairs shed by 3–4 months of age. No treatment is indicated as spontaneous resolution is the rule.

A transient circumscribed patch of nonscarring alopecia develops at the occiput in many infants. Thought to be due to a combination of physiologic telogen effluvium and localized pressure from lying in the supine position, occipital alopecia spontaneously resolves.

Triangular Temporal Alopecia. Triangular temporal alopecia is a form of nonscarring hair loss noted at 2–5 years of age as a triangular-, oval-, or lancet-shaped area of alopecia at the frontotemporal scalp. Often, a thin row of hair separates the affected area from the forehead. The terminal hairs are replaced by vellus hair. The condition is often mistaken for alopecia areata; however, distinguishing features include the typical location and shape, the presence of vellus hairs, and the absence of exclamation point hairs or histologic findings of alopecia areata. There is no known treatment, and the condition persists unchanged. However, triangular temporal alopecia is benign and will not expand.

Figure 107-6 Infantile acne. True comedones and inflammatory papules are noted on the cheeks of a healthy 10-month-old girl.

Alopecia Areata. Alopecia areata occurs in all ages (see Chapter 88). All forms of alopecia areata occur in infants and children (patchy, universalis, etc.), with the same disease presentation and treatment challenges as in adults. Onset at younger than 2 years of age is estimated to occur in 1%–2% of alopecia areata patients; however, it may be under-recognized and more common. Several cases of congenital alopecia areata have been documented. Early onset is considered to be a poor prognostic marker. Total alopecia during the first year of life after having hair at birth should be distinguished from genetic disorders, such as congenital atrichia with papular lesions and vitamin D resistance.

Tinea Capitis. Tinea capitis can occur at any age, including infancy (see Chapter 188). Hair loss associated with scaling, broken hairs, pustules, or black dots should prompt a potassium hydroxide scraping and fungal culture to confirm the diagnosis. Just as in older children, *Trichophyton tonsurans* is the most common dermatophyte, and oral griseofulvin is the treatment of choice. Tinea capitis and fungal infections are discussed in Chapter 188.

BIRTHMARKS.

Birthmarks represent an excess of one or more of the normal components of skin per unit area: blood vessels, lymph vessels, pigment cells, hair follicles, sebaceous glands, epidermis, smooth muscle, collagen, or elastin. Although most birthmarks are of little medical or psychosocial consequence, the social and cultural impact of a disfiguring birthmark should not be underestimated, from both the patient's and the parents' perspectives.[19] The age-old theory of maternal imprinting is still widely accepted in many countries, including the United States, and the mother may be subtly or actively blamed for congenital conditions in the newborn. With selective photothermolysis offered by lasers and advances in surgical and topical therapies, therapeutic options are increasing.

The two most common birthmarks are the nevus simplex (see Chapter 172) and Mongolian spots (see Chapter 122). Nevus simplex (also known as salmon patch, nevus flammeus, angel's kiss, or stork bite) represents a capillary malformation of the skin. It occurs most commonly on the glabella, upper eyelids, and nuchal area. Nevus simplex appears with high frequency in all races, occurring in 70% of white infants and 59% of black infants. Mongolian spots, which represent collections of dermal melanocytes, are seen in 80%–90% of infants of color but in only 5% of white infants.[20,21] Solitary café-au-lait macules are extremely common and benign, however, the appearance of multiple café-au-lait macules raises the possibility of neurofibromatosis type 1 (see Chapter 141). Other common birthmarks are listed in Table 107-2.

HEMANGIOMAS.

Infantile hemangiomas are the most common tumors of infancy. They must be differentiated from vascular malformations and other vascular anomalies. Hemangiomas are discussed in detail in Chapter 126.

TABLE 107-2
Common Birthmarks in the Newborn

- Mongolian spots
- Nevus simplex (nevus flammeus, salmon patch, "stork bite," "angel's kiss")
- Port-wine stain
- Hemangioma of infancy (infantile hemangioma)
- Epidermal nevus, including nevus sebaceus
- Congenital nevocellular nevi
- Congenital melanocytic nevi
- Nevus depigmentosus
- Café-au-lait spots

LYMPHANGIOMAS. Both types of lymphatic malformations, microcystic (lymphangiomas) and macrocystic (cystic hygromas), are discussed in Chapter 172.

UNCOMMON DERMATOSES OF THE NEONATE. Selected dermatoses of the neonate are discussed in the following sections. Table 107-3 lists differential diagnoses for selected cutaneous conditions encountered in neonates and infants.

Cutis Marmorata Telangiectatica Congenita. Cutis marmorata telangiectatica congenita is characterized by persistent coarse cutis marmorata, telangiectasia, and sometimes associated underlying cutaneous atrophy and ulceration (Fig. 107-7). Its incidence is sporadic, and its etiology is obscure. Theories of vascular malformation are currently favored. Diagnosis is usually evident on clinical examination. Usually a lower extremity is involved, but location on the trunk or upper extremity is not uncommon. A multitude of associated anomalies can occur, including limb asymmetry, hemangiomas, other vascular birthmarks, pigmented nevi, and aplasia cutis congenita (ACC). However, the majority of patients have a good prognosis, with half demonstrating improvement of the mottled appearance over the first 2 years.[22]

Figure 107-7 Cutis marmorata telangiectatica congenita. Note the atrophic, dusky, stellate patches with overlying telangiectasias.

TABLE 107-3
Selected Differential Diagnosis of Neonates and Infants

- Pustules
  - Erythema toxicum neonatorum
  - Transient neonatal pustular melanosis
  - Congenital candidiasis
  - Pustular psoriasis
  - Langerhans cell histiocytosis
  - Neonatal cephalic pustulosis
  - Bacterial sepsis
  - Herpes simplex infection
- Blisters
  - Sucking blisters
  - Herpes simplex virus
  - Aplasia cutis congenital
  - Cutaneous mastocytosis
  - Epidermolysis bullosa
  - Neonatal pemphigus
  - Varicella
  - Impetigo
  - Incontinentia pigmenti
  - Epidermolytic ichthyosis
- The red scaly baby
  - Physiologic scaling and redness (postdates) infant
  - Psoriasis
  - Atopic dermatitis
  - Scabies
  - Seborrheic dermatitis
  - Immunodeficiency
  - Hypohidrotic ectodermal dysplasia
  - Netherton syndrome
  - Acrodermatitis enteropathica
- The collodion baby
  - Lamellar ichthyosis
  - Congenital ichthyosiform erythroderma
  - Gaucher syndrome
  - X-linked ichthyosis
  - Epidermolytic ichthyosis
- The "blueberry muffin" baby
  - TORCH infections
  - Congenital leukemia
  - Congenital self-healing reticulohistiocytosis
  - Blue rubber bleb nevus syndrome
  - Twin-twin transfusion

TORCH = *t*oxoplasmosis, *o*ther agents, especially syphilis, but also hepatitis B, *c*oxsackie virus, Epstein-Barr virus, varicella-*z*oster virus, and human parvovirus, *r*ubella, *c*ytomegalovirus, *h*erpes simplex virus.

Subcutaneous Fat Necrosis of the Newborn. Subcutaneous fat necrosis of the newborn is characterized by firm, circumscribed, reddish or purple subcutaneous nodules or plaques that appear over the back, cheeks, buttocks, arms, and thighs (Fig. 107-8; see Chapter 70). The lesions usually begin within the first 2 weeks of life and resolve spontaneously over several weeks.[23]

Figure 107-8 Subcutaneous fat necrosis of the newborn. This infant developed an erythematous firm mass on the back by 2 weeks of age. She later developed hypercalcemia.

Sclerema Neonatorum. Sclerema is diffuse hardening of the skin in a sick premature newborn that is now rare because of improved neonatal care. The onset is characteristically after 24 hours of age. The skin feels hard and immobile and looks yellow and shiny. The trunk is always involved. Severely ill premature newborns that have suffered sepsis, hypoglycemia, metabolic acidosis, or other severe metabolic abnormalities are at risk. Biopsy sections show edema of fibrous septa surrounding fat lobules, but no fat necrosis, differentiating it from subcutaneous fat necrosis of the newborn. The etiology of this rare condition is unclear, and infant mortality is high.

Aplasia Cutis Congenita (ACC). ACC represents a failure of skin to fully develop, most often on the scalp, and less commonly elsewhere (Fig. 107-9). It is often an isolated finding, but a multitude of associated conditions have been described. ACC has no single underlying cause. Some cases may represent a forme fruste of a neural tube defect.[24] In the most common form of ACC, oval, sharply marginated atrophic macules are seen on the midline of the posterior scalp. They are usually solitary, but may be multiple. Aplasia cutis is always hairless, and may appear vesicular, ulcerated, or covered by a thin epithelial membrane. When healed, lesions are usually atrophic scars, but sometimes develop a keloidal scar. Epidermis, dermis, and fat all may be missing, or a single layer may be absent. Lesions may range from a few millimeters to many centimeters in diameter. Lesions at birth of epidermolysis bullosa (see Chapter 62) may resemble ACC, especially on one or both legs. Scalp ulcers at birth of aplasia cutis may be mistaken for obstetric trauma. Other forms of congenital circumscribed hair loss should be considered. Midline blisters or erosions should not be biopsied, scraped for herpes cultures, or otherwise traumatized. After a careful examination to rule out associated malformations, ACC is treated conservatively to allow healing. Surgical revision of the scar later in childhood or adolescence can be done electively to improve cosmesis.

Hair Collar Sign. The "hair collar sign" is a ring of darker and/or coarser terminal hairs on the scalp, typically surrounding ACC, dermoid cyst, encephalocele, meningocele, or heterotopic brain tissue.[25] The hair collar sign itself is a marker of cranial dysraphism and its presence, like aplasia cutis, mandates careful examination of the infant, particularly of midline structures and fusion planes.

Anetoderma of Prematurity. A specific form of iatrogenic anetoderma (see Chapter 67) has been described in extremely premature infants (born at 24–30 weeks' gestation) with very low birthweight and prolonged neonatal intensive care hospitalization.[26]

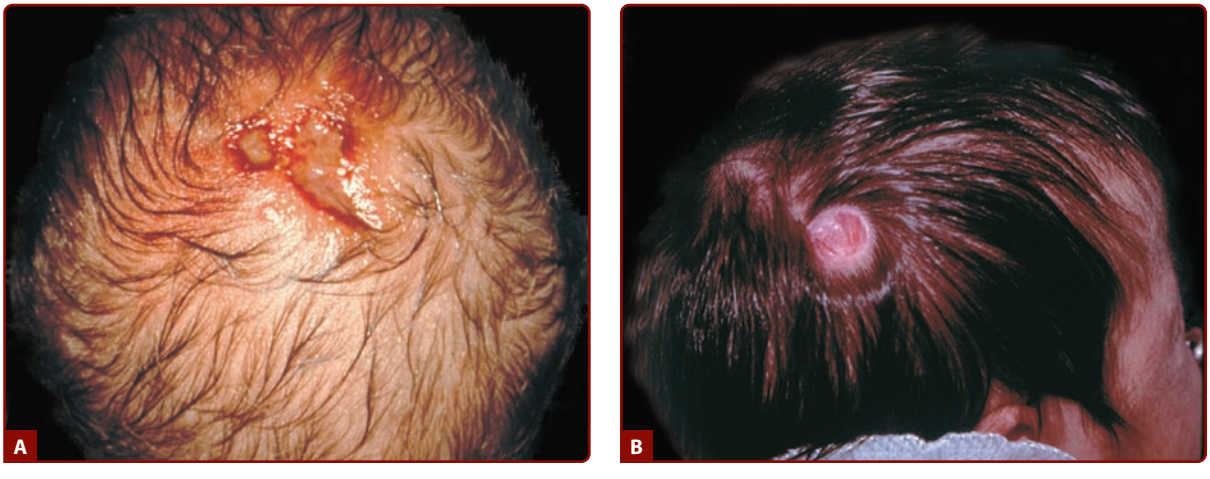

Figure 107-9 Two infants with aplasia cutis congenita. **A.** Scalp erosions grouped at the vertex scalp. Scraping or biopsy is contraindicated. **B.** An atrophic, well-circumscribed round patch with visible capillaries on the scalp of an infant. (**A** used with permission from 1991 Yale Resident Photograph Collection.)

A retrospective review of 11 cases noted the appearance of round, flat atrophic patches on the chest and abdomen (including the periumbilical region), developing at age 6 weeks to 5 months. Eight patients had lesions at sites where adhesive monitoring leads had been removed, and five patients had circular ecchymotic patches from removal of adhesive monitoring leads prior to the occurrence of the anetoderma. The anetoderma did not improve with time. One child underwent surgical excision of the disfiguring lesions at age 7 years. Given the presumed relationship of the development of anetoderma and skin trauma mainly from adhesive leads, avoidance of pressure (e.g., placing leads on the ventral chest when the infant slept on the back) markedly reduced the risk of occurrence.[27]

INFECTIONS OF THE NEONATE

Infants younger than the age of 2 months are less able to localize infection due to immature immunologic function, and life-threatening sepsis can develop insidiously. Subtle clues such as a decrease in body temperature, poor feeding, or other nonspecific signs are taken seriously by the pediatrician, and a "rule out sepsis" admission is implemented when suspicions are high. At a minimum, blood, cerebrospinal fluid, and urine cultures are obtained, and intravenous antibiotic therapy begun pending cultures.

CONGENITAL VIRAL INFECTION. Petechiae, purpura, jaundice, hepatomegaly, splenomegaly, microcephaly, encephalopathy, ocular abnormalities, anemia, thrombocytopenia, conjugated hyperbilirubinemia, or elevated serum hepatic transaminases should prompt the consideration of congenital viral infection, particularly if these signs arise in combination. Cutaneous infections of the neonate are listed in Table 107-4. Bacterial infections, such as staphylococcal scalded skin syndrome; and viral infections, such as varicella, are discussed in Chapters 193 and 194.

TABLE 107-4
Selected Cutaneous Infections in the Neonate

- Staphylococcal infections
- Impetigo
- Staphylococcal scalded-skin syndrome
- Omphalitis
- Breast abscess (usually due to *Staphylococcus aureus* and Gram-negative organisms)
- Viral infections
- Varicella
- Herpes simplex virus
- Fungal/candidal infections
- Scabies

NEONATAL HERPES SIMPLEX VIRUS INFECTION. (See Chapter 193.) It is estimated that untreated neonatal herpes simplex virus (HSV) has a 50% mortality rate, with three-fourths of survivors suffering neurologic sequelae. The greatest risk of neonatal herpes occurs when the delivery is vaginal and the mother has primary genital herpes (as opposed to recurrent herpes, in which the mother has antibodies protective to the neonate), the herpes infection involves the cervix, and the infant is premature and delivered with instrumentation (e.g., scalp electrodes).

The vast majority of cases are due to HSV type 2. The typical lesions of herpes are present in the skin, eye, or mouth in a large majority of infected neonates, but some patients with CNS or disseminated disease never have skin lesions (Fig. 107-10).[28] Vesicles present during the first 24 hours of life suggest in utero acquisition of HSV, but onset during the first week to 10 days of life is more common, representing exposure to the virus during the delivery.[28]

A high index of suspicion should be maintained even in the absence of maternal infection or history of genital herpes. Specimens for Tzanck smear, direct

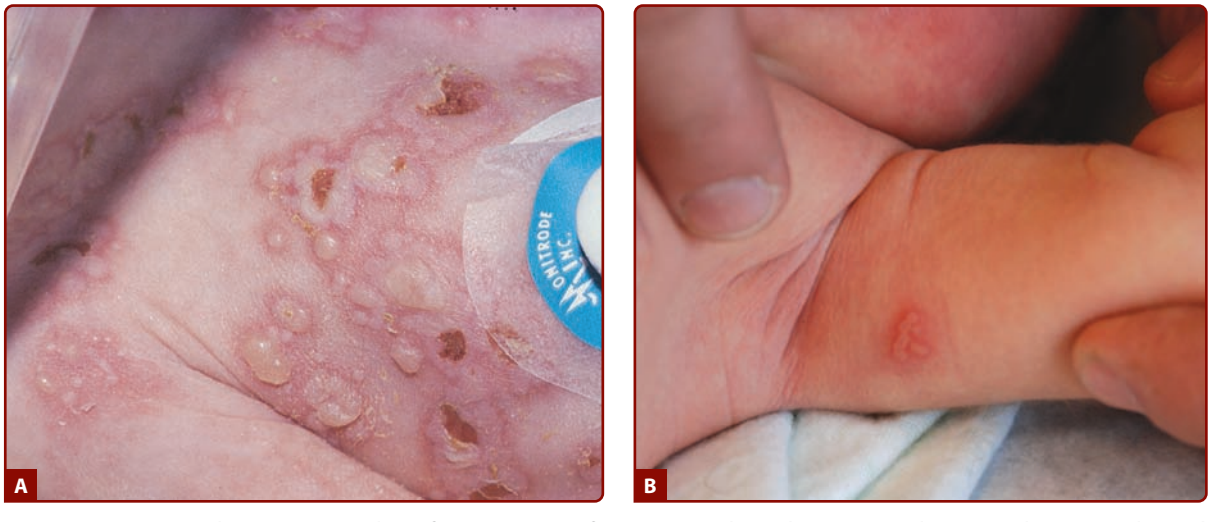

Figure 107-10 **A** and **B.** Herpes simplex infection in two infants. Grouped vesicles on an erythematous base. Pustules and erosions are also present. (A used with permission from Alvin H. Jacobs, MD.)

Figure 107-11 Supernumerary digit, a common minor malformation.

fluorescent antibody assays, and/or viral cultures for HSV should be obtained. Cultures require 12–120 hours to grow, and in all infected or suspected neonates, cultures of skin lesions, urine, nasopharynx, eyes, and cerebrospinal fluid are indicated. If available, a polymerase chain reaction test can be very helpful in rapid diagnosis. Intravenous acyclovir should be instituted as soon as possible after specimens are collected to minimize the chance of replication of virus in the CNS and systemic dissemination of HSV. Prompt recognition and early therapeutic intervention lead to an improved outcome in the HSV-infected infant.[28]

CONGENITAL MALFORMATIONS OF THE SKIN

MINOR ANOMALIES. Congenital malformations are developmental defects and are frequently observed

Figure 107-12 **A** and **B.** Nasal glioma initially thought to be a hemangioma of infancy. A firm, reddish slightly pedunculated was noted off of the midline of the nasal root. The MRI showed no intracranial connection. **C.** Nasal glioma. Firm subcutaneous mass noted at birth.

in newborns. Single minor anomalies occur in approximately 15% of all newborns and are, by definition, of no functional significance. The supernumerary digit (Fig. 107-11), supernumerary nipple and the accessory tragus are common examples of minor malformations. The occurrence of two is less common, however, and the presence of three or more is unusual; a complete thorough physical examination is indicated to rule out other congenital abnormalities.[29,30]

CUTANEOUS MARKERS OF DYSRAPHISM.

The skin and the nervous system are both derived from the ectoderm. The neural ectoderm separates from the epithelial ectoderm during the third to fifth week of gestation, occurring simultaneously with the formation and closure of the neural tube. Hence, errors in neural tube development [i.e., dysraphism (incomplete fusion)] can be associated with cutaneous lesions. Midline facial lesions, such as dermoid cysts, nasal gliomas (Fig. 107-12), and ACC (Fig. 107-9), can be markers of cranial dysraphism, whereas cutaneous lesions seen on the lumbosacral midline can signify underlying spinal dysraphism (Fig. 107-13). Imaging studies should be considered for midline nasal lesions before biopsy to rule out intracranial connections.[31]

A retrospective review of 54 cases of congenital lumbosacral skin lesions (including deviated gluteal cleft)[32] demonstrated that the highest risk of occult spinal dysraphism occurs with the presence of two or more congenital midline lumbosacral skin lesions, or if spinal cord dysfunction exists in the presence of one lumbar skin lesion. In addition, lumbosacral lipoma, human tail, and dermal sinus (as isolated findings) were highly associated with occult spinal dysraphism. Lumbosacral magnetic resonance imaging is indicated when these high-risk congenital lesions are present. An intermediate risk of occult spinal dysraphism was associated with atypical sacral dimple (≥5-mm diameter, or location ≥2.5 cm away from the anus), ACC, overlying hamartoma, or deviated gluteal cleft. In the presence of any of these lesions, ultrasound can be used to screen for occult spinal dysraphism if the infant is less than 4 months of age. If the infant is older, magnetic resonance imaging is needed to rule out dysraphism. Low-risk lesions that do not require imaging include isolated lumbosacral hemangioma, port-wine stain, focal, mild hypertrichosis, pigmented nevus, Mongolian spot, or simple sacral dimple (≤5-mm diameter and location 2.5 cm or closer to the anus).[32] These findings are summarized in Table 107-5.

Figure 107-13 A large, wide tuft of thick terminal hair on the lumbosacral spine noted at birth. She had underlying tethered cord (note midline scar due to surgical repair).

TABLE 107-5
Congenital Lumbosacral Midline Skin Lesions and Risk of Occult Spinal Dysraphism

Risk of Occult Spinal Dysraphism	Congenital Lumbosacral Midline Lesion
High	Group 1: MRI indicated ■ Two or more lesions of any kind ■ One lesion + spinal cord dysfunction ■ Lipoma ■ Tail ■ Dermal sinus
Intermediate	Group 2: Ultrasound if younger than age 4 month (then MRI if ultrasound is abnormal), MRI indicated for age >4 month, or if sonographic expertise unavailable ■ Atypical sacral dimple (deep, farther than 2.5 cm from the anus, size ≥5 mm) ■ Unclassified hamartoma ■ Aplasia cutis congenita ■ Deviation of gluteal crease
Low	Group 3: No imaging needed ■ Port-wine stain ■ Hypertrichosis (unless large and/or unusual) ■ Pigmented nevus ■ Simple sacral dimple (<5-mm diameter, 2.5 cm or closer to the anus) ■ Mongolian spot

MRI = magnetic resonance imaging.

INFANCY AND CHILDHOOD

EVALUATION TECHNIQUES

Observing the play of a child allows for a quick assessment of his or her neurologic development. Interactions between caregivers and child are also informative. Early prolonged or intense eye contact with the young child should be avoided because this can be threatening to the child. If an elective biopsy or procedure is needed, it is often more acceptable for the parent (especially if a neonate) or child if the procedure is scheduled for a second visit rather than the initial one.

If a language barrier exists between the parents and physician, one should resist the urge to have the bilingual patient serve as interpreter for the parents. This

practice places an inappropriate burden of responsibility on the child and may increase fear and anxiety in the child. In addition, inaccurate transmission of information may occur.

Examination of young children may be performed with the child on the parent's lap or while playing with toys on the examination table. If needed, examination of the perineum and genitalia can be accomplished with the child in the knee-chest position on the examination table (eFig. 107-13.1 in online edition) or the parent's lap. Alternatively, the child may sit on the parent's lap with legs held apart by the parent. eFig. 107-13.2 in online edition illustrates anatomic terminology of the young female genitalia for accurate documentation, and can be helpful in conditions such as lichen sclerosus. Caution must be used in interpreting the genital examination in the young female so as not to underdiagnose or overdiagnose disease or abuse. For example, the presence of labia minora adhesions is not diagnostic of trauma or abuse because they occur in as many as one-third of girls who are not abused.[33] The diastasis ani is a normal structure that can be mistaken for perianal scarring.[34] The infantile perianal pyramidal protrusion may be mistaken for condyloma acuminata but is a harmless normal finding (discussed later in this chapter in Infantile Perineal Protrusion).[35,36] Child abuse is discussed in Chapter 106.

PERFORMING PROCEDURES ON THE YOUNG CHILD

Historically, there has been a widespread reluctance to biopsy skin lesions in infants and children. This often leads to a delay in diagnosis in conditions such as childhood melanoma, for example. In addition, many skin conditions in children have a paucity of dermatopathologic information in the literature due to this reluctance. Parents may be anxious about causing pain or scarring, and children may be fearful because of their experience with immunizations, or an age-appropriate fear of bodily mutilation. However, with proper preparation of the parent and child, skin biopsies and other outpatient procedures are easily performed (see Table 107-6). Note that there are certain situations in which a biopsy can be detrimental; examples of these "biopsy pitfalls" are outlined in Table 107-7.

Eutectic mixtures of lidocaine and prilocaine (EMLA cream) or lidocaine alone (LMX cream) are useful in minimizing the pain of intralesional injections or local anesthetic injections for biopsies. As EMLA use has become widespread, reports of toxicity in children have appeared, including methemoglobinemia and seizures. The maximum dose, body surface area exposed to drug, and application time should not be exceeded; these parameters are age dependent and are 1 g for 1–3 month old, 2 g for a 3–12 month old, 10 g for a 1–6 year old, and 20 g was a 7–12 year old.[40] The application of ice or anesthetic cryospray is another option to numb the skin before injections.

Before and during procedures, young infants can be soothed with a pacifier dipped in a sucrose solution. A randomized, controlled, double-blinded study of 201 newborns found that orally administered glucose solution was superior to topical EMLA cream in reducing pain with venipuncture.[41] Infants may be swaddled with a blanket for comfort and immobilization. The young child can be effectively immobilized and comforted with a restraining "hug," by a parent or assistant. Distraction techniques are invaluable as well. For example, instructing the child to blow a colorful toy windmill, blow soap bubbles, or "wiggle" his or her toes during an injection or procedure helps to decrease pain. Older children may be effectively soothed by listening to music with headphones or by watching a movie during procedures.

Alkalinizing local anesthetics to a pH of 7.0 (0.1 mEq/mL sodium bicarbonate or a 1:10 bicarbonate–anesthetic ratio by volume) minimizes the pain of cutaneous infiltration without limiting anesthetic effects.[42] Alkalinization decreases the solution's shelf life to approximately 1 week [43] due to more rapid oxidation of epinephrine. Warming lidocaine also lessens the pain of injection.[42]

Vibrational motions applied with the surgeon's nondominant hand adjacent to injection site and infiltrating slowly are additional helpful techniques to reduce the pain of injection of anesthetic.

Instruments and materials should be laid out ahead of time to ensure rapid performance of the procedure, and are less frightening if kept out of sight by covering with a drape. Needles, instruments, and blood-stained gauze should be kept out of view and out of reach of the patient.

Children sense their parents' anxiety and nervous energy. Parents who are overly anxious can be asked to sit farther away from the operating table, or sometimes are best positioned outside the procedure room.

TABLE 107-6
The ABC's of Successful Outpatient Procedures in Pediatric Dermatology

- **A**: **A**nesthesia techniques: EMLA or ice prior to injection, buffer the lidocaine, apply vibration next to injection site, and infuse slowly. **A**ppointment times in the morning are best for procedures on young children. If they are tired they are less able to focus and cooperate.
- **B**: **B**lood: keep bloody gauze and instruments out of sight of patient and parents.
- **C**: **C**alm parents = calm child. **C**onsent by parents is required if patient is a minor.
- **D**: **D**istraction techniques are essential: MP3 player, DVD player, Where is Waldo? books, and I-Spy books are all very helpful.
- **E**: **E**xpedite the procedure by preparing all instruments and materials before starting.
- **F**: Four hands (minimum) are needed—have at least one assistant to help, preferably not the parent.
- **G**: **G**o to a day surgery setting if patient is unable to participate in local anesthesia due to patient's age or abilities.
- **H**: **H**overing parents—keep them seated and calm, with surgical site out of view.
- **I**: **I**nvest the time, do not rush.

TABLE 107-7
Biopsy Pitfalls in Pediatric Dermatology

Age Group	Lesion and Site	Diagnosis	Danger	Proper Management
Newborn	Erosion or vesicle on the scalp	Aplasia cutis congenita Differential diagnosis: herpes, fetal scalp electrode trauma	Possible intracranial connection, risk of meningitis with biopsy or scraping	Protect site; do not scrape lesion or biopsy, consider ultrasound or MRI of head if a typical
Infant	"Hair collar" sign surrounding lesion on scalp or midline lesion	Encephalocele, spina bifida occulta, meningomyelocele	Possible intracranial connection; risk of meningitis	Preoperative imaging; consider neurosurgical consultation
Infant	Tuft of hair over midline spine	Spina bifida occulta, meningomyelocele	Possible intracranial connection; risk of meningitis	Preoperative imaging; consider neurosurgical consultation
Infant	Preauricular "tag"	Accessory tragus	Risk of chondritis if removed by shave or snip excision or if ligated with suture[37]	Appropriate closure when excised, if cartilaginous component present
Infant or child	Mass along midline scalp, glabella, side of forehead, or other embryonic fusion plane	Dermoid cyst	Intracranial connection in up to 25% for midline dermoids; risk is higher if sinus present[38]; dermoids near the lateral eyebrows rarely have intracranial connections[39]	Consider MRI and neurosurgical consultation
Infant, young child	Nasal midline mass	Nasal glioma, encephalocele, or other dysraphic state Differential diagnosis: "hypertelorism," hemangioma	Intracranial connection in 100% of encephaloceles; gliomas may extend into oropharynx or have intranasal connections[38]	Consider MRI and neurosurgical consultation
Infant, young child	Vascular mass with greatly increased warmth, often with pulsation or bruit	Arteriovenous malformation Differential diagnosis: hemangioma	Uncontrolled bleeding, problematic bony or soft tissue hypertrophy	Consider Doppler studies, MRI, and surgical consultation

MRI = magnetic resonance imaging.

The use of general anesthesia for dermatologic procedures in healthy pediatric patients is very safe when properly performed. Fears of general anesthesia should not be a barrier to delivering necessary surgical or laser procedures to healthy children.[44]

DISEASES OF INFANCY AND CHILDHOOD

INFANTILE PERINEAL PROTRUSION. Also known as *infantile pyramidal protrusion*, infantile perineal protrusion (IPP) is a benign condition that occurs almost exclusively in female prepubertal girls. It appears as a pyramidal, soft-tissue, "tongue-like," smooth, or velvety pink protrusion. It is usually located in the midline just anterior to the anus. IPP is usually asymptomatic, but painful defecation has been reported. It occurs in three settings: constitutional, functional (after constipation, diarrhea, or other irritant exposure), or associated with lichen sclerosus et atrophicus. Often, IPP is misdiagnosed as condyloma acuminatum, hemorrhoids, or as a sign of trauma. Conservative management is indicated. Spontaneous resolution as well as resolution following high-fiber diet to relieve constipation has been noted.[35,36]

DIAPER DERMATITIS. Diaper dermatitis, like hand dermatitis, denotes a group of region-specific dermatoses. Diaper dermatitis is one of the most common dermatologic conditions in infants and children, noted in approximately 1 million pediatric outpatient visits each year.[45] With the advent of superabsorbent disposable diapers in the last decade, severe forms of diaper dermatitis have diminished in incidence. Irritant and candidal diaper dermatitis comprises the vast majority of diaper dermatitides in diaper-wearing individuals of all ages.

The etiology of diaper dermatitis is multifactorial. The initiating factor is prolonged and increased wetness to the skin. This leads to increased frictional damage, decreased barrier function, and increased reactivity to irritants. Other interrelated etiologic factors include contact with urine and feces, fecal proteolytic and lipolytic digestive enzymes, increased skin pH, and superinfection with *Candida* and, less commonly, bacteria.[46]

Irritant Diaper Dermatitis. By far the most common type of diaper dermatitis is irritant diaper dermatitis. This dermatitis occurs in any person who wears diapers, regardless of age. Irritant diaper dermatitis appears as erythematous, moist, and sometimes scaly patches on the convexities of the genitalia and buttocks, beginning in areas in closest contact with the diaper. Shallow erosions are sometimes present on the convex surfaces. It can be asymptomatic or tender.

Candida Diaper Dermatitis. (See Chapter 189). *Candida* diaper dermatitis is the second most common type of diaper dermatitis and presents with bright red erythematous, moist papules, patches, and plaques that tend to involve body folds as well as convex surfaces. Satellite lesions are very characteristic. Oral thrush can be associated. *Candida* from intestinal flora frequently contaminates any type of diaper dermatitis present for greater than 3 days, and *Candida* levels increase with the clinical severity of the dermatitis.[47]

Miliaria Rubra ("Heat Rash"). (See Chapter 84.) Miliaria rubra tends to occur at sites where plastic components of the diaper cause occlusion of eccrine ducts of the skin. It is also seen in the folds of the neck and upper torso, and is particularly common when there is a rapid shift to warm weather, and the child is overdressed.

Pseudoverrucous Papules and Nodules. Pseudoverrucous papules and nodules occur in the diaper and perianal areas in patients of any age with exposure to prolonged wetness. Children who wear diapers due to chronic urinary incontinence are prone to this type of dermatitis for example.

Infantile Granular Parakeratosis. Infantile granular parakeratosis represents an idiopathic form of retention keratosis in diaper-wearing infants. There are two clinical patterns: bilateral linear plaques in the inguinal folds and erythematous geometric plaques underlying pressure points from the diaper. A thick, flake-like scale is present in both forms and is characteristic. Therapeutic responsiveness to topical agents is ambiguous; however, spontaneous clearance after months to 1 year appears to be the rule.[48]

Jacquet Erosive Dermatitis. Jacquet erosive dermatitis is an uncommon, severe diaper dermatitis that can occur at any age. It is characterized by well-demarcated, punched-out ulcers, or erosions with elevated borders. Prolonged contact with urine and feces under occlusion leads to this condition.[49] It is seen less commonly since the advent of superabsorbent disposable diapers.

Granuloma Gluteale Infantum. Granuloma gluteale infantum is an uncommon condition characterized by reddish purplish nodules of different sizes (0.5–3.0 cm) occurring on the convexities of the diaper area in 2- to 9-month-old infants. It arises within preexisting diaper dermatitis. Biopsy shows dense dermal infiltrates of lymphocytes, plasma cells, neutrophils, and eosinophils, but no true granulomas. It appears to be an unusual reaction to the usual irritant factors, candidal infection, and, in some cases, topical steroid use in the diaper region.[49] Treatment consists of avoidance of irritants, use of barrier pastes, and avoidance of topical steroids. Resolution occurs over several months.

Dermatoses Not Etiologically Related to Diaper Wearing. Seborrheic dermatitis, atopic dermatitis, psoriasis (Fig. 107-14), bullous impetigo, acrodermatitis enteropathica, scabies, hand-foot-and-mouth disease, herpes simplex infections, and Langerhans cell histiocytosis are conditions that occur in the diaper region but are not primarily due to the wearing of diapers and should be considered in the differential diagnosis. Skin biopsy is indicated to rule out Langerhans cell histiocytosis (see Chapter 147) if nonhealing erosions or petechiae are seen in the diaper area (Fig. 107-15).

Treatment of Diaper Dermatitis. The treatment of diaper dermatitis is outlined in Table 107-8.[50] Irritant diaper dermatitis and *Candida* diaper dermatitis (or a combination of both) comprise the vast majority of diaper rashes. *Candida* is more likely to complicate diaper rash if present for more than 3 days.

Education of parents and primary care physicians should include instructions regarding the use of topical steroids in the diaper area. Because of greatly increased percutaneous absorption of steroids from

TABLE 107-8
ABCs in the Treatment of Diaper Dermatitis

A = Air. The diaper should be left open as much as possible when the infant sleeps to allow drying of the skin.
B = Barrier ointments. Zinc oxide pastes, petrolatum, and other bland, unmedicated barrier preparations are mainstays of therapy. A continuous layer of barrier paste or ointment should be maintained, reapplying with every diaper change, if necessary. Baby powder on the diaper area offers no antimicrobial benefit to the infant and adds a risk of aspiration.
C = Cleansing and anticandidal treatment. Gentle cleansing with plain water, mineral oil, or unscented gentle cleanser is recommended. Avoidance of friction or rubbing is important. A topical anticandidal agent should be added for any signs of candidiasis. Oral nystatin is indicated if oral thrush is present.
D = Diapers. Diapers should be changed as frequently and as soon after soiling as possible, especially if cloth diapers are used.
E = Education of parents and caregivers.

Modified from Boiko S: Making rash decisions in the diaper area. *Pediatr Ann* **29**:50, 2000.

Figure 107-14 **A.** Infantile psoriasis with involvement in the diaper region. **B.** Infantile psoriasis. This generalized eruption responded well to topical steroids initially and topical tacrolimus later.

moisture and occlusion from diapers, topical steroid use in this anatomic region should be limited to a short course (3–7 days) of hydrocortisone (1% or 2.5%) ointment. This is effective in nearly all cases when a topical steroid is needed. Similarly, use of the combination products containing steroids, such as nystatin plus triamcinolone, and clotrimazole plus betamethasone dipropionate, should be avoided due to increased risks of steroid atrophy and hypothalamic–pituitary axis suppression when used in the diaper area.

Last, parents will be reassured by the fact that even the most problematic diaper dermatitis will resolve when toilet training is achieved, and diapers are not worn.

TINEA CAPITIS. (See Chapter 188.) Scrapings for potassium hydroxide examination and fungal culture should be obtained before administration of systemic antifungal therapy. In children, collection of specimens for tinea capitis may be accomplished by the use of a toothbrush, ring curette, moistened cotton swab, a scalpel, or by collection of infected hairs. Alternatively, a media plate with nonslanted agar may be applied directly to the infected areas of the scalp to collect material.

Figure 107-15 **A** and **B.** Langerhans cell histiocytosis with petechiae and erosions of the skin. This patient also had hepatosplenomegaly.

ADOLESCENT DERMATOLOGY

Dermatologic diagnoses of adolescents overlap with those of general adult dermatology; however, caring effectively for the adolescent patient requires different interviewing skills and strategies to enhance compliance.

EVALUATION TECHNIQUES

Greeting the adolescent first and the parents second, and interviewing the adolescent patient alone at the beginning of the visit help to earn the patient's trust.[51] The confidentiality laws of each state should be considered and the patient's right to privacy respected. Many states protect the adolescent's right to confidential medical care for problems such as drug abuse, sexually transmitted diseases, contraception, pregnancy, and abortion.

The open-ended questioning style used for adults frequently fails with adolescents. Phrasings using the third person and giving choices when asking questions are more effective techniques to obtain information. For example, "Many women on oral contraceptives forget to take their pill once in a while. How often do you forget to take your birth control pills: often, sometimes, or almost never?" will yield a more accurate reply than, "Do you take your birth control pills every day?"

Adolescents lack a well-developed sense of future time and long-term consequences are less valued than immediate outcomes. Goals should be concrete, short term, and relevant to the present. Rather than using goals related to more distant benefits, such as the reduction of potentially serious disease complications (e.g., smoking causes increased risk of lung cancer), emphasis should be placed on immediate and concrete effects (e.g., smoking causes your clothes, hair, and breath to smell bad and your teeth to turn yellow). Body image is a more powerful motivator, and messages such as "tanning salons cause premature wrinkles and ugly skin" are more effective than future health concerns (e.g., "tanning salons increase your risk of skin cancer"). Any treatment that is disfiguring or has visible side effects will meet with resistance.[51]

Physical and psychosocial development may not be congruent. An adolescent should not be expected to shoulder all medical responsibilities for himself or herself or for younger siblings. The physician's role is not to befriend, nor is it to parent the adolescent patient, but rather it is to be a trusted, valuable authority.

ACNE AND THE ADOLESCENT

(See Chapter 80.)

Acne vulgaris is an extremely common and variable disorder that can have far-reaching detrimental effects on self-image and self-esteem. Increased unemployment has been documented among patients with a history of severe acne.[52] For adolescents, a single- or two-drug regimen will optimize compliance and cost-effectiveness.

Females with treatment resistant acne, signs of virilization (including irregular menstrual cycles, hirsutism, and/or obesity) should have evaluation for androgen excess states including polycystic ovary syndrome (see Chapters 80 and 151).

Several oral contraceptives (Yaz®, Yazmin®, and Ortho-Tricyclen®) have Food and Drug Administration (FDA) labeling for the treatment of acne and are an important therapeutic option for adolescent females with recalcitrant acne. The effectiveness of oral contraceptives often allows discontinuation of chronic oral antibiotic therapy. Patients should be counseled that adherence to three cycles of oral contraceptives are often needed to establish treatment efficacy for acne. Oral contraceptives with a higher androgenic component and lower estrogenic component tend to worsen acne. Topical acne medications such as retinoids may need to be continued for best results.

Isotretinoin has been a valuable, unique, and effective agent for nodulocystic acne since 1982. Isotretinoin's teratogenicity is well known. The question of psychopathology induced by isotretinoin is more controversial. The Adverse Drug Event Reporting System of the United States FDA has received reports of depression, suicide, and other psychiatric side effects (e.g., aggression, psychosis) in patients using isotretinoin. The question of isotretinoin-induced depression is complicated by the high baseline incidence of depression and suicide in the adolescent population and by the depression and stress associated with severe acne.[53,54] Case reports, including positive cases of positive dechallenge and rechallenge, have suggested that isotretinoin may induce depression and other psychiatric adverse effects, but larger retrospective and prospective studies have not demonstrated causation.[55] In some studies, depression scores improved when patients' acne improved with isotretinoin therapy.[56] Double-blind, placebo-controlled isotretinoin studies have not yet been done. To date, animal studies have shown conflicting results. Although a causal link has not been established between isotretinoin and depression/suicide at this time, it is likely that uncommon idiosyncratic psychiatric reactions to isotretinoin may occur in predisposed individuals. Pretreatment evaluation and, if cleared to proceed, subsequent comanagement by a psychiatrist or psychologist should be considered for vulnerable patients. If mood changes arise, the drug should be stopped until the patient is evaluated by the pediatrician or psychiatrist. If deemed appropriate, a rechallenge can be done cautiously.

A second unanswered question is whether the risk of inflammatory bowel disease increases with isotretinoin use. Studies have shown conflicting results thus far. It is possible that isotretinoin may trigger inflammatory bowel disease in predisposed individuals. Until we have better data, patients and parents should be counseled that a rare but potentially real risk might exist. If bowel symptoms develop, discontinuation of isotretinoin is advisable until the patient is evaluated by a gastroenterologist.[57,58]

AXILLARY HYPERHIDROSIS

Idiopathic focal hyperhidrosis is a common condition that has been long been under recognized. Axillary hyperhidrosis is much more common but palmar and/or facial sites can be affected as well. It can be familial or sporadic. Although all ages may be affected, patients commonly present during adolescence when the condition becomes socially troubling and impacts significantly on quality of life. The management of focal idiopathic hyperhidrosis is similar to that of adults. If topical and oral treatments fail, injection of botulinum toxin A should be considered. Hyperhidrosis is reviewed in Chapter 84.

INDOOR TANNING

The WHO Cancer Group has classified tanning beds as "carcinogenic to humans." Extensive evidence has linked sunlamp or sun bed exposure to increased risk of melanoma and nonmelanoma skin cancers. Nevertheless, approximately 50,000 tanning salons exist in the United States and tanning bed use is increasing among adolescents and young adults. In addition to the desire for tanned skin and the socialization of the tanning salon, some individuals feel more relaxed, and have improved mood following tanning. Evidence is mounting that tanning bed use is physiologically and psychologically addictive. A study demonstrated that frequent tanners developed a preference for functional UV beds compared to otherwise identical sham light beds.[59] In addition, physiologic withdrawal symptoms arose in some subjects who were given naltrexone prior to their tanning sessions, suggesting that an opioid-mediated mechanism of dependency may exist in frequent tanners.[60]

Psychiatric studies, using modified tools originally used for substance abuse screening, confirm addictive behaviors of people who frequent tanning salons. Among 229 college students who had used indoor tanning facilities, 90 (39.3%) met diagnostic and statistical manual of mental disorders IV-TR criteria and 70 (30.6%) met CAGE (Cut down, Annoyed, Guilty, Eye-opener) criteria for addiction to indoor tanning. In addition, these students also reported greater symptoms of anxiety and greater use of alcohol, marijuana, and other substances than those who did not meet these criteria.[61]

The fight against indoor tanning is becoming similar to the fight against the tobacco industries. Stronger legislation banning tanning bed use in minors, control of false safety claims in advertisements, and extensive education of parents and our youth are needed to wage this war.

SPECIAL TOPICS IN PEDIATRIC DERMATOLOGY

DRUG LABELING FOR PEDIATRIC PATIENTS

The lack of FDA labeling for pediatric use does not imply that a drug is contraindicated or disapproved; it simply means that insufficient data are available to grant approval status. Although attempts have been made to equate off-label prescribing with recklessness in the medical malpractice arena, the American Academy of Pediatrics has stated that failure to prescribe medications for off-label uses when the medication is appropriate under standard of care may constitute malpractice.

The thalidomide tragedy (see Chapter 235) led to more stringent regulation of drugs in the early 1960s, and manufacturers began omitting drug studies in infants and children. In the 1970s, pediatric dosage information in package inserts tended to exclude children from therapeutic benefit. Performing research in healthy children is problematic because of ethical and logistic questions, medicolegal risk, and cost. It has been estimated that approximately 50%–75% of drugs used in pediatrics have not been studied adequately to provide accurate labeling information, and the younger the patient, the more likely the lack of information.[62] Safety and effectiveness information for drug use in children under 2 years of age is particularly lacking. The absence of pediatric testing and labeling poses significant safety risks for children. Additionally, children may be denied the benefits from therapeutic advances because physicians choose to prescribe existing, less effective medications in the face of insufficient pediatric information about new medications. In 1997, as part of the FDA Modernization Act, Congress enacted a law known as the *Pediatric Exclusivity Provision* that provides marketing incentives (i.e., 6 month extension of patent protection) to manufacturers who conduct studies of drugs in children. This law was effective in generating pediatric studies on many drugs, and an increase in labeling information has occurred for some. Unfortunately, many studies have centered on children greater than 6 years of age, and many drug studies were stimulated by market concerns rather than medical need.

Hopefully, with new incentives such as the Pediatric Research Equity Act of 2003, significantly more pediatric drug research will proceed forward. Ideally in the future, physicians caring for children will no longer need to prescribe drugs "off label," and children will no longer be "therapeutic orphans."

TOPICAL MEDICATIONS

While topical medications often have excellent safety and efficacy profiles, one must be aware that infants and young children are at increased risk for toxicity from topically applied agents because of increased surface area:body mass ratio compared to adults. In addition, at times infants and children have altered metabolism of drugs compared to adults. Patients with disorders of cornification (e.g., lamellar ichthyosis) or other forms of skin barrier disruption (e.g., Netherton syndrome) have a much higher risk of toxicity due to increased percutaneous absorption. Patients with Netherton syndrome treated with topical tacrolimus may develop immunosuppressive or toxic blood levels of tacrolimus, without clinical signs or symptoms

TABLE 107-9
Topical Medications Reported to Cause Systemic Toxicity in Children

Topical Medication	Complication	Reference
Tacrolimus 1% ointment	Three children with Netherton syndrome found to have blood levels of tacrolimus in the range of organ transplant requirements	63
Hydrocortisone 1% ointment	Cushing syndrome developed in an 11-year-old boy with Netherton syndrome receiving topical application to extensive areas for over one year	64
Benzocaine, 3% (Lanacane)	Methemoglobinemia in a 2-year-old child	65
Iodoquinol, clioquinol (Vioform)	Neurotoxicity when used as treatment for diaper dermatitis	66,67
Lindane	Neurologic toxicity in children with disrupted epidermal barrier and/or excessive topical application or ingestion	68,69
N, *N*-diethyl-*m*-toluamide (DEET)	Slurred speech, tremors, seizures, and death in children after repeated and extensive application of high concentrations of DEET	70
Povidone-iodine (Betadine)	Hypothyroidism in infants with spina bifida	71
Povidone-iodine (Betadine)	Decreased free thyroxine and elevated iodine levels in infants treated with diluted povidone-iodine during *Staphylococcus aureus* epidemic	72
Salicylic acid	In a 7-yr-old boy treated for ichthyosis vulgaris, life-threatening salicylism occurred with neurologic sequelae lasting 6 month	73
Saline, sodium chloride	Fatalities in infants and children following ancient Turkish custom of "salting"	74
Viscous lidocaine, 2%	Lidocaine overdose following frequent application to oral lesions	75

of toxicity.[63] A heightened awareness of this problem is important because Netherton syndrome is often misdiagnosed as atopic dermatitis, and both conditions often improve with topical tacrolimus therapy. In addition, a patient with Netherton syndrome developed Cushing syndrome after application of hydrocortisone 1% ointment for over 1 year.[64] Examples of inadvertent percutaneous poisoning from topical agents are listed in Table 107-9.

SYSTEMIC MEDICATIONS

DRUG DOSAGES. Pediatric doses of systemic medications are calculated according to body weight (mg/kg) or body surface area to account for size variations between patients of the same age and to account for a child's growth. Prescriptions for liquid medications (syrups or suspensions) must indicate concentration (e.g., milligrams per 5 mL, or teaspoon) to avoid serious error. In addition, the appropriate measuring instrument should be dispensed, along with education on its use. One study demonstrated that dosing cups (commonly provided in OTC children's medications) were associated with a large error in one in four doses—some of which were overdoses of 100%–300%.[76]

For guidelines on indications and dosing of antimicrobials and other medications, the reader is directed to excellent references including the *Red Book*[77] published by the American Academy of Pediatrics, and *The Harriet Lane Handbook*.[78]

SYSTEMIC GLUCOCORTICOIDS. Hypothalamic–pituitary axis suppression, osteonecrosis, and other adverse effects of systemic glucocorticoid therapy affect patients of all ages and are reviewed in Chapter 224. The potential risk of growth suppression is unique to childhood. Exogenous glucocorticoids disrupt the secretion of growth hormone (GH), causing abnormal spontaneous GH secretion with reduced pulse amplitude of GH release and reduced response to provocative stimuli.[79,80] There is also decreased local production of insulin-like growth factor 1. These and other effects of glucocorticoids act to cause delayed growth at the bony epiphyses, with the most noticeable reduction in growth velocity occurring during early childhood and adolescent growth spurts. There is a linear relation between the daily dose and growth suppression. Alternate-day dosing, with single morning doses, may decrease the risk of glucocorticoid growth suppression. Most children will have adequate catch-up growth eventually with reduction of doses, alternate-day therapy, or cessation of therapy.[81] For the pediatric patient on long-term systemic steroid therapy, charting height and weight on a standardized growth curve is the best method for the pediatrician to screen for decreasing growth velocity.

Children taking immunosuppressive doses of systemic glucocorticoids should not be vaccinated with live-virus vaccines (e.g., measles, oral polio, varicella). A dosage equivalent to 2 mg/kg/day or greater of prednisone or a total of 20 mg/day or greater for children weighing more than 10 kg, when given for more than 14 days, is sufficient to warrant withholding immunization with live-virus vaccines.[82] Systemic steroids should not be given to a healthy child if he or she has had recent varicella exposure and is not varicella-immune because varicella infection can be fatal in this situation. In addition, children with ocular herpes simplex and untreated tuberculosis should not be given systemic steroids, and patients with

underlying diabetes, hypertension, peptic ulcer disease, renal insufficiency, or psychosis should be treated with great caution or with an alternative agent.[77]

ANTIMICROBIALS. Use of tetracycline family medications is contraindicated in children younger than 8 years of age because it causes brown discoloration of developing teeth and decreased bone growth. Ciprofloxacin and quinolone use in children younger than 18 years of age is restricted because the fluoroquinolones have been shown to cause cartilage damage in juvenile animal models at therapeutic doses. The mechanism is unknown. It is recommended that its use be restricted to relatively serious infections for which no other oral agent is available or intravenous antibiotics would be impractical and for certain pathogenic infections or situations such as multidrug resistance.[78]

Griseofulvin doses of 20 mg/kg/day of the (125 mg/5 mL) liquid and 15 mg/kg/day of the ultramicrosized tablets for 6–8 weeks have long been considered first-line therapy for tinea capitis. In 2007, terbinafine oral granules (sprinkled on nonacidic food) were approved for the treatment of tinea capitis in children age 4 years and older. Currently, griseofulvin and terbinafine are the only FDA-approved agents for tinea capitis in children. Griseofulvin appears to be superior against *M. Canis* however if access and/or cost prevent the use of the oral granule form of terbinafine, crushed generic terbinafine tablets off-label can be substituted. Although further studies are needed, itraconazole also appears to be effective with a good safety profile. Fluconazole was not very effective in pediatric tinea capitis in a large multicenter, double-blinded randomized trial of 880 children.[83]

CHILD ABUSE

In the United States in 2003, 906,000 children were determined to be victims of child abuse and neglect by child protective agencies; an estimated 1,500 children died of child abuse. Ninety percent of all abused children are said to have suggestive or confirmative dermatologic findings.[84] Ideally, due to the sensitive medical and legal aspects of this important problem, any case of suspected child abuse should be referred to a specialized team specializing in pediatric abuse, however, appropriate evaluation should not be delayed in the absence of such a resource. Child abuse is discussed in Chapter 106.

Chapter 108 :: Skin Changes and Diseases in Pregnancy

:: Julie K. Karen & Miriam Keltz Pomeranz

CUTANEOUS CHANGES COMMONLY ASSOCIATED WITH PREGNANCY AT A GLANCE

- Cutaneous changes result from the altered endocrine, metabolic, and immunologic milieus that characterize pregnancy.
- Pigmentary disturbances, including hyperpigmentation, darkening of the linea alba, and melasma are the changes most commonly observed.
- Significant change in nevi size is not a feature of most pregnancies.
- Structural changes known to occur during pregnancy include, most commonly, striae distensae.
- Pruritus is a common complaint during pregnancy and may be related to flare of a preexisting dermatosis or onset of a specific dermatosis of pregnancy.

CHANGES COMMONLY ASSOCIATED WITH PREGNANCY

Pregnancy is characterized by altered endocrine, metabolic, and immunologic milieus. These dramatic alterations result in multiple cutaneous changes, both physiologic and pathologic. A comprehensive list of physiologic alterations within the skin and appendages is provided in Table 108-1.[1–3]

Pigmentary disturbances are the most common of these physiologic changes (see Table 108-1). Hyperpigmentation of the areola, axillae, and genitalia is well documented in pregnancy. *Linea nigra* refers to the typically reversible darkening of the linea alba, a hypopigmented linear patch extending from the pubis symphysis to the xiphoid process of the sternum (Fig. 108-2). Melasma or chloasma is a related finding comprising irregular, blotchy, facial hyperpigmentation that occurs in up to 70% of pregnant women (see eFig. 108-2.1 in online edition). This tendency is aggravated by sun exposure and by oral contraceptive intake by nonpregnant women. Melasma may regress postpartum, but oftentimes persists, posing a therapeutic challenge.[1]

Changes in melanocytic nevi were historically deemed "normal" during pregnancy. However, few studies have objectively studied whether and how nevi evolve during pregnancy. Pennoyer et al[4] photographically monitored 129 melanocytic nevi throughout the pregnancies of 22 healthy Caucasian women. Only eight nevi (6.2%) changed in diameter from the first to third trimester, with a mean change in size of zero. The authors concluded that significant change in nevus size (excluding nevi on the pregnant abdomen) does not appear to be a feature of most pregnancies.[4] Until further controlled studies are performed, any pigmented lesion in a pregnant woman that undergoes change in morphology (size, color, or shape) or symptomatology (begins to itch, bleed, or scale) should be considered for histopathologic review. Recently, Chan et al identified characteristic histologic features unique to nevi excised during pregnancy, including increased mitotic index.[5]

The most common structural change during pregnancy is striae distensae, also known as *striae gravidarum* or *stretch marks* (Fig. 108-3). Sites of predilection for striae include those areas most prone to stretch, including the abdomen, hips, buttocks, and breasts. Genetic factors as family history, personal history, and race are the strongest predictors of an individual's risk of developing striae distensae, surpassing pregnancy

Figure 108-1 Spider angiomata on the arm of a pregnant woman. These spider nevi, as they are also called, have a central "body" and small vessels (legs) extending out from it. In this example, they are part of a unilateral nevoid telangiectasia, linear grouping of spider angiomata that can become more prominent during pregnancy.

TABLE 108-1
Physiologic Skin Changes during Pregnancy

Pigmentary
- Diffuse hyperpigmentation
- Selective hyperpigmentation (genitalia, axillae, recent scars)
- Secondary areolae
- Linea nigra
- Melasma (chloasma, mask of pregnancy)
- Darkening of ephelides and melanocytic nevi[a]

Hair
- Hirsutism
- Thickening of scalp hair
- Postpartum telogen effluvium
- Postpartum androgenetic alopecia

Nail
- Subungual hyperkeratosis
- Distal onycholysis
- Transverse grooving
- Brittleness
- Accelerated growth

Glandular
- Increased eccrine function (except palms) (miliaria, dyshidrotic eczema, hyperhidrosis)
- Elevated thyroid activity with resultant relative iodine deficiency
- Increased sebaceous function (growth in Montgomery's tubercles) (see eFig. 108-0.1 in online edition)
- Decreased apocrine function

Structural Changes
- Striae distensae (striae gravidarum)
- Molluscum fibrosum gravidarum (acrochordons)

Vascular
- Spider angiomas (spider nevi, nevi aranei) (Fig. 108-1)
- Palmar erythema (see eFig. 108-0.2 in online edition)
- Nonpitting edema (hands, ankles, feet, face)
- Varicosities
- Cutis marmorata
- Vasomotor instability
- Dermographism/pruritus
- Purpura
- Gingival hyperemia or hyperplasia
- Pyogenic granuloma (granuloma gravidarum, pregnancy epulis)
- Hemorrhoids
- Hemangiomas, hemangioendotheliomas, glomangiomas
- Unilateral nevoid telangiectasia (unilateral dermatomal superficial telangiectasia)

Mucosa
- Gingivitis (marginal gingivitis, papillomatous hypertrophy of the gums)
- Jacquemier–Chadwick sign (bluish discoloration of vagina and cervix)
- Goodell's sign (cervical softening)

[a]Although some degree of darkening of nevi during pregnancy may be physiologic, any pigmented lesion noted to change should be evaluated in a pregnant woman, as in nonpregnant women.
Data from Elling SV, Powell FC: Physiological changes in the skin during pregnancy. *Clin Dermatol* **15**:35, 1997; Kroumpouzos G, Cohen LM: Dermatoses of pregnancy. *J Am Acad Dermatol* **45**:1, 2001; and Muzaffar F, Hussain I, Haroon TS: Physiologic skin changes during pregnancy: A study of 140 cases. *Int J Dermatol* **77**:429, 1998.

Figure 108-2 Linea nigra. A hyperpigmented line extends from the pubis symphysis to the xiphoid process of the sternum. Hyperpigmentation is often more pronounced inferior to the umbilicus.

weight gain or changes in body mass index.[6] These findings strongly support a genetic predisposition to this condition.

Pruritus, a common complaint during pregnancy, may be physiologic, but may herald a flare of a preexisting dermatosis or onset of a specific dermatosis of pregnancy. The remainder of this chapter outlines the relatively rare conditions that may be specific to pregnancy. An overview of these conditions is provided in Table 108-2.

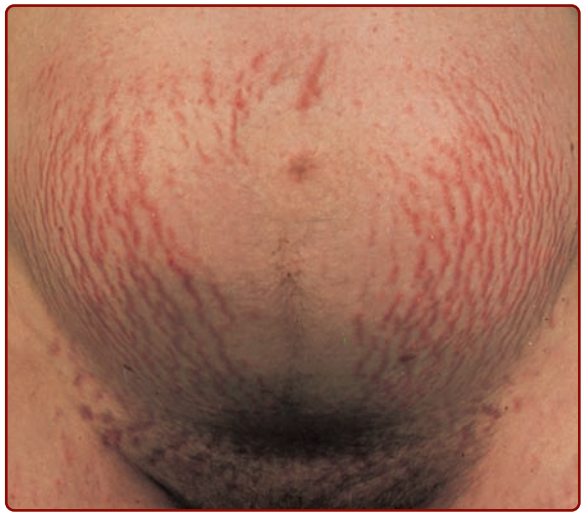

Figure 108-3 Striae distensae.

TABLE 108-2
Summary of Dermatoses of Pregnancy

	Morphology	Distribution	Usual Onset	Fetal Risk	Synonym(s)
Pemphigoid (Herpes) gestationis	Urticarial papules and plaques progress to vesicles and bullae	Begins on trunk, then progresses to generalized eruption Spares face, mucus membranes, palms, soles	Second or third trimester, or immediately postpartum	Small-for-gestational age births Preterm delivery Neonatal pemphigoid gestationis	Herpes gestationis
Intrahepatic cholestasis of pregnancy	Excoriations and excoriated papules ± jaundice	Localized to palms and soles or generalized	Third trimester	Preterm delivery Fetal distress Fetal death	Cholestasis of pregnancy Obstetric cholestasis Recurrent jaundice of pregnancy Cholestatic jaundice of pregnancy Idiopathic jaundice of pregnancy Prurigo gravidarum Icterus gravidarum
Pustular psoriasis of pregnancy	Erythematous patches with subcorneal pustules at their margins	Begins in flexures Generalizes demonstrating centrifugal spread	Third trimester	Placental insufficiency may lead to stillbirth or neonatal death	Impetigo herpetiformis
Pruritic urticarial papules and plaques of pregnancy	"Polymorphous" including urticarial papules and plaques ± vesicles	Begins within abdominal striae Spreads to remainder of trunk and then extremities Spares umbilicus	Third trimester or immediately postpartum	None	Polymorphic eruption of pregnancy Bourne's toxemic rash of pregnancy Nurse's late onset prurigo of pregnancy Toxemic erythema of pregnancy (Holmes)
E-type Atopic eruption of pregnancy	Eczematous patches and plaques	Face, neck, chest, flexural extremities	Second or third (less commonly) trimester	None	Eczema in pregnancy[a]
P-type Atopic eruption of pregnancy	Excoriated or crusted papules	Extremities, occasionally trunk	Second or third (less commonly) trimester	None	Prurigo of pregnancy[a] Besnier's prurigo gestationis Nurse's early onset prurigo of pregnancy Papular dermatitis of Spangler Atopic eruption of pregnancy[a]

NA = not applicable.
[a]A newly proposed classification by Ambros-Rudolph et al[41] combines the previously distinct entities prurigo of pregnancy and pruritic folliculitis of pregnancy into a single entity, atopic eruption of pregnancy, which also includes eczema in pregnancy.

DERMATOSES ASSOCIATED WITH FETAL RISK IN PREGNANCY

DERMATOSES ASSOCIATED WITH FETAL RISK IN PREGNANCY AT A GLANCE

- Pemphigoid gestationis is an immunologically mediated, intensely pruritic, vesiculobullous eruption of mid- to late pregnancy that is associated with fetal risk.
- Intrahepatic cholestasis of pregnancy represents a reversible form of cholestasis in late pregnancy associated with biochemical abnormalities and a risk of fetal complications, but invariably lacking primary cutaneous lesions. Symptoms remit within 2–4 weeks of delivery, but recurrences in subsequent pregnancies are common.
- Pustular psoriasis of pregnancy is a rare, acute, pustular eruption often accompanied by fever, leukocytosis, and an elevated erythrocyte sedimentation rate. This is generally regarded as a variant of psoriasis.

PEMPHIGOID (HERPES) GESTATIONIS

Pemphigoid (herpes) gestationis (PG; see Chapter 59) is an intensely pruritic, vesiculobullous eruption of mid- to late pregnancy and the immediate postpartum period. PG classically begins during the second or third trimester, and is manifest by the abrupt appearance of severely pruritic urticarial lesions on a background of normal or erythematous skin. PG is associated with an increased incidence of small-for-gestational age births and premature delivery. PG is immunologically mediated, and linear deposition of C3 with or without IgG are found at the dermal–epidermal junction by direct immunofluorescence (DIF).[7]

INTRAHEPATIC CHOLESTASIS OF PREGNANCY

NOMENCLATURE AND EPIDEMIOLOGY.

The terms *obstetric cholestasis*, *cholestasis of pregnancy*, *recurrent jaundice of pregnancy*, *cholestatic jaundice of pregnancy*, *idiopathic jaundice of pregnancy*, *prurigo gravidarum*, and *icterus gravidarum* all refer to the same clinical entity, intrahepatic cholestasis of pregnancy (ICP), characterized by a reversible form of cholestasis in late pregnancy. Svanborg and Ohlsson first recognized ICP as a distinct entity, separate from other causes of jaundice during pregnancy in 1939.[8] Jaundice develops in approximately 1 in 1,500 pregnant women. With an estimated incidence of 70 cases per 10,000 pregnancies in the United States, ICP ranks second only to viral hepatitis in terms of etiology of jaundice in pregnant women.[9] Mild cases of ICP, in which pruritus is not accompanied by jaundice, were previously referred to as prurigo gravidarum.

ICP is most common in Scandinavia and South America. The highest reported incidence rates are in Chile (14%–16%), whereas much lower rates are seen among pregnant women in the United States (less than 0.1%–0.7%), Canada (0.1%), Australia (0.2%–1.5%), and Central Europe (0.1%–1.5%).[9]

ETIOLOGY

Although the precise pathogenesis remains unclear, the interplay of hormonal, genetic, environmental, and alimentary factors is thought to induce a biochemical cholestasis in susceptible individuals. A prominent role for hormonal alterations is suggested by the following observations: (1) ICP is a disease of late pregnancy (corresponding to the period of highest placental hormone levels); (2) ICP spontaneously remits at delivery when hormone concentrations normalize; (3) twin and triplet pregnancies, characterized by greater rises in hormone concentrations, have been linked to ICP; and, (4) ICP recurs during subsequent pregnancies in an estimated 45%–70% of patients.[9,10]

Geographic variation and familial clustering indicate a genetic predisposition. ICP appears to be a polygenetic condition. Candidate genes include those mutated in a variety of other forms of inherited cholestasis: *ABCB4* (multidrug resistance gene3), *ABCB11* (Bsep), and *ATP8B1* (*FIC1*). A recent decline in prevalence rates in Chile, reports of higher incidence rates during the winter months, and reports of relative reductions of selenium levels in some ICP patients all point toward etiologic roles for environmental and alimentary factors.[9,11] At least one study confirmed a higher risk of hepatitis C virus infection among women with ICP.[12]

CLINICAL FEATURES. Patients classically present during the third trimester with moderate-to-severe pruritus, which may be either localized to the palms and soles or generalized. Pruritus begins during the first and second trimester in 10% and 25% of cases, respectively. Intense pruritus is oftentimes associated with secondary excoriations, although primary cutaneous lesions are invariably absent. Initially, patients may complain of nocturnal pruritus only, and symptoms generally are more severe at night throughout the course of illness. Constitutional symptoms such as fatigue, nausea, vomiting, or anorexia may accompany the pruritus. Progression to clinical jaundice, dark urine, or lightly colored stools occurs in approximately one in five patients. Pruritus generally precedes the onset of these symptoms by 1–4 weeks.[9]

COURSE. A hallmark of ICP is that symptoms and associated biochemical abnormalities typically resolve within 2–4 weeks of delivery. Recurrences during subsequent pregnancies occur in an estimated 45%–70% of

patients. Some women experience recurrent ICP after exposure to oral contraceptives or to contraceptive aids, such as synthetic estrogens and progestational agents.

Maternal outcomes are generally favorable, although women with severe cases are predisposed to postpartum hemorrhage secondary to vitamin K depletion. Additionally, affected women have a tendency toward the later development of cholelithiasis or gallbladder disease. Fetal risks in ICP include increased rates of prematurity, intrapartal fetal distress, and fetal death. These complications generally correlate with higher bile acid levels and are thought attributable to acute placental anoxia and an increased incidence of meconium-stained amniotic fluid. Such fetal complications may be reduced with treatment and induction of labor after fetal pulmonary maturation has been documented.[9]

LABORATORY STUDIES. Elevation in serum bile acids is the single most sensitive indicator of ICP. In healthy pregnant women, total bile acids (TBAs) are slightly elevated above baseline and levels as high as 11.0 μM are accepted as normal in late pregnancy. Clearly defined biochemical indices of ICP have not yet been established. However, Brites et al[13] identified the following common features of ICP: (1) serum TBA concentrations greater than 11.0 μM (normal range, 4.6–8.7 μM); (2) cholic acid–chenodeoxycholic acid ratio greater than 1.5 (normal range, 0.7–1.5) or cholic acid proportion of TBAs greater than 42%; (3) glycine conjugates–taurine conjugates of bile acids ratio less than 1.0 (normal range, 0.9–2.0) or glycocholic acid concentration greater than 2.0 μM (normal range, 0.6–1.5 μM).[13] Degree of pruritus and disease severity generally correlate with bile acid concentrations.

Mild perturbations in liver function tests, including elevated transaminases, alkaline phosphatase, 5′-nucleotidase, cholesterol, triglycerides, phospholipids, and lipoprotein X are commonly found. Among these parameters, alanine transaminase is particularly sensitive, as an elevation in this enzyme is not a feature of healthy pregnancies, but is commonly seen in ICP. γ-Glutamyl transferase, which is generally low in late gestation, is typically normal or slightly elevated in ICP. Direct (or conjugated) fractions of bilirubin are most commonly elevated in ICP. Albumin may be slightly reduced, whereas α_2-globulins and β-globulins are appreciably elevated. However, routine liver tests alone are not a sufficient basis for the diagnosis of ICP.[13]

Cutaneous biopsy does not aid in the diagnosis of ICP. Although generally unnecessary, hepatic biopsy reveals intrahepatic cholestasis with dilated, plugged bile canaliculi and deposits of bile pigment in centrilobular hepatocytes.[9]

DIFFERENTIAL DIAGNOSIS. Distinction from other causes of pruritus in the pregnant woman can be challenging. The presence of primary lesions points away from a diagnosis of ICP, which lacks primary lesions. Other causes of liver derangement and jaundice, such as viral and nonviral hepatitis, medications, hepatobiliary obstruction, and other intrahepatic diseases (i.e., primary biliary cirrhosis) must be ruled out. Finally, it must be remembered that hyperthyroidism, allergic reactions, polycythemia vera, lymphoma, pediculosis, and scabies may each manifest as generalized pruritus in pregnant as in nonpregnant women.

TREATMENT. Therapy aims to reduce serum bile acid levels and thereby prolong pregnancy, ameliorate maternal symptoms and reduce fetal risks. An interdisciplinary approach characterized by intense fetal surveillance is essential to the management of ICP. Although obstetric management varies, the need for weekly fetal monitoring beginning by the thirty-fourth week of gestation is widely accepted. Additionally, most authors recommend early induction of labor, commonly at 37–38 weeks' gestation, but as soon as there is evidence of fetal pulmonary maturity in severe cases.[9]

In mild cases, adequate relief of maternal symptoms can be achieved with bland emollients and topical antipruritic agents. Antihistamines and Ultraviolet B (UVB) phototherapy are variably effective.[7] Several uncontrolled trials have suggested that the anion exchange resin, cholestyramine, may effectively reduce symptoms in up to 70% of patients with mild ICP. However, the lack of randomized, placebo-controlled cholestyramine trials precludes definite conclusions about the efficacy of this agent. Furthermore, cholestyramine must be administered for several days before taking effect. Its efficacy in treating severe cases has been disappointing, and, importantly, it may precipitate vitamin K and thereby trigger a coagulopathy.[14,15] Other systemic therapies such as dexamethasone, *S*-adenosylmethionine, and plasmapheresis have been reported to sometimes reduce maternal symptoms.[7,9,16,17] However, these agents do not reverse the associated biochemical abnormalities, and thus, do not reduce fetal risks.

Ursodeoxycholic acid (UDCA), a naturally occurring hydrophilic bile acid, is the only treatment that has been shown to reduce maternal symptoms and fetal risk. UDCA exerts a hepatoprotective effect through augmentation of the excretion of hydrophobic bile acids, sulfated progesterone metabolites, and other hepatotoxic compounds. UDCA decreases bile acid levels in colostrum, cord blood, and amniotic fluid. The results of several small, randomized, placebo-controlled trials demonstrate that when administered at doses between 450 mg and 1,200 mg daily, UDCA is well tolerated and highly effective in controlling the clinical and liver function abnormalities that define ICP.[15] Enhanced efficacy may be achieved by coadministration with *S*-adenosylmethionine.[18] Randomized, controlled trials comparing UDCA head-to-head with either dexamethasone[19] or cholestyramine[20] demonstrated UDCA's superior efficacy.

PUSTULAR PSORIASIS OF PREGNANCY (IMPETIGO HERPETIFORMIS)

NOMENCLATURE. Von Hebra first used the designation *impetigo herpetiformis* in 1872 to describe an

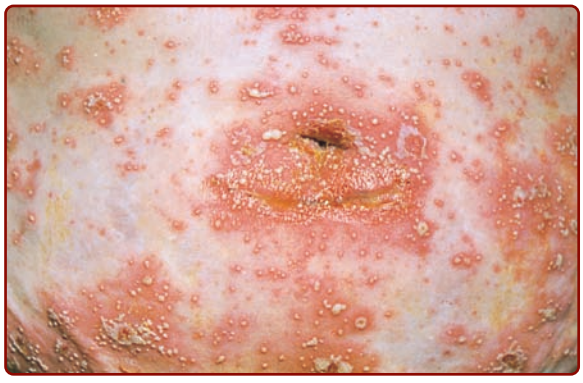

Figure 108-4 Pustular psoriasis of pregnancy. Erythematous patches are studded with subcorneal pustules.

acute pustular eruption with usual onset during the third trimester of pregnancy. It is now generally regarded as a variant of pustular psoriasis attributable to hormonal alterations during pregnancy; however, some authors maintain that it is a distinct clinical entity.[21,22]

CLINICAL FEATURES. Pustular psoriasis of pregnancy is characterized by an acute eruption occurring as early as the first, but generally during the third, trimester of an otherwise uneventful pregnancy. The condition manifests as erythematous patches whose margins are studded with subcorneal pustules (Fig. 108-4). The eruption typically originates in flexural areas but spreads centrifugally and sometimes generalizes. Subungual lesions may result in onycholysis. Rarely, mucous membrane involvement may lead to painful erosions. The face, palms, and soles are commonly spared. The rash may be pruritic or painful. Onset of the eruption is accompanied by such constitutional symptoms as fever, chills, malaise, diarrhea, nausea, and arthralgias. Rarely, tetany, delirium, and convulsions occur if hypocalcemia is severe.[1]

Although generally regarded as a form of pustular psoriasis (see Chapter 18), absence of a positive family history, abrupt resolution of symptoms at delivery, and a tendency to only recur during subsequent pregnancies distinguish this entity from generalized pustular psoriasis. Moreover, factors known to trigger pustular psoriatic flares, such as infection, exposure to culprit drugs, or abrupt discontinuation of systemic corticosteroids are lacking in virtually all patients with pustular psoriasis of pregnancy.[1,22]

LABORATORY STUDIES. Histopathologic examination reveals classic features of pustular psoriasis (see Chapter 18). The most common laboratory derangements include leukocytosis, neutrophilia, an elevated erythrocyte sedimentation rate, hypoferric anemia, and hypoalbuminemia. Less commonly, calcium, phosphate, and vitamin D levels are decreased. Serum parathormone levels are rarely decreased. Cultures of pustule contents and peripheral blood are negative unless secondarily infected.[1]

COURSE. Pustular psoriasis of pregnancy classically presents during the last trimester, but there are reports of cases occurring as early as the first trimester, during the puerperium, in nonpregnant women taking oral contraceptives, and in postmenopausal women. Symptoms are invariably progressive throughout pregnancy. A cardinal feature of this disorder is the rapid resolution of symptoms after delivery. Recurrences in subsequent pregnancies are common and characteristically are more severe with onset earlier in gestation.[1] Several reports of subsequent menstrual exacerbation occurring either during or immediately preceding menses exist in the literature.[23]

More widespread disease generally portends a worse prognosis. Life-threatening maternal complications are infrequent today, but may result from profound hypocalcemia and bacterial sepsis. The most feared complications are placental insufficiency and consequent stillbirth or neonatal death. For these reasons, early induction of labor is often contemplated.[21]

DIFFERENTIAL DIAGNOSIS. Box 108-1 outlines the differential diagnosis of pustular psoriasis of pregnancy.

TREATMENT. Resolution after delivery is the norm. However, given its consistently progressive course, treatment is indicated to reduce the risk of fetal and maternal complications during pregnancy. Topical treatments include wet dressings and topical corticosteroids, but are rarely effective as monotherapy. Systemic corticosteroids are the mainstay of therapy during pregnancy. Cyclosporine, which is categorized as pregnancy category "C," has been successfully used at doses between 5 mg/kg and 10 mg/kg daily to treat cases refractory to high-dose systemic corticosteroids.[24,25] Narrowband UVB combined with topical steroids has been reported to be successful.[26] Infliximab, a TNF-α blocking agent has been successfully used without adverse effect on the fetus.[27] Although

careful consideration of the benefits and risks of TNF-blockade during pregnancy must be considered, these agents (including etanercept, infliximab, and adalimumab) are Class B and may have a role in the management of cases refractory to other therapies.

In all, cases, fluid status and electrolytes should be monitored with rapid correction of imbalances. Fetal monitoring is essential as decelerations in fetal heart rate may be the earliest sign of fetal hypoxemia. Maternal cardiac and renal functions may be compromised with disease progression and therefore should be monitored as well. Induction of labor is an option when symptoms do not remit despite supportive and pharmacologic therapy. The therapeutic armamentarium available after pregnancy termination or after delivery in a non-nursing mother can be extended to include oral psoralen and ultraviolet A (PUVA), oral retinoids, clofazimine, methotrexate, sulfapyridine, and sulfones.[28]

DERMATOSES NOT ASSOCIATED WITH FETAL RISK IN PREGNANCY

DERMATOSES NOT ASSOCIATED WITH FETAL RISK IN PREGNANCY AT A GLANCE

- Pruritic urticarial papules and plaques of pregnancy is a common, self-limited, intensely pruritic dermatosis that occurs almost exclusively in primigravidas during late pregnancy. The term *polymorphic eruption of pregnancy* appropriately encompasses the wide spectrum of clinical presentations.
- Atopic eruption of pregnancy represents a newly introduced complex comprising pruritic folliculitis of pregnancy, prurigo of pregnancy, and eczema of pregnancy. Lesions typically appear before the third trimester and may resemble classic atopic dermatitis (AEP, E-type) or be papular (AEP, P-type).

PRURITIC URTICARIAL PAPULES AND PLAQUES OF PREGNANCY (POLYMORPHIC ERUPTION OF PREGNANCY)

NOMENCLATURE AND EPIDEMIOLOGY. Pruritic urticarial papules and plaques of pregnancy (PUPPP) is a common benign intensely pruritic dermatosis that occurs almost exclusively in primigravidas during late pregnancy. The term *PUPPP*, introduced by Lawley et al in 1979[29] is synonymous with Bourne's toxemic rash of pregnancy, Nurse's late onset PP, toxic erythema of pregnancy, and polymorphic eruption of pregnancy (PEP).[30] *Polymorphic eruption of pregnancy*, a more recent term, best describes the clinical spectrum of this entity, and is favored throughout Europe.[31] The incidence of PUPPP ranges between 1 in 300 pregnancies and 1 in 130 pregnancies.[32]

ETIOLOGY. The pathogenesis remains unknown. An association between PUPPP and multiple gestation is suggested by the higher than expected rates of twin and triplet pregnancies in most published series.[32–34] An unexplained association with male fetuses and delivery by cesarean section has been reported.[32,34] Reports linking PUPPP to increased maternal–fetal weight gain[32,35] are contested. Some postulate that increased abdominal cutaneous distension leads to altered collagen and/or elastic tissue, thereby triggering maternal immune-reactivity to previously non-antigenic stimuli.[32] Additionally, fetal DNA has been detected in involved maternal skin and is hypothesized to be etiologically linked to this condition.[36] Increased progesterone receptor immunoreactivity has been detected in lesional PUPPP, leading some to posit a role for progesterone activation of keratinocytes.[37]

CLINICAL FEATURES. PUPPP typically occurs in primigravidas during the last trimester of pregnancy (mean onset, 35 weeks); however, cases of otherwise classic PUPPP have occurred earlier in pregnancy and in the immediate postpartum period. Polymorphous in nature, lesions may be urticarial (most commonly), vesicular, purpuric, polycyclic, targetoid, or eczematous in appearance (Fig. 108-5).[38] Typical lesions are 1- to 2-mm erythematous urticarial papules surrounded by a narrow pale halo. The eruption begins on the abdomen, classically within the striae gravidarum, and demonstrates periumbilical sparing. Pruritus generally parallels with the eruption and is localized to the involved skin. Rapid spread to the thighs, buttocks, breasts, and arms is the norm. Involvement of the palms, soles, or skin above the breast is exceptional.[1] Severe pruritus may disturb sleep, but no other systemic symptoms are reported.

LABORATORY STUDIES. Laboratory investigations reveal no abnormalities. Histopathologic findings, although nonspecific, generally include parakeratosis, spongiosis, and occasional exocytosis of eosinophils (eosinophilic spongiosis). The adjacent dermis may be edematous and contains a perivascular infiltrate of lymphocytes admixed with variable numbers of eosinophils and neutrophils. DIF studies reveal no specific immunoreactants and indirect immunofluorescence studies are negative.[1]

COURSE. PUPPP mostly affects primigravidas in the last trimester, although it may occur as early as the first trimester. There are several reports of cases occurring in the immediate postpartum period as well. Duration of symptoms is typically brief, averaging 6 weeks. However, severe symptoms rarely persist for more than 1 week. Spontaneous remission within days of delivery is the rule. Recurrences in subsequent pregnancies or with exposure to oral contraceptives are unusual. Fetal and maternal prognoses

Figure 108-5 Pruritic urticarial papules and plaques of pregnancy. **A.** The earliest lesions are 1- to 2-mm, erythematous, urticarial papules localized within and around the striae distensae and sparing the umbilicus. **B.** The papules coalesce to form erythematous plaques that spread to involve the buttocks and thighs. **C.** Urticarial plaques on the breasts. Of note, the breasts also show a "secondary areola," the physiologic darkening, and reticular expansion of the areolar pigmentation. There are also striae distensae visible on the breast as well as Montgomery tubercles on the areolae.

are unaltered.[1] There is a single report of involvement of a newborn.[39]

DIFFERENTIAL DIAGNOSIS. Box 108-2 outlines the differential diagnosis of PUPPP.

BOX 108-2 DIFFERENTIAL DIAGNOSIS OF PRURITIC URTICARIAL PAPULES AND PLAQUES OF PREGNANCY

Most Likely
- Pemphigoid gestationis
- Atopic eruption of pregnancy
- Contact dermatitis

Consider
- Drug eruption
- Viral exanthema
- Pityriasis rosea
- Exfoliative or eczematous dermatitis

Always Rule Out
- Scabies

TREATMENT. Although harmless to the mother and fetus, pruritus is often intense and unremitting. Symptomatic relief of pruritus can usually be achieved with topical antipruritics, antihistamines, and topical corticosteroids. A brief course of oral corticosteroids is rarely required, but effectively controls symptoms in most cases refractory to topical treatment. Early induction of labor has been rarely considered in instances in which severe pruritus is unrelenting, but is generally considered unnecessary.[1,40] Patient reassurance regarding the self-limited nature of PUPPP can help to assuage unnecessary anxiety.

ATOPIC ERUPTION OF PREGNANCY

NOMENCLATURE AND EPIDEMIOLOGY. Ambros-Rudolph et al have proposed the term *atopic eruption of pregnancy* (AEP) to denote the disease complex comprising the previously distinct entities prurigo of pregnancy (PP) and pruritic folliculitis of pregnancy (PFP), as well as *eczema in pregnancy* (EP), which has not previously been considered a specific dermatosis of pregnancy.[41] PFP includes Besnier's prurigo gestationis, and Nurse's early onset PP and papular dermatitis of Spangler are now considered subset of AEP as well.[7]

Figure 108-6 Atopic eruption of pregnancy, P-type (formerly, prurigo of pregnancy). Multiple discrete, excoriated papules demonstrate a predilection for extensor surfaces.

AEP is a benign pruritic condition of pregnancy characterized by an eczematous (AEP, E-type) and/or papular (AEP, P-type) eruption in individuals with a personal and/or familial atopic background and/or elevated serum immunoglobulin E (IgE) levels. AEP comprises about 50% of all pregnancy dermatoses. AEP is thought to be triggered by pregnancy-related shifts in cytokine profile expression leading to preferential expression of T-helper 2 cytokines.[41]

CLINICAL FEATURES. Whereas 20% of AEP patients present with a flare of preexisting atopic dermatitis, the remaining patients experience an atopic eruption for the first time ever (or after a long remission). A classic eczematous eruption primarily affecting flexural surfaces and the face occurs in two-thirds of affected individuals (AEP, E-type). The remaining third present with papular lesions (AEP, P-type) and would previously have been classified as PP. Papular or P-type lesions are discrete, pruritic, excoriated papules with a predilection for extensor surfaces (Fig. 108-6), with truncal involvement less common. Minor features of eczema, including xerosis or hyperlinear palms, may be noted in patients with either subtype. Distinguishing features of AEP include onset early in pregnancy (before the third trimester) and a personal and/or family history of atopy.[41]

LABORATORY STUDIES. Total serum IgE is elevated in 20%–70% of individuals with AEP.[41] Serologic tests reveal no other abnormalities. Histopathologic features are nonspecific. Direct and indirect immunofluorescence studies are negative.[1]

COURSE. Onset is typically during the second trimester. Lesions respond quickly to therapy; however, recurrence with subsequent pregnancies is common, consistent with an atopic diathesis. Maternal and fetal prognoses are excellent, even in severe cases.[1]

DIFFERENTIAL DIAGNOSIS. Other specific dermatoses of pregnancy, especially ICP and PUPPP should be ruled out, as should microbial folliculitis or allergic contact dermatitis occurring in a pregnant woman.

TREATMENT. Treatment seeks to ameliorate pruritus and includes emollients, midpotency topical corticosteroids and antihistamines. Benzoyl peroxide may be helpful for truncal, follicular lesions and UVB phototherapy can be used in severe cases.[1,42,43]

Chapter 109 :: Aging of Skin

:: Mina Yaar & Barbara A. Gilchrest

SKIN AGING AT A GLANCE

- Intrinsic (chronologic) aging occurs throughout the skin and causes primarily functional losses.
- Caused by oxidative damage, cell senescence, amino acid racemization, nonenzymatic glycosylation of proteins.
- Displays flattening of the dermal–epidermal junction, decreased cellularity, decreased dermal thickness, loss of vascular and lymphatic beds.
- Photoaging is the superposition of chronic ultraviolet-induced damage on intrinsic aging and accounts for most age-associated changes in skin appearance.
- Triggered by receptor signaling, mitochondrial damage, and protein oxidation.
- Displays variable epidermal thickness, dermal elastosis, decreased/fragmented collagen, increased matrix degrading metalloproteinases, inflammatory infiltrate, and vessel ectasia.
- Dermatologic problems with increased incidence in the elderly include skin cancer, xerosis, pruritus, varicella-zoster infection, ulcers, bullous pemphigoid, and drug eruptions.

EFFECTS OF AGING

In both developed and developing nations, the number and proportion of older people are increasing. In 2008, 23% of the US population was 55 years of age or older.[1] The number of persons aged ≥65 years is expected to increase to an estimated 71 million in 2030.[1,2] This demographic shift compels health care providers and government officials to confront the pathophysiology of aging and associated health issues.

Aging is a process of progressive decreases in the maximal functioning and reserve capacity of all organs in the body, including the skin. This naturally occurring functional decline in the skin is often compounded and accelerated by chronic environmental insults, such as ultraviolet (UV) and infrared (IR) irradiation as well as environmental carcinogens present in polluted air of major urban centers.

Aging occurs at the cellular level and reflects both a genetic program and cumulative environmentally imposed damage. Mammalian cells can undergo only a limited number of cell divisions and then arrest irreversibly,[3–5] in a state known as *replicative senescence*, after which they are refractory to mitogenic stimuli. This fact has led to the perception that aging evolved in multicellular organisms as a cancer prevention mechanism[6] because it prevents the unlimited and possibly unregulated growth of cells whose DNA has been progressively damaged over their life span. Of note, in general the more proficient the DNA repair mechanisms of the organism, the longer its life span.[7] Furthermore, there is an inverse correlation between the organism's life span and metabolic rate,[8] consistent with the understood role of cumulative oxidative DNA damage, due to aerobic metabolism, in the aging process.[7]

AGING MECHANISMS

TELOMERES AND AGING[9]

Telomeres, the terminal portions of eukaryotic chromosomes, consist of up to many hundreds of tandem short sequence repeats (TTAGGG in all mammals). During mitosis of somatic cells, DNA polymerase cannot replicate the final base pairs of each chromosome, resulting in progressive shortening with each round of cell division. A special reverse transcriptase, telomerase, can replicate these chromosomal ends, but, with the exception of stem cells and germline cells, the enzyme is normally expressed at extremely low levels. Telomeres of patients with premature aging syndromes, such as Werner syndrome also termed "adult progeria" and associated in addition with increased risk of cancer,[10] progeria,[11] and dyskeratosis congenita,[12] are shorter than those of age-matched controls. Also, most of the DNA repair deficiency diseases, such as xeroderma pigmentosum show varying degrees of "accelerated aging," or cancer or both.[13]

Although at low levels, telomerase is expressed in epidermal cells in vivo. In skin, the relatively quiescent fibroblasts and melanocytes have longer telomeres than keratinocytes, but the three cell types exhibit only minor age-dependent telomere shortening of 11–25 bp (base pairs) per year. Some investigators believe that telomerase helps in telomere maintenance of keratinocytes, while dermal fibroblasts and melanocytes maintain their long telomeres due to their low proliferation rate.[14,15] Critically short telomeres signal for proliferative senescence or apoptosis, depending on cell type, and appear to compromise DNA stability and transcription of subtelomeric genes,[16] presumably contributing to the aged phenotype. Thus, telomeres appear to serve as a biologic

clock that determines proliferative life span and functional level of the cell.

DNA DAMAGE AND AGING[17]

In humans, the only genes implicated in the rate of aging are those in which mutations are responsible for premature aging syndromes. For example, Cockayne syndrome patients display mutations in DNA helicases, enzymes that participate in the repair of DNA damage[18]; ataxia telangiectasia is caused by a mutation in the *ATM* gene,[19] encoding a kinase that detects DNA damage; and Werner syndrome is caused by mutation in a protein with DNA helicase and exonuclease domains.[20] Progeria, a disease that leads to death from atherosclerotic heart disease often in the first decade of life, is caused by mutations in lamin A, a protein important in maintaining chromatin organization in the nucleus for transcriptional control and for DNA damage repair.[21,22] These human premature aging diseases suggest that decreased DNA repair capacity is associated with accelerated aging and that cumulative DNA damage plays a major role in the aging process. Still, the role of these genes in normal aging is not established, as patients with so-called *premature aging syndromes* display some manifestations of aging at an accelerated rate but lack other features of normal aging and have characteristic findings that differ greatly from those of normal aging.

Even in DNA repair proficient individuals, throughout life DNA damage accumulates in cells, interfering with cellular metabolism and function. One system that is particularly susceptible to DNA damage is that of growth hormone and insulin growth factor. It is thought that shifting the energy utilization of the cell from growth and proliferation of a damaged cells to preserving the somatic functions of the individual cell has evolved as a way of ensuring the well-being of the organism as a whole and as a cancer preventing mechanism.[23] Epigenetic events also play a role in aging. For example, DNA methylation is likely affected with aging and may result in silencing of tumor-suppressor and repair genes resulting in cellular senescence and increasing cancer incidence.[24]

However, in other species so-called longevity genes have been identified whose mutation or overexpression increase life span. However, in lower organisms all characterized longevity genes encode proteins that assist in control of environmental stress such as starvation, UV irradiation, oxidative damage, and heat shock. Silent information regulator proteins, sirtuins are a class of protein deacetylases implicated in slowing the aging process. Although it is still unclear how they affect aging, it is suggested that they maintain telomere structural integrity, induce transcriptional silencing of genes that promote aging, and/or modulate mitochondrial function in response to caloric restriction.[25] Resveratrol, a phenolic substance present in red wine is thought to be sirtuin activator.[26] A recently identified transcription factor family of proteins, FoxO, regulates cellular metabolism, stress resistance, and life span extension in mammals.[27,28] In addition, FoxO induces the transcription of procollagen I and decreases the transcription of the matrix degrading metalloproteinases (MMP) -1 and -2.[28] Mice with extended life spans show high expression of a small number of gene loci that control immune responses, a critical mammalian defense against environmental insults. In the aggregate, these studies strongly support a role of cumulative cellular damage, particularly DNA damage, in the aging process; and proficient repair of such damage in longevity.

AGING AND THE IMMUNE SYSTEM[29]

The immune system has two major roles: defense against external insults and internal immunologic surveillance. Decreased T cell memory, loss of the naïve T cell population, defective humoral, and cellular immunity characterize the aging immune system. Chronic inflammatory state, decreased immunity to exogenous antigens, and increased autoreactivity compromise the ability to sustain environmental insults.[30,31] With aging, increased reactive oxygen species (ROS) within cells leads to oxidative stress and contributes to low-grade inflammation. Additionally, mitochondrial electron transfer during oxidative phosphorylation is compromised with aging and results in leakage of proinflammatory ROS into the cytoplasm. This ROS imbalance contributes to immune senescence beginning with decline in the innate immune response and culminating with impaired adaptive immune responses.[31] These changes contribute to the increased incidence of infections and malignancies in the elderly.[32]

SKIN AGING

Cutaneous aging includes two distinct phenomena. Intrinsic aging is a universal, presumptively inevitable change attributable to the passage of time alone; extrinsic aging is the superposition on intrinsic aging of changes attributable to chronic environmental insults, sun exposure, which are neither universal nor inevitable. Extrinsic skin aging is also commonly termed photoaging, reflecting the large and well-studied role of chronic sun exposure. The former is manifested primarily by physiologic alterations with subtle but undoubtedly important consequences for both healthy and diseased skin. The latter has major morphologic as well as physiologic manifestations and corresponds more closely to the popular notion of old skin.

INTRINSIC SKIN AGING

The skin changes that occur with aging (Table 109-1) lead to a gradual physiologic decline (Table 109-2).[33] Major age-related changes in the skin's appearance include dryness (roughness), wrinkling, laxity, and a variety of benign neoplasms. Aged skin is inelastic and recovers more slowly after injury.

TABLE 109-1
Histologic Features of Aging Human Skin

Epidermis	Dermis	Appendages
Flattened dermal–epidermal junction	Atrophy (loss of dermal volume)	Depigmented hair Loss of hair
Variable/decreased thickness	Fewer fibroblasts	Conversion of terminal to vellus hair
Variable cell size and shape	Fewer mast cells	Abnormal nail plates
Occasional nuclear atypia	Fewer blood vessels	Fewer glands
Fewer melanocytes	Shortened capillary loops	
Fewer Langerhans cells	Abnormal nerve endings	

MECHANISMS OF INTRINSIC SKIN AGING.

A major aging theory[34] suggests that cumulative damage to biomolecules, including DNA as a result of continuous generation of free radicals, results in increased cellular vulnerability and eventually terminates in senescence or apoptosis. The skin, like other bodily systems, is continuously exposed to ROS generated during aerobic metabolism (eFig. 109-0.1 in online edition). Although the skin contains a network of antioxidant enzymes (superoxide dismutases, catalase, and glutathione peroxidase) and nonenzymatic antioxidant molecules (vitamin E, coenzyme Q10, ascorbate, and carotenoids), this system is less than completely effective and tends to deteriorate with aging.[35]

Oxidative stress upregulates the level of stress regulatory proteins, including hypoxia-inducible factors (HIFs) and nuclear factor κB (NFκB). HIFs influence the expression of genes that regulate cellular metabolism, survival, motility, basement membrane integrity, angiogenesis, hematopoiesis, and other functions.[36] Both HIFs and NFκB induce the expression of proinflammatory cytokines like interleukin (IL)-1 and IL-6, vascular endothelial growth factor (VEGF), and tumor necrosis factor (TNF)-α. These proteins are involved in immunoregulation and cell survival,[37] stimulate the expression of matrix-degrading metalloproteins,[38] and are believed to play a central role in the aging process. Furthermore, HIFs stabilize subpopulations of malignant cells with stem cell properties (cancer stem cells) and induce their self-renewal by stimulating the expression of signaling pathways critical for survival and proliferation. This suggests that age-associated cellular hypoxia could be involved in cancer stem cell maintenance.[36]

Thermoregulation
Vitamin D production
Wound healing

Oxidative damage also affects telomeres. A recent hypothesis suggests a common cellular signaling pathway activated by DNA damage and involving the terminal portion of the telomeres.[39,40] The terminal portion of the 3′ telomeric strand extends beyond the complementary 5′ strand (Fig. 109-1), leaving a single stranded G-rich overhang. It is suggested that during both telomere shortening and repair of telomere damage, such as that encountered during oxidative stress, the normal loop structure at the end of telomeres is disrupted, exposing the 3′ overhang that under baseline conditions is "buried" in the loop structure.[39,40] Exposure of the TTAGGG tandem repeat sequence then appears to activate p53[41] and to stimulate responses known to include proliferative senescence and apoptosis.[40,41] Thus, the intrinsic component of skin aging involves progressive oxidative stress and telomere signaling as telomeres shorten during serial cell division and in response to oxidative DNA damage.[39]

Oxidative damage also affects cellular proteins, leading to the formation of multiple carbonyl groups (C = O). Such proteins are typically targeted for degradation by proteasomes whose function declines with age, leading to the accumulation of damaged proteins that interfere with proper cellular function.[42]

Another mechanism that plays a role in intrinsic aging is cellular senescence, the limited capacity of cells to divide. It is regarded by some as having evolved in multicellular organisms as a cancer-prevention mechanism.[6] Senescent cells display critically short telomeres, irreversible growth arrest,

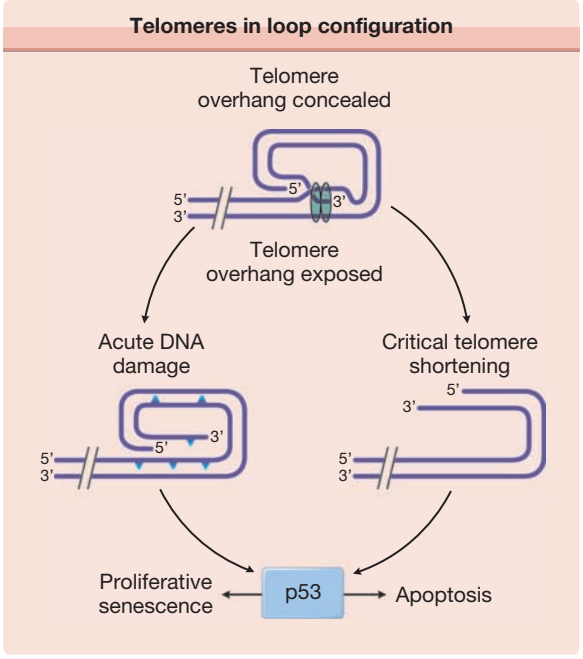

Figure 109-1 Telomeres normally exist in a loop configuration, held in place by the final 150–200 bases (TTAGGG repeats) on the 3′ strand that forms a single-stranded overhang. When the loop is disrupted when telomeres become critically short (e.g., after repeated cell divisions or when telomeres are damaged as a result of UV irradiation or oxidative damage), the overhang becomes exposed, activating the tumor suppressor protein p53 to induce proliferative senescence or apoptosis, depending on the cell type. IL = interleukin. (From Yaar M: Clinical and histological features of intrinsic versus extrinsic skin aging. In: *Skin Aging*. Springer, 2006, p. 9, with permission.)

resistance to apoptosis, and altered differentiation. They also overexpress genes that block progression into the cell cycle[43–45] as well as genes encoding proteins such as fibronectin and proteases involved in modulation of extracellular matrix, such as collagenase and stromelysin. In addition, the levels of certain tissue inhibitors of MMPs are decreased.[46]

Additional mechanisms include amino acid racemization, a process that substitutes D-amino acids for L-amino acids within proteins, affecting protein function and rendering them less susceptible to degradation. Finally, nonenzymatic glycosylation of proteins occurs when reducing sugar aldehydes condense with protein amino groups, resulting in brown discoloration, loss of function, and altered degradation. Glycosylation of extracellular matrix proteins, such as dermal collagen, leads to cross-linking with trapping and sequestration of other unaffected proteins.

EPIDERMIS. Many of the morphologic and functional age-associated changes in skin were documented many years ago[47] and are not specifically referenced here. The most striking and consistent histologic change is flattening of the dermal–epidermal junction with effacement of both the dermal papillae and epidermal rete pegs.[48] This results in a considerably smaller surface between the epidermis and dermis and presumably less communication and nutrient transfer. Dermal–epidermal separation has been demonstrated to occur more readily in old skin, undoubtedly explaining the propensity of the elderly to torn skin and superficial abrasions after minor trauma.

There is an age-associated epidermal thinning of 10%–50% between the ages of 30 years and 80 years.[49] Variability in epidermal thickness and individual keratinocyte size increases, including those of the basal layer. Evidence suggests that epidermal keratinocytes senesce and senescent cells are more resistant to apoptosis. Therefore, such keratinocytes are more likely to accumulate mutations, increasing their risk for malignant transformation. Epidermal stem cells are a population of cells responsible for epidermal maintenance. It is unclear whether there is an age-associated decrease in epidermal stem cells. Some studies also show loss of epidermal stem cell population in aged skin as determined by the loss of cells expressing CD71 (transferrin receptor) and α_6 integrin, accepted markers for keratinocyte stem cells,[50] while others claim that unlike stem cells from other tissues, epidermal stem cells maintain their number and functionality with age and do not display ROS increases.[51,52] The latter has been attributed to high levels of antioxidant enzymes particularly superoxide dismutase-1.[53] At the electron microscopic level, sun-protected old skin is characterized by some widening of interkeratinocyte spaces, by reduplication of the lamina densa and anchoring fibril complex in the basement membrane zone, and by loss of the numerous microvillous projections of basal cell cytoplasm into the dermis.[49]

Average thickness and degree of compaction of the stratum corneum appear constant with increasing age, although individual corneocytes become larger. The skin surface pattern, a patchwork of fine lines possibly determined by papillary dermal architecture, reveals slight age-associated loss of regularity. There is an overall decreased lipid content in the stratum corneum of the elderly as well as decreased water content in part as a result of decrements in cholesterol synthesis.[54] Age-associated increase in stratum corneum pH impedes lipid-processing enzyme activity.[55] Age effects on percutaneous absorption depend in part on drug structure, with hydrophilic substances such as hydrocortisone and benzoic acid being less well absorbed through the skin of old versus young individuals but with hydrophobic substances such as testosterone and estradiol being equally well absorbed.[56] Of perhaps greater clinical importance, aging markedly delays the recovery of barrier function in damaged stratum corneum, apparently because of slow replacement of neutral lipids, leading to decreased amount of lipids in the newly formed lamellar bodies.[57] Lipid synthesis and activities of enzymes required to generate stratum corneum lipids decrease with age possibly because of aberrations in elements that regulate enzyme transcription, or abnormal autocrine/paracrine signaling.[58]

In the elderly, the skin often appears dry and flaky, especially over the lower extremities, an area in which a remarkable age-associated decrease in the content of epidermal filaggrin has been reported.[59] Filaggrin,

required for binding of keratin filaments into macrofibrils, is also decreased in the skin of patients with ichthyosis vulgaris, and its lack has been postulated to cause the increased scaliness in both conditions.[59] Barrier function also may be affected by this structural change.

Epidermal turnover rate and thymidine-labeling index decrease approximately 30%–50% between the third and eighth decades, with a corresponding prolongation in stratum corneum replacement rate. Linear growth rates also decrease for hair and nails. Epidermal repair rate after wounding likewise declines with age.

A decrease in the number of enzymatically active melanocytes per unit surface area of the skin, approximately 10%–20% of the remaining cell population each decade, has been documented repeatedly, presumably reducing the body's protective barrier against UV radiation. Age-associated decline in DNA repair capacity compounds the loss of protective melanin and increases the risk for skin cancer development. The number of melanocytic nevi also decreases progressively with age, from a peak of 15 to 40 in the third and fourth decades to an average of four per person after age 50 years; such nevi are rarely observed in persons beyond age 80.

Between early and late adulthood there is a 20%–50% reduction in the number of morphologically identifiable epidermal Langerhans cells, the skin's immune effector cells responsible for antigen presentation. The remaining cells display morphologic abnormalities, including less and shorter dendrites, and they display reduced antigen-presenting capacity.[60] These changes, compounded by decreases in cytokine production by keratinocytes and lymphocytes and failure of migration through the lymphatic system, presumably contribute to the observed age-associated decrease in cutaneous immune responsiveness.

An endocrine function of human epidermis that declines with age is vitamin D production.[61] Vitamin D, by binding its nuclear receptor, induces the transcription of numerous genes.[62] Vitamin D deficiency in adults leads to osteomalacia and low levels have been implicated in epidemiologic studies as contributing to diabetes, hypertension, and prevalent tumors.[63] Aside from its well-studied role in calcium homeostasis, vitamin D, when bound to its nuclear receptor (1,25D-VDR) influenced transcription of numerous genes including those that encode proteins of the Wnt signaling pathway affecting the formation of the cornified epithelium as well as hair growth. 1,25D-VDR also activates genes that encode proteins that participate in the innate and adaptive immune responses and repress IL-17, a major inducer of autoimmune disorders such as type I diabetes mellitus, multiple sclerosis, lupus, and rheumatoid arthritis. 1,25D-VDR is also anti-inflammatory, as it decreases NFkB and COX2 activation. Finally, 1,25D-VDR induces the activity of the tumor suppressor p53 and p21 proteins and the activity of FoxO, preventing oxidative damage and inducing DNA repair enzymes in skin.[64] Elderly individuals frequently have reduced serum levels of vitamin D. Although avoidance of dairy products (the principal dietary source of vitamin D), insufficient sun exposure, and sunscreen use undoubtedly contribute to vitamin D deficiency in the elderly, the level of epidermal 7-dehydrocholesterol per unit skin surface area also appears to decrease linearly by approximately 75% between early and late adulthood,[61] suggesting that lack of its immediate biosynthetic precursor also may limit vitamin D production. Together these observations suggest that age-associated decrease in Vitamin D could accelerate the aging process and argue for use of vitamin D dietary supplements in the elderly.[65]

With regard to susceptibility to oxidative damage, there is progressive accumulation of damaged cellular proteins and lipids with aging.[49,66] Furthermore, antioxidant defense systems decline with age, and, in addition, there is a decrease in DNA damage repair capacity.[49] These changes in combination increase cellular mutability or their tendency to become senescent, or both.

DERMIS. Loss of dermal thickness approaches 20% in elderly individuals, although in sun-protected sites significant thinning occurs only after the eighth decade.[67] Old dermis is relatively acellular and avascular, and there is age-related loss of normal elastic fibers and dermal collagen.[68,69]

Decreased inflammatory responses in the elderly are the result of decreased synthesis and secretion of keratinocyte-derived cytokines and inflammatory mediators in addition to decreased endothelial response. The dermal microvasculature in middle-aged or elderly subjects also may show mild vascular wall thickening, especially in the lower legs as a result of gravitational forces[70]; vascular wall thinning to less than one-half the normal young adult measurement, associated with absent or reduced perivascular veil cells, has been reported in skin of very elderly subjects and probably contributes to vascular fragility. Loss of elastin contributes to vascular rigidity. Electron microscopic studies show focal degeneration of the elastic component of dermal arterioles. The striking age-associated loss of vascular bed, especially of the vertical capillary loops that occupy the dermal papillae in young skin, and increased distance from the epidermis of existing loops, is thought to underlie many of the physiologic alterations in old skin, including pallor, decreased skin temperature, and the approximately 60% reductions in basal and peak induced cutaneous blood flow.[71]

VEGF of epidermal origin appears to play a major role in maintaining dermal vasculature, inducing the expression of antiapoptotic proteins in endothelial cells,[70] and decreased VEGF level shown in aged mice and rabbits skin probably contributes to endothelial cells apoptosis.[72,73] Also, evidence suggests that there is an age-associated decline of both angiogenic and anti-angiogenic factors, disrupting cutaneous angiogenic homeostasis.[74] Decreased endothelial cell permeability response and decreased capacity to induce white cell adhesion[75] contribute to the compromised immune response. When exposed to intense heat or cold, aging vessels demonstrate reduced ability to constrict, dilate, or shunt.[70] Compromised thermoregulation, which predisposes the elderly to sometimes fatal heat stroke

or hypothermia, may be due in part to reduced vasoactivity of dermal arterioles and, in the latter instance, to loss of heat-conserving subcutaneous fat as well. Reduction in the vascular network surrounding hair bulbs and eccrine, apocrine, and sebaceous glands may contribute to their gradual atrophy and fibrosis with age.

Age-associated decreases in wheal resorption and dermal clearance of transepidermally absorbed materials have been reported,[56] probably due to alterations in both the vascular bed and the extracellular matrix. Conversely, the time required for development of a tense blister after topical ammonium hydroxide application is nearly twice as long in older individuals, suggesting a decreased transudation rate with age in injured skin. Impaired transfer of cells as well as solutes between the extravascular and intravascular dermal compartments is suggested by several studies; multiple factors undoubtedly contribute.

With aging there is a decrease in the density and lumen size of lymphatic vessels accompanied by increased rigidity and decrements in lymphatic drainage, affected by decreased surrounding elastic fibers.[70] The ability to effectively pump lymph from interstitial spaces into the lymphatics is impaired with aging in part because of decreased activity of enzymes that catalyze the production of nitric oxide.[76]

Biochemical changes in collagen, elastin, and dermal ground substance lead to increased skin rigidity primarily due to modifications in collagen. Collagen content per unit area of skin surface decreases approximately 1% per year throughout adult life,[77] and the remaining collagen fibrils appear disorganized, more compact, and granular, and they display increased collagen cross-links.[78–80] The latter is the result of decreased collagen I and III synthesis; decrements in enzymatic processing of collagen as well as nonenzymatic glycosylation, a process that leads to molecular damage of proteins with a long half-life such as collagen[49]; and increased collagenase levels. Such changes almost certainly contribute to impaired wound healing in the elderly.[79]

Beginning in early adulthood, elastic fibers decrease in number and diameter; by old age, they often appear fragmented, with small cysts and lacunae, especially near the dermal–epidermal junction[81] most likely due to enzymatic degradation of elastin. Elastic fibers also show progressive cross-linkage and calcification with age. At the biochemical level, there is an age-associated decrease in numerous elastic fiber components, including elastin, fibrillin, and fibulin-2. With aging, the level of fibulin-5, an extracellular matrix protein that functions as a scaffold for elastic fibers, appears to decrease before other changes are observed, suggesting that loss of fibulin-5 is a marker for skin aging.[82]

The ground substance mucopolysaccharides, glycosaminoglycans (GAGs), and proteoglycans are decreased relative to dry weight or collagen content of the skin, especially hyaluronic acid,[83] possibly due to decreased hyaluronan secretion or due to decreased hyaluronic acid extractability.[84] Aging also affects GAG composition and binding to elastin, impeding the drainage of molecules into lymphatic vessels.[70] These changes may adversely influence skin turgor because proteoglycans bind 1,000 times their own weight in water and also impact collagen fiber deposition, orientation, and size.[85]

Changes with age in the mechanical properties of the skin during adulthood include progressive loss of elastic recovery, consistent with gradual destruction of the dermal elastic network, and marked prolongation of the time required for excised skin to return to its original thickness. In vivo ultrasound studies also show age-associated differences in water distribution in the dermis,[86] no doubt affecting dermal pliability, resilience, and elasticity. Overall, a picture emerges of aging dermis as an increasingly rigid, inelastic, and unresponsive tissue that is less capable of undergoing modifications in response to injury or stress.

SUBCUTANEOUS TISSUE, MUSCLES, AND BONE. Like other striated muscles, facial muscles show accumulation of the "age pigment" lipofuscin, a marker of cellular damage. Compounded by diminished neuromuscular control, this deterioration contributes to wrinkle formation.[87] In addition, subcutaneous fat is depleted from distinct facial regions, including the forehead, preorbital, buccal, temporal, and perioral regions. In contrast, there is a prominent increase in fatty tissue in other areas, including the submental regions, the jowls, the nasolabial folds, and the lateral malar areas. In contrast to the young face in which fat is diffusely dispersed, fat in the aged face, subject to the force of gravity, contributes to sagging and drooping of the skin.[88]

Finally, like other parts of the skeleton, facial bones display reduced mass with age. Bone resorption affects particularly the mandible, maxilla, and frontal bones. Bone loss in these areas enhances the sagging of facial skin and contributes to the obliteration of the demarcation between the contour of the jaw and the neck that is so distinct in young adults.[89]

HAIR. By the end of the fifth decade, approximately half the population has at least 50% gray (white) scalp hair, and virtually everyone has some degree of graying due to progressive and eventually total loss of melanocytes from the hair bulb.[90] Loss of melanocytes is believed to occur more rapidly in hair than in skin because the cells proliferate and manufacture melanin at maximal rates during the anagen phase of the hair cycle, whereas epidermal melanocytes are comparatively inactive throughout their life span. More specifically, hair graying reflects loss of the melanocyte stem cell population in hair follicle bulge due, at least in part, to compromised interaction between two transcription factors, microphthalmia-associated transcription factor (Mitf) and Pax3 (see Chapter 72).[91] Faulty migration of melanocyte stem cells into the bulb area of the hair[92] has also been suggested to contribute. Additionally, high levels of H_2O_2 in the millimolar range have been reported in gray/white scalp.[93] By oxidizing methionine, tryptophan, and cysteine residues on enzymes, H_2O_2 likely to interferes with the activity of tyrosinase as well as antioxidant enzymes by altering their

tertiary structure and may thus affect melanogenesis in the human hair follicle.[93]

Scalp hair may gray more rapidly than other body hair because its anagen to telogen ratio (see Chapter 86) is considerably greater than that of other body hair. Advancing age is also accompanied by a modest decrease in number of hair follicles, due in part to atrophy and fibrosis. In addition, with aging there is an increase in the proportion of telogen hair follicles. Remaining hairs may be smaller in diameter and grow more slowly. One hypothesis suggests that melanocyte loss and lack of melanosomal transfer may increase oxidative stress level in highly metabolic hair follicle keratinocytes, affecting their function and viability.[94]

The process termed *balding* results primarily from the androgen-dependent conversion of the relatively dark, thick, terminal scalp hairs to lightly pigmented short, fine, vellus hairs similar to those on the ventral forearm. Women are affected less often and far less severely than men. However, in postmenopausal women, hair loss is also the result of decreased estrogen levels and estrogen to androgen ratio.[95,96] Besides hair loss, almost 50% of women older than age 60 years display mild facial hirsutism, presumably attributable to the same hormonal changes as scalp hair loss. In susceptible women, testosterone and/or progestin derivatives that are present in some hormone replacement regimens may exacerbate these changes.

CUTANEOUS GLANDS AND NERVES. Eccrine glands decrease by approximately 15% in average number during adulthood in most body sites. Spontaneous sweating is further reduced by more than 70% in healthy older subjects compared with younger controls, attributable primarily to a decreased output per gland, predisposing the elderly to heat stroke. Apocrine gland size and function also decrease with aging. Sebaceous gland size and number appear not to change with age, but there is an exponential decrease in sebum production in both men and women most likely due to a decrease in production of gonadal or adrenal androgens.[97]

Pacinian and Meissner's corpuscles, the cutaneous end organs responsible for pressure perception and light touch, progressively decrease to approximately one-third their initial average density between the second and ninth decades of life and display greater size variation and structural irregularities.

Decreased sensory perception in old skin encompasses optimal stimulus for light touch, vibratory sensation, and corneal sensation; ability to discriminate two points; and spatial acuity.[98,99] Cutaneous pain threshold increases up to 20% with advancing adult age, and compromised arteriolar constriction on changing position from supine to standing is reflective of decreased responsiveness of the sympathetic nervous system.

EFFECTS OF MENOPAUSE. Estrogens play a critical role in female development and reproduction and also influence skin and hair. Not surprisingly, their influence decreases dramatically after menopause. Menopause typically occurs in a woman's early 50s, so that, with life expectancy in the developed world approaching 80 years,[100] women are postmenopausal for approximately one-third of their lives. In premenopausal women, the predominant estrogen is estradiol, which is produced by the ovaries,[101] and after menopause levels decrease by more than 90%,[102] with estron, a less active estrogen, becoming the predominant form.[103] Progestin and androgen levels also fall markedly after menopause.[103] The reduced levels of estrogen underlie many physiologic effects, including hot flashes, atrophy of reproductive tissue, and changes in nonreproductive tissues that are estrogen sensitive.[103] Age-associated decrements in keratinocyte barrier function, immune-regulation, and wound healing appear to be compounded by decreased estrogen levels and/or decreased responsiveness of cells to existing estrogens. Because both estrogen and androgen receptors are expressed by skin-derived cells, both hormones are likely to play a role in skin structure and function.

Structural and Functional Changes in Postmenopausal Skin. Decreased circulatory levels of estrogens are associated with reduced dermal collagen content,[104–106] increased cutaneous extensibility,[107,108] and decreased elasticity.[109] Also, decreased water-holding capacity, increased dryness, and increased fine wrinkling are reported after menopause,[110] as are decreased sebum levels.[111] These changes are related more to menopause than to chronologic age alone,[112] and wrinkling is reported to be more pronounced in postmenopausal women who are not taking hormone replacement therapy than in treated women.[113]

After menopause, the decreased rate of wound healing is associated with reduced levels of collagen I.[114] Estrogen and progesterone are also reported to modulate cutaneous inflammation, enhance keratinocyte proliferation and collagen synthesis, decrease the activity of MMPs, and increase the synthesis of dermal mucopolysaccharides and hyaluronic acid.[96,115]

PHOTOAGING

Clinical and histologic features of actinically damaged skin are listed in Table 109-3. A prominent feature of photoaged skin is elastosis, a process characterized clinically by yellow discoloration and a sometimes pebbly surface (Fig. 109-2) and histologically by tangled masses of degraded elastic fibers that further deteriorate to form an amorphous mass composed of disorganized tropoelastin and fibrillin (eFig. 109-2.1A in online edition). Although fibrillin is abundant in the elastotic material deeper in the dermis, in the upper portions of the dermis at the dermal–epidermal junction, fibrillin is reduced.[116] In addition, the amount of ground substance, largely composed of glycosaminoglycans (GAGs) and proteoglycans, increases in photodamaged skin, whereas the amount of collagen decreases, in part because of increased metalloproteinase activity. In contrast with aged sun-protected skin that demonstrates hypocellularity, photodamaged skin frequently displays an increased number of hyperplastic fibroblasts

TABLE 109-3
Features of Photoaged Skin[a]

Clinical	Histologic
Dryness (roughness)	Increased compaction of stratum corneum, increased thickness of granular cell layer, reduced epidermal thickness, reduced epidermal mucin content
Actinic keratoses (see Chapter 113)	Nuclear atypia, loss of orderly, progressive keratinocyte maturation; irregular epidermal hyperplasia and/or hypoplasia; occasional dermal inflammation
Irregular Pigmentation	
Freckling	Reduced or increased number of hypertrophic, strongly DOPA-positive melanocytes
Lentigines (see eFig. 109-2.2 in online edition)	Elongation of epidermal rete ridges; increase in number and melanization of melanocytes
Guttate hypomelanosis	Reduced number of atypical melanocytes
Diffuse irreversible hyperpigmentation (bronzing) (see eFig. 109-2.3 in online edition)	Increased number of DOPA-positive melanocytes and increased melanin content per unit area and increased number of dermal melanophages
Wrinkling	
Fine surface lines	None detected
Deep furrows (see Figs. 109-2 and 109-3)	Contraction of septae in the subcutaneous fat
Stellate pseudoscars (see eFig. 109-2.4 in online edition)	Absence of epidermal pigmentation, altered fragmented dermal collagen
Elastosis (fine nodularity and/or coarseness) (see Fig. 109-3)	Nodular aggregations of fibrous to amorphous material in the papillary dermis
Inelasticity	Elastotic dermis
Telangiectasia	Ectatic vessels often with atrophic walls
Venous lakes	Ectatic vessels often with atrophic walls
Purpura (easy bruising)	Extravasated erythrocytes and increased perivascular inflammation
Comedones (maladie de Favre et Racouchot) (see eFig. 109-2.5 in online edition)	Ectasia of the pilosebaceous follicular orifice
Sebaceous hyperplasia	Concentric hyperplasia of sebaceous glands

[a]Basal cell carcinoma and squamous cell carcinoma also occur in photoaged skin but, unlike the table entries, affect only a minority of individuals.

as well as increased inflammatory cells (eFig. 109-2.1B in online edition), including mast cells, histiocytes, and other mononuclear cells, giving rise to the term *heliodermatitis* (literally, "cutaneous inflammation due to sun"; Fig. 109-3). Immunohistologic studies show

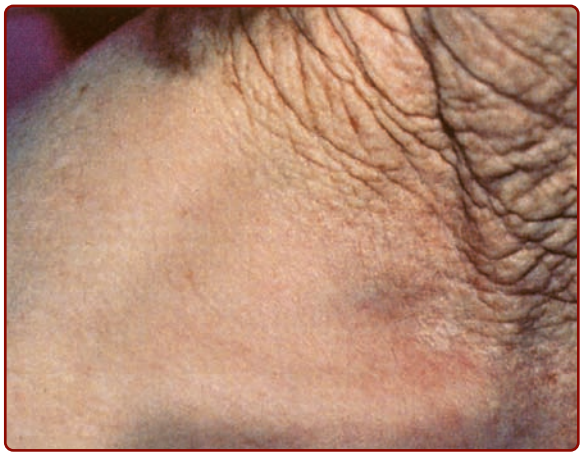

Figure 109-2 Photoaged versus intrinsically aged skin of an elderly man. Habitually sun-exposed skin above the collar line is prominently wrinkled and lax, in contrast with the equally chronologically aged but sun-protected skin of the lower neck and shoulder. Despite the striking difference in appearance, both areas manifest age-associated functional decrements.

increased $CD4^+$ T cells in the dermis. Dermal vasculature in mildly photodamaged skin displays venule wall thickening; in severely photodamaged skin, thin vessel walls with compromised perivascular veil cells display dilations (telangiectases).

In contrast with chronologically aged skin, photodamaged epidermis is frequently acanthotic, although severe atrophy also can be seen in addition to loss of polarity and cellular atypia. Also, there is a more profound decrease in the number and function of Langerhans cells. Additional changes are described in Table 109-3.

The relative severity of sun-induced cutaneous changes varies considerably among individuals, undoubtedly reflecting inherent differences in vulnerability and repair capacity for the solar insult. Photoaging occurs not only in fair-skinned individu-

Figure 109-3 Photoaging: heliodermatitis. Pronounced furrowing, yellow discoloration, and pebbly surface (solar elastosis) with plugged follicles on the neck. *Arrows* denote small actinic keratoses.

als (skin phototypes I and II) but also in individuals with darker skin phototypes III and IV with a history of ample past sun exposure. It usually involves the face, neck, or extensor surfaces of the upper extremities most severely. Interestingly, the gross appearance of photodamaged skin of individuals with skin phototypes I and II differs from that of individuals with darker skin types. The former generally show atrophic and dysplastic skin changes with actinic keratoses and epidermal malignancies, whereas the latter manifest hypertrophic responses such as furrowing, lentigines, and coarseness (eFig. 109-3.1 in online edition).[39] One study noted that patients presenting with basal cell carcinoma (BCC) are less wrinkled than peers of similar complexion and degree of photodamage,[117] suggesting that certain phenotypes of photoaging correlate with a predisposition to mutation and carcinogenesis.

Photoaging is most apparent in whites but also occurs in Asians, Hispanics, and Africans. The differences in clinical appearance of photoaged skin between whites and other groups is primarily due to differences in their UV defense systems. In the latter three groups, melanin is a major form of protection, whereas in whites, melanin plays a lesser role, and stratum corneum thickening is relatively more important.[118] One study reported a sun protection factor for black epidermis of 13.4, compared to 3.4 for white epidermis.[119] Black epidermis transmitted approximately 6% of ultraviolet B (UVB) to the dermis, compared to almost 30% transmission through white epidermis.[119] Similarly, only ~18% of ultraviolet A (UVA) was transmitted into black dermis, compared to more than 55% to white dermis.[119]

Major clinical features of photoaging in Asian skin are solar lentigines and mottled pigmentation.[120] Moderate-to-severe wrinkling occurs in Asians but only in the sixth decade and only in individuals who regularly spent ample time in the sun.[121]

There are no specific studies addressing photoaging in Hispanics, and studies on photoaging of black skin have been published only in African-Americans. As expected, fairer skinned Hispanics and Africans display clinical photoaging signs earlier and more prominently than those with very dark skin.[98] Changes include fine wrinkling and mottled pigmentation.[116,120]

MECHANISMS OF PHOTOAGING.

Mechanisms involved in intrinsic aging also play a role in photoaging.[122] Additional mechanisms are discussed below.

Membrane and Nuclear Signaling. UV irradiation, in part through ROS generation that inhibits phosphatases whose function is to maintain receptors in their inactive state,[123] activates (phosphorylates) cell surface receptors, including receptors for epidermal growth factor, IL-1, and TNF-α, to induce intracellular signaling culminating in activation of the nuclear transcription complex activator protein (AP)-1, composed of the proteins c-Jun and c-Fos.[124] In intact human skin, even suberythemogenic doses of UVB [~0.1 minimal erythema dose (MED)] transcriptionally upregulate and activate AP-1.[125] Increased AP-1 activity interferes with synthesis of the major dermal collagens I and III by blocking the effect of transforming growth factor (TGF)-α, a cytokine that enhances collagen gene transcription.[124,125] AP-1 also decreases the level of TGF-β receptors, further inhibiting collagen transcription,[126] and also antagonizes intrinsic retinoid effects in skin, leading to a functional retinoid deficiency and reducing collagen synthesis normally promoted by retinoic acid bound to its nuclear receptors. Additionally, UV induces the synthesis and secretion of a cysteine-rich growth regulatory factor (CYR61) that reduces type I procollagen synthesis, increases MMP-1 levels, decreases TGF-β receptor level, and induces AP-1 activation.[127] Hence, in habitually UV-irradiated photodamaged skin there is an overall reduction in collagen synthesis.[128] Increased AP-1 activity also increases the levels and activity of several enzymes that degrade extracellular matrix components, notably the MMP-1 (collagenase), MMP-3 (stromelysin-1), and MMP-9 (92-kd gelatinase).[77,124] UV also activates the nuclear factor κB transcription factor that induces the expression of multiple proteins as discussed in Section "Mechanisms of Intrinsic Skin Aging"24 and aggravates the degradation of dermal matrix by increasing the levels of MMP-1 and MMP-9.[125] Matrix degradation is further exacerbated by MMP-8 (collagenase) of neutrophil origin after neutrophil infiltration into UV-irradiated skin.[129] Although there is also a concomitant upregulation of tissue inhibitors of metalloproteinases (TIMPs) that limit matrix degradation, TIMPs presumably are not completely effective in blocking cumulative damage to dermal collagen.[130] UV also decreases FoxO mRNA level further compromising collagen I synthesis and increasing the transcription of MMP-1 and -2 (18C).

UV-induced collagen degradation is generally incomplete, leading to accumulation of partially degraded collagen fragments in the dermis, thus reducing the structural integrity of the skin.[124] In addition, the large collagen degradation products inhibit new collagen synthesis,[131] and, thus, collagen degradation itself negatively regulates new collagen synthesis. Interestingly, increased stress-associated AP-1 activity, increased CYR61 and MMP levels, and reduced collagen production have been documented in intrinsically aged skin,[127,132] suggesting that similar mechanisms may contribute to chronologic aging, perhaps again through the generation of ROS, as discussed in Section "Mechanisms of Intrinsic Skin Aging."

UV radiation, both directly and through generation of ROS induces the transcription of tropoelastin, a component of the mature elastic fibers.[133] Fibulins 2 and 5 and fibrillin-1, components of the microfibrillar fraction of the dermal elastic fiber are also increased in the elastotic material.[82] Furthermore, increased elastase levels are present in photodamaged skin as a result of elastase synthesis and secretion by neutrophils that are attracted to the area by inflammatory mediators.[134] Thus, excessive unbalanced synthesis of elastic fiber components that undergo partial degradation results in the formation of amorphous elastotic material.

Mitochondrial Damage. Mitochondria are cellular organelles that produce energy (adenosine triphosphate) by consuming oxygen. Although equipped with antioxidant defense systems, continuous generation of ROS damages mitochondrial DNA (mtDNA). To date, machinery to remove bulky DNA lesions has not been identified in mitochondria, although they display capacity for base excision repair relevant to repair of oxidative damage. Still, mtDNA mutation frequency is approximately 50-fold higher than that of nuclear DNA, and photodamaged skin has higher mtDNA mutation frequency than sun-protected skin, displaying large DNA deletions[135–138] and resulting in decreased mitochondrial function, leading to further accumulation of ROS and compromising the cell's ability to generate energy. Also, a correlation was noted between decreased mitochondrial function and increased MMP-1 levels without concomitant increase of MMP-1-specific TIMP,[136] exacerbating collagen degradation[135–138] and aggravating skin photoaging.

Protein Oxidation. Proteins are affected by oxidative damage, and photodamaged skin shows accumulation of oxidized, damaged proteins in the upper portions of the dermis.[139] In vitro studies suggest that UVA is a major contributor and the accumulation of such proteins further inhibits proteasomal function and the ability of the cell to successfully degrade additional damaged proteins.[140]

Basement Membrane Damage. In sun-exposed skin, the basement membrane becomes thicker and multilayered in part as a result of damage through MMP activation, affecting molecular transfer between the epidermis and the dermis and compromising epidermal health.[141]

ACTION SPECTRUM.

The action spectrum for human photoaging has not been determined, but many studies have explored the relative contribution of the various spectral bands within sunlight, using animal models.

Despite the well-documented affects of UVB, UVA is suspected of playing a proportionately larger role in photoaging because of its minimally 10-fold greater abundance in terrestrial sunlight, far greater year-round and daylong average irradiance, and greater average depth of penetration into the dermis compared to UVB.

In rodent skin, an elastosis-like condition can be produced by prolonged intense irradiation with either a predominantly UVB or UVA source.[142,143] UVB photons are on average 1,000 times more energetic than UVA photons and are overwhelmingly responsible for sunburn, suntanning, and photocarcinogenesis after sun exposure.[144] UVB is the major cause of direct DNA damage and induces inflammation and immunosuppression, as well as synthesis and release of prostaglandins (PGs), particularly PGE_2, through induction of the enzyme cyclooxygenase-2. UVB also induces ornithine decarboxylase, the rate-limiting enzyme in the biosynthesis of polyamines that stimulates cellular proliferation (contributing to cancer formation) and contributes to cutaneous angiogenesis by decreasing the expression of the angiogenic inhibitor thrombospondin-1 and inducing the expression of VEGF and platelet-derived endothelial cell growth factor, two angiogenic factors.[145,146] UVB also triggers the penetration of elastase-producing leukocytes into the skin, aggravating elastin degradation.

Moreover, human skin exposed daily for only 1 month to suberythemogenic doses of UVA alone demonstrates epidermal hyperplasia, stratum corneum thickening, Langerhans cell depletion, and dermal inflammatory infiltrates with deposition of lysozyme on the elastic fibers.[147] UVA also induces the synthesis and release of cytokines and MMPs, particularly collagenase (MMP-1) and elastase, and triggers mtDNA mutations.[148–151] Both UVA and UVB lead to the generation of ROS that damage cellular lipids, proteins, and DNA.[152,153] Studies using laser-capture microdissection of human skin show that p53-mutant keratinocytes of the basal layer, in addition to UVB signature mutations, have more mutations associated with UVA (and primarily 8-OXO-dG photolesions), suggesting that UVA is an important etiologic factor in the generation of BCC.[42] UVA is more effective than UVB in inducing oxidative damage. Indeed, the degree of solar elastosis and cutaneous photoaging appear to correlate with the level of accumulated dermal protein oxidation[139] but not epidermal oxidation, suggesting a superior antioxidant network and/or better repair capacity in the epidermis.

Sunlight also contains IR (760 nm to 1 mm).[154] Wavelengths of 760–1,400 nm can penetrate the skin to reach the subcutaneous tissue without inducing a significant increase in skin temperature. In contrast, wavelengths of 1,400 nm to 1 mm are primarily absorbed in the epidermis and considerably increase skin temperature.[155] IR is particularly important in regions of high insulation and aggravates UVA-induced dermal changes, producing severe elastosis. Even when delivered without UV, IR affects dermal elastic fibers and increases the amount of dermal ground substance.[155] In the hairless mouse model, IR contributes to UV-induced thickening of the epidermis and dermis and alone induces the expression of MMP-3 and the mouse equivalent of MMP-1.[154] Furthermore, in human skin, the expression of tropoelastin, a major component of elastic fiber that associates with microfibrils, is increased as a result of IR, and IR induces the expression of fibrillin-1, a component of the microfibrils.[156] In addition, the level of MMP-12, the enzyme that degrades elastin, is increased.[156] Thus, IR appears to contribute to UV-induced photoaging.

Many of the age-associated physiologic decrements, such as slowed wound healing and loss of immunoresponsiveness, also appear to be accelerated in sun-exposed skin. Furthermore, cells cultured from chronically sun-exposed skin sites differ from cells cultured from sun-protected sites of the same donors in having shortened culture life spans, slower growth rates, lower saturation densities, and altered responsiveness to retinoic acid,[157] all changes also observed as a function of advanced chronologic donor age. Several of the mechanisms known to be involved in UV-mediated

cellular damage are also postulated to underlie chronologic aging,[158,159] although the changes only appear after the seventh decade.[132] These include DNA injury and/or decreased DNA repair, oxidative damage, lysosomal disruption, elevated MMPs, reduced collagen production, and connective tissue damage.

OTHER CONTRIBUTORS TO EXTRINSIC AGING

Cigarette smoking exacerbates photoaging, particularly in women, with a direct correlation between the number of pack-years smoked and the severity of wrinkling and grayish discoloration.[160,161] Histologic analysis of "smoker's skin" reveals elastic fiber thickening and fragmentation, similar to that found in sun-damaged skin.[162] However, whereas solar elastosis is restricted in the papillary dermis, elastic fiber changes in smoker's skin also occur in the reticular dermis. This dermal elastosis has been suggested to result from increased elastase activity in neutrophils,[163] chronic dermal ischemia, and the pro-oxidant effects of cigarette smoke compounded by decreased levels of vitamin A, which reduce the capacity to quench free oxygen radicals and increase DNA damage.[160,161] Smoking also has been associated with decreased stratum corneum water content[160,161] and accelerated hydroxylation of estradiol, leading to decreased estrogens in the skin that may in turn contribute to dryness and atrophy.[161] Smokers display poor wound healing capacity[164] and increased incidence of skin cancers as well as increased severity of photoaging-like changes compared with nonsmokers who have otherwise similar risk factors,[165] consistent with the possibility that mutagens present in cigarette smoke directly affect cells in the dermis and epidermis. By increasing oxidative stress, cigarette smoke impairs collagen synthesis and induces the synthesis and release of MMPs.[166] Also, the polycyclic aromatic hydrocarbons that are present in cigarette smoke bind to the cytoplasmic aryl hydrocarbon receptor. When activated, the receptor translocates to the nucleus to induce the transcription of xenobiotic-metabolizing genes that encode ptoeins involved in growth control, cytokines, nuclear transcription factors and regulators of extracellular matrix proteolysis.[166]

RELEVANCE TO SKIN DISEASE IN THE ELDERLY

Closely associated with aging is increased vulnerability to disease and injury. Disorders of the skin are known to be common and bothersome in the elderly, and some occur predominantly in this age group.[1] Such disorders often appear to be the consequence of age-associated intrinsic losses of cutaneous cellular function. However, many dermatoses observed more commonly in the elderly reflect the higher prevalence of systemic diseases, such as diabetes, vascular insufficiency, and various neurologic syndromes, that compound physiologic changes in the skin itself. The increased prevalence of some disorders also may reflect reduced local skin care due to immobility or neurologic impairment rather than changes in the skin itself. As well, subtle age-associated changes in immune status may contribute, in analogy to the increased prevalence and severity of skin disease in patients with acquired immunodeficiency syndrome.

Reduced tolerance to systemically administered drugs is well documented in the elderly[167] due to decrements in lean body mass, metabolism, and renal excretion of the active ingredients. Comparable data for topically applied medications do not exist, but it is tempting to postulate that retarded dermal clearance of absorbed material, reduced dermal mass and cellularity, and, possibly, altered metabolic capacity may render old skin more susceptible to both beneficial and adverse effects of topical medications or may at least alter the optimal therapeutic schedule. In the case of glucocorticoid preparations, relative vascular unresponsiveness may render blanching of erythema an unreliable indicator of other effects in old skin.

Selected common cutaneous disorders in the elderly are discussed briefly in the following sections, with special emphasis on their pathogenesis and clinical presentation in this population (Table 109-4). Most of these entities are covered more comprehensively in other chapters.

TUMORS

Benign proliferative growths are especially characteristic of aging skin. Acrochordons, cherry angiomas, seborrheic keratoses, and lentigines begin to appear in middle age and are numerous in nearly every adult beyond age 65 years.

SEBORRHEIC KERATOSES

Seborrheic keratoses are benign papules or plaques that are highly variable in size and color. Because their number increases with aging, independent of sun exposure, they are considered by some as a biomarker of intrinsic aging (see Chapter 118).[168] Seborrheic keratoses represent clonal proliferations of both keratinocytes and melanocytes,[169] presumably the result of focal epidermal homeostatic loss. They have no malignant potential. Although the pathogenesis of these keratoses is not completely understood, lesional keratinocytes express high levels of endothelin-1 and lesional melanocytes have increased tyrosinase expression,[170] leading to the hypothesis that dysregulation of endothelin-1, an inducer of melanogenesis, dendriticity, and proliferation in melanocytes,[171,172] plays an etiologic role in seborrheic keratoses.

SKIN CANCER

(See Chapters 113–115.)

TABLE 109-4
Presumptive Pathophysiology of Common Cutaneous Disorders in the Elderly

Disorder	Pathophysiology
Benign neoplasia	
Seborrheic keratosis	Focal epidermal homeostatic loss leading to increased endothelin-1
Malignant neoplasia	
Squamous cell carcinoma and actinic keratosis	Ultraviolet-induced DNA damage
Basal cell carcinoma	Decreased DNA damage repair capacity
Malignant melanoma	Cumulative age-associated DNA damage
Merkel cell carcinoma	Decreased DNA damage repair capacity; polyoma virus
Angiosarcoma	
Papulosquamous disorders	
Psoriasis	Changes in patient's environment leading to Koebnerization Systemic medications
Xerosis/asteatotic dermatitis	Disturbance of epidermal maturation (decreased filaggrin production and/or altered lipid profile) Decreased water content in outer layers of stratum corneum Slower corneocyte transit
Pruritus	Penetration of irritants through damaged stratum corneum (?) Altered sensory threshold (neuropathy) (?) Metabolic disorder Endocrine disorder Malignant neoplasm Adverse drug reaction Parasitic infestation
Infections	Compromised local cutaneous health predisposing to growth of infective organism Age-associated decreased immune function Underlying systemic disorder associated with decreased immune function
Ulcers	Impaired wound healing capacity (decreased levels of growth factors, decreased cellular proliferative capacity, increased perivascular fibrin deposition) Decreased mobility Underlying systemic disorder Compromised local cutaneous health (venous stasis, arteriosclerosis, hypertension)
Bullous pemphigoid	Flattening of the dermal-epidermal junction Increased circulating autoantibodies
Photosensitivity reactions	Medications with unsaturated ring structures

The age-specific incidence of skin cancer, including melanoma, increases exponentially with age,[148] presumably due in part to cumulative exposure to carcinogens over a lifetime interspersed with cell division, with the attendant risk of mutation. There are also well-documented age-associated decreases in DNA repair capacity[66,173] and immunosurveillance,[174] as well as subtle loss of proliferative homeostasis.

The major etiologic factor for skin cancer is UV irradiation. Habitual sun exposure of fair-skinned individuals induces squamous cell carcinoma as well as actinic keratoses, a premalignant lesion that may evolve into squamous cell carcinoma in a direct dose-response relationship.[175] In contrast, the risk of BCCs and particularly malignant melanoma is related not only to total sun exposure but also to intense intermittent sun exposure.[176] The mechanism underlying these different epidemiologic patterns is unknown, although inducible protective responses and relative resistance of the responsible cell types to apoptosis may contribute.[177]

The elderly, particularly men, present with melanomas (see Chapter 124) that are thicker than those of young adults, presumably in part because of failure to properly examine their skin, poor vision, and other medical problems; and their melanomas arise on a background of multiple benign cutaneous lesions. Presumably because of delayed diagnosis, men older than age 50 years have an increased mortality risk from melanoma compared with women or younger men.[178] Although all types of melanoma have increased age-specific incidences,[179] lentigo maligna melanoma overwhelmingly develops in the 60s or later in habitually sun-exposed skin.[180] Reflectance confocal microscopy is a novel approach to distinguish in vivo between lentigo maligna and lentigo maligna melanoma.[181]

Merkel cell carcinoma (trabecular carcinoma) (see Chapter 120) is a rare cutaneous tumor thought to arise from a pluripotential cell that displays neuroendocrine differentiation.[182,183] It is seen most often in sun-exposed areas of the head, neck, or extremities and presents as a rapidly growing nodule with a poor prognosis. More than 90% of patients diagnosed with this tumor are older than age 50, with the mean age of onset being 68 years. Polyomavirus sequences found integrated within the DNA of tumor cells are likely the etiologic agent for Merkel cell carcinoma,[184] and age-associated subtle losses in cellular immunity may well account for the demographics of this malignancy.

The most common form of angiosarcoma (see Chapter 128) occurs overwhelmingly on the head and neck of the elderly. Its rapid growth, associated with early metastasis, usually results in death within 2 years of diagnosis.[185] Immunohistochemical analysis shows high levels of VEGF and its receptor, VEGF receptor-2, as well as cell cycle-associated proteins in cutaneous angiosarcoma explaining in part the rapid growth of these vascular tumors.[186]

PAPULOSQUAMOUS DISORDERS

XEROSIS AND ASTEATOTIC DERMATITIS

Xerosis is a dry, rough quality of skin that is almost universal in the elderly and may be attributed to a subtle disturbance of epidermal maturation, such as inadequate filaggrin production[59] or altered lipid profile.[57,190] Histologic studies reveal little alteration of either the viable epidermis or the stratum corneum with age. Available data fail to demonstrate an overall decrease in stratum corneum lipids[54,57] or altered amino acid composition as etiologic factors.[191] Water content of the viable epidermis is normal, but there is some reduction in the outermost layers of the stratum corneum.[54] The surface irregularity may be attributed simply to slower transit of corneocytes through the stratum corneum, allowing accumulation of damage in situ. There is no explanation for the pruritus that often accompanies xerosis.[192] Speculations include frequent penetration of irritants through an abnormal stratum corneum and an altered sensory threshold due to subtle neuropathy.

Asteatotic eczema, a condition frequently found in the elderly during the wintertime, is dermatitis superimposed on xerosis. It is often caused by low humidity in a heated environment. It manifests by dry, fissured skin with fine scale and is usually localized to the pretibial region. This condition, which may be extremely pruritic, responds to application of medium-potency topical steroid ointments and/or liberal application of emollients.

PRURITUS[162]

(See Chapter 103.)

Pruritus is perhaps the most common skin-related complaint of the elderly. In a majority of cases, pruritus is attributable only to xerosis, often exacerbated by low humidity, frequent bathing, or application of irritants to the skin. However, in up to 10%–50% of patients in some series, pruritus may have other etiologies. These include metabolic or endocrine disorders, such as diabetes mellitus, renal failure, thyroid disease, or hepatic disease, in particular the obstructive type. Pruritus can be a manifestation of a malignant neoplasm, in particular lymphoma or leukemia, or the result of a hematologic disease such as polycythemia vera. Adverse drug reactions can manifest predominantly or exclusively as pruritus and always should be considered in this segment of the population. Finally, infestations such as scabies lead to intense pruritus, and associated primary skin lesions may be overlooked.

INFECTIOUS PROCESSES

BACTERIAL[193]

Impetigo and folliculitis in the elderly are usually caused by *Staphylococci*, in contrast to impetigo in the pediatric population, which usually is caused by *Streptococci* (see Chapter 176). Hence, in the older age group, impetigo should be treated with penicillinase-resistant semisynthetic penicillin or erythromycin until culture confirms the identity of the organism.[194]

Cellulitis is an infectious inflammatory process that involves the subcutaneous tissue and is caused most frequently by *Streptococci* or *Staphylococci*. Like other inflammatory conditions in the elderly, cellulitis may present with only subtle rubor, tumor, calor, and dolor. Predisposing factors with increased prevalence in the elderly include chronic edema, compromised circulation, diabetes mellitus, surgical sites, and asteatotic eczema.

Distinct forms of cellulitis (see Chapter 178) preferentially affect older individuals. These include orbital cellulitis that is caused by *Streptococcus viridans* alone or in combination with gram-negative bacteria. Another form of cellulitis that is relatively rare in the younger population is *Pseudomonas* cellulitis of the ear, an infectious process that affects elderly diabetic individuals. Erysipelas, a β-hemolytic streptococcal infection of the skin, is more common in the elderly and tends to spread more readily in this age group, creating a life-threatening situation.

Necrotizing fasciitis (see Chapter 179), caused by a strain of *Streptococcus*, is a rare cutaneous infection, but it is more frequent in the elderly and is associated with increased morbidity and mortality in this age group.

Methicillin-resistant *Staphylococcus aureus* (MRSA) has become an increasingly important pathogen in hospital and community acquired infections, and age >80 years is significantly associated with MRSA carriage.[164] Because community-associated MRSA infection most often presents as skin and soft tissue infections, dermatologists should be aware of this possibility when managing infections in the elderly.

PARASITIC[195]

(See Chapter 208.)

Scabies can occur in any age group, but nursing homes provide a fertile ground for rapid spread of the infestation. In the elderly, in part because of their decreased immunity, lesions may be atypical and display less inflammation and pruritus. In addition, the elderly frequently have xerosis, and their pruritus at times may be attributed to this etiology.

DERMATOPHYTES AND YEASTS[196]

(See Chapters 188 and 189.)

Onychomycosis is present in approximately 40% of patients after age 60 years, and tinea pedis is present in approximately 80% of this patient population. Although usually present for decades, tinea pedis may exacerbate with age. Indeed, in elderly diabetic patients, interdigital tinea pedis may ulcerate and predispose to bacterial cellulitis, a presentation that is relatively rare in the young adult immunocompetent patient.

Cutaneous infections due to *Candida albicans* are common in the elderly. When recurrent or difficult to control, candidiasis may be a sign of poorly controlled diabetes, an endocrinopathy, malnutrition, or malignancy.

VIRAL (VARICELLA-ZOSTER VIRUS)[163]

(See Chapter 194.)

The incidence of herpes zoster peaks at approximately 1,500 cases per 100,000 persons annually at age 75 years. Postherpetic neuralgia, uncommon in patients younger than 40 years old, occurs in more than 40% of patients aged 60–69 years and 50% of patients 70 years of age or older.[100] A number of patients older than 60 years also experience paresthesias and muscle weakness. Decreased cellular immunity and impaired wound healing in the elderly may account for slower resolution of the acute eruption, but the pathogenesis of their postherpetic neuralgia is unclear. A new vaccine composed of live, attenuated *varicella zoster* virus is now available and reported to reduce the incidence of postherpetic neuralgia by 66.5%.[197]

ULCERS[198]

Chronic ulcers of all etiologies are more common in the elderly than in younger individuals, presumably due to a combination of impaired wound healing and higher prevalence of underlying diseases. The most common are leg ulcers, usually in the setting of chronic venous insufficiency leading to venous hypertension (see Chapter 174). Exudation of macromolecules such as fibrinogen into the dermis may block the passage of oxygen and nutrients and sequester cytokines and growth factors required for tissue homeostasis, maintenance, and repair. The sclerotic indurated quality of affected skin, termed *lipodermatosclerosis*, is postulated to further impair healing. In addition, diseases such as diabetes mellitus and atherosclerotic peripheral vascular disease may contribute to ulcer evolution.

Decubitus ulcers (see Chapter 100) are proportionately far more common in elderly hospitalized patients than in younger patients, as the former tend to be less mobile, needing help turning in bed, and have additional aggravating disorders such as dry skin over bony prominences, incontinence, sensory deficiency, and/or poor nutritional state.[199,200]

BULLOUS PEMPHIGOID

(See Chapter 56.)

Bullous pemphigoid is far more common after age 60 years than in younger persons, a predilection that may be explained in part by the age-associated increases in circulating autoantibodies and ease of dermal–epidermal separation,[201] although many other autoimmune and blistering dermatoses are not more common in old age. Possibly, age-associated changes in the basement membrane itself render it specifically vulnerable to this disease process. Bullous pemphigoid is a self-limited condition that frequently resolves within 6–12 months, but elderly patients may experience increased morbidity and mortality because of debilitated general health or as a side effect of treatment.

DRUG ERUPTIONS

Adverse drug reactions of all kinds increase with age, in part because the elderly consume more medications than younger age groups and in part because of medical conditions, including impaired renal, cardiac, or hepatic function, that compromise drug metabolism or excretion. The most frequently observed adverse cutaneous drug reactions are pruritus, exanthems, and urticaria, but drug-induced autoimmune reactions, including pemphigus, bullous pemphigoid, and lupus erythematosus, also occur in the elderly. A careful history to elicit all prescription medications as well as over-the-counter preparations is critical to diagnosis and optimal patient care.

Carcinogenesis

Chapter 110 :: Genome Instability, DNA Repair, and Cancer

:: Thomas M. Rünger & Kenneth H. Kraemer

GENOME INSTABILITY, DNA REPAIR, AND CANCER AT A GLANCE

- DNA can be damaged by physical agents (ultraviolet or ionizing radiation) or chemical agents in the environment.
- DNA damage may lead to mutations (changes in DNA sequence).
- The ability of cells to repair DNA damage and to maintain genome stability is of utmost importance to prevent malignant transformation.
- Different agents induce different types of DNA damage, which in turn require different responses and repair pathways.
- A number of hereditary disorders are characterized by genome instability due to defects in genes involved in DNA repair or DNA damage signaling.
- Many different laboratory tests can be used to diagnose genome instability and/or DNA repair defects.
- Inherited or acquired genome instability is associated with an increased cancer risk.

INTRODUCTION

The integrity of the genome of all living organisms is constantly threatened by exogenous and endogenous DNA-damaging agents. Exogenous DNA-damaging agents include physical agents, such as ultraviolet (UV) or ionizing radiation (IR), and a wide variety of chemical agents, such as components of cigarette smoke. Endogenous DNA damage arises from regular metabolic processes within the cell, mediated, for example, by reactive oxygen species. Maintaining the stability of the genome is of utmost importance to all living organisms. Therefore, since early evolution, all organisms ranging from prokaryotes to eukaryotes

TABLE 110-1
Cellular Damage Induced by Physical and Chemical Agents

Agent	Damage
Ultraviolet (UV) radiation	Dipyrimidine cyclobutane dimers (TT, TC, CT, or CC), pyrimidine-pyrimidone (6–4) photoproducts (mostly TC), DNA-protein cross-links
X-irradiation	DNA single- and double-strand breaks, oxidative base damage
Psoralens plus UVA	DNA-psoralen monoadducts, DNA interstrand cross-links (binds to T at TA sequences)
Mitomycin C	DNA interstrand cross-links
Benzo-[a]-pyrene	Bulky adducts
Reactive oxygen species	Oxidative base damage (8-oxo-deoxyguanine, thymine glycol), cyclopurines (A or G) making bulky lesions

have been equipped with mechanisms that react to and repair DNA damage and thereby maintain genomic stability. The types of damage produced include alterations in the structure of nucleotides, DNA strand breaks, DNA cross-links, and DNA adducts. Different types of DNA-damaging agents induce different types of DNA damage (Table 110-1), which in turn require different responses and repair pathways for processing (Table 110-2).[1]

TABLE 110-2
Types of DNA Damage and Associated DNA Repair Pathways

Type of DNA Damage	DNA Repair Pathway
DNA photoproducts (CPDs, 6,4-PP)	Nucleotide excision repair (NER)
Oxidative base modifications (e.g., 8-oxoG)	Base excision repair
Incorrect DNA base pairing	Mismatch repair
DNA double-strand breaks	Nonhomologous end joining, homologous recombination (i.e., recombination repair)
DNA adducts	NER
DNA cross-links (interstrand and intrastrand)	Recombination repair
Persistent DNA lesions	Translesion (bypass) DNA synthesis

CPDs = cyclobutane pyrimidine dimers; 6, 4-PP = 6, 4-pyrimidine–pyrimidone photoproducts; 8-oxoG = 8-oxo-deoxyguanine.

If DNA damage is not repaired adequately, it may lead to altered cell function, cell death, or the formation of mutations (alterations of the DNA sequence) in the damaged cells. These DNA damage-induced mutations will persist as long as the affected cell survives. At a cellular level, mutations in vital genes can lead to alterations of cell functions or malignant transformation. Accumulation of mutations may lead to organ dysfunction, aging, and cancer. Although most DNA damage is adequately repaired, none of the cellular responses is 100% effective in repairing all DNA damage under all circumstances.

A hereditary or acquired impairment in the way cells respond to DNA damage may result in genome instability with an increased rate of mutation formation. Numerous hereditary disorders are characterized by such genome instability (reviewed in Chapter 139). Many, but not all, of those are associated with an increased cancer risk and/or accelerated aging.

Exposure of the skin to UV radiation has multiple cellular and clinical effects, including an increase in skin cancer risk. The photocarcinogenesis cascade of events (Fig. 110-1) exemplifies the link between genome instability, DNA repair, and cancer. UV light produces a type of DNA damage involving the generation of photoproducts, which are alterations in the structure of nucleotides. The major DNA photoproducts are cyclobutane pyrimidine dimers (CPDs; Fig. 110-2) and 6,4-pyrimidine–pyrimidone dimers. Unrepaired CPDs or 6,4-pyrimidine–pyrimidone dimers may result in characteristic mutations: C to T single base and CC to

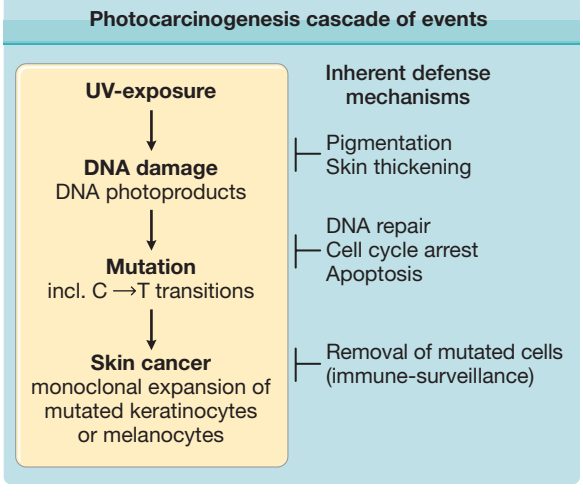

Figure 110-1 Photocarcinogenesis cascade of events. Exposure to ultraviolet (UV) light induces typical types of DNA damage, namely, cyclobutane pyrimidine and 6,4-pyrimidine–pyrimidone photoproducts. These often generate single and tandem base substitution mutations (C→T and CC→TT) that are typical for UV light exposure and are therefore termed *UV-signature mutations*. With sufficient numbers of inactivating mutations in crucial genes (tumor suppressor genes), individual cells may undergo malignant transformation, clonally expand, and form skin cancers. Several inherent defense mechanisms counteract this chain of events (see text).

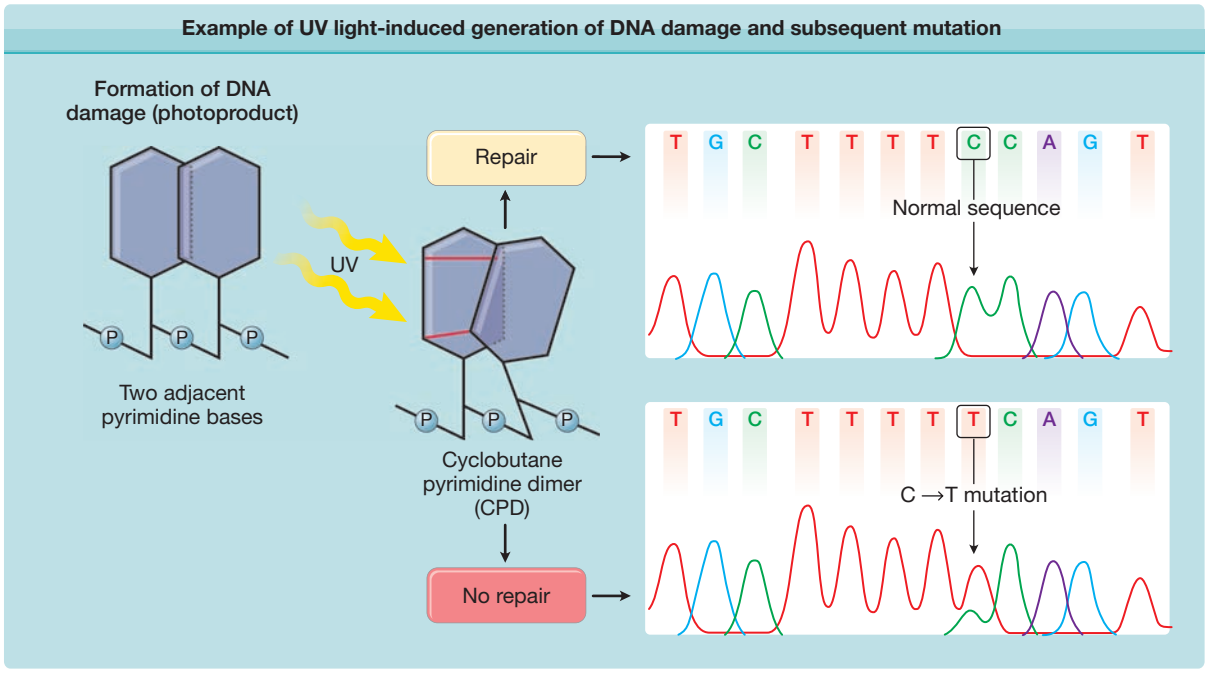

Figure 110-2 Example of ultraviolet (UV) light-induced generation of DNA damage and a subsequent mutation. On direct excitation of the DNA molecule by UV light, adjacent pyrimidine bases (cytosine or thymine) may form covalent bonds between them, which lead to creation of pyrimidine dimers. The illustration shows an example in which two covalent bindings generate a tricyclic cyclobutane ring between two pyrimidines. Hence, this type of UV light-induced DNA damage is called a *cyclobutane pyrimidine dimer*, a common type of DNA photoproduct. The nucleotide excision repair DNA repair system functions to remove this damage, which results in the normal DNA sequence (*upper box*). If the damage is not repaired, this type of DNA photoproduct can lead to formation of a typical C→T single base substitution mutation (*lower box*). This is most likely to occur on replication of damaged DNA and misincorporation of adenine opposite the cytosine-containing photoproduct. An example of such a UV-signature mutation is shown on the right.[4] Note that the mutation is located within a run of seven pyrimidines, a common location for UV-signature mutations.

TT tandem base substitution mutations.[2–4] Such mutations are typical for UV light exposures and only rarely are induced by other mutagens. They have therefore been termed *UV-signature mutations* (see Fig. 110-2). Pleasance et al.[5] sequenced all the genes in cells from a melanoma metastasis and reported that they harbor approximately 25,000 such mutations, accounting for about 70% of all mutations found. This clearly links the mutation burden in this cancer to prior UV-exposures.

DNA repair is an important cellular defense mechanism that prevents mutation formation at sites of DNA damage after UV exposure. However, it is not the only defense mechanism (see Fig. 110-1). Most mutations are generated during replication of damaged DNA. Therefore, a damage-induced arrest in cell cycling, which allows more time for repair, is another important cellular damage response that prevents mutation formation.[6,7] Furthermore, programmed cell death (apoptosis) prevents the survival of cells with overwhelming DNA damage, and through that mechanism the frequency of cells with UV-induced mutations is also reduced.[8] Other inherent defense mechanisms against the ultimately carcinogenic properties of UV light include increased melanogenesis and thickening of the epidermis and stratum corneum, which protect from future DNA damage. Other protection includes removal of mutated cells through host immune responses (see Fig. 110-1).

DNA DAMAGE AND REPAIR

More than 100 DNA repair genes have been identified (http://sciencepark.mdanderson.org/labs/wood/DNA_Repair_Genes.html). The nucleotide excision repair (NER) pathway acts on DNA damaged by UV radiation, repairing CPDs and other photoproducts, as well as on DNA damaged by certain carcinogens (such as benzo-[a]-pyrene) (see Table 110-2). In NER, the damaged nucleotide is removed and replaced with undamaged DNA. A simplified schema of the NER system describing some of the many proteins that act in concert to repair UV-induced DNA damage is shown in Fig. 110-3. Defects in these repair genes can cause human diseases (Table 110-3), including xeroderma pigmentosum (XP), Cockayne syndrome (CS), and trichothiodystrophy (TTD) (for details on these disorders, see Chapter 139). For instance, XP can be caused by a defect in any one of several genes involved in NER. Cells/patients with defects in the same gene are considered to be in the same complementation group, and in different complementation groups if different genes are affected. The term "complementation group" is based on cell fusion experiments, in which cells from different XP patients are fused to investigate if the DNA repair defect in the fused cells is corrected. If DNA repair in the fused cell is increased, each cell

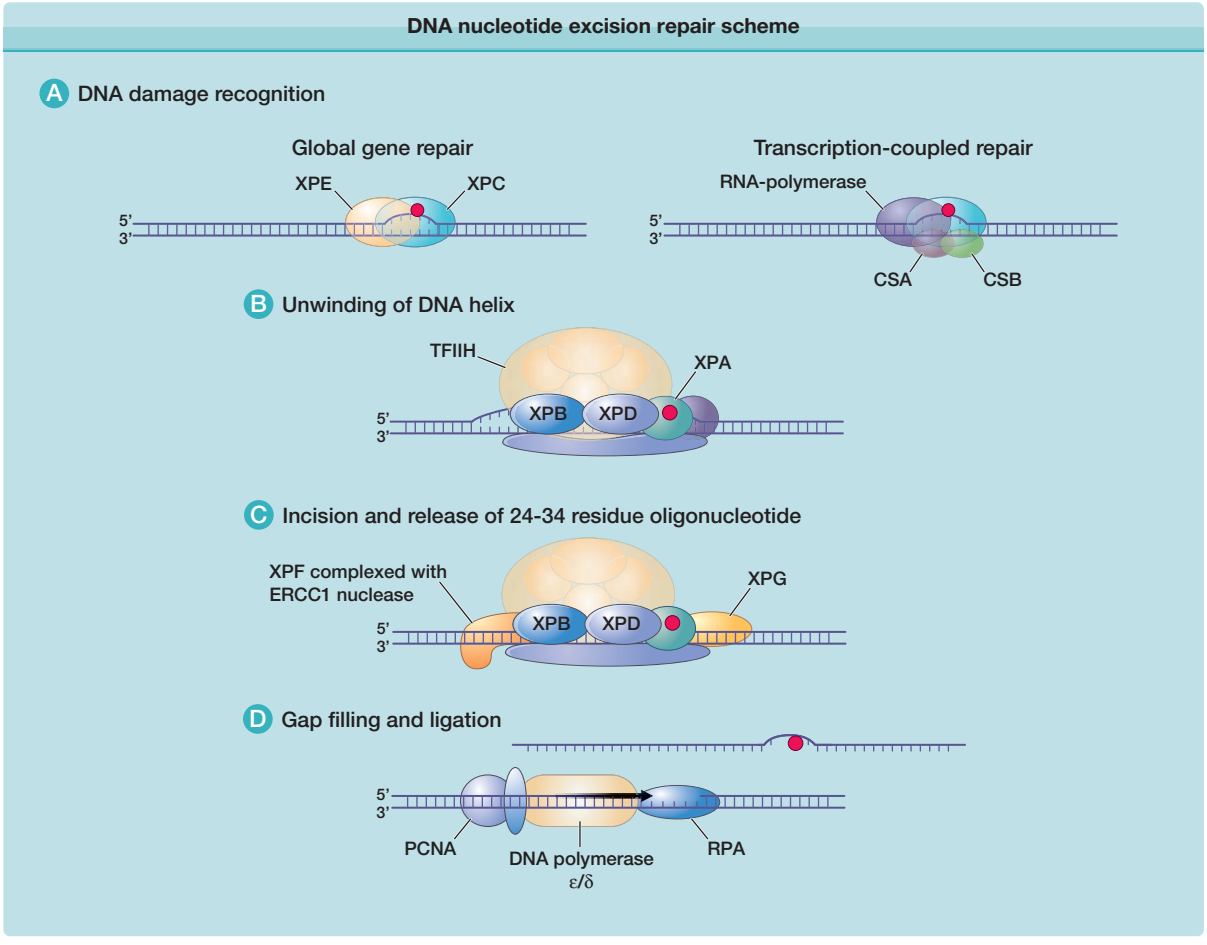

Figure 110-3 DNA nucleotide excision repair scheme. **A.** *Right:* Damaged DNA in actively transcribed genes results in stalling of the RNA polymerase in a process that involves the CSA and CSB proteins. This serves as a signal to initiate transcription-coupled DNA repair. *Left:* Damaged DNA in the remainder of the genome is bound by the XPE and XPC gene products. This serves as a signal to initiate global genome repair. **B.** A portion of the DNA, including the damage, is unwound by a complex of proteins including the XPB and XPD gene products. These proteins are also part of the 10-subunit basal transcription factor IIH (TFIIH). The XPA protein may stabilize the unwound DNA. **C.** The XPF and XPG nucleases make single-strand cuts on either side of the damage, releasing a 24- to 34-residue segment of DNA. **D.** The resulting gap is filled by DNA polymerase in a process that includes the proteins proliferating cell nuclear antigen (PCNA) and replication protein A (RPA). CSA, CSB = Cockayne syndrome complementation groups A and B; ERCC1 = excision repair cross-complementing gene 1; LIG1 = ligase 1; XPA, XPC, etc. = xeroderma pigmentosum complementation groups A, C, etc.

provides proteins that the other is lacking and the cells "complement" each other and are in different complementation groups. If DNA repair in the fused cells is not normalized, the cells do not "complement" each other, meaning that both cells harbor mutations in the same DNA repair gene. Seven such complementation groups have been identified (XP-A to XP-G), which correspond with mutations in seven distinct genes that can cause XP.

Transcribed genes are repaired faster than the rest of the genome. In the NER pathway, the first steps involving DNA damage recognition are different in nontranscribed (global genome NER) and transcribed genes (transcription-coupled NER). In nontranscribed genes and noncoding areas, which represent most of the genome, the *XPE* and *XPC* gene products bind to UV-damaged DNA, marking it for further processing. In contrast, DNA damage in transcribed genes appears to be sensed by a stalled RNA polymerase acting in conjunction with the CS complementation groups A and B (CSA and CSB) gene products. After the DNA damage recognition steps, global genome NER and transcription-coupled NER follow the same pathway. The *XPA* gene product functions in conjunction with replication protein A (RPA), the transcription factor IIH (TFIIH), XPF, and excision repair cross-complementing gene 1 (ERCC1). The following steps occur in both nontranscribed and transcribed gene repair:

- The *XPB* and *XPD* gene products partially unwind the DNA in the region of the damage, thereby exposing the lesion for further processing. These proteins are part of the TFIIH basal transcription factor (see Fig. 110-3B).
- The *XPF* gene product, in a complex with ERCC1, makes a single-strand nick at the 5′ side of the lesion, whereas the *XPG* gene product makes a similar nick on the 3′ side, which results in the

TABLE 110-3
DNA Repair and Telomere Maintenance Genes Associated with Human Diseases[a]

Gene[b]	Chromosome Location	Repair Pathway	Function
XPA	9q22.3	NER	Binding of damaged DNA
XPB (ERCC3)	2q21	NER	DNA helicase, part of TFIIH
XPC	3p25	NER	Binding of damaged DNA, global genome repair
XPD (ERCC2)	19q13.3	NER	DNA helicase, part of TFIIH
XPE (DDB2)	11p12-p11	NER	Binding of damaged DNA, global genome repair
XPF (ERCC4)	16p13.3-p13.11	NER	DNA endonuclease
XPG (ERCC5)	13q22	NER	DNA endonuclease
TTDA (GTF2H5)	6p25.3	NER	Part of TFIIH
CSA (ERCC8)	5q12	NER	Transcription-coupled repair
CSB (ERCC6)	10q11	NER	Transcription-coupled repair
XPV (polymerase eta)	6p21.1-p12	Bypass	DNA damage bypass polymerase
MSH2	2p22-p21	MMR	Mismatch repair (Muir–Torre syndrome, HNPCC)
MLH1	3p21.3	MMR	Mismatch repair (Muir–Torre syndrome, HNPCC)
PMS1	2q31-q33	MMR	Mismatch repair (HNPCC)
PMS2	7p22	MMR	Mismatch repair (HNPCC)
MSH6	2p16	MMR	Mismatch repair (HNPCC)
MLH3	14q24.3	MMR	Mismatch repair (HNPCC)
DKC1	Xq28	Telomere maintenance	Dyskerin, Posttranscriptional pseudouridylation, forms a ribonucleoprotein complex with NOP10 (gene name NOLA3) and NHP2 (gene name NOLA2)
TERT	5p15.33	Telomere maintenance	Telomerase, extends nucleotide repeats at chromosome ends
TERC	3q21-q28	Telomere maintenance	RNA template for telomerase
TINF2	14q12	Telomere maintenance	Part of protein complex shelterin, regulates telomere length
NOLA2	5q35.3	Telomere maintenance	See dyskerin
NOLA3	15q14-q15	Telomere maintenance	See dyskerin

ERCC = human excision repair cross-complementing genes that correct defects in cultured hamster cells; HNPCC = hereditary nonpolyposis colon cancer; NER = nucleotide excision repair; MMR = mismatch repair; TFIIH = transcription factor IIH.
[a]More than 100 DNA repair genes have been identified. An updated list can be found at (http://sciencepark.mdanderson.org/labs/wood/DNA_Repair_Genes.html).
[b]The genes designated XP are defective in the corresponding xeroderma pigmentosum complementation group, and those designated CS are defective in the corresponding Cockayne syndrome complementation group.

release of a region of approximately 30 nucleotides containing the damage (see Fig. 110-3C).
- The resulting gap is filled by DNA polymerase using the other (undamaged) strand as a template in a process involving proliferating cell nuclear antigen (PCNA). DNA ligase 1 seals the region, restoring the original undamaged sequence (see Fig. 110-3D).

Other DNA repair pathways include base excision repair, recombination repair, and mismatch repair. Defects in mismatch repair are also associated with human diseases—Muir–Torre syndrome and human nonpolyposis colon cancer.[1,9–11]

REGULATION OF CELLULAR RESPONSES TO DNA DAMAGE

Several cellular responses to DNA damage contribute to the maintenance of genome integrity, including: cell cycle arrest, apoptosis (programmed cell death), and DNA repair.[6,12–19] These responses need to be carefully

orchestrated, and there are many proteins involved in the signaling of DNA damage and the regulation of DNA damage responses. Different types of DNA-damaging agents and different types of DNA damage require different DNA damage responses. A simplified version of this complex pathway is presented in Figure 110-4. As with defects in DNA repair genes (see Table 110-3), defects in many of these DNA damage-signaling genes (boxed in Fig. 110-4) are also implicated in hereditary disorders of genome instability (Table 110-4; for further details see Chapter 139). These disorders are characterized by an increased cancer risk, which is due to the genome instability from impaired DNA damage signaling.

The tumor suppressor gene p53, termed the *guardian of the genome*,[20] plays a pivotal role in regulating and orchestrating these responses and is mutated in many cancers, including cutaneous squamous cell carcinomas. Upstream regulators of p53 in the cellular DNA damage response pathway are ataxia telangiectasia mutated (ATM) and ataxia telangiectasia- and Rad3-related (ATR) genes. One of p53's several functions is the regulation of the cell cycle in response to DNA damage. After cell division (mitosis), cells have 23 pairs of chromosomes and are in the G_1 phase of the cell cycle. The chromosomes then replicate during DNA synthesis, or S phase, and as a result have twice the number of chromosomes (G_2 phase) just before mitosis (M phase). In response to damage, the cell may stop cycling (arrests) in specific cell cycle phases called *cell cycle checkpoints*. An important downstream effector in preventing cells from entering S phase (G_1/S checkpoint) is p21.[6,12] p53 also induces NER by transcriptionally inducing XPC, XPE/p48, and GADD45.[21,22] This indicates that a cell's capacity to repair DNA damage can be upregulated in response to DNA damage.

If cells enter S phase with unrepaired DNA damage, or if cells are UV exposed during S phase, regular DNA polymerases stall at DNA photoproducts and fall off the DNA strand. For these instances, cells are equipped with several specialized DNA polymerases for translesional

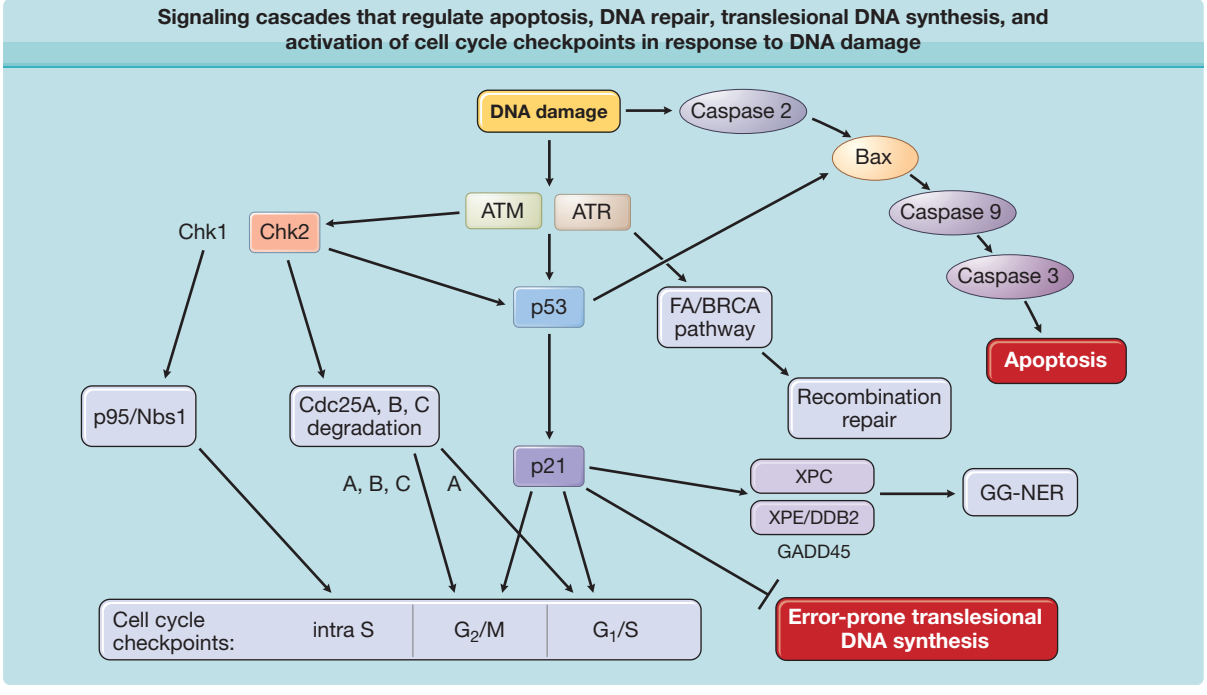

Figure 110-4 Signaling cascades that regulate apoptosis, DNA repair, translesional DNA synthesis, and activation of cell cycle checkpoints in response to DNA damage. This is a highly simplified diagram that depicts only the most important players in the intricate and interwoven DNA damage-signaling networks. The traditional thinking was that ataxia telangiectasia mutated (ATM) gene is activated (phosphorylated) in response to ionizing radiation (IR) and ATR (ataxia telangiectasia- and Rad3-related gene) is activated in response to ultraviolet (UV) radiation, but newer data indicate that both are activated by IR and UV. ATM/ATR can activate (i.e., phosphorylate) p53 either directly or indirectly through activation (phosphorylation) of Chk2 (an ATM target) or Chk1 (an ATR target). Through transcriptional activation of p21 and subsequent inhibition of cyclin-dependent kinases, which usually drive cells from the G_1 into the S phase of the cell cycle, activated p53 activates the G_1/S checkpoint (i.e., arrests cells in G_1). The G_1/S checkpoint is also activated by Chk1/Chk2-induced phosphorylation and then degradation of Cdc25A and subsequent failure to activate cyclin-dependent kinases. Phosphorylation and subsequent degradation of Cdc25A, Cdc25B, and Cdc25C also mediate the G_2/M arrest, as does p21. Intra-S-phase arrest is mediated through activation (phosphorylation) of p95/Nbs1. p53 also induces global genome nucleotide excision repair (GG-NER) through transcriptional activation of XPC, XPE/p48, and GADD45. Translesional DNA synthesis has been shown to be downregulated by p53 via p21. Recombination repair is mediated through the Fanconi anemia (FA)/BRCA pathway, which in turn is dependent on ATR activation. The mitochondrial pathway of apoptosis is activated through activation of Bax by caspase 2 and p53, the initiator caspase 9, and the effector caspases 3, 6, and 7 (for references, see text). Gene products that are defective in hereditary human diseases are boxed. DDB2 = DNA damage binding protein 2; XPC, XPE = xeroderma pigmentosum complementation groups C and E.

TABLE 110-4
DNA Damage-Signaling Genes Associated with Human Diseases[a]

Gene	Chromosome Location	Hereditary Disorder
ATM	11q22.3	Ataxia telangiectasia
ATR	3q22–24	Seckel syndrome
FANCA	16q24.3	Fanconi anemia
FANCB	Xp22.31	Fanconi anemia
FANCC	9q22.3	Fanconi anemia
FANCD1/BRCA2	13q12.3	Fanconi anemia, familial breast cancer
FANCD2	3p25.3	Fanconi anemia
FANCE	6p21-p22	Fanconi anemia
FANCF	11p15	Fanconi anemia
FANCG	9p13	Fanconi anemia
FANCI	15q25-q26	Fanconi anemia
FANCJ	17q22	Fanconi anemia
FANCL	2p16.1	Fanconi anemia
FANCM	14q21.3	Fanconi anemia
FANCN	16p12.1	Fanconi anemia
BRCA1	17q21	Familial breast cancer
p53	17p13.1	Li–Fraumeni syndrome
Chk2	22q12.1	Li–Fraumeni syndrome
CDKN2A ($p16^{INK4}$)	9p21	Familial malignant melanoma
CDK4	12q14	Familial malignant melanoma
Nbs1 (p95)	8q21	Nijmegen breakage syndrome
Rb	13q14.1–14.2	Bilateral retinoblastoma

[a]Please see Fig. 110-4 for the function of these genes in the DNA damage-signaling cascade and Chapter 139 for a clinical descriptions of these disorders.

DNA synthesis.[23] DNA polymerase eta is one of these; it is specialized to bypass DNA photoproducts but may introduce mutations while doing so.[24] It is mutated in XP variant patients, who are clinically indistinguishable from other XP patients with defects in NER (see Table 110-3, Chapter 139).[25,26] This demonstrates the importance of this second line of defense against the mutagenic and carcinogenic consequences of DNA photoproducts. p53 and p21 also downregulate the activity of this translesional DNA synthesis to maintain a low mutagenic activity at the price of reduced damage bypass.[27]

If this translesional DNA synthesis fails, cells can use recombination repair to resolve stalled replication forks.[28] When invoked in response to damage from UV light, this third line of defense is mediated by activation of the Fanconi anemia/BRCA DNA damage response pathway.[29] The exact mechanisms that initiate these DNA damage response signaling cascades is under investigation. Telomeres, which are repeats of TTAGGG that cap the ends of chromosomes and whose ends form a loop structure, are suggested to be important players in sensing DNA damage, for example, through opening of the telomere loop.[30] Other sensors may be stalled DNA or RNA polymerases, or proteins that detect bending of the DNA helix at sites of DNA damage.

Apoptosis is a regulated physiologic process leading to cell death characterized by cell shrinkage, membrane blebbing, and DNA fragmentation. A group of cysteine proteases called *caspases* are central regulators of apoptosis. Triggers may be extrinsic or intrinsic to the cell (e.g., DNA damage) and involve separate initiator caspases (e.g., caspase 2 in response to DNA damage) but share the same downstream effector caspases.[8]

APPROACHES TO DIAGNOSIS OF GENOME INSTABILITY AND/OR DNA REPAIR DEFECTS

When a disorder of genome instability is suspected, the clinician is challenged with choosing the appropriate laboratory tests to secure a diagnosis and to provide

TABLE 110-5
Hallmark Clinical Features That May Indicate a Disorder of Genome Instability or DNA Repair and Prompt Clinicians to Initiate Testing[a]

Disorder	Clinical Features
Xeroderma pigmentosum	Burning or blistering on minimal sun exposure (some patients), childhood freckling, early or multiple skin cancers
Cockayne syndrome	Burning on minimal sun exposure, postnatal growth failure, sensorineural deafness
Trichothiodystrophy	Burning on minimal sun exposure (some patients), brittle hair, ichthyosis
Ataxia-telangiectasia	Telangiectasias, ataxia, leukemias or lymphomas
Bloom syndrome	Photosensitivity, malar erythema, growth retardation, infections, cancers
Fanconi anemia	Aplastic anemia, growth retardation, café-au-lait spots, thumb abnormalities, acute myelogenous leukemia
Dyskeratosis congenita	Triad of reticulated hyperpigmentation, nail dystrophy, and mucosal leukoplakias
Muir–Torre syndrome	Sebaceous tumors, keratoacanthomas, personal or family history of colon cancer

[a]Refer to Chapter 139 for more information.

guidance for affected patients and families. Table 110-5 lists some hallmark clinical features that may indicate the presence of such disorders and should prompt clinicians to initiate testing. Various laboratory tests for genome stability, DNA repair, and response to physical and chemical agents are listed in Table 110-6.

USE OF CULTURED CELLS

Cells obtained directly from patients and grown in culture medium are termed *primary cultures*. Dermal fibroblasts generally grow easily in culture and can generally be established from a 2- to 4-mm sterile skin punch biopsy specimen. The inner surface of the upper arm has proven to be a suitable biopsy site because this area heals easily, the resulting scar is not readily visible, the site is shielded from UV radiation, and attempts to establish cultures from specimens are generally successful. The tissue is placed in sterile culture medium (or sterile saline) with antibiotics and transported to a cell culture laboratory at room temperature.

Human cell cultures are made available for research by the National Institutes of Health-funded Human Genetic Mutant Cell Repository (401 Haddon Ave, Camden, NJ 08103; telephone: 856–966-7377; http://ccr.coriell.org).

TABLE 110-6
Diagnostic Tests of Genome Stability, DNA Repair, and Response to Physical or Chemical Agents[a]

- Intact cell function (proliferation or cell death)
  - Cell counts (growth in mass culture)
  - Thymidine incorporation
  - Colony-forming ability
- Chromosome integrity and breakage
  - Giemsa-stained metaphase karyotype analysis
  - G_2 chromosome breakage
  - Sister chromatid exchanges
  - Fluorescent in situ hybridization
  - Microsatellite instability testing
  - Telomere length
- DNA repair
  - Unscheduled DNA synthesis
  - RNA synthesis inhibition
  - Host cell reactivation
  - Comet assay
  - Immunological analysis of DNA damage and removal (enzyme-linked immunosorbent assay, slot blot)
  - Microsatellite instability testing
- Characterization and expression of defective genes
  - Real-time polymerase chain reaction
  - Western blotting
  - DNA sequencing

[a]Agents are listed in Table 110-1.

DIAGNOSTIC TESTS OF GENOME INSTABILITY AND DNA REPAIR

Tests to assess genome instability and/or DNA repair capacity may be divided into tests of intact cellular function and tests of chromosome integrity and breakage in response to DNA-damaging agents. Other tests measure the mechanism of impairment of a cell function such as DNA repair or characterize or determine the expression of defective genes (see Table 110-6).

TESTS OF INTACT CELL FUNCTION.

Tests of cellular function measure the capacity of the intact cell to recover from DNA damage. These tests do not provide information regarding the specific type of damage resulting in cellular injury or the mechanism of cellular recovery, but they do form the basis for identifying cells as hypersensitive to DNA-damaging agents and are often used as simple screening tests.

Cell Counts or Thymidine Incorporation. One of simplest tests after exposure to UV radiation or X-rays is the assessment of the growth rate in mass culture by using a microscope or an automated cell counter to count the number of cells or by measuring incorporation of radioactive thymidine into newly synthesized DNA (see Tables 110-6 and 110-7).

Colony-Forming Ability. A test of colony-forming ability assesses the capacity of a single cell to proliferate enough to form a visible colony (Fig. 110-5).

TABLE 110-7
Suggested Sequence of Diagnostic Testing for Diseases of Genome Instability or DNA Repair[a]

Disease	Step 1	Step 2	Step 3	Step 4	Testing Available[b]
Xeroderma pigmentosum	Post-UV hypersensitivity	Post-UV DNA repair	DNA sequencing	—	CLIA/R
Xeroderma pigmentosum variant	Post-UV hypersensitivity (with caffeine)	Post-UV DNA repair (normal)	DNA sequencing	—	R
Cockayne syndrome	Post-UV hypersensitivity	Post-UV inhibition of RNA synthesis	DNA sequencing	—	CLIA
Trichothiodystrophy[c]	Post-UV hypersensitivity	Post-UV DNA repair	DNA sequencing	—	CLIA/R
Ataxia telangiectasia	Chromosome breakage	X-ray hypersensitivity	Western blotting for level of protein	DNA sequencing	CLIA/R
Bloom syndrome	Chromosome breakage	Sister chromatid exchange	DNA sequencing	—	CLIA
Fanconi anemia	Chromosome breakage	Hypersensitivity to DNA cross-linking agents	Western blotting for FANCD2	DNA sequencing	CLIA/R
Dyskeratosis congenita	Telomere length	DNA sequencing			
Muir–Torre syndrome	Microsatellite instability	Western blotting for level of protein	DNA sequencing	—	CLIA

CLIA = testing available by laboratories certified under the Clinical Laboratory Improvement Act; R = research testing available; UV = ultraviolet radiation.
[a]These are suggestions only and may change based on availability of different assays or new scientific information. In recent years, sequencing has become much easier and cheaper through automated processes. Thus, DNA sequencing may be considered as a first diagnostic test, in particular for diseases with no or few complementation groups. However other tests (e.g., of cell function or protein levels) may be required to exclude a diagnosis if no mutation is identified.
[b]Testing laboratories are listed on the National Institutes of Health-funded Web site http://genetests.org.
[c]Screen by polarizing microscopic examination of hair followed by measurement of sulfur-containing amino acids in the hair (see Chapter 139).

TESTS OF CHROMOSOME INTEGRITY AND BREAKAGE.

Chromosome breakage is usually assessed in primary cultures of mitogen-stimulated peripheral blood leukocytes or in long-term cultures of fibroblasts or lymphoblastoid cell lines. Cell cycle progression is stopped at metaphase by treatment of the cells with an inhibitor of mitosis such as colchicine. In this procedure, the 23 pairs of metaphase chromosomes from a single cell are spread over a discrete area of the slide and stained (usually with Giemsa stain). Preparations may be analyzed for the number of chromosomes per metaphase, the morphology of the individual chromosomes, and the attachments or rearrangements of chromosomes in relation to each other.

Sister Chromatid Exchange. During DNA replication, chromatids occasionally exchange positions along the arms of a chromosome. This sister chromatid exchange (SCE) may be detected by permitting the cells to grow through two cycles of replication in medium containing the nucleic acid analog bromodeoxyuridine (BrUdR) (Fig. 110-6). SCEs are thought to be related to DNA recombination repair, although their precise significance is not understood.

Telomere Length. Shortened telomeres characterize cells from patients with dyskeratosis congenita. Several methods can be used to measure telomere length, including terminal restriction fragment (TRF) measurement on Southern blots, fluorescence in situ hybridization (FISH) with immunostaining, quantitative polymerase chain reaction (PCR), single telomere length analysis, and flow-cytometry with FISH (flow-FISH).[31] Those tests are usually done on freshly isolated white blood cells, not cultured cells.

TESTS OF DNA REPAIR

Unscheduled DNA Synthesis. One of the most commonly used tests of NER is unscheduled DNA synthesis. This test has been used to measure DNA repair in intact human skin, in cultured epidermal or dermal cells, and in blood cells, and for prenatal diagnosis using amniotic fluid cells. Unscheduled DNA synthesis testing measures the repair-associated DNA synthesis in G_1 or G_2 cells (which usually do not synthesize DNA). Cells are treated with UV radiation or another DNA-damaging agent and then incubated in medium containing radioactive thymidine. During the

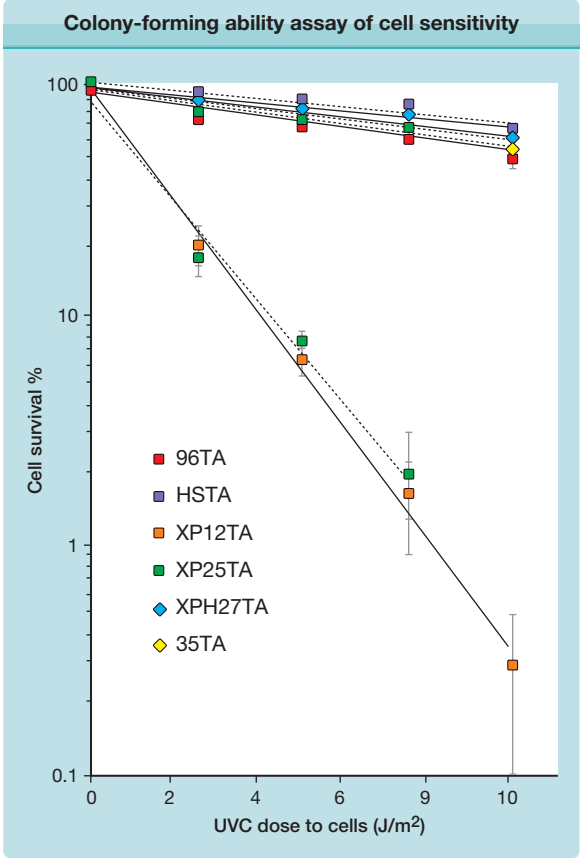

Figure 110-5 Colony-forming ability assay of cell sensitivity. Xeroderma pigmentosum (XP) fibroblasts from two affected siblings (XP12TA and XP25TA), their father (XPH27TA), and an unaffected brother (35TA) as well as normal fibroblasts (96TA and HSTA) were treated with 254-nm ultraviolet C (UVC) radiation and colony-forming ability was determined. The XP complementation group C (XPC) fibroblast strains from the affected siblings were much more sensitive than the normal strains and showed similar post-UVC hypersensitivity. Cells from the unaffected brother and the clinically normal father, a heterozygous carrier of the XPC defect, had normal post-UVC survival. (Modified from Slor H et al: Clinical, cellular, and molecular features of an Israeli xeroderma pigmentosum family with a frameshift mutation in the XPC Gene: Sun protection prolongs life. *J Invest Dermatol* **115**:974, 2000.)

process of NER, the damage is removed and the radioactive thymidine is incorporated into the repaired region. The cells are treated with fixative, coated with autoradiographic (photographic) emulsion, and kept in the dark for an appropriate interval, and then the emulsion is developed. UV radiation of normal fibroblasts results in a large increase in the number of grains seen over all the nuclei. In marked contrast, irradiation of the XP fibroblasts that cannot repair DNA damage results in very few grains over the nuclei.

RNA Synthesis Inhibition. After exposure to UV radiation, normal cells temporarily reduce RNA synthesis from active genes. Synthesis resumes when the damage is repaired. This resumption of RNA synthesis is delayed in cells from patients with CS and some forms of XP.

Host Cell Reactivation. The host cell reactivation assay relies on the fact that plasmids do not have the ability to repair damage to their DNA but depend on cellular repair systems. Thus, when transfecting plasmids with DNA damage into host cells, the DNA repair enzymes of the host cells need to repair the damage before the plasmids' genes can be expressed. Therefore, damaged plasmids would be expected to be expressed at a higher level in cells with normal repair capacity. A nonreplicating plasmid that contains the gene for the firefly enzyme luciferase, constructed to permit expression in human cells,[32] is widely used; generation of light provides a quantitative endpoint for its repair (Fig. 110-7).

Comet Assay. The comet assay is a single cell-based technique that allows detection and quantitation of DNA damage, in particular DNA strand breaks that were either introduced directly by the DNA-damaging agent or by repair endonucleases at sites of other types of DNA damage. For this assay, damaged cells are embedded in agarose, lysed, and exposed to an electric field. In the electrical field, the DNA migrates out of the nucleus forming a "comet" when stained. In presence of DNA strand breaks, DNA migrates out of the nucleus faster and with that generates a longer comet. Thus, the length of the comet is proportional to the fragmentation of the nuclear DNA. This assay can be modified for detection of single-strand or double-strand DNA breaks, UV damage, or oxidative DNA damage. Cells from patients with XP have defective repair in the post-UV comet assay.

Microsatellite Instability. Normal DNA has tens of thousands of regions with repeats of the dinucleotide CA or other short motifs up to five nucleotides long. In normal individuals each of these microsatellites (also called *simple sequence repeats* or *short tandem repeats*) has a uniform size. However, these sizes are highly variable among different individuals and are often used for DNA "fingerprinting." The appearance of abnormally longer or shorter simple sequence repeats in different tissues or tumors from a patient is called *microsatellite instability*. This can be associated with a defect in mismatch repair genes.

CHARACTERIZATION AND EXPRESSION OF DEFECTIVE GENES

Real-Time Polymerase Chain Reaction. Many disease-causing mutations, including those responsible for disorders of genome instabilty disrupt the gene product's function by changing its amino acid sequence. In some genome instability genes, disease-causing mutations create premature stop codons for protein synthesis. These mutations result not only in truncated but also in low levels of messenger RNA (mRNA) for the gene product through a process called *nonsense-mediated message decay*. The mRNA levels can be accurately measured by the use of quantitative reverse transcriptase real-time polymerase chain reaction. For example, low

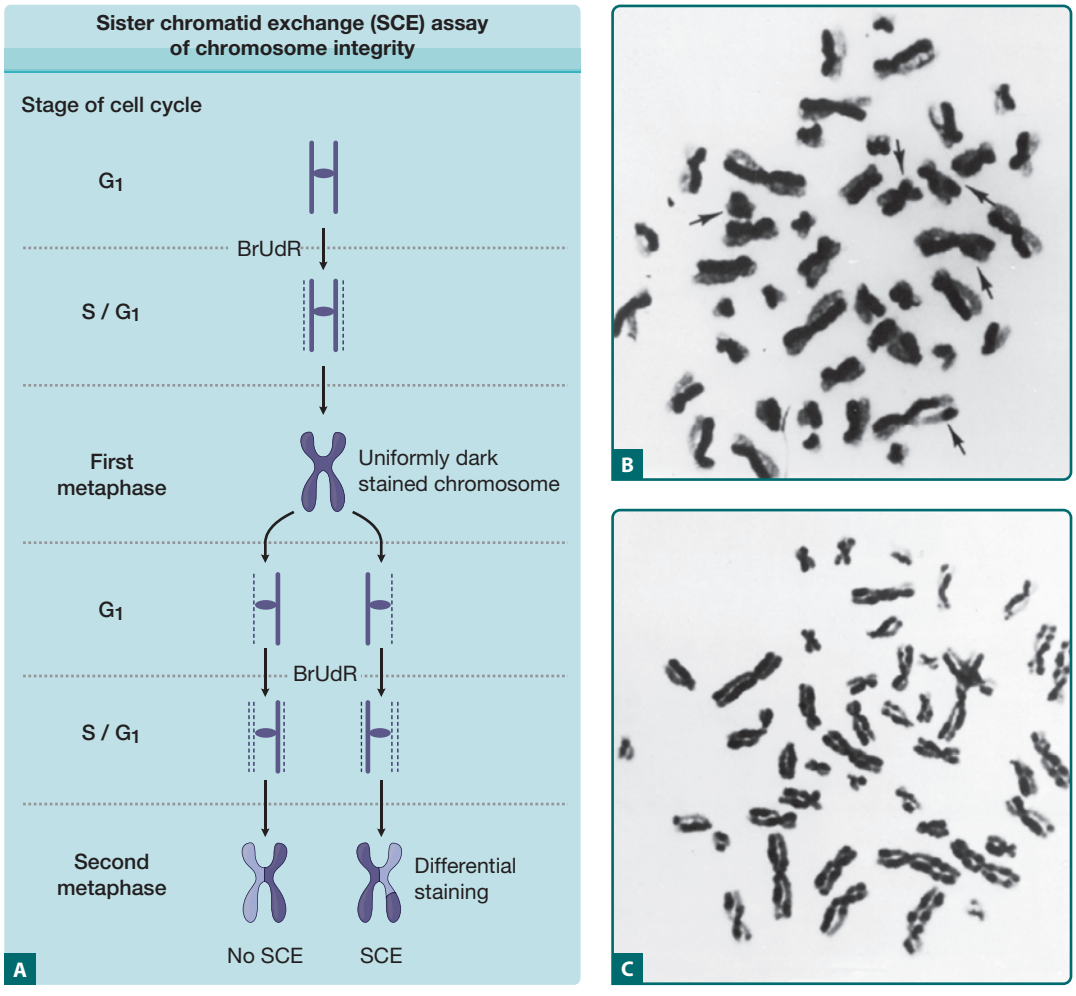

Figure 110-6 **A.** Sister chromatid exchange (SCE) assay of chromosome integrity. After the first cycle of replication, the DNA of the newly synthesized strand is labeled with bromodeoxyuridine (BrUdR), whereas the older strand is unlabeled. Such chromosomes appear uniformly dark with Giemsa stain. After a second cycle of replication in BrUdR-containing medium, one arm of a chromosome will contain two labeled chromatids, whereas the other will contain one labeled and one unlabeled chromatid. The doubly substituted arm will stain lightly, whereas the singly substituted arm will stain darkly. If an SCE occurred during replication, a portion of each chromosome arm will be doubly substituted and the remainder singly substituted with BrUdR. **B.** Undamaged normal cultured peripheral blood lymphocytes have approximately ten SCEs per metaphase. **C.** Cultured peripheral blood lymphocytes from a patient with Bloom syndrome have a manifold increase in SCEs. (From Chaganti RS, Schonberg S, German J: A manyfold increase in sister chromatid exchanges in Bloom's syndrome lymphocytes. *Proc Natl Acad Sci U S A* **71**:4508, 1974, with permission.)

XPC mRNA levels have been found in cells from most XP patients with defects in this gene.[33]

Western Blotting. Some mutations result in reduced levels or size of encoded proteins, often through creation of premature stop codons.[33] Reduced protein levels are most commonly detected by Western blotting. Cells are lysed and the proteins are extracted and separated by gel electrophoresis. The separated proteins are transferred to a membrane and probed with an antibody that is specific for the protein of interest. The intensity of the antibody staining reflects the amount of protein in the cells, and its location on the membrane is an indication of the size of the protein molecules. For example, undetectable or low levels of polymerase eta protein are present in cells from most XP variant patients.[34]

DNA Sequencing. Direct sequencing of defective genes is the gold standard for determination of the presence of a mutation. The final step in confirmation of a diagnosis may be DNA sequencing to determine the disease-causing mutation. By definition, disease-causing mutations alter the function of genes. However, not every alteration in the sequence of a gene alters the function of the encoded protein. In the human genome there are millions of single nucleotide polymorphisms, or changes in one nucleotide, that are not associated with disease and may not even change the amino acid composition of the encoded protein. In recessive disorders, each clinically unaffected parent has one normal allele and one potentially disease-causing mutation in the other allele. The affected child receives an allele with a disease-causing mutation from each parent. The

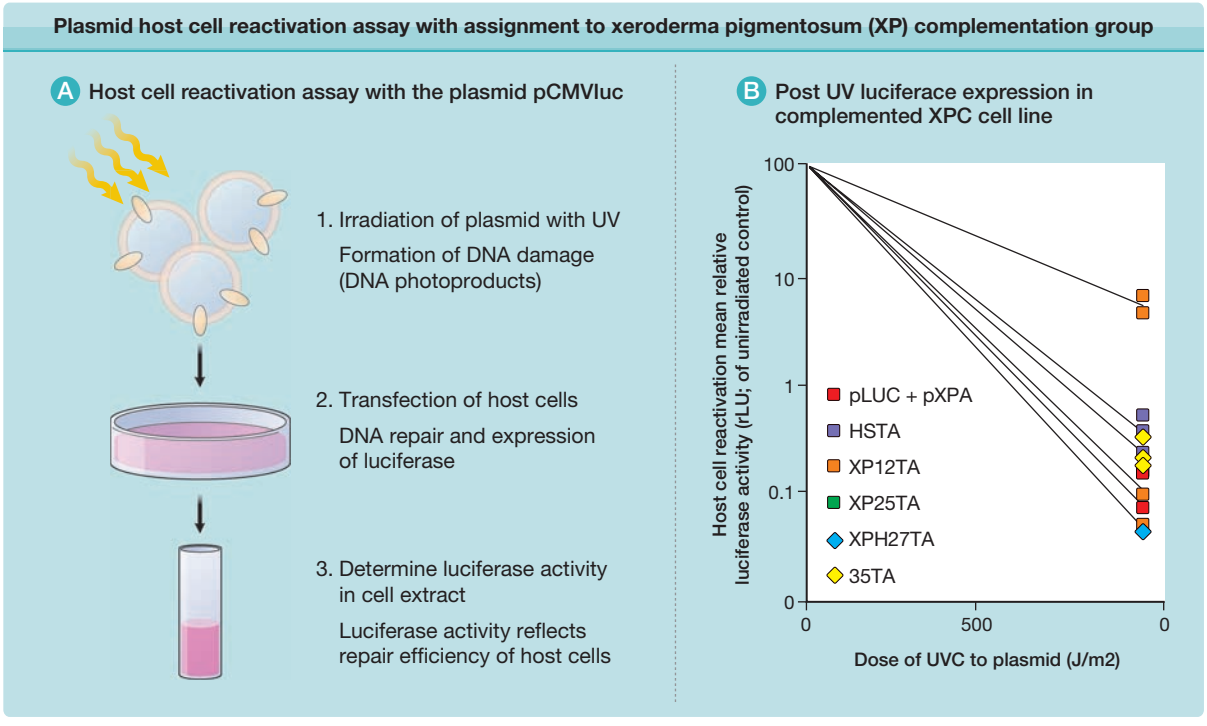

Figure 110-7 Plasmid host cell reactivation assay with assignment to xeroderma pigmentosum (XP) complementation group. **A.** The plasmid is damaged by ultraviolet (UV) radiation and introduced into cultured human cells by a transfection technique. The cells' DNA repair enzymes repair the damage in a manner similar to the repair of cellular DNA. Repaired DNA will then function to transcribe the plasmid-encoded luciferase gene in the human cell. The amount of luciferase activity within the host cells therefore reflects the efficiency of the cellular DNA repair system. This assay can also be used to determine the complementation group by cotransfecting UV-treated plasmid plus plasmids expressing wild-type XP complementary DNA (cDNA). **B.** The results of plasmid host cell reactivation experiments and complementation group assignment with DNA excision repair-deficient XP46DC cells. UV-treated plasmid showed low expression in the XP65BE cells that was increased only by cotransfection with a plasmid expressing the wild-type XPC cDNA. This result indicates that XP65BE cells are in XP complementation group C (XPC). rLU = relative light units; pCMVluc and pLUC = plasmids containing gene for luciferase; pXPA–pXPG = plasmids expressing xeroderma pigmentosum complementation groups A–G.

two mutations must be in the same gene, although they need not necessarily be identical to each other.

CONSIDERATIONS IN DIAGNOSTIC TESTING

Diagnosis of disorders of genome instability or DNA repair is often a multistep process. A suggested sequence of steps is listed in Table 110-7. As new tests are developed and new information is obtained about these disorders, testing procedures may change accordingly. In addition, decisions regarding the extent of testing performed may be made with consideration of how much the tests cost and whether additional information would alter treatment. For example, DNA sequencing is rarely required for establishment of a diagnosis of XP in a child with classical clinical features and cells that are hypersensitive to killing by UV and have defective DNA repair. But if a family has one child affected with XP and is considering having additional children, DNA sequencing might offer them the possibility of prenatal diagnosis through DNA sequencing of a trophoblast biopsy specimen.

Genetic counseling is an important component of patient management for these genetic diseases. This function may be performed by the treating physician or by a trained genetic counselor.

In the United States, only laboratories certified in accordance with the Clinical Laboratory Improvement Act (CLIA) are allowed to perform these specialized tests in the context of patient care. Tests performed in research laboratories generally have limited use in clinical practice. However, a research laboratory may identify a disease mutation in cells from a patient that could then be confirmed in a CLIA-certified laboratory and used in clinical practice. A current listing of laboratory testing facilities for these diseases may be found at the Web site http://genetests.org, funded by the National Institutes of Health.

Chapter 111 :: Chemical Carcinogenesis

:: Adam B. Glick & Andrzej A. Dlugosz

CHEMICAL CARCINOGENESIS AT A GLANCE

- In 1775, Sir Percivall Pott's report of scrotal cancer in chimney sweeps established a link between environmental exposure and cutaneous malignancy.
- Over 200 chemicals have been linked to human cancer development, according to the National Toxicology Program's 11th Report on Carcinogens (2005).
- Chemicals implicated in human skin cancer development include polycyclic aromatic hydrocarbons and arsenic.
- Studies in mouse skin have defined operational stages of epithelial carcinogenesis: initiation, promotion, and malignant progression. Chemicals linked to human cancer are classified as tumor initiators, promoters, or "complete" carcinogens.
- Tumor initiation, associated with gene mutations that permanently alter the cell's biological responsiveness, is irreversible; tumor promotion a nonmutagenic process that provides a selective growth advantage to initiated cells, is reversible at early stages; agents that facilitate malignant progression are generally genotoxic.
- Most carcinogens must undergo metabolic activation, which involves enzymes involved in xenobiotic metabolism, including cytochrome p450 enzymes and glutathione S-transferase.
- An individual's likelihood of developing chemically induced skin cancer is a function of exposure history; presence of additional risk factors (e.g., UV exposure); and genetic background, including gene polymorphisms that influence susceptibility.

CUTANEOUS CANCER AND PUBLIC HEALTH

According to the *American Cancer Society*, it is estimated that over 2,000,000 cases of basal cell carcinoma (BCC) and squamous cell carcinoma (SCC), 46,770 cases of melanoma in situ, and 68,130 cases of invasive melanoma will be diagnosed that in the year 2010.[1] The precise number of nonmelanoma skin cancers is unknown since they are not routinely reported to registries, but recent data suggest that previous approximations are likely to have been underestimates.[2] Although only a small fraction of patients with nonmelanoma skin cancer will die as a result of their cancer, which is SCC in nearly all cases, the frequency of these cancers nonetheless results in an estimated 1,000 and 2,000 deaths per year. In contrast, although much less common than nonmelanoma skin cancer, melanoma has a continually rising death rate now estimated at 8,700 per year, and it is currently predicted that the lifetime risk in Caucasians of developing melanoma is a staggering 1 in 37 for males and 1 in 56 for females.[1] Because they are so common, cutaneous cancers have a major impact on health care costs: in addition to the mortality burden, treatment is associated with considerable morbidity and cosmetic defects. For these reasons, understanding the etiology and pathogenesis of these malignancies is a significant public health goal, and development of rational nondeforming therapies to reduce morbidity and mortality is urgently needed. The high prevalence of skin cancer, the external location of the tumors, and well-defined preneoplastic lesions all provide an excellent opportunity for studying the factors regulating cutaneous cancer induction in humans. Those qualities that facilitate the study of cutaneous neoplasms in human populations have also been useful in establishing relevant animal models. Advances in molecular genetics, keratinocyte cell culture, and development of genetically altered mice and reconstructed human skin models have greatly facilitated the analysis of basic mechanisms of cutaneous carcinogenesis. Our main focus in this chapter will be on nonmelanoma skin cancer: the reader is referred to Chapter 124 for further discussion of melanoma.

AGENTS ASSOCIATED WITH SKIN CANCER INDUCTION IN HUMANS

The ultraviolet radiation (UVR) in sunlight is the primary etiologic agent for all skin cancers, and thus UVR is the major carcinogen in the human environment. The powerful carcinogenic activity of UVR is attributable to its ability to damage DNA and cause mutations, its capacity to clonally expand incipient neoplastic cells whose altered signaling pathways provide a survival advantage in the face of ultraviolet-induced cytotoxicity, its ability to induce reactive oxygen species, and its activity as an immune suppressant (see Chapter 112). The association of UVR with skin cancer is so strongly supported by clinical, epidemiologic, and experimental data that it represents the most clear-cut etiologic factor in human malignancy.

Also implicated in the development of human skin cancer are various chemicals, as a result of environmental, occupational, or medicinal exposures (Table 111-1). In 1775, Sir Percivall Pott[3] attributed the increased incidence of scrotal cancer in chimney sweeps to repeated exposure to soot. This report provided the first link between occupational exposure and the development of cancer as well as the first example of chemical carcinogenesis. According to the National Toxicology Program's 11th Report on Carcinogens, published in 2005 (http://ntp.niehs.nih.gov/ntp/roc/toc11.html), 246 agents are listed as known or likely human carcinogens, and the great majority of these are chemicals. In the last 35 years, the mechanisms by which chemicals cause cancer have been unraveled, and reveal striking similarities to the properties responsible for UVR carcinogenicity, namely DNA damage, selective cytotoxicity, and immune suppression.

The carcinogenic potential of coal and petroleum derivatives is now firmly established as a result of experimental animal studies and epidemiologic reports. Petroleum products, grease as well as insecticides, herbicides, and fungicides are particularly pathogenic for SCC, while fiberglass and dry-cleaning agents increase the incidence of BCC.[4] Cigarette and pipe smokers have an overall twofold increased risk for cutaneous SCC, and the risk increases with the intensity of the tobacco use.[5] Arsenic exposure is associated with the development of premalignant keratoses, Bowen's disease, SCC, and BCC, as well as a number of internal malignancies.[6] While Fowler's solution (1% potassium arsenite) is no longer used in medical practice, certain herbal medicines are still a source of arsenic exposure. Occupational exposures to arsenic as a component of agricultural pesticides, sheep and cattle dip, mining and smelting, glass manufacturing, and other industries are well documented. A more insidious source of environmental arsenic exposure is contaminated drinking water or shellfish, and analysis of affected populations shows a dose-dependent increase in skin cancer.[7] Mouse models have provided evidence for an interaction of ingested arsenic acting as a cocarcinogen with solar radiation to

TABLE 111-1
Environmental Agents Associated with the Development of Human Skin Cancer

Agent	Individual at Risk	Route of Exposure	Tumor Types
UV radiation	General population	T	BCC, BD, SCC, M
Cigarette smoke	Smoker	T or S	SCC
Soot	Chimney sweep	T	SCC
Coat tar, pitch	Coker of coal, steel worker	T	SCC
Petroleum oils	Machinist, textile worker	T and S	SCC
Arsenic	Agriculture worker, living in areas of high groundwater and soil contamination	S and/or T	BD, SCC, BCC
4,4′-Bipridyl	Pesticide manufacturer	T	SCC, BD
Polychlorinated biphenyl	Petrochemical worker	T or S	M
Dry cleaning reagents	Dry cleaner	T or S	BCC
Fiberglass	Insulator	T	BCC
Psoralen (PUVA)	Psoriasis patient	T and S	SCC, BCC, M
Nitrogen mustard	CTCL patient	T	SCC
Immunosuppressants	Transplant recipient, etc.	S	SCC, BCC
Ionizing radiation	Cancer therapy patient	T	BCC, SCC

Abbreviations: T = topical; S = systemic; SCC = squamous cell carcinoma; BD = Bowen's disease; BCC = basal cell carcinoma; PCB = polychlorinated biphenyl; M = melanoma; CTCL = cutaneous T-cell lymphoma.

increase the frequency and size of cutaneous carcinomas and reduce the latency period.[8,9]

A variety of medications have been associated with the development of skin cancer. Systemic treatment with immunosuppressive agents results in an increased incidence of both benign and malignant skin lesions,[10] which is generally attributed to reduced immune-surveillance of nascent tumor cells. However, a more specific mechanism predisposing to skin cancer has been proposed for azathioprine, which may sensitize DNA to ultraviolet A (UVA) radiation via its metabolite 6-thioguanine, leading to the production of mutagenic reactive oxygen species.[11] In addition, cyclosporine A inhibits DNA repair and cell death in UVB-irradiated keratinocytes,[12] raising the possibility that this compound may also increase photocarcinogenesis. Topical nitrogen mustard also increases the risk of developing skin cancer.[13] Despite the clear-cut association between occupational exposure to tars and skin cancer, the use of coal tar in patients with psoriasis or eczema does not appear to increase the risk of developing skin cancer, based on a large study including over 13,000 patients.[14] In contrast, the use of ionizing radiation to treat a variety of skin diseases increases the risk of BCC in all treated patients, and SCC in individuals with sun-sensitive skin.[15]

Systemic administration of 8-methoxypsoralen combined with UVA treatments (PUVA) is associated with a dose-dependent increase in the risk of developing cutaneous SCC that persists following discontinuation of therapy.[16] Patients receiving high-level exposures (≥337 PUVA treatments) had over a 100-fold increase in SCC incidence while those receiving <100 treatments had a fivefold higher than expected incidence. 3.8% of individuals with PUVA-associated SCC developed metastases, and SCCs developed on the male genitalia much more frequently than in the general population.[17] The incidence of BCC and melanoma is also increased in PUVA patients.[18,19] PUVA is thus a potent stimulus for the induction of epithelial skin cancer in humans and also induces SCC in mice.[20] While this implies that PUVA is a complete carcinogen by virtue of its DNA damaging properties, the frequent detection of human papilloma virus DNA in PUVA-induced cancers suggests that immunosuppression may also contribute to carcinogenesis in this setting.[21] In contrast to PUVA, UVB phototherapy does not appear to be associated with an increased risk of developing nonmelanoma skin cancer.[22] There is strong evidence implicating the use of tanning beds in the development of both nonmelanoma skin cancers and melanoma.[23] The World Health Organization now places tanning beds in the category of group I carcinogens,[24] which will hopefully help bring about policy changes leading to strict regulation of the tanning bed industry.[25]

THE NATURE OF CHEMICAL CARCINOGENS: CHEMISTRY AND METABOLISM

How can such a diverse group of chemical and physical agents contribute to cutaneous cancer when the great majority of environmental agents to which humans are exposed are not carcinogenic? We now know that carcinogens can be genotoxic, nongenotoxic, or both.[26] Genotoxic carcinogens have high chemical reactivity (such as alkylating agents like nitrogen mustard) or can be metabolized to reactive intermediates by the host (such as petroleum products). They form covalent adducts with macromolecules and target DNA in the nucleus and mitochondria.[27] Since there is a good correlation between the ability to form covalent DNA adducts and the potency to induce tumors in laboratory animals, DNA is considered the ultimate target for most genotoxic carcinogens. The interaction with DNA is not random, and each class of agents reacts selectively with purine and pyrimidine targets.[27] Furthermore, targeting of carcinogens to particular sites in DNA is determined by nucleotide sequence, by host cell, and by selective DNA repair processes making some genetic material at risk over others. As expected from this chemistry, genotoxic carcinogens are potent mutagens, particularly adept at causing base mispairing or small deletions, leading to missense or nonsense mutations. Others may cause macrogenetic damage such as chromosome breaks and large deletions. In all cases, mutations detected in tumors represent a combination of the effect of the mutagenic change on the function of the protein product and the effect of the functional alteration on the behavior of the specific host cell type.

A number of chemicals that cause cancers in laboratory rodents and contribute to human skin cancer incidence are not demonstrably genotoxic.[28] Synthetic pesticides and herbicides, dry-cleaning reagents, and arsenic may fall within this group. The mechanism of action by nongenotoxic carcinogens is controversial and may be related in some cases to toxic cell death and regenerative hyperplasia. Induction of endogenous mutagenic mechanisms such as DNA oxyradical damage,[29] depurination of DNA, and deamination of 5-methylcytosine may contribute to carcinogenicity of these agents. Nongenotoxic carcinogens may interfere with host protective mechanisms as has been suggested for the action of arsenic in suppressing DNA repair or inhibiting the activity of tumor suppressor genes.[8] Thus, nongenotoxic carcinogens may serve as modifiers in concert with genotoxic agents such as UVR.

While a number of carcinogens can directly interact with DNA, many require bioactivation by cellular metabolic enzymes to form a compound that can react and form adducts with DNA. In general, these reactive intermediates are inadvertent byproducts of xenobiotic detoxification pathways. These pathways are complex and interactive,[30] and genetic polymorphisms both in animal models and humans contribute to cancer susceptibility.[31] This genetic variation in metabolic enzymes leading to differing rates of biotransformation and detoxification among individuals provides an approach to estimate individual risk profiles for particular chemical exposures. Initial stages in metabolic activation are most often carried out by cytochrome P450s, a class of heme containing monooxygenases, although other enzymes can be involved.[32,33] Oxidation

of carcinogens at carbon–carbon double bonds or saturated carbon atoms, or oxidation or reduction at nitrogen moieties, yields reactive intermediates that can be further metabolized and detoxified or can bind to DNA. Further biotransformation involves enzymatic conjugation of one of several different chemical groups such as glucuronide, glutathione, acetyl, or sulfate to reactive intermediates to enhance elimination. However, these conjugation reactions can also activate as well as detoxify carcinogens.[30] A number of metabolic pathways and enzymes such as cytochrome P450s are induced by carcinogen or other chemical exposures through interaction of these xenobiotics with the aryl hydrocarbon receptor (AhR) a cytoplasmic receptor that functions as a transcription factor for detoxifying enzymes.[34] Thus, carcinogen exposure induces detoxifying enzymes, which in turn increase cancer risk through biotransformation. Expression of these metabolic pathways can be modified by diet and hormones, thus, adding further complexity to the process and determination of relative risk of carcinogenesis.

ONCOGENES, TUMOR SUPPRESSOR GENES, AND HEREDITARY CANCER SYNDROMES

If DNA is the target for carcinogens and mutagenesis is the underlying mechanism of cancer pathogenesis, how do we identify the genes that when mutated are responsible for tumor formation? Studies on the molecular basis of cancer development in the last 30 years have revealed two classes of genes, oncogenes and tumor suppressor genes that play a key role in the pathogenesis of cancer. An oncogene is any gene that can transform normal cells in culture and induce cancer in animals. Most oncogenes are derived from proto-oncogenes: normal cellular genes that are critical positive regulators of cell proliferation or inhibitors of apoptosis. Conversion to an oncogene can occur through point mutations resulting in a constitutively active protein, through DNA amplification, or through chromosomal translocations that link a highly active promoter with the proto-oncogene. Both of these later two mechanisms cause increased or inappropriate expression of a proto-oncogene and altered growth regulation of the normal cell. Tumor-suppressor genes normally function to negatively regulate cell proliferation, cause apoptosis, repair damaged DNA, or induce cellular differentiation. In contrast to oncogenes, both copies of a tumor suppressor gene must be inactivated to promote tumor development. Frequently, inactivating point mutations occur in one copy of a tumor suppressor gene, and the remaining normal copy is lost through a process of chromosomal missegregation during mitosis that leads to loss of heterozygosity.[35,36]

Which oncogenes and tumor suppressors contribute to development of cutaneous neoplasms? Considerable insight into the genetic basis of sporadic skin cancers has come from the elucidation of specific genes or genetic loci that define hereditary skin tumor syndromes (Table 111-2).[37] In particular, the importance of DNA as a target for carcinogenesis was strongly supported by the discovery of defects in DNA repair genes that comprise the complementation groups of skin cancer prone xeroderma pigmentosum (XP) patients (Chapters 110 and 139).[38,39] At least six independent genes, on distinct chromosomal loci, define proteins involved in nucleotide excision repair, a process critical for the protection of DNA against both UVR and chemical carcinogen-induced damage.[40] Among these are proteins that recognize and bind to sites of DNA damage (XPA, XPC, XPE), helicases (XPB, XPD) and endonuclease components (XPG, XPF, defects in any of which give a skin cancer-prone phenotype. Potential polymorphisms with functional consequences in these and other DNA repair genes may contribute to susceptibility states in the general population as well.[41–43] Examination of SCCs and BCCs from XP patients has also revealed potential target genes for cancer induction since signature mutations in *PTCH1*, *RAS*, *p53*, and *INK4a-ARF* ($p16^{INK4a}$ and *ARF*) have been found with high frequency.[44]

Chromosomal mapping studies in the basal cell nevus syndrome (Chapter 116), coupled with genetic and functional studies in *Drosophila* and mice, implicated mutations in the *PTCH1* gene and other defects in the Hedgehog (Hh) signaling pathway in the development of hereditary and sporadic BCCs[45] and a variety of internal malignancies.[46] All of these tumors are characterized by elevated Hh signaling activity (Chapter 115). The *INK4a-ARF* locus, specifically mutations in the *p16(INK4A)* gene, was identified in the etiology of melanoma[47] through mapping of the inheritance pattern of familial melanoma. Oncogenic mutations in *BRAF* were discovered in a high proportion of melanoma by systematically screening for alterations in genes in the Ras/MAP kinase signaling pathway,[48] an important growth regulator in many cell types. Detection of specific mutations in Cowden syndrome (*PTEN*),[49,50] Muir–Torre syndrome (*MSH2, MLH1*),[50,51] multiple cylindroma (*CYLD1*),[52] multiple trichoepithelioma (*CYLD1*),[53] Birt–Hogg–Dube syndrome (*FLCN*),[54] and sporadic pilomatricomas (*CTNNB*)[55] and sebaceous tumors (*LEF1*)[56] have illuminated genetic defects associated with the development of adnexal tumors. The delineation of the specific genes mutated in other syndromes where locus mapping is confirmed (Table 111-2) should provide even more insight into the molecular pathogenesis of a broader spectrum of skin neoplasms.

ANIMAL MODELS VERIFY THE GENETIC BASIS FOR CUTANEOUS NEOPLASMS

Using human hereditary cancer syndromes as a guide, genetically based animal models have been developed that validate the contribution of individual genes to human cancer susceptibility by prospective experimental analysis.[57] These models have also contributed to the understanding of gene–environment interactions

TABLE 111-2
Oncogenes and Tumor Suppressor Genes in Human Skin Cancers

Gene	Type	Function	Locus	Tumor Type	Syndrome	Spontaneous
TP53	Tumor suppressor	DNA repair, apoptosis, cell cycle regulation	17p13.1	BCC, SCC	Li Fraumeni (but no increase in skin cancers)	Yes
XPA, XPB *XPC, XPD* *XPF, XPG* PolH (XPV)	Tumor suppressor	DNA repair	9q22.3, 2q21 3p25, 19q13.2-q13.33 16p13.3-p13.13, 13q33 6p21.1	BCC, SCC, melanoma	Xeroderma pigmentosum	Possible
PTCH1	Tumor suppressor	Hedgehog receptor	9q22.3	BCC, trichoepithelioma	Nevoid basal cell carcinoma	Yes
SMO	Oncogene	Hedgehog effector	7q31-q32	BCC	Unknown	Yes
p16(INK4A)	Tumor suppressor	Cyclin-dependent kinase inhibitor	9p21	Melanoma, SCC	Familial melanoma	Yes
BRAF	Oncogene	Cell cycle, survival	7q34	Melanoma	None	yes
HRAS, NRAS	Oncogene	Cell cycle, survival	11p15.5, 1p13.2	SCC, melanoma	None	Yes
CTNNB1	Oncogene	Cell–cell adhesion, transcription factor	3p22-p21.3	Pilomatricoma	Unknown	Yes
LEF1	Oncogene	Transcription factor	4q23-q25	Sebaceous tumors	Unknown	Yes
CYLD	Tumor suppressor	NF-κB inhibitor	16q12-q13	Cylindroma	Multiple cylindroma, multiple trichoepithelioma	Yes
PTEN	Tumor suppressor	Phosphatase	10q23.3	Trichilemmoma melanoma	Cowden's	Unknown
MSH2 *MLH1*	Tumor suppressor	Mismatch repair	2p22-p21 3p21.3	Sebaceous gland carcinoma	Muir–Torre	Unknown
FLCN	Tumor suppressor	Ribosomal protein S6 modulator	17p11.2	Fibrofolliculoma	Birt–Hogg–Dube	Unknown
Unknown		Unknown	9p21	Trichoepithelioma	Multiple trichoepithelioma	Unknown
Unknown		Unknown	Xq24-q27	BCC	Bazex	Unknown
Unknown		Unknown	9q31	Keratoacanthoma	Ferguson-Smith	Unknown

by testing the influence of chemical and physical carcinogens on tumor development in the setting of an altered genetic makeup. The discovery of inactivating *PTCH1* mutations and activating *SMO* mutations in BCCs (see Chapters 115 and 116) led to the development of several mouse models exploring the role of deregulated Hh signaling in BCC tumorigenesis.[45] Keratinocyte-targeted overexpression of SHH[58,59] or an activated form of the Hh pathway signaling molecule SMO (M2SMO)[60,61] resulted in the development of basal cell-like proliferations or follicular hamartomas in mouse skin. Overexpression of SHH in human keratinocytes grafted onto immune-deficient mice also resulted in BCC-like lesions.[62] Mice with heterozygous disruption of the *Ptch1* gene have features in common with basal cell nevus syndrome patients,[63,64] including

microscopic hair follicle-derived tumors and various macroscopic skin tumors, including BCCs, after treatment with UVR or ionizing radiation.[65,66] When GLI1 or Gli2 transcription factors, which are nuclear effectors of Hh signaling are targeted to mouse keratinocytes, multiple skin tumors develop. GLI1 mice display a variety of follicle-derived tumors with relatively few BCCs,[67] while Gli2 mice develop BCCs exclusively.[68] Interestingly, when Gli2 expression was extinguished in gene-switch mice, BCCs regress but leave behind a subset of residual tumor cells, at least some of which may be able to form growing tumors when the Hh pathway is reactivated.[69] Collectively, these findings provide strong evidence supporting the notion that constitutive Hh signaling plays a key role in, and may be sufficient for, BCC development.

The multistage induction of cutaneous SCC (Fig. 111-1)[70] and the absence of a hereditary syndrome

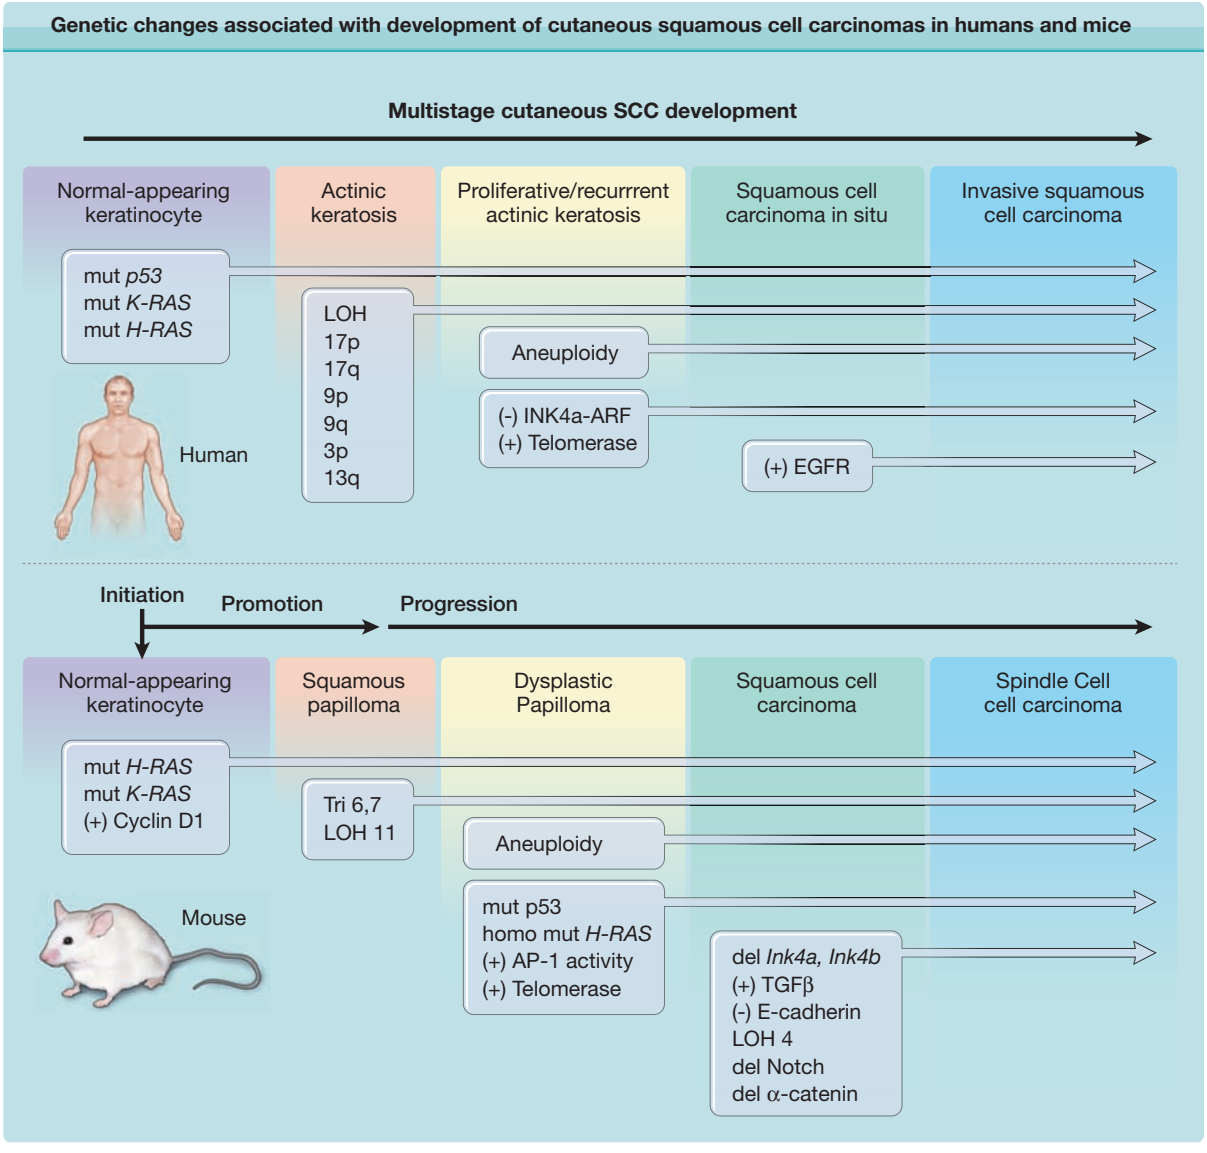

Figure 111-1 Genetic changes associated with development of cutaneous squamous cell carcinomas (SCC) in humans and mice. The multistage evolution of invasive squamous cell cancer in humans is depicted schematically with frequently associated genetic changes. Single base mutations in early lesions frequently are characteristic of ultraviolet light-induced damage, while later changes are associated with genomic instability. Increased activity of telomerase (deletion of inhibitor) or epidermal growth factor receptor (EGFR) tyrosine kinase (gene amplification) may also result from epigenetic changes. In chemically induced mouse cutaneous SCC, the multistage evolution to spindle cell tumors in this model is highly ordered both temporally and genetically. Operationally defined stages include initiation, promotion, and progression. *Ras* mutations are characteristic of chemical mutagens used to initiate tumor formation. Early upregulation of Cyclin D1 and later upregulation of TGFβ1 occur through epigenetic mechanisms and appear to be important components of carcinogenesis. Note that while p53 alterations are seen at early stages of human SCC development and ultraviolet radiation (UVR)-induced mouse SCC development (not shown), p53 mutations occur at later stages during mouse chemical carcinogenesis. (Modified from Dlugosz A, Merlino G, Yuspa SH: Progress in cutaneous cancer research. *J Invest Dermatol Symp Proc* **7**:17, 2002, with permission of Nature Publishing Group, London, UK.)

that specifically imparts uniquely high susceptibility to this lesion have made the delineation of specific genetic loci involved in SCC induction more complex. Nevertheless, the analysis of genetic defects in human SCCs has focused attention on specific targets such as DNA repair genes, *RAS*, *p53*, *p16(INK4A)*, and the epidermal growth factor receptor (EGFR) pathway. Significant progress has been made in defining pathways capable of driving nonmelanoma skin cancer development using reconstructed human skin, comprising genetically altered primary human keratinocytes on architecturally intact dermis, grafted onto immune-deficient mice.[71] Using this powerful system for modeling human skin cancer in mice, it has been shown that coexpression of oncogenic Ras and either Cyclin-dependent kinase 4 (Cdk4), or the NF-κB inhibitor IκB, in human keratinocytes, rapidly leads to invasive SCC development in reconstructed skin grafts.[72,73]

Mouse models for XPA, XPC, and XPE deficiency have been constructed, and all show sensitivity to UVR and enhanced development of SCC after either UVR or chemical carcinogen exposure.[39] A number of other DNA repair-deficient mutant mice are also being tested for cancer susceptibility and may reveal the mechanistic basis for new clinical syndromes by reverse genetics.[74] Mouse mutants targeting the *Ras* gene have revealed important information concerning the contribution of the Ras pathway to particular stages of SCC development. Heterozygous activating *Ras* gene mutations are sufficient to induce a benign squamous papilloma, the precursor to SCC, and the yield of chemically induced tumors in mice genetically deleted in the *H-ras* allele is markedly reduced.[75] Homozygosity of a mutant *ras* gene is associated with progression to SCC,[76] suggesting that high penetrance of the Ras pathway can recruit additional changes required for progression. Transgenic targeting of oncogenic *Ras* to suprabasal epidermis produces terminally benign tumors, while mosaic targeting to basal cells or hair follicle outer root sheath cells encourages progression to SCC,[77] indicating the target cell for early mutations may also determine the tumor phenotype.[78] While heterozygous p53 inactivation is detected early in human SCC, p53 deletion in mice enhances malignant progression but does not increase benign tumor formation.[79] This may be analogous to the common loss of heterozygosity seen at the *p53* locus later in human SCC development.[80] Of particular interest for human tumor development is the frequent observation that double heterozygotes for p53 deletion and other cancer-prone phenotypes (such as DNA repair deficiency) further sensitize mouse skin to tumor induction by UVR or chemical carcinogens. Mice with genetically defined defects in the $p16^{Ink4a}$ locus or its downstream target Cdk4 are sensitive to both squamous tumor and melanoma induction after treatment with carcinogenic chemicals, consistent with defects in this pathway detected in both melanoma and nonmelanoma human skin cancers.[81,82] Elegant mouse modeling studies have confirmed the importance of Braf mutations, when combined with alterations in the tumor suppressor Pten, in the development of metastatic melanoma in mice.[83]

TUMOR BIOLOGY AND BIOCHEMISTRY

GENERAL PRINCIPLES

Malignant tumors exhibit fundamental alterations in behavior that distinguish them from the normal tissues in which they arise. These differences include a reduced requirement for growth stimuli, impaired response to growth inhibitory/differentiation signals, alterations in apoptosis, delayed or blocked senescence, prolonged angiogenesis, and the capacity for invasion and metastasis.[84] Although one or more of these abnormalities can be detected at different stages of tumor progression and may thus be seen in premalignant lesions, all are present in advanced cancers. The driving force behind many of these changes is genomic instability, which facilitates the accumulation of mutations in both oncogenes and tumor suppressor genes that contribute to the observed aberrations in cell function.[85] While some of these changes are cell-autonomous and can be studied in purified populations of tumor cells, others depend on various additional cell types recruited to participate in the development and progression of cancer in intact organisms. Both the intrinsic alterations in neoplastic keratinocytes and the influence of collaborating cell types in skin tumor biology are being elucidated through the use of powerful experimental models.

From analyses of both human SCC pathogenesis and experimental skin tumor induction by chemical carcinogens, specific premalignant and malignant stages have been identified that have typical phenotypic, genetic, and biochemical characteristics (Fig. 111-1).[86,87] Note that in contrast to SCCs and most other cancers, BCCs do not appear to have precursor lesions or give rise to more aggressive cancers. This is likely related to the observation that the genomic instability that fuels neoplastic progression in other tumor types is largely missing in BCCs, even though a substantial proportion of these tumors harbor p53 mutations that would be expected to facilitate the accumulation of additional genetic defects. SCC starts as a single or small number of specific mutations in a cell that has the capacity to cycle, a change understood as the "initiation" of carcinogenesis. Upon clonal expansion, initiated cells form a premalignant lesion, such as a squamous papilloma in the mouse or an actinic keratosis in the human. Agents that enhance clonal expansion of initiated cells are called tumor promoters. Tumor promotion may occur as a consequence of exogenous exposures such as UVR, topical chemicals or medications, infections, or wound healing. Promotion may be an endogenous process influenced by diet, smoking, or immune suppression. The acquisition of additional mutations that provide a growth advantage to the incipient cancer cell may also serve as an autonomous promoting stimulus. Premalignant lesions undergo further phenotypic changes, often in a predictable sequence and commonly multifocal

within a single lesion.[88] Some foci or lesions progress at a faster rate than others, and these are at highest risk for malignant conversion.[89] Premalignant progression encompasses the majority of the tumor latency period prior to malignant conversion, when the lesion shows invasive properties.

Initiation is usually a low frequency genetic event and is directly dependent on carcinogen dose. A large variety of carcinogen classes can initiate skin tumors in rodents (Table 111-3). The phenotype of initiated epidermal cells as defined from in vitro analysis includes a defect in maturation, escape from senescence, and an enhanced growth potential, but initiated cells are still responsive to negative regulation, for example by TGFβ. At the molecular level, initiation involves an alteration in signal transduction pathways that regulate cellular responses to extracellular signals, and these are internally regulated by proto-oncogenes and tumor suppressor genes.[84,90] Tumor promotion is generally a nongenotoxic stimulus that results in a disturbance of tissue homeostasis.[88] Multiple classes of agents have promoting properties in experimental skin carcinogenesis (Table 111-3). The mechanisms of tumor promotion include activation of cell surface receptors, activation or inhibition of cytosolic enzymes, and nuclear transcription factors, stimulation of proliferation, inhibition of apoptotic cell death, and direct cytotoxicity. Chronic inflammation is linked with tumor promotion, and agents that suppress inflammation reduce tumor formation in experimental models.[91] Genotoxic carcinogens also can have promoting properties, and repeated exposures to low concentrations of genotoxic carcinogens can induce tumors more effectively than fewer exposures to the same total dose in experimental carcinogenesis.[92] Exogenous tumor promoters can determine the target site for tumor formation, and the promoting action of UVR may in part contribute to skin targeting for tumors when germ-line mutations produce an initiated state in multiple cell types. In general, initiated cells respond differently to promoters than normal cells, allowing for clonal selection of an initiated population.[93] Premalignant progression in an initiated cell clone occurs spontaneously but is accelerated by additional exposures to genotoxic agents including some cancer chemotherapeutic drugs.[94] Premalignant progression in chemically induced mouse skin carcinogenesis is associated with nonrandom, sequential chromosomal aberrations, including amplifications, duplications, deletions, and loss of heterozygosity,[95] suggesting repeated episodes of cell selection, producing specific chromosomal aberrations that become modally dominant within the progressing focus. Thus, at least one function of the relevant genetic events in premalignant progression must result in a growth advantage for the affected cell. Epigenetic changes are also associated with malignant conversion, and upregulation of AP-1 transcriptional activity, alterations in cell cycle regulatory genes and secreted proteases, changes in gene splicing and expression of modified cell surface molecules have all been reported. Together these changes could facilitate migration and invasion that characterize the malignant phenotypes. Alterations in methylation of DNA in tumor cells could also contribute to this stage of carcinogenesis.[96]

TABLE 111-3
Examples of Agents Capable of Inducing Skin Cancer in Rodents

Initiating Agents	Promoting Agents
Polycyclic Aromatic Hydrocarbons	**Phorbol Esters**
Benzo[a]pyrene[a]	12-*O*-Tetradecanoylphorbol-13-acetate
7,12-Dimethylbenz[a]anthracene	Croton oil[a]
3-Methylcholanthrene	**Aromatics**
Tobacco tar[a]	Phenol[a]
Dibenz(a,h)anthracene[a]	Anthralin[a]
Aromatic Amines	7-Bromomethylbenz[a]-anthracene
2-Acetylaminofluorene	**Other**
Alkylating Agents	Dihydroteleocidin (fungal product)[a]
β-Propriolactone[a]	Wounding[a]
4-Nitroquinoline-*N*-oxide	Abrasion[a]
Bis(chloromethyl)ether[a]	Cigarette smoke condensate[a]
Nitrogen mustard[a]	Benzoyl peroxide[a]
Cisplatin[a]	2,3,7,8-Tetrachlorodibenzo-*p*-dioxin[a]
Nitrosamines and Nitrosamides	Diacylglycerols
N,N'-Dimethylnitrosourea[a]	Ultraviolet radiation[a]
N-Methyl-*N'*-nitro-*N*-nitrosoguanidine[a]	Dodecane
Other	
Urethane[a]	
Dinitropyrene[a]	
Ionizing radiation[a]	
Ultraviolet radiation[a]	

Documented activity of these agents in rodent carcinogenesis models does not necessarily indicate they also contribute to skin cancer development in humans.
[a]Known human exposure.

THE PATHOGENESIS OF BASAL CELL CARCINOMAS

Animal models for induction of skin tumors by chemical and physical agents have been extremely valuable for exploring mechanisms of carcinogenesis in an experimental setting (Table 111-4). Rats exposed to chemical carcinogens (methylcholanthrene, dimethylbenzanthracene) or ionizing radiation preferentially develop BCCs[97] that are phenotypically similar to human BCCs. In contrast, mice are resistant to BCC induction unless they are genetically modified in the laboratory, although one study reported mouse BCC development following either subcutaneous or topical exposure to dehydroretronecine.[98]

As noted in Section "General Principles," BCCs represent an intriguing exception to the rule of multistage cancer development. Individual tumors typically consist of homogeneous, slowly growing cells that very rarely metastasize, although they can cause extensive

TABLE 111-4
Animal Models of Cutaneous Cancer Induction By Exogenous Agents

Agent	Species	Comments
Basal Cell Carcinoma		
3-Methylcholanthrene	Rat	Also other skin tumors
DMBA	Rat	SCC > BCC; lower DMBA doses may increase BCC incidence
Ionizing radiation	Rat	Also other skin tumors
Dehydroretronecine	Mouse	BCC > SCC, also internal tumors
Squamous Cell Tumors		
(PAH, NA, AA) + promoter	Mouse, rat	Predominantly papilloma
(PAH, NA, AA) repeated	Mouse, rat	Predominantly SCC
Ultraviolet B	Mouse	*p53* mutations, immune suppression, SCC
Ultraviolet A	Mouse	Papillomas and SCC

DMBA = 7,12-Dimethylbenz[a]anthracene; PAH = polycyclic aromatic hydrocarbons; NA = nitrosamines; AA = aromatic amines.

local damage. Even those rare BCCs exhibiting cellular atypia generally have a benign course,[99] suggesting that the full complement of factors driving malignant progression in SCCs and other neoplasms is not operating in these tumors. BCC cells exhibit abnormalities in growth control and terminal differentiation, induce clinically apparent angiogenesis, and invade their immediate surroundings. However, transplantation studies using human BCCs or transgenic mouse skin with BCC-like lesions[58] suggest that the tumor cells are critically dependent on adjacent stroma for survival. This property may help explain both the lack of BCC metastases and the difficulty in establishing BCC cell lines. Interestingly, in a recent study in which global gene expression profiling was performed on stromal cells derived from tumors versus normal tissue, the bone morphogenetic protein (BMP) antagonist, GREMLIN 1, was found to be highly expressed in BCC stroma but not normal skin.[100] BCCs express BMP 2 and 4, and GREMLIN 1 stimulates growth of cultured BCC cells in vitro, suggesting that GREMLIN 1 may be a stromal factor needed to support BCC proliferation in vivo, by antagonizing growth-inhibitory effects of BMPs.

Studies performed using human and rodent BCCs have identified additional candidate molecules that may be important in the biology of these tumors. Upregulation of various matrix metalloproteases (MMPs), both in tumor cells and stroma, is likely to be important in the local invasion of BCC, and may impact on growth control and other cellular functions given the emerging role of MMPs in regulating signaling at multiple levels.[101] Expression of several adhesion molecules is downregulated in BCCs, and this may account for the characteristic appearance of artifactual clefts between tumor cells and stroma in histological sections, but the functional significance of this finding in BCC biology has not been established. The antiapoptotic molecule BCL2 is consistently upregulated in BCCs probably because *BCL2* is an Hh target gene,[102,103] but this does not appear sufficient to block apoptosis in these tumors as it does in other settings. Indeed, the remarkably slow growth rate of BCCs has been attributed in part to baseline apoptotic cell loss. Expression studies in human BCCs and experimental models suggest the involvement of growth factor signaling pathways such as PDGF[104,105] and EGFR.[106] Several lines of evidence point to components of the cell cycle machinery as potentially critical targets in mitogenic responses to Hh signaling. Keratinocytes overexpressing Shh have enhanced proliferative potential and fail to undergo growth arrest in response to the cell cycle inhibitor p21[107]; in the absence of Shh, Ptch1 interacts with and may sequester Cyclin B1, a component of M-phase promoting factor which is required for mitosis and cell cycle progression[108]; and Shh can drive proliferation of immature cerebellar cells by causing prolonged induction of Cyclins D1, D2, and E.[109] In skin, Hh-driven proliferation of hair follicle epithelium is likely to be mediated by Cyclin D2 and N-Myc.[110] Oncogenic Hh signaling in skin leads to activation of the Wnt/β-catenin pathway; remarkably, signaling via this additional pathway is required for Hh pathway-driven skin tumor development.[111] The discovery of key molecules and other pathways required for Hh-driven tumorigenesis will provide additional targets for therapy.

THE PATHOGENESIS OF SQUAMOUS CELL CARCINOMAS

Both mice and rats are sensitive to SCC induction by a variety of chemical and physical agents (Table 111-4), and the induction of SCC in mice by UVR mimics the pathogenesis of SCC in human skin (Chapter 114). Multistage chemical carcinogenesis in mouse skin has been a powerful tool for delineating many of the fundamental concepts underlying epithelial carcinogenesis in other organs. Inbred strains of mice differ in their sensitivity to tumor induction using chemical carcinogens and tumor promoters, and extensive genetic analysis has led to identification of loci that confer sensitivity or resistance to induction of either benign and malignant tumors.[112–114] Interestingly, benign tumors that develop in FVB/n mice have a high frequency of conversion to SCC, and this is due to a polymorphism in the FVB/n Ptch allele which enhances Ras-induced SCC development.[115]

Building on the association of deregulated EGFR signaling in human cancer, mouse models suggest that constitutive EGFR activation is an important component of skin tumor formation. Transgenic epidermal targeting of TGFα, which activates the EGFR, can produce a benign tumor phenotype in the absence of activating *Ras* mutations.[116,117] However, activation of the EGFR by ligand overexpression alone is not an

efficient stimulus for autonomous tumor formation, since many of these tumors regressed. Loss of function studies also point to an important role for EGFR in squamous tumorigenesis in skin. Transformation of *Egfr* null keratinocytes with oncogenic *ras*, followed by transplantation onto immune-deficient mice, results in the formation of smaller benign tumors that those arising from *ras*-expressing control keratinocytes. These data imply point to an important role for EGFR signaling in squamous tumors, but suggests that an alternative, *ras*-induced pathway for tumor growth exists in the early, premalignant tumor.[18]

Additional evidence implicating enhanced growth factor signaling in SCC is provided by transgenic studies using a dominant form of SOS, an adapter molecule involved in transducing growth-stimulatory signals from receptor tyrosine kinases like EGFR, which resulted in spontaneous development of papillomas in mouse skin.[119] Overexpression of ErbB2, a receptor tyrosine kinase related to and capable of interacting with EGFR, results in spontaneous skin tumor development in transgenic mice.[120] Insulin-like growth factor 1 (Igf1), when overexpressed in mouse skin, also triggers development of squamous papillomas, some of which progressed to carcinomas.[121] While most of these studies invoke an autocrine mechanism for growth stimulation of tumor cells, factors produced by cells in the tumor stroma may supply mitogenic signals to keratinocytes or angiogenic signals as well.[122] Additional studies performed in mice suggest that specific components of the cell cycle machinery, including E2F1,[123] Cyclin D1,[124] and Cdk4,[125] can contribute to SCC development and/or progression.

The TGFβ signaling pathway is an additional growth factor pathway that contributes to SCC development but in contrast to the EGFR it functions as a negative regulator of epidermal proliferation and to maintain epidermal homeostasis.[126] Reduced levels of intracellular mediators of TGFβ signaling, Smad2 and Smad4, are observed in human SCC,[127,128] suggesting that loss or disruption of this growth control pathway is important in tumor development. Interestingly, SCC that develop in organ transplant recipients receiving antirejection drugs exhibit significant activation of the TGFβ pathway. Thus, in this context the TGFβ pathway may enhance tumor susceptibility.[128]

In addition to deregulated growth control, there is a progressive loss in the capacity for terminal differentiation during SCC progression (Fig. 111-1), culminating in a tumor with a spindle cell morphology that is indistinguishable from malignancies originating in mesenchymal tissues. Although the mechanisms responsible for defective differentiation at different stages of human skin cancer are not known, there is evidence that deregulation of the protein kinase C (PKC) family of enzymes plays a role in aberrant differentiation of mouse skin keratinocytes expressing the Ras oncogene.[88] PKCδ, which has been implicated in terminal differentiation of normal epidermal keratinocytes, is rendered inactive as a result of tyrosine-phosphorylation in ras-transformed keratinocytes. Restoring PKCδ to its native, nontyrosine phosphorylated state reversed the block to terminal differentiation in ras-transformed keratinocytes. In addition, overexpression of PKCδ in the skin of transgenic mice inhibits the development of squamous papillomas and carcinomas.[129] In contrast, skin-targeted overexpression of PKC ε resulted in less differentiated SCCs that rapidly metastasized to regional lymph nodes.[130] Additional work is needed to better understand the mechanism by which SCC tumor cells evade signals that trigger differentiation of normal keratinocytes.

Prostaglandin metabolism is activated by UVR and is constitutively induced in human SCCs, probably due to overexpression of the enzyme cyclooxygenase 2 (COX-2). Although the mechanism by which changes in prostaglandins influence skin cancer is not clear, they appear to operate at the tumor promotion stage. Telomerase activity is detected in a substantial proportion of human skin cancers, suggesting that these tumor cells are capable of evading cellular senescence, and telomerase-deficient mice are resistant to chemical carcinogenesis.[131] Additional contributors that are likely to be involved in SCC development and progression include mediators of angiogenesis, MMPs, and integrins, as well as other molecules involved in cellular adhesion and migration.

Spontaneous or carcinogen-induced tumor formation in genetically modified mice has revealed genes and pathways that appear to be important in skin cancer induction but would not have been apparent from hereditary cancer syndromes or analysis of human skin cancers. Suprabasal targeting of c-Myc in transgenic mice permits suprabasal cells to cycle and produces the papilloma/actinic keratosis phenotype while basal cell targeting of c-Myc is not oncogenic.[132,133] Deletion of the Cyclin/CDK inhibitor $p21^{waf1}$, a downstream effector of p53, increases the number of benign tumors but not the rate of premalignant progression.[134,135] Inactivation of TGFβ signaling enhances premalignant progression while overexpression blocks papilloma outgrowth and promotes invasion and metastasis of established tumors and progression from SCC to a spindle cell phenotype.[136–139] Surprisingly, reduction of cutaneous TGFβ1 also suppresses papilloma formation indicating a critical role for physiological levels of this growth factor in supporting tumor outgrowth.[140] Two AP-1 transcription factors influence distinct stages of skin tumor development, where c-Jun is essential for papilloma and c-Fos is essential for SCC development.[141,142] Inhibition of AP-1 activity in benign papillomas prevents progression to carcinomas, but instead, converts these lesions into benign sebaceous adenomas,[143] supporting the concept that squamous tumors are derived from progenitor cells with multilineage potential. Additional molecules now implicated in SCC development are ornithine decarboxylase, $p16^{Ink4a}$, $p15^{Ink4b}$, E-cadherin, STAT3, c-Myc, Notch, α–catenin, NF-κB, and Smad3.[144–152]

CONSTITUTIONAL MODIFIERS OF CARCINOGENESIS

Inbred mouse strains differ in susceptibility to particular carcinogenic exposures by several orders of magnitude, and transplantation studies indicate sensitivity resides in the target tissue rather than systemically.

Genomic scans of backcrossed mice among sensitive and resistant mouse strains indicate that constitutional determinants are multigenic and distinct for squamous tumor formation or progression.[113,153] Similar studies indicate genetic loci determine the survival potential for tumor bearing animals.[154] Classical genetic approaches are frequently difficult and complex because multiple interacting loci are typically involved in defining cancer susceptibility.[155] However, the study of skin cancer susceptibility may uncover genes of broad relevance to oncology. For example, the identification of a low-penetrance susceptibility gene for mouse skin cancer, *Stk6*,[156] fueled investigation of the human homologue *AURKA* which is now implicated in the development of multiple tumor types. More recently, studies examining the susceptibility of different mouse strains to cutaneous SCC uncovered, surprisingly, an alteration in the *Ptch1* gene,[115] which is strongly implicated in the development of a BCC.[45] Thus, alterations in the same gene can promote either SCC or BCC development, and this may in part be determined by influencing a cell's decision to enter either the squamous or basal cell lineage.

Analysis of genetically modified mouse models has also revealed pathways associated with skin tumor susceptibility. Alterations in p53,[79] drug metabolizing enzymes,[157] T cell function[158] and DNA repair[74] modify risk for experimental skin cancer induction. Remarkably, polymorphisms in drug metabolizing enzymes and DNA repair pathways,[159,160] and variable responses in the p53 tumor suppressor pathway or in T cell immunity after exposure to skin carcinogens[161,162] modify the human risk for skin cancer.

EXOGENOUS MODIFIERS OF CARCINOGENESIS

In experimental models, antioxidants and agents that alter microsomal metabolism of carcinogens can reduce or prevent tumor initiation by inhibiting the formation of ultimate carcinogens or accelerating their detoxification (Table 111-5). Similar mechanisms may influence ultraviolet light or ionizing radiation mutagenesis through inhibition of mutagenic oxyradicals produced endogenously following exposure. Scavengers prevent reactive mutagens from reaching critical targets. Cell cycle inhibitors prevent fixation of mutations, allowing for DNA repair while cytotoxic agents kill initiated cells prior to their expansion into a tumor mass.

A number of agents are effective in the postinitiation phase of experimental tumor development, and some are being clinically evaluated.[163] Inhibitors of COX-2 (celecoxib, indomethacin) and ornithine decarboxylase (difluoromethylornithine) prevent both UVR and chemically induced tumors.[164,165] While the mechanism of action of retinoids as modifiers of tumor development is not clear, retinoids are effective inhibitors of benign tumor formation in mouse skin carcinogenesis studies. Low-dose systemic retinoids also reduce SCC development in organ transplant recipients,[166] but additional studies are needed to assess whether they will be useful in long-term chemoprevention in certain high-risk populations. Predictable and parallel alterations in retinoid receptors in mouse and human cutaneous SCC indicate that the retinoid pathway must be central to cancer development in epidermis.[167,168] Considerable interest has developed in dietary factors that modify skin carcinogenesis. Restricted fat/energy diets reduce papilloma incidence in mouse models[169] and decrease the frequency of actinic keratoses in human populations.[170] Diverse dietary or natural factors such as green tea, caffeic acid phenethyl ester from honey bee hives, resveratrol from grapes, silymarin from milk thistle, ginger extract, crocetin, and ursolic acid from the rosemary plant are among natural products shown to be effective inhibitors of skin tumor formation by topical application or systemic exposure.[171] Several of these agents are believed to be antioxidants, but the precise mechanism of inhibition and their effectiveness as chemopreventive agents for human skin cancer remain to be established. Finally, immune response modifiers such as imiquimod may

TABLE 111-5
Modifiers of Carcinogenesis

Inhibitor Class	Examples
Inhibitors of Initiation	
Antioxidants, scavengers	Butylated hydroxyanisole; butylated hydroxytoluene; selenium; vitamin C; vitamin E; ellagic acid
Inducers of mixed function of oxidase	Polycyclic aromatic hydrocarbons; TCDD; PCB
Inhibitors of mixed function oxidase	α-napthoflavone; glucocorticoids;
Cytotoxic agent	Sulfur mustard
Suppressor of tumor development	Retinoids
Inhibitors of Promotion	
Antiproliferative	Anti-inflammatory steroids: dexamethasone, fluocinolone acetonide; inhibitors of arachidonic acid metabolism: indomethacin, celecoxib; inhibitors of polyamine metabolism: α-difluoromethylornithine
Antioxidant	Antioxidants: tert-butylhydroxyanisole, selenium; protease inhibitors: leupeptin, tosyl lysine chloromethylketone; superoxide dismutase; copper (II) 3,5-diisopropylsalicyclic acid
Natural products and dietary factors	Retinoic acid; vitamin D; green tea; silymarin; resveratrol; ursolic acid; caffeic acid phenethyl ester; curcumin; 1,25-dihydroxyvitamin D_3

TCDD = 2,3,7,8-tetrachlorodibenzo-*p*-dioxin; PCB = polychlorinated biphenyl.

be effective for treating some types of skin cancer by modulating cytokine expression.[172]

NOVEL THERAPEUTIC TARGETS BASED ON MECHANISTIC DATA

The substantial progress in our understanding of factors involved in skin tumor pathogenesis holds the promise of new approaches to treatment and prevention. In addition to the identification of new therapeutic targets, improved strategies are being developed for altering gene and protein function in skin with great selectivity. The abundance and unrivaled accessibility of skin cancers and precancers makes them prime targets for rigorous translational studies and clinical trials. On the basis of the basic research studies outlined above, potential therapeutic targets include p53; COX-2; telomerase; EGFR or other receptor tyrosine kinases, and intracellular signaling elements such as SOS; Ras; ornithine decarboxylase; the DNA repair machinery; MMPs; PKC; molecules involved in cell cycle progression, such as Cyclins D1 and D2, CDK4, p16INK4a, and E2F1; retinoid receptors; and c-Fos. In all cases, the potential efficacy of the proposed treatments would need to be carefully evaluated in animal models or human tissues grown in immune-deficient mice. Although the great majority of cutaneous SCCs are effectively treated using surgery or radiation therapy it is likely that dermatology patients would benefit from agents, which could prevent appearance of premalignant lesions, block neoplastic progression to SCC or cause tumor ablation with minimal invasive methods especially in cosmetically sensitive sites. This is likely to be especially true for genetically predisposed individuals or organ transplant recipients that are prone to multiple aggressive SCC. Along these lines, a double-blind study reported a significant reduction in the development of actinic keratoses and BCCs in XP patients treated topically with the DNA repair enzyme T4 endonuclease V, administered over a 1-year period.[173] Pathogenic mutations in *BRAF* have recently been exploited for the treatment of melanoma, and in a promising phase I trial using a mutated BRAF inhibitor, the majority of individuals with melanomas carrying the V600E BRAF mutation exhibited either a partial or complete response.[174]

In contrast to the multiple genetic and biochemical changes associated with SCC development, the majority of BCCs have mutations in *PTCH1* or *SMO* and essentially all of these tumors exhibit uncontrolled activation of the Hh pathway. Since several experimental models suggest that deregulated Hh signaling plays a central role in BCC development and maintenance, this pathway is a prime target for mechanism-based drug development. Cyclopamine is a natural product which blocks Hh signaling by inhibiting the function of SMO,[175] a pivotal effector of Hh signaling. Cyclopamine and other Hh pathway inhibitors targeting SMO have been shown to effectively inhibit growth of BCC-like cancers and other Hh-activated tumors in preclinical studies.[176] In a phase I clinical trial, a systemic Hh pathway antagonist showed promising results in patients with advanced and metastatic BCC,[177] raising hopes that these cancers, and multiple other malignancies linked to deregulated Hh signaling, may be amenable to treatment with Hh pathway antagonists.[178] BCC is rarely lethal, but its common occurrence on sun-exposed, cosmetically-sensitive sites makes a medical approach to treatment highly desirable, particularly if a topical Hh pathway antagonist is effective in treating tumors or preventing their appearance in high-risk individuals, including those with Nevoid BCC syndrome. Additional trials are currently underway in BCC patients using both systemic and topical Hh pathway antagonists, and if they establish efficacy with an acceptable safety profile, they may change our approach to treating these extremely common cancers. Given the fundamental advances in our understanding of nonmelanoma skin cancer, we can look forward to additional, rationally designed therapeutics to complement and perhaps in some cases replace, surgical management.

Chapter 112 :: Ultraviolet Radiation Carcinogenesis

:: Masaoki Kawasumi & Paul Nghiem

ULTRAVIOLET RADIATION CARCINOGENESIS AT A GLANCE

- Ultraviolet radiation (UVR) from the sun is the most prevalent carcinogen in humans, particularly among Caucasians.
- Annual increases continue in the incidence of all types of skin cancer.
- The importance of exposure timing, dose rate, and total UVR exposure differ between the types of skin cancer.
- Sunlight leaves characteristic mutations that identify key molecular and cellular steps in skin tumor development.
- DNA repair, apoptosis, and cell signaling pathways are critical to preventing skin cancer, and UVR affects each of these processes.
- Genetic polymorphisms in genes for DNA repair, melanin, and free radical scavenging affect skin cancer risk.
- Novel, pathway-based approaches to prevent or treat skin cancer are being developed.
- Educational and behavioral approaches are key to minimizing skin cancer rates in the future.

ULTRAVIOLET RADIATION AS A CARCINOGEN

Skin cancer offers a very clear picture of how a carcinogen causes human neoplasia. The basic principles of carcinogen exposure and slow development were discovered when Sir Percivall Pott traced scrotal cancers in adults to childhood employment as a chimney sweep[1] and they also apply to sunlight-induced cancers.[2,3] The process begins with carcinogen exposure, DNA damage, and failure to repair DNA or failure to apoptotically eliminate a damaged cell.[4–7] A mutant gene arises in a single cell which then expands into a mutant clone.[8] Rare cells of the clone repeat this carcinogenesis cycle to generate mutations in additional genes. Sunlight acts at each of these steps.

EPIDEMIOLOGIC OBSERVATIONS

The lifetime expectation of skin cancer in Australia is ~60%.[9] In the southern United States and Hawaii, nonmelanoma skin cancers exceed all other cancers combined.[10–12] Basal and squamous cell carcinomas (BCC and SCC), and an SCC precursor, actinic keratosis (AK), are most frequent on sun-exposed skin, in outdoor workers, and at lower latitudes.[13–16] SCCs increase more quickly with dose of sun exposure or nearness to the equator than BCCs, and occur later in life, implying that SCC requires more sun-related steps.[16–20] In contrast, one-third of BCCs occur on body sites having only intermittent sun exposure, such as the trunk and legs.[16,21]

Melanoma also depends on sunlight. The relation to latitude is clear,[22–25] yet it is often stated that the predilection for the back and lower legs makes the relation to sunlight uncertain. This predilection likely reflects the large surface area of back and legs. When expressed as lesions per unit area, melanomas are 10–20-fold more frequent on the ears of males and face than on intermittently exposed sites such as the lower legs in women, shoulders, back, or neck.[25,26] Melanomas are rare on the buttocks and soles. Melanoma appears to have two distinct origins:

1. A chronic sun damage (CSD) etiology affects the head and neck and is associated with chronic elastosis—a classic indicator of CSD—as well as gene amplification of the cell cycle genes *CDK4* and *CCND1*.[27] The slow-growing lentigo maligna melanoma and its precursor, lentigo maligna occur on habitually exposed body sites of light-skinned individuals.[28]
2. A non-CSD route involves intermittent sun exposure of sites such as the trunk. Non-CSD melanomas carry mutations in the *BRAF* or *NRAS* oncogene—upstream regulators of cell cycle genes—and the patients have variant alleles of the melanocortin 1 receptor.[27,29,30] Intermittently exposed body sites are the main locations of melanoma increases in recent decades, melanomas in patients younger than age 50 years, and the additional melanomas seen near the equator.[23,25,31] Recreational sunburn may explain these and the twofold higher melanoma incidence in office workers compared to outdoor workers.[32,33]

Sunlight is also implicated by the susceptible population: both classes of skin cancer are more frequent in light-skinned individuals with blonde or red hair who burn rather than tan.[13,34] Compared to dark-skinned individuals, nonmelanoma skin cancer risk rises ~10-fold in Asians and ~100-fold in Caucasians, with a further 2–12-fold risk for people with blonde or, especially, red hair.[13,34–37] The divergence is less for melanoma,

about 1:1:15 (Blacks:Asians:Caucasians).[38] In black skin, BCC is rare even in patients with the hereditary nevoid basal cell carcinoma syndrome (NBCCS or Gorlin syndrome).[39] Skin tumors in black patients are often scar-related, but these may be associated with sunlight as well.[36] Melanin-related effects result from less melanin in light skin,[40] less shielding by pheomelanin than eumelanin, and greater production of photosensitized reactive oxygen from pheomelanin.[41–43]

Molecular epidemiology has provided the most direct evidence for ultraviolet radiation (UVR) as the active component of sunlight: UVB signature mutations are present in human BCC, SCC, AK, and melanoma (see Section "Ultraviolet Radiation-Induced Mutations"). Mutant cells are associated with elastotic dermis, indicating chronic sun exposure.[44] UVB's effectiveness is due to its ability to partially penetrate the ozone layer and stratum corneum and then be absorbed by DNA.[45] The ozone layer absorbs all but 1 part per million of UVC (used in germicidal bulbs), which otherwise would be lethal; UVA penetrates well but is poorly absorbed by DNA.[45,46] Nevertheless, chronic UVA can induce tumors in mice[47] and malignantly transforms predisposed human cells.[48] The cumulative dose of sunlight required to cause BCC or SCC in adults is fairly large, approximately 10,000 and 70,000 hours of exposure, respectively.[16] Psoriasis patients who received long-term maintenance UVB phototherapy had a three- to eightfold higher risk of nonmelanoma skin cancer than people with an outdoor occupation, although the mean annual UVB dose received by psoriasis patients was 22 J/cm^2, lower than the solar UVB dose annually received by individuals with an outdoor occupation (134 J/cm^2).[49]

Some melanomas appear to be independent of sunlight: tumors of the mucosa, palms, soles, and nail beds are equally frequent in whites and blacks and have remained constant over time. In contrast, melanomas of the skin have increased manyfold in recent decades.[50] Ocular melanomas are more frequent in whites than blacks,[51] but have not increased in the last few decades.[52,53] Although the risk of external ocular melanoma (eyelid and conjunctival melanomas) decreases with higher latitude (less sun exposure), the risk of internal ocular melanoma (uveal melanoma), which is not exposed to sunlight, *increases* with higher latitude, as does the risk of other internal malignancies.[53,54]

THE SKIN CANCER EPIDEMIC

The incidence of melanoma and nonmelanoma skin cancers has doubled each decade since the 1960s.[10,23,25,55–57] AK, lentigo maligna, and lentigo maligna melanoma—typically lesions of the middle-aged and elderly—are now seen in young adults. The best evidence that recreational sun exposure is responsible for much of the increase in skin cancers is that intermittently sun-exposed sites, such as the trunk and limbs, account for most of the increase in skin cancers, with little change in melanomas of the head and neck.[10,23,25] Another suspect has been ozone depletion; because of a steep absorption curve in the UVB region, small changes in ozone concentration greatly affect UVB penetration (UVC is fortunately still blocked). Epidemiological data do not support a close relationship between ozone holes and skin cancer rates. The Antarctic ozone hole caused a 50% ozone reduction over southern Chile and Argentina in the last two decades, with UVB increasing up to 40-fold. Yet skin cancers in these areas are increasing at the same rate as elsewhere.[58,59] The Arctic ozone hole has been offset by screening from air pollutants, yet skin cancers in Scandinavia are rising.[60]

An iatrogenic source of increased skin cancer incidence is psoralen plus ultraviolet A (PUVA) therapy for psoriasis, which increases the risk of SCC eightfold; in some but not all patient cohorts it raises melanoma >14-fold (see Chapter 238).[61] Cancer is now increasing as a result of tanning beds. Individuals whose first sunbed exposure occurred as a young adult, or who had long durations or high frequencies of tanning bed exposure, already have a 70% higher risk of melanoma.[62]

CHARACTERISTICS OF ULTRAVIOLET RADIATION-INDUCED CANCERS AND PRECANCERS

In the United States, ~800,000 BCCs are diagnosed annually, as well as 200,000 SCCs and 70,000 melanomas.[11,12] Survival differs strikingly. Fewer than 1 in 10,000 BCCs will metastasize and threaten the patient (see Chapter 115). This number increases to 1 in 40 for SCC, with clinical experience indicating that SCCs on sun-exposed skin are less likely to metastasize than those arising in scars.[63] One in seven invasive melanomas is lethal (see Chapter 124). Merkel cell carcinoma (see Chapter 120) is a sun- and polyomavirus-induced cutaneous neuroendocrine cancer that will kill one in three patients diagnosed with it. Its reported incidence has tripled in the past 15 years to approximately 1,500 per year in the United States.[64,65]

The type of exposure preferentially leading to each malignancy differs. Cumulative lifetime sun exposure is strongly associated with SCC incidence.[16,20] BCC and AK instead seem to depend on reaching a certain threshold of UV exposure, often attained in youth, such that sensitive individuals develop BCC at a relatively early age, and the incidence does not increase with further exposure.[16,20,66] Case-control studies link melanoma with intense exposure early in life, with one or two blistering sunburns doubling the melanoma risk (see Chapter 124).[67]

Children are particularly sensitive to sunlight: moving from England to Australia before age 20 years confers the higher Australian incidence of AK, SCC, BCC, and melanoma, but the risk is much less when adults immigrate.[68,69] This is not simply due to children spending more time outdoors, as <25% of lifetime exposure occurs before age 18 years.[70] One explanation may be that mutant cells created in youth have more years in which to acquire the additional genetic requirements for cancer.

Precursor lesions for SCC (AK) and melanoma (nevi) are also usually related to sun exposure.[14,15,71–73] Accounting for roughly 3 million physician visits each year in the United States, AKs (see Chapter 113) are the fourth leading cause for a visit to a dermatologist.[74] They typically manifest as 1–3-mm scaly papules that involve erythema but often are easier felt than seen. They proceed to SCC in ~1% of cases if left untreated.[75] Actinic cheilitis is an analogous precancerous state on the sun-exposed lip. The importance of ongoing sun exposure is made apparent by clinical studies indicating that diminishing sun exposure can reduce the number of AKs over a span of months. In randomized sunscreen studies, statistically significant decreases in AKs were seen in the sunscreen group over brief periods.[76,77] Common nevi and especially clinically atypical nevi can be precursors of malignant melanoma, with abundant nevi conferring a tenfold risk for cancer.[22,78] Acquired melanocytic nevi begin to appear at age 1–5 years in proportion to sunlight exposure and are most frequent in individuals with freckles and red hair.[71,72,79] Acquired nevi typically carry the *BRAF* mutations seen in non-CSD melanomas, but congenital nevi instead have *NRAS* mutations.[80]

ULTRAVIOLET RADIATION-INDUCED GENETIC ALTERATIONS

ULTRAVIOLET RADIATION-INDUCED DNA DAMAGE AND REPAIR

DNA PHOTOPRODUCTS. The first molecular step in sunlight-induced carcinogenesis occurs when UVB photons induce DNA photoproducts (Fig. 112-1). UVB and UVC tend to be absorbed at the 5–6 double bond of pyrimidines (thymine and cytosine), allowing the bond to open.[81] If two adjacent pyrimidines are activated, their open bonds cross-react. This creates two single bonds (5–5 and 6–6) that result in a cyclobutane pyrimidine dimer (CPD; eFig. 112-1.1A in online edition). The most frequent is TT, but TC, CT, and CC cyclobutane dimers are also made. A single bond between the 6 position of one pyrimidine and the exocyclic group of the other instead creates a pyrimidine (6–4) pyrimidone photoproduct ((6–4)PP) (eFig. 112-1.1A in online edition).[82] The most frequent (6–4)PP is TC. Both photoproducts distort the DNA helix and are recognized by DNA repair enzymes. (6–4)PPs make the DNA helix more distorted, and thus are recognized and repaired much more rapidly than CPDs.[83,84] Half-lives of TT cyclobutane dimers and (6–4)PPs in human skin are 33 hours and 2 hours, respectively.[85] UVB induces 500 photolesions per 10^6 normal bases per J/cm^2 in human skin.[84]

Although there is 20-fold more UVA than UVB in sunlight, UVA requires up to 1,000-fold greater doses for some of its biological effects such as DNA damage.[45–47,86–88] Minimal erythemal doses (MEDs) at 300 nm (UVB) and at 360 nm (UVA) for skin type II are 25 mJ/cm^2 and 32,000 mJ/cm^2, respectively.[89] UVA induces T-containing cyclobutane dimers and lesser numbers of oxidized purines and pyrimidines and single-strand breaks.[84,90] UVA generates these lesions indirectly by photosensitization (see Chapter 90). UVA also efficiently photoisomerizes UVB-induced (6–4)PPs to their poorly repaired and highly mutagenic Dewar valence isomers[88,90] (eFig. 112-1.1A in online edition).

ULTRAVIOLET RADIATION-INDUCED MUTATIONS

UVR-damaged DNA contains characteristic "signature" mutations that are readily detected decades after sun exposure. These mutations have been used to answer many questions about the origin of cancer. A CPD can lead to a mutation in two ways (Fig. 112-2). When the lesion is copied during DNA replication, the DNA polymerase may read a damaged cytosine as a thymine and insert an adenine opposite it. At the next round of replication, the polymerase correctly inserts thymine across from adenine, with the result being a C→T substitution. Although the TT cylobutane dimer is the best known and most frequent photoproduct, the thymines are not mutagenic because the *XPV* gene encodes a specialized polymerase (pol eta) that adds adenines across from a T-containing cyclobutane dimer.[96,97] Alternatively, a mutation can arise because cyclobutane dimers accelerate spontaneous deamination of their cytosines to uracil (eFig. 112-1.1C in online edition), leading to a C→T substitution; no polymerase error is involved.[98] Deamination of cytosines to uracil within photolesions is increased at the transcribed strand, presumably mediated by persistent stalling of the transcription complex at the photolesion.[99] In either case, C→T mutations occur only where a cytosine lies next to a thymine or another cytosine, because the major UV photoproducts join adjacent pyrimidines. If two adjacent cytosines mutate, the result is CC→TT. This distinctive pattern of mutation, C→T where the C lies next to another pyrimidine, including CC→TT, is unique to UVR and is called the *UV signature mutation*.[100]

UV signature mutations (Table 112-1) provide a tool for deducing backward from mutations found in tumors to the original carcinogen. Nearly all experimentally created UVB or UVC mutations are located at adjacent pyrimidines, and about two-thirds are signature mutations.[100] The remaining third, typically G→T and T→C substitutions or one to two base insertions or deletions, are still caused by UV but probably arise

TABLE 112-1
Ultraviolet Radiation-Induced Mutation Patterns

Classical UVB signature mutations	C→T (CC→TT) at dipyrimidine sites
Oxidative mutations (could be induced by UVA)	G→T
UVA signature mutations	T→G
PUVA-type mutations	Mutations at the T of TA, TG, or TT sites

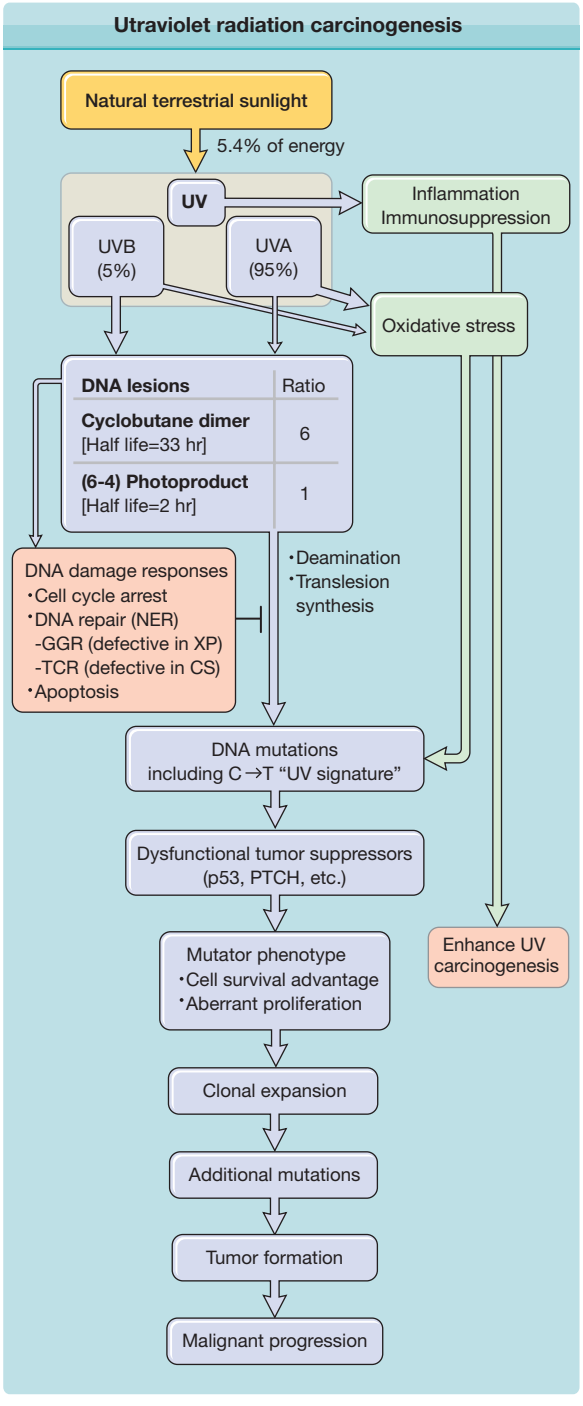

Figure 112-1 Ultraviolet radiation (UVR) carcinogenesis. UVR induces two major DNA lesions at dipyrimidine sites: cyclobutane pyrimidine dimers (CPDs) and pyrimidine (6–4) pyrimidone photoproducts [(6–4)PPs]. Ratio given [6 CPDs per 1 (6–4)PP] is that induced by simulated sunlight. UVB accounts for only 5% of UVR (~0.3% of all terrestrial sunlight energy), but produces the majority of UV-induced DNA lesions. Cells respond to UVR-induced DNA damage by activating DNA damage signaling pathways and inducing cell cycle arrest. Damaged DNA is repaired by nucleotide excision repair (NER), whose subpathways are global genome repair (GGR; defective in xeroderma pigmentosum, XP) and transcription-coupled repair (TCR; defective in Cockayne's syndrome, CS). Despite their DNA repair deficiency, individuals with CS exhibit no increased incidence of UV-induced skin cancer, likely due to enhanced intracellular accumulation of p53 and apoptosis. (6–4)PPs are rapidly repaired by NER. Unrepaired DNA lesions lead to genetic mutations through deamination or error-prone translesion synthesis. Unrepaired cytosine-containing CPDs contribute to UV signature mutation: C→T transition. Mutations in genes responsible for carcinogenesis confer mutator phenotype including resistance to apoptosis. Clonal expansion of mutant cells increases opportunities to receive additional mutations for tumor development.

indirectly by photosensitization-produced reactive oxygen species. G→T transversion can be caused by incorporation of adenine opposite 8-hydroxy-2′-deoxyguanosine (8-OHdG; also called 8-oxo-7,8-dihydro-2′-deoxyguanosine (8-oxo-dG)) (Fig. 112-2),[101,102] a common oxidative DNA lesion that remains at a high level in the epidermis even 7 days after UVR exposure.[103] Because this oxidative class of damage can be caused by many carcinogens, these mutations do not reveal whether their source was UVB, UVA, tobacco smoke, or intracellular oxidative phosphorylation. However, tumors carrying classic UV signature mutations must also contain UV-induced oxidative mutations. UVA, in contrast, only weakly induces UVB signature mutations by photosensitization but also generates oxidation-like mutations and T→G changes. The latter are rare with UVB or other carcinogens and have been proposed to be a UVA fingerprint,[104,105] although the mechanism of induction of T→G mutations remains unclear.

Although (6–4)PPs are rapidly repaired, they are mutagenic if they remain unrepaired. Error-prone DNA polymerases add a guanine opposite a thymine of (6–4)PP, resulting in a T→C mutation (Fig. 112-2).[106]

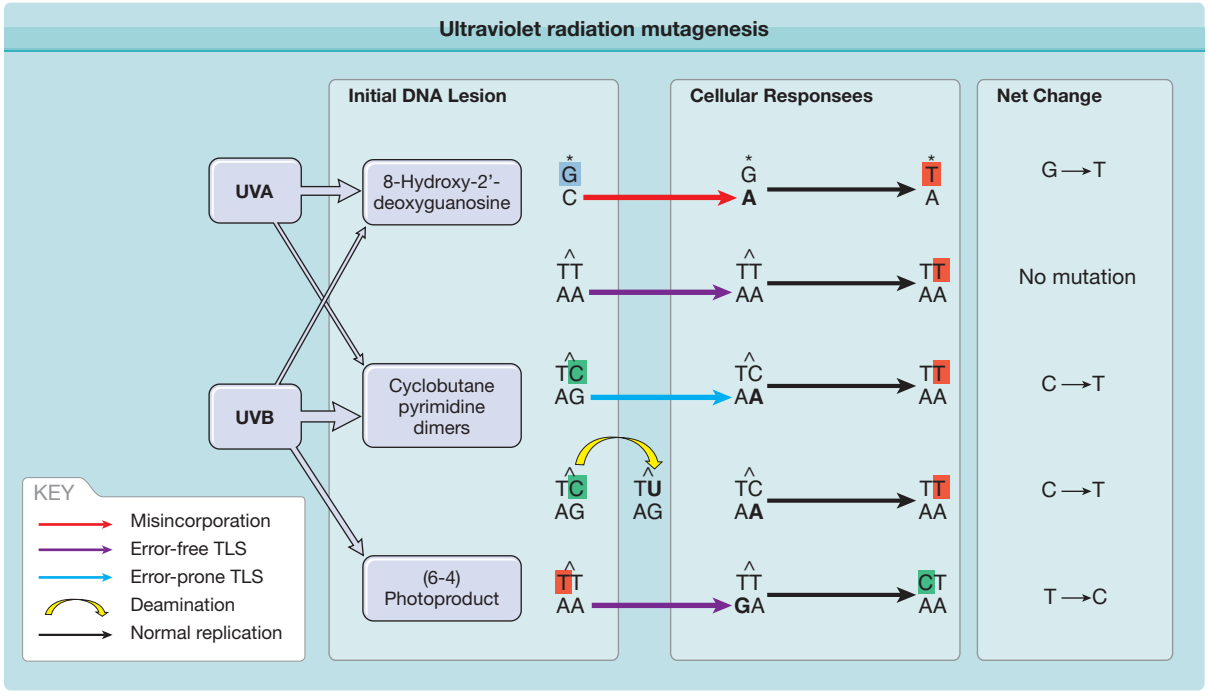

Figure 112-2 Ultraviolet radiation mutagenesis: how replication through unrepaired DNA lesions leads to DNA mutation. Cyclobutane pyrimidine dimers (CPDs) are the most relevant DNA lesions for UV mutagenesis and are primarily induced by UVB. Thymine cyclobutane dimers are most abundant but not mutagenic, because error-free translesion synthesis (TLS) correctly adds adenines opposite a thymine dimer. Cytosines within CPDs are mutagenic: error-prone TLS mistakenly adds adenine opposite cytosine, or deamination converts cytosine to uracil. This leads to the UV signature mutation, a C→T transition. The (6–4) photoproduct induced by UVB and 8-hydroxy-2′-deoxyguanosine induced by oxidative stress via UVA are also mutagenic but relatively rare.

p53

UV signature mutations identified *p53* as critical for preventing SCC and BCC but not melanoma.[100,107] The p53 protein is a transcription factor that controls genes involved in the cell cycle, apoptosis, and DNA repair; it also acts directly on apoptosis proteins.[7] The *p53* gene is mutated in about one-half of all human cancers and is termed a *tumor suppressor gene* because cancer arises from losing its normal function rather than gaining an abnormal function as for oncogenes. Over 90% of SCC in US patients contain these mutations, as well as three-fourths of AK.[108] Although nearly all BCCs overexpress p53 protein, only half carry *p53* mutations. Each mutation changes the amino acid, indicating that the mutation was selected for and contributed to tumor development, rather than being simply an indicator of sun exposure. These *p53* mutations are most frequent at nine mutation hot spots in important functional regions of the protein. Compared to internal cancers, some skin cancer hot spots are displaced several nucleotides to lie at a site of adjacent pyrimidines.[107] Some sites may be hot spots because repair is slower there.[109] Other skin hot spots, like internal cancer hot spots, lie at 5-methylCG sites where body temperature slowly deaminates 5-methylcytosine to thymine; UVR accelerates this process.

The *p53* mutations in AK indicate that these dysplasias are clonal; patients with multiple AKs have different mutations in discrete skin lesions.[108,110,111] The similarity of AK and SCC mutations supports the idea that AKs can progress to SCC. SCCs have more oxidative mutations than AKs, implying the involvement of oxidative stress in progression of AK toward SCC.[105] Aggressive skin tumors from patients exposed to both sun and chemicals contain multiple distinct *p53* mutation patterns, as if several tumors arose in an abnormal field and intermingled.[112] XP tumors contain very frequent CC→TT mutations, perhaps because slow repair allows more time for cytosine deamination.[113,114] Double-base mutations are also seen in conjunctival SCC, a tumor associated with human immunodeficiency virus (HIV) in sunny areas.[115] Sunscreens reduce the level of UV signature mutations.[116] In contrast, arsenic-induced BCC and SCC have non-UV *p53* mutations; *p53* mutations in BCCs from sun-shielded body sites resemble those seen with oxidative damage.[117,118] UV signature mutations in *p53* can also be seen in Merkel cell carcinoma.[119]

Sunlight mutates *p53* early.[108,120] Normal sun-exposed skin carries ~60,000 clones of p53-mutant keratinocytes, three to 3,000 cells in size.[121] By hematoxylin and eosin staining, the cells in these mutant clones appear completely normal.[44] The early appearance of *p53* mutations makes it possible to trace lineages in tumor development. Microdissecting lesions containing AK, carcinoma in situ, and SCC reveals that each stage contains the same *p53* mutation.[122] Although this result shows that each stage arose from

the same founder lesion, it does not show that the stages derived from each other. To show a lineage, it is necessary to find additional mutations that appear in succession. In microdissected BCCs, one *p53* mutation is present throughout the tumor, with various second mutations in different regions of the tumor.[123] Once both *p53* alleles are mutated, the cell is prone to aneuploidy,[124,125] increasing the likelihood of a mutator phenotype.

HEDGEHOG PATHWAY. Most sporadic BCCs have inactivating mutations in the *PTCH* tumor suppressor gene, a part of the hedgehog pathway (see Chapter 115); the remainder has activating mutations in its target, *SMO*. The hedgehog pathway appears to be a "gatekeeper" for basal cell carcinogenesis, needing to be mutated early in BCC: minute BCCs have *PTCH* mutations, as do all histological subtypes; no BCCs have loss on other chromosomes without involvement of *PTCH*; and a congenital lesion that can progress to BCC, the sebaceous nevus, has *PTCH* allelic loss in 40% of cases.[126–128]

In sporadic BCCs, about three-fourths of *PTCH* mutations are UVR-like (either UV signature mutations or the expected UVR-induced oxidative mutations) and a further 15% are 1- or 2-base insertions or deletions, often adjacent to a C→T at a dipyrimidine site.[129] BCCs from XP patients contain UVR-like *PTCH* and *SMO* mutations, with CC→TT mutations overrepresented.[130,131] About 20% of the mutations in sporadic BCCs are not UVR-like and resemble germline mutations seen in basal cell nevus syndrome patients—deletions or insertions larger than two base pairs. This finding may relate to the clinical observation that one-third of BCCs occur on parts of the body that are not chronically sun-exposed, as well as the correlation between truncal BCC and defects in the glutathione radical-scavenging system (see Section "Genetic Risk Factors for Ultraviolet Radiation Carcinogenesis"). *PTCH* mutations tend to code for stop codons or frameshifts that completely inactivate the protein. In hereditary BCCs, nearly all tumors arose after losing the normal allele. This allelic loss appears related to sunlight, as NBCCS tumors are most frequent on sun-exposed skin and are rare in blacks.[39] UVB rarely causes this type of large genetic rearrangement so, in analogy to X-ray sensitivity of NBCCS patients, UVA-photosensitized reactive oxygen may be important.

PSORALEN AND ULTRAVIOLET A LIGHT TUMORS. (See Chapter 238.) In psoralen-treated cells, UVA forms adducts at TA, TG, or TT sequences, as well as cross-links between the two DNA strands at these sites. In human PUVA-induced keratoses, SCCs, and BCCs, about one-fourth of mutations in *p53* or *HRAS* are psoralen-like mutations at the T of TA, TG, or TT; this proportion increases as the PUVA dose increases.[132,133] However, the majority of mutations are UV signature mutations. The UVR-like mutations could have arisen from the UVA in PUVA, UVB treatment for psoriasis, or environmental UVB.

MELANOMA MUTATIONS

(See Chapter 124.)

Despite the correlation between melanoma and sunlight and the fact that UVB signature mutations are present in melanoma,[134,135] genes with UV signature mutations for melanoma development are not prevalent. The *CDKN2A* locus is frequently mutated or deleted in familial and sporadic melanoma. Its two distinct tumor suppressor proteins, INK4A (also known as p16) and ARF, inhibit cell cycle progression via Rb and p53, respectively. INK4A inhibits CDK4/6's inactivation of the retinoblastoma protein, Rb. ARF inhibits MDM2-mediated degradation of p53. Germline mutations in *CDKN2A* are observed in ~25%–40% of familial melanomas.[136,137] In sporadic melanoma, allelic loss of *CDKN2A* is more common than the rare *INK4A* inactivating mutations[138–140] or inactivation of *INK4A* by promoter methylation.[141] The role of sunlight in these genetic events is unknown.

Oncogene mutations are found in the RAS-BRAF-MEK-ERK mitogen-activated protein kinase (MAPK) signaling pathway. This signaling cascade is normally activated on growth factor stimulation, and its sequential phosphorylation regulates cell proliferation and differentiation. Activating mutations in MAPK signaling remove the growth factor requirement. *RAS* mutations are present in 10%–20% of melanomas and have been correlated with UVR exposure.[142–144] The most prevalent *RAF* mutation in melanomas, the *BRAF* V600E point mutation, renders the kinase constitutively active and enhances ERK activation.[142] This mutation is present in ~80% of acquired melanocytic nevi, suggesting a potential early role of BRAF in melanoma development.[144] The V600E mutation is not UVR-like and is associated with intermittent sunlight exposure.[27,29]

ULTRAVIOLET RADIATION-INDUCED STEPS IN CANCER AND CANCER PREVENTION

Skin tumors arise on a background of sun-damaged skin. To prevent sun damage, the skin reacts to acute and chronic UVR exposure by multiple stress responses.

CELLULAR RESPONSES

APOPTOSIS. UV signaling generates sunburn cells—basal and suprabasal keratinocytes with dense, pyknotic nuclei and intensely eosinophilic cytoplasm.[175] This apoptotic morphology is accompanied by pathognomonic DNA double-strand breaks and cleaved caspase 3. UVR-induced apoptosis requires signals from both DNA damage and the cytoplasm: DNA photoproducts in active genes trigger p53 and its regulator MDM2,[108,176] but apoptosis also requires JNK and is partially blocked by antioxidants.[177,178] Although TNF-α is required, injecting TNF-α does not lead to sunburn cells, so UV-induced cytoplasmic signaling is not sufficient.[179,180] In fibroblasts, keratinocytes, or melanocytes

with normal p53 and irradiated with physiologic UVB or UVC doses, apoptosis proceeds through the intrinsic mitochondrial pathway rather than the death-receptor/caspase 8 pathway.[178,181]

Apoptosis then prevents cancer by removing UVR-damaged cells in a process termed "cellular proofreading".[182] Mice accumulate mutations at a rapid rate if they are defective in apoptosis due to a defect in *p53* or Fas ligand, or due to overexpressing the anti-apoptotic protein Survivin.[165,183,184] In Survivin's case, this increases SCC.[184] The epidermal hyperplasia that occurs several days after UVR exposure may replace cells lost by apoptosis or may remove additional damaged or mutant cells by desquamation. The signal for hyperplasia involves both DNA photoproducts and the epidermal growth factor receptor.[185] UVA inhibits UVB-induced apoptosis, suggesting that UVA may enhance UV carcinogenesis by disrupting elimination of UV-damaged cells.[186]

Dermal fibroblasts have a critical role in maintaining appropriate UVR responses of epidermal keratinocytes. The insulin-like growth factor 1 (IGF-1) secreted by normal human fibroblasts is required for appropriate induction of senescence of keratinocytes after UVR. UV-induced senescence protects keratinocytes from propagating UVR-induced mutations. In human geriatric skin, expression of IGF-1 is decreased in dermis and the aged keratinocytes proliferate in the presence of UV-damaged DNA, possibly leading to an increased carcinogenic potential in the skin of older individuals.[187]

STEM CELL POPULATIONS. In chronically UVB-exposed human skin, *p53*-mutant clones are found at both sites of epidermal stem cells (see Chapter 45): the hair follicle, whose bulge region contributes to follicle development and transiently to wound repair, and the interfollicular epidermis, which maintains epidermal homeostasis and can also generate follicles.[121,188,189] SCCs are thought to originate in interfollicular epidermis, whereas histologic evidence and the expression pattern of PTCH indicate that BCCs originate in the follicles.[190,191] Hedgehog signaling through PTCH is crucial for maintaining skin stem cell populations and for regulating hair follicle and sebaceous gland development.[192] Chronically UV-irradiated human or mouse skin contains scattered basal cells with unusually high levels of DNA photoproducts.[193] The tumor promoter TPA (12-*O*-tetradecanoylphorbol 13-acetate), which induces skin stem cells to proliferate,[194] causes these cells to disappear and be replaced by clusters of *p53*-mutant keratinocytes. This behavior resembles that of stem cells that are quiescent and poorly repaired, at least on the parental DNA strand, until triggered to divide.[195] The immortalization-promoting enzyme telomerase is normally present only in the epidermal basal layer, but is elevated in sun-exposed skin, skin precancers, and cancers.[196,197]

CLONAL EXPANSION OF MUTANT CELLS. A single mutant cell must clonally expand to reach a clinically discernible size. Less obviously, clonal expansion facilitates the multiple genetic hit mechanism of cancer. Physiologic UVR doses create mutations at a frequency of ~10^{-4}/gene per cell division.[198] The specific mutations needed to activate an oncogene are infrequent. Spontaneous mutations, which reflect errors by the replication machinery or DNA damage due to body temperature, are also rare, on the order of 10^{-5}/gene per cell division.[198] The probability of mutating five genes, such as an oncogene and both alleles of two particular tumor suppressor genes, is then at best 10^{-20}. Accounting for the 60% lifetime expectation of skin cancer in Australia solely in terms of simultaneous genetic hits in one cell is impossible. In contrast, clonal expansion increases by 1,000-fold the number of targets for the next mutation.

A stem cell's clonal expansion is normally limited to its stem cell compartment.[199] Sunlight is a key driver of clonal expansion beyond this point. The *p53*-mutant clones in human skin are larger in chronically sun-exposed skin.[121] In mice, *p53*-mutant clones stop growing and regress when UVB treatment ends, indicating that clone expansion is due to an ongoing UVR-induced physiologic event rather than an irreversible mutation.[199,200] One of these physiologic events is UVR-induced apoptosis.[184] Once a *p53* mutation arises, the cellular proofreading mechanism backfires: subsequent UVR exposures eliminate damaged normal cells but spare apoptosis-resistant mutants. An apoptosis-resistant mutant is no longer restrained within its stem cell compartment and escapes to colonize the adjacent apoptosis-sensitive compartment. Repeating this process further enhances clonal expansion. AKs also often regress once irradiation stops,[201,202] but SCCs do not, indicating that invasive tumors no longer need a promoter. Apoptosis thus has diverse effects on the stages of skin cancer progression: it prevents new *p53* mutations from initially arising, facilitates the expansion of *p53*-mutant clones and papillomas (via death of apoptosis-capable cells adjacent to mutant clones), and suppresses the mutations that convert a papilloma to SCC.[165,184]

CELL–CELL COMMUNICATION

Cell–cell interactions prevent abnormal cells from proliferating inappropriately. In human autotransplant experiments, BCCs transferred from their original site regressed—suggesting that an abnormal underlying dermis is required for the tumor to persist.[203] Dermal fibroblasts suppress transformed keratinocytes by secreting transforming growth factor-β that induces squamous differentiation.[204] Normal keratinocytes also suppress their transformed neighbors, and UVR interferes with these signals. Normal human keratinocytes eliminate adjacent transformed keratinocytes (mutated in *p53* and *HRAS*) by inducing cell cycle arrest and differentiation.[205] Physiologic doses of UVB cause apoptosis and differentiation in the normal cells, but not in the transformed keratinocytes, allowing the latter to clonally expand.[206] Other intercellular signals are mediated by integrins—membrane receptors for extracellular matrix proteins such as collagen ($\alpha_2\beta_1$ integrin), laminin ($\alpha_3\beta_1$), and fibronectin ($\alpha_5\beta_1$). In keratinocytes,

integrins bound to such ligand provide a "do not differentiate" signal through MAPK pathways, suppressing keratinocyte apoptosis, and allowing a stem cell pool to be maintained.[207,208] Integrin receptors are often dysregulated in tumors. UVB irradiation downregulates the β_1 integrin subunit. UVA downregulates the gap junction communication protein connexin 43, resembling the action of the tumor promoter TPA.[209,210]

Melanocyte proliferation is normally regulated by keratinocytes via cell–cell adhesion receptors such as E-cadherin, P-cadherin, and desmogleins; these receptors are lost in vertical growth phase melanomas.[211] UVR stimulates keratinocytes to secrete endothelin-1, which then downregulates melanocyte E-cadherin and upregulates N-cadherin.[212] This E- to N-cadherin switch diverts melanocyte interactions away from keratinocytes and toward fibroblasts and melanocytes.[211] Endothelin also downregulates the α_6 integrin subunit,[213] upregulates the $\alpha_v\beta_3$ and $\alpha_2\beta_1$ integrins that anchor melanocytes to dermal collagen and are associated with vertical growth phase melanoma, inhibits gap junction communication by phosphorylating connexin 43, and activates metalloproteinases associated with basement membrane invasion.

IMMUNE SURVEILLANCE

In humans, the primary evidence cited for immune surveillance in preventing UVR-induced skin cancer is the 10–20-fold increase in AK and SCC on previously sun-exposed skin in transplant patients receiving chronic immune suppression to prevent organ rejection. In one Australian study, 27% of deaths in a heart transplant cohort were due to skin cancer.[214] The increase begins months to a few years after immune suppression is initiated, and both the AKs and SCCs are unusually aggressive.[215–219] Melanomas are also increased.[220] Several lines of evidence complicate the data that support a role for immune surveillance. Cyclosporine promotes tumor growth in vitro and in immune-deficient mice in which there is no immune system to be suppressed.[221] Azathioprine, often a component of organ rejection therapy, is a mutagen when followed by UVA irradiation.[222] It may thus not only be working via immune suppression. HIV patients do have a modestly increased incidence of SCC, but these tumors at sun-shielded sites are associated with human papillomavirus (HPV).[223] Skin cancers are often said to develop in patients who are immunodeficient due to leukemia or lymphoma. Complicating interpretation, these patients have often received cyclophosphamide, a known mutagen. Most published reports lack controls or patient data, but an eightfold elevation in chronic lymphocytic leukemia seems valid.[224,225]

Merkel cell carcinoma, in part caused by a virus and by UV, appears to be truly sensitive to immune function. Its incidence increases tenfold not only in solid-organ transplant recipients but also in HIV patients (~13-fold) and in chronic lymphocytic leukemia (over 30-fold increase) (see Chapter 120). The chance of metastasis and mortality also increases in all types of immunosuppressed patients. Regardless of why immunosuppressed patients are at increased risk of skin cancer, it is critical that they be monitored closely because, when caught early, even tumors in immunosuppressed patients are curable.

GENETIC RISK FACTORS FOR ULTRAVIOLET RADIATION CARCINOGENESIS

PIGMENTATION AND INITIAL DAMAGE

Melanin has a large role in resistance to skin cancer. The Fitzpatrick skin phototypes are determined not only by baseline pigmentation but also by a person's response to UVR (always burns, tans easily, or rarely burns). This simple UVR skin response scale can account for up to a 100-fold difference in susceptibility to skin cancers.[263] Similarly, the many molecular etiologies of oculocutaneous albinism, which result in a deficiency of normal melanin, markedly increase the risk of skin cancer (see Chapter 73). Increased skin cancer among albinos is mostly nonmelanoma skin cancer, but melanomas seem elevated as well.[264] Another hereditary risk factor, red or blonde hair, is now understood at a molecular level as commonly caused by polymorphisms in the melanocortin 1 receptor (see Chapter 72).[265] This receptor is a G-protein coupled receptor that binds melanocyte-stimulating hormone and functions at a key point in melanogenesis. Certain mutations in this receptor render it insensitive to normal pigmentation signals, resulting in pheomelanin instead eumelanin. This is an important distinction in terms of skin cancer prevention. Red or yellow pheomelanin is a markedly less effective free radical scavenger; indeed, UVR-exposed pheomelanin is degraded with a net formation of superoxide.[42,266] Therefore, pheomelanin can act as a photosensitizer, even inducing apoptosis in nearby cells.[43] Decreased protection and increased damage from pheomelanin in the epidermis may partly underlie the markedly increased risk of skin cancer associated with red-haired individuals.

Reactive oxygen species are largely absorbed by radical scavengers, such as glutathione, before they cause significant membrane or DNA damage. Specific polymorphisms in the genes for glutathione *S*-transferase confer a twofold risk for truncal (minimally sun-exposed) AK, SCC, and BCC.[267] This genetic risk increases to sixfold in patients with high sun exposure and 12-fold in sun-exposed transplant patients.

DNA REPAIR AND APOPTOSIS

Xeroderma pigmentosum (XP; see Chapters 110 and 139) highlights the association between DNA repair capacity and skin cancer. Although defects in any of the XP genes result in some defect in NER, the severity of the XP disorder—number of skin tumors and life expectancy—correlates with DNA repair capacity.[95,268] The correlation between repair capacity and cancer incidence is also present in the general population.

Patients with AK have a 30%–50% reduced excision repair in their normal fibroblasts or lymphocytes.[269–271] Cells from BCC patients have reduced excision repair compared to cells from control individuals.[272] These data suggest that relatively subtle variability in DNA repair capacity contributes to an individual's risk of developing skin cancer.

VIRAL SENSITIVITY

In the rare inherited sensitivity to HPV infection termed *epidermodysplasia verruciformis* (see Chapter 196), roughly one-half of patients will develop SCC. These SCCs are typically on sun-exposed body sites and occur decades earlier than in the general population.[273] HPV may be important in UV carcinogenesis in immunosuppressed transplant patients, as it is detected twice as frequently in SCCs from these patients as in immunocompetent controls.[274]

PREVENTION

The potential of education and sunscreen to control skin cancer remains largely unproven due to the long latency between sun exposure and skin cancer appearance. In contrast, it is clear that adult sunscreen use can reduce AK by twofold.[76,77] Randomized studies of school children who aggressively applied sunscreen indicate that common nevi can be reduced.[275] A regimen of sun protection longer than the typical 2- to 4-year study would likely decrease nevi and subsequent melanoma risk more impressively. Encouraging data are emerging from Australia where education campaigns, covered sidewalks, and covered playgrounds at schools have led to a stabilization of the incidence of nonmelanoma skin cancers.[9] Excitingly, the efficacy of such campaigns is also highlighted by reduced melanoma rates in Australia, particularly in younger age groups.[276] Clearly, an effective campaign to reduce skin cancer needs to begin with school-age children. This is due to the combined factors that children younger than the age of 18 years spend a significant portion of their time in outdoor recreation, and sun damage sustained early in life has more time to contribute to UV carcinogenesis.

One could ask "how much sun is too much?" The answer will vary immensely depending on many factors such as pigmentation, whether sun exposure occurs in modest doses or large exposures, the immune status of the individual, and subtle differences in DNA repair capacity. Avoiding erythemal doses of UV may not be sufficient for preventing skin carcinogenesis, because much lower doses than 1 MED can induce genetic mutations, immunosuppression, and skin cancers.[277] Although highly controversial, there may be some benefit to sun exposure. Several studies have suggested twofold better survival after a diagnosis of invasive melanoma among patients with extensive sun exposure as compared to those with less exposure.[278] A potential explanation is greater vitamin D synthesis induced by UVR, because the antiproliferative and prodifferentiation effects of vitamin D have been demonstrated in melanoma cell lines *in vitro*. However, no association between vitamin D intake and melanoma risk was found in a recent human epidemiological study.[279]

NOVEL THERAPEUTIC APPROACHES

Despite the use of sunscreens and public awareness of the effects of long-term exposure to UVR, the incidence of both melanoma and nonmelanoma skin cancers continues to increase. This has led to investigation of novel chemopreventive agents that interfere with the development of cancer through diverse mechanisms. Perhaps the most important recent advance in this area is the use of imiquimod (see Chapter 221), an activator of the innate immune system through the TLR7 receptor. Imiquimod has recently been approved for treating AKs and superficial BCCs, and reports of imiquimod effects also exist for atypical melanocytic proliferations such as lentigo maligna.[280]

In terms of foods, coffee and tea appear to have chemopreventive activity. Orally administered green or black tea reduces UVR-induced skin cancers in mice to less than one-half of control levels.[281,282] Polyphenols and caffeine appear to be the major chemopreventive components. Oral administration of green tea polyphenols enhances IL-12 production, decreases UV-induced DNA lesions, and reduces subsequent inflammation and UV tumorigenesis.[283] Topical applications of caffeine or (–)-epigallocatechin gallate (EGCG), a major polyphenol in tea, were similarly effective in suppression of UV carcinogenesis in mice.[284] The protective effect of caffeine is attributed to its ability to augment apoptosis after UV irradiation via ATR-Chk1 pathway inhibition.[285,286] Precancerous, UV-damaged cells are more dependent on the ATR-Chk1 pathway, hence its inhibition by caffeine promotes elimination of these damaged cells. Moreover, caffeine and green tea polyphenols have a sunscreen effect that blocks UV-induced cyclobutane dimer formation when the compound is applied topically before UVR.[287,288] Human epidemiological studies showed that caffeine intake in coffee or tea decreases the risk of skin cancer development while de-caffeinated beverages had no such effect.[289–292] Each daily cup of caffeinated coffee was associated with a 5% reduction in nonmelanoma skin cancer among 93,676 Caucasian women.[291]

Topical application of sulforaphane-containing broccoli sprout extracts to mice showed a decreased incidence of UV-induced skin cancers. Sulforaphane possibly acted as an antioxidant.[293] Dietary feeding of proanthocyanidins extracted from grape seeds suppresses UV carcinogenesis in mice, associated with decreased tissue fat level.[294]

Low-fat diets have been well studied as an approach to preventing skin cancer. Animal studies have shown that high-fat diets shorten the time between UVR exposure and tumor formation and markedly increase the number of tumors per animal.[295] In human trials of patients with nonmelanoma skin cancer, restricting

calories from fat reduced the appearance of AKs by two-thirds and the development of new nonmelanoma skin cancers by one-half.[296,297] Although association of increasing total fat intake with overall risk of BCC and SCC is still controversial, a recent prospective study showed that high intakes of total fat increase the risk of developing SCC, but not BCC, among people who have a history of skin cancer.[298]

Retinoids inhibit UVR-induced AP-1 activation that contributes to human skin cancer progression, and they have been examined in several clinical trials for chemoprevention in individuals at high risk of developing nonmelanoma skin cancers.[299] One clinical trial demonstrated that daily supplementation of retinol lowered the incidence of SCC, but not BCC.[300]

Glycolic acid, derived from fruit and milk sugars, has been used as a cosmetic ingredient. It inhibits UV tumorigenesis in mice, by decreasing expression of the cell-cycle regulatory proteins.[301]

Chronic UVB exposure induces inflammatory responses that have been linked to tumor formation. Inflammation induces cyclooxygenase enzymes and prostaglandins. Because prostaglandins promote keratinocyte proliferation and block differentiation, inhibiting prostaglandin formation is expected to be chemoprotective. Topical application of a nonsteroidal anti-inflammatory drug (Diclofenac) is effective in treating AKs, with 50% of target lesions resolving after Diclofenac treatment versus 20% in placebo.[302] Celecoxib, a systemic inhibitor of cyclooxygenase 2, inhibits the development of UVR-induced skin tumors in mice by twofold.[303,304] Given the cardiovascular side effect profile of systemic cyclooxygenase 2 inhibitors, it is unlikely they will be developed for this indication.

An inducible repair process has been observed using DNA oligonucleotides that share sequence with the telomere.[305] In animal models and cell culture, these oligonucleotides can initiate multiple cellular responses, including melanin production and p53 activation, apparently in the absence of DNA damage. Topical application of these oligonucleotides to UV-irradiated mice diminished UVR-induced mutations and malignant lesions by fourfold.[306] If a therapeutically appropriate mechanism can be devised to activate this pathway, it may have utility in reversing DNA damage and preventing malignancies.

A recent development in the area of chemoprevention is the ability to augment normal DNA repair pathways. If one could increase DNA repair capacity, the mutations, chromosomal aberrations, and cell death known to be causal for skin tumors should be reduced. The most direct application of this concept is the use of a viral enzyme (T4 endonuclease V) capable of recognizing cyclobutane dimers and accelerating the initial incision step of the NER pathway. This enzyme has been formulated into a liposomal preparation, allowing penetration into the relevant layers of skin. Indeed, studies in XP patients have shown efficacy in decreasing the residual DNA damage as well as the number of AKs.[307] Also, cyclobutane dimers could be repaired by a photolyase that is absent in humans but found in certain animals and converts cyclobutane dimers to their original monomers by photoreactivation. Indeed, cyclobutane dimers were removed from UV-irradiated human skin by topical application of an encapsulated photolyase.[308] Transgenic mice that ubiquitously express the photolyase that can reverse CPDs showed marked inhibition of UV-induced skin cancers, suggesting that rapid removal of UV-induced CPDs is a powerful way to protect skin from UV carcinogenesis.[241] There are thus diverse emerging approaches by which chemopreventive therapies may increasingly serve as an adjunct to classical UVR protection with sunscreens and avoidance of UVR exposure to skin.

SECTION 21

Epidermal and Appendageal Tumors

Chapter 113 :: Epithelial Precancerous Lesions

:: Karynne O. Duncan, John K. Geisse, & David J. Leffell

A precancerous or premalignant lesion is one that has a strong likelihood of transforming into a malignancy. There is much debate about the validity of the concept of precancerous lesions, and the terminology has been confusing.[1–4] Lesions discussed in this chapter are those that have a clinically demonstrated potential to become invasive carcinomas and are characterized by histologic atypia confined to the epidermis. The focus is only on the precancerous keratinocyte lesions and not on those of other epithelial cells such as the melanocyte, Merkel, and appendageal cells. Discussion of malignancies and premalignancies associated with these cells can be found in (Chapters 119, 120, and 123) respectively.

A common feature of all premalignant keratinocyte tumors (Table 113-1) is that they have the potential to become invasive squamous cell carcinoma (SCC). These precancerous lesions and SCC are considered by many to represent a continuum of disease with dysplasia at one end of the spectrum and invasive carcinoma at the other.

ACTINIC KERATOSES AT A GLANCE

- Precancerous lesions on a spectrum from photodamaged skin to squamous cell carcinoma (SCC).
- Strongest predictors of subsequent development of nonmelanoma skin cancer and melanoma.
- Risk factors include individual susceptibility, cumulative ultraviolet (UV) radiation exposure, immunosuppression, prior history of skin cancers, genetic syndromes.
- Long-term and cumulative UV radiation exposure is the most important contributing factor for development of actinic keratoses (AKs).
- Risk of progression of AK to SCC varies from less than 1%–20%.
- AKs should be treated because their course is unpredictable, they are often symptomatic, and they can progress to SCC if untreated.
- Treatment methods include cryotherapy, curettage with or without electrosurgery, shave excision, topical agents, and photodynamic therapy.

ACTINIC KERATOSES

Actinic keratoses (AKs) or solar keratoses are cutaneous neoplasms consisting of proliferations of cytologically abnormal epidermal keratinocytes that develop in response to prolonged exposure to ultraviolet (UV) radiation. The concept of a precancerous keratosis was first presented by Dubreuilh in the late 1800s.[5] AKs were first identified and named *keratoma senilis* by Freudenthal in 1926.[6] In 1958, Pinkus further characterized these lesions and coined the term *actinic keratosis*.[7] These lesions have also been called *solar keratoses* and *senile keratoses*. *Actinic keratosis* literally means a condition (*-osis*) of excessive horny (*kerat-*) tissue induced by a ray of light (*aktis*), presumably UV light. AKs have historically been considered precancerous or premalignant lesions with a potential for developing into SCCs. However, in recent years there has been an effort to redefine AKs as malignant neoplasms, because these lesions are essentially intraepithelial SCCs in evolution. Although not all AKs become SCCs, AKs are the initial lesion in a disease continuum that may progress to SCC. This concept of a progression along a spectrum is analogous to that of cervical carcinoma, for which cervical intraepithelial neoplasia (CIN) is the initial, "precancerous" lesion.[8]

AKs are clinically important lesions, not only because of their potential to develop into SCC, but because they are one of the strongest predictors that an individual may subsequently develop melanoma or nonmelanoma skin cancer (NMSC).[9–11] With the increasing incidence and prevalence of melanomas

TABLE 113-1
Precancerous Keratinocytic Lesions

- Actinic keratoses (AKs)
- Arsenical keratoses (ArKs)
- Thermal keratoses (TKs)
- Hydrocarbon keratoses (HKs)
- Chronic radiation keratoses (CRKs)
- Reactional keratoses (RKs)
- PUVA keratoses
- Viral-associated precancerous keratinocytic lesions
  - Bowenoid papulosis (BP)
  - Epidermodysplasia verruciformis (EV)
- Bowen disease (BD) or squamous cell carcinoma (SCC) in situ
- Precancerous lesions of the lower anogenital tract
  - Vulvar intraepithelial neoplasia (VIN)
  - Anal (AIN) and perianal (PaIN) intraepithelial neoplasia
  - Penile intraepithelial neoplasia (PIN)
- Potentially malignant disorders of the oral cavity
  - Leukoplakia
  - Erythroplakia

PUVA = psoralen plus ultraviolet A radiation therapy.

and NMSCs (discussed in Chapters 114, 115, 123, and 124), persons with AKs are the perfect candidates for careful longitudinal observation for prevention of cutaneous malignancy and early intervention.

EPIDEMIOLOGY

A joint project of the American Academy of Dermatology Association (AAD) and the Society for Investigative Dermatology (SID) reported that in 2004 the prevalence of AKs in the United States was 39.5 million, the estimated annual costs were $1.04 million, and that AKs accounted for more than 10% of all dermatology visits.[12] AKs are second only to acne vulgaris as the most common reason for patients to visit a dermatologist and it is estimated that almost all persons over the age of 80 have AKs.[13]

Various risk factors have been identified for the expression of AKs. The two major ones are individual susceptibility and cumulative UV radiation exposure (Table 113-2). One of the most important susceptibility risk factors is age, because all the epidemiologic studies indicate that AKs increase in prevalence with increasing age, with rates ranging from less than 10% in white adults aged 20–29 years to 80% in white adults aged 60–69 years. Males appear to have more AKs than females in most epidemiologic studies, which presumably reflects greater cumulative sun exposure in males than in females.[14] This gender differential is more pronounced at younger ages. Other individual susceptibility risk factors include a phenotype of fair skin that easily burns and freckles, and rarely tans; blue or light-colored eyes; and red or blond hair.[14] Another individual risk factor is immunosuppression, because it is known that organ transplant recipients and patients receiving certain chemotherapy agents and possibly even biologic therapies are at increased risk of developing AKs and SCCs.[15–18] In addition, persons with certain genetic syndromes, namely, albinism and xeroderma pigmentosum, and possibly Rothmund–Thomson and Bloom syndromes, are at greater risk of developing AKs.

TABLE 113-2
Risk Factors for Development of Actinic Keratoses

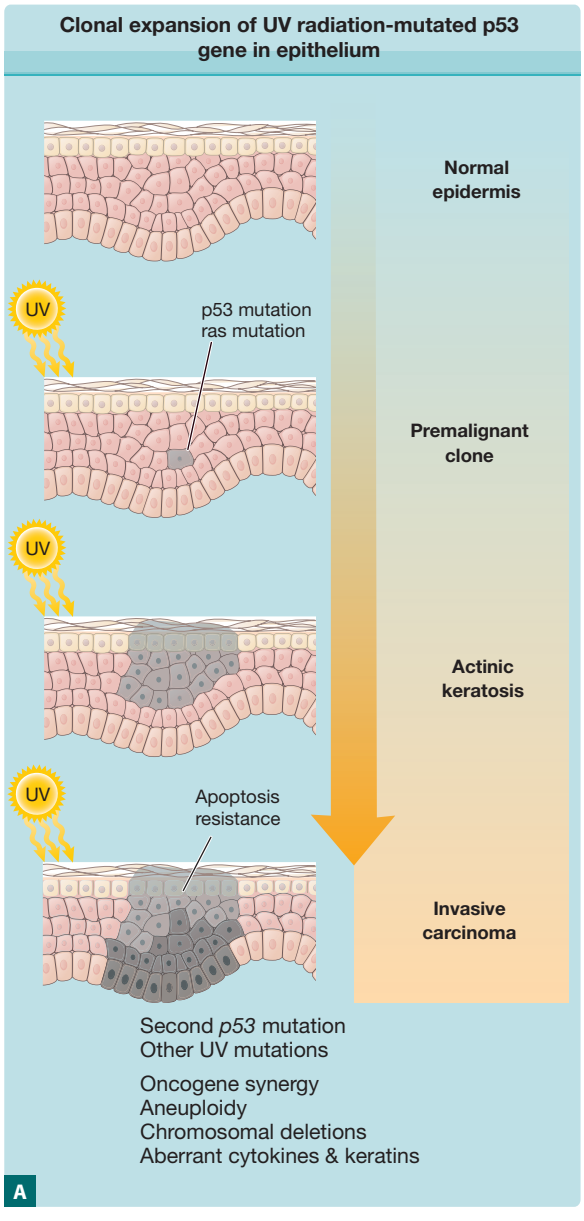
- Individual susceptibility
  - Older age
  - Male gender
  - Fair skin that easily burns and freckles
  - Blond or red hair
  - Light-colored eyes
- Cumulative ultraviolet radiation exposure
- Immunosuppression
- Prior history of actinic keratoses or other skin cancers
- Genetic syndromes
  - Xeroderma pigmentosum
  - Bloom syndrome
  - Rothmund–Thomson syndrome

Cumulative exposure to UV radiation, including tanning beds, is the other major risk factor for developing AKs. Evidence that sun exposure plays a role in the development of AKs is the fact that over 80% of all AKs are distributed on habitually sun-exposed areas of the body, such as the scalp, head, neck, forearms, and dorsal hands.[14] Variables that affect a person's cumulative UV radiation exposure include age, gender, occupation, recreational activities, and place of residence. As previously stated, the older the individual, the greater the prevalence of AKs and, intuitively, the greater the cumulative exposure to UV radiation. The age at which a person received the greatest amount and intensity of exposure to UV radiation appears to be significant, with such exposure in childhood apparently posing the greatest risk. In migration studies in Australia, British immigrants who moved to Australia before the age of 20 had fewer AKs than the native white Australians early in life, but they had the same rate of AKs as the native Australians in later years. British immigrants who moved to Australia after the age of 20 years never showed the same rate of AKs as the native Australians or the British immigrants who arrived at a young age.[19]

ETIOLOGY AND PATHOGENESIS

Although genetic and environmental factors may play a role in the development of AKs and SCC, it has long been recognized that the most important contributing factor is habitual exposure to UV radiation, namely, sunlight exposure. UV radiation is responsible for the development of AKs, and eventually SCC, in two ways: first, it causes mutations in cellular DNA that, when not repaired, lead to unrestrained growth and tumor formation; and second, it acts as an immunosuppressant preventing tumor rejection[20] (see Chapters 109, 110, and 112).

UV radiation-induced mutations in the tumor suppressor gene *p53* play a pivotal role in the initiation of AKs and their development into SCC (Fig. 113-1; see Chapter 112). Multiple UV radiation-induced cellular insults to the skin result in a pathway to SCC that begins with photodamaged skin, progresses to the development



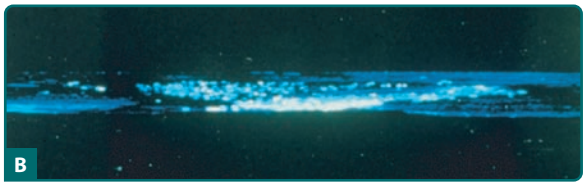


Figure 113-1 **A.** Development of clonal expansion of ultraviolet (UV) radiation-mutated *p53* gene in epithelium. In the multistage model of carcinogenesis, UV radiation-induced mutations provide selective growth advantage to neighboring cells, which leads to clonal expansion. (Adapted from Grossman D, Leffell DJ: The molecular basis of nonmelanoma skin cancer. *Arch Dermatol* **133**:1263, 1997.) **B.** Confocal microscopy revealing expansion of UV radiation-induced clone of abnormal keratinocytes in sun-damaged skin. (From Jonason et al: Frequent clones of *p53*-mutated keratinocytes in normal human skin. *Proc Natl Acad Sci U S A* **93**:1402, 1996, with permission.)

of AKs, and eventually leads to some SCCs. AKs on photodamaged skin clinically represent expanded clones of genetically mutated cells that have escaped apoptosis and immune surveillance and have gone on to proliferate into clinically evident premalignant lesions.

CLINICAL FINDINGS

The typical patient with AKs is an older, fair-skinned, light-eyed individual who has a history of significant sun exposure, who burns and freckles rather than tans, and who has significant solar elastosis on examination (Fig. 113-2). AKs can be seen in younger individuals if these individuals have sustained sufficient sun exposure over their lives. Eighty percent of AKs are found on habitually sun-exposed sites of the body, such as the head, neck, forearms, and dorsal hands. Common signs and symptoms include pruritus, burning or stinging pain, bleeding, and crusting. The typical AK lesion, sometimes called the *erythematous AK*, presents most commonly as a 2–6-mm erythematous, flat, rough, gritty or scaly papule. It is usually more easily felt than seen. AKs can vary in size and sometimes reach to several centimeters in diameter. They are most often found against a background of photodamaged skin or dermatoheliosis, with solar elastosis, dyspigmentation, yellow discoloration, ephelides and lentigos, telangiectases, and sagging skin notably prominent. At times, the number and confluence of AKs are so great that the patient appears to have a rash.

In addition to the typical erythematous AK, there are several other clinical subtypes (Table 113-3). The hypertrophic AK (HAK) presents as a thicker, scaly, rough papule or plaque that is skin-colored, gray–white, or erythematous (Fig. 113-3A). It can be found on any habitually sun-exposed site on the body but has a propensity for the dorsal hands, arms, and scalp. A

- Atrophic actinic keratosis
- Bowenoid actinic keratosis
- Pigmented actinic keratosis
- Proliferative actinic keratosis
- Lichenoid actinic keratosis
- Acantholytic actinic keratosis
- Clear cell actinic keratosis

typical erythematous AK can progress into an HAK. It can be difficult to distinguish an HAK from an SCC, clinically necessitating a biopsy. Biopsies must be taken to a level deep enough to ensure that the dermal extent of the keratinocytic proliferation can be evaluated in order to obtain an unequivocal histopathologic diagnosis. Induration or thickness, pain, and ulceration are the main clues to the transition of AK to SCC.

Cutaneous horn, also known as *cornu cutaneum*, refers to a reaction pattern and not a particular lesion (Fig. 113-4). In reference to AKs, a cutaneous horn is a type of HAK that presents with a conical hypertrophic protuberance emanating from a skin-colored to erythematous papular base. Classical definitions of a cutaneous horn maintain that the height is at least one-half of the largest diameter. Thirty-eight percent to 40% of all cutaneous horns represent AKs.[21] The pathology underlying a cutaneous horn can be a number of different lesions, such as AK, SCC, seborrheic keratosis, filiform verruca vulgaris, trichilemmoma, or keratoacanthoma. The most common underlying lesion in elderly, fair-skinned persons is an HAK.

Actinic cheilitis represents confluent AKs on the lips, most often the lower lip (Fig. 113-5). Persons with this condition have red, scaly, chapped lips, and at times erosions or fissures may be present. The vermillion border of the lip is often indistinct, and focal hyperkeratosis and leukoplakia may also be seen. Individuals with this condition often complain of persistent dryness and cracking of the lips, and the diagnosis of actinic cheilitis should always be suspected in photodamaged patients with such complaints. Persistent ulcerations or indurated areas on the lip require biopsy to ensure that SCC is not present.

PROGNOSIS AND CLINICAL COURSE

The prognosis of AK includes persistence, regression, or malignant transformation into invasive SCC. The relative risk of progression to SCC depends on factors related to the AK itself, such as the length of time an AK has been present and the number of baseline AKs that are on the skin. In addition, the risk for SCC increases with increased UV radiation exposure and with certain individual patient characteristics, such as suppressed immune status. Berhane et al observed that before an AK progresses to SCC it may become clinically tender and inflamed. Histopathologic examination of such clinically inflamed AKs revealed the actual presence of overt SCC in 50%.[31] Thus, pain and inflammation in an AK may be a marker of progression to SCC.

Several studies have attempted to determine the risk for the progression of AK to SCC, but most of them are inadequate in one respect or another. The risk for progression of AK to SCC reported in the literature varies from less than 1%[32] to 20%.[33] In a review of five clinical research studies carried out between 1988 and 1998, Glogau found that the published risk of progression of AK to SCC for individual lesions ranged from 0.025% to 16% per year.[34] Extrapolation from these clinical studies suggests a rate of risk of progression of AK to SCC of approximately 8%, computed as an average of the cited statistical rates.[34] A more recent study by Criscione et al found that the risk of progression of AK to primary SCC (invasive or in situ) was 0.60% at 1 year and 2.57% at 4 years.[35] The risk of

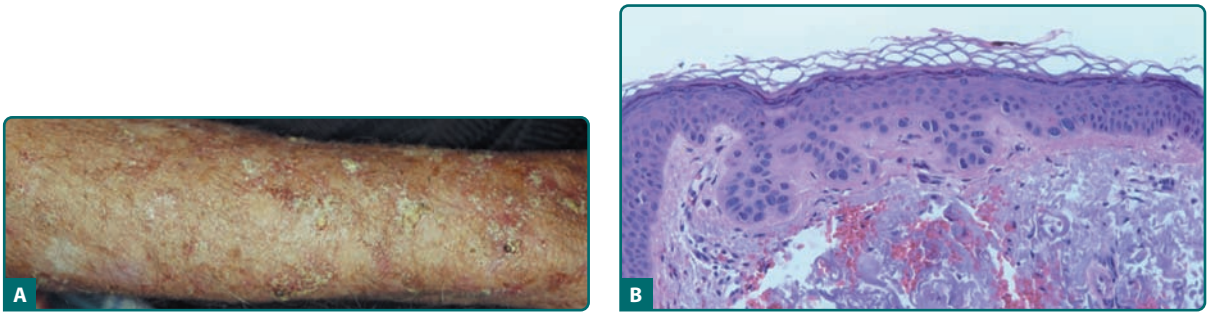

Figure 113-3 **A.** Severe solar damage of the dorsal arm demonstrating hypertrophic actinic keratoses (AKs) and AKs. **B.** Histopathologic preparation of actinic keratosis demonstrates atypical cells along the basal layer with sparing of adnexal epithelium.

Figure 113-4 **A.** Cutaneous horn of the ear. Only biopsy will confirm whether this is an actinic keratosis or a squamous cell carcinoma. **B.** Cutaneous horn of the cheek.

malignant transformation can also be assessed by evaluating the percentage of SCCs that arise from preexisting AKs. Several older studies have approached this issue by histopathologically examining invasive SCC specimens and determining the percentage of cases in which an associated or contiguous AK could be identified. An associated AK was identified at the periphery or within the SCC in 60%,[32] 82.4%,[36] 97%,[37] 97.2%,[38] and 100%[39] of reviewed cases in various studies. There has been one prospective study in which all SCCs treated by the authors in one calendar year were evaluated histopathologically to see if an AK was present in the specimen. They found a contiguous AK within a histopathologically confirmed SCC in 72% of cases.[40] The most recent 2009 VATTC trial by Criscione et al showed that the majority of primary SCCs (65%) and, interestingly, 36% of all primary BCCs arose within a previously clinically diagnosed AK.[35] Their findings that a sizeable number of initially clinically identified AKs were later determined to be BCCs at follow-up translated into a risk of progression of 0.48% at 1 year and 1.56% at 4 years. The authors commented that it was not clear if the initially identified AKs developed into BCCs, a phenomenon that has never before been reported, or if the BCCs were previously misidentified as AKs. We have to assume the latter, as BCCs originate from the follicular germ cells and are distinct from AK/SCC.[41]

Figure 113-5 Actinic cheilitis of the lower lip in a young man with a marine occupation. The patient is at risk for developing squamous cell carcinoma of the lip. Preventative treatment of the actinic cheilitis can include laser, cryosurgery, and topical treatment.

Their conclusion, however, was that there was an almost linear increased risk of clinically diagnosed AKs progressing to either SCC or BCC at 4 years, demonstrating that AKs have a significant role in the overall burden of keratinocyte carcinomas and are an important marker for the development of NMSC.[35]

Spontaneous regression of AKs has been reported, but it is impossible to predict for any particular AK lesion.[35,42,43] One study reported that up to 25% of AKs remitted over a 1-year period, especially if sun exposure was limited during that time.[44] Another study found that more AKs regressed in individuals who routinely wore sunscreen.[29] The 2009 VATTC study reported that 55% and 70% of AKs followed clinically were not present at 1-year and 5-year follow-up points, respectively.[35] However, the authors noted that most importantly the vast majority (87%) of AK lesions identified at the 1- and 5-year visits were not clinically identified during at least one of the 6-month intervals, suggesting that AKs come and go.[35]

The presence of AKs indicates long-term sun damage and identifies a group of people who are at high risk for developing SCC, BCC, and, to a lesser extent, melanoma.[9–11]

The estimated rates of metastases arising from actinically derived SCC have ranged from 1% to 2% to over 20% depending primarily on depth of invasion, location (with the lip, ear, and scalp representing the sites of highest risk), differentiation, and the presence of perineural invasion.[45]

TREATMENT

The inability to predict which AKs will persist, regress, or become SCCs makes treatment of these lesions equally confusing. Although some clinicians have argued that because of the low malignant transformation risk, treatment of AKs is unnecessary, most dermatologists advocate the treatment of AKs to avoid any chance of progression to invasive SCC.[46,47] The 2009 VATTC trial researchers concluded from their findings that despite the possibility of AK regression, new AKs and keratinocyte carcinomas can develop and that active treatment of AK lesions is warranted, especially given the overall contribution of AKs to SCC and BCC burden.[35] Treatment of this disease is also warranted to minimize symptoms, such as pain and pruritus, in affected patients.

In selection of the proper treatment, there are no absolute guidelines or algorithms because published studies vary considerably in their design, measured outcomes, and follow-up time (Fig. 113-6). The clinical diagnosis of AK even by expert dermatologists can be inconsistent.[27]

Treatment modalities for AKs can be broadly divided into lesion-targeted therapies and field therapies (Box 113-1).

LESION-TARGETED TREATMENTS FOR ACTINIC KERATOSIS. The majority of the lesion-targeted therapies for the treatment of AKs are destructive, i.e., they work by physically removing the AK. Such destructive treatments are currently the most common methods used to treat AKs.[48]

BOX 113-1 TREATMENT OF ACTINIC KERATOSES

LESION-TARGETED THERAPIES

- Liquid nitrogen cryotherapy
- Curettage with or without electrosurgery
- Shave excision

FIELD THERAPIES

- Topical
  - 5-fluorouracil cream and solution
  - imiquimod cream
  - 3% diclofenac gel
- Procedural
  - Cryopeeling
  - Dermabrasion
  - Medium-depth chemical peel
  - Deep chemical peel
  - Laser resurfacing
  - Photodynamic therapy

LIQUID NITROGEN CRYOSURGERY. Liquid nitrogen cryosurgery is the most common destructive procedure and is typically administered with a spray device or a cotton-tipped applicator (see Chapter 246). The first prospective study looking at efficacy rates of cryosurgery was performed in 2004.[49] The overall complete clearance rate when the patients were checked 3 months after treatment was 67.2%. A subgroup analysis of these data based on actual freeze times indicated that a complete response occurred in 39% of cases with freeze times of 5 seconds or less, in 69% with freeze times between 6 seconds and 20 seconds, and in 83% with freeze times longer than 20 seconds. Hypopigmentation was seen in 29% of sites from which AK was eradicated most probably those with longer freeze times as the melanocyte is particularly susceptible to cold injury. The investigators concluded that the ideal freeze time was somewhere between 10 seconds and 15 seconds.

The benefits of cryosurgery are its ease of administration in trained hands, the lack of need for anesthetic, and the lack of reliance on patient compliance other than in posttreatment care of treated lesions. Potential disadvantages of cryosurgery include pain and discomfort, the presence of unsightly blisters and crusted wounds for a week or longer, hypopigmentation, scarring, and possible alopecia in treated areas.[50] In rare cases, serious injury to underlying tendons and nerves may occur with deep or prolonged liquid nitrogen application to the hands. Most important, cryosurgery is best used to treat a limited number of clinically perceptible or symptomatic lesions.

CURETTAGE. Curettage, with or without electrosurgery (see Chapter 246), is another destructive lesion-targeted treatment for AKs. This procedure and cryosurgery together constitute approximately 80% of all treatments for AKs in the United States.[48] A curette is used to mechanically scrape away the atypical keratinocytes comprising the AK. Electrosurgery may or may not be used to further destroy atypical cells and to provide hemostasis. If electrosurgery is employed, minimal use is advised to enhance the final cosmetic result. A local anesthetic is needed for this procedure, and hemostatic agents such as aluminum chloride can be used to stop the bleeding if electrosurgery is not utilized. There are no controlled studies addressing cure rates with the use of this technique for the treatment of AKs, but experience says it is quite effective, at the expense of potential scarring. Patients can expect some discomfort with injection of the local anesthetic, and the treated area will take a few weeks to heal completely. This technique is most appropriate for patients with relatively few AKs. It is also beneficial for treatment of lesions after biopsy and for the treatment of HAKs. Potential side effects include infection, scarring, and dyspigmentation. If a biopsy is to be performed, procurement of a shaved specimen before curettage provides a much more acceptable histopathologic portrait

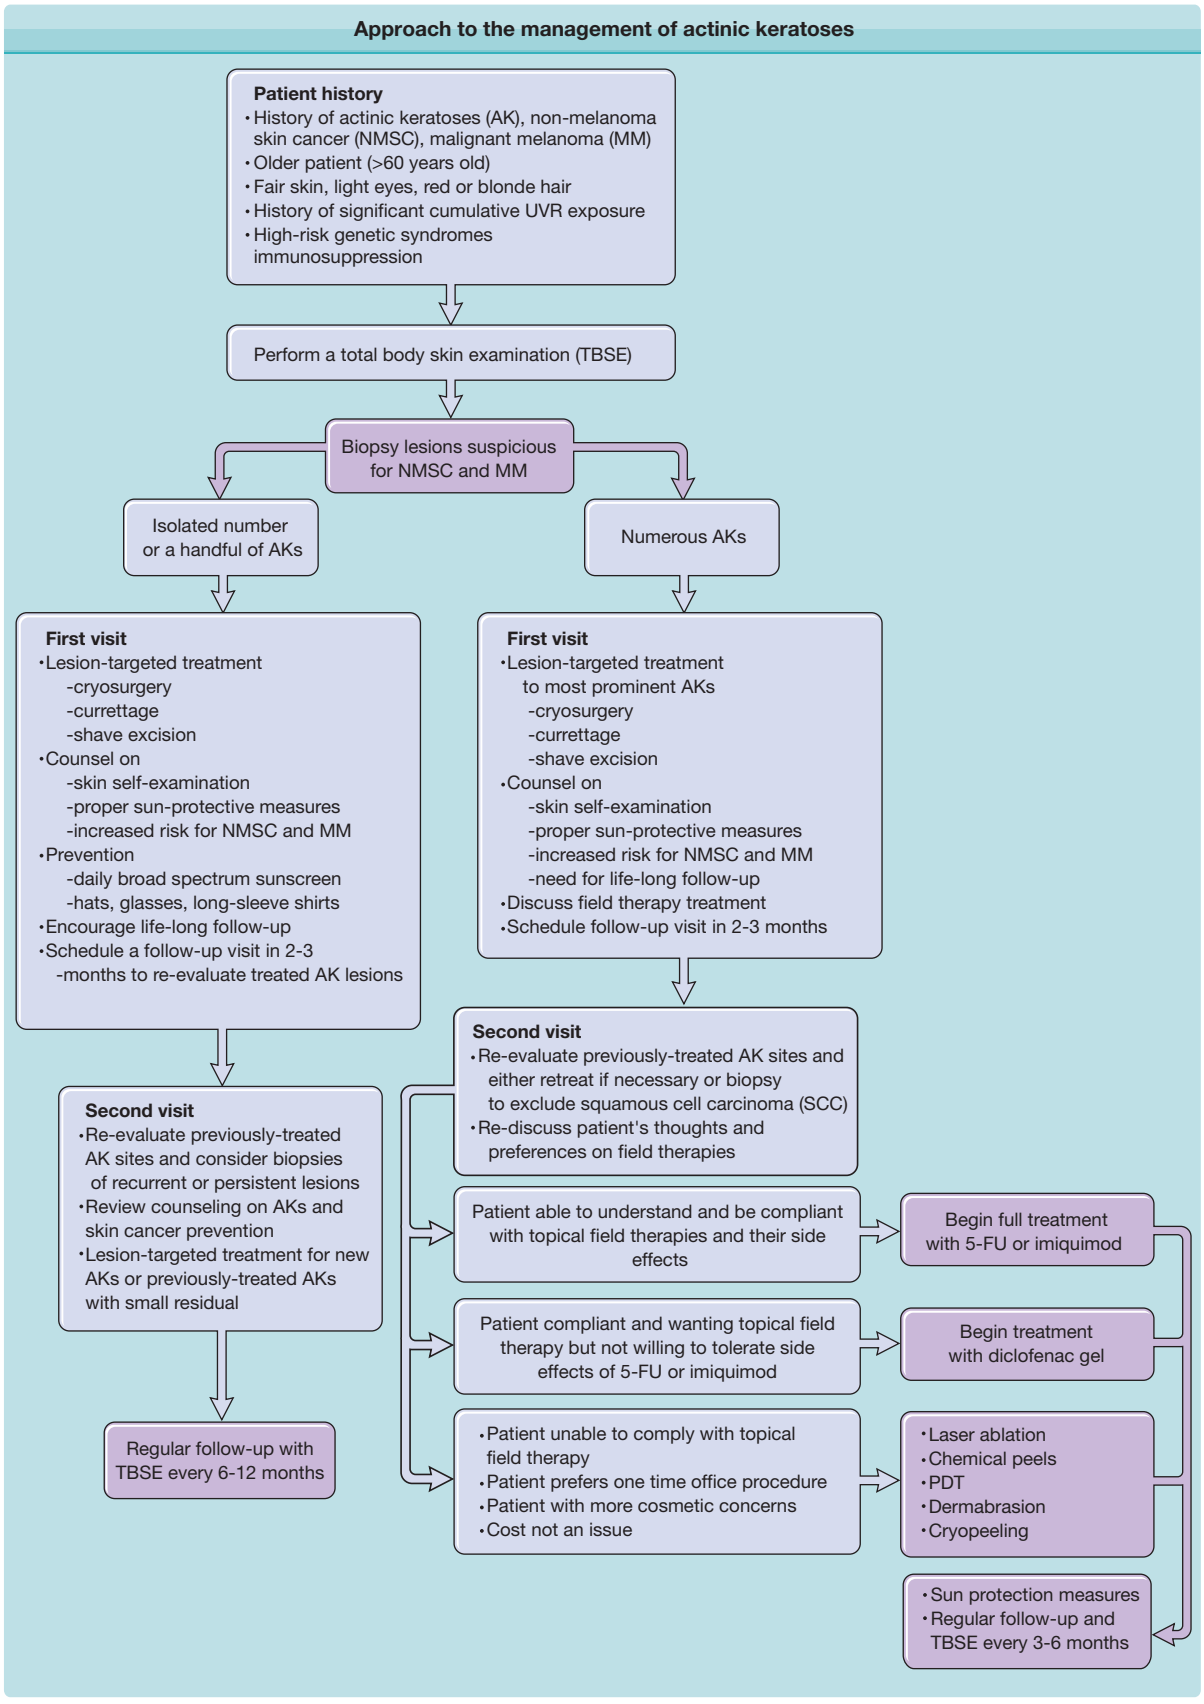

Figure 113-6 Approach to the management of actinic keratoses. 5-FU = 5-fluorouracil; PDT = photodynamic therapy; UVR = ultraviolet radiation.

and avoids overinterpretation or underinterpretation. Obtaining biopsy samples through curettage produces crushed and fragmented specimens that are difficult to interpret, which can lead to erroneous diagnoses.

SHAVE EXCISION. The third lesion-targeted destructive therapy for AKs is shave excision. This technique involves injection of a local anesthetic followed by tangential excision of the lesion with a surgical blade (see Chapter 243). Hemostatic agents must also be used to stop the bleeding. No data exist on the cure rate of this technique, but as with curettage, anecdotal experience says it is effective. Healing time may be 1–2 weeks, and potential complications include infection, scarring, and dyspigmentation. Use of this technique is most often indicated when a clinically apparent AK is suspicious for SCC or BCC and histopathologic examination is needed. Shave excision offers the patient an attempt at curative therapy simultaneous with a diagnostic procedure. Signs and symptoms that should arouse suspicion of SCC include marked erythema, pain, ulceration, bleeding, induration, or failure to respond to prior destructive therapies. Care must be taken to shave deeply enough to avoid transecting the AK at the deep margin, because this precludes unequivocal interpretation due to the proclivity for invasive SCC to develop at the deepest extensions of the atypical keratinocytes in AKs.

FIELD THERAPIES FOR ACTINIC KERATOSIS. Field therapies treat larger areas of photodamaged skin that contain both clinical and subclinical AK lesions. Field therapies can be further categorized into topical/medical and procedural field therapies. Such treatments are best used in patients with moderate to severely photodamaged skin and numerous AKs that would be too burdensome and painful to treat with the lesion-targeted therapies. Many patients with AKs, upon close inspection, are found to be extensively affected with early disease in sun-exposed areas, which may make field therapy a more rational approach to this difficult problem.

Topical Field Therapy. Several topical agents are available and approved by the US Food and Drug Administration (FDA) for the generalized treatment of AKs, including 5-fluorouracil (5-FU), 5% imiquimod cream, and 3% diclofenac gel (Box 113-2). A full discussion of these therapies can be found in the online edition.

PROCEDURAL FIELD THERAPY. The second category of field therapies for treating diffuse AKs is the procedural field therapies. These include cryopeeling (see Chapter 246), dermabrasion, medium and deep chemical peels (see Chapter 251), laser resurfacing (see Chapter 251), and photodynamic therapy (PDT) (see Chapter 238).

Cryopeeling consists of extensive liquid nitrogen cryosurgery to the areas of discrete AKs as well as to the surrounding actinically damaged skin.

Dermabrasion is an older technique that is quite effective in the treatment and prophylaxis of AKs but is now rarely used for this purpose. It causes physical destruction of the AKs with abrasion using either drywall sanding sheets or dermabrasion diamond fraises, which are powered or handheld (see Chapter 251).

Medium-depth chemical peels using Jessner's solution and 35% trichloroacetic acid (TCA) are moderately effective in treating diffuse AKs, especially when a series of such peels are administered over time[69,70] (see Chapter 251). A combined peel, in which 35% TCA is used, after applied to obtain uniform frosting after Jessner's solution degreasing and deepithelialization, has been shown to be equivalent in efficacy to 5-FU therapy.[71]

Deep chemical peeling using phenol or high concentrations of TCA is more effective in treating thick AKs or those with appendageal epithelial atypia but are rarely used because of the potential cardiac and renal toxicity of phenol, the greater risk of scarring and infection, and the dramatic hypopigmentation that may occur postoperatively.

Laser resurfacing for the treatment and prophylaxis of AKs is another procedural field therapy that has been utilized. The carbon dioxide (CO_2) laser and the erbium:yttrium-aluminum-garnet (er:YAG) laser are the two laser systems that have primarily been investigated for these purposes (see Chapter 252). Both of these devices ablate the epidermis at varying depths allowing reepithelialization with adnexal keratinocytes that are less actinically damaged.

In preliminary small series, both laser resurfacing systems have been reported to be effective in short-term clearing of multiple facial and scalp AKs[72–74] and in the long-term prevention of recurrences[75] and possibly the development of NSMC.[72] Laser resurfacing is probably best reserved for use by specially trained and experienced physicians and for patients with

BOX 113-2 TOPICAL FIELD THERAPIES OF ACTINIC KERATOSES*

MEDICATION	TOPICAL PREPARATION	DOSAGE
5-Fluorouracil	2% solution 5% solution 1% cream 5% cream	Twice daily for up to 4 weeks
	0.5% micronized cream	Once daily for 4 weeks
Imiquimod	5% cream	Twice per week for 16 wks

	2.5% cream	
Diclofenac	3% gel	Twice daily for 90 days

*FDA-approved regimens

more cosmetic concerns or with diffuse AKs for which topical field therapies and/or chemical peeling have failed. They are also excellent modalities for patients with severe actinic cheilitis and for those patients with multiple, thicker AKs.

PDT is another procedural therapy available for the treatment of multiple and diffuse AKs. The FDA has approved two PDT systems for the treatment of non-HAK lesions on the face and scalp (see Chapter 238). The first to receive approval was the combination of 5-aminolevulinic acid (ALA) with a blue light source in 1998. More recently, the FDA approved a system that has been widely available in Europe, combining a methyl ester of aminolevulinic acid (MAL) with a red light source. The topically applied ALA or MAL accumulates preferentially in the more rapidly dividing atypical cells and is converted sequentially to protoporphyrin IX, a heme precursor and photosensitizer. When the ALA or MAL-treated skin is then exposed to a light source of the appropriate wavelength several hours later, the accumulated protoporphyrin IX generates a phototoxic reaction that destroys the treated cells.[76–79]

Randomized, placebo-controlled studies have demonstrated the efficacy of both ALA and MAL PDT for the treatment of AKs.[79–82] A more recent, randomized, double-blind, prospective study comparing the safety and efficacy of ALA-PDT with MAL-PDT found both forms to have no significant difference in efficacy of decreasing AK lesion burden, but that ALA-PDT was associated with more painful and adverse effects and a longer duration of discomfort compared with MAL-PDT.[82] Patients can expect some discomfort with PDT, including erythema, edema, and burning or stinging during exposure to the light source. In a subgroup of patients with severe sun damage, PDT can create intolerable pain that sometimes results in premature discontinuation of treatment. Allergic reactions to ALA and MAL have also been reported. Severe phototoxic reactions can occur if patients do not follow the protocol and practice strict sun avoidance for the recommended period after ALA and MAL application. Cosmetic outcomes have been good to excellent in those who complete adequate treatment.

There is a paucity of comparative effectiveness research amongst these various field therapies for AKs. In general, topical 5-FU, 5% imiquimod cream, diclofenac gel, and PDT are all effective in decreasing the AK lesion burden. From the mostly small comparative studies that have been published, a few additional points can be made. Topical 5-FU and topical 5% imiquimod cream seem to create more inflammation, irritation, and patient discomfort compared with topical diclofenac gel. There is some data to suggest that topical 5% imiquimod cream may have lower, long-term recurrence rates of AKs, in part by creating longer term immune memory and antitumor response.[56,83] A pharmacoeconomic study of AK field treatment modalities (5% imiquimod vs. diclofenac gel vs. 5-FU vs. ALA-PDT) in combination with liquid nitrogen cryosurgery found that ALA-PDT was the least costly and that imiquimod was the most expensive.[84]

In summary, evidence supports the treatment of AKs to prevent the progression to malignancy. There are a number of effective lesion targeted and field treatments available to choose from to decrease the burden of AKs. Consideration of the individual's needs, the physician's skills, the mechanisms of action of the various treatments and their side effect profiles, plus the cost of treatment should all be considered when choosing a treatment strategy. To help physicians in choosing a treatment strategy for their patients, the American Academy of Dermatology and the European Dermatology Forum has proposed guidelines for the management of AKs, based upon available evidence at the time of their writings.[85,86] In addition, the authors of this chapter have proposed a treatment algorithm (Fig. 113-6).

PREVENTION

Given the potential of AKs to progress to malignant lesions, it is important to focus on the prevention of these precancerous lesions. Educational and preventive efforts should be directed toward children, targeted high-risk populations, and all patients. Avoidance of UV radiation is the single most effective means of decreasing the risk of AKs. A strategy designed to limit the amount and intensity of sun exposure, starting in childhood and continuing throughout the person's life, will likely decrease the number of AKs an individual will develop. Because complete avoidance of the sun is impractical, the next best preventive measures are to avoid exposure to intense midday sun; consistently apply and reapply broad-spectrum sunscreens; wear UV-protective clothing, hats, and sunglasses; install UV-protective windows where indicated; and make sure to take an oral vitamin D supplement if necessary to avoid vitamin D insufficiency or deficiency.[90]

Numerous randomized studies have shown that the use of sunscreen can decrease the incidence and prevalence of AKs, reduce the number of AK lesions, and increase their rate of regression.[29,91–94] There is also evidence that sunscreen use can prevent certain types of skin cancer, mostly SCC.[93,94] There is limited evidence that adhering to a diet low in fat may decrease the incidence of AKs[95,96] and NMSC.[97,98] In older studies, topical retinoids were shown to reduce the number of AKs after long-term consistent use,[99,100] and in another study, long-term treatment with topical retinoic acid was shown to reduce keratinocyte and melanocyte atypia in photoaged skin.[101] However, the more recent multicenter VATTC trial found that up to twice-daily application of 0.1% tretinoin cream over 1.5–5.5 years in mostly elderly (n = 1,131, mean age = 70 years) males (95%) at very high risk for NMSC was ineffective for preventing BCC and SCC.[102] This study was stopped 6 months prematurely because of excess mortality in the treatment group. However, the authors could not establish a cause and effect relationship.[103] They also concluded that retinoids may have very different clinical effects when administered topically as opposed to orally.[102]

Unlike the controversy with topical retinoids, there is strong evidence for the use of systemic retinoids in preventing NMSC and AKs, especially in high-risk populations, such as organ transplant recipients, patients with xeroderma pigmentosum, and other chronically immunosuppressed patients.[104–107] Unfortunately, the systemic retinoids are only effective while the patient is taking them and their use is also limited by the frequent occurrence of systemic toxicities, including hypercholesterolemia, hypertriglyceridemia, mucocutaneous xerosis, musculoskeletal abnormalities, and alteration in liver function. Thus, when considering the use of systemic retinoids in such high-risk patients, one must weigh these risks and benefits.

Topical imiquimod has also been safely used in the organ transplant population to prevent the development of cutaneous SCC.[65,108]

ARSENICAL KERATOSES

ARSENICAL KERATOSES AT A GLANCE

- Arsenical keratoses (ArKs) are precancerous lesions associated with chronic arsenicism.
- ArKs have the potential to become squamous cell carcinomas (SCCs).
- Chronic arsenicism has resulted from medicinal, occupational, and environmental exposures.
- Clinical appearance is of punctuate, keratotic, yellow papules overlying pressure points on palms and soles.
- Chronic arsenicism is associated with ArKs, Bowen disease, basal cell carcinoma, SCC, and internal malignancies, with latency periods of up to 40 years.
- No standard recommendations for treatment; most lesions are followed clinically or treated symptomatically.

Arsenical keratoses (ArKs) are precancerous lesions found in association with chronic arsenicism. These lesions have the potential to develop into invasive SCC. Arsenic is a ubiquitous element that has no color, taste, or odor. It has the potential to cause characteristic acute and chronic syndromes in persons exposed to it, and such exposures are typically obscure because medicinal, occupational, and environmental sources still exist. Detection of acute and chronic arsenicism is important, because the acute form can be fatal and the chronic form is associated with a variety of cutaneous and internal malignancies. ArKs are associated with chronic arsenicism.

PROGNOSIS AND CLINICAL COURSE

ArKs and arsenical-induced BD tend to persist for many years, and progression to invasive SCC is believed to be relatively rare. However, invasive SCCs that arise in ArKs are more locally aggressive and have a greater chance of metastasis than SCCs arising in AKs.[110] In lesions of arsenical-induced BD, locally invasive SCC has been seen histopathologically in up to 20% of cases. Once invasive SCC has occurred in BD, it is said that at least one-third will demonstrate evidence of metastasis unless adequate treatment is provided.[122]

TREATMENT

Management of patients with chronic arsenicism and ArKs should include regularly scheduled total-body skin examinations and general physical examinations, possibly every 6 months.[121] The exact incidence of internal malignancies associated with chronic arsenicism is unknown, so there is no standard protocol for the evaluation of potential internal malignancies. Exhaustive evaluations to detect such malignancies have not been recommended. Biannual detailed history taking and physical examination, yearly chest radiography, and selective testing when clinically indicated are probably reasonable recommendations.

Treatment of ArKs likewise is not standard and not mandatory, although treatment of these lesions is sometimes initiated to relieve the associated discomfort that some patients experience. Available treatment options include surgical excision, cryosurgery, curettage with or without electrosurgery, CO_2 laser treatment, and topical chemotherapy with 5-FU, although 5-FU therapy is less successful in treating ArKs than in treating AKs.[110] PDT has also been used to treat these lesions. Limited studies suggest that oral retinoids and keratolytics may be useful in treating ArKs.[123,124] One case report of effective treatment of ArKs, BD, and BCC lesions in one patient with chronic arsenicism with topical 5% imiquimod cream has been reported.[125]

THERMAL KERATOSES

THERMAL KERATOSES AT A GLANCE

- Precancerous lesions that result from long-term exposure to infrared radiation; can progress to squamous cell carcinoma (SCC).
- Sources of infrared radiation include open fires, railway engines, wood-burning stoves, heating pads and blankets, and laptop computers.
- Precursor lesion is erythema ab igne; biopsy should be performed on any hyperkeratotic papule or plaque within such a patch.
- Risk of progression of thermal keratosis to SCC is unknown.

HYDROCARBON KERATOSES

HYDROCARBON KERATOSES AT A GLANCE

- Hydrocarbon keratoses (HKs) are also known as *pitch keratoses*, *tar keratoses*, and *tar warts*.
- They occur in persons who are occupationally exposed to polycyclic aromatic hydrocarbons (PAHs).
- Occupations at risk include tar distiller, shale extractor, roofer, asphalt worker, road paver, highway maintenance worker, brick mason, diesel engineer, and chimney sweep.
- HK can progress to squamous cell carcinoma (SCC), but the rate of progression and risk are unknown.
- Latency periods between PAH exposure and development of HK or SCC range from 2.5 years to 45 years.
- Presence of atypical keratoses on the nostril rims, upper lip, and genitalia should prompt a search for occupational exposures to PAHs.
- Other skin findings include patchy hyperpigmentation, acne, and telangiectases.

CHRONIC RADIATION KERATOSES

CHRONIC RADIATION KERATOSES AT A GLANCE

- Chronic radiation keratoses (CRKs) are precancerous lesions that may arise at irradiated sites years after such exposure and may progress to squamous cell carcinoma (SCC).
- Ionizing radiation sources include X-rays, grenz rays, and contaminated gold rings.
- Common sites are the palms, soles, and mucosal surfaces.
- Clinically present as hyperkeratotic papules or plaques within areas of chronic radiation dermatitis and occasionally on clinically normal skin.
- Latency for the development of CRKs can be up to 56 years after exposure.
- Ionizing radiation-induced SCC can be extremely aggressive.
- Patients with ionizing radiation exposure and CRKs are also at risk for internal malignancies.

CHRONIC SCAR KERATOSES

CHRONIC SCAR KERATOSES AT A GLANCE

- Chronic scar keratoses (CSKs), or *cicatrix keratoses*, are precancerous lesions that arise in long-standing scars from various causes.
- *Marjolin's ulcer* describes malignant changes within a burn scar but can also refer to such changes in chronic ulcers or sinus tracts.
- Approximately 2% of burn scars will undergo malignant changes.
- Most burn scar carcinomas are squamous cell carcinomas (SCCs), but basal cell carcinomas (BCCs), melanomas, sarcomas, and malignant fibrous histiocytomas have also been described.
- Acute Marjolin's ulcer develops within 1 year of the time of injury; chronic Marjolin's ulcer develops more than 1 year after an injury, with an average latency period of 36 years.
- Sites of predilection are the extremities and overlying joints.
- Any persistent lesion, erosion, or ulceration within a scar requires biopsy.
- Prevention includes excellent wound care, early skin grafting, avoidance of contractures, and early excision of any tissue showing degenerative changes.

VIRAL-ASSOCIATED EPITHELIAL PRECANCEROUS LESIONS

Several types of precancerous epithelial lesions have a viral association (Box 113-3), including bowenoid papulosis (BP), epidermodysplasia verruciformis (EV), vulvar intraepithelial neoplasia (VIN), anal and perianal intraepithelial neoplasia (AIN and PaIN), and penile intraepithelial neoplasia (PIN). Extensive research has shown that certain oncogenic or high-risk HPV (hrHPV) types play a significant role in the p s of these precancerous lesions.[144] Over 100 types of HPV have been discovered, and the hrHPV subtypes that have been associated with these precancerous epithelial lesions are shown in Box 113-3. The role of the human papillomavirus (HPV) in the etiology and development of these precancerous lesions, as well as other malignant neoplasms, is further discussed in

VIRAL-ASSOCIATED PRECANCEROUS LESIONS AT A GLANCE

- Two viral-associated precancerous lesions are bowenoid papulosis (BP) and epidermodysplasia verruciformis (EV).
- BP is a precancerous condition of the genitalia caused by infection with human papillomavirus (HPV); oncogenic types 16, 18, and 33 are most commonly involved.
- BP may regress spontaneously, persist, or rarely transform into Bowen disease (BD) or squamous cell carcinoma (SCC).
- Treatment options include topical imiquimod, curettage, excision, and laser vaporization.
- Sexual partners of patients must be examined and followed closely for development of cervical, vulvar, or penile carcinoma.
- EV is a rare genodermatosis associated with mutations in the *EVER1* and *EVER2* genes.
- Affected individuals show a propensity toward infection with certain strains of HPV-5 and HPV-8.
- Clinical presentation is with widespread flat wart-like papules and plaques in childhood; risk of developing SCC later in life is high.
- Sun avoidance, sun-protective measures, regular dermatologic follow-up, and screening of family members for the disease are important.

Figure 113-7 Bowenoid papulosis of the penis. (Used with permission from James E. Fitzpatrick, MD.)

Chapter 196. The premalignant lesions of the lower anogenital tract (VIN, AIN, PaIN, PIN) are discussed later in this chapter.

BOWENOID PAPULOSIS

BP is characterized clinically by the presence of pigmented verrucous papules and plaques primarily on the genitalia of predisposed, usually younger, individuals, and histopathologically by the presence of SCC in situ-like changes (Fig. 113-7) (see also Chapters 77 and 78). Genital lesions that histopathologically resembled SCC in situ were first described by Lloyd in 1970 as multicentric pigmented BD of the groin.[145] In 1977, Kopf and Bart described multiple bowenoid papules of the penis.[146] In 1979, Wade et al coined the term *bowenoid papulosis of the genitalia*.[147] Other terms used for this condition include *pigmented penile papules with carcinoma in situ changes*, *genital keratinocytic dysplasia*, and *penile carcinoma in situ associated with HPV infection*.

BOX 113-3 VIRAL ASSOCIATED PREMALIGNANT NEOPLASMS

PREMALIGNANT LESION	ASSOCIATED VIRUS	
	Most Often Detected	***Less Often Detected***
Bowenoid papulosis (BP)	HPV-16,18	HPV-31–35,39,42,48,51–54
Epidermodysplasia verruciformis (EV)	HPV-5,8	HPV-9,12,14,15,17,19,25,26,38,47,50, etc.
Vulvar intraepithelial neoplasia (VIN)	HPV-16	HPV-18,31,33
Anal intraepithelial neoplasia (AIN)	HPV-16	HPV-18,31,33
Perianal intraepithelial neoplasia (PaIN)	HPV-16	HPV-18,31,33
Penile intraepithelial neoplasia (PIN)	HPV-16	
Digital or periungual Bowen disease	HPV-16	

BP is caused by infection with HPV, and numerous HPV types have been linked to BP, particularly hrHPV subtypes 16 and 18, but also including 31–35, 39, 42, 48, and 51–54 (see Chapter 196). Lesions are pink, reddish brown, or violaceous (see Fig. 113-7). Differential diagnosis includes early condylomata acuminata (see Chapters 77 and 78).

Histopathologically, the epidermis is usually hyperplastic with atypia, disordered maturation, scattered mitotic figures, and dyskeratotic keratinocytes.

The course of BP is variable, but mostly benign, ranging from spontaneous regression to persistence of lesions to rarely transformation into BD and invasive SCC. It has been estimated that the risk of malignant transformation is quite low, ranging from less than 1%–2.6 %.[144,148] BP is highly contagious and patients with BP and their sexual partners should be followed and examined periodically, because of the increased risk of developing SCC, cervical, and vulvar neoplasia.[149] Patients with persistent disease should probably undergo testing for altered immune status. Treatment of BP is recommended, and it typically responds well to local therapy, although recurrences are common. Therapeutic options include local destructive measures such as curettage with or without electrosurgery, CO_2 laser, neodymium:YAG laser, cryosurgery, and excision. Topical tretinoin, topical 5-FU, and topical cidofovir have been used in anecdotally reported cases with mixed results.[150] More recently, topical 5% imiquimod cream has shown promising results in a few case reports and would be the logical choice given its efficacy against HPV.[151–156]

EPIDERMODYSPLASIA VERRUCIFORMIS

(See Chapter 196)

EV is a rare inherited skin condition that arises when genetically susceptible individuals are infected with certain HPV subtypes, most notably HPV 5 and HPV 8, but also including HPV types 9, 12, 14, 15, 17, 19, 25, 36, 38, 47, and 50. EV individuals present in childhood with numerous thin, pink, flat papules and plaques that resemble verruca plana. They also have widespread scaly, erythematous, or hypopigmented macules and flat papules that appear similar to tinea versicolor. Approximately 30%–60% of persons with EV will develop cutaneous malignancies in these wart-like lesions, most often in the fourth to fifth decades of life and usually on sun-exposed areas of the skin. About 90% of these EV-related SCCs have been associated with HPV subtypes 5 and 8. A susceptibility for EV was localized to chromosome 17q25 in 1999,[157] and mutations in two novel genes from this same region (*EVER1* and *EVER2*) were identified and associated with EV more recently.[158] In addition to the host genetic background, these EV-HPVs are activated by UV exposure and immunosuppression.

EV histopathologically may mimic other skin conditions and therefore a combination of patient history, clinical and histopathologic findings, plus viral and genetic testing is crucial to making the diagnosis of EV. Lastly, as EV-like lesions have been observed in the setting of immunosuppression (acquired EV), patients suspected of having EV should also be tested for HIV and other etiologies for impaired cell-mediated immunity should be considered.[159] No specific or successful treatments exist for EV lesions. Mixed results have been seen with topical 5% imiquimod cream.[159]

SQUAMOUS CELL CARCINOMA IN SITU (BOWEN DISEASE)

SQUAMOUS CELL CARCINOMA IN SITU (BOWEN DISEASE) AT A GLANCE

- Bowen disease (BD) is squamous cell carcinoma (SCC) in situ, with the potential to progress to SCC.
- Etiologic factors include ultraviolet (UV) radiation exposure, chronic arsenicism, previous therapy with psoralen and UVA radiation, immunosuppression, exposure to ionizing radiation, and infection with human papillomavirus (HPV).
- Clinical variants are pigmented, intertriginous, periungual, and subungual BD.
- Histopathologic features include full-thickness epidermal atypia with adnexal involvement.
- Lesions progress to invasive carcinoma in 3%–5% of cases.
- Treatment methods include excision and Mohs micrographic surgery, which permit histopathologic evaluation to exclude invasive SCC.
- Curettage treatment of BD may miss appendageal involvement.
- Topical therapy may be used in areas that are difficult to treat with other methods with limited trials supporting their use.

Bowen disease (BD) is SCC in situ, originally described in 1912 by John T. Bowen, a Boston dermatologist.[160] It affects both skin and mucous membranes and has the potential to progress to invasive SCC.

EPIDEMIOLOGY

BD may occur at any age in adults, but it is rarely seen in individuals younger than 30 years. The

typical patient with BD is older than 60 years. The disease is said to occur with an equal incidence in men and women, although most studies report a slight preponderance in women.[161] BD can be found on any body site, including both sun-exposed and nonsun-exposed regions of the body, although it appears to have a predilection for sun-exposed surfaces such as the head and neck and for the lower legs of women, in particular. The exact incidence of BD in the United States is unknown, but in one population study in Hawaii, the incidence was estimated at 142 per 100,000 persons.[162] Lesions of BD are usually solitary but are multiple in up to 10%–20% of individuals.

ETIOLOGY AND PATHOGENESIS

A number of different factors have been implicated in the development of BD, including a history of significant sun exposure, arsenic exposure, ionizing radiation, immunosuppression, and certain types of HPV infection. Up to 30% of extragenital BD lesions have been found to harbor HPV DNA.[163,164] The age group and sites of predilection of BD suggest a strong association with sun exposure. BD is also rare in more heavily pigmented individuals, and it has been described with increased frequency in patients undergoing psoralen plus ultraviolet A (PUVA) therapy. The association with arsenic exposure has already been discussed. SCC in situ is seen commonly in organ transplant recipients after years of immunosuppressive drug therapy. Infection with HPV has been implicated in causing certain subtypes of BD. In particular, HPV-16 has been detected in many cases of anogenital BD and in some cases of finger and periungual BD.[165]

CLINICAL FINDINGS

BD typically presents as a discrete, slowly enlarging, pink to erythematous thin plaque with well-demarcated, irregular borders and overlying scale or crust (Fig. 113-8A) resembling a psoriatic plaque. Hyperkeratotic and verrucous surface changes may be seen, and a pigmented variant of BD has been reported in fewer

Figure 113-8 **A.** Large plaque of Bowen disease (BD) of the leg. **B.** BD of the nail unit. **C.** BD showing full-thickness atypia of epithelium.

than 2% of cases.[166] Individual lesions may measure up to several centimeters in diameter, and multiple lesions are not uncommon. As previously mentioned, sites of predilection include sun-exposed areas such as the head and neck and lower legs, although any body site may be affected.

A few clinical variants of BD deserve special mention. Intertriginous BD can present as an oozing, erythematous, dermatitic plaque or as a pigmented patch or plaque. BD involving the periungual region may appear as an erythematous, scaly, thin plaque around the cuticular margin, a crusted erosion, nail discoloration, erythronychia, onycholysis, a verrucous plaque, or destruction of the nail plate (Fig. 113-8B). BD of the mucosal surfaces can present as verrucous or polypoid papules and plaques, erythroplakia, or a velvety erythematous plaque. These last two entities are discussed below in the sections on precancerous lesions of the oral cavity and the lower anogenital tract, respectively.

HISTOPATHOLOGY

The epidermis displays full-thickness atypia, including in the intraepidermal portions of the adnexal structures (see Fig. 113-8C). Involvement reaches from the stratum corneum down through the basal cell layer, although the basement membrane remains intact. Characteristically, parakeratosis and hyperkeratosis are present, as is acanthosis, with complete disorganization of the epidermal architecture. At times, the hyperkeratosis and parakeratosis are so pronounced that a cutaneous horn is present. Throughout the epidermis are numerous atypical, pleomorphic, hyperchromatic keratinocytes. These cells are sometimes vacuolated and have a prominent pale-staining cytoplasm, reminiscent of the cells in Paget disease. These cells show loss of maturation and polarity, in addition to numerous mitotic figures. Individually, keratinized cells with large, rounded, eosinophilic cytoplasm, and hyperchromatic nuclei can be found in the epidermis, as can multinucleated cells. These atypical cells also are seen throughout the pilosebaceous units, within the acrotrichia, follicular infundibula, and sebaceous glands. The upper dermis is typically infiltrated by numerous chronic inflammatory cells, including lymphocytes, plasma cells, and histiocytes.

Several histopathologic subtypes of BD can be seen. Psoriasiform BD displays parakeratosis and marked acanthosis with broad, sometimes fused, epidermal rete ridges. Atrophic BD, like atrophic AK, demonstrates a thinned epidermis, but in addition there is full-thickness atypia and lack of maturation, as well as adnexal involvement. Acantholytic BD shows marked acantholysis in the epidermis. Epidermolytic BD has changes of incidental epidermolytic hyperkeratosis (EHK) present. The phenomenon of intraepidermal epithelioma of Borst-Jadassohn—namely, nesting of the atypical cells within the epidermis, or so-called *pagetoid BD*—can also be seen.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Clinically, BD is most often mistaken for superficial BCC; patches of dermatitis, psoriasis, or lichen planus; AK; benign lichenoid keratosis (BLK) or lichen planus-like keratosis; irritated seborrheic keratosis; or amelanotic melanoma (Box 113-4). More

BOX 113-4 CLINICAL AND HISTOPATHOLOGIC DIFFERENTIAL DIAGNOSIS OF BOWEN DISEASE

CLINICAL DIFFERENTIAL DIAGNOSIS OF BOWEN DISEASE

- Erythematous Bowen disease
  - Superficial basal cell carcinoma
  - Dermatitis, eczema
  - Psoriasis
  - Seborrheic dermatitis
  - Lichen planus
  - Benign lichenoid keratosis
  - Irritated or inflamed seborrheic keratosis
  - Actinic keratosis
  - Squamous cell carcinoma
  - Amelanotic melanoma
- Hyperkeratotic Bowen disease
  - Verruca vulgaris
  - Seborrheic keratosis
  - Discoid lupus erythematosus
  - Hypertrophic lichen planus
  - Squamous cell carcinoma
- Pigmented Bowen disease
  - Melanoma
  - Bowenoid papulosis
- Intertriginous Bowen disease
  - Inverse psoriasis
  - Seborrheic dermatitis
  - Candidiasis
  - Paget disease
  - Hailey–Hailey disease
- Subungual or periungual Bowen disease
  - Nail dystrophy
  - Onychomycosis
  - Squamous cell carcinoma
  - Amelanotic melanoma

HISTOPATHOLOGIC DIFFERENTIAL DIAGNOSIS OF BOWEN DISEASE

- Paget disease
- Pagetoid melanoma in situ
- Intraepidermal eccrine carcinoma
- Intraepidermal Merkel cell carcinoma
- Intraepidermal sebaceous carcinoma
- Bowenoid papulosis
- Podophyllin-induced changes in a wart

hyperkeratotic or verrucous lesions of BD may be difficult to distinguish clinically from viral warts, seborrheic keratoses, and SCC, and pigmented BD lesions can be mistaken for melanoma. Superficial BCC can sometimes be distinguished by its raised, subtle, and translucent border. Histopathologically, BD must be differentiated from Paget's disease; pagetoid melanoma in situ; eccrine, Merkel, and sebaceous carcinomas; BP; and *podophyllin*-induced changes in a wart (see Box 113-4). Both Paget's disease and BD may have the findings of vacuolated cells, but in contrast with BD, Paget's disease shows no dyskeratosis. Also, the material present in Paget's cells is periodic acid-Schiff (*PAS*) positive and diastase-resistant, whereas the PAS-positive material sometimes present in BD cells (i.e., clear cell BD) is glycogen and therefore PAS labile. Finally, staining for carcinoembryonic antigen yields positive results in Paget's disease but negative results in BD. Pagetoid melanoma in situ can be difficult at times to distinguish histopathologically from BD. In BD, the intercellular desmosomal bridges should be identifiable between the atypical keratinocytes, and melanocyte specific immunoperoxidase staining gives positive results in melanoma cells but negative results in BD and Paget's disease cells. The other rare pagetoid neoplasms are usually recognizable, but erroneous diagnoses can be made by the unwary. BP may lack the full-thickness epidermal atypia present in BD, but the clinical setting is paramount. Podophyllin applied topically to skin lesions causes metaphase arrest with resultant bizarre keratinocyte formation and sometimes a pattern of pseudoepitheliomatous hyperplasia that can be mistaken for BD. These changes typically resolve after a few days to a week.[167]

PROGNOSIS AND CLINICAL COURSE

The risk that untreated BD will progress to invasive carcinoma has been estimated in one older study at approximately 3%–5%.[163] Estimates are that once invasive carcinoma occurs in BD [see thumbnail image in "Squamous Cell Carcinoma In Situ (Bowen Disease) At a Glance" box], approximately 13% of these carcinomas will metastasize, and of these cases, 10% will end in death from widespread dissemination.[168]

The presence of BD in any given individual is a marker for a high risk of developing a subsequent NMSC.[169] In studies addressing the association between the presence of BD and the risk of other NMSCs, approximately 30%–50% of BD patients had either previous or subsequent NMSC. Another study estimated the incidence ratio for subsequent NMSC to be 4.3.[169] Previous studies also claimed that the presence of BD is a marker for internal malignancy, although a significant number of other investigations have been unable to substantiate this association. Critical analysis and meta-analysis of these past studies do not support the need for routine investigation for internal malignancy in persons with BD. The one exception to this position is in cases of BD related to previous arsenic exposure, in which the possibility of internal malignancy is real, as previously discussed. Also, BD involving the vulvar region in females and the perianal region in males has been associated with an increased risk of uterine, cervical, vaginal, and anal cancer, possibly due to HPV infection, as discussed.[122,170]

TREATMENT

A number of different modalities are available for the treatment of BD. Such treatments can be divided into three main categories: surgical and destructive therapies, topical therapies, and nonsurgical ablative therapies (Box 113-5). Surgical and destructive therapies include excision, Mohs micrographic surgery, curettage with or without electrosurgery, chemoablation with TCA, and cryosurgery. Topical therapies include 5-FU and 5% imiquimod cream (see Chapter 221). Nonsurgical ablative therapies are laser ablation, radiotherapy, and PDT (see Chapter 238). Although some of these modalities have reported cure rates that are better than others, no one treatment is right for all forms of BD. Therapy must be guided by the size and location of the BD, in addition to individual patient characteristics, such as age and healing capability. BD warrants definitive surgical therapy if it has previously failed topical chemotherapy or ablative surgery, due to its propensity to eventually affect large surface areas and to become invasive.

BOX 113-5 TREATMENT OF BOWEN DISEASE

SURGICAL AND DESTRUCTIVE THERAPIES
- Excision
- Mohs micrographic surgery
- Curettage with or without electrosurgery
- Liquid nitrogen cryosurgery

TOPICAL THERAPIES
- 5-Fluorouracil (5% cream bid for 6–16 weeks)
- 5% imiquimod (daily for 16 weeks)

NONSURGICAL ABLATIVE THERAPIES
- Laser ablation
- Radiotherapy
- Photodynamic therapy

PRECANCEROUS LESIONS OF THE LOWER ANOGENITAL TRACT

ANAL (AIN) AND PERIANAL (PaIN) INTRAEPITHELIAL NEOPLASIA AT A GLANCE

- Anal intraepithelial neoplasia (AIN) is an human papillomavirus (HPV)-associated precursor lesion of anal squamous cell carcinoma (SCC) and has been previously called anal squamous intraepithelial neoplasia (ASIL) or anal dysplasia; it is embryonically and histopathologically analogous to cervical intraepithelial neoplasia (CIN).
- Perianal intraepithelial neoplasia (PaIN) is a precursor lesion of perianal, cutaneous SCC and has also been called genital Bowen disease (GBD), SCC in situ, and sometimes bowenoid papulosis (BP); it is less likely associated with HPV than AIN; and only 5% of such cases may progress to invasive SCC.
- AIN1 is a low-grade lesion and not a direct precursor of anal SCC.
- AIN2 and AIN3 are high-grade precursor lesions of anal SCC and histopathologically display moderate and severe dysplasia, respectively.
- The greatest risk factors for AIN are HPV infection, receptive anal intercourse, HIV infection, smoking, and a history of CIN in females.
- AIN is associated with oncogenic hrHPV types 16, 18, 31, and, less so, HPV-33.
- AIN may be asymptomatic or present with pruritus, pain, bleeding, tenesmus, or discharge.
- PaIN may present with a variety of clinical patterns, including well-demarcated erythematous, or variably pigmented plaques.
- Histopathology of PaIN is that of cutaneous SCC in situ and that of AIN is analogous to CIN.
- Dermatologists play a role in high-risk patients by examining the perianal skin and, if PaIN is diagnosed, initiating treatment for PaIN and then referring such patients to an expert in diagnosing and managing AIN and CIN for further evaluation.
- Treatment options for PaIN include wide local excision, Mohs micrographic surgery, and various topical agents.
- There is a high-risk of recurrence of AIN and an increased association with other anogenital intraepithelial neoplasias (Ins), necessitating referral and ongoing surveillance.
- HPV vaccination of males for prevention of AIN is undergoing investigation.

VULVAR INTRAEPITHELIAL NEOPLASIA (VIN)

VULVAR INTRAEPITHELIAL NEOPLASIA (VIN) AT A GLANCE

- Vulvar intraepithelial neoplasia (VIN) is a high-grade precancerous lesion of the vulva that may progress to vulvar squamous cell carcinoma (SCC).
- It is primarily a disease of younger females (75% of all cases) and its incidence is rising globally.
- There are three categories of VIN: (1) usual type, (2) differentiated type, and (3) unclassified type.
- VIN, usual type associated with hrHPV-16, 18, 31; occurs in younger premenopausal females; presents with multifocal and multicentric lesions; has 50% association with cervical intraepithelial neoplasia (CIN).
- VIN, differentiated type less common than usual type; usually not associated with HPV; affects postmenopausal females; is associated with lichen sclerosus; unifocal presentation.
- A diagnosis of VIN mandates referral to gynecologist to look for CIN.
- VIN has a varied clinical presentation and the differential diagnosis includes lichen sclerosus, lichen planus, condyloma acuminata, and cutaneous melanoma.
- No consensus on best treatment; consult with gynecologist.
- HPV vaccine in young females can prevent HPV-related VIN.

PENILE INTRAEPITHELIAL NEOPLASIA (PIN)

PENILE INTRAEPITHELIAL NEOPLASIA (PIN) AT A GLANCE

- Penile intraepithelial neoplasia (PIN) is a precursor lesion to penile squamous cell carcinoma (SCC); two clinical variants of PIN are the genital Bowen disease (GBD) and the erythroplasia of Queyrat (EQ) variants.
- PIN and penile cancer are rare in the Western world but increasing in incidence in developing countries.
- PIN and penile SCC are mainly diseases of older, uncircumcised males.
- Risk factors in uncircumcised males include poor hygiene, smegma retention, phimosis, chronic inflammatory and infectious conditions of the penis; and less so coinfection with oncogenic hrHPV (primarily 16, but also 18, 31, and 33), lichen sclerosus, HIV infection, immunosuppression, smoking, PUVA and UVR exposure of the genitalia.
- About 40%–45% of PIN and penile SCC are associated with HPV.
- There are two independent pathways in the development of PIN and penile SCC: an HPV-positive pathway and an HPV-negative pathway.
- The HPV-positive pathway is morphologically associated with the warty and basaloid subtypes of penile SCC and is thought to be more aggressive.
- The HPV-negative pathway is morphologically associated with the usual or differentiated type of penile SCC, which is the major type (~49%) of all of the penile SCCs.
- The EQ variant of PIN is the most common type of PIN and is always associated with HPV-8 and most often with concomitant HPV-16 coinfection; presents as a well-demarcated, glistening, erythematous, velvety plaque or plaques on the mucosal surfaces of the penis.
- The GBD variant of PIN is less common than the EQ variant; presents as a well-demarcated, erythematous to variably pigmented plaque on the shaft of the penis.
- Histopathology of both the GBD and EQ variants of PIN show SCC in situ changes, but EQ has more epithelial hypoplasia and plasma cells in the dermal infiltrate.
- EQ variant of PIN is more likely to progress to invasive SCC (~30%) vs. the GBD variant (3%–6%).
- No definitive treatment guidelines for PIN and treatment options are similar as those for other forms of SCC in situ; must be individualized to preserve anatomy and function as best as possible.
- Prevention is important and can be advocated with neonatal circumcision; in uncircumcised males, must advocate proper hygiene, stopping smoking, treating chronic inflammatory and infectious penile conditions, and avoiding genital PUVA and UVR exposure; HPV vaccine is investigational.

POTENTIALLY MALIGNANT DISORDERS OF THE ORAL CAVITY

In a World Health Organization (WHO) workshop held in 2005, the terminology, definitions, and classification of oral lesions with a predisposition to malignant transformation were discussed.[193] The term *potentially malignant* was preferred over *premalignant* or *precancerous*. In addition, it was recommended that the traditional distinction between potentially malignant *lesions* and potentially malignant *conditions* be abandoned and that the term *potentially malignant disorders* be used instead. In this chapter the focus will be on oral leukoplakia (OL) and erythroplakia.

LEUKOPLAKIA

Leukoplakia is a clinical term that refers to a predominantly white lesion of the oral mucosa that cannot be rubbed off or characterized by any other definable lesion or known disease.[194] Leukoplakia is the most common precancerous lesion of the oral mucosa, with

LEUKOPLAKIA AT A GLANCE

- Leukoplakia is a clinical diagnosis of exclusion for a fixed white lesion in the oral cavity that does not resolve spontaneously.
- Oral leukoplakia (OL) is the most common precancerous lesion of the oral mucosa, with the potential to become oral squamous cell carcinoma (OSCC).
- Prevalence is 0.2%–5.0%.
- Approximately 50% of OSCCs are associated with precancerous lesions.
- OL and oral erythroplakia (OE) are markers for increased risk for additional oral or upper aerodigestive tract malignancies.
- Risk factors for OL are the use of any tobacco product, concomitant alcohol use, history of previous OSCC or premalignant lesions, and infection with certain human papillomavirus (HPV) subtypes.
- No consensus exists on how best to treat OL.

the potential to become oral SCC (OSCC).[195] OL is in the same clinical spectrum of disease as oral erythroplakia (OE), but unlike OE it is a much more frequently diagnosed lesion with a much lower rate of malignant transformation.

EPIDEMIOLOGY

The reported prevalence of OL varies from 0.2% to 5%, although such rates vary significantly among different geographical areas and demographic groups.[196] In a worldwide systematic review of OL that included multiple studies involving more than 1,000 subjects, prevalence rates varied between 0.50% and 3.46%.[197] The pooled prevalence estimate of OL in this study was between 1.49% and 4.27%.[197] Leukoplakia is six times more common among smokers than among nonsmokers.[198] Alcohol is an independent risk factor, regardless of beverage type or drinking pattern.[199] There are conflicting results as to the possible role of HPV infection.[200–202]

In addition to potentially becoming a malignant growth, OL, and for that matter OE, have come to be viewed as risk factors or markers for other epithelial cancers of the oral cavity and upper aerodigestive tract. The concept of field cancerization applied to the oral mucosa implies that its entire surface can be affected by carcinogens. Indeed, approximately 20% of patients with SCC of the head and neck will develop another malignancy or precancerous lesion within 5 years of the first diagnosis.[203]

ETIOLOGY AND PATHOGENESIS

Given the current definition of leukoplakia, identification of an etiologic factor for a given white lesion would exclude this diagnosis. Two factors in this setting are tobacco use and candidiasis. Tobacco use is believed to be a strong risk factor for the development of OL. Tobacco-related white lesions of the oral mucosa have been identified and then subsequently found to disappear once the habit of tobacco use has been discontinued. By current definitions and standards, such tobacco-related white lesions are thought to be different entities than true OL, which would not disappear with cessation of tobacco use.

Likewise, there has been much debate as to whether or not *Candida* infection is a cause of leukoplakia or a superimposed infection within a preexisting OL lesion. If one adheres to the strict and accepted definition of leukoplakia, a white lesion that disappears upon treatment of *Candida* infection is not leukoplakia. Thus, it is probably best to make a preliminary diagnosis of leukoplakia and then treat any underlying candidal infection and have the patient discontinue use of any tobacco products to see if the white lesion resolves. If such a lesion then resolves, it is not true leukoplakia.

The development of OL has been associated most strongly with the use of tobacco products, including smoked tobacco (cigarettes, cigars, pipe tobacco), smokeless tobacco (snuff, chewing tobacco), pan masala, and betel nut quid, as well as alternative tobacco products like bidis and kreteks. Also, combined tobacco use and alcohol consumption are thought to be synergistic in the development of OL and OSCC. Persons with a previous malignancy or premalignancy of the upper aerodigestive tract are at increased risk for further such lesions and malignancies, as previously mentioned. Preliminary studies suggest that HPV infection is two to three times more prevalent in oral precancerous mucosa and four to five times more prevalent in OSCC than in normal epithelium.[204] In the same meta-analysis, hrHPV (16 and 18) were more frequently associated with OSCC than were low-risk HPV types.[204]

One study addressed the clinical risk factors for OL in a representative sample of the US population drawn from among the 15,811 participants in the US National Health and Nutrition Examination Survey III.[205] In this study, females were less likely than males to have OL. The strongest independent risk factor was tobacco smoking. Three other independent predictors of OL were diabetes, increasing age, and lower socioeconomic status. Alcohol consumption, race and ethnicity, years of education, and body mass index all showed no independent association with OL.[205] Investigators strongly urged further studies to confirm these findings (see Chapter 76).

CLINICAL FINDINGS

OL is clinically divided into two subtypes: homogeneous OL and nonhomogeneous OL. Homogeneous OL has been defined as a mostly white, flat, uniform lesion

that may have shallow cracks and a smooth, wrinkled, or corrugated surface that is consistent throughout.[206] Nonhomogeneous OL has been defined as a mostly white or white and red lesion (erythroleukoplakia) that may be irregular and flat, nodular (speckled), ulcerative, or verrucous. Nonhomogeneous OL purportedly has a risk of malignant transformation that is four to five times higher than that of homogeneous OL. Another clinical subtype of OL is proliferative verrucous leukoplakia, which is most often found in patients who do not use tobacco products. This subtype has a high rate of transformation to malignancy.[207]

HISTOPATHOLOGY

If the provisional diagnosis of OL is at all in doubt and/or a waiting period to assess for possible regression or disappearance of a white lesion after eliminating possible causative factors has not resulted in resolution of the lesion, the next advisable step in evaluating the oral white lesion is to obtain a biopsy specimen for histopathologic diagnosis. This is where the concepts of epithelial dysplasia and carcinoma in situ enter the picture.

In relation to the oral mucosa, epithelial dysplasia has been defined as a "precancerous lesion of stratified squamous epithelium characterized by cellular atypia and loss of normal maturation and stratification short of carcinoma in situ."[212] Carcinoma in situ of the oral cavity has been described as "a lesion in which the full thickness, or almost the full thickness, of squamous epithelium shows the cellular features of carcinoma without stromal invasion."[212] Criteria have been put forth for diagnosing these changes, and the more prominent and numerous the designated features are, the more severe the grade of dysplasia.[195,206]

On the basis of these subjective criteria, lesions are usually graded into mild-, moderate-, and severe epithelial dysplasia. A number of studies have shown significant intra- and interexaminer inconsistencies in assessing the presence or absence of oral epithelial dysplasia as well as its grade on histopathologic examination.[195] Other studies have shown great variability in the number of lesions that go on to develop into malignancies based on their degrees of dysplasia. Some studies have shown a positive correlation between the degree of dysplasia and the development of malignancy, and others have demonstrated no correlation whatsoever.[195]

On the basis of these inconsistencies, three major problems have been identified in attaching significance to the degree of epithelial dysplasia in OL lesions as predictors of their malignant potential. First, the diagnosis of epithelial dysplasia is largely subjective. Second, although a definite correlation between degree of dysplasia and malignant potential has been shown, not all dysplastic lesions will progress to malignancy, and some may even regress. Third, OSCC has been shown to develop from nondysplastic oral epithelial lesions.[195]

As imperfect as this histopathologic grading system is, epithelial dysplasia in its varying degrees is still one of the few indicators available of an increased risk for OSCC.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

A diagnosis of leukoplakia is made when a fixed white lesion of the oral mucosa is detected and cannot be identified as any other definable lesion or condition. Some suggest distinguishing between a provisional clinical diagnosis of OL and a definitive diagnosis of OL.[194] A provisional diagnosis of OL is made at the time of the initial examination when no other diagnosis for the white lesion is obvious. At this point, other possibilities to consider in the differential diagnosis are tobacco-associated lesions, *Candida*-associated lesions, lichen planus, leukoedema, lupus erythematosus, Epstein–Barr virus-associated oral hairy leukoplakia, oral white sponge nevus, mechanical or frictional irritation, contact lesions, cheek/lip/tongue biting, linea alba, aspirin burn, OSCC, and verrucous carcinoma (Box 113-6). If causative factors for the white lesion

BOX 113-6 CLINICAL DIFFERENTIAL DIAGNOSIS OF ORAL LEUKOPLAKIA AND ORAL ERYTHROPLAKIA

CLINICAL DIFFERENTIAL DIAGNOSIS OF ORAL LEUKOPLAKIA

- Tobacco-associated lesion
- *Candida*-associated lesion
- Leukoedema
- Lichen planus
- Lupus erythematosus
- Linea alba
- Habitual cheek biting
- Frictional lesion
- Aspirin burn
- Oral white sponge nevus
- Oral hairy leukoplakia
- Verrucous carcinoma
- Squamous cell carcinoma

CLINICAL DIFFERENTIAL DIAGNOSIS OF ORAL ERYTHROPLAKIA

- Erythematous candidiasis
- Atrophic lichen planus
- Lupus erythematosus
- Pemphigus
- Cicatricial pemphigoid
- Kaposi sarcoma
- Chronic contact or allergic contact dermatitis
- Chronic mechanical trauma
- Thermal or mechanical injury
- Squamous cell carcinoma
- Amelanotic melanoma

are suspected, it is recommended that these factors be eliminated for a period of 2–6 weeks to observe for regression of the white lesion. If upon reevaluation the white lesion persists, biopsy should be performed. If the lesion is clinically at high-risk for OSCC, biopsy should be performed before such a waiting period.

PROGNOSIS AND CLINICAL COURSE

Once a definitive diagnosis of OL has been made, the risk of transformation to OSCC needs to be evaluated. The rate of malignant transformation of OL into OSCC has been found to vary from almost 0% to 20% in 1–30 years.[213] A study based on European epidemiologic data investigated the natural limit of malignant transformation of OL to OSCC. This study concluded that the upper limit of the annual malignant transformation rate of OL is unlikely to exceed 1%.[196]

The commonly recognized variables that statistically carry an increased risk for malignant transformation into an SCC are listed in Box 113-7. Of these variables, the presence of dysplasia is the most important indicator. However, it should be recognized that not all dysplastic lesions progress to malignancy. Some remain clinically unchanged and others may spontaneously regress. Furthermore, malignant transformation may occur in nondysplastic leukoplakia.

In spite of great progress in the field of molecular biology, there is not yet one single marker or set of markers that reliably enables prediction of malignant transformation of leukoplakia in an individual with OL.[193]

TREATMENT AND PREVENTION

The goal of treatment is to prevent the malignant transformation of OL to OSCC and to relieve patient symptoms, although there is no evidence that treatment of OL can prevent the future development of OSCC. There is no consensus on the most appropriate treatment for OL. Some recommend the following approach: if no or mild epithelial dysplasia exists histopathologically, pursue treatment if the OL is in a high-risk location or is large; if moderate or severe dysplasia exists histopathologically, then active treatment to remove the entire lesion is recommended.[206] A systematic review of all the randomized, controlled trials of all therapies for OL ($n = 7$) concluded that there is no known nonsurgical therapy to prevent OL from developing in the first place or to prevent OL from transforming into OSCC.[213] The reviewers did find some evidence that treatment with *vitamin A*, retinoids, and β-carotene may completely resolve the oral lesions and that treatment with *retinoic acid* may prevent histopathologic worsening, but these findings were based on only a small number of patients.[213]

Postexcision recurrences are common and occur in 10%–20% of cases, and OSCC develops within excised areas in 3%–9% of instances.[210] In addition, surgical excision with histopathologically clear margins did not prevent OSCC or improve survival outcomes in the group of patients with aneuploid dysplastic OL, the most likely form of OL to progress to OSCC, in one study.[214]

CO_2 laser vaporization is another commonly employed treatment modality—again without substantial data to support its use. In one review of 200 patients with 282 OL lesions treated with CO_2 laser vaporization between 1976 and 2001, 89% (n = 251) had no recurrence during a mean follow-up time of 52 months; 9.9% (n = 28) had local recurrence between 5 months and 168 months after treatment; and 1.1% (n = 3) developed OSCC within the treated area at 7, 17, and 19 months after the CO_2 laser treatment.[215]

Because the recurrence of OL after treatment is common and the risk of OSCC is present with or without treatment, and because patients with OL are at increased risk for additional head and neck malignancies, these patients need to be followed at regular intervals with thorough examinations and potentially with additional biopsies. Follow-up intervals may vary from every 3 months in high-risk individuals to every 6 months in those at lower risk, for the rest of the patients' lives.

Despite all the controversies and inconsistencies surrounding OL, standard historical, clinical, and histopathologic findings are still the most important factors for predicting the possibility of malignant transformation of precancerous oral lesions. Treatment plans are guided mostly by findings from careful clinical and oral examinations, especially in individuals at high risk, and by histopathologic evaluation for the presence and degree of epithelial dysplasia (Fig. 113-9).

BOX 113-7 SIGNIFICANT RISK FACTORS FOR THE CONVERSION OF ORAL LEUKOPLAKIA (OL) INTO ORAL SQUAMOUS CELL CARCINOMA[a]

Most Important Risk Factor

- Presence of epithelial dysplasia

Other Risk Factors

- Female gender
- Long duration of oral leukoplakia (OL)
- OL in nonsmokers
- Location on the floor of the mouth or tongue
- Size >200 mm^3
- Nonhomogeneous type of OL

[a]Adapted from van der Waal I: Potentially malignant disorders of the oropharyngeal mucosa: Terminology, classification, and present concepts of management. *Oral Oncol* **45**:317, 2009.

ERYTHROPLAKIA (ERYTHROPLASIA)

Erythroplakia, or *erythroplasia*, is a clinical term used to describe a red macule or patch on a mucosal surface that cannot be categorized as any other known disease

ERYTHROPLAKIA (ERYTHROPLASIA) AT A GLANCE

- Erythroplakia is a clinical diagnosis of exclusion for a persistent fixed red patch in the oral cavity.
- It is the least common of all oral precancerous lesions but has the greatest potential to harbor or become oral squamous cell carcinoma (OSCC).
- Risk factors are use of tobacco products and alcohol use.
- Early and effective treatment is important.
- Treatment for severely dysplastic lesions or in situ carcinoma is complete excision or Mohs micrographic surgery.

Approach to the management of leukoplakia

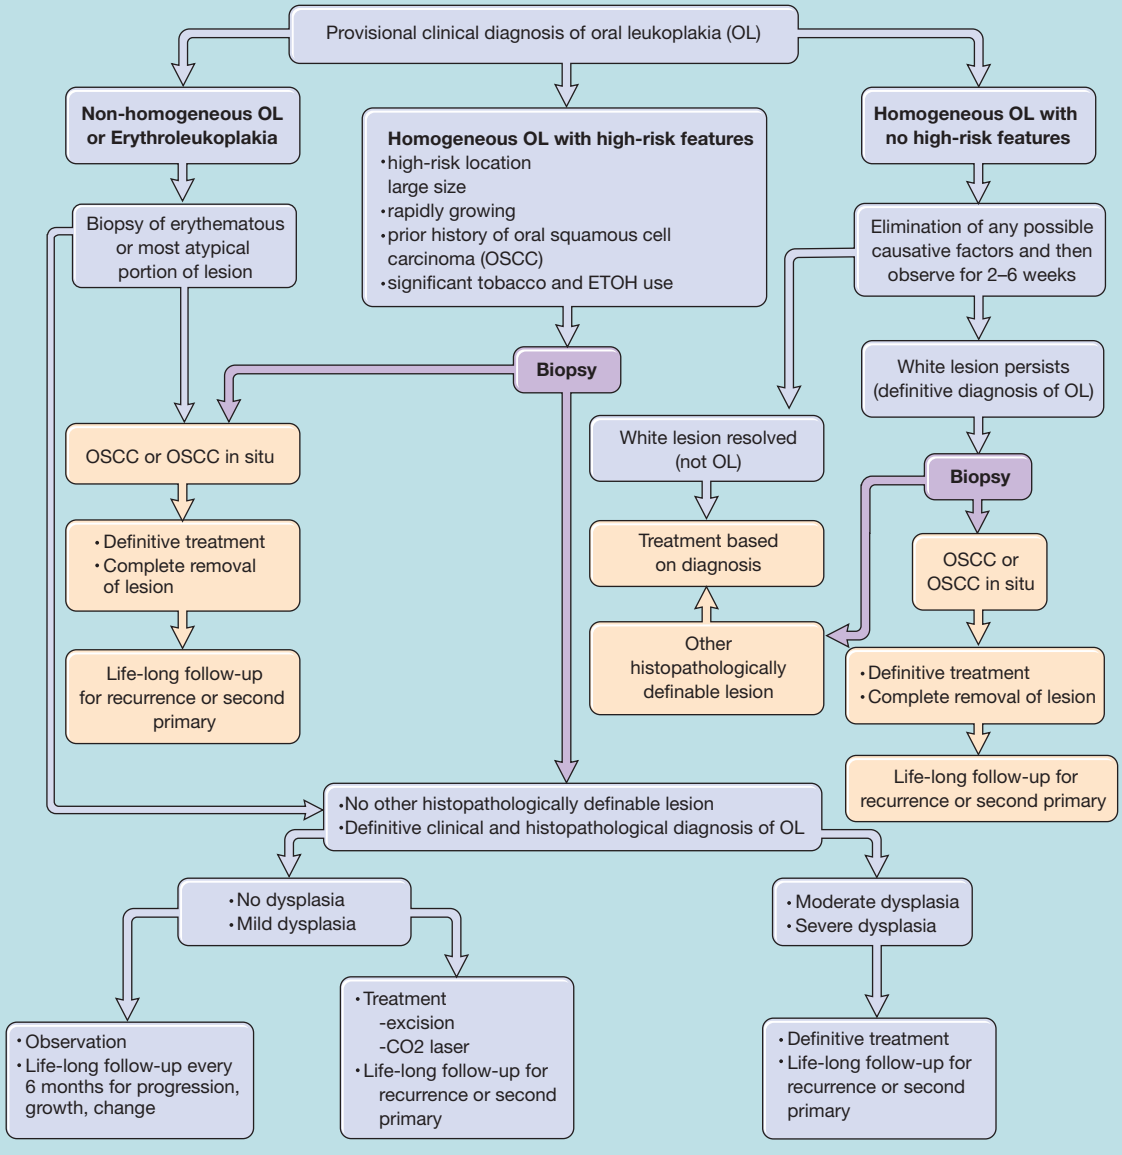

Figure 113-9 Approach to the management of oral leukoplakia. ETOH = ethanol.

entity caused by inflammatory, vascular, or traumatic factors. Histopathologically, it almost always displays either findings of SCC in situ or focal areas of invasive SCC, and thus is considered a precancerous lesion at best and always warrants treatment. Erythroplakia can involve any mucosal surface but most commonly occurs on the oral mucosa in more than half of all cases. Of all oral precancerous lesions, it is considered to be the most dangerous and carries the greatest risk of progressing to or harboring invasive carcinoma.

EPIDEMIOLOGY

Erythroplakia is an uncommon lesion in the oral cavity, and it is said to be one of the least commonly diagnosed lesions among the group of oral lesions that may or may not become malignant.[216] The prevalence, based on a small number of worldwide studies, is between 0.02% and 0.83%.[217] Both tobacco and alcohol are considered etiologic factors, and it mainly occurs in middle-aged individuals without a gender preference. It has been well described in the chutta smokers (reverse cigar smokers) of India.[217]

CLINICAL FINDINGS

OE is usually found either intraorally or on the vermillion surface of the lower lip. The most common areas in the oral cavity are the soft palate, the floor of the mouth, and the buccal mucosa. OE usually presents as a solitary, subtle, asymptomatic, erythematous macule or patch. Most often it is less than 1.5 cm in its widest diameter, but lesions up to 4 cm in diameter have been described.[217] Characteristically, it is sharply demarcated from the surrounding pink mucosa, and its surface is most often smooth and homogeneous in color. On occasion lesions of erythroplakia demonstrate a pebbled or stippled surface change and on palpation may have a soft and velvety feel. Induration indicates the presence of invasive carcinoma in many instances. Erythroplakia is commonly seen in association with leukoplakia, a condition termed *erythroleukoplakia*. It is the red patches of erythroleukoplakia that are most likely to contain or develop into a malignancy.

Chapter 114 :: Squamous Cell Carcinoma

:: Douglas Grossman & David J. Leffell

SQUAMOUS CELL CARCINOMA AT A GLANCE

- With basal cell carcinoma, most common human malignancy.
- Diagnosis is by biopsy.
- Caused by ultraviolet radiation in most cases.
- Precursor lesion is actinic keratosis.
- Treatment options are excision, Mohs micrographic surgery, and radiation.

Cutaneous squamous cell carcinomas (SCCs) are malignant neoplasms derived from suprabasal epidermal keratinocytes. These and basal cell cancers are the nonmelanoma skin cancers that represent the most common malignancies in humans. Whereas basal cell carcinoma (BCC) (see Chapter 115) is thought to arise de novo, SCC probably evolves in most cases from precursor lesions of actinic keratosis (AK) and Bowen disease (SCC in situ) (see Chapter 113). This chapter focuses on clinical aspects of invasive SCC. Cutaneous SCC represents a broad spectrum of disease ranging from easily managed, superficially invasive cancers to highly infiltrative, metastasizing tumors that can result in death. The clinical presentation can be variable despite the existence of easily identified typical

lesions. The cellular and molecular aspects of SCC carcinogenesis are discussed elsewhere (see Chapter 113).

HISTORICAL ASPECTS

EPIDEMIOLOGY

INCIDENCE. The precise incidence of BCC and SCC is unknown, because these cutaneous malignancies are not generally documented by the National Cancer Institute or most state cancer registries. However, it is generally accepted that well over 1 million cases are diagnosed in the United States each year, with approximately 200,000 representing SCC.[10] Although less common than BCC, SCC carries a risk of metastasis and thus accounts for the majority of the several thousand deaths attributable to nonmelanoma skin cancer each year. By comparison, cutaneous melanoma accounts for only 60,000 cases, but approximately 9,000 deaths, annually.[11] Similar trends for SCC have been noted in Australia[12] and the Caribbean.[13]

SCC is strongly associated with advanced age, and a sharp increase in incidence is seen after age 40 years.[14] Today, the lifetime risk of SCC among whites is approximately 15%, almost double that of two decades ago. Increased exposures to ultraviolet (UV) radiation (through greater use of tanning salons, increased time spent outdoors, changes in clothing styles, and ozone depletion) and greater longevity have been suggested as possible causes for the increase in disease. It is likely that this trend will continue as a result of further depletion of the ozone layer and the aging of the US population. The rising incidence of SCC over the past several decades has been paralleled by a 20% decrease in mortality, attributed largely to increased public awareness and aggressive treatment of high-risk lesions.[15] After a diagnosis of SCC, patients have a 44%–50% cumulative risk of developing another nonmelanoma skin cancer (18%–30% risk of SCC) in the subsequent 3–5 years.[16] In addition, these patients are at increased risk for extracutaneous–cancers.[17]

DEMOGRAPHICS

Squamous cell cancer is twice as common in men as in women, probably as a result of greater lifetime UV exposure in men. Similarly, longer hairstyles and use of lipstick may account for the lower frequency of SCC on the ears and lips of women. There is an inverse relationship between skin pigmentation and SCC incidence, largely because of the protective effect of eumelanin. Thus, persons with white skin, blue eyes, fair complexion, red hair, and Celtic ancestry who tan poorly are at greatest risk. Increased pigmentation is associated not only with a lower incidence of SCC, but also with an inversion in the BCC/SCC ratio. In comparison with whites, the incidence of SCC is decreased by 30-fold in American blacks and the BCC/SCC ratio falls to 0.8:1.[14] Tanzanian albinos all develop SCC by young adulthood, and the ratio of BCC to SCC is only 0.2:1. Asians and Polynesians, with intermediate skin pigmentation, have correspondingly intermediate levels of SCC. A gene (*MC1R*) involved in melanogenesis that encodes the melanocortin 1 receptor is a major determinant of skin pigmentation and hair color. The *MC1R* gene is highly polymorphic, with more than 20 variants described.[18] Several variant *MC1R* alleles are associated with increased risk of SCC that is independent of skin type and hair color.

ETIOLOGY AND PATHOGENESIS

PREDISPOSING FACTORS

There are a number of factors, including both acquired and genetic skin conditions that may predispose to SCC (Table 114-1). Patients often demonstrate a multiplicity of factors that together are sufficient to induce SCC development. For example, a given skin site may be exposed to both UV radiation and another environmental carcinogen.

PRECURSOR LESIONS. Most SCCs develop from precursor lesions such as AKs or Bowen disease (see Chapter 113).

ULTRAVIOLET RADIATION EXPOSURE. UV radiation is considered the predominant risk factor for SCC. Importantly, there is a linear correlation between the incidence of SCC and exposure to UV radiation. The incidence of SCC has been reported to double with each 8°–10° decline in geographic latitude and is highest at the equator.[19] World War II veterans stationed in the Pacific developed much higher rates of SCC than did their colleagues who served in Europe.[20] Similarly, SCC is more prevalent in Japanese people who emigrated to Hawaii than in those who remained in Japan.[21] Excessive UV radiation appears to be related more to the development of SCC than to the development of BCC. Rates of SCC rise more rapidly than those of BCC with increasing UV exposure,[22] and UV radiation-induced skin cancers in mice are almost exclusively SCCs rather than BCCs.[23] Moreover, in patients receiving long-term therapy with psoralen plus ultraviolet A (UVA) radiation for treatment of

TABLE 114-1
Predisposing Factors for Squamous Cell Carcinoma

- Precursor lesions (actinic keratosis, Bowen disease)
- Ultraviolet radiation exposure
- Ionizing radiation exposure
- Exposure to environmental carcinogens
- Immunosuppression
- Scars
- Burns or long-term heat exposure
- Chronic scarring or inflammatory dermatoses
- Human papillomavirus infection
- Genodermatoses (albinism, xeroderma pigmentosum, porokeratosis, epidermolysis bullosa)

psoriasis there is an associated 30-fold increase in nonmelanoma skin cancers, most of which are SCCs.[24]

IONIZING RADIATION. There is a strong association between SCC and exposure to ionizing radiation. In one survey of SCC patients, an association with radiation therapy was observed only in those whose skin was likely to sunburn (see Chapter 113).

ENVIRONMENTAL CARCINOGENS. Numerous occupational and environmental carcinogens, such as arsenic and aromatic hydrocarbons, predispose to the development of SCCs. With the exception of 3-methylcholanthrene and anthramine, chemical carcinogens generally produce SCCs rather than BCCs.[25] Exposures to insecticides and herbicides have also been associated with SCCs. In addition, smoking and alcohol use are strongly associated with SCCs of the oral cavity.

IMMUNOSUPPRESSION. Chronic immunosuppression may lead to an increase in SCCs, primarily on sun-exposed sites.[26] An 18-fold increase in SCC has been reported in renal transplant patients[27]; these tend to appear 3–7 years after the onset of long-term immunosuppressive therapy, with corticosteroids, azathioprine, and cyclosporine most frequently implicated. With the increase in the total number of organ transplant patients, management of SCCs in this population is becoming more important. In patients with leukemia and lymphoma, SCCs are both increased and more aggressive.[28] Although multiple SCCs have been described in patients infected with human immunodeficiency virus, advanced human immunodeficiency virus infection has generally not been associated with an increased incidence of SCC, possibly because many patients do not live long enough to develop them.

SCARS AND UNDERLYING DISEASES. Historically, SCC was associated with both burn scars and chronic ulcers as noted earlier, but such associations are seldom seen today. Also rare but reported is the development of SCCs in the context of chronic infections, particularly those associated with draining sinuses and scarring, such as perianal pyoderma, osteomyelitis, chromomycosis, hyalohyphomycosis, granuloma inguinale, lupus vulgaris, and leprosy. Chronic inflammatory processes, particularly those associated with scarring, such as venous ulcer, snakebite ulcer, discoid lupus erythematosus, oral lichen planus, morphea, lichen sclerosus, pilonidal cyst, acne conglobata, hidradenitis suppurativa, Hailey–Hailey disease, dissecting folliculitis of the scalp, and necrobiosis lipoidica, all can give rise to SCCs. An exception is vaccination scars, which are associated with BCCs rather than SCCs. SCCs have also been observed in transplanted skin, epidermal cyst, dental cyst, and dermoid cyst.

THERMAL FACTORS. Long-term heat exposure can lead to SCCs. The role of thermal radiation in the development of skin cancer has long been recognized in many cultures, where common practices include placing hot ashes under the clothes to keep warm in winter or smoking opium while lying on heated beds. The incidence of SCCs is increased in persons who habitually sit in front of heating stoves and at sites of erythema ab igne (see Chapter 113).

VIRAL INFECTION. A role for human papillomavirus (HPV) infection has been well established in some types of SCCs. Verrucous carcinoma appears to be associated with several HPV types, as noted later. Head and neck and periungual SCCs are frequently associated with HPV-16. Patients with epidermodysplasia verruciformis are chronically infected with HPV, most commonly type 5, and one-third of these patients ultimately develop SCCs (see Chapters 113 and 196). Recently, the MCPyV polyoma virus, originally discovered in Merkel cell carcinoma, was identified in approximately 15% of cutaneous SCCs from immunocompetent patients.[A] An etiological role for MCPyV in SCC remains to be demonstrated.

GENODERMATOSES. A variety of heritable diseases predispose to SCC development. Patients with oculocutaneous albinism develop predominantly SCCs (rather than BCCs) at an early age (see Chapter 73). Xeroderma pigmentosum (see Chapters 110 and 139), a disorder of DNA repair, is also characterized by early development of SCCs. SCCs have been reported to develop in the Mibelli, disseminated superficial actinic, and palmaris et plantaris disseminata forms of porokeratosis (see Chapter 52), and in oral lesions of dyskeratosis congenita. As noted in Section "Viral Infection," lesions of epidermodysplasia verruciformis can degenerate into SCCs (see Chapter 196). Finally, patients with the dystrophic form of epidermolysis bullosa are at increased risk for SCC (see Chapter 62).

MOLECULAR ASPECTS

As in most cancers, the development of SCC from normal keratinocytes begins with mutations in the cellular DNA and genomic instability. Alterations in gene expression lead to loss of growth controls, penetration of the basement membrane, and ultimately invasion into surrounding tissue. Along the pathway to SCC, keratinocytes become resistant to apoptosis (programed cell death) and immune attack.

GENETIC ALTERATIONS. Most analyses of genetic alterations in SCCs have been performed in cases of oral or head and neck SCCs. Chromosomal deletions (loss of heterozygosity) commonly involve chromosomes 3, 9, 11, and 17; the regions most commonly identified include 9p21 and 17p13 where the INK4A (p16/Arf) and *p53* tumor suppressors, respectively, are located.[29] Similar genetic lesions were found in a study of young patients (younger than 40 years of age).[30] It is unclear whether these genetic markers will serve as useful prognostic indicators.

***p53* IN THE DEFENSE AGAINST SKIN CANCER.** A role for *p53*, cyclin D1, human telomerase reverse transcriptase, p16, and thrombospondin 1 has

been identified in the multistep process of human skin carcinogenesis.[31]

Apoptosis of keratinocytes that have sustained UV radiation-induced DNA damage, termed *sunburn cells*, requires the *p53* tumor suppressor and represents a key protective mechanism against skin cancer by removing premalignant cells that have acquired mutations. In keratinocytes, UV radiation upregulates *p53*,[32] which delays cell cycle progression until DNA damage can be repaired or facilitates cell elimination by apoptosis.[33] Compromise of *p53* function could undermine this apoptosis-based defense mechanism, giving UV-damaged cells a selective advantage to survive additional cycles of UV exposure.[34] Further impairment of *p53* and other genes through additional UV radiation-induced mutations may then lead to even greater resistance to apoptosis, increased proliferation, and ultimately development of SCC. The increased susceptibility of *p53*-deficient mice to UV radiation-induced SCC[35] highlights this protective role of *p53*.

_p53_ MUTATIONS IN SQUAMOUS CELL CARCINOMA. Consistent with the scenario described in Section "*p53* in the Defense Against Skin Cancer," mutations in the *p53* gene are a common finding in SCC.[36] In most cases, these are C→T single base and CC→TT tandem transition mutations at dipyrimidine sequences, i.e., "UVB-signature" mutations.[37] Most SCCs exhibit loss of heterozygosity with respect to *p53* and isolated mutations on the remaining allele. In one study, the *p53*-apoptosis pathway was disrupted in 50% of oral SCCs. With respect to SCC precursors, *p53* mutations were found in up to 75% of AK and SCC in situ lesions.[38] Interestingly, although different *p53* mutations were found in separate AKs, all cells within a single precursor lesion had the same mutation.[31] Mutations in *p53* can also be detected in keratinocytes from clinically normal sun-exposed skin.[39] Keratinocytes with *p53* mutations occur in clonal patches that are larger and more frequently in sun-exposed skin.[40] These findings substantiate a clonal basis for UV radiation-induced SCC and suggest that *p53* mutation is an early event in the development of SCC.

In addition to undergoing mutation, *p53* can be compromised in keratinocytes infected with HPV. The E6 protein encoded by oncogenic HPV types binds *p53* and targets it for rapid degradation, which disables the *p53*-apoptosis pathway. This is a primary mechanism by which HPV infection predisposes to SCC (see Chapter 196).

OTHER APOPTOTIC REGULATORS IN SQUAMOUS CELL CARCINOMA. In addition to dysregulation of *p53*, dysregulation of other apoptotic regulatory proteins has been described in SCC. In a study of vulvar SCC, expression of the apoptotic inhibitor Bcl-2 correlated with metastasis.[41] Similarly, in esophageal SCC, expression of the apoptotic inhibitor Bcl-XL correlated with tumor invasion and metastasis.[42] In SCC of the tongue, low apoptotic index and decreased expression of the proapoptotic Bcl-2-associated X protein (Bax) correlated significantly with poor prognosis, whereas low Bcl-2 expression was associated with a favorable clinical outcome.[43] Expression of the antiapoptotic Bcl-2-associated athanogene 1 (BAG-1) was associated with nodal metastasis in oral SCC.[44] Consistent with these observations, transgenic mice expressing Bcl-2 and Bcl-XL in the skin exhibit increased susceptibility to chemical-induced tumorigenesis. In addition to these Bcl-2 family members, the inhibitor of apoptosis protein survivin is expressed in both SCC and precursor lesions,[45] and in one study its expression correlated with aggressive tumor phenotype.[46] Interestingly, survivin may be negatively regulated by the binding of *p53* to its promoter.[47] More recent studies in transgenic mice have yielded paradoxical results, which suggests that apoptosis may be required in the initial phase of UV radiation-induced clonal expansion.[48]

IMMUNE EVASION. Working with UV radiation-induced SCCs in mice, Kripke and colleagues first demonstrated the importance of immunosuppression in UV radiation-induced SCC in the 1970s (see Chapter 90). They found that although UV radiation-induced SCC was promptly rejected when transplanted into genetically identical recipient mice, the transplanted tumors grew rapidly, and rejection did not occur if recipient mice were first treated with a subcarcinogenic dose of UV radiation. These experiments suggested that UV radiation not only induced SCC but also impaired the ability of host animals to mount protective immune responses against foreign tumor antigens.

CLINICAL FINDINGS

In white men and women, the majority of SCCs arise on sun-exposed areas such as the head, neck, and dorsal hands. SCC of the legs is more common in women.[49] On the other hand, in blacks SCCs tend to be distributed equally on sun-protected and sun-exposed areas.[50] SCC typically presents in solitary fashion, arising from precursor lesions as noted earlier. An exception is in immunosuppressed patients, who may manifest eruptive SCCs.

DEVELOPMENT FROM PRECURSOR LESIONS

(See Chapter 113)

AKs often occur as a multiplicity of lesions, ranging in size from pinpoint to over 2 cm, and the borders are usually ill defined. A dry adherent scale gives them a rough, gritty texture. By contrast, lesions of Bowen disease are usually solitary, sharply demarcated, scaling papules or plaques, often initially mistaken for eczema, psoriasis, or lichen simplex. The latter disorders are often pruritic, whereas Bowen disease is usually not. In sun-protected sites, Bowen disease may have a noneczematous appearance. For example, it may appear verrucous in the anogenital area, nail bed, and eyelid, and as a dark patch or oozing erythematous plaque in intertriginous areas. These precursor lesions

Figure 114-1 Papular squamous cell carcinoma (SCC) of the ear. The differential diagnosis includes chondrodermatitis nodularis helicis, which, unlike SCC, is associated with pain.

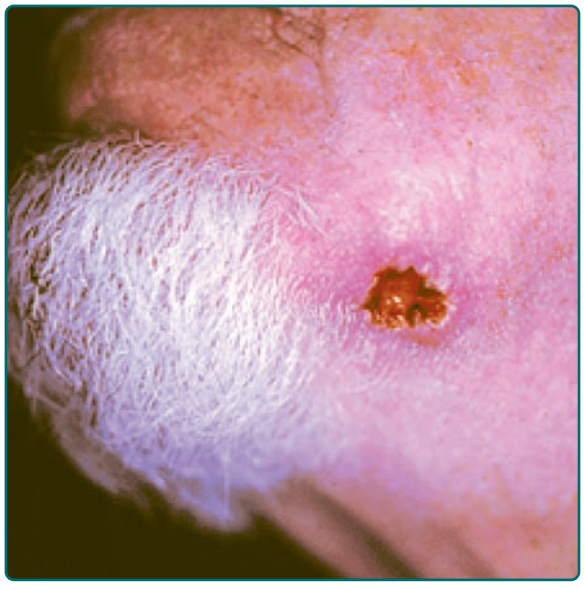

Figure 114-2 Ulcerative squamous cell carcinoma of the jaw. In this region, extension of the cancer can invade the marginal mandibular nerve.

are usually asymptomatic, and the development of tenderness, induration, erosion, increased scale, or enlarging diameter may herald evolution into SCC. Typically, a patient with multiple AKs may present with a single lesion that gradually becomes more prominent than the rest (Fig. 114-1), or with a solitary, persistent, nonpruritic, scaling patch that is unresponsive to treatment with topical steroids.

SQUAMOUS CELL CARCINOMA MORPHOLOGIES

A firm, flesh-colored or erythematous, keratotic papule or plaque is most common (see Fig. 114-1), but SCCs may also be pigmented. Other presentations include as an ulcer (Fig. 114-2), a smooth nodule (Fig. 114-3), or a thick cutaneous horn. SCC may also be verrucous or present as an abscess, particularly if in a periungual location (see Fig. 113-9 in Chapter 113). The margins may be indistinct. With enlargement, there is usually increased firmness and elevation. Progressive tumor invasion ultimately results in fixation to underlying tissues. Especially in the head and neck region, an enlarged lymph node nearby that is firm and nontender may indicate tumor metastasis (Fig. 114-4).

ORAL SQUAMOUS CELL CARCINOMA

SCC of the oral cavity usually occurs in patients with a long history of cigarette smoking, tobacco chewing, or alcohol use, but it has now been documented in younger adults without these traditional risk factors. There is a male predominance, and the palate and tongue are the most common sites. Oral SCC most commonly evolves from lesions of erythroplakia and is usually asymptomatic (see Chapter 113). Distinct patterns include a persistent rough red patch or granular velvety red plaque that ultimately becomes firm and nodular. Surprisingly, the risk of transformation to SCC does not appear to correlate with the degree of epithelial dysplasia.[51] The floor of the mouth, ventrolateral tongue, and soft palate are considered high-risk sites. It may also present as a peritonsillar abscess.

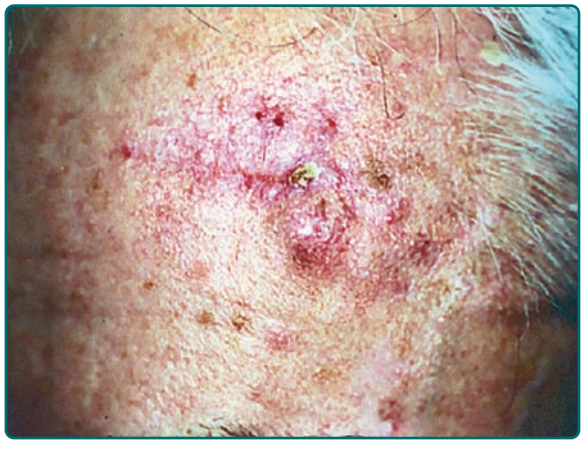

Figure 114-3 Nodular squamous cell carcinoma of the forehead. This lesion is recurrent and can be seen arising in the previous surgical scar. It should be considered high risk.

Figure 114-4 Preauricular mass resulting from metastasis of cutaneous squamous cell carcinoma (SCC). Involvement of the parotid gland can result from metastasis of SCC in the temple and ear region.

LOWER LIP SQUAMOUS CELL CARCINOMA

SCC of the lower lip begins as a roughened papule of actinic cheilitis or scaly leukoplakia, with slow progression to a tumor nodule (Fig. 114-5). Clinical clues associated with evolving SCC include persistent lip chapping with localized scale or crust, red and white blotchy atrophic vermilion zone of the lip, indistinct or "wandering" vermilion border, and small fissuring or ulceration within an area of indurated actinic cheilitis. Symptoms of underlying pain or altered sensation should be investigated as a potential sign of perineural invasion.

Figure 114-5 Squamous cell carcinoma of the lower lip that developed in the setting of habitual sun exposure and actinic cheilitis. There is a large but subtle nodule, better felt than seen, on the lower lip. There are areas of hyperkeratosis and ulceration. Metastasis to draining lymph nodes can occur.

GENITAL SQUAMOUS CELL CARCINOMA

SCC of the vulva most commonly occurs on the anterior labia majora, beginning as a small warty nodule or an erosive erythematosus plaque. These lesions may be asymptomatic but more often are associated with pruritus or bleeding. Lesions of lichen sclerosus are another common precursor of SCC of the vulva. SCC of the cervix is associated with HPV infection, most commonly with type 16. SCC of the scrotum begins as a small pruritic verrucous lesion that becomes friable with increasing size. SCC of the penis usually occurs in uncircumcised males (see eFig. 114-5.1 in online edition) and, although very uncommon in Western countries, may account for 10% of cancers in places where genital hygiene is poor. A distinct precursor of penile SCC is erythroplasia of Queyrat (see Chapter 113), characterized by a velvety red plaque. In addition to lack of circumcision, penile SCC has been associated with a history of condyloma and phimosis and lichen sclerosus et atrophicus (see Chapters 65 and 78). The genitalia were once thought to be a common location for SCC after long-term therapy with psoralen and UVA radiation, but this complication can be avoided by shielding the genitalia during treatment, and such an association is rarely seen today. Perianal SCC may also occur (Fig. 114-6).

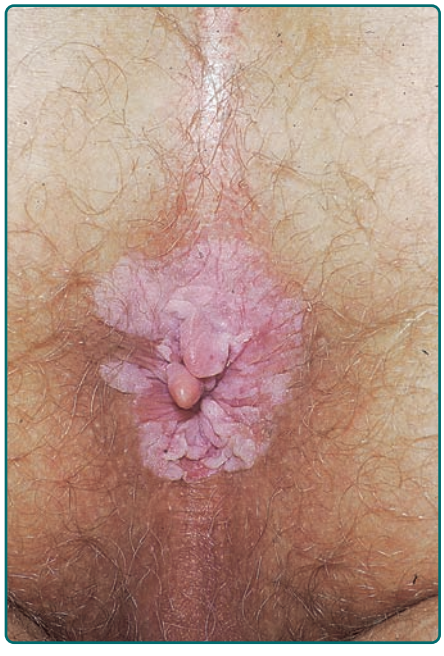

Figure 114-6 Perianal squamous cell carcinoma (SCC) in situ. Identification of these lesions requires thorough proctoscopic examination and monitoring for invasive SCC.

SCAR SQUAMOUS CELL CARCINOMA

SCCs arising in scars typically begin decades after injury, with skin breakdown and persistent erosion. Most commonly this occurs on the lower extremities at sites of chronic pyogenic or venous stasis ulcers. Gradually nodularity develops, although detection is often delayed because of concealment by surrounding indurated scar tissue. However, when SCC arises in chronic sinuses nodularity may not be present. The development of increased pain, drainage, or bleeding alone should raise concern and warrants further investigation.

KERATOACANTHOMA

(For Full Discussion, See Chapter 117)

The hallmark of keratoacanthoma is rapid growth, up to several centimeters in weeks, and then gradual involution over a period of months in most cases (see Chapter 117). The typical presentation is in an elderly patient on a sun-exposed site, particularly an extremity. Morphologically, keratoacanthoma is usually a large, smooth, dome-shaped, verrucous nodule with a central keratotic crater. Although historically viewed as a benign neoplasm because of its tendency toward spontaneous resolution, keratoacanthoma can be locally destructive and aggressive and must be viewed as a clinical subtype of SCC. This tumor may occur in association with sebaceous neoplasms and gastrointestinal malignancies in Muir–Torre syndrome.

VERRUCOUS CARCINOMA

Verrucous carcinoma is a form of SCC that encompasses several clinical entities, all characterized by slow-growing exophytic tumors with a cauliflower-like appearance that develop at sites of chronic irritation.[52] They may be clinically mistaken for giant warts. Four subtypes are recognized based on site of occurrence. Type I consists of oral tumors on the buccal mucosa of elderly male tobacco chewers and has been referred to as *oral florid papillomatosis* (Fig. 114-7). Representing 2%–12% of all oral cancers, these tumors are most commonly found on the buccal mucosa, tongue, gingiva, and floor of the mouth. Type II is the anogenital type, as described by Buschke and Loewenstein. It occurs on the glans penis of young uncircumcised males, on the scrotum, on the perianal region in both sexes, and, less commonly, on the female genitalia. Type III, also known as *epithelioma cuniculatum*, is a malodorous tumor often found on the plantar area in elderly men (Fig. 114-8) It usually involves the skin underlying the first metatarsal head and tends to form draining sinuses that are caniculated (like rabbit burrows) in appearance. Finally, type IV occurs at other sites, including the scalp, trunk, and extremities. Detection of sequences from HPV types 6, 11, 16, and 18 in epithelioma cuniculatum and type 11 sequences in oral verrucous carcinoma raises the possibility that these tumors evolve from verruca vulgaris.

Figure 114-7 Verrucous carcinoma presenting as a thick plaque arising on the buccal mucosa. This type of tumor was formerly called *oral florid papillomatosis*.

METASTATIC SQUAMOUS CELL CARCINOMA

Metastatic SCC in the skin can have a variety of presentations. It may be signaled by a palpable lymph node near the site of treatment of a previous SCC. On the other hand, it may present as large keratotic papules or nodules resembling the primary lesion (Fig. 114-9). Metastatic SCC on the skin may be the first sign of internal malignancy, initially presenting in the skin as clusters of firm pink or red papules that may be keratotic centrally.

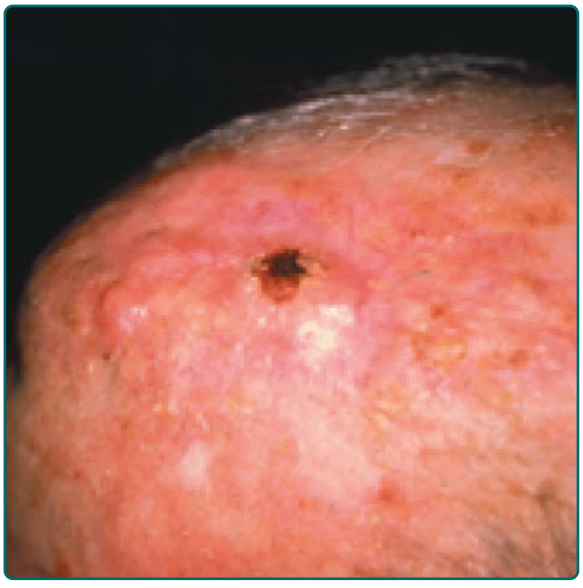

Figure 114-9 Squamous cell carcinoma metastatic to skin.

HISTOPATHOLOGY

GENERAL CONSIDERATIONS

The hallmark of invasive SCC is the extension of atypical keratinocytes beyond the basement membrane and into the dermis (Fig. 114-10). The absence of a connection between tumor cells and the epidermis should raise concern for metastatic SCC, although this may simply reflect undermining from adjacent tumor. In every case, it is important to note clues that may indicate a precursor lesion or particular etiology. For example, the presence of solar elastosis and keratinocyte atypia at the margins would suggest that the SCC is actinically derived. On the other hand, the presence of scar tissue may indicate recurrent disease or a sinister scar-associated SCC. These considerations have important implications for treatment and prognosis, as discussed in Section "Treatment."

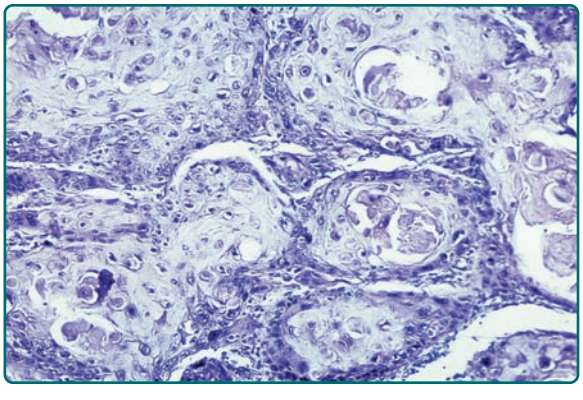

Figure 114-10 Squamous cell carcinoma demonstrating invasive cancer with atypical keratinocytes and foci of keratinization.

BASIC FEATURES

The tumor may appear as single cells, small groups or nests of cells, or a single mass. The inferior border may broadly impose on the dermis or be represented by individual foci of microinvasion. Invasive tumor is usually confined to the dermis and subcutaneous involvement is unusual. There are typically varying proportions of normal-appearing and atypical squamous cells, the latter characterized by increased mitoses, aberrant mitotic figures, nuclear hyperchromasia, and loss of intercellular bridges. Squamous differentiation is seen as foci of keratinization in concentric rings of squamous cells called *horn pearls*. Loss of differentiation is associated with decreased keratin production.

GRADING

Histologic grading of SCC is based on the degree of cellular differentiation. Low-grade tumors are comprised of uniform cells, resembling mature keratinocytes, with intracellular bridges and keratin production. By contrast, high-grade SCCs are characterized by atypical cells, loss of intracellular bridges, and minimal or absent keratin production. Another feature of higher grade tumors is a less distinct demarcation between malignant cells and adjacent normal stroma. In 1932, Broders[53] introduced a formal grading system based on keratinocyte differentiation that is still used today. Tumors are graded on a scale of 1–4 based on increasing percentages of undifferentiated cells (Table 114-2). In addition to grade, the depth of penetration, tumor thickness, and hair follicle involvement should also be reported.

HISTOLOGIC SUBTYPES

There are many histologic subtypes of SCC.[54] In the adenoid (or pseudoglandular) SCC, there is a tubular microscopic pattern and keratinocyte acantholysis. In clear cell SCC, the keratinocytes appear clear as a result of hydropic cytoplasmic swelling and accumulation of lipid vacuoles. Spindle cell SCC reveals spindle-shaped atypical cells. Signet-ring cell SCC is

TABLE 114-2
Broders' Grading System for Squamous Cell Carcinoma

Grade	% Undifferentiated Cells	Other Features
1	<25	Keratinization
2	<50	
3	<75	
4	>75	Atypia, loss of intracellular bridges

a rare variant characterized by concentric rings composed of keratin and large vacuoles corresponding to markedly dilated endoplasmic reticulum. In addition, a basaloid variant has been described. In verrucous carcinoma, the superficial component resembles verruca vulgaris with prominent acanthosis and papillomatosis, whereas the deeper component extends downward, displacing collagen bundles. Finally, keratoacanthoma reveals a symmetric keratin-filled crater, with the epidermis on each side extending over to form a distinct lip.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

DETERMINATION OF THE DIAGNOSIS

The diagnosis of SCC is always made by skin biopsy. Any persistent, enlarging, or nonhealing lesion, particularly if on a sun-exposed site, warrants biopsy evaluation. It is important that the biopsy be of sufficient depth so that invasive SCC can be distinguished from in situ disease. If a lesion is flat or minimally elevated (less than 1 mm), the superficial shaving technique can be used to minimize wound size and scarring and is usually adequate. For elevated lesions, the punch technique or a deep shave excision should be used to ensure that a specimen of adequate depth is taken. Because the diagnosis of keratoacanthoma depends largely on overall architecture, performing excisional biopsy or taking an incisional ellipse through the entire lesion is recommended. A tangential excision through the deep dermis also usually suffices.

DIFFERENTIAL DIAGNOSIS

Clinically, the differential diagnosis of SCC is long, but it can be narrowed based on lesion morphology. For verrucous or scaly lesions, benign conditions to consider include wart, seborrheic keratosis, AK, melanocytic nevus, pyogenic granuloma, eccrine poroma, and deep fungal infections such as chromomycosis. The entity "erosive pustular dermatosis of the scalp" is a benign condition that is often initially mistaken for SCC but responds to potent topical steroids.[55] Other malignant verrucous lesions include atypical fibroxanthoma, BCC, Bowen disease, verrucous melanoma, Merkel cell carcinoma, and, of course, metastatic SCC. Pigmented SCC in particular may mimic melanoma. For ulcerative lesions, additional diagnoses include trauma, BCC, and herpes virus infection (with either herpes simplex virus or varicella-zoster virus).

Histologically, the differential diagnosis of well-differentiated SCC includes verruca vulgaris and inverted follicular keratosis. In addition, reactive epidermal hyperplasia (pseudoepitheliomatous hyperplasia) secondary to mycosis, eruptions in response to halogenated drugs (bromoderma and iododerma), and even mechanical trauma can mimic SCC. However, in these hyperplasias the keratinocytes usually remain well differentiated; the margins of the proliferating epidermis are often pointed or irregular, rather than bulbous; there is leukocyte invasion with occasional keratinocyte disintegration; and granulomas or intraepidermal abscesses may be present.[56] Some adenoid SCCs may demonstrate a pseudovascular pattern, with erythrocytes in pseudovascular spaces, and may be confused with angiosarcoma; these tumors do not express factor VIII antigens or bind ulex agglutinin. Clear cell SCC may simulate adnexal tumors with sebaceous differentiation or sebaceous carcinoma. Distinguishing spindle cell SCC from atypical fibroxanthoma is difficult. The differential diagnosis of poorly differentiated SCC also includes fibrosarcoma, Merkel cell carcinoma, and melanoma. In most cases, SCC can be distinguished from these others by special stains for various cytokeratins, but in difficult cases electron microscopy may be needed to establish the diagnosis. In general, SCC does not stain for melanocyte (S100 protein, homatropine methylbromide) or smooth muscle (vimentin, actin) markers.

RECURRENCE AND METASTASIS

SCC, like BCC, may cause local tissue destruction, but it also has significant potential for metastasis. Metastases, when they occur, are generally to regional lymph nodes and are detected 1–3 years after initial diagnosis and treatment.[19] In many cases, metastasis is preceded by local recurrence at the site of the primary lesion. Historically, the reported rate of metastasis for SCC has ranged from 0.5% to 6%,[57] and metastasis tends to occur with tumors that are large, recurrent, and involve deep structures or cutaneous nerves (Fig. 114-11).

HIGH-RISK LESIONS

In a classic study, Rowe et al[58] reviewed all major series of SCC dating back to 1940 to determine risk factors associated with recurrence and metastasis. Table 114-3 summarizes the characteristics of "high-risk" lesions. With respect to size, tumors smaller than 2 cm in diameter are low risk, with an overall metastatic rate of roughly 1%. In one study,[59] the metastatic rate increased to 9.2% and 14.3% for tumors of 2–5 cm and larger than 5 cm, respectively. With respect to depth and invasion, tumors less than 4-mm deep and rated as Clark levels I–III have limited metastatic potential,

TABLE 114-3
High-Risk Squamous Cell Carcinoma

- Diameter >2 cm
- Depth >4 mm and Clark level IV or V
- Tumor involvement of bone, muscle, nerve
- Location on ear, lip
- Tumor arising in scar
- Broders grade 3 or 4
- Patient immunosuppression
- Absence of inflammatory infiltrate

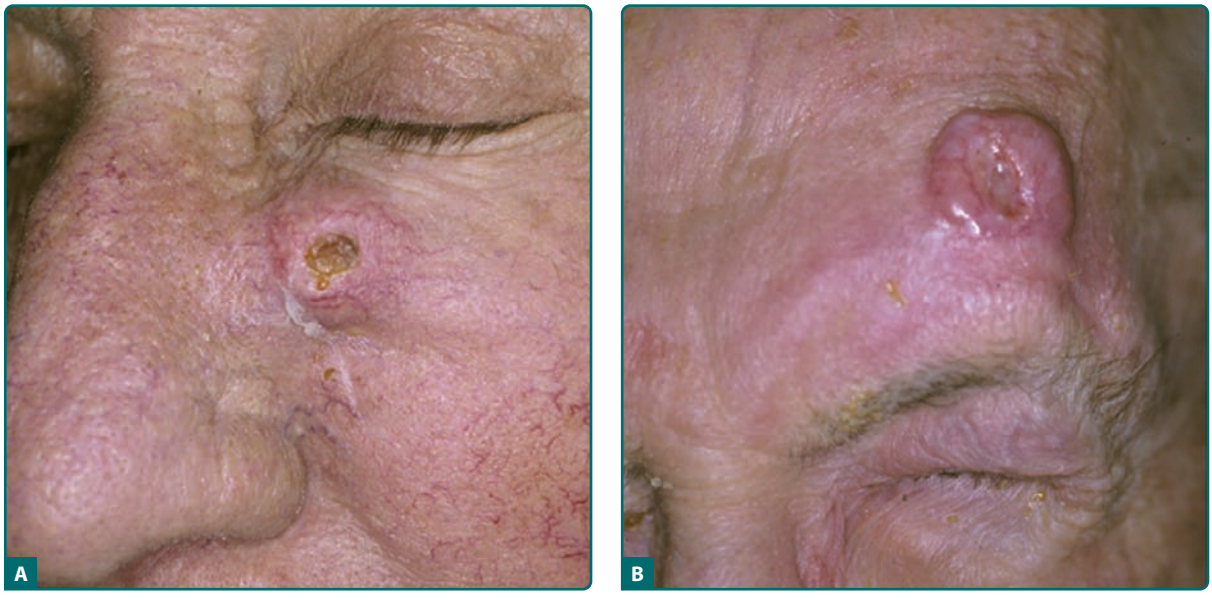

Figure 114-11 **A.** Infiltrative squamous cell carcinoma (SCC) demonstrating retraction of underlying tissue of the left cheek, where extension might involve infraorbital nerve. **B.** SCC of left side of forehead, where extension to bone with invasion or along the supraoptic nerves might lead to death.

whereas close to half of those deeper than 4 mm and at Clark levels IV or V were metastatic in some series. Tumor involvement of bone, nerve, or muscle tissue is strongly associated with metastasis. With respect to anatomic site, SCC of the ear has the highest rate of recurrence (18.7%), whereas lip SCC has the highest rate of metastasis (13.7%), with half of lip metastases present at the time of initial diagnosis. All SCCs arising in scars are high risk, with metastatic rates approaching 40% in some series.[60] By contrast, SCCs arising in actinically damaged skin are of considerably lower risk, with an average metastatic rate of 5.2%. Poorly differentiated SCCs (Broders grade 3 or 4) demonstrate a recurrence rate of 28.6% and a metastatic rate of 32.8%, compared with 13.6% and 9.2%, respectively, for well-differentiated tumors. The prognosis is particularly poor for spindle cell SCCs.[61] Immune status is another important consideration. One study[62] found that 23% of patients with metastatic SCC were immunosuppressed. A heavy inflammatory response appears to be a favorable prognostic sign, because absence of infiltrate has been correlated with higher rates of recurrence and metastasis.

TREATMENT

Box 114-1 summarizes the various modalities available for treatment of SCCs. Treatment selection is directed largely by assessment of tumor risk for recurrence and metastasis, as discussed in the previous section. Ablative techniques such as electrodesiccation and curettage, liquid nitrogen cryotherapy, carbon dioxide laser, intralesional chemotherapy, and photodynamic therapy are superficial, do not allow histologic margin control, and thus are generally inappropriate for treatment of invasive SCCs. Topical chemo/immuno therapy may be appropriate for SCC in situ, and topical 5-fluorouracil has been used for treatment of conjunctival SCCs.[63]

SURGICAL EXCISION

Conventional surgical excision is viewed by many as the treatment of choice for small primary SCCs. Recommended margins are 4 mm for low-risk lesions or SCCs with a depth of less than 2 mm; for lesions with a depth of more than 6 mm or a diameter larger than 1 cm, Mohs micrographic surgery is recommended.[64] Mohs micrographic surgery is also recommended in specific circumstances when the highest cure rate and minimal tissue destruction are desired (Table 114-4). Specifically, tumors involving the periocular or periauricular areas; recurrent or large tumors; lesions with poorly defined clinical margins; tumors at sites where tissue preservation is important (nasal tip, lip, eyelid, ear, genitalia); deeply infiltrative tumors; lesions

BOX 114-1 TREATMENT OF SQUAMOUS CELL CARCINOMA

- Nonexcisional ablative techniques (in situ disease only, or in special circumstances)
- Mohs micrographic surgery
- Conventional surgical excision
- Topical therapy (in situ disease only)
- Radiation therapy

at sites that were previously irradiated; tumors with involvement of underlying structures (nerve, bone, muscle); tumors in immunosuppressed patients; and lesions at sites associated with high recurrence rates should strongly be considered for Mohs micrographic surgery.[65] Additional indications include verrucous carcinomas and high-risk SCCs such as those arising from chronic scarring conditions.

RADIATION

Radiation can be used to treat superficially invasive to moderate-risk lesions and serves as an important adjuvant to excisional surgery in treating residual microscopic disease and providing prophylaxis against metastatic disease. It has been shown to be particularly useful for SCCs of the external auditory canal,[66] although radiation therapy may lead to hearing loss.[67] Radiation therapy is not advised for verrucous carcinoma, in which there is an associated low rate of anaplastic transformation. Radiation may also be used as adjuvant therapy in cases in which perineural SCC was identified in surgical pathologic specimens but treatment failures occurred.

TOPICAL THERAPY

Both topical 5-fluorouracil and imiquimod have been used in patients with SCC in situ Practice varies, but most regimens consist of application either once or twice daily for 2–4 weeks (5-fluorouracil) or three to five times per week for 2–4 months (imiquimod). Recent evidence suggests that efficacy of imiquimod may be due to enhanced interferon-γ production and effector function of T cells infiltrating the tumor.[B] Topical therapy is not appropriate for invasive disease since there will be minimal penetration of drug into the dermis.

RECURRENCE RATES

Many risk factors for recurrence and metastasis have been identified.[9] In their review noted in Section "High-Risk Lesions," Rowe et al[58] also assessed responses to treatment. They reported increasing combined rates of recurrence for each of the following treatment modalities (for primary cancers): Mohs micrographic surgery (3.1%), electrodesiccation and curettage (3.7%), excisional surgery (8.1%), and radiation (10%). A review of the use of Mohs micrographic surgery to treat SCC with 4-year follow-up reported a cure rate of 92%.[68] The surprisingly low rate of recurrence for electrodesiccation and curettage likely reflects its judicious use for treatment of low-risk lesions. Similarly, the recurrence rates for both Mohs micrographic surgery and excisional surgery may be somewhat skewed by their use in treating high-risk lesions. A systematic review of studies using topical therapy for SCC in situ (with at least 6 months histologic follow-up) revealed clearance rates of 27%–85% with 5-fluorouracil and 73%–88% with imiquimod.[C] For lip SCC, the overall recurrence rate was 2.3% with Mohs micrographic surgery compared with 10.5% with other treatment modalities; for ear SCC, the recurrence rates were 5.3% and 18.7%, respectively. For all recurrent tumors, cure rates were 76.7% with excision, compared with 90% with Mohs micrographic surgery. For low-risk SCCs, overall recurrence rates were 1.9% with Mohs micrographic surgery versus 16.5% with all other modalities. Overall 5-year survival rate for patients with metastatic SCCs was 26.8%, with poorer outcomes among patients with lip lesions[69] and those treated with surgery alone (and no radiation).

TREATMENT OF HIGH-RISK LESIONS

Management of high-risk lesions is reviewed elsewhere.[70] Oral 5-fluorouracil has been used to treat aggressive lesions refractory to conventional therapies. Additional treatments, including β-carotene, interferon, and retinoids, have been employed with variable results. High-risk lesions may require formal staging. Computed tomography or magnetic resonance imaging may be useful in the detection of advanced perineural involvement of head and neck SCC.[71] Sentinel lymphadenectomy has been combined with Mohs micrographic surgery.[72] Involvement of lymph nodes may warrant radical lymph node dissection and radiation therapy. Elective cervical lymphadenectomy may be indicated for high-risk lesions of the lip.[73] When a clinical lymph node examination yields negative results, further intervention may still be indicated if the tumor is considered sufficiently high risk.

PATIENT FOLLOW-UP

After a diagnosis of SCC, all patients should be considered at high risk for developing additional lesions of SCC as well as BCC. They should be seen at regular intervals, ranging from 3 months to 12 months, depending on the degree of risk of prior lesions, status of precursor lesions, and individual patient compliance. A complete skin examination should be performed at each visit, including examination of the oral mucosa. In addition, sites of previous lesions and treatments should be assessed for signs of recurrence. Finally, a lymph node examination is indicated to monitor for metastatic disease.

PREVENTION

Those at risk for SCC—namely, persons with a prior history of nonmelanoma skin cancer or any of the predisposing conditions discussed earlier—should be monitored closely. They should receive complete skin examinations on a regular (annual or semiannual) basis.

SUN PROTECTION

The most effective preventive measure is protection from sun exposure. It is likely that adequate sun protection beginning in early childhood could prevent most SCCs.[74] This requires establishing patterns of behavior at an early age, such as applying sunscreen repeatedly, wearing hats and protective clothing, and avoiding the sun during the hours of peak intensity. However, the importance of sun exposure prevention in childhood should not be construed to mean that sun protection later in life will be of no benefit. There is evidence that aggressive sun protection throughout life can prevent the development of SCC precursor lesions and cancers themselves.

TREATMENT OF PRECURSOR LESIONS

Treatment of precursor lesions is expected to reduce the incidence of SCC. Several options are available for treatment of AK (see Chapter 113). Isolated lesions can often be effectively removed by liquid nitrogen cryotherapy. For patients with many AKs or areas of skin with a multitude or confluence of lesions, topical chemotherapy using 5-fluorouracil or imiquimod is a better option. Topical diclofenac has also been introduced as therapy for widespread AK. Photodynamic therapy using aminolevulinic acid is also an option for areas involving multiple lesions.

OTHER PREVENTIVE MEASURES

A number of additional preventive measures can be taken that may reduce the incidence of SCC in individual patients. For example, the use of condoms can prevent transmission of HPV and may thereby reduce the risk of genital SCC. Decreased alcohol consumption and smoking cessation is likely to reduce the risk of oral SCC. Several years ago there was great interest in the use of both retinoids and interferons as systemic chemopreventive agents. Low-dose etretinate (10 mg/day) has been used successfully in renal transplant patients.[75] A more recent recommendation is isotretinoin (Accutane; 10 mg every day or every other day) in addition to topically applied tretinoin.[76] The introduction of a vaccine for the prevention of infection with HPVs and of precancerous lesions of the cervix may one day translate into the prevention of all HPV-induced precancerous lesions of the skin.[78]

Chapter 115 :: Basal Cell Carcinoma

:: John A. Carucci, David J. Leffell & Julia S. Pettersen

BASAL CELL CARCINOMA AT A GLANCE

- Most common cancer in humans.
- Caused by exposure to ultraviolet light; associated with *PTCH* gene mutation in many cases.
- Incidence increasing in younger populations.
- Locally destructive.
- Treated by surgical excision, electrodesiccation and curettage, Mohs micrographic surgery, and occasionally irradiation.

BCC EPIDEMIOLOGY

BCC is the most common cancer in humans. It is estimated that over 1 million new cases occur each year in the United States. The malignancy accounts for approximately 75% of all nonmelanoma skin cancers (NMSC) and almost 25% of all cancers diagnosed in the United States.[1] Epidemiological data indicate that the overall incidence is increasing worldwide significantly by 3%–10% per year.[2]

BCC is more common in elderly individuals but is becoming increasingly frequent in people younger than 50 years of age. Christenson et al noted a disproportionate increase in BCC in women under age 40.[3] Men are affected slightly more often than are women. Levi et al reported that the incidence of BCC rose steadily in the Swiss Canton of Vaud between 1976 and 1998 to levels of 75.1 in 100,000 in males and 66.1 in 100,000 in females.[4,5] Stang et al in Westphalia, Germany found that the incidence rate of BCC during a 5-year period (1998–2003) was 63.6 in men and 54.0 in women.[6] A study of NMSC in Aruba supported these findings.[7] In that study, BCC was the most common type of skin cancer diagnosed between 1980 and 1995. Tumors were more frequent in patients older than 60 years of age, and 57% were in men. The highest percentage of lesions occurred on the nose (20.9%), followed by other sites on the face (17.7%).[7] Incidence in Europe was examined by the recent study in Croatia. From 2003 to 2005, the crude incidence rate for the Croatian population of 100,000 was 54.9 for men and 53.9 for women. The vast majority of BCCs were located on the head and neck.[8]

BCC character develops on sun-exposed skin of lighter skinned individuals. Incidence rates of BCC in Asians living in Singapore increased from 1968 to 2006, especially among the older, more fairly complected Chinese patents. Skin cancer trends in Asians from 1968–2006 showed BCC rates increased the most among persons older than 60 years.[9]

BCC is rare in dark skin because of the inherent photoprotection of melanin and melanosomal dispersion. An estimated 1.8% of BCCs occur in blacks, and BCC is approximately 19 times more common in whites than blacks.[10]

Risk factors for BCC have been well characterized and include ultraviolet light (UVL) exposure, light hair and eye color, northern European ancestry, and inability to tan.[1] An Italian study indicated the important role of sunburns, and therefore intense sun exposure, rather than that of prolonged sun exposure to increase the risk of BCC.[11]

BCC ETIOLOGY AND PATHOGENESIS

The pathogenesis of BCC involves exposure to UVL, particularly the ultraviolet B spectrum (290–320 nm) that induces mutations in tumor suppressor genes.[12,13] UVB radiation damages DNA and affects the immune system resulting in a progressive genetic alterations and neoplasms. UV-induced mutations in the *p53* tumor suppressor gene have been found in about 50% of BCC cases.[14]

Currently, it is thought that the upregulation of the mammalian development signaling pathway, Hedgehog (HH), is the pivotal abnormality in all BCCs, and there is evidence that little more than this upregulation is required for BCC carcinogenesis.[15,16] The mutations that activate the aberrant HH signaling pathway are found in PTCH1 and Smoothened (SMO). Approximately 90% of sporadic BCCs have identifiable mutations in at least one allele of *PTCH1*, and an additional 10% have activating mutations in the downstream SMO protein.[17] The most frequently identified mutations in PTCH1 and SMO are of a type consistent with UV-induced damage.[18–20]

The contribution of high-intensity sunlight exposure to BCC development in the general population is well established.[11] A latency period of 20–50 years is typical between the time of UV damage and the clinical onset of BCC. Therefore, in most cases, BCC develops on sun-exposed skin in elderly people, most commonly in the area of head and neck.[21]

Some studies indicate that intermittent brief holiday exposures may place patients at higher risk than occupational exposure.[9,22] An Italian study confirmed the role of intermittent sun exposure as a strong risk factor for BCC.[11] Ramani and Bennett reported a significantly higher incidence of BCCs in World War II servicemen stationed in the Pacific theater than in those stationed in Europe. This suggests that several months or years of intense exposure to UVL may have deleterious long-term effects.[23] Truncal BCCs can result from acute intense exposures sufficient to cause sunburn on the skin of the trunk among people whose ability to tan makes the skin of their face generally less susceptible to the carcinogenic effects of UV radiation.[24]

Other factors that appear to be involved in the pathogenesis include mutations in regulatory genes,[17,25] exposure to ionizing radiation,[26,27] and alterations in immunosurveillance.[28–30]

The propensity to develop multiple BCCs may be inherited. Included among heritable conditions predisposing to the development of this epithelial cancer are nevoid basal call carcinoma syndrome or basal cell nevus syndrome (BCNS),[31] Bazex syndrome,[32] and Rombo syndrome.[33] Patients with BCNS may develop hundreds of BCCs and may exhibit a broad nasal root, borderline intelligence, jaw cysts, palmar pits, and multiple skeletal abnormalities. BCNS occurs due to mutations in the tumor suppressor *PTCH* gene.[34,35]

Bazex syndrome is transmitted in an X-linked dominant fashion.[32] Patients have multiple BCCs, follicular atrophoderma, dilated follicular ostia with ice pick scars, hypotrichosis, and hypohidrosis. In contrast, Rombo syndrome is transmitted in an autosomal dominant fashion.[33] Patients have vermiculate atrophoderma, milia, hypertrichosis, trichoepitheliomas, BCCs, and peripheral vasodilation. Hypohidrosis is not a feature of Rombo syndrome.

The role of the immune system in the pathogenesis of skin cancer is not completely understood. Immunosuppressed patients with lymphoma or leukemia[36,37] and

patients who have received an organ transplant have a marked increase in the incidence of squamous cell carcinoma but only a slight increase in the incidence of BCC.[28–30,38] Bastiaens et al found that transplant recipients developed more BCCs on the trunk and arms than did nonimmunosuppressed patients.[39] Harwood et al found that fewer BCCs occurred on the head and neck of renal transplant recipients, while more BCCs were found on the trunk and arms compared to the immune competent patients.[38] Patients with human immunodeficiency virus infection develop BCCs at the same rate as immunocompetent individuals, based on similar risk factors.[19,40,41] Immunosuppressed long-term alcoholics tend to develop infiltrative BCCs with increased frequency.[20,42] A potential link between UVL and decreased immunity has been suggested by Gutierrez-Steil et al, who demonstrated that UVL-induced BCCs express Fas ligand (CD95L).[43] They further showed that these cells were associated with CD95-bearing T cells undergoing apoptosis.[43,44] This represents a potential mechanism by which UVL might help tumor cells avoid being killed by cytotoxic T lymphocytes. Kaporis et al showed that immune suppressive regulatory T cells are surround BCC tumor nests thus providing another potential mechanism for BCC to evade host antitumor immunity.[45]

CLINICAL MANIFESTATIONS

PRESENTATION

The presence of any friable, nonhealing lesion should raise the suspicion of skin cancer. Frequently, BCC is diagnosed in patients who state that the lesion bled briefly then healed completely, only to recur. BCC usually develops on sun-exposed areas of the head and neck but can occur anywhere on the body. Features include translucency, ulceration, telangiectasias, and the presence of a rolled border. Characteristics may vary for different clinical subtypes, which include nodular, superficial, morphea-form, and pigmented BCCs and fibroepithelioma of Pinkus (FEP). The anatomic location of BCC may favor the development of a particular subtype.[46]

BASAL CELL CARCINOMA SUBTYPES

NODULAR BASAL CELL CARCINOMA. Nodular BCC is the most common clinical subtype of BCC (Fig. 115-1).[47,48] It occurs most commonly on the sun-exposed areas of the head and neck and appears as a translucent papule or nodule depending on duration. There are usually telangiectasias and often a rolled border. Larger lesions with central necrosis are referred to by the historical term *rodent ulcer* (Fig. 115-2). The differential diagnosis of nodular BCC includes traumatized dermal nevus and amelanotic melanoma.

PIGMENTED BASAL CELL CARCINOMA. Pigmented BCC is a subtype of nodular BCC that exhibits increased melanization. Pigmented BCC appears as a hyperpigmented, translucent papule, which may also be eroded (eFig. 115-2.1 in online edition). The differential diagnosis includes nodular melanoma.

Figure 115-1 Basal cell carcinoma (BCC), nodular type.

SUPERFICIAL BASAL CELL CARCINOMA. Superficial BCC occurs most commonly on the trunk and appears as an erythematous patch (often well demarcated) that resembles eczema (Fig. 115-3).[47] An isolated patch of "eczema" that does not respond to treatment should raise suspicion for superficial BCC.

MORPHEAFORM (SCLEROSING) BASAL CELL CARCINOMA. Morpheaform BCC is an aggressive growth variant of BCC with a distinct clinical and histologic appearance. Lesions of morpheaform BCC may have an ivory-white appearance and may resemble a scar or a small lesion of morphea (eFig. 115-3.1 in online edition). Thus, the appearance of scar tissue in the absence of trauma or previous surgical procedure

Figure 115-2 Basal cell carcinoma, rodent ulcer type.

Figure 115-3 Superficial basal cell carcinoma. The well-demarcated plaque with a rolled edge characteristically occurs on the trunk.

or the appearance of atypical-appearing scar tissue at the site of a previously treated skin lesion should alert the clinician to the possibility of morpheaform BCC and the need for biopsy.

FIBROEPITHELIOMA OF PINKUS. FEP classically presents as a pink papule, usually on the lower back.[25,50] It may be difficult to distinguish from an acrochordon or skin tag. Similar to basal cell carcinomas, fibroepitheliomas of Pinkus express androgen receptors, supporting its classification as a basal cell carcinoma.[51] The differential diagnoses of FEP includes acrochordon.[52]

BIOLOGIC BEHAVIOR

LOCAL INVASION

The greatest danger of BCC results from local invasion (Fig. 115-4). In general, BCC is a slow-growing tumor that invades locally rather than metastasizes.[26,27,53,54]

Figure 115-4 BCC, if untreated, can result in extensive local tissue damage.

The doubling time is estimated to be between 6 months and 1 year. If left untreated, the tumor will progress to invade subcutaneous tissue, muscle, and even bone. Anatomic fusion planes appear to provide a low-resistance path for tumor progression. Tumors along the nasofacial or retroauricular sulcus may be extensive. Metastases are rare and most are said to more closely correlate to the size and depth of tumor invasion and less so to the histologic subtype of the original tumor.[1]

Although metastases are rare, significant patient morbidity, such as local tissue destruction and disfigurement can occur. In one informative case, a patient documented the progression of his own tumor with photographs over a 27-year period.[28,55] The lesion, which encompassed an entire side of the face, including the maxillary sinus, apparently doubled over a 10-year period and grew rapidly in the 2 years before hospital admission. This scenario occurs in the context of physical or psychiatric disability that interferes with judgment or access to health care. In one of the first reports of giant BCC in India, a patient presented with a non-healing ulcer of the face, which had been present and increasing in size for over 20 years. On examination, the ulcer covered the entire left side of the face involving the preauricular, infraorbital, and bucco mandibular units of the cheek and the orbit and resulted in loss of vision.[56] In another case, a 35-cm BCC on the back of a 65-year-old man recurred after wide local excision and X-ray therapy (XRT), resulting in spinal cord compression.[57] Lethal extension to the central nervous system from aggressive scalp BCC has been reported.[58,59]

PERINEURAL INVASION

Perineural invasion (PNI) is uncommon in BCC and occurs most often in histologically aggressive or recurrent lesions.[54] The presence of PNI has been correlated with recurrent lesions, increased duration and size of lesions, and orbital invasion.[60] In one series, Niazi and Lamberty identified PNI in less than 0.2% of cases. In that series, perineural BCC was seen most often with recurrent tumors located in the preauricular and malar areas.[61] Brown and Perry found the incidence of PNI to be 3% in aggressive BCC cases. This incidence approaches that reported for cutaneous squamous cell carcinomas.[62] Leibovitch et al found an incidence rate of 2.74%.[63] Ratner et al found a higher incidence in their study (3.8%); however, this was a smaller study.[64] Leibovitch et al reported perineural spread in more than 50% of periocular BCCs eventuating in orbital invasion. These tumors required extensive surgery and in some cases exenteration (Fig. 115-5).[65] Perineural spread may manifest as pain, paresthesias, weakness, or paralysis. The presence of focal neurologic symptoms at the site of a previously treated skin cancer should raise concern about nerve involvement.

METASTASIS

Metastasis of BCC occurs only rarely, with rates varying from 0.0028% to 0.55%.[34–36,66–68] Involvement of regional lymph nodes and lungs is most

Figure 115-5 BCCs involving the canthus can invade the orbit.

common. Cases of pulmonary metastasis continue to be reported.[69] Metastasis to the bone and bone marrow has been reported.[70] Aggressive histologic characteristics, including morpheaform features, squamous metaplasia, and PNI, have been identified as risk factors for metastasis.[68] Von Domarus et al reported five cases of metastatic BCC in which perineural or intravascular invasion had been noted in three.[71] Squamous differentiation was not observed in the primary tumors in the cases they presented but was noted in two of five cases of metastatic cancer. Overall, squamous differentiation was present in 15% of the primary or metastatic tumors from the 170 cases reviewed in that series.

DIAGNOSIS

Diagnosis of BCC is accomplished by accurate interpretation of the skin biopsy results. The preferred biopsy methods are shave biopsy, which is often sufficient, and punch biopsy. A sterilized razor blade, which can be precisely manipulated by the operator to adjust the depth of the biopsy specimen, is often superior to a No. 15 scalpel for shave biopsies. A punch biopsy may be useful for flat lesions of morpheaform BCC or for recurrent BCC occurring in a scar. When biopsying a lesion, adequate tissue should be taken. Small, fragmented tissue samples may make diagnosis difficult; potentially compromising the ability to accurately assess BCC subtype and thickness, which can affect treatment choice.[72]

HISTOPATHOLOGY

Histopathologic features vary somewhat with subtype, but most BCCs share some common histologic characteristics. The malignant basal cells have large nuclei and relatively little cytoplasm. Although the nuclei are large, they may not appear atypical. Usually, mitotic figures are absent. Frequently, slit-like retraction of stroma from tumor islands is present, creating peritumoral lacunae that are helpful in histopathologic diagnosis.[73] The most common form of BCC is nodular, followed by superficial, then morpheaform. Also, nodular and morpheaform are most commonly found on the head and neck, while superficial is most often found on the trunk region.[74]

NODULAR BASAL CELL CARCINOMA

Nodular BCCs account for half of all BCCs and are characterized by nodules of large basophilic cells and stromal retraction (Fig. 115-6A). The term micronodular BCC is used to describe tumors with multiple microscopic nodules smaller than 15 µm (see Fig. 115-6B).[73] Clinically, this is the type of BCC that most commonly shows a translucent pearly papule or nodule with a rolled border and telangiectasia. The nodular form of BCC is characterized by discrete nests of basaloid cells in either the papillary or reticular dermis accompanied.[1]

PIGMENTED BASAL CELL CARCINOMA

Pigmented BCC shows histologic features similar to those of nodular BCC but with the addition of melanin.[38] Approximately 75% of BCCs contain melanocytes, but only 25% contain large amounts of melanin. The melanocytes are interspersed between tumor cells and contain numerous melanin granules in their cytoplasm and dendrites. Although the tumor cells contain little melanin, numerous melanophages populate the stroma surrounding the tumor.[73]

SUPERFICIAL BASAL CELL CARCINOMA

Superficial BCC is characterized microscopically by buds of malignant cells extending into the dermis from the basal layer of the epidermis.[38] The peripheral layer shows palisading cells. There may be epidermal atrophy, and dermal invasion is usually minimal. There may be a chronic inflammatory infiltrate in the upper dermis. This histologic subtype is encountered most often on the trunk and extremities, but may also appear on the head and neck.[73]

MORPHEAFORM BASAL CELL CARCINOMA

Morpheaform BCC, also called infiltrative or sclerosing BCC, consists of strands of tumor cells embedded within a dense fibrous stroma (see Fig. 115-6C).[73] Tumor cells are closely packed columns and, in some cases, only one to two cells thick enmeshed in a densely collagenized fibrous stroma. Strands of

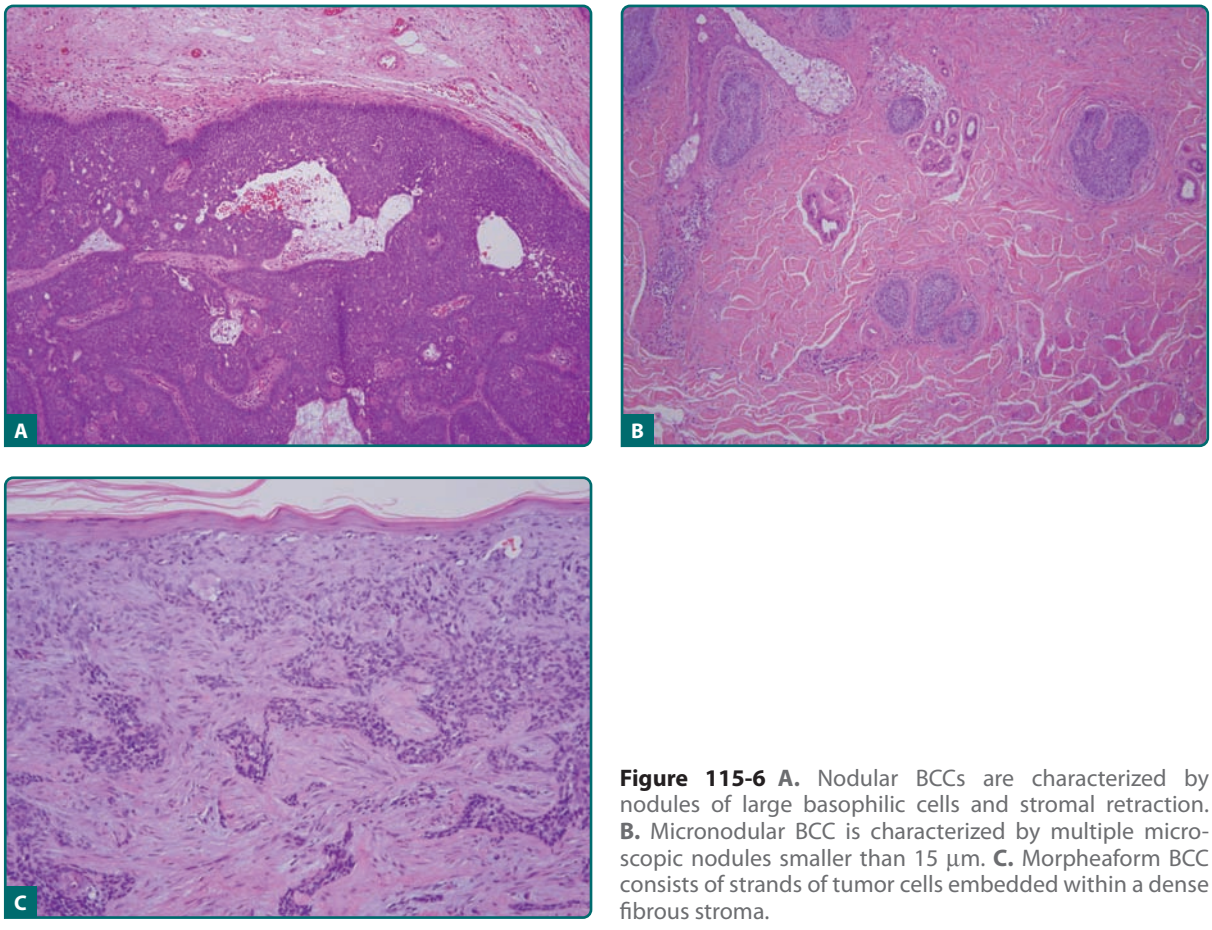

Figure 115-6 A. Nodular BCCs are characterized by nodules of large basophilic cells and stromal retraction. **B.** Micronodular BCC is characterized by multiple microscopic nodules smaller than 15 µm. **C.** Morpheaform BCC consists of strands of tumor cells embedded within a dense fibrous stroma.

tumor extend deeply into the dermis. The cancer is often larger than the clinical appearance indicates. Recurrent BCC may also demonstrate infiltrating bands and nests of cancer cells embedded within the dense fibrous stroma of scar.

FIBROEPITHELIOMA OF PINKUS

In FEP, long strands of interwoven basiloma cells are embedded in fibrous stroma with abundant collagen.[38] Histologically, FEP shows features of reticulated seborrheic keratoses and superficial BCC.[73]

BASOSQUAMOUS CARCINOMA

Basosquamous carcinoma is a form of aggressive growth BCC. It can be confused with squamous cell carcinoma and promotes controversy considering its precise histomorphologic classification as it shows both basal cell and squamous cell carcinoma differentiation in a continuous fashion.[1] Histologically, basosquamous carcinoma shows infiltrating jagged tongues of tumor cells admixed with other areas that show squamous intercellular bridge formation and cytoplasmic keratinization.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for BCC is summarized in Box 115-1.

BCC TREATMENT

Management of BCC is guided by anatomic location and histological features. Approaches include standard surgical excision, destruction by various modalities, Mohs micrographic surgery (MMS), and topical chemotherapy.[73] The best chance to achieve cure is through adequate treatment of primary BCC, because recurrent tumors are more likely to recur and cause further local destruction. An algorithmic approach to management is summarized in Fig. 115-7. While most trials have only evaluated BCCs in low-risk locations, surgery and radiotherapy appear to be the most effective treatments with surgery showing the lowest failure rates. Although cosmetic outcomes appear good with PDT, long-term follow-up data are needed. Other treatments might have some use but few have been compared to surgery. An ongoing study comparing imiquimod to surgery should clarify whether imiquimod is a useful option.[75] Overall, removal of the tumor with clear margins remains the gold standard for treating basal cell carcinoma.

BOX 115-1 DIFFERENTIAL DIAGNOSIS

NODULAR BCC
- Dermal nevus
- Squamous cell carcinoma
- Appendageal tumor
- Dermatofibroma

PIGMENTED BCC
- Nodular melanoma
- Superficial spreading melanoma
- Lentigo maligna melanoma
- Appendageal tumor
- Compound nevus
- Blue nevus

SUPERFICIAL BCC
- Bowen's disease
- Mammary or extramammary Paget's disease
- Superficial spreading melanoma
- Single plaque of psoriasis
- Single plaque of eczema

MORPHEAFORM BCC
- Scar
- Morphea
- Trichoepithelioma

FIBROEPITHELIOMA OF PINKUS
- Skin tag
- Fibroma
- Papillomatous dermal nevus

MOHS MICROGRAPHIC SURGERY

MMS offers superior histologic analysis of tumor margins while permitting maximal conservation of tissue compared with standard excisional surgery.[76,77] Rowe, Carroll, and Day report a recurrence rate of 1% for primary BCCs treated by MMS. This was superior to the rate for other modalities, including standard excision (10%), curettage and desiccation (C&D) (7.7%), XRT (8.7%), and cryotherapy (7.5%).[78] Recurrent BCCs treated by MMS reappeared at a rate of 5.6%, which was again superior to the rate for other modalities, including excision (17.6%), XRT (9.8%), and C&D (40%).[79] Leibovitch et al found that after 5 years BCC recurrence was diagnosed in 1.4% of primary and in 4% of recurrent tumors. This low 5-year recurrence rate of BCC with MMS emphasizes the importance of margin-controlled excision over other modalities.[80] MMS is the treatment of choice for morpheaform, poorly delineated, incompletely removed, and otherwise high-risk primary BCCs. It is the preferred treatment for recurrent BCC and for any BCC that occurs at a site where tissue conservation is desired. MMS is particularly useful in treating BCCs at high-risk anatomic sites, including the embryonic fusion planes represented by the nasofacial junction and retroauricular sulcus. Based on the fact that MMS provides the lowest recurrence rates, it is the treatment of first choice for primary facial BCCs with an aggressive histopathological subtype and for recurrent facial BCCs.[81] MMS has shown greater efficacy than surgical excision for the treatment of recurrent facial BCCs.[80] Mosterd et al also found that treatment with MMS leads to a significantly lower number of recurrences than treatment with surgical excision in recurrent facial BCCs.[77] From a patient perspective, one large prospective cohort study found that MMS was an independent factor for higher long-term patient satisfaction, when compared to standard excision or C&D.[82]

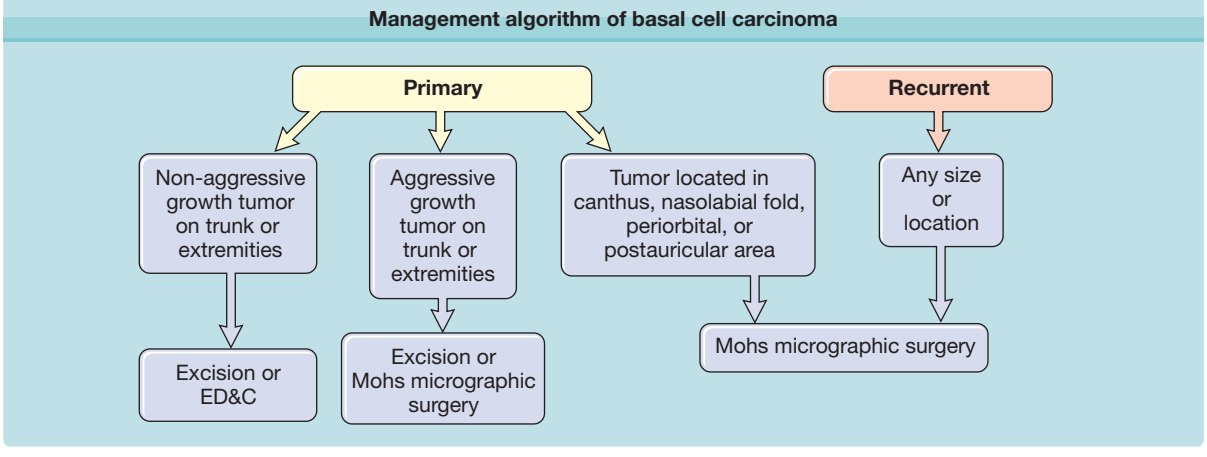

Figure 115-7 Algorithm for the management of basal cell cancer.

STANDARD EXCISION

Compared with nonexcisional techniques, standard surgical excision offers the advantage of histologic evaluation of the removed specimen; however, depending on the sectioning method used (e.g., bread-loafing), areas of margin involvement can be missed during routine histologic evaluation.[83] The authors of a recent Cochrane review concluded that, based on the available published work, surgery is the standard treatment of choice for BCC.[75] Although standard excision is appropriate for many BCCs, cure rates for standard excisional surgery are inferior to those for MMS in cases of primary morpheaform BCCs, recurrent BCCs, and tumors located in high-risk anatomic sites.[78,79] One disadvantage of standard surgical excision is the potential for incomplete margin control. The incidence of incomplete excision has varied, with reports ranging from 4.7% to 13.2% of treated patients.[84–88] Farhi et al found the pathologically reported incomplete excision rate was over 10% and was significantly associated with the location on the face, particularly on the nose and inner canthus, and with infiltrative and multifocal histologic types.[89] Wolf and Zitelli demonstrated that margins of 4 mm were adequate for 95% of nonmorpheaform BCCs smaller than 2 cm in diameter when treated by standard excision.[90] Huang and Boyce found that, for a 95% cure rate, BCCs <1 cm in diameter required a 0.5-cm margin, those between 1 cm and 2 cm in diameter required a 0.8-cm margin, and a 1.2-cm margin was required for those >2 cm in diameter.[91] Johnson, Tromovitch, and Swanson reported a 96.7% cure rate when the excision included a 2-mm margin beyond the area defined by curettage. Tumor was present in 64 of 403 curette margins and in 12 of 403 excision margins. The histologic subtype was aggressive in 11 of 12 cases with positive excision margins. Margins of 5 mm are necessary for primary morpheaform BCC or recurrent BCC.[92] Preoperative curettage decreases the frequency of positive margins in the management of BCC. Chiller et al found that curettage before excision decreased the surgical failure rate for BCC by 24% ($P = .03$).[93]

CURETTAGE AND DESICCATION

C&D is one of the most frequently used treatment modalities for BCC.[94] That C&D is operator-dependent was shown by Kopf et al, who identified a significant difference in cure rate between patients treated by private practitioners (94.3%) and those treated by residents (81.2%).[95] High 5-year cure rates of up to 98.8% have been obtained after C&D of primary, nonfibrosing BCCs of medium- and high-risk areas of the face when performed by a *skilled* operator.[96]

Spiller and Spiller reported a cure rate of 97% in 233 patients. Cure rate decreased as a function of primary lesion size: for lesions smaller than 1.0 cm, the cure rate was 98.8%; for lesions between 1.0 cm and 2.0 cm, 95.5%; and for lesions larger than 2.0 cm, 84%. Recurrences were noted most often on the forehead, temple, ears, nose, and shoulders. C&D is not recommended for large primary BCC, morpheaform BCC, or recurrent BCC.[97] For appropriately selected lesions and locations, C&D remains an efficacious and cost-effective treatment modality.[83]

CRYOSURGERY

Cryosurgery is another destructive modality that has been used in the treatment of BCC. Two freeze-thaw cycles with a tissue temperature of –50°C (–58°F) are required to destroy BCC. In addition, a margin of clinically normal tissue must be destroyed to eradicate subclinical extension.[83] A systematic review of recurrence rates published between 1970 and 1997 indicated that cryotherapy in the treatment of primary BCC resulted in a 5-year recurrence rate from 4% to 17%.[98] Cryosurgery lacks the benefit of histologic confirmation of tumor removal. Kuflik and Gage reported 99% cure rates in 628 patients followed for 5 years. Possible complications of cryosurgery include hypertrophic scarring and postinflammatory pigmentary changes.[99] In regards to cosmesis, patient satisfaction was found to be higher with surgical excision than with cryosurgery and should be taken into consideration when choosing a treatment option.[100] Another potential serious adverse outcome is the obscuring of tumor recurrence by fibrous scar tissue. Any recent change in a cryosurgery scar after normal healing is completed should raise the suspicion of recurrent BCC.

TOPICAL TREATMENT

IMIQUIMOD. Imiquimod (5% cream) has been used in the treatment of skin cancers.[101] Approved in 2004 by the FDA for the topical treatment of biopsy-confirmed, small (less than 2 cm), primary superficial BCC, imiquimod is a Toll-like receptor 7 agonist believed to induce interferon-α, tumor necrosis factor-α, and other cytokines to boost T helper 1 type immunity. In two double-blind, randomized, vehicle-controlled trials, clinical and histological clearance rates for dosing five and seven times per week were 75% and 73%, respectively, for superficial BCC.[102,103] In another study, 10 of 19 nodular BCCs (approximately 53%) cleared after treatment with imiquimod.[104] In general, adverse side effects are limited to local skin reactions; however, researchers have noted the significant correlation between the severity of the local skin reaction (erythema, erosion, and crusting) and the histological clearance rate.[102]

The safety and effectiveness of imiquimod for other types of BCC have not been established, and with up to 25% of treated patients failing therapy (or *with*

a one in four failure rate), this possible clinical consequence should be discussed and strongly considered when choosing the appropriate treatment. The cost of imiquimod can easily exceed the costs of destructive or surgical modalities as well.[105] A case series of 24 patients[105] highlights the clinical consequences of imiquimod failure rescued with MMS. The cost of imiquimod can easily exceed the costs of destructive or surgical modalities as well.

Imiquimod can be consideration as a monotherapy only for superficial BCCs limited to small tumors in low-risk locations in patients who will not or cannot undergo treatment with other better-established therapies.[106]

5-FLUOROURACIL. 5-Fluorouracil (5-FU), a topically applied chemotherapeutic agent used in the treatment of actinic keratoses, has also been used to treat BCCs. In one series, Epstein showed a 5-year recurrence rate of 21% after 5-FU treatment, which was reduced to 6% when curettage was performed initially.[107] Gross et al observed a 90% histologic clearance rate 3 weeks after 5-FU treatment, but with no follow-up. 5-FU was also found to be generally well tolerated with a good cosmetic outcome, with the majority of patients having no pain or scarring and only mild erythema.[108] 5-FU is metabolized by dihydropyrimidine dehydrogenase (DPD), and its use is contraindicated in patients deficient in that enzyme. A 2-(13)C-uracil breath test can identify DPD-deficient individuals.[109–111] The use of 5-FU to treat BCC should be considered carefully and should include an evaluation of the risk of recurrence and treatment failure. Topical therapies may be associated with adverse effects, produces lower clearance rates, may be more difficult to administer, and, in some instances, costs more than other well-established therapies for BCC.[106]

HEDGEHOG INHIBITORS. With strong evidence of HH activation in BCC, there has been significant recent development of HH inhibitors (HHI) for the treatment of metastatic or locally aggressive BCCs. The well-known HHI compound is the plant alkaloid, cyclopamine, which competitively inhibits SMO protein signaling and therefore the growth of malignant cells driven by HH activation.[112,113]

In a phase 1 trial, GDC-0449, an orally active small molecule derivative that targets the HH pathway via SMO, appears to have antitumor activity in locally advanced or metastatic BCC (ClinicalTrials.gov number, NCT00607724).[114] Further studies are needed to ascertain the full efficacy and adverse-effect profiles. Topical HH pathway inhibitors are also being developed for the treatment of BCC.

PHOTODYNAMIC THERAPY

Photodynamic therapy (PDT) involves the activation of a photosensitizing drug by visible light to produce activated oxygen species that destroy the constituent cancer cells. Exogenous δ-aminolevulinic acid increases intracellular production of the endogenous photosensitizer protoporphyrin type IX, which preferentially accumulates in tumor cells.[115] Morrison et al reported an 88% initial clearance of 40 large (>2 cm) BCCs after one to three treatments. The time of follow-up was between 12 months and 60 months.[116] Basset-Seguin et al reported complete response rates for superficial BCCs from 85% to 93% at 3 months and a response rate on par with cryosurgery at 60 months (75% vs. 74%).[117] Marmur et al reviewed PDT for nonmelanoma skin cancer and reported recurrence rates ranging from 0% to 31% for BCC.[118] A clinical study comparing methyl-aminolevulinate PDT (MAL-PDT) and surgery in small superficial BCC found that MAL-PDT offers similar high efficacy and a much better cosmetic outcome than standard excision surgery in the treatment of superficial BCC; however, at 12 months, 9.3% lesions recurred with MAL-PDT and none with surgery.[119] The long-term cure rates for superficial BCC with PDT remains around 75% and because of the appreciable nonresponse and recurrence rates, patients should be monitored closely during the first 2–3 years after PDT, which is when most lesion recurrences are seen.[120] The Cochrane collaboration found that cosmetic outcome for PDT was significantly better than surgery. However, there were also comparatively high failure rates associated with PDT when compared to surgery, radiotherapy and cryotherapy. PDT requires a number of hospital visits and this may not suit all people with BCC.[75] Reports of high recurrence rates suggest that this method may be best reserved for select situations in which better established methods are not feasible, particularly in situations where surgery may be problematic or where patients have multiple lesions.

RADIATION THERAPY

Radiation therapy (XRT) may be useful in cases of primary BCC or in cases in which postsurgical margins are positive for cancer. Advantages include minimal patient discomfort and avoidance of an invasive procedure for a patient unwilling or unable to undergo surgery. XRT may be a very useful modality as adjunct treatment for BCC when margins are positive after excision or for extensive perineural or large nerve involvement.[83] Potential disadvantages include lack of histologic verification of tumor removal, prolonged treatment course, cosmetic result that may worsen over time (cutaneous atrophy and telangiectasia), and predisposition to aggressive and extensive recurrences. Local control rates of 93%–97% have been reported; however, cosmesis has been rated inferior to results achieved surgically.[116,121]

The Cochrane Collaboration found surgery and radiotherapy to appear the most effective treatments for BCC, while the best overall results being obtained with surgery.[75]

SPECIAL MANAGEMENT ISSUES

INCOMPLETELY EXCISED BASAL CELL CARCINOMA. On the basis of data from the 1960s suggesting that 50%–70% of incompletely excised BCCs do not recur, some physicians adopted a "wait and see" approach.[122] In some cases, flap and graft repair may have been performed before confirmation of negative margins, so that the anatomy was distorted. This confounds identification of positive margins for definitive treatment. Incomplete resection was addressed by Robinson and Fisher,[61,123] who reported on 994 patients consecutively referred for treatment of incompletely excised BCCs with subsequent clinical recurrence. Of these, only 32 were referred for MMS for complete tumor removal at the time the original operating surgeon received the pathologic confirmation of positive excision margins. For the remaining 962 recurrent BCCs, the nose was the most common anatomic site (43%), and flap repair was the most common form of reconstruction (52%). The authors recommend MMS for the treatment of incompletely excised BCC. Ideally, patients should receive treatment at the time of diagnosis, because delay will likely result in increased local tissue damage (eFigs. 115-7.1A and 115-7.1B in online edition). Patients unable to undergo re-excision to achieve clear margins should be evaluated for XRT.

NEUROTROPIC BASAL CELL CARCINOMA. PNI by BCC is a rare event (<0.2% of cases). Defined as the observation of malignant cells in the perineural space of nerves,[124] when PNI is detected, every effort should be made to clear the tumor, preferably by MMS. Patients with gross PNI manifested by neurologic symptoms would benefit from preoperative magnetic resonance imaging to assess extent of tumor spread. Classic examples include brow paralysis due to involvement of the temporal branch of the facial nerve and midface paresthesias secondary to involvement of the trigeminal nerve.[64,65]

METASTATIC BASAL CELL CARCINOMA. Although it is exceedingly rare, the possibility of metastatic disease exists and may need to be addressed. If nodal disease is suspected on surgical examination, lymph node biopsy and imaging studies, as well as evaluation by medical and surgical oncologists, are indicated.[68] Platinum-based chemotherapy has been used with modest results in treatment of metastatic BCC; however, rapid clinical response was reported using a combination of cisplatin and paclitaxel.[125] Complete response to carboplatin and paclitaxel has been reported as well.[126]

COURSE AND PROGNOSIS

With appropriate treatment, the prognosis for most patients with BCC is excellent. Control rates as high as 99% have been achieved by MMS. Although tumor control rates for primary tumors are high, patients must be monitored for recurrence and development of new primary BCCs. The risk for development of a second primary BCC ranges from 36% to 50%.[127] Periodic full-body skin examinations and counseling about sun protection are recommended for any patient with a history of BCC. This is especially important because patients with a history of BCC are at increased risk for melanoma. The prognosis for patients with recurrent BCC is favorable, although recurrent tumors are more likely to appear again and to behave aggressively. Patients with a history of recurrent disease must be monitored more frequently for the development of further recurrences and new primary tumors. An estimated 40%–50% of patients with primary carcinoma will develop at least one or more further BCCs within 5 years.[128] For the rare patient with metastatic disease, prognosis is poor, with a mean survival of 8–10 months from the time of diagnosis.

Chapter 116 :: Basal Cell Nevus Syndrome

:: Anthony E. Oro & Jean Y. Tang

BASAL CELL NEVUS SYNDROME AT A GLANCE

- A rare autosomal dominant disorder with phenotypic abnormalities that include developmental anomalies and postnatal tumors, especially basal cell carcinomas (BCCs).
- The three most characteristic abnormalities are tumors such as medulloblastomas or BCCs, pits of the palms and soles, and odontogenic cysts of the jaw.
- Related findings include calcification of the falx cerebri, enlarged body habitus, and skeletal abnormalities of the ribs and skull.
- Diagnosis is suspected in a patient with multiple BCCs arising at an unexpectedly early age with an average age of onset of 21 years.
- Histologic features of tumors in BCNS patients are similar to those of sporadic BCCs or medulloblastomas.
- Several new therapeutic agents, including SMO antagonists and celecoxib, have been shown to have efficacy in treating disease along with photodynamic therapy, imiquimod, and 5-fluorouracil.

Basal cell nevus syndrome (BCNS), also known as *nevoid basal cell carcinoma syndrome* and *Gorlin syndrome* [Online Mendelian Inheritance in Man (OMIM) #109400], is a rare autosomal dominant disorder associated with a panoply of phenotypic abnormalities that can be divided into developmental anomalies and postnatal tumors, especially basal cell carcinomas (BCCs).[1] Although individual aspects had been reported previously, their syndromic association was first appreciated widely in the late 1950s.[2,3]

EPIDEMIOLOGY

The prevalence of BCNS is variously estimated to be 1 in 60,000 and 1 in 120,000 persons.[4,5] The syndrome affects both sexes and occurs in a wide variety of cultural groups, and therefore does not have a predilection for a particular skin type. The condition appears to have complete penetrance but variable expressivity of traits, such that their clinical presentation within families is nonuniform. Further, as with many dominantly inherited conditions, new mutations are common. As a result, many patients may have no apparent affected ancestors or siblings.

ETIOLOGY AND PATHOGENESIS

GENETIC ABNORMALITY

Almost all known BCNS patients thus far carry mutations in the *PATCHED1* (*PTCH1*, UniGene Hs. 494538) gene residing on the long arm of chromosome 9.[6,7] PTCH1 plays a central role in the hedgehog signaling pathway that is essential for the establishment of normal body and limb patterning in metazoan organisms.[8] The *PTCH1* locus behaves like a classic tumor suppressor gene (Fig. 116-1). The appearance of BCCs in small numbers at an older age in sporadic cases and in larger numbers at a younger age in patients with BCNS is reminiscent of differences in sporadic and hereditary cases of retinoblastoma.[9] BCNS, like other tumor susceptibility syndromes, is inherited in an autosomal dominant manner, with inheritance of a loss-of-function allele followed by somatic loss of the remaining copy before tumor formation.

Identification of the gene mutation responsible for BCNS facilitated a molecular verification of the predicted PTCH1 tumor suppressor function.[6,7] BCNS patients inherit one defective *PTCH1* allele and their tumors contain an additional somatic mutation. As with other tumor suppressor genes, *PTCH1* mutations have also been found in older adults with sporadic BCCs and other sporadic tumors known to be overrepresented in BCNS patients (e.g., medulloblastomas and meningiomas), which supports the idea that two somatic "hits" are required in sporadic tumors.

In contrast, the two-hit genetic model proposed for PTCH1-dependent tumor development may not fully explain the developmental abnormalities seen in BCNS, which occur earlier. *PTCH1* heterozygote mice display many of the developmental abnormalities seen in BCNS patients despite a wild-type copy of the nonaffected allele.[10,11] This argues that certain tissues (skeleton, limb, neural tube) require higher levels of PTCH1 to regulate tissue development and that heterozygotes cannot compensate for loss of the other allele (haploinsufficiency). In addition, the *PTCH1* locus appears to be regulated in part by silencing. Recent observations indicate that methylation blockers can reactivate PTCH1 expression shut off during tumor formation, suggesting that silencing of PTCH1 expression may also play a role in normal development.[12]

Are *PTCH1* mutations the only cause of BCNS? Despite direct sequencing of *PTCH1* exons in patients, somatic mutations are found in fewer than half of BCCs and germ-line mutations in fewer than 100% of BCNS patients.[13,14] This suggests that mutations in

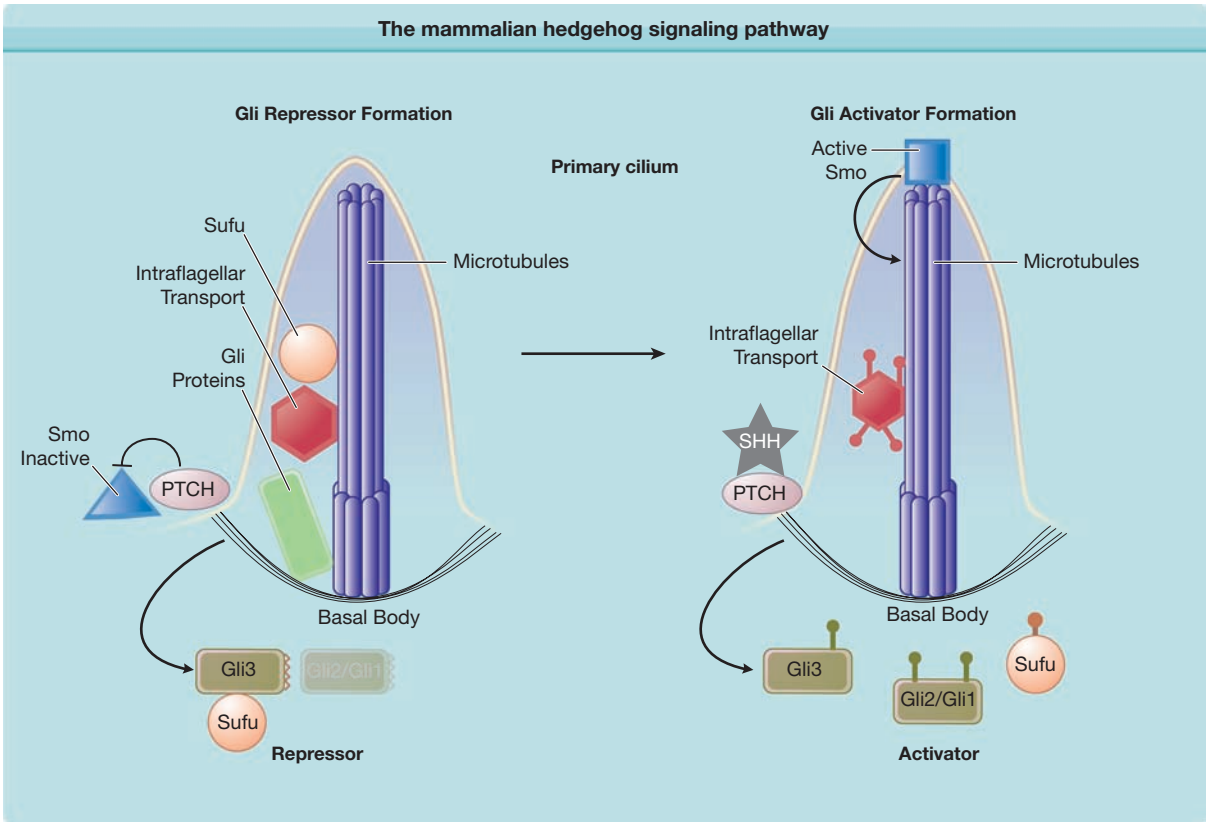

Figure 116-1 The mammalian hedgehog signaling pathway. PTCH1 is the receptor for the growth factor hedgehog and inhibits the function of smoothened (SMO) by sequestering it in an inactive state outside of the microtubule-based organelle, the primary cilum. Sonic hedgehog (SHH) inhibits PTCH1, allowing activation of SMO in the cilium. SMO inhibits Suppressor of Fused (SUFU), which in turn inhibits the GLI transcription factors GLI1, GLI2, GLI3. Intraflagellar transport proteins help mediate GLI processing.

other unidentified genes may underlie the disease. However, early linkage studies found a strong association with the *PTCH1* locus. Moreover, although mutations are not found in *PTCH1* exons in some patients, hedgehog signaling pathway abnormalities are still present in these tumors. Recently, one family with BCNS and atypical features (medulloblastoma, plantar pits, but no BCCs) was found to have germ-line mutations in Suppressor of Fused (SUFU)—a tumor suppressor gene and negative regulator of sonic hedgehog (SHH) signaling (Fig. 116-1).[15] This suggests mutations may be found in other members of the signaling pathway in rare cases.

PTCH1 FUNCTION

PTCH1 protein plays a critical role in the hedgehog-signaling pathway (Fig. 116-1). Genetic and biochemical studies in *Drosophila* and mammals indicate that PTCH1 protein inhibits this signaling pathway by inhibiting the function of the central G protein-coupled receptor smoothened (SMO), and that the extracellular ligand hedgehog abrogates this inhibition. Signaling by SMO results in the activation of the Glioma associated oncogene (GLI) family of zinc finger proteins that mediate all the transcriptional effects of hedgehog signaling. Three GLI proteins mediate activation and suppression of hedgehog target genes, with GLI1 and GLI2 acting as activators and GLI2 and GLI3 as suppressors. SMO signaling tips the balance toward activation and away from target gene suppression. In mammals, GLI activity is controlled by the novel cytoplasmic protein SUFU, which promotes the transcriptional repression and inhibits activation.[16] SMO inhibits SUFU activity, thus releasing GLI proteins to become transcriptional activators. When hedgehog binds to PTCH1, PTCH1 inhibition of SMO is relieved and the pathway is activated. Thus, loss of PTCH1 function allows unregulated SMO activity and initiates tumor formation.

How PTCH1 functions as a tumor suppressor is still under investigation. A significant function of PTCH1 is to inhibit SMO, although how PTCH1 accomplishes this is yet unknown. PTCH1 acts in an enzymatic manner as only a few molecules are necessary to inhibit SMO by several fold.[17] Moreover, PTCH1 and SMO are thought to exist in distinct endosomes and thought not to physically interact. Recent studies demonstrate that components of the hedgehog pathway are localized to a novel microtubule based organelle called the primary cilium (Fig. 116-1).[18] Mutations that affect the structure and function of the cilium, known collectively as the human ciliopathies, are also known to disrupt maximal hedgehog signaling and the patients

have some similarities to BCNS. SMO accumulates in the cilia via intraflagellar transport proteins and this accumulation is correlated with pathway activation. PTCH1 is localized at the base of the organelle and appears to prevent SMO entry. Loss of PTCH1 or mutations that allow SMO to move into the cilium result in increased pathway activity.[19] PTCH1 shares homology with sterol-sensing domain-containing proteins such as SREBP (sterol regulatory element-binding protein) and β-hydroxy-β-methylglutaryl–coenzyme A reductase.[20] It also shares significant structural identity with the resistance-nodulation-division (RND) permease family of small-molecule transporters, which suggests that PTCH1 may act as a molecular pump. This evokes the tantalizing hypothesis that PTCH1 regulates SMO entry and activation within the cilium by regulating the production or distribution of small-molecule second messengers in the cell.

MUTATIONS IN SONIC HEDGEHOG PATHWAY IN BCCs

The identification of mutations in members of the SHH pathway in both BCNS patients and in sporadic BCCs supports the central role of SHH target gene induction in BCC pathogenesis. PTCH1 mutations are by far the most common and are found in approximately 40% of tumors.[21] Epidemiologic evidence implicates ultraviolet light in the pathogenesis of sporadic BCCs. UV signature mutations have been found in PTCH1 and these provide additional evidence for a role of sunlight in cancer development.[22]

Mutations of SMO protein have been identified in approximately 10% of BCCs, and these mutations appear to render SMO protein resistant to PTCH1 inhibition.[23] Indeed, experimental transfection of cells with mutant SMO sequences can transform them to a malignant phenotype. This finding that BCCs may have upregulation of hedgehog target gene expression due to mutations in either *PTCH1* or *SMO* argues that it is the upregulation of hedgehog signaling rather than the specific mutation that is crucial to BCC formation. Consistent with this is the finding that mutations in the gene encoding SUFU have been reported to underlie formation of medulloblastomas and BCNS.[15,24]

The identification of these molecular abnormalities in BCCs for the first time has permitted the development of mouse models of this tumor. Previously, tumor-initiating insults to mouse skin (ultraviolet, ionizing radiation or chemical carcinogens) have produced papillomas and carcinomas of the squamous, but not the basal cell lineage. Mouse models that show spontaneous development of BCC-like tumors include those with epidermal overexpression of hedgehog,[25] of mutant SMO,[23] or of GLI1[26,27] or GLI2.[28,29] In addition, *ptc1*$^{+/-}$ mice, which, like BCNS patients, have one instead of two functioning alleles of *PTCH1*, not only develop BCCs and related tumors but also develop plantar pits, medulloblastomas, and rhabdomyosarcomas, as do BCNS patients. The mouse BCCs (mimicking human BCCs) occur spontaneously in low numbers and in small sizes, but in much higher numbers and of larger size in mice exposed to ultraviolet or ionizing radiation.[30]

CLINICAL FINDINGS

CUTANEOUS LESIONS

Hedgehog signaling plays a critical role in the expansion of progenitor cells in a wide variety of tissues in both invertebrate and vertebrate organisms. PTCH1 normally is expressed both during development and in the adult, which suggests an ongoing postnatal role. Studies involving experimental models inappropriately expressing components of the hedgehog signaling pathway have revealed significant developmental anomalies.[31] The resemblance of these anomalies to those characteristic of BCNS implies that aberrant activation of the hedgehog signaling pathway is a sufficient explanation for the developmental and tumorigenic anomalies of BCNS, even if the precise pathogenic mechanisms have yet to be elucidated.

Patients with BCNS show multiple abnormalities, none of which is unique to this syndrome (eTable 115-0.1 in online edition).[5,13,14] The three abnormalities considered to be most characteristic of the syndrome are tumors such as medulloblastomas or BCCs, pits of the palms and soles, and odontogenic cysts of the jaw.

Individual BCCs from patients with BCNS cannot be distinguished from those in sporadic cases (see Chapter 115), which is not surprising in view of the similar pathogenesis in familial and sporadic cases. What is distinguishing is their appearance in large numbers starting at an early age. They may be banal appearing and confused grossly with nevocytic nevi—hence the name *basal cell nevus*. They may also have a translucent, papulonodular appearance more characteristic of sporadic BCCs and may invade locally. In rare cases, they may even metastasize and cause death. Although the ratio of sun-protected to sun-exposed BCCs may be higher in BCNS than in sporadic cases, sunlight and ionizing radiation clearly accelerate BCC formation in BCNS patients, and darkly pigmented BCNS patients may have few to no BCCs (Figs. 116-2–116-4).

Palmoplantar pits are small defects in the stratum corneum and may be pink or, if dirt has accumulated, dark in color (Fig. 116-5). They appear early in life and can be a valuable aid in diagnosis in addition to jaw cysts or medulloblastoma. Their basis is poorly understood, but they are thought to be due to aborted attempts to generate hair follicles in the palms. They are also seen in mouse *PTCH1* heterozygotes.[31]

RELATED PHYSICAL FINDINGS

Tissue overgrowth, which is also a feature of hedgehog signaling pathway activation in *Drosophila*, often is manifested by an overall body size larger than that of other family members. Limbs may be particularly long, giving a marfanoid appearance (Fig. 116-6), and a large head circumference (at least in probands) and frontal bossing are often described.

Figure 116-2 Face of a man with severe scarring from growth and treatment of multiple basal cell carcinomas (BCCs). Note multiple outlined new BCCs despite extensive and frequent surgery.

Figure 116-4 Basal cell carcinoma (BCC) on the toe of a patient with basal cell nevus syndrome (BCNS), which illustrates that the whole skin surface of BCNS patients is susceptible to BCC formation.

Jaw cysts often are the first detectable abnormality (Fig. 116-7).[5,13,14] They may be asymptomatic and therefore diagnosed only radiologically. However, they also may erode enough bone to cause pain, swelling, and loss of teeth. They occur more often in the mandibular jaw than in the maxillary jaw.[32] These jaw cysts presumably form from inappropriate SHH induction of dental epithelium and can recur often and be the most debilitating aspect of the syndrome.[33]

eTable 116-0.1 in online edition lists the phenotypic abnormalities that have been reported often enough that they probably are true components of the syndrome.

Figure 116-3 Upper back of man with basal cell nevus syndrome with innumerable basal cell carcinomas, some of which are nodular and most of which are flat, erythematous patches.

These include tissue overgrowth seen in other epithelial organs such as the meninges or ovaries that give rise to meningiomas or ovarian fibromas. Variation in clinical severity is typical even within a single kindred, and this heterogeneity is likely due to both environmental differences (e.g., exposure to ultraviolet and ionizing radiation) and genetic background differences.

Of interest is the finding that SHH signaling plays a key role in up to 25% of all human cancers, including small cell lung cancer, pancreatic cancer, and prostate cancer.[30,34] This finding suggests a wider role for hedgehog signaling than that seen in BCNS patients. Although BCNS is a rare syndrome and exhaustive prospective studies have not been performed, no excess of these associated cancers has yet to be documented in BCNS patients. This might reflect a different mechanism of tumor development, because these visceral tumors demonstrate hedgehog ligand overexpression rather than the loss of PTCH1 as seen in BCCs. Alternatively, pathway induction in older adults may have different consequences than pathway activation in younger individuals.

DIAGNOSIS

Because the individual abnormalities are not unique to BCNS patients, it is possible to diagnose BCNS clinically only when multiple typical defects are present (Table 116-1). The severity of abnormalities may differ markedly among members of a single kindred, and diagnostic certainty may be difficult for specific individuals even if they belong to a kindred with known BCNS.[35] Generally, the diagnosis is suggested to the dermatologist when multiple BCCs arise in a patient at an unexpectedly early age and in unexpectedly large numbers, with the average age of onset in the early 20s.

Figure 116-5 **A.** Unusually florid palmar pits in a patient with basal cell nevus syndrome (BCNS). **B.** Larger magnification showing that these lesions in BCNS are really punched-out pits.

Further evaluation should include (1) questions about whether other family members have had abnormalities consistent with BCNS (although perhaps 30% of patients with BCNS have no affected ancestors) and whether the patient is taller and heavier than his or her relatives; (2) examination for palmoplantar pits and skin cysts and assessment of body and head size; and (3) radiologic evaluation for jaw cysts (which often appear around the start of the second decade), calcification of the falx (which occurs in nearly all adults with BCNS and may be present in early childhood in BCNS patients, thus suggesting the diagnosis of BCNS in those patients with early-onset medulloblastomas), and abnormalities of the ribs, spine, and phalanges (flame-shaped lucencies), each of which is present in one-third to one-half of BCNS patients.[5,13,14,36] Kimonis and colleagues proposed a set of major and minor criteria for presumptive diagnosis of BCNS, which has since been modified (see Table 116-1).[13] For cases in which the diagnosis is in doubt, or for genotyping of other family members, identification of *PTCH1* gene mutations is now available commercially through GeneDX (Gaithersburg, MD).

TABLE 116-1
Diagnostic Criteria for Basal Cell Nevus Syndrome (BCNS)

Major Criteria
1. Basal cell carcinoma before age 20 years
2. Odontogenic keratocysts before age 15 years
3. Three or more palmar and/or plantar pits
4. Bilamellar calcification of the falx cerebri (if younger than 20 years)
5. Fused, bifid, or markedly splayed ribs
6. First-degree relative with BCNS
7. *PTCH* gene mutation in normal tissue

Minor Criteria
1. Macrocephaly determined after adjustment for height
2. Congenital malformations: cleft lip or palate, frontal bossing, "coarse face," moderate or severe hypertelorism
3. Skeletal abnormalities: Sprengel deformity, marked pectus deformity, or marked syndactyly of the digits
4. Radiologic abnormalities: bridging of the sella turcica; rib anomalies such as bifid or splayed ribs; vertebral anomalies such as hemivertebrae, fusion, or elongation of the vertebral bodies; modeling defects of the hands and feet; or flame-shaped lucencies of the hands or feet
5. Ovarian fibroma
6. Medulloblastoma

Data from Kimonis VE et al: Clinical manifestations in 105 persons with nevoid basal cell carcinoma syndrome. *Am J Med Genet* **69**:299, 1997; and First BCCNS Colloquium, St. Louis, May 2005.

DIFFERENTIAL DIAGNOSIS

Other syndromes exist that are characterized by the development of multiple BCCs. These include Bazex syndrome (OMIM #301845),[37] Rombo syndrome (OMIM #180730),[38] and a syndrome observed in a family with BCCs, milia, and coarse, sparse hair.[39] Hair abnormalities are present in all three syndromes, which is a finding of interest in view of the often-repeated suggestion that BCCs arise from hair follicles rather than from interfollicular epidermis. The exact nosologic relationships among these three syndromes are uncertain, but patients with BCNS have normal hair, and all three syndromes seem quite different from BCNS.

Two other syndromes that have been described include multiple hereditary infundibulocystic BCC[40]

Figure 116-6 Skeletal and radiographic findings in basal cell nevus syndrome. **A.** Unusually large body habitus and extremities. **B.** Syndactyly in digits. **C.** Calcification of the falx cerebri. **D.** Rib development abnormalities, including rib fusion (*arrow*).

and generalized basaloid follicular hamartoma.[41] Both demonstrate histologic variants of BCCs, with more hamartomatous lesions, and are characterized by palmar pits and milia. The latter syndrome is acquired and associated with autoimmune disease, which suggests an immunologic stimulation of the hedgehog pathway. The former appears to be linked to the PTCH1 locus and thus may be due to a PTCH1 allele.

BCNS shares some developmental abnormalities with the group of human diseases known as the ciliopathies.[42] This likely occurs because the hedgehog pathway can be localized within the primary cilium and that defects in the functioning of this organelle can result in hedgehog signaling defects seen in BCNS patients such as polydactyly and craniofacial abnormalities. The ciliopathies do not manifest skin and cerebellar tumor predispositions. Furthermore, retinal degeneration, a hallmark of many ciliopathies, is not commonly seen in BCNS patients.

Patients with long-term arsenic ingestion may have multiple BCCs. Their dyschromia and lack of other phenotypic abnormalities differentiate them from BCNS patients (see Chapter 113). Patients with xeroderma pigmentosum develop multiple BCCs but are readily differentiated from BCNS patients by their severe photosensitivity and other phenotypic abnormalities (see Chapter 139).

The most challenging patients are those who have a marked propensity to develop multiple BCCs early in life, sometimes sporadically or in rare cases after

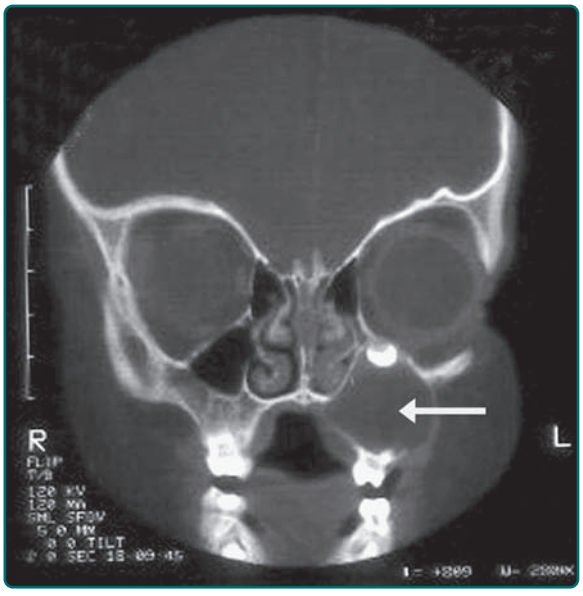

Figure 116-7 Radiographic findings of odontogenic keratocyst (*arrow*).

therapeutic irradiation (e.g., for Hodgkin disease) without showing any of the other signs of BCNS. These cases occasionally produce diagnostic confusion because, due to the variable expressivity of individual PTCH1 alleles, it is not known whether their defect is related to the hedgehog pathway, to DNA repair, to an unknown toxin, and/or to yet undescribed mechanisms. One insightful study argues against germ-line PTCH1 mutations as the cause of multiple BCCs, because PTCH1 mutations have not been found in individuals who do not have at least one other key manifestation of BCNS.[43]

COMPLICATIONS, PROGNOSIS, AND CLINICAL COURSE

Although disease pathogenesis involves abnormalities in SHH signaling, the wide variability in clinical course among families, and even between generations of the same family, make prediction of clinical course difficult. If BCNS is suspected or confirmed, physicians should also screen for the most frequent sequelae of the disease during childhood or adolescence (Fig. 116-8). No large-scale survival studies have been performed to determine whether BCNS patients die earlier because of their disease.[13,44] The major complications are developmental delay, physical impairment in children and the childhood tumors that arise, such as medulloblastoma. The latter often occur within the first 5 years of life and are frequently the initial sign of BCNS. Complications arising from medulloblastoma treatment (radiation, shunt placement) are relatively common, and multidisciplinary teams of physicians are required to optimally treat these patients.

In the skin, BCCs that arise are locally aggressive but very rarely metastasize.[45] No reports document an increased risk for metastatic BCCs, which suggests

Approach to a patient with known or suspected basal cell nevus syndrome (BCNS)

Pediatric patients

- Baseline MRI of brain, repeat yearly (if asymptomatic) until age 8
- Baseline dermatologic exam, repeat yearly until first BCC develops, then every 6 months or more frequently as needed) throughout life
- Digital panorex of jaw at age 3 or 4 years (or as soon as tolerated), then yearly until first jaw cyst develops. Repeat yearly (or more frequently as needed), until age 21
- Pelvic u/s in girls at menarche (or earlier if symptomatic)
- Molecular diagnosis, (if desired) for patients with family history and known mutation
- Baseline scoliosis assessment at year of age and then annually for progression if present
- Routine developmental screening and referral for all children who do not meet developmental milestones

Adult patients

- Baseline MRI of brain (if not done at age 8 or later)
- Dermatologic exam at 4 months (or more frequently if new lesions present at each exam)
- Digital panorex of jaw twice yearly until cyst free for two years, then yearly or less frequently (depending on patient's concern about radiation)
- Prenatal or preconception counseling if desired

Figure 116-8 Approach to the patient with known or suspected basal cell nevus syndrome (BCNS). BCC = basal cell carcinoma; MRI = magnetic resonance imaging; u/s = ultrasonography. (Data from Kimonis VE et al: Clinical manifestations in 105 persons with nevoid basal cell carcinoma syndrome. *Am J Med Genet* **69**:299, 1997; and First BCCNS Colloquium, St. Louis, May 2005.)

that the basic character of the tumor is similar to that seen in sporadic BCC cases. However, because of the high numbers and wide distribution of the tumor, even in the absence of sun exposure, involvement of key epithelial surfaces or membranes is likely and can be disfiguring for the patient.

TREATMENT

Therapy must be directed at the individual lesions as they arise, and the most important aspect of management is frequent examination, enthusiastic counseling about avoidance of sun exposure, and early treatment of small tumors. In animal models of BCNS, small clinically undetectable tumors arise throughout the skin. This suggests that many more tumors form than are detectable visibly by the clinician.[27,31] This has several therapeutic ramifications. One is that clinicians caring for BCNS patients should become confident in their clinical acumen so that they can diagnose and treat tiny BCCs without histopathologic confirmation. This would eliminate multiple scar-inducing biopsies in

addition to potentially disfiguring treatments. Another is that invasive treatments should be focused on those lesions that are potentially most harmful, such as those invading mucous membrane or adjacent structures. Repetitive surgical treatments run the risk of severe disfigurement for the patient. Finally, clear surgical margins may be difficult to achieve when using Mohs surgery, so aggressive pursuit of a clear margin needs to be balanced against other factors in treating these patients.

Nonsurgical approaches to BCC treatment should be used aggressively in BCNS patients when possible. Because the key is to convince the patient to accept frequent treatments, minimization of discomfort and scarring is a major goal. Approaches that may be of benefit are topical treatment with 5-fluorouracil (with or without occlusion, depending on the degree of inflammation produced),[46] the Toll-like receptor agonist imiquimod,[47] and photodynamic therapy.[48] Oral therapy with retinoids also may be of value, but often only at a dosage that causes severe side effects. There are several ongoing clinical trials for new agents for BCC prevention in BCNS patients based on positive results obtained from *ptc1*$^{+/-}$ mice. UV exposure induces inflammation and cyclooxygenase (COX) expression in tumor cells and stroma.[49] In addition, COX2 gene polymorphisms are thought to modify BCC risk.[50] Collectively, these data suggest a role for COX2 in BCC carcinogenesis: this is further supported by murine studies in which overexpression of COX2 in keratinocytes of *ptc*$^{+/-}$ mice resulted in a twofold increase in BCCs, while germ-line COX2 deletion resulted in a 75% reduction. A Phase 2 randomized, controlled trial of celecoxib (a COX2 inhibitor) was recently completed in 60 BCNS subjects. Overall, there was a trend of oral celecoxib decreasing BCC development by 30% and a significant reduction of 50% in the subset of patients with less severe disease.[51] Therefore, nonsteroidal anti-inflammatory drugs (NSAIDS) may have efficacy particularly in patients at lower risk. However, potential cardiovascular risks associated with celecoxib may preclude its use as a common chemoprevention strategy in patients with BCC.[52]

Studies have now identified a natural antagonist of the hedgehog pathway derived from the *Veratrum californicum* plant called *cyclopamine*.[12] This substance binds and antagonizes SMO and has been shown to be effective in animal models of BCCs. Other small-molecule hedgehog pathway antagonists with similar properties have been identified and are currently being tested for their clinical efficacy.[53] In a Phase 1 trial of the first of these specific hedgehog inhibitors, GDC-0449, 33 patients with locally advanced or metastatic BCCs were treated. The results were extremely promising in that there was significant shrinkage of metastatic and advanced cutaneous BCCs with relatively mild systemic toxicity.[54] Of the nine patients with advanced BCC, six partially responded, two had stable disease and one had disease progression. This early clinical data confirm that direct SHH pathway inhibition may be an effective therapy for those tumors driven by SHH pathway activation. Because of this initial success, GDC-0449 has now entered Phase 2 testing in patients with advanced BCC and BCNS, as well as for metastatic colorectal and ovarian cancer (NCT00959647). Unfortunately, as been the case with several other such molecularly targeted anti-cancer drugs, at least some of these advanced tumors driven by SHH signaling may eventually develop resistance to the targeted therapy.[55] The molecular mechanism(s) by which the tumors acquired resistance at least includes mutations in SMO.[56] Other SMO antagonists currently being developed for clinical application and that have entered Phase 1 clinical trials for treating BCCs include IPI-926,[57] XL-139 and LDE-225 (eTable 116-1.1 in online edition).

Figure 116-9 Basal cell nevus syndrome. Multiple large, fungating basal cell carcinomas (BCCs) arising in a portion of the lower back treated years earlier with superficial ionizing for BCCs.

The ionizing radiation treatment of BCCs has been advocated in otherwise normal patients who are not surgical candidates. However, excessive radiation should be avoided if possible, because enhanced radiation-induced carcinogenesis (e.g., in the skin of the portals of irradiation for childhood medulloblastomas) is characteristic of BCNS. Patients with BCNS who receive radiation have developed an unusually large number of basal cell tumors in the irradiated area a short time after exposure (Fig. 116-9). Radiosensitivity in PTCH heterozygotes has also been detected at the cellular level, although the mechanism is poorly understood.[58]

Genetic counseling is appropriate. With the availability of direct sequencing of the PTCH1 locus, genotyping for prenatal diagnosis is potentially achievable for interested families. Because PTCH1 is transmitted with complete penetrance, half of the children of affected individuals are expected to develop BCNS.

ACKNOWLEDGMENTS. The authors would like to thank Drs. Sheri Bale and Thierry Magnaldo for patient information.

Chapter 117 :: Keratoacanthoma

:: Lorenzo Cerroni & Helmut Kerl

KERATOACANTHOMA AT A GLANCE

- A common, rapidly growing epithelial tumor with histopathologic features similar to squamous cell carcinoma and a tendency to spontaneous regression.
- Considered by some a variant of squamous cell carcinoma because of potential of metastases and local tissue destruction if untreated. Considered by others a *pseudocancer*, but this issue is unresolved.
- Clinically, keratoacanthoma is mostly a rapidly growing, hyperkeratotic solitary tumor. Multiple keratoacanthomas occur.
- Predilection for sun-exposed areas.
- May be associated with Muir–Torre syndrome.
- Pathology reveals a central keratotic plug surrounded by an epithelial proliferation with atypical keratinocytes and mitoses; neurotropism may be observed.

Keratoacanthoma is a common epithelial tumor of the skin characterized by rapid growth, histopathologic features similar to those of cutaneous squamous cell carcinoma, and a certain tendency toward spontaneous regression. The exact nosology and classification of keratoacanthoma are still a matter of debate. Some authors regard keratoacanthoma as a benign cutaneous tumor that is the prototype of a "pseudomalignant" tumor of the skin, whereas others maintain that it is a malignant neoplasm and should be regarded as a variant of cutaneous squamous cell carcinoma.

EPIDEMIOLOGY

The exact incidence of keratoacanthoma is unknown. The tumor is more frequent in light-skinned persons, and rarer in dark-skinned and Japanese persons. The relative frequency in comparison with squamous cell carcinoma of the skin is controversial, but most studies show a lower incidence of keratoacanthoma than of squamous cell carcinoma. Discordant results may be explained, at least in part, by differences in classification of these lesions.

Studies on gender distribution reveal that both sexes are affected equally, possibly with a slight predilection for men. Keratoacanthoma occurs mostly in adult life, with a peak between the ages of 55 and 65 years; it has been observed rarely in younger patients. The

familial type of keratoacanthoma occurs often during adolescence, and a neonatal case has been reported.[8] Although the incidence was thought to remain stable after a peak in the sixth decade, a study conducted in a defined population in Hawaii revealed that keratoacanthoma increases with age, in a fashion similar to that observed for cutaneous basal and squamous cell carcinomas.[9]

RELATIONSHIP TO SQUAMOUS CELL CARCINOMA

The authors of earlier reports considered keratoacanthoma to be a form of epithelial cancer of the skin, and named it accordingly. However, since the introduction of the concept of keratoacanthoma as a benign, self-healing neoplasm distinct from squamous cell carcinoma, the relationship between these two epithelial tumors has been the subject of debate. In their paper published in 1950, Rook and Whimster wrote, "This disease is evidently not cancerous or precancerous."[2] On the other hand, Kwittken, in 1975, stated, "I have come to the firm conclusion that all of these lesions are malignancies and that the formerly accepted concept of a self-healing squamous cell carcinoma of the skin is a correct one,"[10] and in 1979, even Rook amended his initial concept by writing, "…transformation from keratoacanthoma to squamous cell carcinoma occurs frequently."[11] Cases of typical keratoacanthoma with metastases have been observed,[12] and four possible explanations for this phenomenon have been suggested: an initial misdiagnosis of keratoacanthoma; the presence of both keratoacanthoma and squamous cell carcinoma in the same lesion; the malignant transformation of keratoacanthoma into squamous cell carcinoma; and, finally, the possibility that keratoacanthoma may be a peculiar variant of squamous cell carcinoma.[13] The debate is not settled yet, and some authors still maintain that keratoacanthoma represents a benign epithelial tumor, distinct from squamous cell carcinoma,[14] whereas others hold that it is a variant of squamous cell carcinoma with tendency to spontaneous regression, but with the potential for giving rise to lethal distant metastases.[15] Two studies of large numbers of cases highlighted the impossibility of reliably differentiating keratoacanthoma from squamous cell carcinoma using histopathologic criteria alone.[16,17] A patient under infliximab therapy developed multiple squamous cell carcinomas as well as keratoacanthomas, suggesting a common pathogenetic pathway on immunosuppression.[18] In addition, multiple keratoacanthomas and multiple squamous cell carcinomas may be observed at the same skin site ("field cancerization") (Fig. 117-1). Keratoacanthomas have a higher proliferation rate than squamous cell carcinomas.[19] Other investigations pointed at similarities among squamous cell carcinoma and keratoacanthoma in the expression of oncogenetic and cell-cycle-regulating proteins as well as regarding the presence of trisomy 7 in a subset of tumors in both groups, thus suggesting a close relationship between these two entities.[20–25] On the other hand, studies on loss of heterozygosity, on expression

Figure 117-1 Multiple keratoacanthomas and invasive squamous cell carcinomas on the upper chest of a 90-year-old man.

of angiotensin type 1 receptor and of desmogleins 1 and 2, on adhesion molecules vascular cellular adhesion molecule and intercellular adhesion molecule, on telomerase activity, on apoptotic and cell adhesion markers, and on chromosomal aberrations assessed by comparative genomic hybridization showed differences among keratoacanthomas and squamous cell carcinomas.[26–33] Using different molecular techniques, both similarities and differences between keratoacanthoma and squamous cell carcinoma have been recently demonstrated.[34] In short, at present, and in spite of the great amount of clinical and experimental data collected over the decades, the exact nosology of keratoacanthoma is not clear, and the term *abortive malignancy* has been proposed.[35]

ETIOLOGY AND PATHOGENESIS

Different etiologic factors are probably involved in the development of keratoacanthomas in different patients, and it seems likely that these different factors act synergistically to induce the onset of a lesion in a given patient. The role of chronic ultraviolet (UV) light exposure in the etiology of keratoacanthoma is well documented by the frequent occurrence on sun-exposed areas, as well as by the presence of keratoacanthomas in patients with xeroderma pigmentosum and after prolonged psoralen and UVA light (PUVA) treatment. In patients with multiple keratoacanthomas, PUVA treatment accelerates the development of the tumors,[36] but the risk for keratoacanthoma after therapy with PUVA seems lower than that for squamous or basal cell carcinoma.[37] An etiologic link to UV light has been confirmed also by experimental studies in mice.

The relationship of keratoacanthoma to chemical carcinogens has been well documented in humans and in several animals.[38] In fact, the incidence of keratoacanthoma is higher in industrial towns, and among industrial workers coming in contact with pitch, mineral oils, and tar. Chemical carcinogens may act in conjunction with UV rays to induce the onset of keratoacanthomas. Smokers seem also to be more affected than nonsmokers.[38]

Keratoacanthomas have been reported at the site of injury. The association with trauma is also documented by the report of cases occurring after skin grafting, at both the donor and the recipient sites, and at the site of arterial puncture and vaccination.[39–41] A recent report described the onset of keratoacanthoma at the site of tattoo, particularly with red ink.[42] One of these patients had four keratoacanthomas arising within two separate tattoos. The role of human papillomavirus (HPV) remains controversial. Evidence of HPV infection has been documented by polymerase chain reaction technique,[43,44] but other studies failed to detect viral material within lesions of keratoacanthoma.[45] Some studies found an association with HPV-25, and HPV-19 and HPV-48 have been isolated in a lesion arising in a human immunodeficiency virus (HIV) patient.[46,47] Several other types of HPV have been linked to keratoacanthoma, including types 6, 9, 14, 16, 19, 35, 37, 58, and 61.

Genetic factors probably play a major role in the familial type of keratoacanthoma. In the other variants of keratoacanthoma, it seems likely that genetic aspects interplay with other etiologic factors (i.e., UV rays, trauma, infections) by providing the genetic predisposition for the development of the tumor. Keratoacanthomas are commonly observed in patients with Muir–Torre syndrome, suggesting that the genetic defect(s) of this syndrome also plays a role in the development of keratoacanthoma.[48–52] In addition, keratoacanthomas have been observed in patients affected by a variety of skin diseases including psoriasis, lupus erythematosus, lichen planus, atopic dermatitis, herpes zoster, acne conglobata, and pemphigus foliaceus, among others.[39]

Keratoacanthomas also have been observed in patients under immunosuppression as a result of bone marrow transplantation, cyclosporine treatment, or infection with HIV, thus suggesting that immunosuppression may play an etiologic role in some cases. In these patients, most lesions of keratoacanthoma tested for presence of HPV proved positive, suggesting that immunosuppression may contribute by decreasing the immune response against possible causative agents.[53] Similarly, UV light may act not only by direct carcinogenesis, but also by virtue of the local immunosuppression caused by sun exposure.

Little is known about the pathogenesis of keratoacanthoma, and about the exact mechanisms of regression in the absence of any treatment. Studies on p53 oncoprotein expression and *p53* gene mutations revealed expression of p53 oncoprotein in the great majority of tested cases, and association with a point mutation in the *p53* gene in slightly more than 10% of these cases, suggesting a possible role of *p53* gene in the development of some keratoacanthomas.[21,25]

Patients with incontinentia pigmenti may develop subungual keratoacanthomas. Incontinentia pigmenti is caused by genetic alterations of the NF-κB essential modifier (NEMO). There is evidence that loss of activity of NF-κB is related to development of skin cancer, but somatic mutations of NEMO have not been detected in keratoacanthomas not associated with incontinentia pigmenti.[54]

Multiple keratoacanthomas of the Ferguson–Smith type show a familial distribution and are transmitted in an autosomal dominant fashion. The gene responsible for this syndrome is localized to chromosome 9q. The majority of the cases have been described in some Scottish families, and in these patients, the syndrome is thought to be caused by a single genetic mutation that occurred before 1790.[55]

CLINICAL FINDINGS

Keratoacanthomas occur mostly on sun-exposed skin of the face, forearms, and dorsal aspects of the hands (Figs. 117-1 and 117-2). Actinic damage is commonly found in the surrounding skin. In most instances, they are located on hairy skin, but lesions with similar clinicopathologic aspects have been described in the oral cavity, the subungual region, the genital mucosa, and the conjunctiva.

The stereotypic example of keratoacanthoma is represented by a solitary lesion growing rapidly within a few weeks, and subsequently showing a slow involution over a period of a few months. Three clinical stages have been described: proliferative, mature, and resolving.[39] Lesions in the proliferative stage are rapidly enlarging erythematous papules that grow up to a dimension of 1–2 cm or more. In this stage, the lesions are symmetric and firm and show a smooth surface. In the mature stage there are symmetric, firm, erythematous or skin-colored nodules with a central keratotic core (Figs. 117-2 and 117-3). The central part can appear crateriform if the keratotic core is removed. Ghadially divided mature keratoacanthomas into three main morphologic types: type 1, or bud-shaped; type 2, or dome shaped; and type 3, or

Figure 117-2 Mature keratoacanthoma on the neck of an elderly man with prominent keratotic aspect.

Figure 117-3 Mature keratoacanthoma. Note central keratotic core giving a white–yellowish appearance to the superficial part of the lesion.

berry shaped.[40] Regressing lesions are characterized by a keratotic, partly necrotic nodule that becomes progressively flat upon elimination of the keratotic plug, eventually leaving a hypopigmented scar (Fig. 117-4; Box 117-1).

SYSTEMIC ASSOCIATIONS

Keratoacanthomas may be associated with multiple internal cancers in patients with Muir–Torre syndrome and the related hereditary nonpolyposis colorectal cancer syndrome. Patients with multiple keratoacanthomas should always be evaluated for the presence of typical traits of Muir–Torre syndrome, where cutaneous sebaceous tumors and low-grade visceral malignancies can be observed (most commonly carcinomas of the gastrointestinal tract, but also carcinomas of the lung and genitourinary system, and, occasionally, colonic polyps). It has been suggested that at least some of the patients with multiple keratoacanthomas of the Ferguson–Smith type may have an incomplete form of the Muir–Torre syndrome.

Figure 117-4 Regressing keratoacanthoma on the lower leg of a 59-year-old man. There is a whitish flattened plaque with superficial ulceration in the center.

BOX 117-1 CLINICAL DIFFERENTIAL DIAGNOSIS OF KERATOACANTHOMA

Most Likely

- Squamous cell carcinoma

Consider

- Well-developed tumors
  - Common warts
  - Molluscum contagiosum
  - Prurigo nodularis
  - Metastatic carcinoma
- Regressing tumors
  - Regressing lesions of lymphomatoid papulosis
  - Regressing lesions of anaplastic large cell lymphoma
  - Amelanotic melanoma

Keratoacanthomas may also occur in patients with xeroderma pigmentosum and, rarely, in patients with lymphomatoid papulosis. Subungual keratoacanthomas may be observed in patients with incontinentia pigmenti.

VARIANTS

Several variants of keratoacanthoma have been described, and different morphologic types of keratoacanthoma have been observed in a single patient.[56]

GIANT KERATOACANTHOMA

In some instances, keratoacanthomas may reach dimensions of several centimeters (Fig. 117-5), and even a tumor reaching 15 cm in its diameter has been observed. Giant keratoacanthomas show a predilection for the nose and the dorsum of the hands. In some

Figure 117-5 Giant keratoacanthoma on the cheeck of an elderly man.

Figure 117-6 Large keratoacanthoma on the tip of the nose of a 52-year-old man. Note the destructive appearance of the tumor.

cases, the growth of the tumor may be associated with destruction of underlying tissues (Fig. 117-6).

KERATOACANTHOMA CENTRIFUGUM MARGINATUM

Keratoacanthoma centrifugum marginatum is characterized by multiple tumors growing on a localized area, usually on the face, trunk, or extremities (Fig. 117-7).[57] Tumors are annular, polycyclic, or circular in morphology. The area affected may reach 20 cm in diameter, and resolution may be slower than in solitary keratoacanthoma.

MULTIPLE KERATOACANTHOMAS OF THE FERGUSON–SMITH TYPE

The Ferguson–Smith type is a familial form of keratoacanthoma that affects both sexes with approximately equal severity, which is characterized by the appearance of multiple, sometimes hundreds of keratoacanthomas, each with the clinicopathologic aspects of a solitary keratoacanthoma. The disorder is inherited in an autosomal-dominant manner, and the majority of the cases have been described in a few Scottish families. Patients develop keratoacanthomas during adolescence and early adulthood, but onset during childhood is not infrequent. It has been suggested that at least some of these patients may have an incomplete form of the Muir–Torre syndrome.

Figure 117-7 Multiple keratoacanthomas with an annular arrangement and central, keratin-filled craters on the back of the hand (keratoacanthoma centrifugum marginatum). This 42-year-old male patient also had lupus erythematosus.

GENERALIZED ERUPTIVE KERATOACANTHOMAS OF GRZYBOWSKI

Keratoacanthomas of Grzybowski is a variant characterized by the presence of hundreds to thousands of tiny follicular keratotic papules disseminated all over the body, with predominance on sun-exposed areas. Facial involvement is usually severe, and coalescence of lesions around the eyes may cause ectropion. The mucosal regions (oral, genital) may be affected, whereas palms and soles are usually not involved. The age of onset is similar to that of solitary keratoacanthoma, and clustering in families has not been observed.

SUBUNGUAL KERATOACANTHOMA

Subungual keratoacanthoma (Fig. 117-8) differs from the other types of keratoacanthoma by being persistent and often causing destruction of the underlying bone. The tumor originates in the distal nail bed, separating the nail plate from the nail bed, and can grow rapidly causing destruction of the entire phalanx.

KERATOACANTHOMA OF THE MUCOSAL REGIONS

Keratoacanthomas have been described in the oral mucosa, the conjunctiva, the nasal mucosa, and the genital mucosa. In fact, involvement of the oral and genital mucosa is common in the generalized eruptive keratoacanthomas of the Grzybowski type. Keratoacanthomas arising on mucosal regions, especially on the oral

Figure 117-8 Subungual keratoacanthoma in a 55-year-old woman.

mucosa, present clinically as slowly growing crateriform lesions that tend to persist for many months or years.

PATHOLOGY

The histopathologic diagnosis of keratoacanthoma rests mainly on the silhouette of the tumor as assessed at scanning magnification; inadequate specimens (i.e., punch biopsies, shave biopsies, curettage) do not allow a diagnosis and differentiation from squamous cell carcinoma. Two large studies on the histopathologic criteria for diagnosis of keratoacanthoma emphasized the overlapping features between this tumor and squamous cell carcinoma, which render differentiation very difficult or even impossible in given cases.[16,17]

The histopathologic features of keratoacanthoma depend on the stage of evolution of the tumor. In early, proliferative lesions, the epithelium is markedly hyperplastic, and the central keratotic plug is not as pronounced as in fully developed lesions. The lesion has an overall symmetric aspect (Fig. 117-9A). Although atypical cells do not represent the majority of the cells in typical keratoacanthoma, there may be atypical keratinocytes and mitoses, especially at the lower margin of the tumor. Nests of epithelial cells may detach from the main tumor mass and be found in the superficial reticular dermis. Fully developed, mature lesions are characterized by a large central core of keratin surrounded by a well-differentiated proliferation of squamous epithelium that in some cases may resemble squamous cell carcinoma (Fig. 117-9A). The epidermis at both sides of the central core extends over the keratotic area in a fashion that has been described as "lipping" or "buttressing," giving a distinct crateriform appearance to the lesion. Nests and strands of keratinocytes may be found apart from the main bulk of the tumor but usually do not extend lower than the level of sweat glands (Box 117-2). In regressing lesions the shape of a crater can still be recognized, but epithelial hyperplasia and atypical cells are no longer visible (Fig. 117-10); in the superficial dermis below the regressed lesion there is fibrosis with sparse inflammation.

Cytomorphologically, large keratinocytes with eosinophilic cytoplasm are commonly observed, together with atypical cells and mitoses (Fig. 117-9B). An inflammatory infiltrate containing lymphocytes, plasma cells, histiocytes, eosinophils, and neutrophils is a common feature, and in some instances may be conspicuous. Neurotropism and even vascular invasion can be observed in otherwise typical keratoacanthomas, but the prognosis does not seem to be affected by these histopathologically worrisome features (Fig. 117-9C).[14]

BOX 117-2 HISTOPATHOLOGIC DIFFERENTIAL DIAGNOSIS OF KERATOACANTHOMA

Most Likely

- Squamous cell carcinoma

Regressing Tumors: Consider

- Other regressing benign and malignant epithelial tumors
- Regressing lesions of lymphomatoid papulosis
- Regressing lesions of anaplastic large cell lymphoma

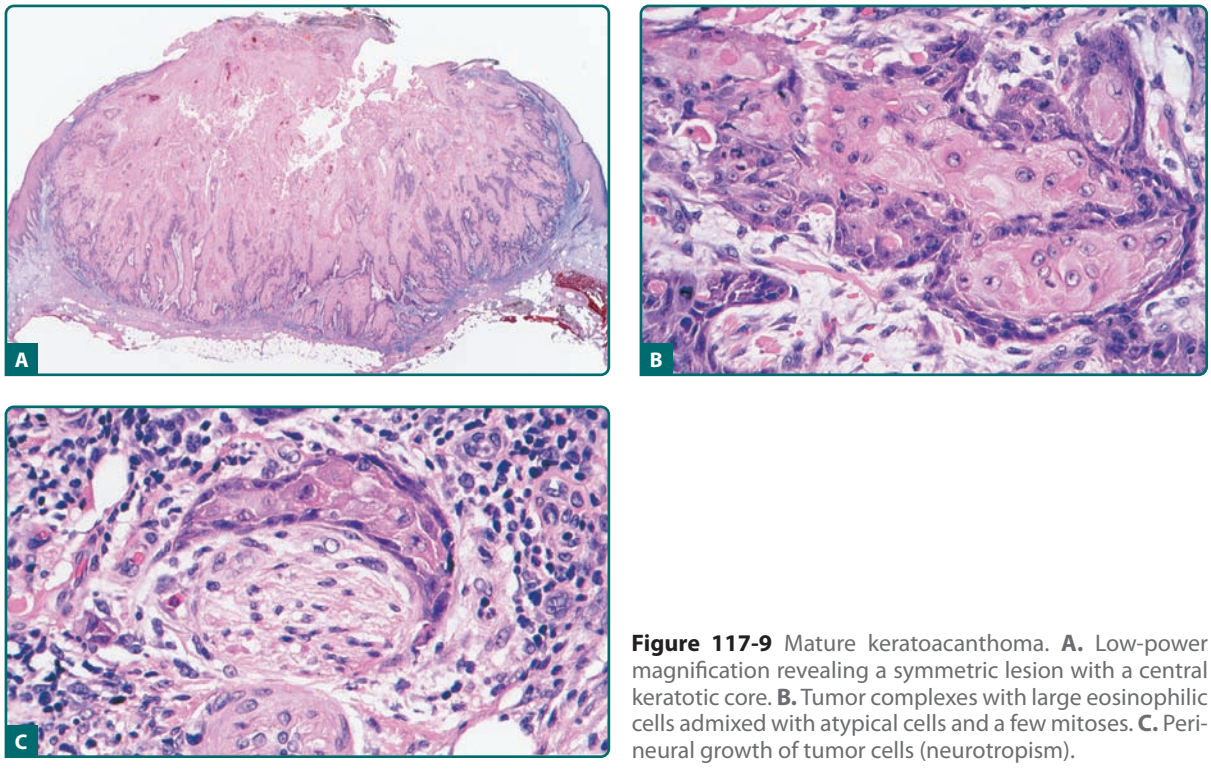

Figure 117-9 Mature keratoacanthoma. **A.** Low-power magnification revealing a symmetric lesion with a central keratotic core. **B.** Tumor complexes with large eosinophilic cells admixed with atypical cells and a few mitoses. **C.** Perineural growth of tumor cells (neurotropism).

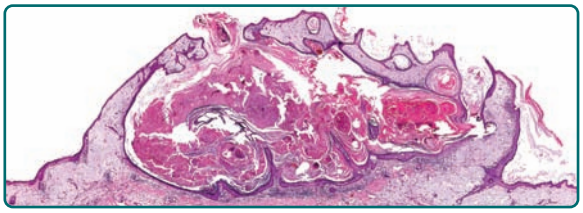

Figure 117-10 Regressing keratoacanthoma. Note exophytic collarette with keratotic core but lack of epithelial hyperplasia.

PROGNOSIS

Solitary keratoacanthoma behaves as a benign tumor in the majority of the cases, but lymph node and visceral metastases have been observed in a small number of patients. Central facial keratoacanthoma may behave aggressively. There are no clear-cut features to predict the biologic behavior of a given tumor, but persistent and recurrent lesions should be managed by complete surgical excision. Histopathologic features that are associated with a poor prognosis in common squamous cell carcinoma, such as neurotropism and vascular invasion do not seem to have prognostic implications in keratoacanthomas.[14] Ungual keratoacanthomas do not show a tendency to spontaneous regression and often are the cause of massive bone destruction.[58] However, in spite of aggressive local behavior, distant metastases have not been observed in ungual and mucosal types of keratoacanthoma.

TREATMENT

(See Box 117-3)

Keratoacanthomas show a tendency to spontaneous regression, and, in typical cases, an acceptable therapeutic option may be to adopt the so-called watchful waiting strategy. However, because of the uncertainty regarding the exact nosology of this tumor, as well as the difficulty in differentiating it clinically from squamous cell carcinoma, complete conservative excision is advised in most cases, especially in those of solitary keratoacanthoma and in keratoacanthoma of the face.[59] Removal by shave excision below the base to preserve architecture for diagnostic purposes followed by electrodesiccation and curettage are being increasingly performed for keratoacanthoma.[60] Punch biopsies never allow differentiation of keratoacanthoma from well-differentiated squamous cell carcinoma and should be avoided. For diagnostic purposes, a longitudinal biopsy that includes normal skin at both margins of the lesion as well as the underlying fat tissues is acceptable. Mohs micrographic surgery has been adopted for difficult cases such as recurrent lesions, lesions in the central facial area, giant lesions, or lesions of keratoacanthoma centrifugum marginatum that may cover a large area of the body.[61] Therapy by laser vaporization, electrodesiccation, and cryosurgery with liquid nitrogen has also been used, but does not allow the histopathologic verification of the clinical diagnosis.

BOX 117-3 TREATMENT FOR KERATOACANTHOMA

FIRST LINE

- Complete surgical excision

SECOND LINE

- Curettage followed by electrodesiccation
- Radiotherapy
- Intralesional chemotherapeutic agents, intralesional interferon
- Oral retinoids
- Photodynamic therapy
- Specific types of keratoacanthomas may require other treatment modalities (e.g., generalized eruptive keratoacanthomas of Grzybowski)

Keratoacanthomas have been treated by radiotherapy (electron beam, or the voltage radiation, superficial x-ray) with excellent results.[62] This type of treatment is particularly indicated for lesions that can be difficult to manage surgically. Intralesional instillation of chemotherapeutic agent (methotrexate, bleomycin, and 5-fluorouracil) has also proved therapeutically successful,[39,63] and 5-fluorouracil has been applied also topically.[64] Some keratoacanthomas have been treated by intralesional injection of interferon-α2a,[65,66] and others have been successfully treated with intralesional application of triamcinolone. Successful topical treatment has been performed with podophyllin, either alone or in combination with other treatment modalities. However, podophyllin is also capable of inducing keratoacanthomas. Multiple keratoacanthomas have been treated successfully with oral retinoids in several cases, but larger studies have not been performed.[67] Systemic treatments include chemotherapy with methotrexate, cyclophosphamide, or 5-fluorouracil.

Photodynamic therapy with δ-aminolevulinic acid is an additional treatment option for keratoacanthoma of both solitary and multiple types. The treatment is simple and has been shown to achieve good therapeutic and cosmetic results.[68,69] Topical imiquimod has been reported to induce regression of keratoacanthoma.[70] Recently, a case of aggressive keratoacanthoma centrifugum marginatum has been successfully managed with epidermal growth factor receptor inhibitor erlotinib.[71]

PREVENTION

Preventive measures against the development of keratoacanthomas are similar to those applied for basal and squamous cell carcinoma of the skin. In predisposed subjects (i.e., fair skin, history of multiple actinic keratoses, basal and/or squamous cell carcinomas, Muir–Torre syndrome), avoidance of direct sun exposure should be achieved, and skin protection creams applied.

Chapter 118 :: Benign Epithelial Tumors, Hamartomas, and Hyperplasias

:: Valencia D. Thomas, Nicholas R. Snavely, Ken K. Lee & Neil A. Swanson

Benign epithelial tumors, hamartomas, and hyperplasias comprise a large and disparate group of tumors and no single classification system unifies them, as their cells of origin and clinical presentation can vary substantially. In this chapter, the clinical entities are grouped by clinical or histologic features to better present them from a practical diagnostic and treatment perspective (Table 118-1).

SEBORRHEIC KERATOSIS

SEBORRHEIC KERATOSIS AT A GLANCE

- Seborrheic keratosis is the most common benign epidermal tumor.
- Usually begin as well-circumscribed, dull, flat, tan, or brown patches with pseudohorn cysts.
- Rapidly growing, symptomatic, or atypical lesions should be biopsied to rule out malignancy such as basal cell carcinoma, squamous cell carcinoma, or melanoma.
- Clinical and histopathologic variants include the common seborrheic keratosis, reticulated seborrheic keratosis, stucco keratosis, clonal seborrheic keratosis, irritated seborrheic keratosis, seborrheic keratosis with squamous atypia, melanoacanthoma, and dermatosis papulosa nigra.
- Hallmark histopathologic findings: acanthosis, papillomatosis, pseudohorn cysts, hyperkeratosis.
- Internal malignancy: individuals can develop multiple, eruptive seborrheic keratoses (Leser–Trélat sign). Adenocarcinoma of the stomach is most common associated malignancy.

EPIDEMIOLOGY AND CLINICAL FEATURES

Seborrheic keratoses (SKs) are the most common benign epidermal tumor of the skin and a frequent focus of patient concern because of their variable appearance. These lesions are common in middle-aged individuals and can arise as early as adolescence.[1] Although there are many clinical variants of the lesions, these lesions usually begin as well-circumscribed, dull, flat, tan, or brown patches. As they grow, they become more papular, taking on a waxy, verrucous, or stuck-on appearance (Figs. 118-1 and 118-2). Many lesions display distinctive pseudohorn cysts that likely represent plugged follicular orifices. SKs may arise on any nonmucosal surface, and multiple lesions may be distributed in a Christmas tree pattern along skin folds or

Overview

- Seborrheic keratosis
  - Common seborrheic keratosis
  - Reticulated seborrheic keratosis
  - Stucco keratosis
  - Melanoacanthoma (pigmented seborrheic keratosis)
  - Dermatosis papulosa nigra
  - Clonal seborrheic keratosis
  - Irritated seborrheic keratosis
  - Seborrheic keratosis with squamous atypia
  - Leser–Trélat sign
- Epidermal nevi
  - Linear verrucous epidermal nevus-localized, systematized
  - Nevus unius lateris
  - Ichthyosis hystrix
  - Inflammatory linear verrucous epidermal nevus
  - Nevus sebaceous of Jadassohn
  - Nevus comedonicus
  - Eccrine nevus
  - Apocrine nevus
  - Becker's nevus
  - White sponge nevus
  - Epidermal nevus syndrome
- Lichen striatus
- Clear cell acanthoma
- Warty dyskeratoma
- Acanthoma fissuratum
- Chondrodermatitis nodular helicis
- Cysts of epithelial origin
  - Epidermal cyst
  - Trichilemmal cyst
  - Milium
  - Steatocystoma multiplex
  - Dermoid cyst
  - Branchial cyst
  - Preauricular cyst and sinus

Figure 118-2 Multiple small seborrheic keratoses.

in Blaschko's lines.[2] The color of these lesions ranges from pale white to black. At times, distinguishing these lesions from a nevus or melanoma can be clinically challenging. Because melanoma, basal cell carcinoma, and other cutaneous malignancies have been reported to arise in SKs, care must be taken to critically evaluate rapidly growing, symptomatic, or unusual lesions.[3,4]

ETIOLOGY

The name seborrheic comes from the Greek word for sebum, and is a misnomer for these common growths. While the precise etiology of SKs is unknown, it is a tumor of keratinocytic origin. Genetics, sun exposure, and infection have all been implicated as possible factors. Many individuals with SKs have a positive family history for the condition. SKs demonstrate irregularities in the expression of the apoptosis markers p53 and Bcl-2, though no genetic locus or chromosomal imbalance has been detected to date.[5,6] The higher prevalence of SKs on sun-exposed skin implies a possible causative role.[7]

Viral infection has also been considered a possible cause of SKs based on occasional clinical similarities to warts. Although no human papillomavirus (HPV) DNA was detected in a study of 40 genital SK biopsies, nongenital skin yielded different results. Epidermodysplasia verruciformis-associated HPV DNA has been demonstrated in 42 of 55 (76%) nongenital SK biopsies compared to only 13 of 48 (27%) healthy controls ($p < 0.005$).[8] These findings indicate the possible role of viral infection in the development of SKs in nongenital skin.

Although the etiology of SKs remains unknown, the monoclonal nature of these neoplasms has been established in 2001.[9] By tracking polymorphisms in a human androgen receptor, researchers found that more than half of the 38 SKs sampled, regardless of subtype, were clonal in nature.[9] The development of SKs has also been associated with circulating epidermal growth factors and melanocyte-derived growth factors in addition to the local increased expression of tumor necrosis factor-α and endothelin-converting enzyme.[10] The latter two are associated with an increased expression of the keratinocyte melanogen, endothelin-1, resulting in hyperpigmentation within SKs.

CLINICOPATHOLOGIC VARIANTS

There are many clinicopathologic variants of SKs, and while distinction is usually unnecessary, the commonplace nature of SKs makes these variants relevant.

COMMON SEBORRHEIC KERATOSIS. A common SK is classically described as a stuck-on, verrucous plaque (Figs. 118-1 and 118-2) with pseudohorn cysts (Fig. 118-3). Hyperkeratosis, acanthosis, and papillomatosis are hallmark pathologic findings. An increased number of melanocytes may also be present, giving lesions a tan or dark brown color. SKs are

Figure 118-3 Seborrheic keratosis (basal cell papilloma) showing a papillomatous acanthotic epidermis consisting of basaloid cells.

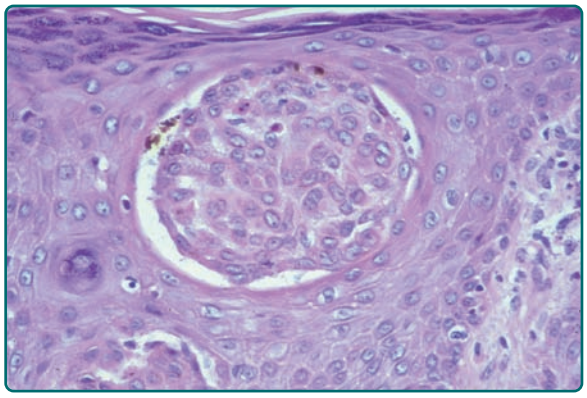

Figure 118-5 Clonal seborrheic keratosis showing round nests of keratinocytes and some melanocytes.

usually asymptomatic but may itch. Common SKs spare the palms, soles, and mucosa.

RETICULATED SEBORRHEIC KERATOSIS. Reticulated SKs are also known as *adenoid SKs*. Some believe a solar lentigo usually precedes this often pigmented patch or papule. Histologically, there are small horn cysts suspended among interwoven strands of basophilic cells (Fig. 118-4).[11]

STUCCO KERATOSIS. Stucco keratoses are also described as *verrucous*, *serrated*, *hyperkeratotic*, and *digitate*. These lesions are commonly 1- to 3-mm, flat-topped, white to tan papules that adhere tightly to the skin on the lower legs (eFig. 118-4.1 in online edition). Histologically, no keratinocytic vacuolar changes or viral cytopathic changes are observed, thus distinguishing them from verruca plana.

MELANOACANTHOMA. Melanoacanthoma is also known as *pigmented SK*. This benign, slow-growing SK resembles melanoma clinically, and is often located on the trunk, head, or neck of older individuals. The term *melanoacanthoma* was introduced in 1960 to describe a pigmented lesion composed of nested melanocytes and keratinocytes.[12]

Dermatosis Papulosa Nigra. Dermatosis papulosa nigra are small dark brown to black papules that are commonly found on the face of individuals of Fitzpatrick skin phototype IV or greater. They are histologically identical to SKs (Fig. 118-5).

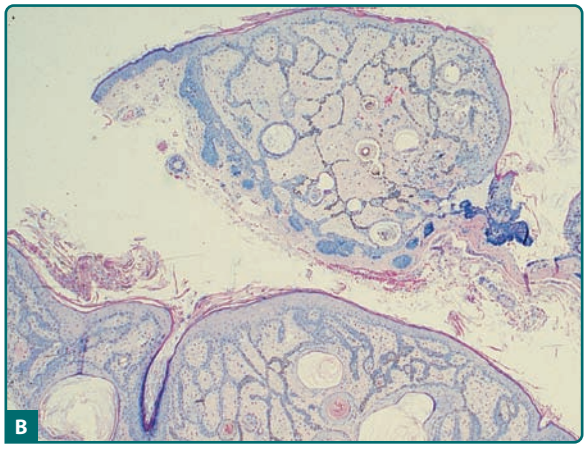

Figure 118-4 **A.** Multiple reticulated seborrheic keratoses. **B.** Reticulated seborrheic keratosis showing reticulated cords of basaloid cells descending from the base of the epidermis.

SKIN TAGS. While often felt to be a distinct entity, some skin tags share clinical and histologic overlap with some SKs. These rough, 1- to 2-mm pedunculated papules are commonly located in areas of friction. The axilla, inframammary area, and neck are common locations where these papules commonly appear. Spontaneous regression can occur.

HISTOLOGIC VARIANTS

CLONAL SEBORRHEIC KERATOSES. Clonal SK is a histologic term used to describe intraepithelial nests of basophilic keratinocytes of varying sizes with admixed melanocytes (Fig. 118-6). As previously stated, in one study, more than half of the 38 SKs sampled, regardless of subtype, were clonal in nature.[9]

IRRITATED SEBORRHEIC KERATOSIS. Irritated SKs represent SKs that have been mechanically or chemically irritated or are involved in immunologic responses. Although inciting trauma is occasionally associated with irritated SKs, spontaneous inflammation is common (Fig. 118-7). Histologically, the dermis underlying these lesions is filled with a dense inflammatory infiltrate predominantly of lymphocytes. This inflammation is occasionally lichenoid or neutrophil rich. Swirled collections of eosinophilic keratinocytes can be seen in the epidermis.[13] Eczematous changes in or around the lesion, also known as *Meyerson phenomenon*, can also be seen.[14]

Association with Skin Cancers. Varying degrees of squamous atypia can be seen in SKs. Bowenoid transformation of benign SKs into squamous cell carcinoma in situ has been documented but the development of basal or squamous cell carcinoma in a SK is rare.[15] Lesions demonstrating the histology of both SKs and malignancies have been reported.[16,17] Although it is likely that most of these lesions represent collision tumors, malignant transformation of SKs into basal cell carcinomas, squamous cell carcinomas, and melanomas can occur. In a retrospective study of 813 lesions histologically diagnosed as SKs, 5.3% were associated with nonmelanoma skin cancer. In this study, the most common malignancy was squamous cell carcinoma in situ, followed by basal cell carcinomas and invasive squamous cell carcinomas; no melanomas were observed.[17] Clinically atypical or rapidly growing SKs should be biopsied to rule out the possibility of malignancy.

Figure 118-6 Inflamed, irritated seborrheic keratoses occurring during cytarabine therapy. This is in the submammary region, and there are also pustules of *Candida* infection.

Figure 118-7 Dermatosis papulosa nigra.

LESER–TRÉLAT SIGN. In the context of internal malignancy, individuals can develop multiple, eruptive SKs also known as the *Leser–Trélat sign*. Adenocarcinoma of the stomach is the most commonly associated malignancy,[18,19] though adenocarcinoma of the lung and colon have also been linked. Other diseases reported to occur with eruptive SKs are leukemia, lymphoma, lepromatous leprosy, human immunodeficiency virus infection, erythrodermic eczema, and melanoma.[20–23] Inflammation of eruptive SKs during chemotherapy, especially cytarabine, is known to occur (Fig. 118-7).[24] The presentation of eruptive SKs with acanthosis nigricans led many to speculate a common reactive mechanism.[25] Abnormal immune responses may also play a role in the development of this clinical sign.

TREATMENT

Rapid growth, atypical morphologic features, unusual lesion location, or symptoms should all be considered when evaluating SKs, and care should be taken not to

destroy a lesion that begs further pathologic examination. For any lesion with a possibility of malignancy, removal must be performed in a fashion that yields tissue for evaluation.

For clearly benign, yet symptomatic or cosmetically undesirable lesions, destruction with cryotherapy, electrodesiccation followed by curettage, curettage followed by desiccation, or laser ablation have all been shown to be effective. Reports of giant SKs measuring many centimeters have been treated successfully with either dermabrasion or topical fluorouracil.[26,27] Surgical excision is also an accepted treatment approach, especially if the lesion is pedunculated and can be transected at its base. Common complications of these destructive measures include scarring, pigmentary alteration, incomplete removal, or recurrence. Recurrence of the lesions may occur, and it is not uncommon to require multiple treatments to ensure the complete destruction of the initial lesion. It is preferable to ensure that the method of removal minimizes the risk of scarring.

EPIDERMAL NEVUS

EPIDERMAL NEVUS AT A GLANCE

- Epidermal nevi are hamartomatous proliferations of the epithelium, including keratinocytes, sebocytes, pilosebaceous units, eccrine glands, or apocrine glands.
- Six different epidermal nevus syndromes: epidermal nevi present with developmental abnormalities of the nervous, cardiovascular, urogenital, or skeletal systems.
- Linear configurations common on limbs following Blaschko's lines or in relaxed skin tension lines. Tend to appear between birth and adolescence.
- Epidermal nevus presenting with pruritus, erythema, scaling is likely a variant known as *inflammatory linear verrucous epidermal nevus*.
- Differential diagnosis: lichen striatus, linear Darier disease, linear porokeratosis, linear lichen planus, linear psoriasis, and verrucous stage of incontinentia pigmenti.

Epidermal nevus is a generalized term for hamartomatous proliferations of epithelium. The subtypes of this tumor differ according to the distribution of the lesions or the predominant histologic cell type: keratinocyte (verrucous epidermal nevus), sebaceous gland (nevus sebaceous), pilosebaceous unit (nevus comedonicus), eccrine gland (eccrine nevus), or apocrine gland (apocrine nevus). eTable 118-1.1 in online edition provides a classification of one framework to discuss this large and diverse entity. Currently, there are six different epidermal nevus syndromes described: (1) Proteus, (2) congenital hemidysplasia with ichthyosiform nevus and limb defect syndrome, (3) phakomatosis pigmentokeratotica, (4) sebaceous nevus, (5) Becker's nevus, and (6) nevus comedonicus.[28]

EPIDEMIOLOGY

Epidermal nevi occur in 1 in 1,000 live births.[29] Eighty percent of lesions appear within the first year of life, with the majority of lesions appearing by age 14 years. There are rare reports of adult onset of epidermal nevi, with the oldest patient being a 60-year-old woman.[30] Such late-developing epidermal nevi probably represent lesions that have always been present subclinically, but recent growth resulted in clinical recognition.[31] There is an equal male–female prevalence, and most cases are sporadic. However, some familial cases have been documented.[32]

VERRUCOUS EPIDERMAL NEVUS

Verrucous epidermal nevus is also known as linear verrucous epidermal nevus or *linear epidermal nevus*.

CLINICAL FEATURES. Verrucous epidermal nevi are characterized by localized or diffuse, closely set, skin-colored, brown, or gray–brown verrucous papules, which may coalesce to form well-demarcated papillomatous plaques (Fig. 118-8). Linear configurations are common on the limbs as is distribution in Blaschko's lines or in relaxed skin tension lines (Fig. 118-9).

Extensive distribution of a verrucous epidermal nevus is termed *systemized epidermal nevus*. Variants of this type of nevus include nevus unius lateris (Fig. 118-10), epidermal nevi distributed on one-half of

Figure 118-8 Verrucous epidermal nevus.

Figure 118-9 Verrucous epidermal nevus showing linear configuration.

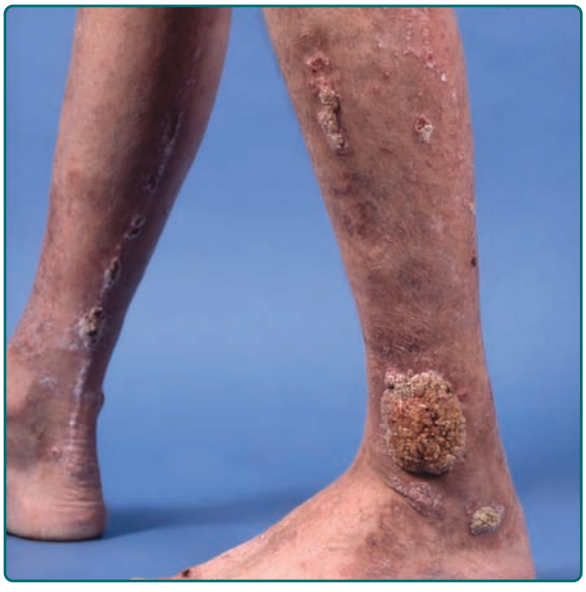

Figure 118-11 Inflammatory linear verrucous epidermal nevus showing psoriasiform erythema, scaling, and hyperkeratosis. The nodule on the left leg was a giant wart.

the body; and ichthyosis hystrix, epidermal nevi distributed bilaterally. Commonly, systematized nevi take on a transverse configuration on the trunk and linear configuration on the limbs.

An epidermal nevus presenting with pruritus, erythema, and scaling is likely a variant of the epidermal nevus termed an *inflammatory linear verrucous epidermal nevus* (ILVEN) (Fig. 118-11). These lesions are found most commonly on the buttocks and lower extremities.

Figure 118-10 Nevus unius lateris. Epidermal nevus affecting one-half of body.

COURSE AND COMPLICATIONS.

Linear epidermal nevi tend to appear between birth and adolescence. Although congenital lesions tend not to expand significantly, lesions that present after birth may expand during childhood, stabilizing in size at or around puberty.[33] Although intertriginous lesions may become macerated and secondarily infected, the majority of epidermal nevi remain quiescent after adolescence. Rare cases of basal cell carcinoma and squamous cell carcinoma arising within epidermal nevi have been reported. This malignant transformation is most common in middle-aged or elderly individuals, though the youngest reported case occurred in a 17-year-old woman.[34]

Epidermal nevi may present in conjunction with other epidermal lesions such as café-au-lait macules, congenital hypopigmented macules, and congenital nevocellular nevi and may be associated with abnormalities in other systems.[33] (See Section "Epidermal Nevus Syndrome").

Rarely, patients with epidermal nevi have offspring with epidermolytic hyperkeratosis (EHK), a condition resulting from a mutation in keratin 10 (K10). Paller et al[35] investigated three families with this occurrence. The analysis of skin samples of parents and offspring with EHK demonstrated a parental mutation in one of the two K10 alleles within the epidermal nevus; nonlesional skin showed no mutation. Offspring showed the same K10 mutation as their parents.[35] The presence of two genetically distinct cell lines in the parents, also known as *mosaicism*, is a result of postzygotic mutation during embryogenesis.[36] If histopathologic evaluation of an epidermal nevus reveals findings consistent with EHK, the patient is at risk of having a child with EHK. Prenatal counseling may be very important for these patients.

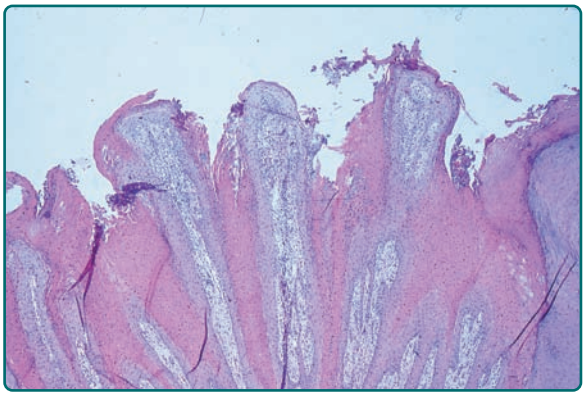

Figure 118-12 Epidermal nevus showing hyperkeratosis, acanthosis, papillomatosis, and elongation of rete ridges.

PATHOLOGY. There are ten histologic variants of the epidermal nevus, with over 60% of lesions displaying acanthosis, papillomatosis, and hyperkeratosis (Fig. 118-12).[37] Rare variants may have features similar to SKs, with thin, elongated rete ridges; or EHK, with compact orthokeratosis, vacuolization of the granular layer of the epidermis, and large keratohyalin granules within or outside cells.[38] Epidermal hyperkeratosis may be a more common finding in ichthyosis hystrix. ILVEN is a histologically distinct variant of the epidermal nevus that displays a chronic dermal inflammatory infiltrate, psoriasiform epidermal hyperplasia, and alternating bands of ortho- and parakeratosis. In this variant, the granular layer is absent underlying the areas of parakeratosis.[39]

DIFFERENTIAL DIAGNOSIS. (See Box 118-1). Lichen striatus, linear Darier disease, linear porokeratosis, linear lichen planus, linear psoriasis, and the verrucous stage of incontinentia pigmenti may all have similar clinical presentations as the linear verrucous epidermal nevus. Lichen striatus may mimic ILVEN clinically, but is self-limited as compared with epidermal nevi. Histology may be useful in differentiating these entities. Linear Darier disease and linear porokeratosis can be differentiated pathologically with linear Darier disease having the distinct pathologic findings of acantholytic dyskeratosis, and linear porokeratosis having coronoid lamellae. Although some consider linear lichen planus and linear psoriasis to be variants of the ILVEN, the genetics and the immunology has yet to be fully characterized.[40–42] Incontinentia pigmenti can be distinguished clinically based on the transient nature of this phase and the preceding verrucous phase. Histologically, this entity can be distinguished by its dyskeratosis, pigment incontinence, eosinophilic exocytosis, and basal layer vacuolization.

BOX 118-1 DIFFERENTIAL DIAGNOSIS OF LINEAR EPIDERMAL NEVUS

- Lichen striatus
- Linear Darier disease
- Linear porokeratosis
- Linear lichen planus
- Linear psoriasis
- Incontinentia pigmenti

TREATMENT. Complete excision of an epidermal nevus to the level of the deep dermis is necessary to prevent recurrences. However, based on the size and distribution of the lesion, excision may not be an appropriate treatment option. Multiple other surgical and medical treatments are available to treat or destroy these lesions. Laser ablation, electrofulguration, cryotherapy, and medium to full-depth chemical peels may offer partial or full destruction of lesions. Although topical retinoids and calcipotriene offer little relief, these medications can be used as an adjunctive therapy to increase the efficacy of the surgical intervention. Systemic retinoids and antipsoriatic agents may offer some clinical improvement. There are reports of successful treatment of ILVEN with etanercept.[43] If malignant transformation is confirmed within an epidermal nevus, the lesion should be completely excised.

NEVUS SEBACEOUS

NEVUS SEBACEOUS AT A GLANCE

- Linear, hairless, yellow, waxy, and verrucous plaque presenting from birth to adolescence.
- Benign tumor of sebaceous gland: immature sebaceous glands located high in the dermis and malformed pilosebaceous units are key features.
- Most common benign tumors arising within a nevus sebaceous: syringocystadenoma papilliferum, trichoblastoma.
- Differential diagnosis: epidermal nevi, aplasia cutis, congenital triangular alopecia.
- Rapidly growing papules or nodules: require pathologic evaluation to rule out malignancy but excision should be considered on a case-by-case basis.

Nevus sebaceous is also known as nevus sebaceous of Jadassohn and organoid nevus.

CLINICAL FEATURES. Nevus sebaceous presents as a linear, hairless, yellow, waxy, and verrucous plaque (Fig. 118-13). It can be flat at birth, becoming plaque-like under the hormonal influences of puberty. These nevi are common in the scalp, but there are reports of lesions on the face, chest, and in oral mucosa. Tumors can arise within nevus sebaceous. The most common benign tumors are syringocystadenoma papilliferum

Figure 118-13 Nevus sebaceous.

and trichoblastoma.[44] Other benign tumors reported to arise in a nevus sebaceous are the leiomyoma, syringoma, spiradenoma, hidradenoma, and keratoacanthoma.[45] It was once believed that individuals with this tumor were at increased risk of basal cell carcinomas, but a retrospective review of 596 cases by Cribier et al revealed that most lesions initially diagnosed as basal cell carcinoma were actually trichoblastomas.[46] A second retrospective study of 757 tumors confirmed this finding.[47] This does not exclude the possibility of the development of basal cell carcinoma in these lesions. Rarely, malignant tumors such as apocrine carcinoma, squamous cell carcinoma, and malignant eccrine poromas may arise within nevus sebaceous.[48]

Nevus sebaceous syndrome is the very rare association of an extensive, congenital nevus sebaceous with ocular abnormalities and cerebral defects such as mental retardation or seizures. This syndrome is also known as *Schimmelpenning-Feuerstein-Mims syndrome* or *organoid-nevus syndrome*.[49,50]

PATHOLOGY. Immature sebaceous glands located high in the dermis and malformed pilosebaceous units are features of nevus sebaceous (Fig. 118-14). Vellus hairs are more common than terminal hairs in these lesions. Epidermal acanthosis, hyperkeratosis, and pseudoepitheliomatous hyperplasia can also be seen.

DIFFERENTIAL DIAGNOSIS. Epidermal nevi and aplasia cutis may be clinically similar to nevus sebaceous but biopsy can easily distinguish between these entities.

TREATMENT. Excision of nevus sebaceous was common when these lesions were thought to carry an increased risk of basal cell carcinoma. Rapidly growing papules or nodules demand pathologic evaluation to evaluate for rare malignancies, but excision should be considered on a case-by-case manner.[48]

Figure 118-14 Nevus sebaceous showing epidermal hyperplasia and increased numbers of sebaceous glands and apocrine glands in the dermis.

NEVUS COMEDONICUS

NEVUS COMEDONICUS AT A GLANCE

- Presents as comedo-like dilated pores with keratinaceous plugs; linear, nevoid, bilateral, or zosteriform pattern.
- Nevus comedonicus syndrome: association of nevus comedonicus with noncutaneous findings such as skeletal defects, cerebral abnormalities, and cataracts.
- Hallmark findings: keratin-filled epidermal invaginations associated with atrophic sebaceous glands or follicles.
- Differential diagnosis: acne vulgaris, acne neonatorum, milia nevus sebaceous, linear Darier disease.
- Inflammatory variant can result in significant suppuration and pain, requiring medical or surgical intervention.

Nevus comedonicus is also known as *comedo nevus*, *nevus follicularis keratosis*, *nevus acneiformis unilateralis*, and *nevus zoniforme*.[51] Nevus comedonicus is a rare hamartoma of the pilosebaceous unit.[52,53] Clinically, comedo-like dilated pores with keratinaceous plugs present in a linear, nevoid, bilateral, or zosteriform pattern (Fig. 118-15).[52] An inflammatory variant also exists, with suppurative cysts and acne-like lesions. These lesions appear on the face, chest, or upper arms at birth or during childhood.[28] Nevus comedonicus syndrome is the association of nevus comedonicus with noncutaneous findings such as skeletal defects, cerebral abnormalities, and cataracts.[54]

Figure 118-15 Nevus comedonicus consisting of linear closely set comedones.

COURSE AND COMPLICATIONS. Nevus comedonicus lesions follow a noninflammatory or inflammatory course and do not resolve spontaneously. The inflammatory course may result in scarring. Nevus comedonicus syndrome results in developmental, cerebral, skeletal, or ocular defects that present by the age 15 years.[55]

PATHOLOGY. The hallmark findings in nevus comedonicus are keratin-filled epidermal invaginations associated with atrophic sebaceous glands or follicles. EHK may be seen.[56]

DIFFERENTIAL DIAGNOSIS. The differential diagnosis of this lesion includes acne vulgaris, milia, acne neonatorum, nevus sebaceous, and linear Darier disease.

TREATMENT. The noninflammatory variant of nevus comedonicus is usually asymptomatic, with treatment based on the cosmetic concerns of the patient. The inflammatory variant can result in significant suppuration and pain, requiring medical or surgical intervention. Inflammation may be controlled with tazarotene cream or other retinoids, tacrolimus ointment, calcipotriene cream, and intralesional steroids.[57] Keratolytics may be of some help. Systemic antibiotics may help to control infection or inflammation. Surgical interventions, such as extraction, excision, dermabrasion, or laser resurfacing, may result in good clinical results.[58,59]

ECCRINE NEVUS

An eccrine nevus, the simplest form of eccrine hamartoma, is characterized by an increase in the number or size of eccrine coils.[60–63] Fewer than 20 cases of eccrine nevi have been described in the literature. Distributed on the trunk, arms, or legs, these lesions occur equally in men and women. Although there seems to be a childhood predominance, the onset ranges from birth to the eighth decade.[64] The morphology of eccrine nevi may vary, appearing clinically as tan papules or normal skin.[65–66] These lesions do not always display hyperhidrosis, however, when they do, treatment is targeted at the control of that symptom. Agents such as aluminum chloride solution, anticholinergics, antidepressants with anticholinergic activity, botulinum toxin, iontophoresis, or sympathectomy have been reported to help control the hyperhidrosis. Surgical excision of the lesion is also an acceptable treatment.[67,68]

APOCRINE NEVUS

Apocrine nevi are hamartomatous proliferations of mature apocrine glands often found within a nevus sebaceous. Clinical presentation varies, but they can be found as soft nodules or papules in the axilla or on the upper chest. Histologically, the apocrine glands extend from the epidermis to the fat. These lesions can be surgically excised if desired.[69]

EPIDERMAL NEVUS SYNDROME[59]

EPIDERMAL NEVUS SYNDROME AT A GLANCE

- Epidermal nevus syndrome is the association of any type of epidermal nevus with various cutaneous, ocular, neurologic, skeletal, cardiovascular, or urogenital developmental abnormalities.
- Historically, six epidermal nevus syndromes described: Proteus syndrome, congenital hemidysplasia with ichthyosiform nevus and limb defects, phakomatosis pigmentokeratotica, sebaceous nevus, Becker's nevus, and nevus comedonicus.
- Affects men and women equally, and presents within the first 40 years of life.
- Patients with extensive epidermal nevi or those with epidermal nevi and systemic abnormalities should be suspected of having the epidermal nevus syndrome.
- Evaluation and management: require multidisciplinary team approach involving the dermatologist, pediatrician, ophthalmologist, neurologist, plastic surgeon, and orthopedic services.

Epidermal nevus syndrome is also known as *Schimmelpenning syndrome*, *Feuerstein–Mims syndrome*, and *Solomon syndrome*. Epidermal nevus syndrome is the association of any type of epidermal nevus with various cutaneous, ocular, neurologic, skeletal, cardiovascular, or urogenital developmental abnormalities. Historically, there have been six epidermal nevus syndromes described: (1) Proteus syndrome, (2) congenital hemidysplasia with ichthyosiform nevus and limb defects, (3) phakomatosis pigmentokeratotica, (4) sebaceous nevus, (5) Becker's nevus, and (6) nevus comedonicus. Some authors argue that epidermal nevus syndrome is a collection of many different distinct clinical syndromes.

Happle[70] proposed that the epidermal nevus syndrome is not a single entity but consists of at least six distinct diseases that differ in genetic origin and share the common feature of mosaicism. The entities include Schimmelpenning syndrome; nevus comedonicus syndrome; pigmented hairy epidermal nevus syndrome; Proteus syndrome; congenital hemidysplasia, ichthyosiform dermatitis, and limb defects syndrome; and phacomatosis pigmentokeratotica.

EPIDEMIOLOGY. Epidermal nevus syndrome affects men and women equally and presents within the first 40 years of life. Inheritance is sporadic, although anecdotal reports of familial transmission have been reported.[70] Although the exact incidence of epidermal nevus syndrome is unknown, a study of 119 cases of epidermal nevi showed that 33% of patients showed one or more extracutaneous abnormalities, 16% showed two or more abnormalities, 10% showed three or more abnormalities, and 5% showed five or more abnormalities.

CLINICAL FEATURES. Solomon and Esterly provided a detailed account of the spectrum of epidermal nevi seen in the epidermal nevus syndrome.[29] They described seven types of lesions. The majority of patients had nevus unius lateris; 20% of patients had ichthyosis hystrix; and another 20% had what the authors termed the *acanthotic form* of epidermal nevus. These lesions presented as large, unilateral, brown, slightly scaly patches. About 10% of patients had linear nevus sebaceous involving the scalp and face. Localized linear verrucous nevus and a velvety epidermal nevus in the axilla similar to acanthosis nigricans were seen in a minority of cases. Some patients had a mixture of several types of lesions.

Table 118-2 lists the mucocutaneous changes other than epidermal nevus that may be seen in patients with epidermal nevus syndrome.[71] Hemangiomas and pigmentary changes are found in 10%–20% of patients. Less common findings are hair abnormalities, dental abnormalities in association with mucosal epidermal nevi, and dermatomegaly. This last condition involves an increase in skin thickness, warmth, and hairiness. As discussed earlier, various cutaneous tumors may develop within the epidermal nevus.

TABLE 118-2
Cutaneous Findings in Epidermal Nevus Syndrome

- Epidermal nevus
- Hemangioma
- Pigmentary changes
  - Café-au-lait spots
  - Hypopigmentation
  - Melanocytic nevi
- Dermatomegaly
- Cutaneous malignancies
  - Keratoacanthoma
  - Basal cell carcinoma
  - Squamous cell carcinoma
  - Syringocystadenoma papilliferum
  - Other adnexal tumors

A wide range of skeletal abnormalities has been reported (eTable 118-2.1 in online edition).[70–72] The incidence of skeletal changes has ranged from 15% to 70%.

Neurologic abnormalities occur in 15%–50% of cases (eTable 118-2.2 in online edition).

From 9% to 30% of patients with epidermal nevus syndrome have ocular abnormalities (eTable 118-2.3 in online edition).[73]

As in isolated epidermal nevi, malignant transformation may occur within the epidermal nevi in patients with epidermal nevus syndrome. This occurrence is most common in those with nevus sebaceous. Perhaps less well known is the association of visceral malignancies with the epidermal nevus syndrome. The following tumors are reported to occur at a higher frequency and at an earlier age in patients with epidermal nevus syndrome: tumors of the genitourinary system (Wilms' tumor, nephroblastoma, metastatic transitional cell carcinoma of the bladder, and rhabdomyosarcoma of the bladder); tumors of the gastrointestinal tract (hepatic adenoma, salivary gland adenocarcinoma, and carcinoma of the esophagus and stomach); and tumors of the central nervous system (astrocytoma, mixed glioma, and meningioma). Breast carcinoma, mandibular ameloblastoma, chondroma, odontoma, and endometrioma are other tumors associated with epidermal nevus syndrome.[41] However, these associations have not been confirmed by case-controlled studies.

MANAGEMENT. Patients with extensive epidermal nevi or those with epidermal nevi and systemic abnormalities should be suspected of having the epidermal nevus syndrome. Evaluation and management of patients with epidermal nevus syndrome requires a multidisciplinary team approach involving the dermatologist, pediatrician, ophthalmologist, neurologist, plastic surgeon, and orthopedic services. These patients require a careful history

with particular attention given to developmental history, attainment of milestones, history of seizures, and abnormalities of the bones, eyes, and urinary tract. Thorough mucocutaneous, neurologic, ophthalmologic, and orthopedic examinations are necessary. Most cases of Proteus syndrome are caused by a mosaic activating mutation in *AKT1*. (*N Engl J Med* **365**:611-619, 2011). A regular follow-up program should be planned for the patient.

LICHEN STRIATUS

LICHEN STRIATUS AT A GLANCE

- Lichen striatus is a rare, idiopathic, linear, papular eruption that usually resolves in 1–2 years.
- Occurs most commonly on the limbs of females.
- Eruption is characterized by the sudden onset of flat-topped, 1–3 mm, pink, tan, or hypopigmented papules in a linear configuration or Blaschkoid distribution.
- Differential diagnosis: lichen planus, psoriasis, linear porokeratosis, lichen nitidus, Darier disease, and inflammatory linear verrucous epidermal nevus.

Lichen striatus is a rare, idiopathic, linear, papular eruption that usually resolves in 1–2 years.

ETIOLOGY AND EPIDEMIOLOGY

Lichen striatus, which is also known as *Blaschko linear acquired inflammatory skin eruption*, most commonly affects individuals from 4 months to 15 years of age.[74] The etiology is unknown. This self-limited dermatosis occurs most commonly on the limbs in females. However, distribution on the face and trunk has been reported.[75] Nail changes are uncommon.[76] Most cases are distributed in Blaschko's lines, though axial distributions have been reported. A retrospective analysis of 155 cases of children with lichen striatus revealed an association with atopic dermatitis in 70 of the cases.[77]

CLINICAL FEATURES[78]

Lichen striatus is an eruption characterized by the sudden onset of flat-topped, 1–3 mm, pink, tan, or hypopigmented papules in a linear configuration or Blaschkoid distribution (Fig. 118-16). Bilateral eruptions have been reported, though unilateral lesions are the norm. These flat-topped papules may have an associated scale. Longitudinal ridging and nail plate thinning can be seen. This eruption is usually self-limited, lasting from a few months to 2 years before spontaneously regressing.

Figure 118-16 Lichen striatus. Linear configuration of slightly scaling papules in Blaschkoid distribution on the leg.

PATHOLOGY

Lichen striatus is characterized by a lichenoid, lymphocytic infiltrate involving three to four adjacent dermal papillae with overlying epidermal acanthosis, dyskeratosis, hyperkeratosis, and occasional parakeratosis.[78,79] Intraepidermal vesicles containing Langerhans cells can be seen in half of the cases.[80]

DIFFERENTIAL DIAGNOSIS

Lichen planus, psoriasis, linear porokeratosis, lichen nitidus, Darier disease, and ILVEN can have similar morphology and distribution to lichen striatus. These clinical entities can usually be separated based on histopathology. ILVEN can be distinguished clinically because of its earlier onset and lack of spontaneous regression.[80]

TREATMENT

Symptomatic control of pruritus with topical steroids may be necessary. Otherwise, treatment is generally not necessary for this self-limited condition.

CLEAR CELL ACANTHOMA

CLEAR CELL ACANTHOMA AT A GLANCE

- Clear cell acanthoma is a tumor of epidermal origin.
- Solitary, shiny, erythematous or orange to brown, blanching, well-demarcated papule or nodule with collarette of scale.
- Composed of distinctive, glycogen-rich keratinocytes.
- Differential diagnosis: lichenoid keratosis, basal cell carcinoma.

EPIDEMIOLOGY

Clear cell acanthoma is most commonly found equally in men and women ages in the sixth to eighth decade.

ETIOLOGY

The etiology of clear cell acanthoma, also known as *Degos acanthoma* and *pale cell acanthoma*, is unknown. When initially described by Degos et al in 1962, the lesion was thought to be benign tumor of epithelial origin.[81] Although initially thought to be of follicular or sweat-gland origin, the expression of involucrin and epithelial membrane antigen by clear cell acanthomas indicates an epithelial origin.[82–84] The cytokeratin staining patterns, interestingly, reveal staining patterns commonly found in inflammatory dermatoses such as lichen planus, psoriasis, and discoid lupus.[85] The presence of clear cell acanthomas on psoriatic plaques has led many to question the role of inflammation in the development of these lesions.[86]

CLINICAL FEATURES

Clear cell acanthoma is commonly a solitary, shiny, erythematous to brown, well-demarcated papule or nodule that blanches almost fully with pressure (Fig. 118-17). Surrounding the lesion is a collarette of scale. These lesions range from 5 mm to 2 cm, although the giant clear cell acanthoma can measure greater than 5 cm.[87] The lesions are usually found on the legs but can be located on the trunk and face. Although commonly solitary, multiple lesions have been reported. The dermatoscopic findings of the clear cell acanthoma are similar to that seen in psoriasis, with vascular puncta prominent in the lesion.[88] These lesions bleed with trauma.

PATHOLOGY

Sharply demarcated, pale-staining keratinocytes within a background of epidermal psoriasiform hyperplasia is characteristic in a clear cell acanthoma (Fig. 118-17). The glycogen-rich keratinocytes in the epidermis stain distinctively with periodic acid-Schiff, which then can be washed out by diastase that digests the glycogen.[89] Other epidermal findings include suprapapillary plate thinning, neutrophils, and sparing of adnexal epidermis. A mixed inflammatory infiltrate,

Figure 118-17 **A.** Clear cell acanthoma presenting as a flat orange nodule on the sole. **B.** Histologically, it is a well-circumscribed epidermal tumor composed of clear (glycogen-rich) cells.

papillary dermal edema, and enlarged vessels can be seen in the dermis.

TREATMENT

Cryotherapy, curettage and electrodesiccation, laser ablation, or surgical excision, have been used to successfully treat this lesion.[90]

WARTY DYSKERATOMA (ISOLATED DYSKERATOSIS FOLLICULARIS)[91]

WARTY DYSKERATOMA AT A GLANCE

- Solitary focus of acantholytic dyskeratosis.
- Lesions: solitary, skin-colored, umbilicated papules located on the head or neck.
- Histology: cup-shaped epidermal invagination with acantholysis and dyskeratosis filled with keratinaceous material.
- Differential diagnosis: actinic keratosis, squamous cell carcinoma.
- Treatment: excision.

ACANTHOMA FISSURATUM

ACANTHOMA FISSURATUM AT A GLANCE

- Fissured or ulcerated, usually retroauricular nodule that appears in areas of friction, as with ill-fitting eyeglasses.
- Differential diagnosis: basal-cell carcinoma, squamous-cell carcinoma, chondrodermatitis nodularis helicis.
- Usually resolve after correction of ill-fitting appliance.

CHONDRODERMATITIS NODULARIS HELICIS

Also called clavus helicis, chondrodermatitis nodularis helicis (CNH) is a chronic, solitary, tender, ulcerated nodule on the helix of the ear, first described in 1915.[97]

CHONDRODERMATITIS NODULARIS HELICIS AT A GLANCE

- Chondrodermatitis nodularis helicis is a chronic, solitary, tender, nodule on the helix of the ear. Sometimes ulcerated.
- Thought to be a disease of degenerated collagen that undergoes transepithelial elimination.
- Often: History of a suddenly appearing, skin-colored to pink papule or nodule on the ear that grew rapidly and subsequently remained quiescent.
- Differential diagnosis: Basal cell carcinoma, keratoacanthoma, wart, rheumatoid nodules, squamous cell carcinoma, clavus, tophus.
- Treatment: conservative, includes pressure-relieving pillows with a doughnut, steroid injection. If needed: excision.

ETIOLOGY AND PATHOGENESIS

Many etiologic factors have been suggested for CNH. It is thought to be a disease of degenerated collagen that undergoes transepithelial elimination.[98] Vascular insufficiency, pressure, injury to the cartilage, sun-exposure, and low temperature have all been implicated in inciting cartilage damage. Recently, Magro et al described 24 patients with early-onset CNH who had concomitant microvascular disease, strengthening the argument for the role of ischemia in the development of this process.[99] Reports of CNH in association with the pressure from cell phone use has also been documented.[100] The finding of solar elastosis histologically at the periphery of many lesions along with the prevalence of CNH in lightly pigmented populations raise the possible link between sun-exposure and CNH.[101]

CLINICAL FEATURES

This disorder is found overwhelmingly in adult men over the age of 50, with the male–female prevalence being greater than 2:1.[102] Two cases of CNH in children have been reported.[103,104] Patients present with a history of a suddenly appearing, skin-colored to pink papule or nodule on the ear that grew rapidly and subsequently remained quiescent. These lesions tend to be on the right helix, measure less than 1 cm, and are associated with pain (Fig. 118-18). The pain can be paroxysmal or associated with changes in ambient temperature. The lesion may have a central ulceration with an adherent hemorrhagic or scale crust. Spontaneous resolution of CNH is unlikely. A possible subset

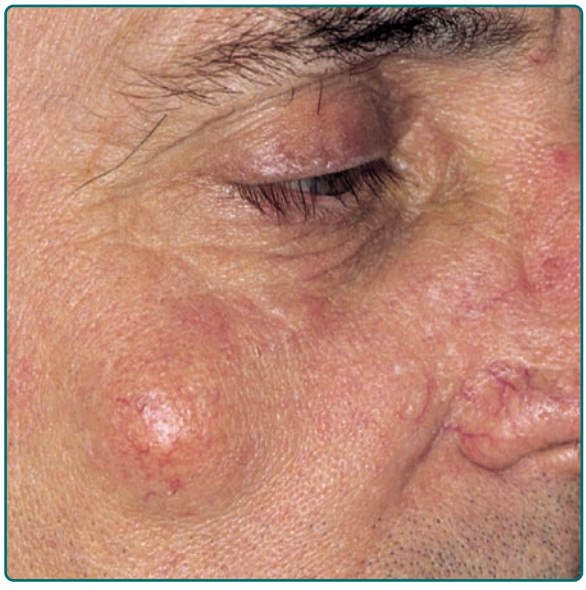

Figure 118-18 Epidermoid cyst presenting as a dome-shaped protuberance of the cheek.

of CNH may be seen in elderly women who have a history of prior trauma. For these women, spontaneous regression is not uncommon.

DIFFERENTIAL DIAGNOSIS

Basal cell carcinoma, keratoacanthoma, warts, rheumatoid nodules, squamous cell carcinoma, clavus, and tophus are all within the differential of CNH.

PATHOLOGY[105]

In the epidermis, there is commonly hyperkeratosis and parakeratosis; ulceration may be present. Occasionally, degenerated collagen is seen in the epidermis, indicating a transepidermal elimination process. A brisk, predominantly lymphocytic infiltrate is noted in the dermis with admixed histiocytes and few neutrophils. Telangiectasias and solar elastosis are often noted in the adjacent dermis. The perichondrium shows inflammation and fibrous thickening. The cartilage may show hyalinization, necrosis, and, at times, ossification.

TREATMENT

Conservative treatment includes pressure-relieving pillows with a doughnut shape that are commercially available. In a recent study examining the role of such pressure-relieving devices, 13 of 15 patients (87%) were healed at follow-up after 1 month of conservative treatment.[106] High-potency steroids, intralesional steroids, and laser ablation may also be used to induce symptom control or regression of the lesion.[107] Excision of CNH nodules using a shave or excisional technique through and around the affected cartilage is also an accepted treatment option, though recurrences may occur at the edge of the lesion.[108]

CYSTS OF EPIDERMAL ORIGIN

CYSTS OF EPIDERMAL ORIGIN AT A GLANCE

- Epidermoid cysts are keratin-filled epithelial-lined cysts.
- Result most commonly from a plugged pilosebaceous unit.
- Classically dermal or subcutaneous mobile nodules with a central punctum.
- Brisk, foreign-body giant cell reaction is possible if epidermoid cysts rupture into surrounding tissue.
- Trichilemmal cysts are keratin-filled, epithelial-lined cysts usually on the scalp arising from outer root sheath of the hair follicle. These pilar cysts are mobile, firm, well-circumscribed nodules. Pathology: cyst wall without a granular layer.
- Milia: Thought to be the result of pilosebaceous or eccrine sweat duct plugging.
- Pathology similar to epidermal cyst that is smaller in scale.
- Steatocystoma multiplex: numerous, epithelial-lined, sebum-filled dermal cysts with characteristic sebaceous glands in the cyst walls.
- Dermoid cysts: collections of epidermis located along embryologic fusion planes most commonly on the forehead, lateral eye, or neck.
- Branchial cysts: asymptomatic cysts caused by the occlusion of branchial cleft sinuses that are located along the angle of the mandible if arising from the first branchial cleft and the middle to lower third of the anterior border of the sternocleidomastoid in cases arising from the second branchial cleft.
- Preauricular cysts or sinuses: epithelial invaginations located in the preauricular area that arise from the incomplete fusion of the first and second branchial arches in the preauricular area.
- Rupture or secondary infections are the most common complications of epidermal cysts.
- Removal of the entire cyst wall is required to prevent cyst recurrence.

EPIDERMOID CYST

An epidermoid cyst, also known as a *follicular cyst-infundibular type*, *keratin cyst*, *epidermal cyst*, *epidermal inclusion cyst*, or an *epithelial cyst*, is a keratin-filled epithelial-lined cyst. The term *sebaceous cyst* is a misnomer and should be avoided, as these cysts do not involve sebaceous glands, nor do they contain sebum.

EPIDEMIOLOGY. Epidermoid cysts are found most commonly in adult men and women. Genetic disorders, such as Gorlin syndrome (nevoid basal cell carcinoma syndrome), pachyonychia congenita type 2 (Jackson–Lawler type), and Gardner syndrome, may predispose individuals to having this type of cyst.

ETIOLOGY AND PATHOGENESIS. Epidermal cysts are most commonly the result of plugged pilosebaceous units. These cysts express the same cytokeratin profile as the follicular infundibulum.[109] Epidermal cysts can also be caused by the traumatic implantation of epidermal cells into deeper tissues or by the proliferation of viable epidermal remnants along embryonic fusion planes.[110,111] Epidermoid cysts can be located anywhere on the body and are characterized by their distinctive pathology. Recently, HPV type 57 and 60 DNA has been detected in palmoplantar epidermoid cysts.[112,113]

CLINICAL PRESENTATION. Epidermoid cysts are classically dermal or subcutaneous mobile nodules with a central punctum (Fig. 118-19). Lesions not associated with trauma are commonly located on the upper chest, upper back, neck, or head. Traumatic lesions are more common on the palms, soles, or buttocks. The punctum, when present, represents the plugged pilosebaceous unit from which foul smelling cheesy debris may be expressed. These lesions can be skin-colored, yellow, or white. Cysts are usually slow growing and asymptomatic, though rupture is common.

COMPLICATIONS. A brisk, foreign-body giant cell reaction is possible if epidermoid cysts rupture into surrounding tissue. This foreign-body reaction may mimic that of secondary bacterial infection. However, polymicrobial infection of a cyst with aerobic or anaerobic organisms may occur. Common aerobes include *Staphylococcus aureus*, group A *Streptococcus*, and *Escherichia coli*, while common aerobes include *Peptostreptococcus* species and *Bacteroides* species. Polymicrobial infection is most common. Although the clinical course of epidermoid cysts is benign, basal cell carcinoma, squamous cell carcinoma, epithelioid carcinoma, and other malignancies have been reported to occur in conjunction with these cysts, though malignant transformation is rare.[114–116]

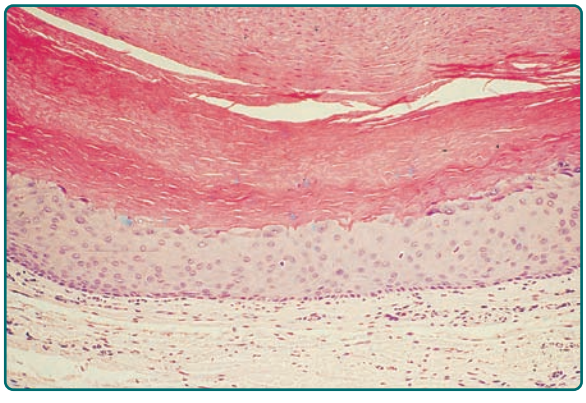

Figure 118-19 Epidermoid cyst lined by stratified epithelium with a granular layer. Within the cyst, the keratinous material is arranged in laminated layers.

Figure 118-20 A trichilemmal (pilar) cyst on the scalp.

PATHOLOGY. An epidermoid cyst has a stratified, squamous lining with an intact granular layer (Fig. 118-20). These cysts contain central, eosinophilic, keratinaceous debris that can incite a foreign-body reaction of multinucleated giant cells and histiocytes when released into the dermis and surrounding tissue.

DIFFERENTIAL DIAGNOSIS. Steatocystoma multiplex, pilar cysts, and lipomas can all mimic epidermoid cysts. However, clinically, steatocystoma multiplex usually express a liquid rather than a cheesy material, pilar cysts are most commonly on the scalp, and lipomas are softer, deeper, and without a punctum. Pathology also distinguishes between these lesions.

TREATMENT. Complete excision or destruction of the cyst lining is the definitive treatment, and is required to prevent cyst recurrence. Intralesional steroids at a concentration of 5 mg/mL can be used to control small, inflamed, symptomatic lesions. If the cyst becomes inflamed, painful, or purulent, infection must be considered. Incision and drainage with oral antibiotic therapy to treat *S. aureus* should be initiated. Wound cultures with directed therapy may be

indicated, based on the clinical presentation of the lesion. If the cyst has ruptured or has become infected, excision of the lesion should be deferred until the inflammation has decreased which will decrease the likelihood of wound dehiscence.

TRICHILEMMAL CYST (PILAR CYST)

Trichilemmal cysts are keratin-filled, epithelial-lined cysts usually on the scalp that arise from the outer root sheath of the hair follicle.

EPIDEMIOLOGY. Trichilemmal cysts can be found in 5%–10% of the population, most commonly in middle-aged women.

ETIOLOGY AND PATHOGENESIS. Pilar cysts arise from the epithelium located between the orifice of the sebaceous gland and the arrector pili muscle. This squamous epithelium undergoes rapid keratinization resulting in a cyst wall without a granular layer.

CLINICAL FEATURES. Pilar cysts are mobile, firm, well-circumscribed nodules located overwhelmingly in the scalp (Fig. 118-21). These lesions can also be found on the face, head, and neck. Most patients have more than one lesion, with 10% of people having more than 10 lesions. Rapid growth is abnormal and can be a sign of infection or malignant transformation.[117]

COMPLICATIONS. Although these lesions largely remain asymptomatic, rupture and infection can occur. Proliferating trichilemmal tumors are a variant of this benign lesion and are commonly found on the scalp of elderly women. This lesion can destroy adjacent lesions and ulcerate, mimicking skin cancer. Malignant degeneration of pilar cysts into malignant proliferating trichilemmal cysts can occasionally occur.

PATHOLOGY. The hallmark finding of these cysts is the absence of a granular layer within the cyst wall (Fig. 118-22). The cyst content is usually eosinophilic keratin, but basophilic areas of calcification may occur in the lumen of these lesions. If lobules of squamous epithelium are seen in the walls of the lesion, it is most likely a proliferating trichilemmal cyst. Invasion of the cyst lining into the surrounding tumor indicates malignancy.

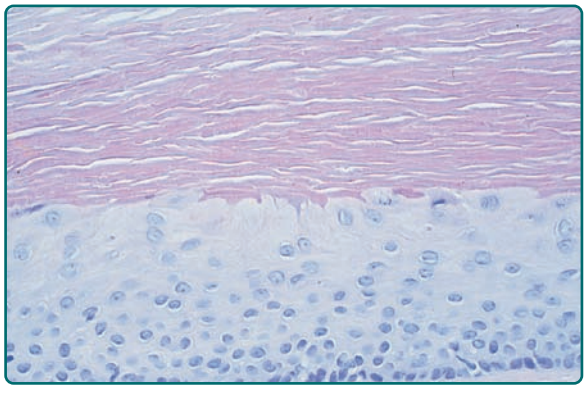

Figure 118-21 Trichilemmal cysts showing an epithelial lining that lacks a granular layer.

Figure 118-22 Primary milium. A 3-mm, hard, seed-like white papule.

DIFFERENTIAL DIAGNOSIS. See Section "Differential Diagnosis" under "Epidermoid Cyst."

TREATMENT. The treatment is the same as with epidermoid cysts. Because the cyst wall of these tumors is clinically more firm than that of epidermoid cysts, it is possible to extract the lesion through a small incision made with a dermal punch trephine.

MILIUM

Milia are minute epidermoid cysts, lined with epidermis and filled with keratin.

EPIDEMIOLOGY. Milia are common congenital and acquired lesions in both infants and adults. Men and women are affected equally.

ETIOLOGY AND PATHOGENESIS. Milia are thought to result from pilosebaceous or eccrine sweat duct plugging. These superficial lesions can be primary or secondary, with the latter resulting from injury to the basement membrane of the skin. Secondary lesions are common in subepidermal blistering diseases such as epidermolysis bullosa and porphyria cutanea tarda, burns, after dermabrasion or ablative laser resurfacing, or in conjunction with topical therapy such as glucocorticoid therapy or 5-fluorouracil treatment.[118–121]

CLINICAL FEATURES. Milia are 1- to 2-mm, white, domed papules commonly located on the cheeks and eyelids of adults (Fig. 118-23). In infants, milia are common on the face and the mucosa. Epstein's pearls are milia on the palate. Eruptive milia have been reported, though this is a rare occurrence.[121] *Milia en plaque* is a plaque-type, inflammatory variant of milia that is commonly located on the ear.[122] Acquired milia

Figure 118-23 Steatocystoma multiplex. Multiple skin-colored cystic lesions on the trunk.

Figure 118-24 Painful nodule of the ear: a typical lesion of chondrodermatitis nodularis helicis.

(eFig. 118-23.1 in online edition) can be located anywhere the predisposing trauma or other factors have occurred.

PATHOLOGY. The pathology of a milium is similar to that of an epidermoid cyst, but the small size and occasional connection to eccrine ducts or vellus hair follicles distinguish these two entities. Bacteria are not usually seen in milia.

TREATMENT. Congenital milia tend to spontaneously resolve. Acquired milia can resolve spontaneously as well, but can also be removed by disrupting the overlying epidermis with light electro-desiccation or incision, usually with an 11-blade and expressing the keratin contents.

STEATOCYSTOMA MULTIPLEX

Steatocystoma multiplex are numerous, epithelial-lined, sebum-filled dermal cysts with characteristic sebaceous glands in the cyst walls.

ETIOLOGY AND PATHOGENESIS. Steatocystoma multiplex, (sebocystomatosis, epidermal polycystic disease) can be a sporadic or autosomal-dominant disorder. These lesions can also be found in syndromes such as Alagille syndrome and pachyonychia congenita type II. In the latter, lesions are associated with mutations in K17. Sporadic solitary lesions are termed *steatocystoma simplex*.

CLINICAL FEATURES. These lesions present as asymptomatic, yellow or skin-colored dermal papules or cysts located most commonly on the trunk, upper arms, scrotum, or chest (Fig. 118-24). Oily material can be expressed from these lesions when incised. These lesions can become infected and suppurate, resulting in sinus formation and scarring.

PATHOLOGY. The cyst walls of steatocystoma multiplex are composed of stratified, squamous epithelium with an absent granular layer. Sebaceous glands are located in the cyst wall (eFig. 118-24.1 in online edition). There is an eosinophilic cuticle on the luminal side of this wall with keratin, oil, and hairs in the lumen.

DIFFERENTIAL DIAGNOSIS. Eruptive vellus hair cysts can mimic steatocystoma multiplex clinically. They may have a tuft of hairs protruding from the cyst centrally, with findings of vellus hairs in the lumen with follicles in the wall. Epidermal inclusion cysts also have to be excluded. The pathogenesis of steatocystoma, epidermal inclusion cysts, and eruptive vellus hair cysts may be similar.[123]

TREATMENT. At times, simple excision or drainage with manual removal of the cyst wall results in the clinical resolution of lesions.[124,125] Inflamed lesions have been reported to respond to intralesional steroids, carbon dioxide laser, oral retinoids, or cryotherapy.[126]

DERMOID CYST

Dermoid cysts are epithelial-lined cysts containing various appendageal structures resulting from retained epithelium along embryonic fusion planes. These cysts are either congenital or develop in childhood. The prevalence is equal in men and women.

CLINICAL FEATURES. Dermoid cysts are smooth, occur in the midline, and commonly possess a deep sinus tract that connects to the epidermis. They can measure between 1 cm and 4 cm, and are most commonly located on the forehead, lateral eye, or neck.[127,128] A superficial dermoid cyst located on the dorsal nose is referred to as *fistula of the dorsum of the nose* and is characterized by a central tuft of hair or communication intracranially. Dermoid cysts can be located deep in the subcutaneous tissue, intracranially, or intraorbitally.[129]

COMPLICATIONS. Infections, rupture, and abscess formation from the manipulation of these cysts are possible serious complications.

PATHOLOGY. Stratified squamous epithelium with a variety of adnexal structures may be present in the walls of dermoid cysts. Smooth muscle, pilosebaceous units, apocrine or eccrine glands, or goblet cells may also be present in the cyst walls. These cysts contain keratin and hairs.

DIFFERENTIAL DIAGNOSIS. The differential diagnosis of dermoid cysts includes gliomas, encephaloceles, hemangiomas, soft tissue sarcomas, and other epidermal cysts such as branchial cleft cysts and thyroglossal duct cysts.

TREATMENT. Imaging studies that help to characterize the extent of the tumor are necessary before excision is undertaken. Consultation with neurosurgery, otolaryngology, or plastic surgery may be indicated.

BRANCHIAL CYST (BRANCHIAL CLEFT CYST)

Sequestration of first or second branchial cleft membranes results in these cysts, sinuses, or tags.

EPIDEMIOLOGY. Branchial cleft cysts are largely sporadic, but autosomal dominant cases have been reported. There is no gender predominance. Ten percent of lesions are bilateral.

ETIOLOGY AND PATHOGENESIS. These cysts result from the occlusion of branchial cleft sinuses.

CLINICAL FEATURES. These asymptomatic lesions are often located along the angle of the mandible if arising from the first branchial cleft and the middle to lower third of the anterior border of the sternocleidomastoid in cases arising from the second branchial cleft. They may present after an upper respiratory infection as a painful mass. These lesions tend to drain internally, but communication with the epidermis can occur. Branchial cysts may become complicated by infection.

PATHOLOGY. Branchial cleft cysts are lined with epithelium containing lymphoid follicles, mucous glands, or smooth muscle. A dense lymphocytic infiltrate may also be seen. The cyst contents contain mucin.

TREATMENT. Excision is the treatment of choice. Infected cysts may require incision and drainage or antibiotic therapy.

PREAURICULAR CYST AND SINUS (CONGENITAL AURICULAR FISTULA, EAR PITS)

Preauricular cysts or sinuses are epithelial invaginations located in the preauricular area.

Chapter 119 :: Appendage Tumors and Hamartomas of the Skin

:: Divya Srivastava & R. Stan Taylor

APPENDAGEAL TUMORS AT A GLANCE

- Tumors differentiate from cutaneous adnexal structures into sebaceous, apocrine, eccrine, and follicular neoplasms.
- Clinically, tumors are indistinct and typically present as papules and nodules, requiring histopathologic evaluation. Anatomic location, presence of single or multiple lesions, and knowledge of distribution of adnexal structures should be considered in development of a differential diagnosis.
- Appendageal tumors often serve as markers of underlying genetic syndromes.
- Risk of malignant degeneration varies with individual lesions, and is more common with sweat gland tumors than pilosebeceous tumors.

CLASSIFICATION AND PATHOGENESIS

Appendageal tumors of the skin comprise a wide spectrum of benign and malignant neoplasms that exhibit morphological differentiation toward one or more adnexal structures in normal skin. The classification and diagnosis of appendageal tumors is challenging due to the wide variety of tumor types, complicated nomenclature, and numerous classification systems that categorize these neoplasms.[1–8] Traditionally, cutaneous adnexal tumors are classified into four groups according to differentiation toward follicular, sebaceous, apocrine, and eccrine structures. These adnexal tumors can be further classified by a gradient of decreasing differentiation into three groups: hyperplasias and hamartomas, benign neoplasms, and malignant neoplasms (Table 119-1). This classification is similar to the approach of the World Health Organization International Histological Classification of tumor monographs.[4] The hyperplasias are characterized by an increased number of normal cells in a normal arrangement. Hamartomas are described as an abnormal arrangement of normal tissue. Benign neoplasms lack the potential to metastasize, whereas malignant tumors have the ability to cause local destruction and to metastasize to lymph nodes and viscera.

While adnexal tumors are classified based on differentiation, often a tumor is not easily classified into one group because the lesion exhibits histologic features of two or more adnexal cell lines. Since adnexal tumors originate from pluripotent stem cells in the epidermis and its appendages, neoplastic cells may aberrantly express one or more lines of appendageal differentiation. The ultimate histologic characteristics of a tumor are related to the activation of molecular pathways responsible for forming the normal mature adnexal structure, in conjunction with tumor genetics, local vascularity, and microenvironment.[4]

During embryogenesis, the eccrine apparatus develops separately from the folliculosebaceous-apocrine apparatus. Eccrine glands develop directly from the embryonic epidermis during the third to fifth months of fetal development. Hair follicles also arise directly from the epidermis during the third to fourth months of fetal life. Follicular development differs from eccrine development because mesenchymal cells, which serve as precursors of the follicular papilla, descend into the dermis with the developing epidermal elements. Sebaceous and apocrine glands and ducts begin as secondary structures from the bulges along the hair follicle. Clinically, as predicted by embryogenesis, follicular, sebaceous, and apocrine tumors coincide in the same individuals, whereas eccrine tumors are unrelated.[8]

Cytogenetics and molecular studies have further elucidated the pathogenesis of certain adnexal tumors. Mutations in p53 have been detected in some adnexal tumors, suggesting an etiologic role for ultraviolet light.[9] Germ-line mutations have been reported in various genodermatoses, suggesting a role for these genes in the pathogenesis of certain adnexal tumors. For instance, mutations in the patched (PTCH) genes have been demonstrated in follicular tumors in patients with the basal cell nevus syndrome.[10] Mutations in the tumor suppressor gene *PTEN* have been identified in patients with Cowden's syndrome.[11] Microsatellite instability and mutations in *MSH2*, *MLH1*, and *MSH6* mismatch repair genes have been detected in patients with Muir–Torre syndrome.[12] Technologies such as cDNA microarrays, microRNA microarrays, and proteomic studies may lead to the elucidation of additional molecular markers useful in classifying these neoplasms.

DIFFERENTIAL DIAGNOSIS

Clinically, appendageal tumors are indistinctive, and often present as flesh-colored papules or nodules. Lesions may be solitary or multiple. The anatomic distribution of these lesions corresponds to the normal location of the adnexal structure from which the

neoplasms originates. When patients present with multiple lesions, a characteristic anatomic distribution, autosomal dominant inheritance pattern, and association with visceral abnormalities may be observed. Often, appendageal tumors serve as a marker for genetic syndromes. While most lesions are benign, a malignant counterpart exists for most tumors, and it is often associated with a poor outcome.

The most important tool for diagnosing and classifying appendageal tumors is histopathology. The histopathology of the adnexal tumor can be interpreted by comparing its microscopic features to the histology of normal cutaneous appendages. Follicular tumors show a range of morphologic features that recapitulate specific portions of normal hair and the hair follicle such as the infundibulum, isthmus, stem, and bulb. The finding of matrical cells reflects differentiation toward follicular bulbs. Trichohyalin granules and blue–gray corneocytes indicate differentiation toward the inner root sheath. Differentiation toward the outer root sheath is manifested by the presence of either clear columnar cells aligned in a palisade at the bulb, subtly cornified cells with pink cytoplasm at the stem, or fully cornified cells with red cytoplasm, which corresponds to trichilemmal keratinization at the level of the isthmus. Sebaceous tumors reveal areas with sebocytes distinguished by a vacuolated cytoplasm, scalloped nuclei, and tubular structures. Ductal differentiation characterizes apocrine and eccrine tumors. Features of apocrine glands such as decapitation secretion are seen in ductal structures of apocrine neoplasms, whereas a flattened ductal epithelium distinguishes eccrine neoplasms.[4]

Immunohistochemical analysis has traditionally been of little value in definitively diagnosing adnexal tumors given the significant overlap of immunohistochemical features between apocrine tumors with ductal differentiation and certain visceral malignancies.

Determination of whether an appendageal neoplasm is benign or malignant requires assessment of architectural and cytomorphologic characteristics. Great care is necessary when applying traditional morphologic criteria of malignancy such as asymmetry, poor circumscription, and presence of epithelial aggregations with

prominent atypia and mitotic activity. Some malignant aggressive adnexal neoplasms have deceptively bland microscopic appearance. Furthermore, there are certain neoplasms whose malignant potential is not always predictable on histologic grounds alone.

TREATMENT

A diagnostic biopsy of a suspicious lesion yielding a correct diagnosis is the initial step in appropriate management of patients with appendageal skin tumors. A number of tumor-related and patient-related factors influence the choice of treatment. Tumor-related factors include the type, size, and anatomic location. Patient-related factors include life expectancy, comorbid conditions, and cosmetic concerns.

Specific treatment of benign appendageal tumors is sometimes unnecessary. In some cases, removal of the tumor is indicated for cosmetic reasons only. The treatment of choice for the majority of benign appendageal tumors is surgical excision. A variety of superficial ablative techniques such as electrodessication and curettage and cryotherapy have proven to be effective in selected patients. A number of other alternative treatment options, including the use of systemic retinoids, lasers, and photodynamic therapy have also been advocated for use in some cases; however, most do not have sufficient data for universal application.

Treatment of malignant appendageal tumors aims mainly at eradication of the cancer, preservation or restoration of normal function, and cosmesis. High-risk patients with tumors known to recur or metastasize most frequently require wide local excision, Mohs micrographic surgery, and/or radiotherapy. Notably, sentinel lymph node biopsy is sometimes valuable in staging of patients with eccrine and apocrine carcinomas.

SEBACEOUS NEOPLASMS

Sebaceous tumors consist of a wide spectrum of neoplasms from hamartomas, hyperplasias, and benign lesions to highly aggressive malignant tumors. Sebaceous neoplasms, with the exception of sebaceous hyperplasia, are relatively rare compared to the other appendageal tumors. Sebaceous lesions are associated with two systemic syndromes: Muir–Torre syndrome and the epidermal nevus syndrome.

Sebaceous glands develop from the hair sheath, and are located near hair follicles, apocrine ducts, and arrector pili muscles. Sebaceous glands are located in all hair bearing regions of the body, and are most abundant in the head and neck region.[13] Ectopic sebaceous glands are common and considered a normal variant. Fordyce spots are located on the vermilion border of the lip and labia minora, Tysons glands on the prepuce and mucosa of the penis, and Montgomery tubercles on the female areola.[14]

Terminology regarding sebaceous neoplasms remains controversial. The term sebaceous adenoma has been applied to superficial benign sebaceous neoplasms with predominantly mature sebocytes, whereas sebaceous epithelioma and sebaceoma have been used to describe lesions consisting of primarily germinative seboblasts. Others have used the term sebaceoma to describe benign sebaceous proliferations deep in the dermis as opposed to the more superficial sebaceous adenoma.[15] In this chapter, the term sebaceous adenoma is used to encompass superficial and deep sebaceous proliferations with varying degrees of sebocyte maturity.

HAMARTOMAS AND HYPERPLASIAS

NEVUS SEBACEUS OF JADASSOHN

Epidemiology. Nevus sebaceous of Jadassohn, described in 1895, is a benign hamartoma with epidermal, follicular, and apocrine elements.[16] It occurs in 3/1,000 neonates.[14]

Etiology and Pathogenesis. Nevus sebaceous is postulated to develop due to genetic mosaicism in stem cells that expand in the lines of Blaschko. The human papilloma virus (HPV) has been detected in nevus sebaceous tissue, with evidence of viral integration of HPV DNA into genomic DNA.[17] These results suggest that maternal transmission of HPV DNA to fetal ectodermal cells could result in epigenomic mosaicism and subsequent cutaneous changes. In familial cases, a paradominant mode of transmission has been suggested.[18] Loss of heterozygosity of the patched gene has also been demonstrated in some nevus sebaceous lesions.[19]

Clinical Findings. Nevus sebaceous presents as a well-demarcated, yellow–orange, alopecic, verrucous plaque that ranges in size from a few millimeters to several centimeters. It most commonly occurs on the scalp (59.3%), but can also occur on the face (32.6%), preauricular area (3.8%), and neck (3.2%).[20] It is usually solitary and linear or crescentic, and is distributed in the lines of Blaschko.[21]

Mehregan and Pinkus described three stages in the clinical and histological evolution of a nevus sebaceous.[22] The lesion is slightly raised and barely discernible at birth. The initial stage is characterized by papillomatous epithelial hyperplasia and underdeveloped hair follicles. The second stage commences at puberty and is associated with remarkable sebaceous gland development, epidermal verrucous hyperplasia, and the maturation of apocrine glands. Clinically, this correlates with progressive thickening and development of a pebbly verrucous surface. The final stage involves the development of benign and malignant neoplasms within the nevus sebaceous.

Several neoplasms have been described arising within a nevus sebaceous.[20,23] The most common benign neoplasm to occur in nevus sebaceous is trichoblastoma, followed by syringocystadenoma papilliferum. Trichoblastomas, seen in about 5% of nevus sebaceous, presents with new pigmented papules or nodules. The development of basal cell carcinoma is seen in less than 1% of lesions. Other tumors reported

to develop in nevus sebaceous include nodular hidradenoma, syringoma, trichilemmoma, proliferating trichilemmal cyst, squamous cell carcinoma, sebaceous carcinoma, apocrine carcinoma, and eccrine poroma.[24]

Histopathology. In early nevus sebaceous, the epidermis is acanthotic and papillomatous. The sebaceous gland is underdeveloped and decreased in number, leading to difficult diagnosis. The presence of immature hair follicles that resemble the embryonic stage of hair follicles can aid diagnosis in early lesions. At puberty, the epidermis is papillomatous, verrucous, and hyperplastic. Abundant sebaceous glands and vellus hairs are noted in the superficial dermis. Apocrine glands are seen in two-thirds of patients at puberty.[22,25]

Prognosis. The risk of malignancy in nevus sebaceous is quite low, with the incidence of basal cell carcinoma at 1%. The risk of malignancy increases with age with the majority of studies indicating that children are unlikely to develop malignant tumors.[23]

Nevus sebaceous is associated with the linear nevus sebaceous syndrome, a subset of the epidermal nevus syndrome. Also known as Schimmelpenning Syndrome, this syndrome is characterized by linear nevus sebaceous, mental retardation, seizures, ophthalmic, skeletal, cardiovascular, and urologic defects. Appropriate work-up in these patients includes electroencephalogram, cerebral computed tomography or magnetic resonance imaging, skeletal survey, analysis of renal and liver function, and calcium and phosphate levels.[26]

Treatment. Treatment is primarily cosmetic, and surgical excision to adipose or galea is the treatment of choice. Given the low risk of malignancy, many advocate that observation until adolescence is warranted as opposed to early excision. For facial lesions, consideration should be given to excision during childhood when scarring is minimal. Other treatment modalities including photodynamic therapy, carbon dioxide laser resurfacing, and dermabrasion have been advocated. However, since they fail to completely eradicate the lesion, there is a risk of recurrence or development of new tumors.[27–29]

SEBACEOUS HYPERPLASIA

Epidemiology. Sebaceous hyperplasia, a benign enlargement of the sebaceous lobule around a follicular infundibulum, is a common lesion especially in patients with significant sun exposure. The age of onset is 40, with males more commonly affected than females. Prevalence increases with time.[21]

Etiology and Pathogenesis. The cause of sebaceous hyperplasia is unknown. Although it is seen in individuals with extensive sun exposure, studies do not show an association with solar elastosis or skin type.[30] Sebaceous hyperplasia is associated with renal transplantation and chronic immunosuppression with cyclosporine.[31,32] Ten percent to 15% of patients on cyclosporine develop sebaceous hyperplasia, which can occur several years after starting the medication, and may affect ectopic locations such as the oral mucosa. Other associations include chronic renal failure, hemodialysis, corticosteroids, Muir–Torre syndrome, pachydermoperiostosis, and X-chromosomal ectodermal dysplasia.[33]

Clinical Findings. Sebaceous hyperplasia presents as solitary or multiple small ~3 mm yellow or flesh-colored telangiectatic papules with a central dell on the central face (Fig. 119-1A).[21] Nonfacial locations such as the neck, chest, areola, vulva, and penis have also been described.[34–36] Atypical presentations include giant or linear lesions, diffuse growths, and juxtaclavicular beaded lines.[21,36] Some reports have described sebaceous hyperplasia developing over neurofibromas, melanocytic nevi, verruca vulgaris, and acrochordons.[37] Premature or functional familial sebaceous hyperplasia occurs in adolescence and is typified by thick diffuse plaque-like lesions on the face, chest, and upper back.[38] Clinically, sebaceous hyperplasia can resemble basal cell carcinoma, and biopsy is performed to rule out malignancy. Dermoscopy can facilitate diagnosis of sebaceous hyperplasia, and reveals a yellow papule with telangiectasias and a central crater.[39]

Histopathology. Sebaceous hyperplasia reveals large mature sebaceous lobules clustered around discrete, often dilated, infundibula located in the upper dermis.

Prognosis and Clinical Course. The most common variant, the senile variant, is associated with an increased risk of nonmelanoma skin cancer in renal transplant patients.[31] Sebaceous hyperplasia may be associated with Muir–Torre syndrome, although it does not serve as a marker for the syndrome, given its high prevalence in the population.[40]

Treatment. Treatment of sebaceous hyperplasia is for cosmetic purposes. The following destructive modalities have been shown to be effective: excision, cryotherapy, electrodessication and curettage, electrocautery, photodynamic therapy with aminolevulinic acid, and laser therapy with the argon, carbon dioxide, pulse dye,

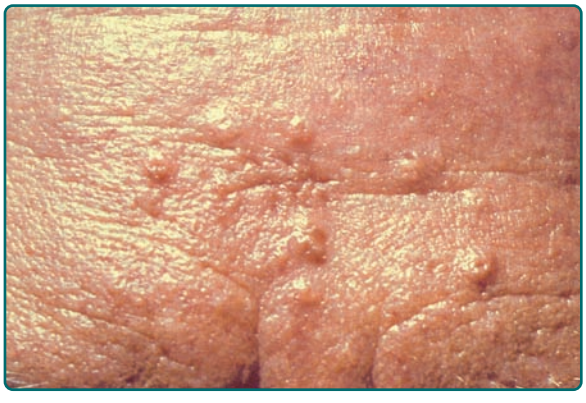

Figure 119-1 Sebaceous hyperplasia. One- to 3-mm smooth papules with central umbilication on the forehead.

and 1,450 nm diode lasers. These can be associated with scarring, hypopigmention, bleeding, and recurrence.[21,33] Isotretinoin has been shown to be effective, but lesions recur rapidly after the medication is continued.[33]

BENIGN NEOPLASMS

SEBACEOUS ADENOMA

Epidemiology. Sebaceous adenomas are rare benign tumors that typically present on the head and neck of elderly individuals.[41] These tumors serve as a marker for Muir–Torre syndrome.[40]

Etiology and Pathogenesis. As a marker of the Muir–Torre syndrome, these lesions demonstrate microsatellite instability and mutations in DNA mismatch repair genes *MSH2*, *MLH1*, and *MSH6*.[12]

Clinical Findings. A sebaceous adenoma usually presents as a smooth, well-circumscribed, slow-growing pink, flesh-colored, or yellow papule or nodule measuring less than 0.5 cm (Fig. 119-2A). The most common location is the head (70%), followed by the neck, trunk, and legs (30%). Lesions may bleed, ulcerate, and cause pain.[42]

Histopathology. Sebaceous adenomas reveal multiple well-circumscribed sebaceous lobules. Each lobule has two cell populations: peripheral basaloid germinative cells and mature lipid-filled vacuolated sebocytes in the center of the lobule. Usually, mature sebocytes outnumber the undifferentiated germinative cells (Fig. 119-2B). These lesions lack atypia, necrosis, and invasive growth, which differentiate them from sebaceous carcinoma. Mitoses can be seen in the germinative layers, and is not necessarily indicative of malignancy.[4]

Prognosis and Clinical Course. Sebaceous adenomas are the most common neoplasm associated with Muir–Torre syndrome, occurring in 68% of patients. In these patients, lesions tend to occur on the trunk. There are no reports of metastases from these neoplasms.[26]

Treatment. The treatment of choice is complete surgical excision. Persistence or recurrences are common. Mohs micrographic surgery may be beneficial for conservation of the nipple.[21] Cryosurgery may be useful in the treatment of some patients.

Excision. Work-up for Muir–Torre syndrome should be initiated in patients with a sebaceous adenoma.

MALIGNANT NEOPLASMS

SEBACEOUS CARCINOMA

Epidemiology. Sebaceous carcinoma is a rare aggressive neoplasm that typically presents on the eyelids of elderly individuals. It represents 1%–5.5% of all eyelid malignancies.[43] The mean age of onset is 63 years, although it has been reported in children.[44] While women and Asians were previously thought to have a higher incidence, an analysis of 1,349 cases in the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) database revealed a slight male predisposition and no Asian predominance.[45] Other risk factors include previous irradiation, genetic predisposition for the Muir–Torre syndrome, and immunosuppression with renal transplantation or HIV.[45]

Etiology and Pathogenesis. Most sebaceous carcinomas develop de novo, although they can also originate from benign sebaceous neoplasms. These tumors are also associated with the Muir–Torre syndrome and may demonstrate microsatellite instability in DNA mismatch repair genes.[26]

Clinical Findings. The most common clinical presentation is a painless, slowly enlarging, subcutaneous

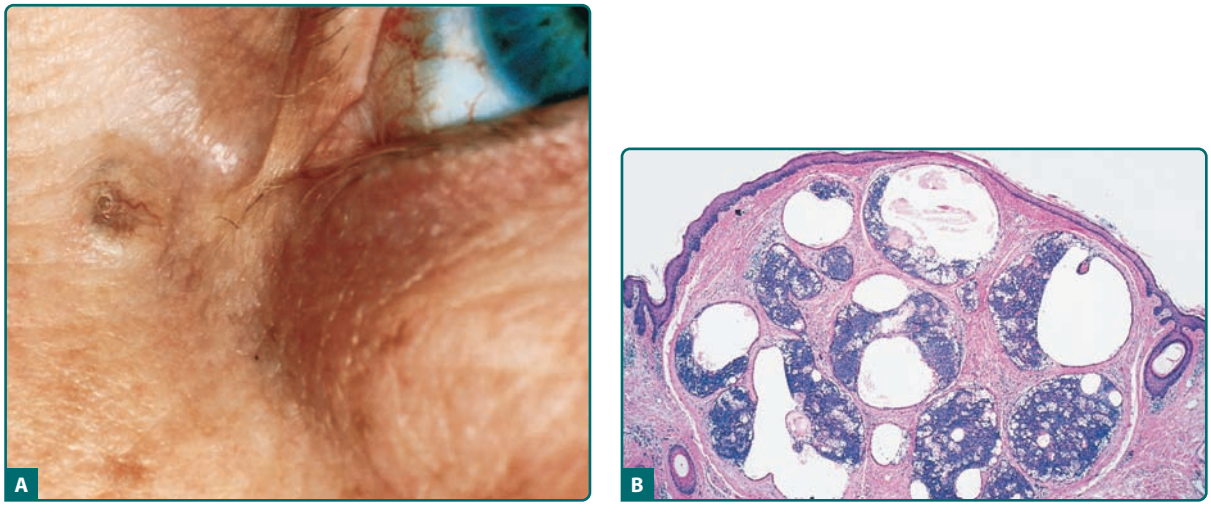

Figure 119-2 Sebaceous adenoma. **A.** Yellowish nodule near the inner canthus of the eye. **B.** Well-circumscribed tumor composed of basaloid aggregations admixed with sebocytes and ductal as well as cystic structures.

nodule.[45] Other clinical presentations mimic chalazion, blepharoconjunctivitis, and basal cell carcinoma, leading to delays in diagnosis.

The most common location is the eyelid, with upper eyelid involvement more frequent than lower eyelid involvement.[46] These tumors develop from the meibomian glands and glands of Zeis. Extraocular lesions present as firm, yellow, ulcerated, or bleeding nodules on the head and neck, and less commonly, on the trunk, feet, external genitals, and oral mucosa.

Histopathology. Sebaceous carcinoma is characterized by asymmetric, irregular sebaceous lobules centered in the dermis. Lesions are classified as well, moderately, or poorly differentiated, based on varying degrees of differentiation. Four patterns are recognized: lobular, comedocarcinoma, papillary, and mixed. Tumor cells show remarkable variation in nuclear shape and size, pleomorphism, hyperchromatism, and mitotic activity. Tumors may extend into the subcutaneous fat or muscle.[21]

Prognosis and Clinical Course. Sebaceous carcinoma is highly aggressive, with a potential for nodal and distant metastases. Recurrence after excision is common. Ocular lesions have a recurrence rate of 11%–30% with distant metastases occurring in up to 25% of patients. Extraocular sebaceous carcinoma is associated with a 29% recurrence rate, and 21% metastatic rate.[45] It was previously believed that ocular tumors were more aggressive than extraocular tumors, but this has been challenged, with many reports of metastatic extraocular disease.[47,48] The most common site of metastasis is regional lymph nodes, but there are reports of metastases extending to the liver, small bowel, urinary tract, lung, and brain.[49]

Mortality rates range from 9% to 50%.[21] Overall 5-year survival rates for ocular versus extraocular disease is 75.2% and 68%, respectively.[45] Negative prognostic signs include upper and lower lid involvement, lymphovascular invasion, multicentric disease, size larger than 1 cm, poorly differentiated tumors, and pagetoid spread.[45]

Treatment. The standard treatment has been wide local excision with 5–6 mm margins. However, this has been associated with high recurrence rates of 36% and a 5-year mortality rate of 18%.[21] Studies have shown that Mohs micrographic surgery may be more effective with recurrence rates of 12%.[46] Sentinel lymph node biopsy has been advocated by some authors, although there are minimal studies in this area.[23] Orbital exenteration is recommended for extensive orbital or bulbar conjunctival disease. Radiation has not been shown to be effective.

MUIR–TORRE SYNDROME

Epidemiology. In 1967, Muir and Torre independently described a syndrome of sebaceous cutaneous neoplasms, keratoacanthomas, and internal malignancy.[50,51] The occurrence of Muir–Torre syndrome in patients with an identified sebaceous neoplasm has been reported as high as 42%, and patients present with sebaceous neoplasm at a mean age of 63.[26]

Etiology and Pathogenesis. Muir–Torre syndrome is inherited in an autosomal dominant fashion. It occurs due to inactivating germ-line mutations in the DNA mismatch repair genes *MSH2*, *MLH1*, and *MSH6*, leading to microsatellite instability.[12] *MSH2* is the most commonly mutated gene.[52] Muir–Torre syndrome is considered a phenotypic variant of the Lynch Syndrome, or hereditary nonpolyposis coli cancer family syndrome, which is also associated with defects in the DNA mismatch repair system.

Clinical Findings. Muir–Torre syndrome is characterized by sebaceous neoplasms, keratoacanthomas, internal malignancies, and personal or family history of Muir–Torre syndrome. Internal malignancy usually precedes cutaneous lesions in 59% of patients. However, up to 32% of cases report the development of a sebaceous neoplasm occurring prior to visceral malignancy.[26] The sebaceous adenoma is the most specific marker for Muir–Torre syndrome, occurring in 68% of cases, but sebaceous hyperplasia, cystic sebaceous neoplasms, and sebaceous carcinoma can also be seen.[26] Extrafacial sites are more common in Muir–Torre syndrome than the typical central facial location for sebaceous neoplasms.[40]

The most common visceral malignancy is colon cancer, followed by genitourinary cancers, breast cancer, and hematologic disorders. *MSH2* mutations are associated with a higher risk of colon cancer, whereas *MSH6* mutations are associated with increased endometrial cancer.[53]

Histopathology. Histopathology is consistent with that of the sebaceous neoplasm present in the individual. Other diagnostic methods include immunohistochemical staining for mismatch repair genes, which has been supported as a sensitive, rapid, inexpensive, convenient method for screening patients with suspected Muir–Torre syndrome.[54] Gene sequencing confirms the diagnosis. Sebaceous neoplasms and keratoacanthomas in Muir–Torre syndrome are now included in the tumors to be tested for microsatellite instability via genotyping.[12]

Prognosis and Clinical Course. Visceral tumors tend to behave less aggressively in Muir–Torre syndrome than in sporadic tumors, with a longer median survival in patients with Muir–Torre syndrome for the same tumor types.[12] Aggressive cancer surveillance with colonoscopy and urinary cytology should be performed in these patients. Genetic counseling should also be provided.

Treatment. Surgical excision is the treatment of choice for cutaneous lesions. Clinically involved nodes should also be removed. Low dose isotretinoin has been effective.[26]

APOCRINE NEOPLASMS

Sweat gland neoplasms have traditionally been divided into apocrine tumors and eccrine tumors. However, the distinction between these can be

quite difficult due to numerous terms applied to the same histological entity, overlap between classic apocrine and pure eccrine features, and the coexistence of both tissue types in hamartomas or mixed tumors.

The anatomic distribution of apocrine tumors reflects that of the normal location of glands producing apocrine secretion. Therefore, these lesions are generally confined to the head and neck, axilla, genitals, and perianal skin. Additional sites include the umbilicus, eyelid (Moll's glands), areola, and external auditory meatus.[6]

Apocrine tumors are generally benign, although they possess the ability to degenerate into malignant lesions. An adnexal carcinoma developing from its benign counterpart generally has a history of explosive enlargement of a stable longstanding plaque or nodule. Adnexal carcinomas that develop de novo are more difficult to diagnose clinically, and require histopathologic evaluation. Features such as asymmetry, lack of circumscription, and infiltrative growth pattern support a malignant diagnosis. Histologically, these must be differentiated from cutaneous metastases from breast and gastrointestinal adenocarcinomas. Malignant adnexal tumors rarely metastasize, and treatment of choice is often Mohs micrographic surgery or local excision.

Histopathologically, apocrine lesions are characterized by cells with abundant eosinophilic cytoplasm, eccentric basally located nuclei, and decapitation secretion in the luminal cells. Cells contain periodic acid Schiff (PAS) positive diastase resistant granules. The luminal cells are also reactive to Carcino-embryonic antigen (CEA) and epithelial membrane antigen (EMA), while the secretory cells are positive for low molecular weight cytokeratin and gross cystic disease fluid protein-15 (GCDFP-15).[6]

HYPERPLASIAS AND HAMARTOMAS

APOCRINE HIDROCYSTOMA

Epidemiology. Apocrine hidrocystomas are relatively common cystic lesions that present in middle-aged or elderly individuals. There is a slight female predilection.[55,56]

Etiology and Pathogenesis. Apocrine hidrocystomas arise from a benign proliferation of apocrine glands.

Clinical Findings. The cystic lesions typically present as solitary, smooth, translucent, flesh-colored or bluish, 1–3 mm papules on the head or neck, particularly in the periorbital region (Fig. 119-3A). Rare presentations include multiple lesions, giant tumors, and childhood onset.[57] Apocrine hidrocystomas have been reported to appear within nevus sebaceus.[23,55]

Multiple lesions on the bilateral upper and lower eyelid margins are seen in Schopf–Schulz–Passarge syndrome, an ectodermal dysplasia characterized chiefly by multiple eyelid apocrine hidrocystomas, palmoplantar keratoderma, hypodontia, hypotrichosis, and nail dystrophy. While an autosomal recessive inheritance has been suggested, it can also be sporadic.[58,59]

Histopathology. On histologic examination, there is a unilocular or multilocular cyst located in the dermis. The epithelial lining consists of a single or double layer of cuboidal–columnar epithelium lying adjacent to an outer myoepithelial layer. Decapitation secretion is notable. Prominent papillations protruding into the lumen are seen in some cases (Fig. 119-3B).[55]

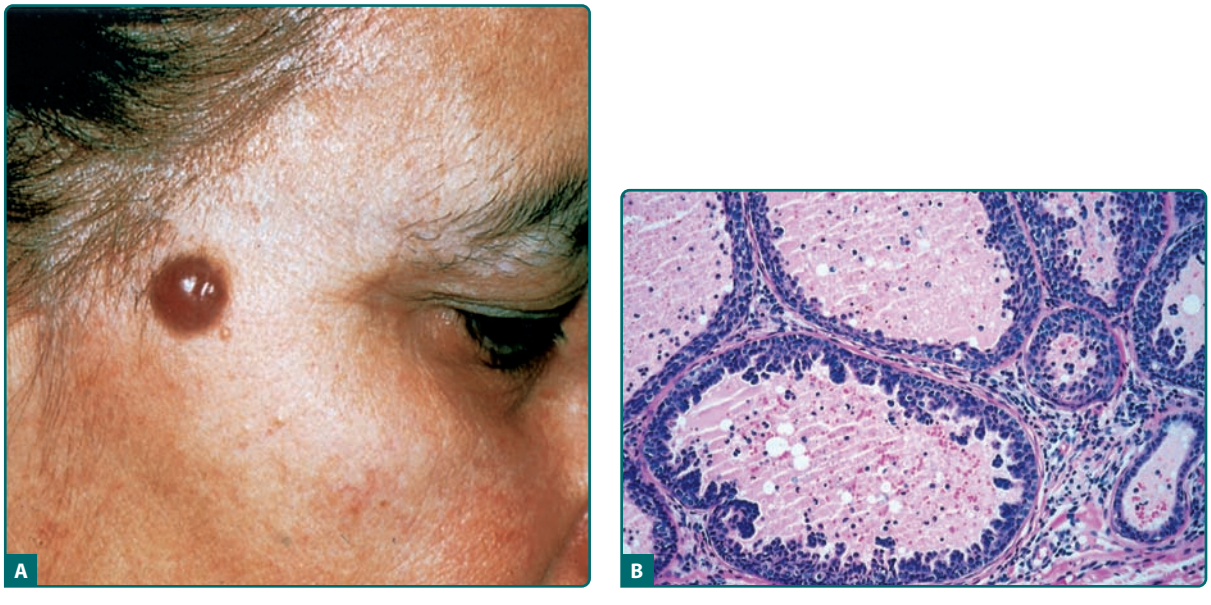

Figure 119-3 Apocrine hidrocystoma. **A.** Reddish-brown to bluish cystic nodule. **B.** Multilocular tumor with papillary projections ("apocrine secretion").

Prognosis and Clinical Course. Lesions tend to be asyptomatic, and enlarge until a certain size is attained.

Treatment. The treatment of choice for solitary lesions is surgical excision. Multiple lesions can be treated with electrodessication and curettage, carbon dioxide or pulsed dye lasers, local application of trichloroacetic acid, topical atropine, or botulinum toxin.[60–63]

APOCRINE NEVUS

Epidemiology. Apocrine nevus is a rare hamartoma consisting of a proliferation of normal appearing apocrine glands in the dermis.

Clinical Findings. There are two clinical variants of apocrine nevus. A pure apocrine nevus is quite rare, and presents as a unilateral or bilateral, soft, lobulated, dermal mass in the axilla or scalp.[1] A more common variant occurs as a part of a nevus sebaceus. Cases of apocrine nevus occurring as multiple papules on the chest have been reported.[64]

Histopathology. There are numerous, discrete, closely spaced tubular structures in the dermis and/or subcutaneous fat. The tubules are lined with typical apocrine glandular epithelium and contain a homogenous vacuolated pink secretion. An apocrine nevus that develops within a nevus sebaceous is usually deeper in the dermis and can coexist with syringocystadenoma papilliferum or trichoblastoma.[23]

Treatment. The treatment of choice is surgical excision.

APOCRINE FIBROADENOMA

Epidemiology. Apocrine fibroadenoma is a rare cutaneous apocrine neoplasm that occurs primarily in women younger than 25 years of age.[1,65]

Etiology and Pathogenesis. Apocrine fibroadenoma is considered analogous to fibroadenoma of the breast.[65] The etiology is unclear. Some feel that it most likely results from a proliferation of ectopic mammary tissue in response to excessive circulating estradiol over progesterone, whereas others believe it is derived from apocrine tissue.

Clinical Findings. Apocrine fibroadenoma typically presents as single or multiple firm, rubbery, smooth, mobile, painless nodules up to 2 cm in diameter. It most commonly occurs in the axilla, vulva, and perianal region.[65]

Histopathology. Histopathology reveals a variably hyalinized stroma surrounding a proliferation of ductal structures with decapitation secretion.

Treatment. The treatment of choice is complete surgical excision.

EROSIVE ADENOMATOSIS OF THE NIPPLE

Epidemiology. Erosive adenomatosis, also known as adenoma of the nipple or florid papillomatosis, is a rare benign neoplasm of breast lactiferous ducts. The peak incidence is in women in the fifth decade, although it has been reported in males and children.[66]

Etiology and Pathogenesis. The tumor derives from terminal lactiferous ducts and subareolar breast tissue.

Clinical Findings. The classic presentation of erosive adenomatosis is with a unilateral erythematous, eroded, crusted papule on the nipple of middle-aged females. Ulceration and serosanguinous discharge may also occur. The lesion is usually asymptomatic, but patients may complain of irritation, burning, pain, and pruritus. Secretion may vary during the menstrual cycle.[67] Clinically, the lesion is often indistinguishable from Paget's disease. Other entities in the differential diagnosis include allergic contact dermatitis, psoriasis, and infection.

Histopathology. Microscopically, erosive adenomatosis reveals a nonencapsulated endophytic proliferation of tubular structures in the dermis with a verrucous or ulcerated surface. Some of the tubular structures exhibit cystic dilations with discrete papillations. The tubules are lined by an inner apocrine secretory epithelium and an outer myoepithelial layer. Differentiating the histologic pattern from intraductal carcinoma of the breast is important. A lack of atypia and necrosis support the diagnosis of erosive adenomatosis.

Prognosis and Clinical Course. Studies have not supported a strong association with breast adenocarcinoma or fibrocystic disease of the breast.[66]

Treatment. Surgical excision and Mohs micrographic surgery are effective treatment choices. Traditionally, complete excision involved removal of the entire nipple and underlying tissue. However, this treatment is associated with recurrence and significant deformation of the cosmetically and functionally sensitive nipple requiring reconstruction.[68,69] More recently, Mohs micrographic surgery has been an effective treatment, with a lower recurrence rate, and minimal deformation. Unique reconstructive techniques, including closure with a purse-string suture, have been employed after Mohs micrographic surgery.[70]

HIDRADENOMA PAPILLIFERUM

Epidemiology. Hidradenoma papilliferum, also known as papillary hidradenoma, is a relatively uncommon benign neoplasm most commonly presenting in females between the ages of 30 and 49 years.[1,71]

Etiology and Pathogenesis. This benign neoplasm develops from the anogenital apocrine glands.

Clinical Findings. The lesion typically presents as a small, unilateral, asymptomatic, flesh-colored nodule on the female vulva. There are reports of ectopic or nonanogenital lesions on the head and neck, where it presents as a subcutaneous nodule, tumor, or cyst. Lesions have been reported on the eyelid, external auditory canal, lip, and nasal ala.[72] Hidradenoma papilliferum has also been reported to develop within a nevus sebaceous.[23]

Histopathology. On histopathology, there is a well-circumscribed dermal nodule that is partly solid or solid-cystic. It lacks an epidermal connection. The nodule consists of an anastomosing pattern of numerous glandular structures and papillary folds. The lumina are made of a double layer of cells: an inner layer of secretory cells demonstrating decapitation secretion, and an outer layer of cuboidal myoepithelial cells (Fig. 119-4). Hidradenocarcinoma papilliferum is notable for high cellularity and asymmetry.

Prognosis and Clinical Course. Hidradenoma papilliferum usually follows a benign course. Malignant transformation into hidradenocarcinoma papilliferum has been reported. It presents as a small, solitary, ulcerated nodule in the anogenital region, and rarely in the axilla. Patients may complain of slight pain or brown watery discharge. Fatal metastases, initially involving regional lymph nodes, have been described. Lesions have been seen in association with extramammary Paget's disease.[1,73]

A fatal metastasizing squamous cell carcinoma arising in a hidradenoma papilliferum has also been reported.[74] There are also rare cases of ductal carcinoma in situ arising in hidradenoma papilliferum.[75]

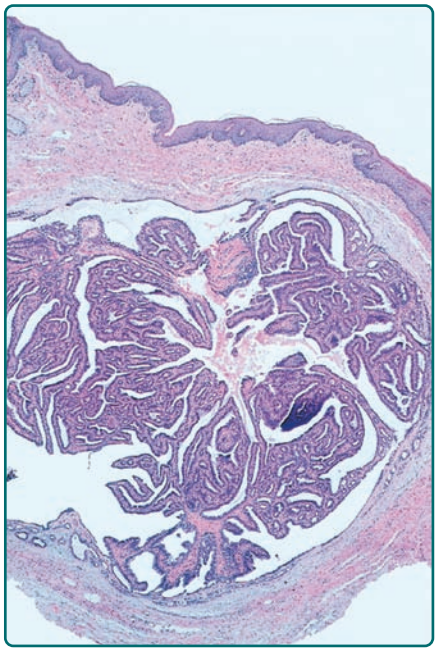

Figure 119-4 Hidradenoma papilliferum. Cystic tumor with papillary and glandular areas.

Treatment. The treatment of choice is surgical excision. In the case of perianal tumors, consultation with colorectal surgery is recommended to preserve anal sphincter function. Sentinel lymph node biopsy may be of value in patients with hidradenocarcinoma papilliferum.

SYRINGOCYSTADENOMA PAPILLIFERUM

Epidemiology. Syringocystadenoma papilliferum is a rare benign adnexal neoplasm that presents in young adults. Fifty percent are present at birth or early childhood, and an additional 15%–20% develop before puberty.[76,77]

Etiology and Pathogenesis. The derivation of syringocystadenoma papilliferum is unclear, with evidence supporting both apocrine and eccrine origin. Forty percent of lesions develop within a nevus sebaceous.[78] Some studies show that mutations in the tumor suppressors, PTCH and p16, may play a role in the evolution of syringocystadenoma papilliferum.[79]

Clinical Findings. Syringocystadenoma papilliferum presents as an asymptomatic, solitary, firm, pink papule or plaque measuring 1–3 cm. A small fistula draining clear, bloody, or malodorous fluid may develop (Fig. 119-5A). At puberty, the lesion often grows and becomes increasingly papillated and hyperkeratotic. The most common location is the scalp.[80] Rare presentations include unusual locations such as the trunk, arms, or vulva, and multiple or linearly arranged cutaneous nodules.

The lesion has been seen in conjunction with a wide variety of other adnexal tumors including nevus sebaceous, apocrine nevus, tubular apocrine adenoma, apocrine hidrocystoma, clear cell syringoma, eccrine nevus, verrucous carcinoma, and adenocarcinoma.[80] This tumor has also been noted in a patient with focal dermal hypoplasia due to a novel *PORCN* mutation. Additional apocrine neoplasms seen in this genetic condition include apocrine nevi and apocrine hidrocystomas.[81]

Histopathology. Syringocystadenoma papilliferum presents with papillomatous epidermal invaginations lined with a double layer epithelium composed of basilar cuboidal cells and an inner columnar layer of secretory cells (Fig. 119-5B). A plasma cell rich infiltrate is also characteristic. There is typically a connection between the epithelial invagination and adjacent glands in the dermis.

The malignant counterpart, syringocystadenocarcinoma papilliferum, is characterized by asymmetry, poor circumscription, extension to the deep subcutaneous tissue, and increases in cellularity, cellular atypia, and mitoses.

Prognosis and Clinical Course. Basal cell carcinoma has been reported to occur in as high as 9%

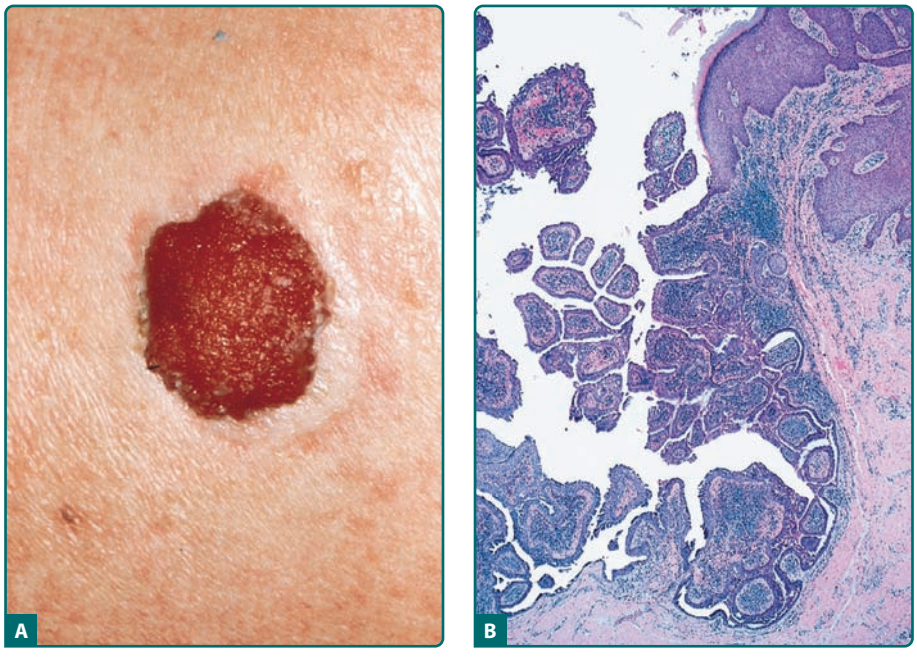

Figure 119-5 Syringocystadenoma papilliferum. **A.** Erosive nodule on the forehead. **B.** Epidermal invagination with papilliferous projections.

of cases, although this has not been corroborated by others.[76,78] Malignant degeneration into syringocystadenocarcinoma papilliferum has been reported, with signs of malignant behavior including rapid growth, ulceration, pain, and pruritus.[82,83] There is a low risk of regional lymph node metastases, while distant metastases have not been reported.

Treatment. Complete surgical excision is recommended given the malignant potential of syringocystadenoma papilliferum, although the benefit of prophylactic excision is unclear. In anatomic areas unfavorable for excision or grafting, carbon dioxide laser may be an alternative option.[84] For syringocystadenocarcinoma papilliferum, excision and Mohs micrographic surgery have been effective treatment options.[82]

CYLINDROMA

Epidemiology. Cylindromas are benign neoplasms that are more common in females and typically present in the third decade.[1,85]

Etiology and Pathogenesis. Cylindromas are thought to originate from apocrine glands although some support an eccrine or follicular origin.[86] Multiple cylindromas are seen in Brooke–Spiegler syndrome, an autosomal dominant condition with variable penetrance and expressivity, that presents with multiple cylindromas, eccrine spiradenomas, and trichoepitheliomas. Inactivating germ-line mutations or loss of heterozygosity in the tumor suppressor gene *CYLD* result in this disfiguring condition.[87] *CYLD* encodes a ubiquitin hydrolase implicated in the negative regulation of cell proliferation through the nuclear factor κB (NF-κB) pathway. Mutations in *CYLD* cause an increased expression of NF-κB, and lead to apoptotic resistance and development of tumors seen in Brooke–Spiegler syndrome.[88] Some also believe that ultraviolet radiation may play a role given that the most common presentation is on sun-exposed areas such as the face and scalp.

Clinical Findings. Cylindromas most commonly present as slow growing, pink, firm, smooth, alopecic, painful nodules ranging in size from 0.5 cm to 6 cm on the scalp. When multiple lesions coalesce on the scalp forming a confluent mass, the term "turban tumors" has been applied (Fig. 119-6A). While they can present as solitary lesions, the familial variant typically manifests with numerous tumors. Aside from pain, conductive deafness and sexual dysfunction have been reported in periauricular and pubic lesions.[86]

Patients with Brooke–Spiegler syndrome present with cylindromas, trichoepitheliomas, spiradenomas, sebaceous nevi, basal cell carcinoma and milia.[89] Incidental associations with cylindroma include polycystosis of the lungs and kidneys, cervical, breast, and parotid carcinomas, and multiple fibromas.[89]

Histopathology. Cylindromas are characterized by dermal aggregates of large epithelial cells with abundant cytoplasm in the center and small basaloid cells in the periphery. The nodules are lined by thick basement membrane-like material, and arranged in a classic jigsaw puzzle pattern (Fig. 119-6B).[90]

Prognosis and Clinical Course. Patients with Brooke–Spiegler syndrome are at risk for basal cell carcinomas, tumors of the salivary glands, and parotid adenomas.[91] Malignant degeneration of cylindromas into cylindrocarcinoma has been reported. Malignant transformation more commonly occurs in cases of multiple tumors, females, and in middle-aged to elderly

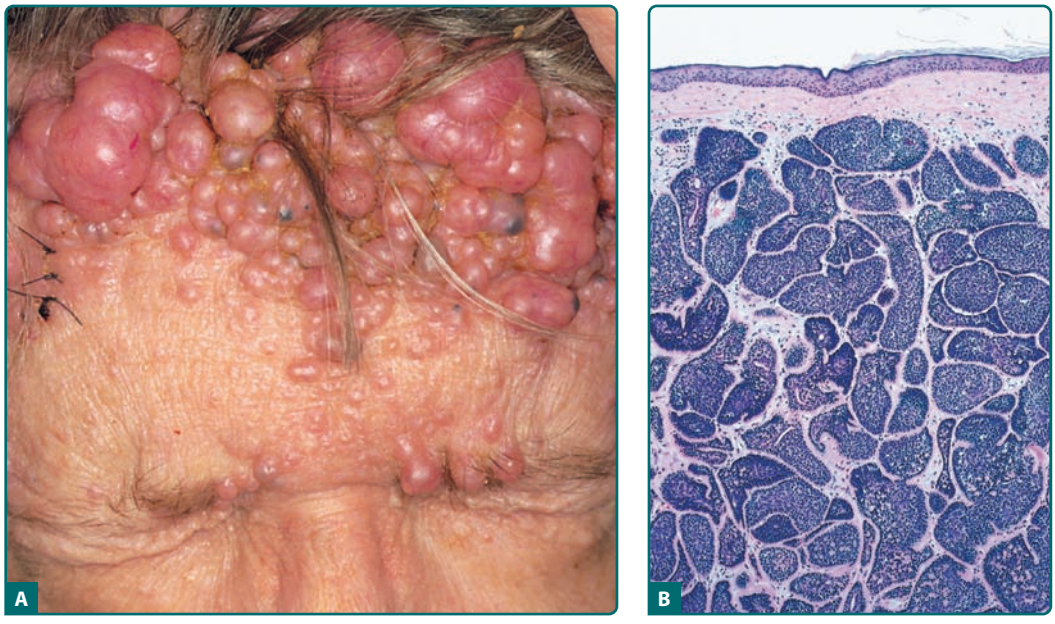

Figure 119-6 **A.** Cylindroma or turban tumor. **B.** Cylindroma with irregularly shaped aggregations of basaloid cells arranged in a "jigsaw puzzle" pattern.

patients.[92] Clinical signs include pink to blue discoloration, ulceration, rapid growth, and bleeding. These are highly aggressive tumors with potential for local destructive growth, metastases, and recurrence.[92,93] Metastases to the lymph nodes, stomach, thyroid, liver, lung, and bones have been reported.

Treatment. The treatment of choice for a cylindroma is surgical excision. In the case of multiple confluent tumors on the scalp, this can pose a challenge. Entire scalp excision carries the risk of significant blood loss requiring a blood transfusion and skin graft failure.[85] Alternative treatments include electrosurgery, dermabrasion, carbon dioxide laser, cryotherapy, and radiotherapy.[85,94] New insights into the role of *CYLD* in the NF-κB pathway has lead to the use of topical salicylic acid in cylindromatosis, with some reports showing complete remission after 6 months.[95]

MALIGNANT LESIONS

APOCRINE ADENOCARCINOMA

Epidemiology. Apocrine adenocarcinoma comprises a rare group of cutaneous adenocarcinomas that show apocrine differentiation. It most commonly presents in middle-aged to elderly males.[96]

Etiology and Pathogenesis. The lesion usually arises de novo; however, there are reports of it developing in association with apocrine adenoma, cylindroma, nevus sebaceus, extramammary Paget's disease, and accessory nipple.[96,97]

Clinical Findings. There is significant variation in the clinicopathologic presentation of apocrine adenocarcinoma. It generally presents as an indolent, slow-growing, rubbery, solid to cystic nodule or tumor ranging in size from 1.5 to 8 cm. The color varies from red to purple, and ulceration may be present.[98] There are rare presentations that can mimic cellulitis.[99] The most common location is the axilla followed by the anogenital skin, regions of high apocrine gland density.[98] Less frequent locations include the scalp, forehead, eyelid, upper lip, chest, nipple, and finger.[96] Patients may complain of pain, restricted range of motion, ulceration, and purulence.[96] Clinically, cutaneous metastases from breast and gastrointestinal cancers must be considered.

Histopathology. Histopathologically, apocrine adenocarcinoma presents with a dermal and/or subcutaneous non encapsulated tumor with infiltrative margins. The carcinoma is composed of large cells with eosinophilic cytoplasm, hyperchromatic nuclei, mitotic figures, and decapitation secretion. The epithelial component shows variable papillary, cribiform or trabecular, and solid patterns.[100–102] Signet ring cells and pagetoid spread have been reported.[100]

Prognosis and Clinical Course. Apocrine adenocarcinoma is a locally invasive neoplasm with potential for regional lymph node metastases. Despite its aggressive behavior, mortality is relatively low.[98,100] Local recurrence after wide local excision has been reported at 27.5%.[96] Over 40% of reported cases presented with nodal metastases at initial diagnosis. Distant metastases to the lungs, bones, brain, and parotid gland have been reported.[96]

Treatment. The treatment of choice is wide local excision with clear margins. Some believe that there is a role for sentinel lymph node biopsy and nodal dissection given the high rate of regional nodal metastases.[96] Adjunctive chemotherapy and radiation have

been used. In some cases, the presence of steroid receptors in the tumor has lead to the use of tamoxifen.[100]

ECCRINE TUMORS

Eccrine glands are widely distributed in the skin. Therefore, eccrine tumors have a wider anatomic distribution than apocrine tumors. Histologically, eccrine tumors comprise a large spectrum of lesions with differentiation toward various portions of the normal eccrine apparatus, including intraepidermal (acrosyringium), dermal, and secretory ducts. The distinguishing feature is the tendency to form lumina with flattened epithelium. Distinction from apocrine tumors is not always straightforward, as decapitation secretion can be observed in certain tumors traditionally classified as "eccrine." Similar to apocrine tumors, eccrine tumors are typically benign, but possess the ability to degenerate into malignant lesions.

HYPERPLASIAS AND HAMARTOMAS

ECCRINE HIDROCYSTOMA

Epidemiology. Eccrine hidrocystomas are common lesions found in middle-aged to elderly patients, predominantly in females.[103]

Etiology and Pathogenesis. Eccrine hidrocystoma is a benign proliferation of eccrine glands.

Clinical Findings. There are two clinical variants of eccrine hidrocystoma. Robinson first described multiple eccrine hidrocystomas in 1893.[104] The solitary type was first reported by Chernosky and Smith in 1973.[105] The lesions are typically translucent, skin-colored or blue, dome-shaped, cystic papules on the head and neck. Multiple lesions clustered in the periorbital region may be a sign of ectodermal dysplasia.[103] Multiple lesions have also been associated with warm climates, hyperhidrosis, and Graves disease.[106]

Histopathology. The cyst lining is a double layer of flattened epithelium lacking decapitation secretion. Eosinophilic contents may be seen.

Prognosis and Clinical Course. Eccrine hidrocystoma follows a benign course.

Treatment. Solitary lesions can be surgically excised. Destructive methods such as electrodessication, curettage, laser ablation, and pulsed dye laser therapy have been employed but are often associated with scarring. Botulinum toxin injections have been used with success.[103]

ECCRINE NEVUS

Epidemiology. Eccrine nevi, first described in 1976, encompass a variety of rare benign eccrine hamartomas that appear in childhood and adolescence.[107] Some lesions may be congenital, whereas others present at advanced ages.[108]

Etiology and Pathogenesis. Eccrine nevi originate from eccrine glands. Several distinct forms exist. The two main subtypes are the rare pure eccrine nevus and the common eccrine angiomatous hamartoma. Other presentations include the mucinous eccrine nevus and porokeratotic eccrine ostial and dermal duct nevus (PEODDN).[109]

Clinical Findings. The clinical presentation of eccrine hamartomas is variable depending on the subtype. Pure eccrine nevi classically present with a solitary, well-circumscribed, hyperhidrotic plaque with little to no epidermal change. Hyperhidrotic episodes are triggered by temperature, stress, and exercise. The most common location is the forearm (50%) followed by the back and trunk.[109,110] Rare presentations include hyperpigmented patches, linear lesions, centrally depressed plaques, and scaly borders.[110]

Eccrine angiomatous hamartomas (EAH) are more common and are often present at birth. They present with a solitary or multiple flesh-colored, red, or blue–brown nodules or plaques on the extremities, especially the legs. EAH can be painful.[109]

Mucinous eccrine nevi are extremely rare lesions that present with nodules or plaques with hyperhidrosis.[109,111] Porokeratotic eccrine ostial and dermal duct nevus (PEODDN) is a rare disorder of keratinization involving the intraepidermal eccrine duct or acrosyringium.[112] PEODDN presents with congenital punctuate keratoses on the hands and feet, and has been associated with deafness, developmental delay, seizures, scoliosis, anhidrosis, alopecia, onychodysplasia, and palmoplantar involvement.[113] Lesions are typically linear and follow the lines of Blaschko.

There are rare reports of coexistence with other cutaneous lesions such as clear cell syringoma and neurofibromatosis I.[114]

Histopathology. There is an increase in the number or size of normal eccrine glands. EAH also shows an increase in the number of capillaries. Mucinous eccrine nevi are characterized by large mucin deposits surrounding eccrine glands. PEODDN demonstrates parakeratotic coronoid lamellae over the eccrine ostia.[109]

Prognosis and Clinical Course. These lesions are benign. Indications for treatment include pain and excessive hyperhidrosis.

Treatment. The treatment of choice is surgical excision. Often, the lesions are quite large and surgery is not feasible. Alternative therapies include aluminum chloride, systemic and topical anticholinergic agents, clonazepam, antidepressants, and botulinum toxin injections.[108] PEODDN has been treated with the carbon dioxide laser and topical retinoids.[115]

SYRINGOMA

Epidemiology. Syringomas are common benign neoplasms most frequently seen in adult females. There is an increased frequency in Down's syndrome, with 18% of patients exhibiting this cutaneous sign.

An increased frequency has also been observed in Marfan's syndrome, Ehlers Danlos, and Nicolas balus syndrome. An eruptive form most commonly presents in adolescent females. The clear cell variant has been linked to diabetes.[116]

Etiology and Pathogenesis. Syringomas derive from the intradermal eccrine duct or acrosyringium. Local factors, including ductal obstruction by keratin plugs leading to ductal proliferation, may play a role in pathogenesis.[117,118] The etiology of eruptive syringomas is unclear. It has been hypothesized that these eruptive lesions demonstrate reactive eccrine gland proliferation following an inflammatory condition.[119]

Clinical Findings. Syringomas present with numerous, small, firm, smooth, flesh-colored or yellowish papules on the face, especially the lower eyelids, of adult females (Fig. 119-7A). Other sites, such as the scalp, axillae, abdomen, forehead, penis, and vulva can be affected. Four clinical variants have been described: a localized form, lesions associated with Down's syndrome, a generalized eruptive form, and a rare autosomal dominant familial form.[120,121]

The localized form traditionally occurs in the periorbital region, and can also present with scalp alopecia, a unilateral nevoid appearance, large lesions, and genital lesions.[122] Genital syringomas can be remarkably pruritic, and are often mistaken for genital warts.[123]

Eruptive syringomas, first described by Jacquet and Darier in 1987, present as a sudden onset of successive crops of numerous disseminated syringomas on the upper trunk, especially the anterior neck, chest, trunk, axilla, upper medial arms, and periumbilical region of adolescent females.[124]

Histopathology. Syringomas are well-circumscribed, symmetric collections of small tadpole-shaped tubular structures in the superficial dermis. These tubules are lined by a single or double layer of bland, monomorphic, cuboidal epithelial cells (Fig. 119-7B). Clear cell syringomas are notable for abundant cytoplasm. The tubular structures are surrounded by thickened collagen bundles. If the biopsy specimen is very superficial, microcystic adnexal carcinoma should be considered in the differential diagnosis.

Treatment. Numerous destructive methods have been described for the treatment of syringomas, including excision, dermabrasion, laser resurfacing, trichloroacetic acid, cryotherapy, and electrosurgery.[125,126] Unfortunately, these are often associated with significant scarring and recurrence. Topical and oral retinoids, and topical atropine have also been utilized with suboptimal results.[117] The Q-switched Nd:Yag laser has been used after temporary tattooing and shows promising results.[126]

POROMA

Epidemiology. Poromas were first reported by Pinkus in 1956, and represent 10% of all sweat gland tumors.[127,128] Poromas can occur in all age groups, but onset is usually over the age of 40.[129]

Etiology and Pathogenesis. Poromas represent a group of benign eccrine tumors composed of cuticular and poroid cells similar to those seen in the eccrine acrosyringium. Poromas are classified based on the location relative to the epidermis. Intraepidermal lesions are referred to as hidroacanthoma simplex. Poromas comprise lesions that span the epidermis and dermis, whereas dermal duct tumors exist entirely in the dermis. The etiology is unclear, but occurrence after trauma and radiation has been reported.[128–130]

Clinical Findings. Hidroacanthoma simplex presents as a solitary hyperkeratotic plaque on the extremities of middle-aged and elderly females. Eccrine poromas classically present as a solitary, slow growing, flesh-colored or bright red, pruritic, painful, pedunculated papule or nodule on the palms and soles of adults. There is a predilection for the sole and sides of the feet, followed by the hands, fingers, head, neck, and trunk.[131] A distinct feature is a cup-shaped shallow depression from which the tumor protrudes.[14] While poromas tend to be solitary, multiple lesions can exist. When hundreds of poromas are present, the condition is denoted "poromatosis" and is observed in patients with hidrotic ectodermal dysplasia.[132] Dermal duct tumors present with deep nodules on any part of the body.

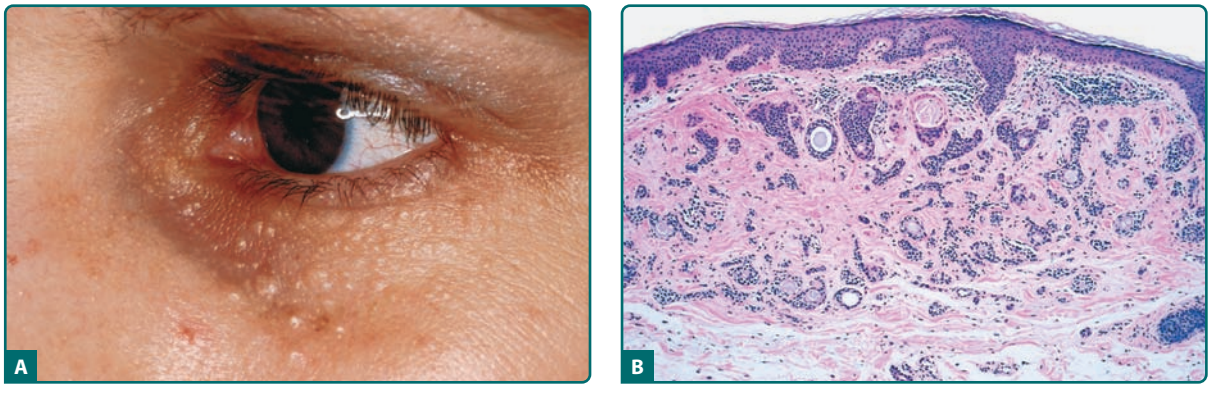

Figure 119-7 Syringoma. **A.** Multiple, small papules on the periorbital skin of a young woman. **B.** Solid, tubular, and cystic structures in the upper dermis. Note "tadpole"-like morphology of tumor lobules.

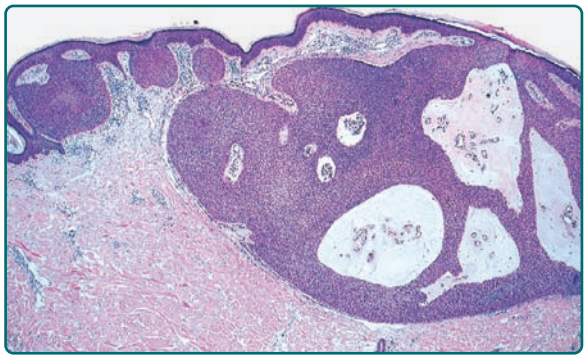

Figure 119-8 Eccrine poroma. Nodular aggregations of basaloid cells extend from the epidermis into the superficial dermis.

Histopathology. Hidroacanthoma simplex displays sharply demarcated aggregations of cuboidal to ovoid cells in the epidermis. Eccrine poromas reveal aggregations of uniform basaloid cells that radiate from the basal layer of the epidermis into the dermis (Fig. 119-8). Dermal duct tumors consist of several sharply circumscribed dermal nodules consisting of poroid cells with frequent ductal structures

Prognosis and Clinical Course. Eccrine poromas rarely progress to porocarcinoma, although porocarcinoma is the most common form of sweat gland carcinoma.[14] Clinically, porocarcinoma presents as a blue–black nodule or infiltrated plaque on the legs, feet, face, thighs, and arm. Interestingly, there is rare involvement of the palms and soles. The average age of onset is 75 years old, although there are reports as early as 12 years of age.[7] Porocarcinoma evolving from a poroma is characterized by rapid growth up to 10 cm, bleeding, and ulceration. There is a propensity to form multiple cutaneous metastases. Regional nodal metastases can occur in 20% of cases, but distant metastases are extremely rare. Porocarcinoma has a tendency to recur locally with a 20% recurrence rate after excision. Mortality is 65% if there are positive nodal metastases. Survival with distant metastases ranges from 5 to 24 months.[133]

Treatment. Mohs micrographic surgery is evolving as the treatment of choice for localized disease with a lower recurrence rate than local excision.[134,135]

ECCRINE SYRINGOFIBROADENOMA

Epidemiology. Eccrine syringofibroadenoma was first described by Mascaro in 1963.[136] It presents in older adults particularly in the seventh to eighth decades.[136–138]

Etiology and Pathogenesis. Eccrine syringofibroadenoma originates from or is differentiating toward the acrosyringium or eccrine dermal duct.[138] There is controversy as to whether the lesion is a hamartoma, reactive hyperplasia, or a true neoplasm. The lesion has been classified into five distinct subtypes: multiple lesions associated with an ectodermal dysplasia, multiple lesions with no additional cutaneous pathology, unilateral linear lesions, solitary lesions, and reactive lesions.[139] Reactive lesions have been reported in association with erosive lichen planus, trauma due to diabetic neuropathy, elephantiasis, bullous pemphigoid, burn scars, and peristomal skin.[138,140] Human papillomavirus 10 may also play a role in the development of eccrine syringofibroadenomas.[141]

Clinical Findings. The clinical presentation is nonspecific and variable. Eccrine syringofibroadenomas can range from solitary lesions to multiple papules, plaques, and nodules in a symmetrical and linear or nevoid pattern. The most common site is the limb.[137] Additional locations include the face, torso, buttocks, and nail.[138]

Eccrine syringofibroadenomas are observed in ectodermal dysplasia, and specifically, Clouston' syndrome. Clouston's syndrome is an autosomal dominant condition with progressive hyperkeratosis of the palms and soles, patchy alopecia, nail dystrophy, normal teeth, and normal sweating. It results from mutations in the *connexin 30* or *GJB6* gene.[141]

Histopathology. Unlike the variety of clinical presentations, the histologic picture is quite consistent. There are multiple anastomosing cords of benign epithelial cells surrounded by a loose fibrovascular stroma. The epithelial cords demonstrate ductal differentiation. Occasional luminal eccrine ducts are noted within the anastomosing cords.

Prognosis and Clinical Course. The course of eccrine syringofibroadenomas is typically benign, although malignant transformation into squamous cell carcinoma or eccrine syringofibroadenocarcinoma has been reported.[137,138] This occurrence is extremely rare and generally arises in elderly male patients. Signs of malignancy include ulceration, rapid growth, and crusting.

Treatment. Given the malignant potential, complete surgical excision is recommended. If the lesions are too numerous or large for excision, the pulse dye laser has shown promising results.[138]

ECCRINE SPIRADENOMA

Epidemiology. Eccrine spiradenoma is a benign adnexal tumor first described by Kersting and Helwig in 1956.[142] It is relatively common, and presents in young and middle-aged adults between age 15 and 35. Rare familial cases have been reported.[7]

Etiology and Pathogenesis. Eccrine spiradenoma derives from the intradermal straight eccrine duct.

Clinical Findings. Eccrine spiradenoma typically appears as a solitary, slow growing, 1–2 cm, red–brown deep-seated nodule (Fig. 119-9A). There may be a slightly bluish hue, and paroxysmal pain is a distinct trait. Rare atypical variants include large lesions, vascular lesions, and multiple lesions arranged in a linear or zosteriform configuration.[143–145] There is a predilection for the ventral

Figure 119-9 Spiradenoma. **A.** Reddish-brown tumor on the scalp. **B.** Tumor cells arranged in a trabecular pattern. Note hyaline material in the background.

upper trunk.[7] Eccrine spiradenoma has been observed growing within a nevus sebaceus.[146] These tumors are also seen in the setting of Brooke–Spiegler syndrome, an autosomal dominant condition with numerous cylindromas, eccrine spiradenomas, and trichoepitheliomas due to an inactivating mutation in the *CYLD* gene.

Histopathology. Biopsy reveals one or several well-circumscribed basophilic nodules in the dermis and/or subcutaneous tissue. Epithelial aggregates are arranged in sheets and cords or in a trabecular pattern. There are two distinct cell populations: small darkly staining basaloid cells rimming the periphery and larger cells with a pale nucleus in the center of the lesion. Tubular or cystic structures are noted within the epithelial aggregations. The basaloid cells are often arranged in rosettes. PAS-positive hyaline material is noted within the tumor (Fig. 119-9B).

Prognosis and Clinical Course. Malignant transformation to eccrine spiradenocarcinoma is extremely rare.[147] Long-standing lesions that rapidly enlarge, bleed, ulcerate, or change color should raise the suspicion of malignancy. The average age of presentation is 62. Lesions tend to present on the trunk and extremities and achieve an average size of 7.5 cm. Metastatic disease is most frequently seen in the regional lymph node basin, but can also be seen in the lung, liver, brain, spinal cord, bone, and parotid gland. Metastases can be fatal, and overall mortality has been reported between 20% and 40%.[148]

Treatment. The treatment of choice for eccrine spiradenoma is surgical excision with clear margins. There is no satisfactory treatment for pain. For spiradenocarcinoma, wide local excision is recommended. The role of sentinel lymph node biopsy, radiation, and tamoxifen for estrogen-receptor positive tumors is unclear.[149]

PAPILLARY ECCRINE ADENOMA

Epidemiology. Papillary eccrine adenoma is a rare benign adnexal tumor. While it can present from childhood to advanced age, the mean age is in the fifth decade. It is more common in women.[150] An African-American predilection has been noted.[151]

Etiology and Pathogenesis. Papillary eccrine adenomas exhibit eccrine differentiation. There are architectural similarities to the tubular apocrine adenoma.[4] Some classify these two entities under the heading of papillary tubular adenoma.[152]

Clinical Findings. It most commonly presents as a solitary, firm, flesh-colored nodule on the distal extremity. The size varies from 0.5 to 4 cm in diameter.[152]

Histopathology. Microscopic examination reveals a well-circumscribed, nonencapsulated dermal nodule comprised of numerous dilated tubules surrounded by a fibrous stroma. The tubules are lined with an outer layer of flattened epithelial cells and an inner layer of cuboidal or columnar cells with intraluminal papillary projections. The lack of atypia and mitoses differentiates this benign entity from aggressive digital papillary adenomas and adenocarcinomas.

Prognosis and Clinical Course. Papillary eccrine adenoma typically follows a benign clinical course with rare recurrence and no reports of metastatic disease.

Treatment. The treatment of choice is surgical excision with clear margins. Mohs micrographic surgery

is an effective therapeutic option, given the potential ability to preserve sensory and motor function of the hand.[152]

NODULAR HIDRADENOMA

Epidemiology. Nodular hidradenoma, also known as eccrine acrospiroma, is a benign adnexal tumor that presents most commonly in middle-aged and elderly females.[7,153]

Etiology and Pathogenesis. Nodular hidradenoma shows features of eccrine and apocrine differentiation, although it is typically classified as an eccrine tumor. It is also closely related to poroma, and both entities are often regarded together as acrospiromas.

Clinical Findings. Nodular hidradenoma usually presents as a slow-growing, solitary, firm, flesh-colored or red to blue, mobile, solid or cystic nodule that measures 1–2 cm in diameter. The most common locations are the scalp, face, and trunk (Fig. 119-10A).[7] Atypical presentations include childhood onset, large lesions, painful tumors, or rapidly growing lesions.

Histopathology. Nodular hidradenoma presents as a well-circumscribed, nonencapsulated nodular, solid, or solid-cystic lesion in the dermis and occasionally extends to the subcutaneous fat. Ductal differentiation is present. The closely packed tumor cells have a biphasic population with small dark polygonal cells and larger clear cells (Fig. 119-10B). Features such as poor circumscription, large size, solid sheet-like growth pattern, necrosis, and vascular and lymphatic invasion, pleomorphism, and high mitotic rate are suggestive of malignant nodular hidradenoma or hidradenocarcinoma.[154]

Figure 119-11 Hidradenocarcinoma. Large ulcerated tumor.

Prognosis and Clinical Course. Despite local excision, nodular hidradenoma has a recurrence rate of 12% if not fully excised.[6] Rarely, nodular hidradenoma can degenerate into hidradenocarcinoma (Fig. 119-11). Most hidradenocarcinomas arise de novo. The prognosis for hidradenocarcinoma is poor, with a 50% recurrence rate and a 60% metastatic rate. The prognosis for a 5-year disease free survival is only 30%. The most common site of metastases is the regional lymph nodes. Hematogenous spread to distant lymph nodes, bones, viscera, and pleura has been reported.[155]

Treatment. The treatment of choice for nodular hidradenoma is surgical excision with clear margins. Hidradenocarcinoma should be treated aggressively with wide local excision of 3–5 cm. Moh micrographic surgery has also been employed for margin control in irregular tumors.[156,157] Sentinel lymph node biopsy

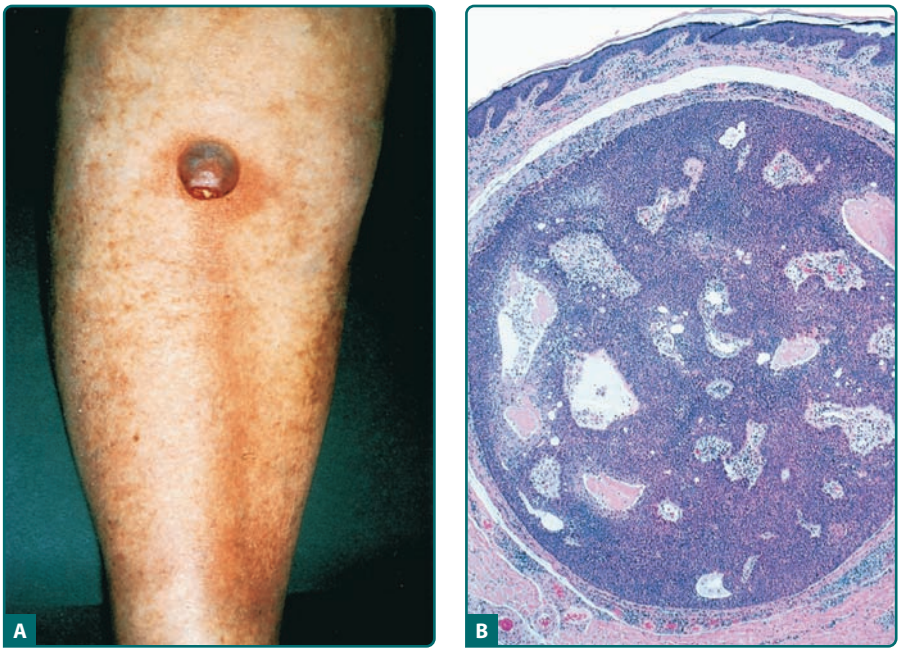

Figure 119-10 Hidradenoma. **A.** Dome-shaped nodule on the leg. **B.** Well-circumscribed, dermal nodule composed of two cell types.

has been advocated by some authors, but there is no known benefit.

CHONDROID SYRINGOMA

Epidemiology. Chondroid syringoma, or mixed tumor of the skin, is an uncommon benign appendageal tumor of mixed differentiation that was first described by Hirsch and Helwig in 1961.[158] It is generally observed in middle-aged and elderly males.[159]

Etiology and Pathogenesis. Chondroid syringoma comprises a group of adnexal neoplasms with ductal differentiation and a fibromyxochondroid stroma. The etiology of chondroid syringoma is unclear. It displays features of both folliculosebaceous-apocrine and eccrine differentiation. It is analogous to mixed tumor of the salivary gland.

Clinical Findings. Clinically, chondroid syringoma presents with slow-growing, painless, nonspecific, firm nodules on the head and neck, especially the nose, cheeks, and upper lip (Fig. 119-12A).[6] It can also be seen on the upper trunk, axilla, and genital regions. Lesions range in size from 5 to 30 mm, although lesions as large as 7 cm have been reported.[160]

Histopathology. Chondroid syringoma presents with a circumscribed dermal nodule with bland epithelial cells arranged in cords, ducts and tubules, embedded in a myxoid-cartilaginous stroma (Fig. 119-12B). Eccrine variants exhibit tubules with a small lumen lined with a single row of cuboidal cells. The apocrine variant is lined with two layers of epithelial cells and displays decapitation secretion.

Prognosis and Clinical Course. Chondroid syringomas very rarely transform into malignant chondroid syringomas. The malignant variant tends to present on the extremities and trunks of females, unlike its benign counterpart that predominates on the head and neck of males. The average age of onset is 48 years old. Malignant chondroid syringoma is associated with a nearly 50% metastatic rate to the lymph nodes, bone, and lung.[161]

Treatment. The treatment of choice for chondroid syringoma is complete surgical excision. Electrodessication, dermabrasion, and vaporization with argon or carbon dioxide laser have been tried with variable results.[162] Malignant chondroid syringoma requires a wide local excision with at least a 1 cm margin and possible adjuvant radiation.[162]

MALIGNANT NEOPLASMS

AGGRESSIVE DIGITAL PAPILLARY ADENOMA AND ADENOCARCINOMA

Epidemiology. Aggressive digital papillary adenoma (ADPA) and adenocarcinoma (ADPAca) are rare eccrine gland tumors that present primarily in Caucasian males in their fifties. There are three case reports of this condition occurring in children.[163]

Etiology and Pathogenesis. The origination of ADPA and ADPAca is controversial. While these entities have traditionally been classified as eccrine neoplasms, decapitation secretion and sebaceous differentiation have been noted in some cases of ADPAca. However, since most lesions present acrally, an anatomic site rich in eccrine units and devoid of apocrine glands, the most likely derivation is eccrine. ADPA and ADPAca exist on a spectrum, where ADPAca represents a more aggressive disease with metastatic potential, although ADPA can also behave in a destructive manner. This entity is not associated with the benign papillary eccrine adenoma.[163–165]

Clinical Findings. These tumors present as a solitary, firm, tan or pink, rubbery nodule on the acral extremities. Specifically, the most common location is the volar surface of the skin between the nail bed

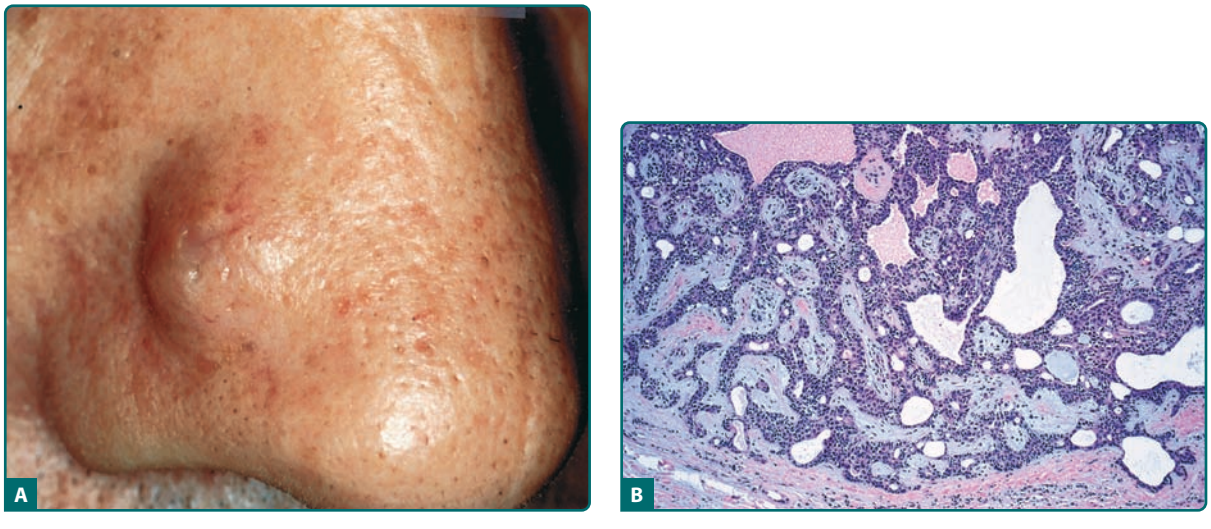

Figure 119-12 Chondroid syringoma. **A.** Chondroid syringoma on the nose. **B.** Solid cords and tubular structures in a background of a fibromyxoid stroma.

and distal interphalangeal joint.[164] While the lesions are generally asymptomatic, patients may experience pain, bleeding, ulceration, and rarely, limited range of motion.

Histopathology. Histologically, these lesions are multinodular dermal and/or subcutaneous proliferations of ductal and glandular structures with focal solid and cribriform zones. Ductal structures exhibit cystic dilatations, in which several papillary projections are present. A fibrocollagenous stroma surrounds the epithelial components. Atypia, necrosis, and invasion of bone and vasculature are signs of an aggressive tumor.

Prognosis and Clinical Course. ADPA and ADPAca are highly aggressive tumors with frequent local recurrence and metastases. The local recurrence rate is nearly 50% after surgical excision, with recurrence occurring as early as two months to 9 years.[163–165] Metastases occur in approximately 15% of cases, with the most common site being the lung.[164] Other sites of metastases include lymph nodes, brain, kidney, bone, or retroperitoneum.[165]

Treatment. ADPA and ADPAca should be treated aggressively with excision or digital amputation. Metastatic disease has been treated with chemotherapy with variable results. Annual monitoring for metastatic disease, including physical examination and chest X-ray, is recommended for 10 years after diagnosis.[165]

MUCINOUS ECCRINE CARCINOMA

Epidemiology. Mucinous eccrine carcinoma is a rare low-grade eccrine tumor that presents in elderly males. It is most commonly seen in Caucasian and African-American males.[6,166]

Etiology and Pathogenesis. Mucinous eccrine carcinoma originates from the deepest portion of the eccrine duct.[167] It is analogous to mucinous carcinoma of the breast, and may express estrogen and progesterone receptors.

Clinical Findings. Mucinous eccrine carcinoma typically presents with an asymptomatic, round, elevated, reddish, ulcerated mass. It most commonly occurs on the head and neck in 75% of cases, with 40% of cases on the eyelid. There is a propensity for sudden enlargement.[168] Metastatic mucinous gastrointestinal cancers must be excluded.

Histopathology. Histopathologically, mucinous eccrine carcinoma is a well-demarcated, lobular, dermal tumor with frequent extension into the subcutaneous tissue. It consists of PAS-positive, diastase-resistant multilocular pools of mucin, in which nests of bland polygonal cells are embedded. There are rare mitoses.

Prognosis and Clinical Course. This tumor has a favorable prognosis with low metastatic potential. While regional metastases are 15% and distant metastases are 7%, the local recurrence rate is much higher at 36%.[167,169]

Treatment. The treatment of choice is surgical excision. Wide local excision is associated with high recurrence rates, even with 1–2 cm margins.[169] Mohs micrographic surgery has been attempted with good results.[166,168,170]

MICROCYSTIC ADNEXAL CARCINOMA

Epidemiology. Microcystic adnexal carcinoma (MAC), also known as sclerosing sweat duct carcinoma or syringomatous carcinoma, is a rare adnexal tumor first described by Goldstein in 1982.[171] It is typically seen in middle-aged to elderly patients, with an average age in the seventh decade. Some reports reveal a slight female predilection.[172] While there is a Caucasian predominance, there are reports in African-American individuals.[173]

Etiology and Pathogenesis. MAC shows features of eccrine, apocrine, and follicular differentiation. Risk factors include immunosuppression and a prior history of therapeutic radiation.[6]

Clinical Findings. MAC presents as a slow-growing, firm, indurated plaque or nodule with indistinct borders on the face, especially the upper lip. The tumor is generally asymptomatic, but numbness, burning, anesthesia, and paresthesia have been noted.[7] The most common location is the head and neck with nearly 75% of lesions occurring in that region.[172] There is an increased prevalence on the left side versus the right side of the face.[174] The upper lip is nine times more common than the lower lip, unlike squamous cell carcinoma.[175] MAC has also been reported to occur on the nipple, axilla, vulva, external auditory canal, extremities, and perianal skin.[173,176] The average tumor size in 15 mm.

Histopathology. MAC is a poorly circumscribed dermal tumor embedded in a desmoplastic stroma that can extend into the subcutaneous tissue and muscle. Superficially, the tumor is composed of ducts, keratin horn cysts, and small cords of basaloid cells, resembling syringoma. The deeper component exhibits smaller strands and cystically dilated tubules and ductal structures. There is a lack of cytologic atypia. Perineural invasion is common and extensive. The histologic differential diagnosis includes syringoma, morpheaform basal cell carcinoma, and desmoplastic trichoepithelioma.

Prognosis and Clinical Course. MAC is a deeply infiltrative and locally aggressive tumor with significant morbidity. Local recurrence is common, with a recurrence rate in 50% of cases. Recurrence has been reported to occur several years after initial diagnosis. Local recurrence is attributed to the high rate of perineural invasion, seen in 17%–60% of cases. While recurrence is common, metastases are rare at a rate of 2.2%. Mortality is 0.4%.[177]

Treatment. The treatment of choice is Mohs micrographic surgery with a recurrence rate between 0% and 12%.[174,177–179] Wide local excision is associated with

recurrence rates of 50%. Radiation does not have an effect on survival, and may even lead to conversion into a more histologically and clinically aggressive tumor.[179]

FOLLICULAR NEOPLASMS

Follicular tumors demonstrate histopathologic features that resemble different portions of a normal hair follicle, including the hair germ, matrix, and outer root or trichilemmal sheath. Unlike apocrine and eccrine tumors that generally have a malignant counterpart, follicular tumors are generally benign with a rare chance of degeneration into a malignant lesion. Pilomatricoma and trichoblastoma have well-documented transformation into carcinomas. Malignant proliferating trichilemmal cysts and trichilemmal carcinoma are thought to be variants of squamous cell carcinoma, as opposed to true adnexal carcinomas.

HAMARTOMAS AND HYPERPLASIAS

HAIR FOLLICLE NEVUS

Epidemiology. The hair follicle nevus, also known as congenital vellus hamartoma, is a rare lesion present in all age groups. Often it is apparent at birth.[180]

Etiology and Pathogenesis. Some believe that the hair follicle nevus is a variant of trichofolliculoma or accessory tragus.[181]

Clinical Findings. Hair follicle nevus presents as a dome-shaped, skin-colored papule or nodule from which hair protrudes. It is most common on the hair-bearing surfaces, including the face and periauricular region.[180,182] Linear arrangement of multiple papules has been observed. Some authors also advocate that the faun tail, palmoplantar follicles, and Becker's nevus are variants of the hair follicle nevus.[183] Rare associations include ipsilateral alopecia, leptomeningeal angiomatosis, multiple epidermal nevi, and frontonasal dysplasia.[180]

Histopathology. Numerous closely packed mature vellus follicles confines to a focal well circumscribed area in the upper dermis. Follicles are surrounded by a prominent sheath of perifollicular connective tissue, which in turn are surrounded by clefts. Sebaceous lobules may be present.

Prognosis and Clinical Course. The relative size of the lesion decreases with time as the child grows. Therefore, excision may be deferred as it becomes a less prominent cosmetic issue over time.

Treatment. Treatment is not necessary. Surgical excision is effective for cosmetic purposes.

BASALOID FOLLICULAR HAMARTOMA

Epidemiology. Basaloid follicular hamartoma (BFH), also known as benign follicular hamartoma, is a rare follicular neoplasm that can be congenital or develop during adulthood.

Etiology and Pathogenesis. BFH may be related to dysregulation of the PTCH signaling pathway, similar to basal cell carcinomas.[184]

Clinical Findings. Clinically, there are five variants of BFH: a solitary 2–3 mm papule, a localized plaque with alopecia, linear or blaschkoid, generalized dominantly inherited familial type, and generalized papules associated with myasthenia gravis and diffuse alopecia.[184] The familial form presents early in childhood, and can also be associated with milia, comedones, hyperpigmented papules, hypotrichosis, hypohidrosis, and palmar pits. Other systemic associations include systemic lupus erythematosus and cystic fibrosis.[185,186] There are reports of circulating autoantibodies, namely antinuclear and antiacetylcholine receptor antibodies.

Histopathology. Histopathologically, there are anastomosing strands of basaloid cells with numerous epidermal connections. Central areas of epithelial aggregations occasionally reveal cells with a squamoid appearance. Features of follicular differentiation, including horn cysts, rudimentary germs, and follicular papillae, are variably present.

Prognosis and Clinical Course. BFH are benign lesions. Patients may have an increased risk of basal cell carcinoma, although it does not arise within the hamartoma. This association may be related to dysregulation of the patched (PTCH) signaling pathway.

Treatment. The treatment of choice is surgical excision.

BENIGN NEOPLASMS

DILATED PORE OF WINER AND PILAR SHEATH ACANTHOMA

Epidemiology. Dilated pore of Winer and pilar sheath acanthoma share the commonality of a central pore, and histologically, exhibit a large cystic space with squamous epithelium that is continuous with the surface epidermis, and filled with keratinaceous material. The dilated pore was described by Winer in 1954, and presents on the face of elderly males.[187] In 1978, the pilar sheath acanthoma was described as a separate entity observed on the upper lip of middle aged and elderly individuals.[188]

Etiology and Pathogenesis. There is a debate as to whether these entities are follicular cysts versus benign neoplasms.[3]

Clinical Findings. The dilated pore of Winer presents as a solitary, open comedo on the head and neck of elderly males.[189] It may arise in a background of cystic acne or actinic damage. It lacks palpable induration. The pilar sheath acanthoma is a solitary, open comedo filled with keratin on the upper lip.[188]

Histopathology. Histologically, the dilated pore reveals a single or several contiguous, markedly, dilated infundibula in upper dermis. The epithelial

lining reveals focal acanthosis and finger-like projections into the surrounding dermis. Dilated infundibula contain cornified cells arranged in basket-weave and laminated patterns. Heavy pigmentation of the epithelium can be observed. The pilar sheath acanthoma differs by exhibiting a larger more irregular branching cystic cavity. Rather than the thin projections seen in dilated pore, there are multiple lobulated masses of cells radiating from the central cavity into the dermis.

Prognosis and Clinical Course. These are benign entities.

Treatment. Treatment is not necessary. Surgical excision can be performed for cosmetic purposes.

TRICHOFOLLICULOMA

Epidemiology. Trichofolliculoma is a benign follicular neoplasm that presents at any age, but is most commonly seen in adults.

Etiology and Pathogenesis. Trichofolliculoma displays differentiation toward the hair follicle with intermediate differentiation between a hair follicle nevus and a trichoepithelioma.

Clinical Findings. Trichofolliculoma classically presents as a small dome-shaped nodule measuring 5 mm on the face, especially the nose or scalp. A fine tuft of hairs protrudes from a central pore (Fig. 119-13). Trichofolliculoma has been reported in association as a collision tumor with basal cell carcinoma.[190]

Histopathology. Trichofolliculoma has a characteristic histopathologic appearance with one or more central large dilated follicles with radiating secondary follicles. The secondary follicles display varying degrees of differentiation ranging from immature rudimentary matrix to well-formed follicles with papillae, matrix, trichohyalin granules, and fine hairs. If prominent sebaceous lobules are observed, the lesion is denoted a sebaceous trichofolliculoma.[191]

Figure 119-13 Trichofolliculoma. Papule on the forehead with a hair emanating from its central pore.

Prognosis and Clinical Course. Trichofolliculomas are benign. However, a single case of perineural invasion has been documented in the literature.[192]

Treatment. The treatment of choice is surgical excision.

FIBROFOLLICULOMA, TRICHODISCOMA, AND FIBROUS PAPULE

Epidemiology. Fibrofolliculoma, trichodiscoma, and fibrous papule or perifollicular fibroma are clinically indistinct from one another, and likely are on the same spectrum of follicular proliferations with differentiation toward the mantle. They also possess a specialized periadventitial dermis that surrounds the upper hair follicle.[3] These lesions are rare, appear in adulthood, and are seen in multiplicity together in the Birt–Hogg–Dube syndrome.

Etiology and Pathogenesis. These three lesions represent different stages of differentiation toward the follicular mantle.[193] The folliculin gene, a tumor suppressor, is mutated in Birt–Hogg–Dube syndrome and may play a role in the pathogenesis of these follicular tumors.

Clinical Findings. Fibrofolliculomas and trichodiscomas present as multiple small whitish papules measuring 2–4 mm on the head and neck, upper trunk, and arms. They are rarely solitary. Fibrous papules are solitary papules or multiple dome-shaped, skin-colored, pigmented or reddish lesions on the face, especially the perinasal area.[3] Multiple fibrous papules are seen in tuberous sclerosis, known as adenoma sebaceum, or Birt–Hogg–Dube syndrome.[194]

Multiple familial lesions are seen in Birt–Hogg–Dube syndrome, an autosomal dominant condition due to a mutation in folliculin. Although the function of folliculin is not entirely clear, it has been linked to the mammalian target of rapamycin (mTOR) pathway.[195] Cutaneous lesions include fibrofolliculomas, trichodiscomas, fibrous papules, and acrochordons. Patients have a predisposition to colonic polyposis, spontaneous pneumothorax, and renal cell carcinoma. Renal cancer risk is higher in males. The overall incidence of renal cell carcinoma, specifically renal oncocytomas and chromophobe renal carcinomas, is 12% in adults over the age of 40. Eighty percent of patients have pulmonary cysts, and nearly 25% are at risk of spontaneous pneumothorax, which typically presents at a younger age.[195]

Histopathology. Fibrofolliculomas present with a dome shaped lesion with a central relatively well-differentiated hair follicle displaying a single or several contiguous, dilated, keratin-filled infundibula. The infundibula are connected to several thin, focally anastomosing epithelial strands that extend in a radial fashion into the stroma. The infundibula are surrounded by a distinct fibrillary collagenous or mucinous stroma with scant elastic tissue.

Histologically, trichodiscomas reveal the fine fibrillary collagenous stroma containing ectatic blood vessels. A hair follicle may be found at the margin of the lesion, although the primary distinguishing characteristic of trichodiscoma is the stromal component.

Fibrous papule presents as a dome-shaped or polypoid lesion consisting of one or more poorly formed hair follicles surrounded by a cellular stroma with numerous proliferative small blood vessels in the dermis.

Prognosis and Clinical Course. While the cutaneous tumors themselves are benign, these patients should be screened for Birt–Hogg–Dube syndrome. In the case of multiple fibrous papules, a suspicion of tuberous sclerosis should be raised. Genetic counseling should be provided if a diagnosis is confirmed.

Treatment. Solitary lesions can be excised, although this is difficult for multiple lesions. Laser resurfacing with the erbium:Yag or carbon dioxide laser, electrodessication, cryotherapy, and dermabrasion have been tried with variable results.[195]

TRICHOBLASTOMA

Epidemiology. Trichoblastoma is a rare benign follicular neoplasm that presents in adults between the fourth and sixth decades. Childhood presentation outside the context of a nevus sebaceous is highly rare.[196]

Etiology and Pathogenesis. Trichoblastoma comprises a group of tumors with follicular germinative differentiation.

Clinical Findings. Trichoblastoma presents with a solitary, well-defined, slow-growing, brown or blue–black nodule on the head or neck, especially the scalp (Fig. 119-14A). It can reach up to 3 cm in diameter, although cases up to 10 cm have been reported.[197] Multiple lesions are seen in Brooke's disease, which is not associated with other anomalies. Trichoblastomas are the most common neoplasm to arise within a nevus sebaceous. They can also coexist with basal cell carcinoma.[23]

Histopathology. Histologically, there are several dermal and subcutaneous smooth-bordered collections of basaloid cells arranged in nodular, cribriform, retiform, and racemiform patterns.[198] The stroma is characteristically sclerotic or hyalinized. Peripheral palisading and rudimentary follicular papillae are also observed (Fig. 119-14B). Heavy melanin pigmentation and horn cysts can also be seen. The differential diagnosis includes trichoepithelioma and basal cell carcinoma. Cutaneous lymphadenoma is a variant with extensive infiltration of tumors nests with lymphocytes and histiocytes.

Prognosis and Clinical Course. Transformation to trichoblastic carcinoma or trichoblastic sarcoma is extremely rare. Trichoblastic carcinoma has been associated with fatal metastases.[199,200]

Treatment. Complete surgical excision is recommended given the potential for malignancy and difficult distinction from basal cell carcinoma.

TRICHOEPITHELIOMA

Epidemiology. The solitary trichoepithelioma presents in elderly patients. Multiple trichoepitheliomas, as seen in the autosomally dominant inherited Brooke–Spiegler syndrome, present in childhood or puberty.

Etiology and Pathogenesis. Trichoepithelioma shows follicular germinative differentiation. Some consider it a variant of trichoblastoma.

Clinical Findings. There are three clinical variants of trichoepithelioma: solitary, multiple, and desmoplastic. Solitary trichoepithelioma is a small 5–8 mm, skin-colored papule on the nose, upper lips, and cheeks.[3] It can also develop on the trunk, neck, or scalp. It is often mistaken for basal cell carcinoma. Occasionally, they can grow quite large to several centimeters. This giant solitary trichoepithelioma is most commonly seen on the thigh or perianal region of the elderly.[3]

Multiple trichoepitheliomas are seen in adolescents in the setting of Brooke–Spiegler syndrome, an

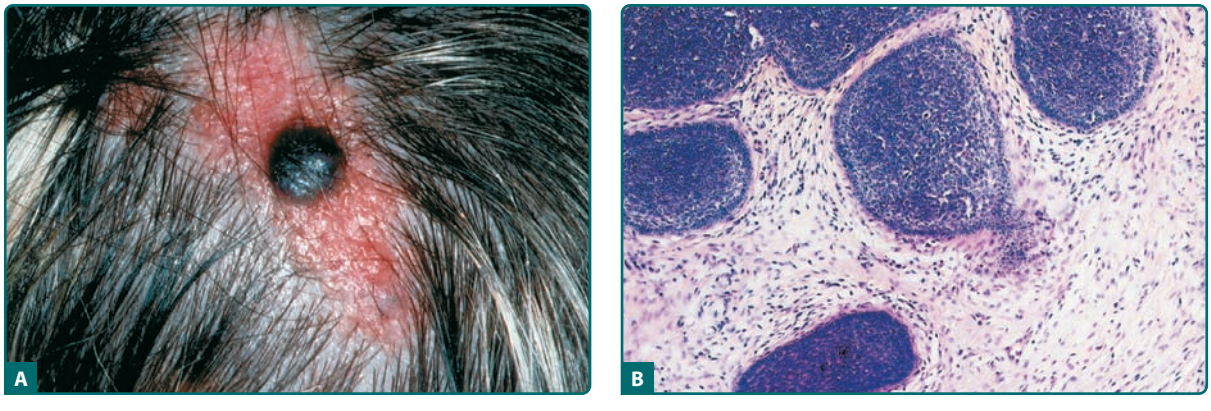

Figure 119-14 Trichoblastoma. **A.** Pigmented type arising in a nevus sebaceous. **B.** Nodular aggregations of basaloid cells surrounded by abundant fibrous stroma. Note prominent peripheral palisading of nuclei and a focus with a follicular germ and papilla.

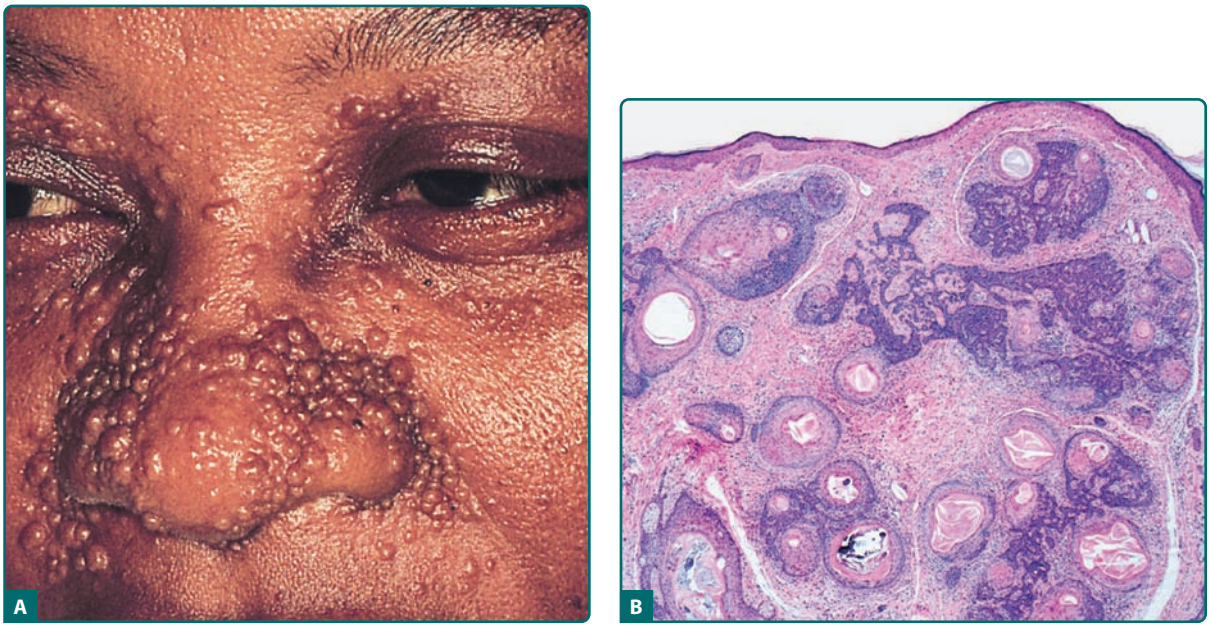

Figure 119-15 Trichoepithelioma. **A.** Multiple familial type. **B.** Well-circumscribed, multilobular dermal tumor consisting of solid and branching basaloid aggregations admixed with horn cysts surrounded by abundant fibrous stroma. Note a focal cribriform pattern.

autosomal, dominant condition characterized by multiple cylindromas, eccrine spiradenomas, and milia. It is due to germ-line mutations in the *CYLD* gene, which encodes an inhibitor of NF-κB.[201] Patients present with numerous small, shiny, firm papules on the face with a predilection for the upper lip, nasolabial folds, and eyelids (Fig. 119-15A).

Multiple trichoepitheliomas are also seen in Rombo syndrome, which is characterized by atrophoderma, milia, hypotrichosis, basal cell carcinomas, and peripheral vasodilatation.[202] Multiple trichoepitheliomas also have an association with systemic lupus erythematosus and myasthenia gravis.

Histopathology. Trichoepitheliomas present with sharply circumscribed, symmetric, dome shaped lesions composed of aggregates of relatively monomorphic basaloid cells in the upper dermis surrounded by abundant fibrous stroma with stromal–stromal retraction. The most common pattern is cribriform, but nodular, racemiform, and retiform patterns have also been observed (Fig. 119-15B). Trichoepitheliomas also exhibit peripheral palisading and papillary mesenchymal bodies.

Prognosis and Clinical Course. There are very few case reports that describe malignant degeneration into malignant trichoepithelioma or trichoblastic carcinoma.[203]

Treatment. The treatment of solitary trichoepithelioma is surgical excision. This is not feasible for multiple lesions. Cryotherapy, electrodessication, and carbon dioxide laser resurfacing can be employed as destructive methods.[201]

DESMOPLASTIC TRICHOEPITHELIOMA

Epidemiology. Desmoplastic trichoepithelioma, also known as sclerosing epithelial hamartoma, is a rare benign adnexal neoplasm initially described by Brownstein and Shapiro in 1977.[204] While it most frequently appears in young women, there are reports of congenital lesions.[205,206]

Etiology and Pathogenesis. Desmoplastic trichoepithelioma may be a variant of trichoblastoma or trichoepithelioma with extensive stromal sclerosis.

Clinical Findings. Desmoplastic trichoepithelioma presents as a solitary, firm, skin-colored to white–gray, sclerotic annular plaque with a central depression on the upper cheek or angle of the lip of a young female (Fig. 119-16). The lesion typically measures 1 cm and is asymptomatic. It is extremely rare to have multiple lesions. It is often mistaken for basal cell carcinoma.[205]

Figure 119-16 Desmoplastic trichoepithelioma located on the infraorbital region.

Histopathology. Histopathologically, there is a well-circumscribed lesion consisting of cords of basaloid cells that are 1–3 cells thick in the upper two-third of the dermis. There are small keratinous cysts and a characteristic desmoplastic stroma that exhibits stromal–stromal retraction. Histologic differential diagnosis includes morpheaform basal cell carcinoma and microcystic adnexal carcinoma.

Prognosis and Clinical Course. Desmoplastic trichoepithelioma behaves in a benign fashion. However, uncertainty regarding the histologic diagnosis often leads to excision.

Treatment. The treatment of choice is Mohs micrographic surgery or excision.[205,207] Alternatives include dermabrasion and laser surgery, although these are associated with a higher recurrence rate.

TRICHOADENOMA

Epidemiology. Trichoadenoma is a rare follicular tumor, described by Nikolowski in 1958, most commonly seen in adults.[208] It has also been reported in children, as well as in a congenital case.[209]

Etiology and Pathogenesis. Trichoadenoma is a follicular tumor with differentiation toward the infundibular portion of the folliculosebaceous canal. It lies on a differentiation spectrum between trichofolliculoma and trichoepithelioma.[3,210]

Clinical Findings. Trichoadenoma presents as a solitary slow-growing, grayish nodule measuring up to 1.5 cm. The most common location is the face, followed by the buttocks.[4,211] It can be vegetative or verrucous.

Histopathology. Microscopic examination reveals a dome-shaped, sharply defined nodule composed of numerous round infundibulocystic structures in the dermis. The infundibulocystic structures are lined by squamous epithelium. Conspicuous collagenous stroma surrounds the tumor nests.

Prognosis and Clinical Course. This is a benign tumor.

Treatment. While treatment is not necessary, excision can be performed for cosmetic purposes.

PILOMATRICOMA

Epidemiology. Pilomatricoma, also known as calcifying epithelioma of Malherbe and pilomatrixoma, is most frequently seen in children. However, a bimodal onset is observed with the majority occurring in the first and sixth decades. There is an increased prevalence in girls.[3]

Etiology and Pathogenesis. Pilomatricoma is derived from hair matrix cells.[212] It is associated with activating mutations in β-catenin, a mediator in the Wnt signaling pathway.

Clinical Findings. Pilomatricoma presents as a solitary, skin-colored or bluish, firm, cystic nodule on the head, neck, or proximal upper extremities (Fig. 119-17A). It displays a "tent-sign" with many angles and surfaces apparent on skin stretch. Overlying epidermal atrophy is common and designated "anetodermic" variant. Additional variants include multiple lesions, bullous, or giant tumors.[213] Giant pilomatricoma has been associated with hypercalcemia and elevated parathyroid hormone-related protein (PTH-rp).[214]

Multiple lesions are seen in Gardner's syndrome, myotonic dystrophy, Rubinstein–Taybi, and Turner syndrome.[215] More recent associations have been

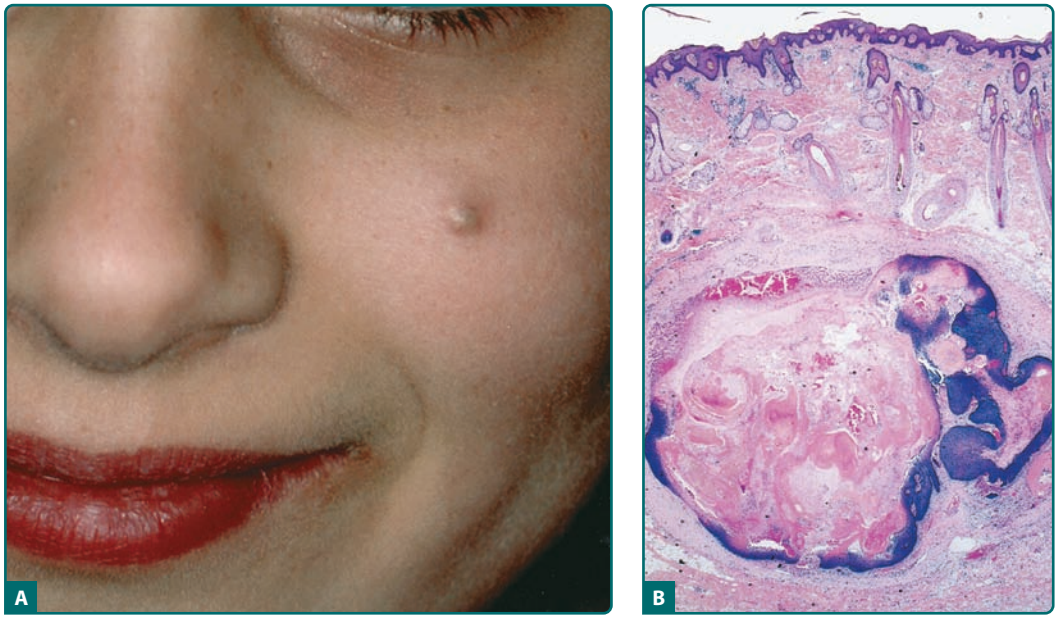

Figure 119-17 Pilomatricoma. **A.** A tumor in a young girl. **B.** Cystic lesion lined focally at the periphery by basaloid epithelium and filled with masses of eosinophilic, cornified material with shadow cells.

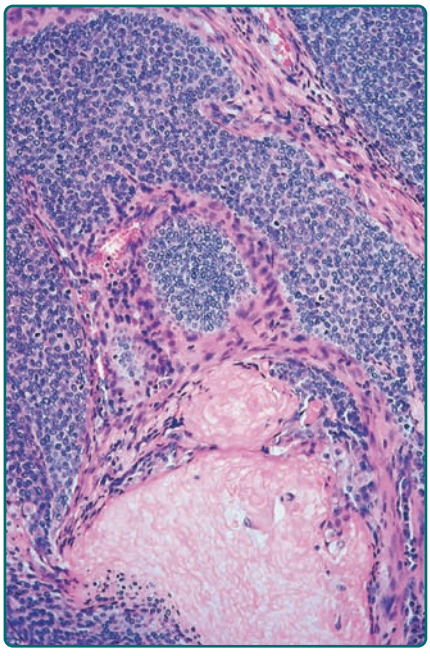

Figure 119-18 Pilomatrical carcinoma. Irregular aggregations of atypical basaloid cells continuous with an area of cornified material containing shadow cells.

made with trisomy 9, sarcoidosis, HIV, and Sotos syndrome.[215]

Histopathology. Pilomatricoma reveals a fairly characteristic encapsulated mass of basophilic cells with minimal cytoplasm that evolve into eosinophilic shadow or ghost cells toward the center of the lesion. Calcification can be prominent (Fig. 119-17B). Pilomatrical carcinoma demonstrates irregularly sized and variably sized islands of basaloid cells. Atypia, mitoses, and necrosis are notable (Fig. 119-18).

Prognosis and Clinical Course. Pilomatricomas rarely recur locally after excision. Rare malignant transformation to pilomatrical carcinoma has also been reported. Lesions tend to be on the head, neck, upper limbs, and buttocks. It tends to occur in older male patients with sun-damaged skin, as opposed to its benign counterpart pilomatricoma, which is more commonly seen in young females. Metastases to regional lymph nodes and distant sites can occur in 10% of patients.[216] Fifty percent of pilomatrical carcinoma recur with local excision. Pilomatrical carcinoma can rarely arise de novo.

Treatment. The treatment of choice for pilomatricoma is excision, and it is associated with a low recurrence rate. Pilomatrical carcinomas should be excised with a wide margin. Mohs micrographic surgery has been employed with good results.[216]

TRICHILEMMOMA

Epidemiology. Trichilemmoma is a benign follicular neoplasm first described by Headington and French in 1962.[217] It typically presents in adulthood.

Etiology and Pathogenesis. Trichilemmoma exhibits differentiation toward the outer root sheath or trichilemmal sheath at the level of the bulb. Some feel that trichilemmoma represents a viral wart, although DNA sequencing has not revealed papillomavirus in these lesions, making it less likely.[3]

Mutations in the *PTEN* gene have been implicated as multiple trichilemmomas have been observed in Cowden's syndrome, an autosomal dominant condition with germ-line mutations in the tumor suppressor *PTEN* gene. *PTEN* encodes phosphatase and tensin homolog, a phosphatase in the phosphoinositol-3-kinase (PI3K) pathway, which normally inactivates signals in the antiapoptotic PI3K/AKT kinase pathway. When *PTEN* is absent, decreased, or dysfunctional, there is uninhibited phosphorylation of AKT leading to the inability to undergo apoptosis.[218]

Clinical Findings. Trichilemmoma can present as a solitary, small 3–8 mm, flesh-colored, asymptomatic, keratotic papule on the face with a predilection for the nose and upper lip. It can be seen arising within a nevus sebaceous.[219]

Multiple lesions are a maker for Cowden's syndrome (multiple hamartoma syndrome), an autosomal dominant condition due to mutations in the tumor suppressor *PTEN* gene.[218] Additional cutaneous manifestations include oral papillomas and acral palmoplantar keratoses. There is an increased risk for breast, thyroid, and endometrial cancer. The most common cancer is breast cancer with a lifetime risk of 25%–50%, with two-thirds presenting in females between the age of 38 and 46. Trichilemmomas often precede the diagnosis of breast cancer, and therefore appropriate

Figure 119-19 Proliferating pilar tumor. Ulcerated giant nodule on the scalp.

dermatologic diagnosis is critical.[218,220] The second most common neoplasm is thyroid cancer, specifically follicular and papillary subtypes. Endometrial cancer is seen in 10% of cases.[218] Other manifestations include colonic polyps, breast adenomas, thyroid adenomas, fibrocystic breast disease, and Lhermite–Duclos disease or dysplastic gangliocytoma of the cerebellum.

Histopathology. On histologic examination, there is an exo-endophytic, lobular proliferation of polygonal, pale staining, glycogen containing squamoid cells extending from the epidermis. There is peripheral palisading of columnar cells, and a conspicuous PAS-positive basement membrane surrounding the lesion. The desmoplastic trichilemmoma variant displays tumor cells embedded in a sclerotic stroma.

Prognosis and Clinical Course. There are rare reports of trichilemmal carcinoma, although many feel that this is a variant of squamous cell carcinoma. There is a low metastatic potential associated with this entity.[221]

Treatment. The treatment of choice is excision. Mohs micrographic surgery has been used for desmoplastic trichilemmomas in cosmetically sensitive areas.[221] Alternatives for multiple lesions include cryotherapy, electrodessication and curettage, and laser ablation.

TUMOR OF THE FOLLICULAR INFUNDIBULUM

Epidemiology. Tumor of the follicular infundibulum (TFI), also known as isthmicoma, was first described by Mehregan and Butler in 1961.[222] It presents in middle-aged and elderly adults. It is unclear whether there is a male or female predominance as conflicting reports exist.[223,224]

Etiology and Pathogenesis. TFI is a neoplasm that demonstrates differentiation toward the follicular isthmus, not the infundibulum as the name would suggest.

Clinical Findings. TFI presents as a solitary, small, asymptomatic, thin, keratotic papule on the head or neck.[223] It is often misdiagnosed as a seborrheic keratosis or basal cell carcinoma. There are rare cases of numerous eruptive lesions, which typically appear as atrophic or hypopigmented macules and papules.[223,224] TFI has been shown to be associated with basal cell carcinoma and nevus sebaceous.[224]

Histopathology. Histopathologically, TFI reveals a horizontally oriented, plate-like tumor in the upper dermis with the epithelial component showing multiple connections to the epidermis or hair follicles. The epithelium exhibits a fenestrated pattern with interconnecting cords and columns. There is a surrounding collagenous stroma. Clear glycogenated cells, sebaceous differentiation, ductal structures, and papillary mesenchymal bodies are observed.

Prognosis and Clinical Course. TFI is generally considered a benign lesion. Two cases of degeneration to basal cell carcinoma have been reported.[225]

Treatment. Various destructive methods including excision, electrodessication, cryotherapy, and laser ablation have been attempted but are associated with potential scarring.[226] Topical corticosteroids, keratolytics, retinoic acid, and imiquimod have also been employed as less destructive treatments.[223,226]

PROLIFERATING TRICHILEMMAL CYST

Epidemiology. Proliferating trichilemmal cyst (PTC), also known as proliferating trichilemmal tumor or proliferating pilar tumor, presents on the scalp of elderly individuals. There is a female predominance.

Etiology and Pathogenesis. PTCs derive from the outer root or trichilemmal sheath.[227] It is felt that there is an evolution, histologically and clinically, from a pilar cyst to proliferating trichilemmal cyst to malignant proliferating trichilemmal cyst. PTC may evolve from a pilar cyst as a result of inflammation or trauma.[228] It is felt that PTC degenerates into malignant PTC with the loss of p53.[228,229]

Clinical Findings. PTC classically presents on the scalp or posterior neck of elderly patients. Other sites include the trunk, groin, vulva, and gluteal region.[227] PTC usually starts as a nodule and develops into a large, elevated, rubbery, lobulated mass that can enlarge to 10 cm (Fig. 119-19).[7] Lesions often ulcerate. PTC can be associated with nevus sebaceus and basaloid follicular hamartoma.

Histopathology. Histopathologic examination reveals a sharply circumscribed cystic neoplasm occupying the lower dermis and subcutaneous tissue. There is a proliferation of bland squamous cells lining nearly the whole lesion and extending within it in a radial fashion. A characteristic feature is the presence, in the center of lobules, of trichilemmal cornification, i.e., abrupt formation of compact eosinophilic keratin without granular layer interposition. Foci with keratohyaline granules, small horn pearls and squamous eddies, and calcification is noted.

Prognosis and Clinical Course. PTCs have a variable clinical course. While some lesions are well circumscribed, others recur locally, and still others display invasive growth patterns with infiltration into nerves and lymphovasculature.[230] Nearly 4% of PTCs recur after excision. There are thirty reported cases of degeneration of PTC into malignant PTC. The malignant tumor is associated with metastatic spread in 35% of cases. Many believe that malignant PTC is actually a variant of squamous cell carcinoma.[231]

Treatment. The treatment of choice is complete excision or Mohs micrographic surgery.[222] Malignant PTC should be treated like a squamous cell carcinoma with excision with clear margins.

Chapter 120 :: Merkel Cell Carcinoma

:: Andrew Tegeder, Olga Afanasiev, & Paul Nghiem

MERKEL CELL CARCINOMA AT A GLANCE

- Lower relative survival (54%) than melanoma (91%) at 5 years.
- Reported incidence quadrupled from 1986 to 2006.
- Affects elderly/whites/immunosuppressed and is associated with a newly discovered virus: Merkel cell polyomavirus (MCPyV).
- Consider in differential diagnosis of any rapidly growing, nontender nodule on a sun-exposed area.
- Sentinel lymph node biopsy, surgery, and radiation are indicated in many cases.
- Imaging (computed tomography/magnetic resonance/positron emission tomography): poor sensitivity and specificity at time of diagnosis and in early stages.
- Management is challenging as therapy is unique and controversial.
- Avoid overaggressive surgery: adjuvant radiation therapy highly effective.
- Adjuvant chemotherapy: high morbidity, no proven benefit.
- Optimal care: multidisciplinary coordination between dermatologists, surgeons, radiation, and medical oncologists referring to National Comprehensive Cancer Network Guidelines.

Merkel cell carcinoma (MCC) is an increasingly common neuroendocrine skin cancer that is associated with ultraviolet (UV)-light exposure, advanced age, immune suppression and a recently discovered polyomavirus. The reported incidence of MCC has more than tripled in the past 20 years[1] to approximately 1,500 US cases/year[2] and is expected to grow with the aging population. Although it is 40 times less common than malignant melanoma, it carries a markedly poorer prognosis, with disease-associated mortality at 5 years of 46%[3] as compared with 9% for invasive melanoma.[4] Management of MCC is challenging and optimal therapy is controversial, at least in part due to a lack of prospective or randomized data on which to base treatment decisions.

MCC is a relatively recently described entity, although the Merkel cell was identified more than 100 years ago. In 1875, human Merkel cells were first described by Friedrich S. Merkel (1845–1919). He named these cells *Tastzellen* (touch cells) assuming that they had a sensory touch function within the skin due to their association with nerves. In 2009, a series

of studies using elegant mouse models resolved several long-standing debates by conclusively establishing that (1) Merkel cells are essential for light touch responses,[5] (2) Merkel cells have an epidermal origin,[5,6] and (3) Merkel cells do not divide, but are renewed by a reservoir of epidermal progenitor cells.[6]

In terms of what we now call Merkel cell carcinoma, in 1972, Toker described five cases of "trabecular cell carcinoma of the skin." In 1978, Tang and Toker found that cells from these tumors contained dense core granules on electron microscopy that were typical of Merkel cells and other neuroendocrine cells. In 1980, the name Merkel cell carcinoma (MCC) was first applied to this tumor because of the characteristic ultrastructural features it shares with normal Merkel cells. In 1992, it was found that antibodies to cytokeratin-20 stain normal skin Merkel cells as well as the vast majority of MCC tumors. This critical finding allows specific and relatively easy diagnosis of MCC to be made through immunohistochemistry. Since that time, electron microscopy is no longer used to make this diagnosis.

EPIDEMIOLOGY

Over the 20-year period between 1986 and 2006, the reported incidence of MCC quadrupled from 0.15 per 100,000[1] to 0.6 per 100,000.[7] There are likely two factors that contribute to this increase in reported incidence that is more rapid than that of any other type of skin cancer. One factor is an increase in the accurate diagnosis of this malignancy through the routine use of cytokeratin-20 immunohistochemistry and the improved recognition of this malignancy by dermatopathologists. In the past, MCCs were often mischaracterized as lymphoma, melanoma, or undifferentiated carcinoma in the era before immunohistochemistry. A second likely reason is an increase in the number of people over age 65 years with extensive sun exposure history and people living with prolonged immune suppression. Each of these factors is a known risk factor for MCC and several are discussed in Section "Etiology and Pathogenesis."

As of 2008, there are approximately 1,500 MCC cases per year in the US.[2] This cancer is far more common in whites than in blacks, consistent with a known role for UV radiation in MCC pathogenesis. Specifically, the rates in whites have been reported as 0.23 per 100,000 as compared to 0.01 per 100,000 for blacks.[8] Although not specifically reported, rates in Hispanics and Asians are likely intermediate between those in blacks and whites. MCC tends to be more common in men than in women (2:1 in ratio).[9] Furthermore, men also tend to have a worse prognosis than women, with reported 10-year disease-associated survival rates of 51% for men and 65% for women.[7]

ETIOLOGY AND PATHOGENESIS

There are several known risk factors for MCC that will likely continue to lead to an increase in the incidence of this disease.

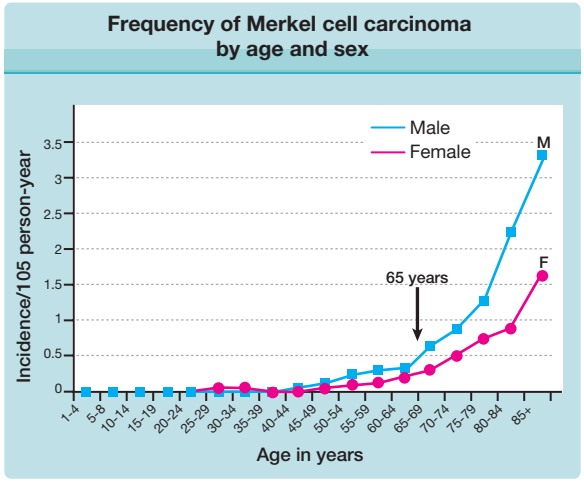

Figure 120-1 Frequency of Merkel cell carcinoma by age and sex. The most significant risk factor for Merkel cell carcinoma is age. M, male (■); F, female (●). (Reprinted from Agelli M, Clegg LX: Epidemiology of primary Merkel cell carcinoma in the United States. *J Am Acad Dermatol* **49**:832, 2003, with permission.)

AGE GREATER THAN 65 YEARS

The median age for diagnosis of MCC is 70 years, and there is a five- to tenfold increase in incidence after age 70 as compared with age less than 60 years, as shown in Fig. 120-1. Indeed, only about 10% of MCC cases present in patients under age 50 and it is extremely rare in childhood.[10]

SUN EXPOSURE

Sunlight, prolonged UV exposure, and photochemotherapy are all associated with an increased risk of MCC. As seen in Fig. 120-2, the vast majority (81%) of MCC tumors present on sun-exposed skin.[10] However, it is clear that sun is not required for MCC to develop. MCC cases can occur on sun-protected skin, including buttocks and vulva as well as portions of the scalp that are covered by hair.

IMMUNE SUPPRESSION

As compared to most cancers, MCC is strongly linked to immune suppression. Indeed, 7.8% of MCC patients are profoundly immune suppressed, a 16-fold overrepresentation compared with expected.[10] Multiple forms of immune suppression are associated with an increase in MCC risk. These include HIV/AIDS,[11] chronic lymphocytic leukemia,[10] and the immune suppressive regimens associated with solid organ transplant.[9] Additionally, there are 19 reported cases of complete spontaneous regression in the MCC literature, a far greater number than expected for its rarity, perhaps suggesting a sudden immune recognition and clearance of MCC.[8,12]

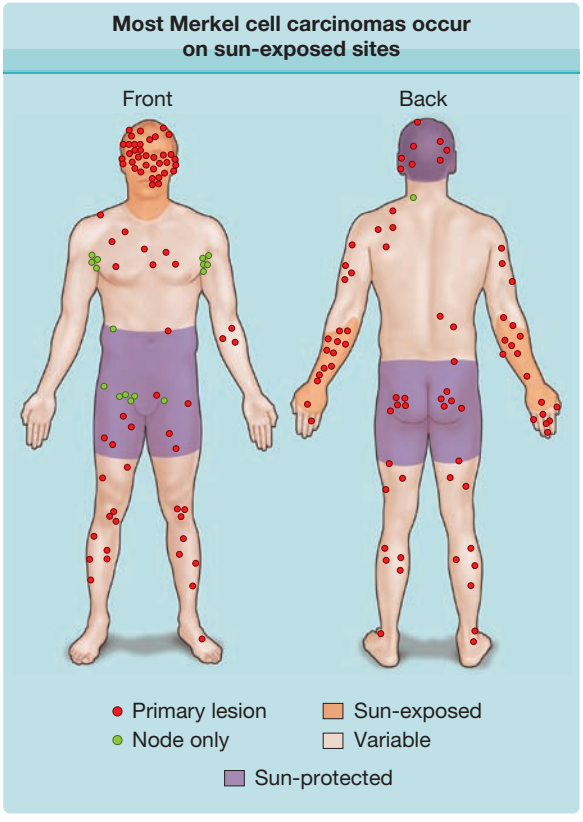

Figure 120-2 Most Merkel cell carcinomas (MCCs) occur on sun-exposed sites. This diagram shows the locations of tumor presentation for 195 MCC patients. For 168 patients, the site of the primary skin tumor is shown (**red** circles). The remaining 27 patients had no known primary and instead presented with nodal metastasis (**green** circles). The majority of patients (81%) presented with a primary tumor located on the heavily sun exposed face, neck, or dorsal forearm (**brown** shading). Five percent of patients presented with tumors in completely sun protected skin areas (**purple** shading), and 14% of patients presented with MCC in partially sun-protected skin (**skin tone**). (Adapted from Heath M et al: Clinical characteristics of Merkel cell carcinoma at diagnosis in 195 patients: The AEIOU features. *J Am Acad Dermatol* **58**:375-81, 2008.)

MERKEL CELL POLYOMAVIRUS

In 2008, a new polyomavirus, the Merkel cell polyomavirus (abbreviated MCV or MCPyV), was discovered by extensive sequencing of MCC tumor RNA. MCPyV was reported to be present in 80% of MCC tumors compared to only 7% of skin controls.[13] Numerous groups across several continents (over 25 literature citations) have verified the association between MCPyV and MCC, and all groups observed that the virus is strongly associated with MCC. MCPyV is a small, circular, double-stranded DNA virus related to other known polyomaviruses (SV40, BK, JC, KI, WU). MCPyV is unique among the human polyomaviruses as it is the only one proven to integrate into a human cancer. Monoclonal integration of MCPyV into MCC tumors suggests that the virus is present prior to or very early in tumorigenesis.

A large fraction of the population has been infected with MCPyV. By the age of 5, prevalence of antibodies is about 35%, but increases to 50% by the age of 15.[14] Interestingly, among MCC patients, the prevalence is significantly higher (88%) than age and sex-matched controls (53%).[15] Importantly, despite how common exposure is to this virus in the general population, the incidence of MCC is very low. Therefore, viral infection alone is clearly insufficient for the development of this cancer.

CLINICAL PRESENTATION OF MERKEL CELL CARCINOMA

A systematic analysis of 195 MCC patients characterized clinical features that may serve as clues in the diagnosis of MCC.[10] The most significant features can be summarized in an acronym: "AEIOU" (Table 120-1). This study found that 89% of 62 MCC cases exhibited at least three of the five features listed below. If a lesion exhibits at least three of these features, suspicion of MCC should increase and biopsy be considered. In particular, a lesion that is red or purple, rapidly growing, but nontender should be of concern. Strikingly, the clinician listed as clinical impression a benign diagnosis in over one half of cases. In particular, a cyst or acneiform lesion was the single most common of these (Box 120-1 and Figs. 120-3A and 120-3B) and nonmelanoma skin cancer was also relatively frequent as a presumptive diagnosis (Fig. 120-3C).

PATHOLOGY

As shown in Fig. 120-4A, the classic histologic features of MCC include sheets of small basophilic cells with scant cytoplasm, fine chromatin, and no nucleoli. There are numerous mitotic figures and occasional individual necrotic cells. Lymphovascular invasion is a very common feature and often can be found when it is specifically searched for even in a "negative" margin. This helps to explain the high local recurrence rate in MCC for narrow or even relatively wide margin excision when adjuvant radiation therapy is not given.

TABLE 120-1
Clinical Features of Merkel Cell Carcinoma

Asymptomatic (non-tender, firm, red, purple, or skin-colored papule or nodule; ulceration is rare; see Figs. 120-3A and 120-3B)
Expanding rapidly (significant growth noted within 1–3 months of diagnosis, but most lesions are <2 cm at time of diagnosis)
Immune suppression (e.g., HIV/AIDS, chronic lymphocytic leukemia, solid organ transplant)
Older than 50 years
Ultraviolet-exposed site on a person with fair skin (most likely presentation, but can also occur in sun-protected areas; Fig. 120-2)

BOX 120-1 DIFFERENTIAL DIAGNOSIS OF MERKEL CELL CARCINOMA

Most Likely

- Cyst
- Basal cell carcinoma
- Squamous cell carcinoma (see Fig. 120-3C)
- Amelanotic melanoma
- Cutaneous lymphoma
- Adnexal tumor

Consider

- Metastasis
- Dermatofibromasarcoma protuberans
- Keratoacanthoma
- Neuroblastoma

HEMATOXYLIN AND EOSIN STAIN

Three histologic patterns have been described up to now and none is clearly associated with a better or worse prognosis. The most common type is the "intermediate type." This has uniform small cells with minimal cytoplasm, pale nuclei, and a dispersed chromatin appearance. On hematoxylin and eosin staining, the differential diagnosis for this presentation is that of the small, blue-cell tumors including melanoma and lymphoma. The second most common pattern is the "small cell type." This takes its name from small cell lung carcinoma, which is the principal differential diagnosis for this pattern. It shows irregular, hyperchromatic cells with scant cytoplasm and malignant cells that are arranged in linear patterns infiltrating stromal structures. The least common but perhaps most histologically distinctive type is the "trabecular" type. This is the pattern originally described by Toker in 1972. It has a lattice-like, or network appearance, and the differential diagnosis includes metastatic carcinoid tumor.

Figure 120-3 Clinical appearance of Merkel cell carcinoma (MCC). **A.** MCC frequently has a "cyst-like" appearance. This is reflected in the differential diagnoses given by clinicians at the time of the biopsy, with cyst/acneiform lesion being the most common clinical impression. **B.** MCC on the knee of a 70-year-old woman with chronic lymphocytic leukemia. For 6 months this lesion was thought to be a "cyst"; consequently, diagnosis and treatment were delayed. Pen marks indicate palpable satellite metastases that developed several months after the primary lesion, presumably tracking via lymphatics. **C.** MCC on the ear of an 87-year-old woman. The lesion grew rapidly and was nontender. After approximately 3 months, it was biopsied by a clinician who listed squamous cell carcinoma as the presumptive diagnosis.

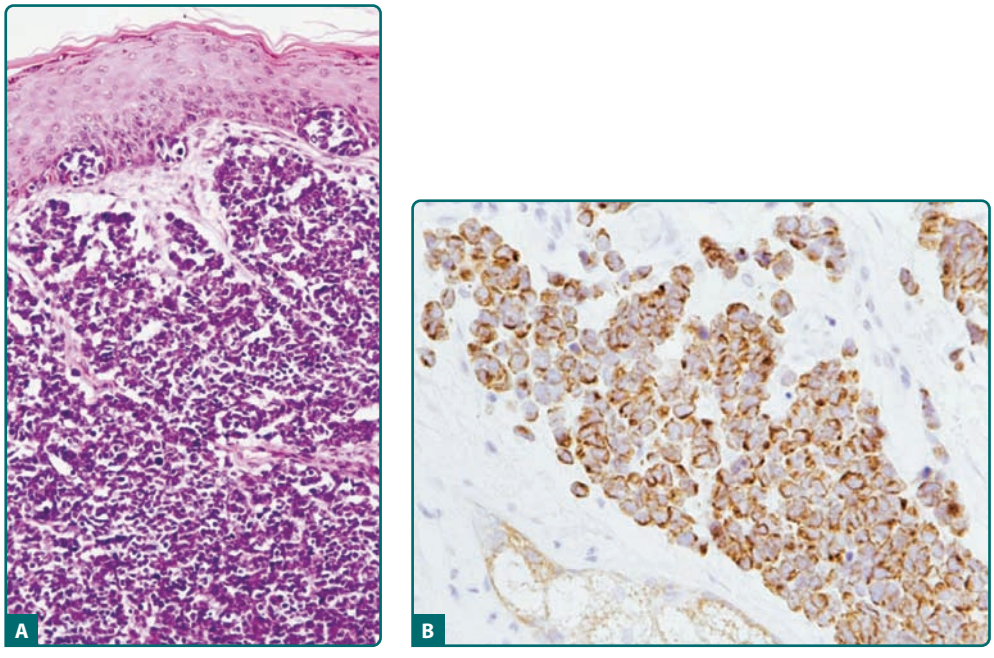

Figure 120-4 Merkel cell carcinoma pathology. **A.** Hematoxylin and eosin. There is diffuse dermal as well as intraepidermal involvement with Merkel cell carcinoma. This case was seen in consultation, with an initial diagnosis of cutaneous T-cell lymphoma. **B.** Cytokeratin-20. Showing the pathognomonic "perinuclear pattern" of cytokeratins (CAM5.2). [Reprinted from Nghiem P, Mckee P, Haynes H: Merkel cell (cutaneous neuroendocrine) carcinoma. In: *Skin Cancer, Atlas of Clinical Oncology*, edited by A Sober, F Haluska, American Cancer Society, 2001, with permission.]

IMMUNOHISTOCHEMICAL STAINS

The use of antibody-based stains has greatly facilitated the ease and specificity of MCC diagnosis (Table 120-2). The single most useful of these stains is cytokeratin-20.

CYTOKERATIN-20

Intermediate filament protein is expressed in MCC as well as in adenocarcinomas of the colon, stomach, and pancreas. However, within the skin the expression of cytokeratin-20 is limited to Merkel cells. A "perinuclear dot" pattern of cytokeratin is essentially pathognomonic for MCC (see Fig. 120-4B).

ANTIBODIES TO CAM5.2

CAM5.2, a cocktail of antibodies that detects multiple human cytokeratin epitopes, typically reacts with both MCC and small cell lung carcinoma. Although it is useful as an initial screening tool to detect tumors of squamous origin, its lack of selectivity relative to cytokeratin-20 means that it cannot be used to definitively diagnose MCC.

THYROID TRANSCRIPTION FACTOR-1

Thyroid transcription factor-1 is negative in MCC and positive in small cell lung cancer and thus useful for the differential diagnosis between these two tumors that can look identical by routine histology.

TABLE 120-2
Immunohistochemistry Panel

	Cytokeratin-20	Cytokeratin-7 and Thyroid Transcription Factor-1	Leukocyte Common Antigen	S-100
Merkel cell carcinoma	+	–	–	–
Small cell lung carcinoma	–	+	–	–
Lymphoma	–	–	+	–
Melanoma	–	–	–	+

TABLE 120-3
Description of MCC Staging and Associated Predicted Survival Percentages

	1-year Survival	3-year Survival	5-year Survival
Stage I: Local, Tumor Diameter ≤2 cm			
IA: Nodes microscopically negative and not clinically detectable	100%	86%	79%
IB: Nodes not clinically detectable (no pathologic evaluation of nodes done)	90%	70%	60%
Stage II: Local, Tumor Diameter >2 cm			
IIA: Nodes microscopically negative and not clinically detectable	90%	64%	58%
IIB: Nodes not clinically detectable (no pathologic evaluation of nodes done)	81%	58%	49%
IIC: Primary tumor is invading into bone/muscle/fascia/cartilage	72%	55%	47%
Stage III: Regional Nodal Disease			
IIIA: Micrometastasis	76%	50%	42%
IIIB: Macrometastasis (clinically detectable nodes)	70%	34%	26%
Stage IV: Distant Metastatic Disease	44%	20%	18%

CYTOKERATIN-7

Cytokeratin-7 has the same staining pattern as thyroid transcription factor-1, that is, typically negative in MCC and positive in small cell lung carcinoma; it is also expressed in epithelial cells of the lung, ovary, and breast.

STAGING AND PROGNOSIS

In 2010, the American Joint Committee on Cancer (AJCC) adopted a new staging system for MCC that replaced five existing—and conflicting—staging systems.[16] According to the new AJCC guidelines, there are four stages for MCC based on clinical and pathological features at the time of presentation. This new staging system is summarized in Fig. 120-5 and Table 120-3. Survival after a diagnosis of MCC is highly dependent on the stage at presentation. Patients with local disease have estimated 5-year relative survival between 60% and 79%. Survival decreases markedly with nodal involvement and metastatic disease (Fig. 120-5). Unlike malignant melanoma, if MCC recurs it tends to do so rapidly with ~80% of recurrences occurring within 2 years of diagnosis.[17]

Until 2009, MCC did not have its own specific International Classification of Diseases (ICD) code. Instead, MCC was often coded as "173.x: other malignant neoplasm of the skin." Specific ICD codes are important because they allow for more streamlined therapy, faster insurance approvals and improved tracking of patients and costs for clinical research purposes. As of 2010, MCC now has its own set of ICD codes (209.3x) to better facilitate treatment and tracking of patients with MCC.[18]

SENTINEL LYMPH NODE BIOPSY AND STAGING OF MERKEL CELL CARCINOMA

Over the past 20 years, sentinel lymph node biopsy (SLNB) has become quite common in staging malignant melanoma presenting with a depth of greater than 1 millimeter. More recently, several studies have indicated that SLNB is also a sensitive test for detecting MCC spread to the lymph nodes.[19–21] Interestingly, MCC is far more likely to have occult lymph node involvement (approximately 30% for the average 1.7 cm MCC) than melanoma (~1% for melanomas with the average Breslow thickness of 0.63 mm).[21,22] SLNB clearly has less morbidity than an elective lymph node dissection. Ideally, an SLNB should be performed at

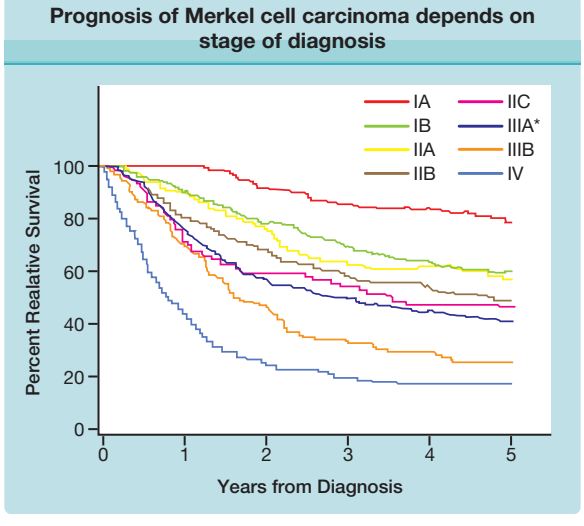

Figure 120-5 Prognosis of Merkel cell carcinoma depends on stage at diagnosis. This figure shows relative survival curves for 2,856 Merkel cell carcinoma patients by stage. Stage IIIA could not be directly derived from this dataset. The survival curve marked "IIIA*" represents pathologically node positive patients who had either clinically node-negative disease or clinically unknown node status. It is anticipated that true Stage IIIA patients (clinically node-negative disease) have better survival than the line marked with "IIIA*." (Reprinted from Merkel cell carcinoma. In: *AJCC Cancer Staging Manual*, 7th edition, edited by S Edge et al, Springer-Verlag, 2009, with permission.)

the time of the wide resection as opposed to after the wide excision when local lymphatics have been disturbed. The importance of performing an SLNB is that one-third of patients with local-only disease as determined by clinical palpation of lymph nodes, in fact, have microscopic disease in the lymph nodes that very much affects their subsequent survival (Fig. 120-5, Table 120-3).[21] Specifically, one-third of patients would be understaged by clinical exam only, and would shift to stage IIIA disease with microscopic examination. Identification of microscopic nodal disease also importantly alters therapy for the node bed, as discussed below.

RADIOLOGIC IMAGING STUDIES

Although many patients who present for management of MCC have not had an SLNB, the majority have had computed tomographic (CT) scans. We studied our own series of patients to determine the sensitivity and specificity of CT scans in patients presenting with MCC.[21] We found that scans were not sensitive (missing 90% of positive cases) in terms of detecting nodal involvement of MCC as compared with SLNB. Among patients who had low-risk disease (negative sentinel lymph nodes or very small primary tumors) all of the "positive" scan results were, in fact, false positives.[21] Therefore, we typically reserve CT or PET-CT scans for patients presenting with more advanced disease, such as positive nodal involvement or clinical evidence of metastatic disease.

PROGNOSTIC FINDINGS ON HISTOLOGY

A recently published retrospective study evaluated several histologic features of MCC and performed survival analyses on these features. This large study had over 4 years of average follow-up time and analyzed the primary tumor lesions from 156 patients with MCC. In addition to tumor stage, two new histologic features were of particular interest: (1) lymphovascular invasion (LVI) and (2) tumor growth pattern. LVI was defined as tumor emboli within vascular spaces. Persons with MCC tumors with detectable LVI had a worse overall survival as compared to those with tumors without LVI (hazard ratio, 3.84; $P = 0.007$).[23] Tumor growth pattern was described as nodular (well-circumscribed interface between tumor and surrounding tissue) or infiltrative (rows, trabeculae, or single cells that penetrate the dermis). Tumors that exhibited both features were considered infiltrative. An infiltrative tumor growth pattern was associated with poor outcomes as compared to MCC tumors with a nodular growth pattern (hazard ratio, 6.85; $P = 0.001$).[23]

TREATMENT

Optimal therapy for MCC is controversial and there is no broad consensus on how to manage this disease. The best summary of consensus treatment for MCC is available through the National Comprehensive Cancer Network (http://www.nccn.org) and is updated annually (these guidelines and other useful information can also be found at www.merkelcell.org/usefulinfo/index.php). The best outcome for MCC is clearly obtained when multidisciplinary management is carried out by an experienced team. Each major treatment modality is summarized below.

SURGERY AT PRIMARY SITE

The initial management in most cases of MCC is surgical excision of the tumor. When carried out without subsequent adjuvant radiation, surgery may have a relatively high recurrence rate depending on the margins chosen and the risk profile for the tumor. Surgery alone with 0.5 cm margins resulted in a 100% recurrence rate in 38 patients.[24] When wide local excision was carried out with 2.5 cm margins, the recurrence rate fell to 49%.[25] For Mohs surgical excision, the local recurrence rate was 16% for surgery alone and 0% in patients who also had adjuvant radiation therapy, although this difference was not statistically significant.[26] There are no data to suggest that extremely wide excision margins improve overall survival. Depending on the location of the tumor, significant morbidity can result when 2–3 cm margins are taken. Numerous studies show that if surgery is the sole treatment, recurrence rates are significantly higher than if radiation therapy is added to the regimen. Excision with narrow but clear margins (carried out at the time of SLNB) followed by adjuvant radiation therapy is a reasonable approach to management in many cases. Overly aggressive surgery, including amputation, or very wide margins in cosmetically sensitive areas, decreases quality of life, increases morbidity, delays time to initiation of adjuvant radiation, and does not appear to improve survival or local control rates.

SURGERY AT THE DRAINING NODE BED

Completion lymphadenectomy is typically carried out if there is gross involvement of the draining node bed detected clinically. However, the role of completion lymphadenectomy in MCC is controversial. For example, a 2010 study suggests that patients with nodal MCC disease who underwent complete lymphadenectomy had comparable outcomes with patients who only underwent radiation therapy to the nodal bed.[27] These two options have similar and excellent control rates for node-positive disease. Although either can be chosen, depending on the clinical situation, it is clear that for microscopic nodal disease, only one of these two modalities should be performed. This is because regional control rates were 100% for each modality and the combination of radiation and surgery to the lymph node bed greatly increases risk of chronic lymphedema.

RADIATION THERAPY

MCC is an unusually radiosensitive tumor.[25,28] Recently, there have been reports of successful treatment of MCC with radiation as monotherapy. One study of 43 patients with MCC for whom surgical excision was not possible demonstrated an excellent infield control rate (75%) after treatment with radiation therapy alone.[29] In a separate cohort, there were no recurrences among nine patients treated with radiation monotherapy.[28] One of our cases treated with radiation monotherapy is shown in Fig. 120-6. In most of these cases, the lesion was felt to be inoperable and radiation was given for palliation, but typically resulted in long-lasting local control.

The much more common use of radiation is as an adjuvant to surgery. Adjuvant radiation clearly is critical if surgical margins are positive or if microscopic margins are relatively narrow (<0.5 cm). A retrospective review of the literature indicates a statistically significant improved local and nodal rate of control in this cancer if radiation is added.[30] A cancer registry-based study also indicates improved survival in patients with adjuvant radiation therapy.[31] In this study, patients who received adjuvant radiation therapy had a median survival of 63 months compared to median survival of 45 months in patients who did not receive adjuvant radiation. The typical doses of radiation for MCC are 50–56 Gy for a primary site with negative excision margins. Detailed dosing regimens can be found in the National Comprehensive Cancer Network's MCC Guidelines. Radiation doses are typically given in 2-Gy fractions, five times/week over 4–6 weeks. Acute side effects from radiation therapy include erythema at the site and mild-to-moderate fatigue that peaks toward the end of radiation and usually resolves within 1–2 months of completing a 5-week course. Chronic radiation skin changes include temporary or permanent alopecia within the irradiated field, epidermal atrophy, loss of adnexal structures leading to skin or mucosal dryness, and risk of subsequent secondary skin cancers in the irradiated region in patients with a life expectancy of greater than 20 years after the radiation treatment. Perhaps the most significant potential side effect is lymphedema. This is more commonly an issue in lower extremities, when radiation therapy is given to the inguinal lymph nodes, especially after surgery has also been carried out in that region. Early referral to a physical therapist trained in lymphedema management is indicated to minimize the severity and incidence of this potential complication in higher risk cases.

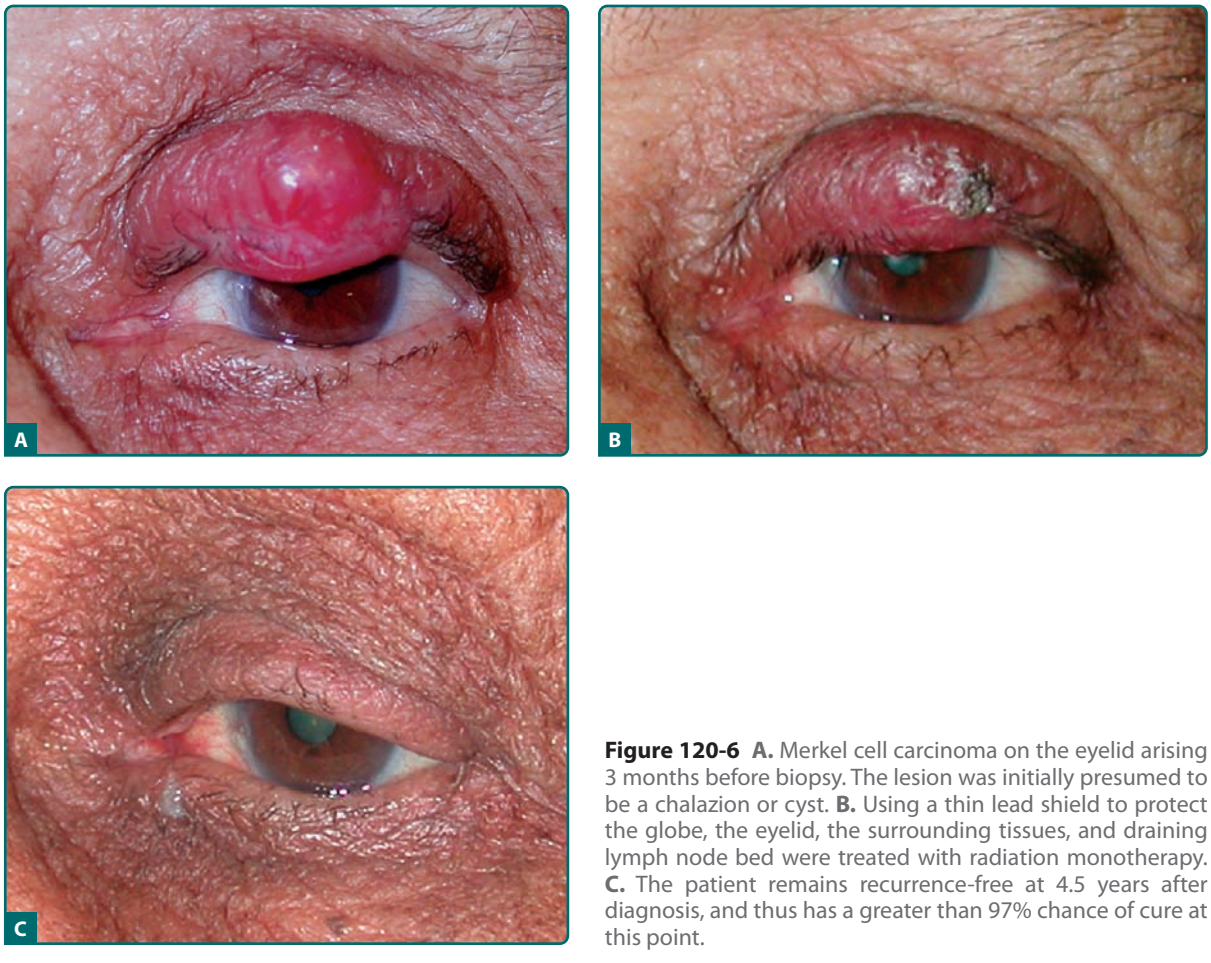

Figure 120-6 **A.** Merkel cell carcinoma on the eyelid arising 3 months before biopsy. The lesion was initially presumed to be a chalazion or cyst. **B.** Using a thin lead shield to protect the globe, the eyelid, the surrounding tissues, and draining lymph node bed were treated with radiation monotherapy. **C.** The patient remains recurrence-free at 4.5 years after diagnosis, and thus has a greater than 97% chance of cure at this point.

CHEMOTHERAPY

The most commonly used chemotherapeutic regimen for MCC is the combination of etoposide and either cisplatin (perhaps more clinically effective) or carboplatin (less nephrotoxic). Chemotherapy is often useful in palliation for symptomatic disease that is otherwise inoperable. MCC patients receiving chemotherapy for the first time usually have a significant response with shrinkage of the tumor. Unfortunately, in almost all cases, the tumor grows back and is resistant to chemotherapy even if entirely different agents are used on a subsequent round of chemotherapy. After careful analysis of the literature, we currently do not recommend adjuvant chemotherapy for patients whose MCC has been treated with surgery, radiation therapy, or both. There are six reasons why we currently do not recommend adjuvant chemotherapy:

1. *Mortality:* There is a 4%–7% acute death rate due to adjuvant chemotherapy in MCC partly due to the fact that these patients are often elderly.[32,33]
2. *Morbidity:* Neutropenia has been reported to occur in 60% of patients with fever, and sepsis in 40%.[34]
3. *Decreased quality of life:* This can be quite severe in this older population, including fatigue, hair loss, nausea, and vomiting.
4. *Resistance to chemotherapy:* MCC that recurs after chemotherapy is less responsive to later palliative chemotherapy.
5. *Immunity:* Chemotherapy suppresses immune function, and this is known in general to be very important in preventing and controlling MCC.
6. *Apparent poorer outcomes:* Among patients with nodal disease, there was a 60% survival if chemotherapy was not given among 53 patients. In contrast, survival was only 40% among node positive MCC patients who did receive adjuvant chemotherapy.[17] Although this is not a randomized trial and was not statistically significant, it certainly does not suggest a major survival benefit for administrating adjuvant chemotherapy.

OPTIMAL TREATMENT FOR MERKEL CELL CARCINOMA

In general, optimal treatment for MCC should involve obtaining pathologically clear margins by surgery, typically with 1- to 2-cm margins as possible, depending on the site. More narrow margins or even positive margins can often be effectively treated by local radiation, typically extending 3–5 cm beyond the tumor bed. We also recommend treating the draining lymph node bed, likely with radiation therapy, for patients with high-risk disease including a positive SLNB, immune suppression, or a tumor greater than 2 cm in diameter. Although still controversial, we currently do not recommend adjuvant radiation therapy for MCC patients with all of the following five good prognostic features: (1) primary tumor diameter ≤1 cm; (2) microscopic margins that are confidently negative following surgery; (3) no lymphovascular invasion noted in the tumor; (4) no profound immune suppression (HIV, chronic lymphocytic leukemia, etc.); and (5) SLNB that was negative with proper immunohistochemistry studies.

CLINICAL COURSE AND COMPLICATIONS

In more than 90% of cases, MCC is an unanticipated diagnosis at the time the pathology results become known. Most commonly, the lesion in question was thought to be a cyst or acneiform lesion. Although most patients and physicians are not familiar with this disease or its specific management, MCC can be lethal and there is a need to initiate therapy rapidly. In one Australian study, a high fraction of patients (45%) developed progressive disease while waiting for adjuvant radiation therapy to begin (median wait time 41 days).[35] Because of the rarity of this cancer, patients and physicians increasingly resort to the Internet for medical information. One Web site, http://www.merkelcell.org, is devoted to aiding patients and physicians by presenting current data and referral center availability.

Among patients who experience a recurrence of their MCC, ~80% of these happen within 2 years of diagnosis. The most common site of recurrence is the draining nodal basin or adjacent skin.[17] For those who have recurrences, the locations and frequencies are skin (28%), lymph nodes (27%), liver (13%), lung (10%), bone (10%), brain (6%), bone marrow (2%), pleura (2%), and other sites (4%).[33] Once MCC has spread to viscera, it is typically incurable.

Fortunately, for more than 50% of patients, a good outcome can be anticipated. Those who have had no recurrences for 3–5 years, unlike for melanoma, enjoy a greatly reduced risk of recurrence. The complications for those who do not experience a metastasis depend very much on the therapy they received. We believe that treatment with surgical excision and radiation therapy as outlined in this chapter has relatively minimal complication rates and the best possible chance of cure based on current literature. However, for those who receive very aggressive surgical excision, amputation or chemotherapy for low-risk disease, complication rates tend to be higher without improved outcomes.

Chapter 121 :: Mammary and Extramammary Paget's Disease

:: Sherrif F. Ibrahim, Roy C. Grekin, & Isaac M. Neuhaus

MAMMARY AND EXTRAMAMMARY PAGET'S DISEASE AT A GLANCE

- Rare intraepithelial adenocarcinoma occurring in apocrine gland-bearing skin in patients over 50.
- Erythematous, scaly, eczematous plaque frequently misdiagnosed as inflammatory or infectious dermatitis.
- Most commonly affected sites: unilateral nipple/areola complex [mammary Paget's disease (MPD)], vulva, perianal skin, scrotum, and penis [extramammary PD (EMPD)].
- Most cases are associated with underlying breast carcinoma (MPD); EMPD not usually associated with underlying neoplasm but may be present in minority (15%) of cases.

EPIDEMIOLOGY

Mammary Paget's disease (MPD) represents approximately 1% to 3% of breast neoplasms.[1] The peak incidence is between 50 and 60 years of age and almost all reported cases occur in women.

Extramammary Paget's disease (EMPD) is a rare neoplasm that affects apocrine gland-bearing skin such as the vulva, perianal region, scrotum, and penis. The majority of patients are in the sixth through eighth decades of life.[2–4] The genitals are the most commonly affected area, with EMPD representing 2% of all vulvar malignancies.[3]

ETIOLOGY AND PATHOGENESIS

MPD is almost always associated with underlying in-situ or invasive intraductal adenocarcinoma of the breast (up to 98% of cases in some studies).[5,6] Malignant cells directly extend from the underlying tumor into the epidermis via the lactiferous ducts. Rare cases are reported to have originated primarily in the epidermis of the nipple.[7]

Unlike MPD, in which almost all cases have a documented underlying neoplasm, EMPD does not have a consistent histogenesis. Primary EMPD occurs in the absence of underlying malignancy and accounts for the majority of patients with the disease. These cases represent a primary intraepithelial neoplasm of apocrine origin. The malignant cells are thought to originate from intraepidermal apocrine glands or from pluripotential cells of the epidermis. The neoplasm can then invade the dermis and metastasize via lymphatic spread. In contrast, cases of secondary EMPD are associated with an underlying apocrine carcinoma or internal malignancy. These cases are due to epidermotropic spread of malignant cells from the underlying tumor. Approximately 15% of cases are associated with an underlying internal carcinoma. The most common visceral malignancies associated with EMPD are carcinomas of the rectum, bladder, urethra, cervix, and prostate.[4,8,9]

CLINICAL FINDINGS

HISTORY

Both MPD and EMPD present with a long-standing history of pruritic, erythematous, scaly, or velvety patches on the breast or in apocrine-rich areas such as the groin, perineum, or axilla. Given the rather nondescript appearance, there is frequently a significant delay in diagnosis as initial treatment often involves topical steroids and/or antifungal agents for presumed inflammatory or infectious dermatitis. After continued recalcitrance to therapy, a diagnostic biopsy is performed and the correct diagnosis is made.

CUTANEOUS LESIONS

MPD frequently presents as a unilateral, erythematous, scaly plaque involving the nipple and/or the

Figure 121-1 Paget disease of the nipple. Sharply circumscribed erythematous and scaly plaque involving the nipple and areola.

areola (Fig. 121-1). Ulceration and weeping with an eczematous appearance is frequently present. Nipple erosion and discharge may occur. Retraction of the nipple can be seen. Pain, burning, and pruritus are frequently reported by patients. See Box 121-1 for differential diagnosis of MPD and EMPD.

Lesions of EMPD are clinically similar to MPD and often present as a well-defined, moist, erythematous, scaly, eczematous plaque. Hypo- and hyperpigmentation can occur. Burning and intense pruritus are commonly reported. Lesions typically involve apocrine gland-bearing skin (i.e., genitoperineal region and axilla). The most frequent site is the vulva, but perineal, scrotal (Fig. 121-2), perianal (Fig. 121-3), and penile skin are also common areas. Rarely, ectopic EMPD has been reported in areas that are relatively free of apocrine glands, such as the chest, abdomen, thigh, eyelids, face, and external auditory canal.[10–14]

Figure 121-2 Extramammary Paget disease. Moist, well-demarcated, eroded, oozing plaque on the scrotum of an older man.

Given the less established association with underlying carcinoma in EMPD as compared to MPD, a palpable mass or other malignant stigmata are much less frequently found on physical examination.

RELATED PHYSICAL FINDINGS

Up to one-half of all patients with MPD have a palpable underlying breast mass.[5,6,15,16] Of those patients with a palpable underlying tumor, half have axillary adenopathy due to lymph node metastasis.[5,6] Palpable lymph nodes are less frequently present in EMPD. Complete physical examination including thorough full body skin exam is required in all cases of MPD and EMPD. Patients may present with symptoms and physical findings reflective of an underlying carcinoma or metastatic disease.

LABORATORY TESTS

PATHOLOGY. The intraepidermal adenocarcinoma of EMPD and MPD has a similar histologic appearance.

BOX 121-1 DIFFERENTIAL DIAGNOSIS OF MAMMARY (MPD) AND EXTRAMAMMARY PAGET'S DISEASE (EMPD)

	MOST LIKELY	CONSIDER	ALWAYS RULE OUT
MPD	Nipple eczema Erosive adenomatosis Psoriasis Dermatophyte infection	Hailey–Hailey disease Pemphigus	Bowen disease Basal cell carcinoma Malignant melanoma
EMPD	Candidiasis Tinea cruris Psoriasis Seborrheic dermatitis Nummular dermatitis	Lichen sclerosus et atrophicus Pemphigus Lichen simplex chronicus Lichen planus Drug eruption	Bowen disease Erythroplasia of Queyrat Malignant melanoma

Figure 121-3 Perianal Paget disease presenting as moist, superficially eroded patch.

There are groups, clusters, or single cells within the epidermis that show nuclear enlargement with atypia, prominent nucleoli, and well-defined ample cytoplasm (Fig. 121-4).[15] Intercellular bridges are absent. The cells can be within all levels of the epidermis and can compress but preserve the basal layer without junctional nest formation. The cells can extend into the contiguous epithelium of hair follicles and sweat gland ducts. Acanthosis, hyperkeratosis, and parakeratosis are often present. These cells have a "pagetoid" appearance and simulate other intraepidermal malignancies, such as melanoma, pagetoid squamous cell carcinoma in situ, mycosis fungoides, cutaneous adnexal carcinomas (sebaceous carcinoma, porocarcinoma, and others), Merkel cell carcinoma, Langerhans cell histiocytosis, and other epidermotropic cutaneous metastases. The cells of MPD and EMPD can be pigmented, which does not necessarily indicate they are melanocytic.

Paget's cells have intracellular mucopolysaccharides, with EMPD having a greater amount of mucin as compared to MPD. As a result, cells frequently show positive staining for periodic acid-Schiff and diastase resistance, mucicarmine, Alcian blue at pH 2.5, and colloidal iron (see eFig. 121-4.1 in online edition). However, there are can be focal "skip areas" that are devoid of mucin, resulting in sections of negative staining.

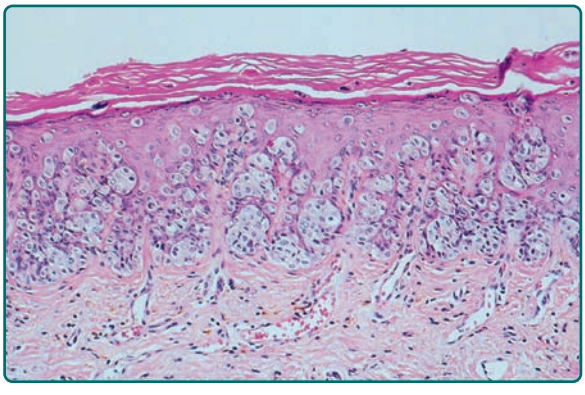

Figure 121-4 Paget disease, hematoxylin and eosin stain. Paget's cells have distinctive pale-staining cytoplasm and are usually randomly dispersed throughout the epidermis.

Immunohistochemistry is invaluable in making the correct diagnosis. Low-molecular-weight cytokeratin stains cytokeratin 7 (CK7) and anticytokeratin (CAM 5.2) are sensitive markers for both MPD and EMPD (see eFig. 121-4.2 in online edition). They are not completely specific, however, as both Toker and Merkel cells also exhibit CK7 positivity. The cells of MPD and EMPD may stain with carcinoembryonic antigen (CEA), epithelial membrane antigen (EMA), Ber-EP4, BRST-2, and HER-2/neu.[17–19] The most useful keratin markers for Paget's disease are CAM 5.2 and CK7, as they stain more than 90% of Paget's cells but do not react with epidermal or mucosal keratinocytes.[16,20] The cells of pagetoid squamous cell carcinoma in situ typically do not stain with CK7 and CAM 5.2. S100, Melan-A (MART-1), and HMB-45 are useful markers to exclude melanoma, and are typically negative in MPD and EMPD. CK20 positivity has been found more frequently in cases of secondary EMPD with underlying carcinoma as compared to those cases of primary intraepithelial EMPD ($CK7^+/CK20^-$).[21]

Gross cystic disease fluid protein-15 (GCDFP-15) is a marker for apocrine epithelium and is typically positive in primary EMPD (not associated with underlying neoplasm). In contrast, GCDFP-15 is frequently negative in those cases of secondary EMPD with an associated malignancy.[22]

Mucin core protein (MUC) expression is useful in the diagnosis of MPD and EMPD.[23] MUC1 positivity is noted in both MPD and EMPD. MUC2 expression is generally negative in primary EMPD, but may be expressed in those cases of secondary EMPD with an associated underlying gastrointestinal adenocarcinoma. MUC5AC is frequently positive in primary EMPD and less commonly noted in secondary EMPD or those cases of primary intraepithelial EMPD that becomes invasive. *CDX2* is a regulatory gene involved in intestinal proliferation and has been suggested as a useful maker in EMPD associated with underlying colorectal tumors.[19,24]

Recent studies investigating the role of androgen receptor and 5α-reductase suggest an elevated 5α-reductase level in invasive (81%) compared with noninvasive (45%) cases of EMPD.[25] For invasive cases, men had a significantly higher level of androgen receptor and 5α-reductase double positivity than women (70% vs. 17%), suggesting an autocrine synthesis of androgens in EMPD and gender-specific microenvironments that may contribute to invasiveness of the disease.

Expression of human telomerase reverse transcriptase (hTERT) has been shown to be significantly higher in patients with invasive lesions of EMPD as opposed to noninvasive cases.[26]

SPECIAL TESTS. Complete workup of MPD and EMPD should include a thorough search for underlying malignancy. Mammography is required in all cases of MPD, with immediate biopsy of any detectable breast mass.

In cases of EMPD, workup is directed toward the possibility of an underlying gastrointestinal or genitourinary neoplasm. Imaging of the abdomen and pelvis, colonoscopy, barium enema, cystoscopy, intravenous pyelogram, chest X-ray and mammogram (for the rare association of EMPD and MPD), and blood work are appropriate tests. In two recent studies, patients with significantly elevated carcinoembryonic antigen (CEA) had a greater risk of death from the disease compared with patients with normal serum CEA, and the level of CEA paralleled disease course.[4,8] Some reports have suggested that positron emission tomography (PET) scans may be useful for cases of invasive EMPD to evaluate for lymph node involvement and metastases.[8,27,28] The role of sentinel lymph node biopsy (SLNB) for patients with EMPD is discussed below.

COMPLICATIONS

Failure to identify and adequately treat cases of MPD can lead to metastatic disease with a poor prognosis. EMPD, if left untreated, can become invasive and metastatic disease can ensue with a less favorable outcome.

PROGNOSIS AND CLINICAL COURSE

Overall survival in patients with MPD is affected by lymph node status and the presence of an underlying breast mass. Patients with negative lymph nodes have been shown to have a 10-year survival rate of 75% to 95%, whereas those with positive lymph nodes have a survival rate of 20% to 45%.[5] Patients with a palpable breast mass have a 5-year survival probability of 35% to 51%, as compared to 75% to 82% in patients without a palpable mass.[6]

The prognosis for primary EMPD confined to the epidermis is excellent with appropriate treatment. Careful monitoring for early detection of local recurrence is critical given the multifocal pattern often present in EMPD. In contrast, invasive EMPD has a high rate of metastasis and carries a poor prognosis. The depth of invasion appears to be an important prognostic factor, with microscopic invasive disease (less than 1 mm) having a more favorable prognosis as compared to those with deeper invasion.[4,9,29,30] Lymphovascular invasion and regional lymph node metastases markedly reduce overall survival rate and indicate a very poor prognosis. Presence of clinically apparent nodules in the primary tumor and elevated CEA level have an association with decreased survival.[4] Clitoral EMPD has been shown to have a higher incidence of death from the disease as compared to other vulvar EMPD locations.[29] Gender and tumor size have not been shown to correlate significantly with survival.[4]

The most common sites of metastases are lymph nodes followed by bone and lung.[4,8] In a recent study of 44 patients with EMPD, those patients with metastatic involvement were younger and had elevated levels of CEA. Metastatic disease was present in all patients with elevated CEA; however, not all patients with metastases demonstrated increased serum CEA. Deeper invasion, lymphovascular involvement, and negative E-cadherin were important histologic prognostic factors for metastatic potential. The 2-year survival rate in patients with metastatic EMPD was 48%.[8]

In cases of secondary EMPD, the prognosis is related to the underlying carcinoma.

TREATMENT

MAMMARY PAGET'S DISEASE

(Fig. 121-5)

Treatment of MPD is surgical; however, optimal surgical management of MPD remains to be defined, and treatment choice is frequently based on the presence or absence of an underlying breast mass. Mastectomy remains the standard definitive treatment yet emerging evidence suggests that MPD treated with breast-conserving surgery results in local control and survival rates similar to those achieved with mastectomy.[31,32] Proper preoperative imaging is required to rule out multifocal disease that would make breast-conserving therapy less effective and favor mastectomy.[33] Lymph node evaluation via axillary dissection or SLNB must be considered in MPD. Adjuvant therapy with radiation, chemotherapy, or hormonal therapy is recommended based on lymph node status and specific features of the primary tumor.[5] All diagnoses of MPD require referral to a physician with expertise in the management of breast cancer.

EXTRAMAMMARY PAGET'S DISEASE

(Fig. 121-6)

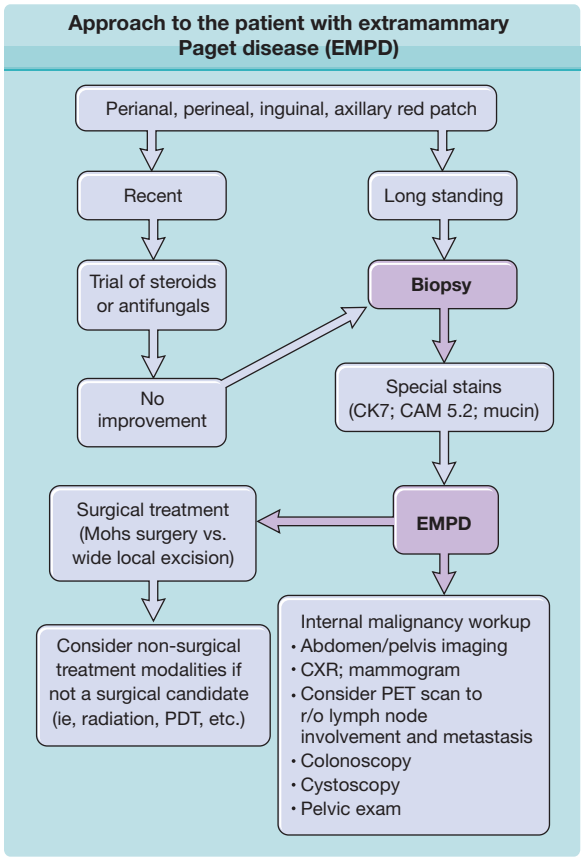

Figure 121-6 Approach to a patient with extramammary Paget disease (EMPD). CAM 5.2 = anticytokeratin stain; CK7 = cytokeratin 7 stain; CXR = chest X-ray; PDT = photodynamic therapy; PET = positron emission tomography; r/o = rule out.

EMPD has been treated with a variety of different modalities. Although surgical management of the disease is the most frequently used method, various other treatments have a role for poor surgical candidates and as adjuvant therapy.

SURGERY. Surgery remains the treatment of choice for EMPD in those patients that can tolerate the procedure. High local recurrence rates are seen after standard surgical excision, even when wide margins are used. This is most likely due to the ill-defined borders, multifocal nature of the condition, and subclinical involvement of apparently unaffected skin. Furthermore, because these tumors commonly occur in the genitoperineal region, wide excision may be technically difficult and disfiguring.

Several reviews have shown an overall recurrence rate of up to 44% with wide local excision.[2,34,35] The local recurrence rates are higher in cases of invasive disease as compared to those limited to intraepithelial involvement. In addition, more radical and extensive surgeries are associated with lower rates of local recurrence. Patients with primary vulvar EMPD treated with radical vulvectomy, radical hemivulvectomy, and wide local excision have reported recurrence rates of 15%, 20%, and 43%, respectively.[34]

In one study of 76 patients with EMPD, 66 patients underwent surgical excision, five developed local recurrence; however, recurrence rate did not differ between wide (>2 cm) and narrow (<2 cm) surgical margins, despite scouting biopsies.[4]

Multiple scouting biopsies to help delineate the extent of the disease before surgery can be a useful adjuvant technique.[36] Intraoperative staining with CK7 is the preferred immunostain for intraoperative tissue evaluation.[37] SLNB has been described in the treatment of EMPD.[38] Although this technique has been limited to a small number of reported patients and most cases of EMPD have in situ disease, SLNB may prove beneficial for those patients with increased risk of lymph node involvement and metastasis (i.e., dermal invasion of Paget's cells, elevated CEA).[39] Some advocate the use of SLNB and/or regional lymphadenectomy in all high-risk EMPD cases, despite negative findings on PET/CT, as micrometastases are undetectable with this form of imaging.[8] Due to the nature of inguinal lymphatic drainage, bilateral sentinel lymph nodes are not uncommon.

MOHS MICROGRAPHIC SURGICAL EXCISION. Given the high rates of local recurrence and the significant morbidity associated with radical and repeated surgeries, Mohs micrographic surgical excision (MMS) has been used to improve cure rates and for tissue sparing of critical genitourinary anatomic structures as compared to wide local excision.[2,35,37,40,41] The recurrence rate after treatment with MMS has been reported as 16% for primary EMPD and 50% for recurrent EMPD. Ninety-seven percent of the cases treated with MMS required margins of 5 cm from the clinical tumor margin. However, if surgical margins of only 2 cm were used, as may be the case because wider margins may not be feasible when operating on the genitalia, only 59% of the tumors would have been cleared. The 40% expected recurrence rate with 2 cm margins is consistent with what is seen in various reports of EMPD treated with standard wide excision. This further validates a potential benefit of frozen horizontal sectioning for complete peripheral and deep margin mapping and reduces the possibility of residual tumor. Immunohistochemical staining with CK7 during Mohs surgery has also been employed.[17]

RADIOTHERAPY. Although surgery remains the traditional treatment for EMPD, radiotherapy may be indicated in those patients who are poor surgical candidates or are concerned with the risk of compromising genitourinary function due to extensive surgery that is often required for curative treatment.[42–44] In addition, radiotherapy has been described as useful for local recurrence after surgery or as an adjuvant therapy in those patients with a high risk of recurrence.[43,45] No randomized controlled studies comparing surgery to radiotherapy have been performed to date.

TOPICAL CHEMOTHERAPY AND IMMUNOMODULATORS. Topical agents, including 5-fluorouracil (5-FU), bleomycin, and imiquimod, have been used to treat EMPD with varying degrees of success.

5-FU may be useful as a preoperative adjunctive treatment to highlight the subclinical extent of disease before

MMS or for early postoperative detection of recurrence.[46] However, topical 5-FU has not proven to be a reliably curative agent in the treatment of EMPD.[47] This is likely due to the limited penetration of the drug and the inability to reach the deeper epidermal layers and adnexal structures that are frequently involved in EMPD.

Imiquimod has been reported to result in clinical and histologic cure in several case reports.[48–52] Given the limited number of patients treated with this medication, further studies and long-term follow-up in a larger cohort is necessary.

SYSTEMIC CHEMOTHERAPY. Systemic chemotherapy has been used to treat patients with invasive and metastatic disease and may be considered in rare cases in which surgery and radiotherapy are contraindicated. Limited reports of systemic chemotherapy for the treatment of EMPD have been described, including a combination of low-dose 5-fluorouracil and cisplatin[53]; a combination of 5-FU, cisplatin, mitomycin C, epirubicin, and vincristine[54,55]; and docetaxel.[8,56,57]

PHOTODYNAMIC THERAPY. Given the patchy nature of EMPD and extension beyond clinically visible tumor, photodynamic therapy (PDT) is a potentially useful treatment modality. Although the limited number of studies and reports makes further investigation necessary, PDT may be considered in patients who are poor surgical candidates, are at risk for significant functional morbidity due to the anatomic location of the disease, or have recurrent postsurgical disease.[58–61] Limiting treatment to intraepithelial disease is prudent given the limitations of current PDT technology. PDT has been described as an adjuvant to surgical treatment to better define clinical margins and improve recurrence rates.[37]

PREVENTION

Both EMPD and MPD are not preventable diseases. Rather, early diagnosis is the key to a favorable prognosis, and any unilateral eczematous rash on the breast or in the groin that does not respond to an appropriate course of topical treatment warrants a biopsy. Routine mammography may allow early detection of underlying breast carcinoma in women of appropriate screening age.

SECTION 22

Melanocytic Tumors

Chapter 122 :: Benign Neoplasias and Hyperplasias of Melanocytes

:: James M. Grichnik, Arthur R. Rhodes, & Arthur J. Sober

Benign melanocytic proliferative lesions form a spectrum of disorders ranging from a massive accumulation of cells in multiple tissue elements to epidermal foci with a simple increase in epidermal melanocyte number. Here these lesions are separated into *melanocytic neoplasias* and *melanocytic hyperplasias.* The term *melanocytic neoplasia* is used to describe the presence of melanocytic cells in epidermal nests [defined as three or more melanocytic cells in direct contact (also known as *thèque*)], within the dermis, or in other tissues. The melanocytic neoplasms are referred to as nevi (singular: nevus) and the melanocytic cells forming these nevi are referred to as *nevomelanocytes*. The term *melanocytic hyperplasia* is used to indicate increased melanocytes confined to the basal layer of the epidermis.

The specific molecular events causing melanocytic neoplasias and hyperplasias are beginning to be defined. Given the presence of immature (less melanized) cells in many melanocytic neoplasias, it seems likely that specific underlying mutations (such as *N-RAS*, *GNAQ*, and *B-RAF*) disrupt normal melanocytic development and result in accumulation of the nevomelanocytic cells that do not complete typical migration and differentiation. The melanocytic hyperplasias are comprised of epidermal melanocytes at an increased concentration and thus alterations of normal melanocytic homeostatic mechanisms appear to be operative. These alterations could be due to a primary melanocytic defect [such as an ultraviolet (UV)-induced mutation] or homeostatic signaling changes in the local environment (possibly driven by mutations within the local keratinocytes, fibroblasts, or other resident cells).

This heterogeneous group of disorders is currently loosely subcategorized based on clinical features and microscopic characteristics. The neoplasias described include congenital nevomelanocytic nevi (CNNs), nevus spilus, common acquired nevomelanocytic nevi (excluding atypical/dysplastic nevi covered in Chapter 123), blue nevi, pigmented spindle cell nevi (PSCN), Spitz nevi, and nodal nevi. Cutaneous melanoma is covered separately in Chapter 124. The benign melanocytic hyperplasias described in this chapter include lentigo simplex (including agminated lentigines) and solar lentigines.

CONGENITAL NEVOMELANOCYTIC NEVI

CONGENITAL NEVOMELANOCYTIC NEVUS AT A GLANCE

- Melanocytic neoplasm often exhibiting extensive nevomelanocytic infiltration of the dermis with potential involvement of the underlying adipose and muscular tissue.
- Lesions may be small or cover a substantial portion of the body surface. Nevi are generally darker than the surrounding skin, have a rugose or smooth elevated surface, and may demonstrate long, darker, thicker hairs.
- Present at birth (or shortly thereafter—tardive congenital nevomelanocytic nevus).
- Large lesions have a significant risk of melanoma development. Cranial or midline lesions and large congenital nevomelanocytic nevus lesions with satellite lesions have an increased risk of leptomeningeal involvement.
- Synonyms: garment nevus, nevus pigmentosus et pilosus, giant nevus, verrucous nevus, and giant pigmented nevus.

EPIDEMIOLOGY

The vast majority of CNNs noted at birth are small and singular, and no gender predilection has been

Figure 122-1 Familial aggregation of small congenital nevomelanocytic nevi. Note small congenital nevus on the thigh of a 3-year-old white boy and on the back of his 5-year-old male sibling.

Figure 122-2 Congenital divided nevomelanocytic nevus of the eyelid. The nevus is contiguous when the eyelids are closed, suggesting that the lesion was formed in the developing fetus before the eyelids split (i.e., before 24 weeks).

demonstrated. The most reliable prevalence rate for CNN in a homogeneous ethnic group was obtained by biopsying all pigmented lesions in 841 white infants examined within 72 hours of birth: of 21 infants with pigmented lesions, 7 babies (0.83% of 841) had a biopsy-confirmed nevomelanocytic nevus.[1] According to other studies, the prevalence of CNN appears to be slightly higher in nonwhites compared to whites. Many other series have yielded equivalent results. CNNs of 99 mm or more in diameter occur in only 1 of every 20,000 newborns, and CNNs with a garment distribution occur in only 1 of every 500,000 newborns.[2] Familial aggregation has been demonstrated for both large and small varieties of CNN (Fig. 122-1). Discordance for giant CNNs has been demonstrated for identical twins in at least three cases and for nonidentical twins in two cases.

ETIOLOGY AND PATHOGENESIS

CNNs represent a developmental abnormality of normal melanocytic development. This is presumably due to a mutation (often *NRAS*)[3] that occurs in a progenitor cell that results in the abnormal extensive accumulation of melanocytic cells along migration pathways during normal development. The events leading to the nevomelanocyte accumulation may also have effects on the surrounding tissue (i.e., increased length/darker hair) possibly due to changes in the local cytokine environment of the nevomelanocytic cells. Clinical findings such as a congenital divided nevus of the eyelid (Fig. 122-2) can give us insight into when these events occur.[4] The eyelids form at between 5 and 6 weeks in utero, begin to fuse at about 8 to 9 weeks, and reopen during the sixth uterine month.[5] Because of the contiguous nature of this lesion on the upper and lower eyelids, it may be presumed that the nevomelanocytes migrated into this location sometime during or after eyelid fusion but before the eyelids split.

CLINICAL FINDINGS

(Fig. 122-3)

HISTORY. Most CNNs are present at birth; however, there are also rare varieties of relatively large nevomelanocytic nevi (>1.5 cm) that appear for the first time between 1 month and 2 years of life, according to parental observations and corroborated by photographs (tardive congenital nevi). As a child grows, the CNN should grow relatively proportionally[6] and continue to "mature." History of disproportionate growth, especially after 6 months, or change in a nonuniform manner is of concern for possible melanoma. Both small and large varieties of CNNs have been associated with loss of pigmentation, halo depigmentation, and even regression.

CUTANEOUS LESIONS. Although CNNs are on average larger than acquired nevi, for lesions less than 1.5 cm in diameter there is no specific size limitation that can be used to predict reliably whether a given nevus is congenital or acquired. Lesions attaining a diameter of 1.5 cm or more are likely to be congenital, atypical melanocytic nevi, or melanoma.

There is no completely satisfactory way to categorize CNNs as small or large. Definitions have been based on ease of removal and termed *small* if they can be excised and the wound defect closed primarily without significant deformity. Arbitrary size criteria have also considered small (<1.5 cm; see eFig. 122-3.1 in online edition), medium (1.5–19.9 cm), and large (≥20 cm). Size, of

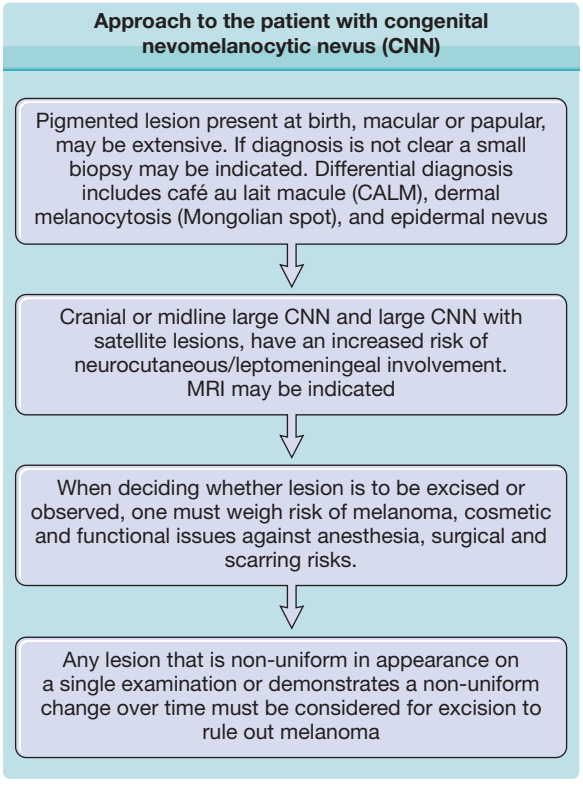

Figure 122-3 Approach to the patient with congenital nevomelanocytic nevus (CNN). MRI = magnetic resonance imaging.

Figure 122-4 Giant congenital pigmented nevus in the bathing trunk distribution. Note the satellite nevi.

course, is all relative to the affected anatomic location and the patient. *Giant* has been variously defined as a lesion as large as the patient's palm if it occurs on the head and neck (and twice that area for other anatomic sites), 30% of the body surface, or 900 cm^2 in adults (or smaller if it involves a major anatomic area) (see Fig. 122-4). Depending on the definition used, lesions that are regarded as small or medium in the newborn period may be designated medium or large, respectively, by late childhood or adulthood, given that CNNs appear to grow in proportion to the affected anatomic site.[6]

The contour of CNNs is usually smooth, regular, and sharply demarcated, and skin markings distort the skin surface at least slightly when assessed by oblique lighting. Some CNNs are relatively hairless. However, coarse, long, darkly pigmented hair may be present at birth, appear within the first year or two of life, or be delayed for several years. Lesions may have a smooth, pebbly, rugose, verrucous, cerebriform, or grossly lobular surface. CNNs with a cerebriform appearance may present as cutis verticis gyrata.

Dermoscopy may reveal a reticular pattern or globular/cobblestone pattern and may be useful in the identification of small foci of melanoma. In large congenital nevi, there can be significant variability in pigmentation and structure, and melanomas may develop in the deep components potentially reducing the utility of dermoscopy in these lesions.

Unique varieties of CNNs may have an atypical appearance and be striking for their haphazard, very dark-brown, black, or blue–black pigmentation or discontinuous pigmentation and poorly demarcated and/or irregular outlines, often associated with atypical histopathologic features. Very darkly pigmented CNNs are distinctly uncommon in whites and should suggest the possibility of atypical histopathologic features. In darkly pigmented infants, CNNs are usually darkly pigmented.

RELATED PHYSICAL FINDINGS. CNNs of the head, neck, or posterior midline, and/or the presence of multiple satellite lesions associated with large CNN may be complicated by underlying cranial and/or spinal leptomeningeal melanocytosis. This phenomenon may be asymptomatic or may give rise to communicating or noncommunicating hydrocephalus, seizures, focal neurologic deficits, mental retardation, or even melanoma. CNNs need not be giant to be associated with this underlying disorder.

There is a significant association between neurofibromatosis and giant CNNs. In a study by Crowe et al,[7] 3 of 223 patients with neurofibromatosis had extensive CNNs. In his monograph on neurofibromatosis, von Recklinghausen described 1 of 28 patients as having a giant CNN.[8] Tumors indistinguishable from neurofibroma in the absence of von Recklinghausen neurofibromatosis may develop in association with giant varieties of CNN.

Malignant degeneration of large CNNs may be associated with the relatively sudden appearance of a dermal or subcutaneous nodule, very dark pigmentation, itching, pain, bleeding, or ulceration. Often, CNN-associated melanomas appear to have evolved in nonepidermal locations.[9] Therefore, early detection of melanoma in association with a giant CNN may be difficult and not recognized until a dermal nodule or metastatic disease appears. The prognosis for patients who develop melanoma in association with giant CNNs is

usually grave.[9] Unlike melanoma in general, there is no ethnic predilection for melanoma developing in giant CNN. There have been multiple cases of lethal melanoma developing in association with small, medium, large, and giant CNNs in black children.

LABORATORY TESTS

HISTOPATHOLOGY. CNNs are characterized by the presence of nevomelanocytes in the epidermis as well-ordered thèques and/or nevomelanocytes in the dermis, which are present as sheets, nests, cords, and/or single cells. Although histopathologic features are cited as being useful in distinguishing nevi as congenital or acquired, there are no known features with absolute specificity and sensitivity. The histopathologic features of very large CNNs may be divided into nevomelanocytic, neuroid, epithelioid cell and/or spindle cell, blue, and mixed types.

In the nevomelanocytic type of large CNN, the histopathologic appearance may be identical to typical acquired nevi, with nevomelanocytes in the epidermis as well-defined thèques and/or nevomelanocytes in the papillary dermis as sheets, cords, or nests. CNNs are more likely than acquired nevi to have nevomelanocytes in the lower two-thirds of the reticular dermis and to be associated with appendageal and neurovascular structures (Fig. 122-5). There may be preferential involvement of one or more appendageal structures in CNN, such as eccrine ducts, and these structures may be abundant and malformed. Veins may be preferentially involved, with an "inflammatory" appearance showing nevomelanocytes within and around blood vessel walls. Subendothelial protrusion by nevomelanocytes in lymphatic vessels may be prominent. Arrector pili may be malformed, large, and infiltrated by nevomelanocytes. Hair follicles are often quite large and frequently associated with abundant melanin in the hair bulb. Nevomelanocytes in the deep reticular dermis may be distributed as single cells or as a single-file array insinuating among collagen bundles, sheets of cells, or combinations of patterns.

In the neuroid type of giant CNN, melanocytic elements take on the appearance of Wagner–Meissner corpuscles (lames foliacée), a palisaded arrangement of cells around a cellular mass of homogeneous material (Verocay body), and sheathing of nerves by neuroid tissue (neuroid tubes). The neuroid type of nevus may be responsible for lobulation and redundancy of tissue (pachydermatous or cerebriform appearance) due mainly to the production of connective tissue elements such as reticulin, collagen, and sometimes mucinous stroma. The neuroid type of giant CNN may take on the appearance of a pigmented neurofibroma and may be associated with congenital anomalies of bone (club foot, spina bifida, and atrophy) as well as with a "neurosarcomatous" morphologic variant of melanoma.

In the spindle cell and/or epithelioid cell type of giant CNN, the dermis may be infiltrated in whole or in part by nests or sheets of epithelioid cells and/or spindle cells. Unlike the usual variety of acquired epithelioid cell and/or spindle cell nevus, the epithelioid and spindle cell elements in CNN may involve deep reticular dermis, often intermixing with neuroid elements and ordinary nevomelanocytes. The epithelioid cell and/or spindle cell elements in giant CNN may have atypical cellular and architectural features, making differentiation from melanoma extremely difficult. In some cases, large epithelioid cells may comprise superficial papillary zones of the nevus, and smaller nevomelanocytes may appear in the same lesion in deeper zones of the reticular dermis, with a grenz zone separating the two elements.

In the blue (dermal melanocytic) type of giant CNN, the appearance may be that of a giant blue nevus, or the lesion may have elements of blue nevus (either common or cellular type) with heavily pigmented spindle-shaped melanocytic cells alone or intermixed

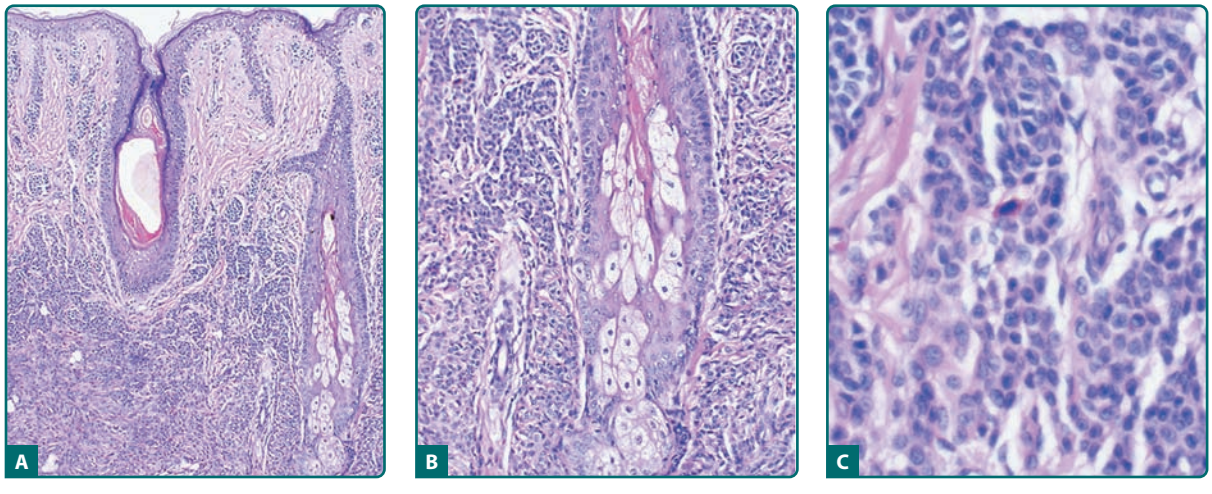

Figure 122-5 Histopathologic features of congenital nevomelanocytic nevus. Nevomelanocytes in the low-magnification image (**A**) reveal dense accumulation in the lower two-thirds of the dermis; at medium magnification (**B**), these cells encroach on dermal adnexal structures (follicular, sebaceous, and eccrine); and higher magnification (**C**) reveals dense collections of small nevomelanocytic cells.

with nevomelanocytes in the reticular dermis or deeper tissues. There may be some biologic overlap with nevus of Ito/Ota and Mongolian spot.

Unique to the very large CNN is the occasional presence of nevomelanocytes within the substance of muscle, bone, placenta, umbilical cord, cranium, and dura mater. Very extensive CNN may be intermixed with elements of vascular malformation, hemangiomas, increased numbers of mast cells, cartilage, calcification, and even bone. There may be sparse mononuclear cell infiltrates associated with some giant CNNs. In addition to melanoma, associated tumors developing in CNN include schwannoma, neuroid tumor, lipoma, rhabdomyosarcoma, neurofibroma, sebaceous nevus, hemangioma, lymphangioma, and mastocytoma. A possible explanation for these mixed neoplasms containing melanocytic, neuronal, and other elements is that the CNN precursor cell, at least in some cases, is a pluripotent stem cell that has the capacity to give rise to multiple cell types.

In giant CNNs, nevomelanocytes have been found in regional lymph nodes without further evidence of progressive metastatic disease. Whether this deposition occurred during the migration of the cells through the dermis or was secondary to migration from the skin after the neoplasm developed is unknown. The presence of nevomelanocytes in the nodal tissue from these lesions does not imply malignancy (see Section "Nodal Nevi").

CNNs may also give rise to proliferative nodules that may be difficult to differentiate from melanoma.[10]

SPECIAL TESTS. For patients with concern of possible leptomeningeal involvement, magnetic resonance imaging should be considered. For patients with concern of melanoma metastatic, positron emission tomography scan may be considered.

DIFFERENTIAL DIAGNOSIS

(Box 122-1)

BOX 122-1 DIFFERENTIAL DIAGNOSIS OF CONGENITAL NEVOMELANOCYTIC NEVUS

- Café-au-lait macule
- Nevus spilus
- Lentigo simplex
- Nevus of Ota/Ito
- Dermal melanocytosis (Mongolian spot)
- Becker's melanosis
- Arrector pili (smooth muscle) hamartoma
- Epidermal nevus
- Nevus sebaceous
- Solitary mastocytoma

COMPLICATIONS

The relationship between melanoma and large CNNs is well documented. The risk of melanoma development appears to be proportional to the size of the congenital nevus. The cumulative 5-year risk has been calculated to be 2.3%[11] and 5.7%[12] in patients with congenital nevi that involve over 5% of the body surface. The lifetime risk of melanoma for patients with very large CNNs has been estimated to be at least 6.3%, based on a questionnaire follow-up study of 151 persons with CNNs examined between 1915 and 1973 in Denmark.[13] Melanoma may develop in large CNNs at any time, but the diagnosis of melanoma was established in the first 3–5 years of life in approximately one-half of published cases in which patients ultimately developed melanoma in association with giant CNN.

A causal association between small CNNs and melanoma is more difficult to establish than for large CNNs. When histopathologic features were studied, 6% to 8% of primary melanomas were found to be in contiguity with nevi that had microscopic features characteristic of CNN.[14,15] These findings support the concept of melanoma risk even with small congenital nevi, given the expected chance association based on body surface area considerations.[16]

For cranial, midline, or CNN with multiple satellite lesions, there is a risk of leptomeningeal involvement. Symptomatic leptomeningeal melanocytosis carries a poor prognosis, even in the absence of malignant degeneration.

PROGNOSIS AND CLINICAL COURSE

CNNs have a dynamic evolution during body growth. CNNs at birth usually distort the skin surface at least slightly when assessed by oblique lighting and may become more elevated over time. Surface pigmentation also may change. Lightly pigmented CNNs may become more darkly pigmented, and darkly pigmented CNNs eventually may become less pigmented. CNNs may also develop a halo of depigmentation, potentially heralding spontaneous regression. Loss of pigmentation has been associated with regression of underlying nevomelanocytes and the replacement with sclerosis in some cases. Relatively hairless CNNs at birth may develop long, dark, coarse hair, or may maintain a relatively normal hair density. With few exceptions, CNNs generally expand in direct proportion to growth of a given anatomic zone, although disproportionately rapid area expansion of some congenital nevi may occur during early infancy.[6] Lesions in fully grown individuals should remain stable.

TREATMENT

The treatment of CNNs, large and small, depends on the perceived risk of melanoma plus cosmetic and functional considerations.

Melanoma may arise in very large CNNs even in the first several years of life. Therefore, excision of very

large CNNs should be considered as early as possible, but it is probably prudent to wait until after the first 6 months of life to reduce surgical and anesthetic risks. Management of patients with very large CNNs must be individualized. Extensive involvement of the body surface, with little or no normal skin available for graft sites, may necessitate abandoning efforts at prophylactic excision and accepting lifelong surveillance to detect the earliest signs of malignant change. It may be impossible to remove every nevomelanocyte in very large CNNs, particularly when there is involvement of vital structures or deep anatomic zones. The treatment goal is to remove as much of the nevus as possible while preserving function and improving cosmetic appearance. Other indications for surgical excision of very large CNNs include chronic pruritus, ulceration, and infection. Unlike surgical excision, dermabrasion and other modes of destructive therapy do not address the malignant potential of CNN; nevomelanocytes may still be left behind in the dermis, and the cosmetic results associated with destructive therapy are unpredictable. Melanoma has been reported after dermabrasion of large CNNs.[17] "Pseudomelanoma" has been described after laser treatment of a giant CNN.[18]

The approach to small CNNs needs to be considered carefully. It appears that the risk of melanoma development depends on CNN size, and therefore, smaller lesions appear to have less risk. However, due to the smaller size, complete excision of small congenital nevi may be relatively straightforward, resulting in excellent cosmetic results. Although atypical-appearing CNNs should be considered for immediate excision, careful surveillance without excision may be an option for clinically benign lesions depending on gross appearance, size, location, cosmetic and functional deficits (or improvement) resulting from excision, and general health issues. Given the risk of general anesthesia, for lesions perceived to be at low risk during the first decade of life it is appropriate to consider waiting until the child is old enough to tolerate local anesthesia. All CNNs should be documented at birth, preferably in the form of high-quality photographs that can be used to aid follow-up by parents and physicians. Follow-up is complicated by the natural evolutionary changes that take place in a nevus during body growth (i.e., surface, size, color, and hair), and periodic updates of photographs may be warranted. Suspicious changes in color, surface, or size require urgent evaluation.

PREVENTION

There is no known preventive approach to avoid the development of congenital nevi. UV radiation (UVR)-induced mutations clearly play no role in the initial development of the lesions already present at birth. There are no current data on parental exposure that may give rise to congenital nevus formation in their offspring. The role of subsequent UVR exposure for secondary development of melanoma is unclear. However, it seems prudent to protect lesions from unnecessary UVR exposure.

NEVUS SPILUS

NEVUS SPILUS AT A GLANCE

- Localized collection of melanocytic neoplasias forming in the background of a melanocytic hyperplasia. The neoplastic elements within the lesion tend to be histologically similar in appearance. In some lesions, the darker elements may only demonstrate increased hyperplasia compared to the background lesion.
- Clinically, the lesion appears as a hyperpigmented patch with scattered darker flat or raised elements clinically similar in appearance.
- Background lesion may be present at birth, but generally develops during infancy or early childhood. The neoplastic or hyperplastic elements may continue to develop within the lesion over time.
- Overall, risk is low but melanoma has been noted to develop in nevus spilus.
- Nevus spilus (derived from Greek *spilos*, meaning *spot*)—spotted nevus. Synonyms: speckled lentiginous nevus and zosteriform lentiginous nevus.
- Related variants with localized collection of nevomelanocytic neoplasias without the background of melanocytic hyperplasia are referred to as agminated nevomelanocytic nevi.
- Related variants with localized collection of melanocytic hyperplasias without the background of melanocytic hyperplasia are referred to as *agminated lentigines* (see Section "Lentigo Simplex").

EPIDEMIOLOGY

Nevus spilus occurs in less than 0.2% of newborns, 1% to 2% of white school children, and 2% of white adults.[19] There are no prevalence data in darkly pigmented persons. There does not appear to be a gender predilection.[19] When viewed as a risk marker for melanoma, nevus spilus shows a trend for being more common in melanoma cases than in controls. Kopf et al[19] detected nevus spilus in 5 (4.8%) of 105 white adults with melanoma compared with 14 (2.3%) of 601 dermatology outpatients.

Approach to the patient with nevus spilus

Background evenly hyperpigmented patch but also including scattered hyperpigmented foci. Wood's light maybe required to visualize background hyperpigmention.

↓

New hyperpigmented foci may develop over time. If one of the foci is unusual compared to the others, is non-uniform, and/or changing, it should be excised to exclude the possibility of melanoma.

Figure 122-6 Approach to the patient with nevus spilus.

ETIOLOGY AND PATHOGENESIS

Nevus spilus may be postulated to develop along similar pathways as a congenital nevus, but instead of the underlying mutation creating a massive accumulation of nevomelanocytic cells in the dermis, the genetic defect creates a field of cells that are susceptible to a secondary event leading to the development of focal individual melanocytic neoplasms within the localized melanocytic hyperplasia. The specific mutations, chromosomal aberrations (mosaicism), and/or dysregulated pathways involved in this process are unknown.

CLINICAL FINDINGS

(Fig. 122-6)

HISTORY. Rarely, nevus spilus may be present at birth. More commonly, the lesion becomes evident during infancy or early childhood. More darkly pigmented, flat, or raised elements are usually present when the lesion is first recognized, but new pigmented elements may appear over time.

CUTANEOUS LESIONS. Clinically, the lesion presents as a circumscribed macule/patch of tan pigmentation with features consistent with lentigo or café-au-lait macule including scattered, more darkly pigmented nevomelanocytic (or more hyperplastic) macular and/or papular elements. The tan macular background pigmentation ranges from less than 1 cm to greater than 10 cm in diameter (Fig. 122-7). Although nevus spilus may occur anywhere, lesions have been noted primarily on the torso and extremities. A divided nevus spilus of the eyelid has been reported.[20] Lesions may be localized or have a segmental distribution. Giant varieties of nevus spilus may occur.

RELATED PHYSICAL FINDINGS. Nevus spilus has been associated with other anomalies of vascular, central nervous system, or connective tissue origin. Multiple granular tumors and nevus flammeus have been associated with a giant nevus spilus. Large varieties of nevus spilus may be associated with muscle atrophy, other neurological disorders, and phacomatosis pigmentokeratotica.[21]

LABORATORY TESTS

HISTOPATHOLOGY. The tan background pigmentation usually consists of increased numbers of

Figure 122-7 Nevus spilus. **A.** Nevus spilus appearing first at age 3 years on the ankle and foot of a 25-year-old white woman. **B.** Congenital nevus spilus on the arm of a 10-year-old white male.

melanocytes in a lentiginous epidermal pattern. Routine and electron microscopic studies of nevus spilus may demonstrate melanin macroglobules in some cases. The flat, dark elements of nevus spilus may demonstrate foci of increased melanocytic hyperplasia or melanocytic dysplasia (architectural disorder and variable cellular atypia), whereas the raised elements usually contain collections of nevomelanocytes in the epidermis and/or dermis. The neoplastic elements of nevus spilus may also consist of epithelioid and/or spindle cell nevi, nevi with dysplastic features, or blue nevi.

SPECIAL TESTS. There are no identified molecular tests of value, at least currently.

DIFFERENTIAL DIAGNOSIS

(Box 122-2)

COMPLICATIONS

There are insufficient data to be certain of the natural history of nevus spilus or to comment specifically about its malignant potential; however, caution must be exercised in affected individuals. More than 20 cases of melanoma have been reported to develop in contiguity with nevus spilus, with some cases ending in metastatic disease and death.

PROGNOSIS AND CLINICAL COURSE

In general, nevus spilus is a benign lesion that may develop more spotted elements over time. Once developed, nevus spilus lesions are presumed to persist throughout life, although it is possible that some elements within the nevus spilus or even the entire nevus spilus itself could regress with time. There are no long-term follow-up studies of nevus spilus.

TREATMENT

No standard guidelines exist for the management of patients with nevus spilus. Clinical appearance (typical or atypical), history of stability or instability of pigmented elements, congenital or noncongenital onset, perceived risk of developing melanoma, and cosmetic concerns are considerations when determining whether to excise or recommend periodic clinical evaluation for life. Atypical-appearing new and/or unstable elements in nevus spilus should be evaluated by histopathologic examination to exclude melanoma. A nevus spilus with dysplastic or congenital features may have a greater risk of developing melanoma.[22,23]

BOX 122-2 DIFFERENTIAL DIAGNOSIS OF NEVUS SPILUS

- Agminated nevomelanocytic nevi
- Agminated lentigines
- Becker melanosis
- Congenital nevomelanocytic nevus with heterogeneous pigmentation
- Café-au-lait macule

PREVENTION

It is theoretically possible that increased UVR exposure results in the development of new nevomelanocytic proliferations or increased malignant potential of nevus spilus.

COMMON ACQUIRED NEVOMELANOCYTIC NEVUS

COMMON ACQUIRED NEVOMELANOCYTIC NEVUS AT A GLANCE

- A spectrum of nevomelanocytic neoplasias often subcategorized based on location of cells: cells in the epidermis (junctional), dermis (intradermal), or both areas (compound). Pathologically, the cells in the deeper dermis tend to be smaller in size and express melanocytic antigens at reduced levels. Melanocytes in the epidermis may be normal or increased in number compared to adjacent nonaffected skin.
- Clinically, the lesions tend to be uniform in appearance and relatively small in size.
- Primarily develop during childhood/young adulthood.
- Increased numbers of acquired nevi suggest an increased risk for melanoma development (also see Chapters 123 and 124).
- Synonyms: nevus cell nevus, nevocellular nevus, nevocytic nevus, soft nevus, neuronevus, pigmented nevus, pigmented mole, common mole, melanocytic nevus, hairy nevus, cellular nevus, and benign melanocytoma.

EPIDEMIOLOGY

Common (also called *typical*) acquired nevomelanocytic nevi develop after birth, slowly enlarge symmetrically, stabilize, and after a period of time may regress. The majority of common acquired nevi appear to develop during the second and third decades of life, although some lesions may appear in the first 3–6 months of life.

A number of studies have quantified the number of typical acquired nevi in different age groups. In 432 European whites between the ages of 4 days and 96 years, nevi that were 3 mm in diameter or larger were detected in females and males, respectively, at median numbers of 0 and 2 in the first decade, 10 and 16 in the second decade, 16 and 24 in the third decade, 10 and 19 in the fourth decade, 12 and 15 in the fifth decade, 4 and 12 in the sixth decade, and 2.0 and 3.5 in the seventh through the ninth decades.[24] In a series of Australian whites, the average number of nevi per person peaked at 43 for males and 27 for females during the second and third decades, respectively, and decreased to very few in the sixth and seventh decades.[25] A similar age-related prevalence rate for nevi has been documented in other countries. A difference in frequency distribution of nevi according to gender is not clear, although most series show a close to equal prevalence in males and females.

The prevalence of acquired nevi varies according to ethnicity. In African blacks, the overall prevalence of nevi (regardless of size) tends to be higher in those with lighter skin versus those with darker skin.[26] When prepubertal whites were examined for nevi, a significant association for excess nevi was documented for pale skin, blue or green eyes, blond or light-brown hair, and a tendency to sunburn, but not a tendency to freckle.[27] Other studies show variable relationships to these same parameters.

Environmental exposure to UVR appears to be a critical permissive or inciting factor for the development of nevomelanocytic nevi. In an Australian study, nevus density has been shown to increase with increasing sun intensity in the northern parts of the continent.[28] Furthermore, the use of UVR-blocking sunscreens has been shown to decrease the number of new nevi in children.[29]

Genetic factors appear to play a role in the development of nevomelanocytic nevi. The size, frequency, and distribution patterns of acquired nevi tend to aggregate in families. This observation is well documented for atypical nevi in the setting of familial cutaneous melanoma (see Chapter 123) and CNN.

Acquired nevi may be attacked by the patient's immune system, resulting in the development of a halo nevus (see Section "History"). Of 8,298 whites aged 12–16 years, there were 51 males (1.2%) and 22 females (0.5%) who had one or more halo nevi, for an overall prevalence rate of 0.9%.[30] In one large series of halo nevus,[31] individuals ranged in age from 3 to 42 years (mean age, 15 years), with the vast majority of cases occurring before age 20 years. The halo phenomenon has been associated with prominent numbers of common nevi, prominent numbers of atypical nevi, and CNN both small and large.

ETIOLOGY AND PATHOGENESIS

There has been an ongoing debate as to the origin of nevomelanocytic nevi. Although many theories have been proposed, and some supporting data are available, the critical events leading to nevus development remain a mystery. Although data suggest that nevomelanocytic nevi are clonal,[32–34] the *B-RAF*[35] mutation that is present in the majority of common acquired (including atypical) nevi appears to be polyclonal[36] suggesting that *B-RAF* mutation is either a secondary event or that nevomelanocytic nevi can incorporate multiple precursors. Melanocytic "precursor" cells have been shown to be present in adult human skin[37] and melanocytic stem cells have been identified in the mice.[39] It is assumed that these melanocytic stem cells accumulate mutations, and when needed to replenish melanocytes, they produce nevomelanocytes instead. Presumably, these nevomelanocytes then attempt to migrate along normal developmental pathways from the dermis into the epidermis. Dependent on the underlying mutation, some cells might also migrate aberrantly. The defect, timing, and local tissue influences could allow for the creation of a variety of different melanocytic neoplasias.[38]

The clinical phenomenon of eruptive nevi also further confounds the location of the cell of origin issue. In these patients, there is the abrupt appearance of numerous similar appearing nevi often in the setting of immunosuppression or chemotherapy. Although it is generally assumed that these lesions all directly originate in the skin, drawing a comparison with epidermotropic metastatic melanoma leaves open the possibility of a circulating nevomelanocytic precursor.

CLINICAL FINDINGS

(Fig. 122-8)

HISTORY. Acquired nevi primarily develop during childhood and early adulthood. Although nevi can clearly persist in a stable state for decades, many eventually regress. In a study following patients with dysplastic/atypical nevi, the highest rate of nevus development and nevus regression was present in patients younger than 30 years of age.[40] In later adult years, nevus counts are significantly less than those in young adulthood, and the rate of new or growing nevi declines, while melanoma incidence increases. Thus, a growing lesion in an older adult has a greater risk of being melanoma although new or changing moles still significantly outnumber melanomas.[40]

Spontaneous and concurrent development of scattered nevomelanocytic nevi often similar in appearance has been termed *eruptive nevi*. Often, these patients have experienced a blistering skin disease, immunosuppression, cytokine administration, or chemotherapy. Eruptive nevi may have a pattern consistent with common acquired nevi, but Spitz nevi and blue nevi have also been described.

Patients may also present with the history of spontaneous development of a zone of depigmentation around a preexisting nevus. This phenomenon has been called a *halo nevus*. The halo phenomenon may be associated with acquired and CNN as well as with melanoma and nonmelanocytic tumors. This phenomenon often, but not always, indicates the onset of involution and subsequent regression of the melanocytic nevus.

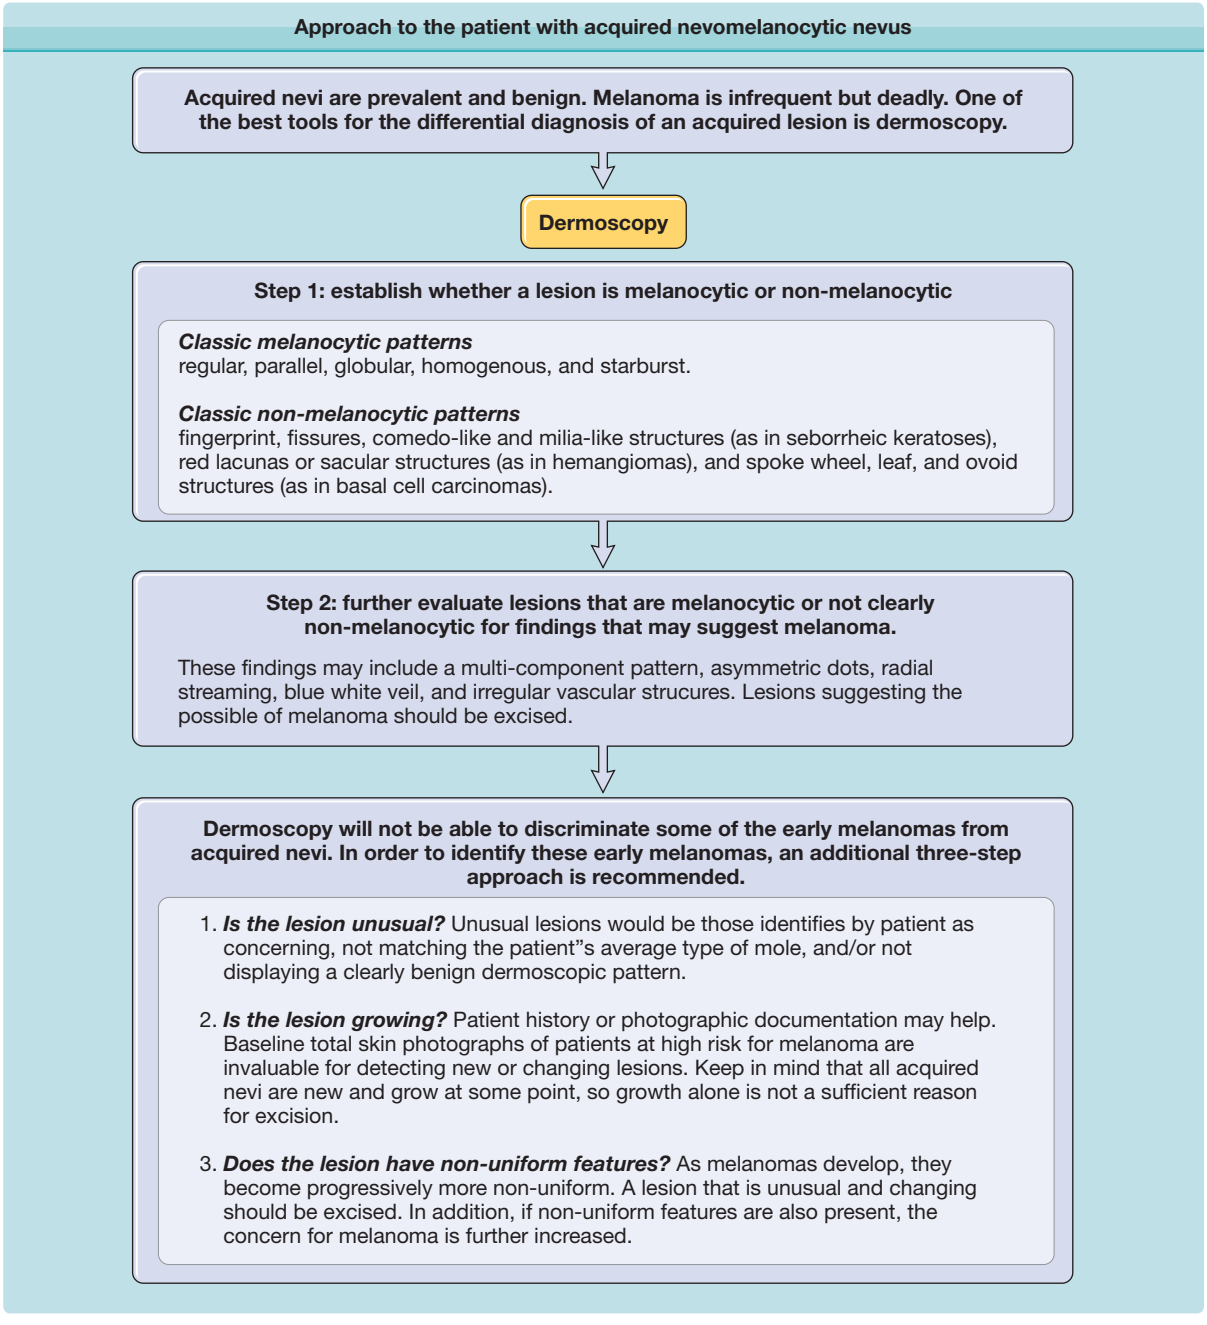

Figure 122-8 Approach to the patient with acquired nevomelanocytic nevus.

Other names for this phenomenon include *leukoderma acquisitum centrifugum*, *Sutton's nevus*, *leukopigmentary nevus*, *perinevoid vitiligo*, and *perinevoid leukoderma*. Time for full evolution to depigmentation of the halo is not known, but patients report the phenomenon occurring over days to weeks, with little change occurring in the halo thereafter. The central nevus may persist or eventually disappear. Disappearance may take months to years. Areas of depigmentation that remain after the central nevus disappears may remain stationary for many years or repigment after months to years. There are lesions in which the nevus does not involute, and repigmentation of the depigmented halo may occur. Halo may be associated with depigmentation at other sites, and the depigmentation may resolve when the CNN is excised (see Fig. 122-10).

CUTANEOUS LESIONS. Common acquired nevi vary considerably in their gross appearance. In general, appearance to the naked eye is orderly: the lesions have a homogeneous surface and coloration pattern, round or oval shape, regular outlines, and relatively sharp borders (Fig. 122-9). Common acquired nevi may be papillomatous, dome-shaped, pedunculated, or flat-topped and are usually skin-colored, pink, or brown. More elevated acquired nevi tend to be more

Figure 122-9 Typical acquired nevomelanocytic nevi. **A.** Junctional nevus. A uniformly dark brown macule, round in shape, with smooth, regular border. **B.** Two compound nevi. A uniformly pigmented papule and domed nodule. The upper lesion is flatter and tan with slight central elevation. The lower lesion is older and is uniformly elevated due to an increased intradermal component.

lightly pigmented, and flatter acquired nevi tend to be more darkly pigmented. More elevated and less pigmented lesions tend to have a prominent intradermal nevus component, whereas flatter and darker lesions have a more prominent junctional melanocytic or nevomelanocytic component and a less prominent dermal component. Very dark brown and black are unusual colors for common acquired nevi in lightly pigmented people. In contrast, dark pigmentation is usual for common acquired nevi in people who have darkly pigmented skin. Blue, gray, red, and white areas in a nevus are not typical features and ought to be viewed with suspicion. The surfaces of nevi may reveal hair that is less than, equal to, or greater than that of surrounding skin. Hair in nevi may be coarser, longer, and darker than that in surrounding skin (often these lesions reveal congenital features). Lesions on palms and soles are usually hairless. Size, shape, skin markings, and hair quality of nevi in darkly pigmented persons are similar to those in whites.

Dermoscopy reveals a number of diagnostic patterns in common acquired nevi. In general, these lesions reveal a reticular or globular pattern. On the palms or soles, a parallel-furrow, lattice, or fibrillar pattern may be present. Nonuniform patterns and parallel-ridge patterns are worrisome for melanoma.

Pigmented nevi of the nail apparatus may be a dark or light brown, extending from the nail matrix to the distal edge of the nail plate (see eFig. 122-9.1 in online edition); extension of the pigmentation onto the skin of the nail fold or beyond the distal nail groove should be considered suspicious for melanoma. Nevi on palms and soles, even compound nevi, may not distort the skin surface, perhaps because of a thickened stratum corneum in these sites.

The typical halo nevus has a pink or brown central nevomelanocytic nevus surrounded by a symmetric round or oval halo of depigmented skin. The central nevus may be small in typical acquired nevi, or large in acquired atypical or congenital nevi (Fig. 122-10). The halo of depigmentation is variable in size, usually a radial zone 0.5–5.0 cm around the central lesion. White hairs may be seen in hair-bearing depigmented areas. Alopecia areata surrounding a halo nevus has been reported. The number of halo nevi per person may be one or many, multiple lesions occurring in 25% to 50% of patients. For patients who have multiple lesions, only a few nevi are usually affected, but as many as 90 halo nevi have been reported in a single person. Any nevus in any anatomic site may be involved, but the posterior torso is involved most commonly. Lesions are usually asymptomatic. UVR may cause redness and even blistering in the perinevic halo. An atypical gross appearance of the central nevus or an asymmetric halo of depigmentation around a suspicious nevus, particularly in adults, should raise suspicion for melanocytic dysplasia or melanoma. The depigmented halo associated with melanoma tends to be irregular and surrounds the tumor asymmetrically, and the central lesion usually has an atypical appearance. Unfortunately, this appearance is not always the case and a high index of suspicion for melanoma must be maintained in patients who have prominent numbers of atypical nevi (with or without melanoma) and also have halo nevi.

A second process that may provide some insight into factors involved in melanocytic interactions with the

Figure 122-10 Halo nevomelanocytic nevus. **A.** Acquired halo nevus on the chest of a 16-year-old white boy whose maternal grandmother had melanoma. **B.** Acquired halo nevi on the back of a 6-year-old white boy who has dysplastic nevi in the hairy scalp and a history of melanoma in his maternal grandmother. Scale in millimeters. **C.** Halo congenital nevomelanocytic nevus on the neck of a 4-year-old female of a black African-American mother and white father. This child also had scattered areas of vitiligo-like depigmentation in other sites. A 3-year follow-up after excision of the nevus revealed almost total repigmentation of the widely scattered previously depigmented areas.

immune system is a process that results in the development of an eczematous dermatitis presenting as a red halo around nevi (halo dermatitis, Meyerson's nevus). Unlike halo nevi, regression of the nevus does not usually occur, and the eczematous changes clear over the course of several months.

RELATED PHYSICAL FINDINGS. For patients with multiple nevi, there is an increased risk for cutaneous melanoma (see Chapters 123 and 124). This risk is further increased in the setting of atypical nevi and/or a personal or family history of melanoma. For patients with eruptive nevi, there may be findings suggestive of a blistering disease or immunosuppression. For patients with halo nevi, the most common associated condition is vitiligo, occurring in 18% to 26% of patients. Halo nevus may be associated with poliosis, Vogt–Koyanagi–Harada syndrome, pernicious anemia, prominent numbers of nevi, atypical nevi, and a personal or family history of melanoma (including ocular melanoma). Relatively large and numerous nevi are common in Turner syndrome and Noonan syndrome.

LABORATORY TESTS

HISTOPATHOLOGY. Nevomelanocytes in the epidermis have a nuclear size similar to or larger than nuclei of epidermal melanocytes. Epidermal nevomelanocytes are arranged in nests surrounded by a smooth perimeter of epidermis, and the epidermis is separated from nevomelanocytes by a retraction artifact (Fig. 122-11). Nevomelanocytes have abundant pale-staining eosinophilic cytoplasm and may have pseudopodic or dendritic extensions that are more evident when enzymatic or immunohistochemical techniques are used for visualization. Nuclei of nevomelanocytes are pale-staining, characterized as vacuolated or reticulated; a nucleolus is usually visible.[41] Epidermal melanocytes between junctional thèques of nevomelanocytes in typical nevomelanocytic nevi are disposed as single typical cells, with overall numbers equal to or slightly greater than that in adjacent sun-exposed skin (see Fig. 122-11).[42] The overlying epidermis is often normal in appearance but may be thickened in a lentiginous pattern (elongated and club-shaped rete ridges), with an appearance similar to seborrheic keratosis complete with horn cysts or epidermal verrucous hyperplasia similar to epidermal nevus.

The dermal component of nevi has an orderly progression from top to bottom, with larger epithelioid cells above (epidermis and superficial papillary dermis) blending into a pattern of smaller cells in the deeper dermis.

Nevomelanocytes in the epidermis and upper papillary dermis frequently resemble epithelial cells, with an oval or cuboidal shape, a well-outlined cytoplasm that is homogeneous in character, a nucleus not much larger than nuclei of basal keratinocytes, and a visible nucleolus. In the epidermis and superficial dermis nevomelanocytes frequently contain small amounts of melanin. In the middle or deep dermis they are usually smaller than nevomelanocytes in the superficial dermis or epidermis and frequently resemble lymphoid cells. Nevomelanocytes in the deep dermis may be round or oval and often resemble Schwann cells or fibroblasts when they are singly disposed and may be difficult to differentiate from fibroblasts unless they are disposed in sheets, cords, or patchy aggregates (see Fig. 122-11).[43] Usually, dermal nevomelanocytes are interposed among collagen bundles, and there is no distinct rim of collagen or retraction artifact between surrounding collagen and cellular aggregates. Nevomelanocytes in the dermis of typical acquired nevi have a monotonous similarity one to another within the same anatomic level and an overall symmetry of architecture from top to bottom and side to side.

Some acquired lesions are found to have congenital features (reviewed in Section "Congenital Nevomelanocytic Nevi") suggesting that though these features may be present in congenital nevi, they are not limited to those present at birth. Other acquired nevi may be found to have atypical features (see Chapter 123).

Inflammatory cellular infiltrates in typical, stable acquired nevi are usually scanty[41] or absent.

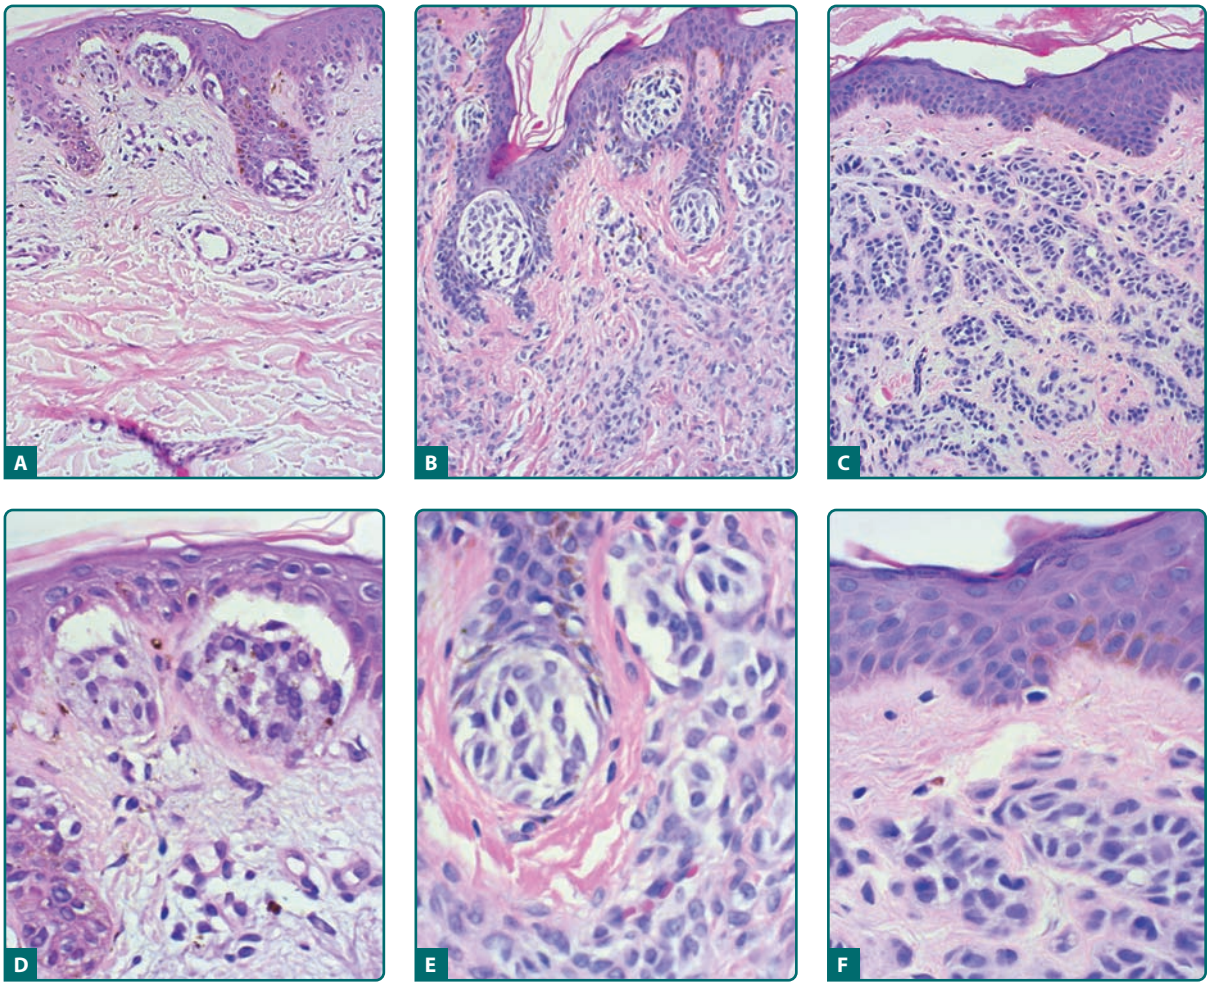

Figure 122-11 Histopathologic features of acquired nevi. Junctional nevus (**A**) and higher magnification (**D**). Compound nevus (**B**) and higher magnification (**E**). Intradermal nevus (**C**) and higher magnification (**F**). Well-formed nests of nevomelanocytes are present in the junctional and compound nevi. Sheets and cords of nevocytes are present in the dermis of the compound and intradermal nevi. A grenz zone free of nevomelanocytes is present just below the epidermis in the intradermal nevus (**C** and **F**).

Melanin-laden macrophages are usually apparent in the superficial papillary dermis of nevi, their number usually proportional to degree of melanin production.[41] Blood vessel proliferation, eosinophilic fibrosis, and lamellar fibroplasia (features frequently seen in atypical melanocytic nevi) are usually not prominent in typical acquired nevi. Langerhans cell density overlying typical acquired nevi and atypical nevi is increased compared with adjacent skin.[44]

Intradermal nevi that have few or no junctional nests frequently have a grenz zone relatively free of nevomelanocytes just below the epidermis (see Fig. 122-11).

Multinucleated nevomelanocytes occur occasionally and may be interpreted as a sign of benignity. Nevomelanocytes in the deep dermis may be disposed within a collagenous framework that is loose, pale, and wavy in formations called *neuroid tubes,* similar to a neurofibroma; they may be disposed in concentrically arranged whorls resembling Meissner's tactile corpuscles; and they may be spindle-shaped and embedded in loosely arranged connective tissue (neural nevi). Both neural nevi and neurofibromas show nonspecific cholinesterase activity. Myelin basic protein is detected in various neural tumors but not in melanocytic or nevomelanocytic tumors, and melanosomes are present in nevomelanocytes but not in neurofibromas or nerve tissue. Cutaneous neural lesions may be distinguished from melanocytic tumors by the presence of myelin basic protein and neurofilaments, and the absence of vimentin.

The *balloon cell nevus* is composed of peculiar foam cells comprising a portion or all of a given lesion. In addition to clear cells with single basophilic nuclei, multinucleated balloon cells and multinucleated giant cells are seen frequently. Electron microscopic studies suggest that vacuolization of nevomelanocytes in balloon cell nevi is due to enlargement and destruction of melanosomes. There appears to be no distinguishing gross features of balloon cell nevi.

The *combined nevus* refers to the incontiguity association of different types of melanocytic nevi. Most combined blue nevi are found in association with a benign compound nevus (acquired or congenital).

Recurrent melanocytic nevus (pseudomelanoma) is the name given to recurrent lesions after incomplete

removal of a benign nevomelanocytic nevus.[45] Recurrent nevi are relatively common after superficial destructive procedures (i.e., shave biopsy or dermabrasion). A markedly atypical clinical and histopathologic appearance may accompany this recurrence, making these lesions worrisome for possible melanoma. Clinically, the recurrent nevus is confined to the scar but may be markedly irregular. Histopathologically, recurrent lesions often demonstrate melanocytic hyperplasia in a lentiginous or junctional pattern (often to a greater extent than the original nevus). Moderate nuclear atypia may be present in 12% of recurrent nevi, mitotic figures in 8%, and pagetoid upward migration in 3%, raising concern about the potential biologic behavior of some recurrent lesions.[46] It is important to review the original histopathologic specimen when making re-excision and margin decisions.

No definitive and consistent histopathologic features have been described for eruptive nevi.

For halo nevi, the usual histopathologic findings are a central nevomelanocytic nevus associated with a dermal band-like lymphohistiocytic infiltrate and a depigmented zone totally or almost totally devoid of epidermal melanocytes. Immunohistochemical staining—melanoma antigen recognized by T cells (Mart-1), S100 protein, or other melanocytic markers—may help to identify residual epidermal melanocytes or the nevomelanocytes in the inflammatory infiltrate. Lymphocytes in halo nevi appear to be antigenically stimulated, and 80% are T lymphocytes, whereas B lymphocytes are scarce or absent. The T cells appear to belong to the $CD8^+$ phenotype.[47]

Other findings have been identified in nevi that may suggest modes of regression or elimination of melanocytic elements. Some of the findings include neuroid, fibrous, mucinous, and fatty degeneration.[48] Nevomelanocytes in the stratum corneum[49] represent transepidermal elimination. Psammoma bodies and amyloid bodies, present occasionally in nevi, also may be related to degeneration or regression. Fibrosis may occur as an age-related phenomenon, whereas true desmoplasia appears to be a reactive process or functional transformation by the nevomelanocytes. Follicular mucinosis has been reported in nevi in at least two cases. Spicules of bone are observed occasionally in nevi, possibly related to reactive metaplasia, trauma, or infection.

Histopathologic artifacts may occur in nevomelanocytic nevi. Shrinkage clefts may resemble lymphatics or vascular spaces, prominent in the midportion of nevi and particularly in areas with hemorrhage. Separation of sheets of nevomelanocytes into parallel rows may be caused by improper cutting. Local anesthesia injection directly into the nevus also may be associated with artifactual changes.

The state of the nevus at the time of excision may also influence the histopathologic appearance. Nevi acutely sunburned or traumatized may have features worrisome for melanoma, and these changes resolve over a short time period.[50] Nevi in a rapid growth phase also may have atypical features such as epithelioid cell appearance and pagetoid upward migration, but these observations require corroboration.

Worrisome features for possible melanoma include pagetoid upward migration of cells in the epidermis, atypical features of epidermal melanocytes [including irregularity of size and shape of cells, condensation of chromatin on nuclear membranes, a heterochromatin (clumping) pattern], failure of the cells to "mature" in the deeper dermis, persistence of pigment production in the deep dermis, lack of symmetry, frequent mitotic figures, focal areas of necrosis, and desmoplasia or fibrosis in the dermis.

SPECIAL TESTS. Special tests are not generally required in the gross and microscopic assessment of melanocytic or nevomelanocytic nevi. However, for patients who have eruptive nevi, given the association with immunosuppression, immunologic tests may be in order. Immunohistochemical profiles may be of value for difficult to diagnose lesions. Low Ki67 activity and loss of HMB45 in dermal (deeper) cells may help confirm a benign diagnosis. Compared to melanoma, common acquired nevi are genomically stable.[51] FISH (*f*luorescence *i*n *s*itu *h*ybridization) or CGH (*c*omparative *g*enomic *h*ybridization) analysis may ultimately be useful in discriminating benign lesions from lesions with a metastatic tendency.

DIFFERENTIAL DIAGNOSIS

(Box 122-3)

COMPLICATIONS

Multiple studies demonstrate that prominent numbers of nevi indicate an increased melanoma risk. Tucker et al[52] noted a 3.4 (95% confidence interval: 2.0 to 5.7) adjusted relative risk for patients with 100 nevi or more (>2 mm and <5 mm) compared with those with fewer than 25 nevi. The relative risk was increased to 12 (95% confidence interval: 4.4 to 31.0) for patients with ten or more atypical nevi compared with patients without atypical nevi. Absence of direct site specificity of nevi and melanoma suggests that nevus proneness per se indicates a general melanoma risk,[53] largely independent of hair and eye color and overall sun exposure.[54] Other traits, including skin color and freckles, may be multiplicative to the number of nevi in increasing melanoma risk.[55] The annual risk of a melanoma developing in a mole has been calculated to be approximately 1 in 200,000.[56] Furthermore, it has been reported that only 26% of melanomas are found in association with nevus elements.[57] Thus, it is likely that the majority of melanomas develop directly from normal skin (see Chapter 124). In patients with numerous nevi (and/or atypical nevi) these nevi are best viewed as risk markers, not precursors (or precancers) of melanoma.

PROGNOSIS AND CLINICAL COURSE

It is likely that acquired nevi evolve through a life cycle, first becoming apparent after infancy in the vast majority of cases, peaking in number during the second

BOX 122-3 DIFFERENTIAL DIAGNOSIS OF COMMON ACQUIRED NEVOMELANOCYTIC NEVUS

PIGMENTED LESIONS

- Solar lentigo
- Lentigo simplex
- Café-au-lait macule
- Blue nevus
- Pigmented fibrous histiocytoma (dermatofibroma)
- Kaposi sarcoma
- Pigmented basal cell carcinoma
- Pigmented actinic keratoses
- Mastocytoma
- Seborrheic keratoses
- Epidermal nevus
- Subungual hematoma
- Supernumerary nipple
- Pigmented spindle cell nevus
- Spitz nevus
- Sclerosing hemangioma
- Pyogenic granuloma
- Atypical (dysplastic) melanocytic nevus
- Cutaneous melanoma
- Nonpigmented/pink lesion
- Basal cell carcinoma
- Fibrous papule
- Verruca vulgaris
- Molluscum contagiosum
- Dermal mucinosis
- Spitz nevus (epithelioid cell nevus)
- Appendageal tumors
- Clear cell acanthoma
- Large cell acanthoma
- Other lesions with halo phenomenon
- Congenital nevomelanocytic nevus
- Atypical melanocytic nevus
- Melanoma
- Spitz nevus
- Histiocytoma
- Molluscum contagiosum
- Flat wart
- Acrochordon
- Basal cell epithelioma
- Neurofibroma
- Congenital dermal melanocytosis (mongolian spot)
- Blue nevus
- Lichen planus
- Sarcoidosis
- Psoriasis
- Angioma
- Angiokeratoma

and third decades of life, and then disappearing by the seventh to ninth decades.[24,25,48] Regression of nevi is believed to occur by neuroid, fibrous, mucinous, or fatty degeneration.[47] Transepidermal elimination of nevomelanocytes has also been noted.[49,58] Nevi also may involute during the course of inflammatory halo depigmentation (halo nevi). The pathogenesis of the halo phenomenon is poorly understood. Available evidence suggests that both humoral and cellular factors may be responsible for nevus destruction in halo nevi. Atypical nevi, melanoma, and vitiligo may occur more frequently in individuals with halo nevi.

Eruptive nevi occur as the spontaneous appearance of multiple nevomelanocytic or melanocytic nevi. These nevi are often similar in appearance to each other clinically and histopathologically. Reports generally link the initiating event to a blistering skin disease, systemic immunosuppression, chemotherapy, or treatment with "biologics."[59] The setting allowing for eruptive nevi may also predispose to melanoma development, as reported for some transplant patients. Patients who have eruptive nevi need to be monitored carefully.

There may be relatively sudden changes in nevi that are unrelated to malignant transformation. Any single nevus that is noted to suddenly change independently should be cause for concern. Causes of sudden changes in a nevus (color, surface, or size, with or without pain, itching, ulceration, or bleeding) over days or weeks include cystic dilatation of a hair follicle, epidermal cyst formation, folliculitis, abscess formation, trauma, hemorrhage, and, in the case of a pedunculated nevus, strangulation and thrombosis. These benign causes of sudden change may require close observation for several weeks until resolution occurs, or excision for histopathologic examination.

The vast majority of acquired nevi are harmless. New nevi may continue to appear and disappear throughout life, but most develop during childhood and early adulthood. New or growing nevi in older individuals are more worrisome. Melanoma risk appears to be related to the number and size of nevi; patients with numerous nevi, atypical nevi, and a personal or family history of melanoma should be considered for periodic surveillance examinations for life.

TREATMENT

The vast majority of acquired nevomelanocytic nevi require no treatment. Indications for removal of benign-appearing lesions may include cosmetic concerns or continual irritation. Lesions with worrisome clinical features need to be excised for histopathologic examination. These features are further addressed in Chapters 123 and 124. Dermoscopy may be used to differentiate benign from potentially malignant features. Photographic surveillance can play a critical role in identifying change, or lack of change, in suspicious nevi. All nevomelanocytic nevi have an initial growth phase. Thus, additional factors, such as unusual gross morphologic features, are required for decision-making for any particular lesion.[60]

Although a benign-appearing nevus associated with halo depigmentation does not require excision, it

is reasonable to recommend periodic examination of affected individuals for atypical melanocytic nevi, vitiligo, and melanoma. Atypical-appearing central nevi, presence of an asymmetric halo, eccentric placement of a melanocytic lesion in the halo, or the setting of atypical melanocytic nevi and/or melanoma (personal or family) suggest the need for histopathologic examination for melanoma. Cover-ups or sunscreens should be recommended for sun-exposed areas of depigmentation to prevent acute burn, chronic actinic damage, and UVR-induced carcinogenesis.

Complete removal of nevi is best accomplished by excision. Leaving a partially excised nevus, regardless of the initial pathology, is fraught with potentially concerning consequences of repigmentation and/or regrowth (pseudomelanoma).[45] Incisional biopsy, even for melanoma, is necessary at times, particularly for lesions that cannot be excised easily but require histopathologic diagnosis. Destructive modes of therapy (electrodesiccation, cryotherapy, dermabrasion, and laser) should be avoided. These destructive modes of therapy preclude histopathologic assessment of the treated nevi. They have the disadvantage of not providing tissue for histopathology. Although dermabrasion has been used to eliminate pigmentation of nevomelanocytic nevi, residual nevomelanocytes in the dermis are to be expected, cosmetic outcome is often unpredictable, and recurrence with worrisome clinical features may complicate future management. Laser treatment of melanocytic and nevomelanocytic lesions has the theoretic risk of malignant transformation, but a clear demonstration of this possibility is still wanting.

PREVENTION

There appears to be a direct relationship between the number of acquired nevi and sun exposure, and a decrease with sunscreen use. While there is no direct cause and effect relation between most cases of melanoma and UVR, patients at increased risk should be encouraged to minimize UVR overexposure without impeding day-to-day activities. Sensible UVR exposure includes confining outdoor activities to the early morning or late afternoon/evening, and avoiding the most intense UVR fluence occurring 2 hours either side of high noon. Cover-up clothing that blocks light transmission should be worn during intense UVR exposure. Clothing is often easier to put on than sunscreen and does not rapidly wear off with swimming or sweating. Effective sunscreens should be used as part of a comprehensive sun-protection program. Vitamin D supplementation should be recommended for patients who diligently practice UVR avoidance and protection.

BLUE NEVUS

EPIDEMIOLOGY

Blue nevi are present in fewer than 1 of 3,000 newborns, in approximately 1 of 1,000 children ≤5 years, in 1% to 2% of white school children, in 3% of Japanese adults, and in 0.5% to 4.0% of healthy white adults. The vast majority of blue nevi are single, small, deep-blue macules or papules approximately 1–3 mm in diameter.

Multiple blue nevi may be associated with lentigines, cardiac myxoma, and mucocutaneous myxomas [Carney complex/LAMB syndrome (*l*entigines, *a*trial myxomas, *m*ucocutaneous myxomas, and *b*lue nevi)]. Blue nevi have been associated with nodular mastocytosis, and a histogenic relationship has been claimed for melanocytes and mast cells.[61] Blue nevi have been reported to occur in oral mucosa, uterine cervix, vagina, spermatic cord, prostate, and lymph nodes.[62]

BLUE NEVUS AT A GLANCE

- Melanocytic neoplasia comprised of pigmented spindle and/or epithelioid melanocytes in the middermis. Includes common blue, cellular blue, combined blue, atypical, and large patch/plaque lesions.
- Lesions appear as blue, blue–gray, or blue–black papule, nodule, or plaques.
- Lesions are generally acquired but may be congenital.
- Cellular blue nevi may have an elevated risk for development of melanoma.
- Synonyms: benign mesenchymal melanoma, blue neuronevus, chromatophoroma, melanofibroma, Jadassohn–Tièche nevus, and dermal melanocytoma.
- Related lesions include nevus of Ota/Ito, Hori's nevus, and dermal melanocytosis.

ETIOLOGY AND PATHOGENESIS

The origin of common blue nevi and cellular blue nevi is unknown, but they may be derived from a mutant precursor cell resulting in the accumulation and differentiation of the melanocytic cells in the dermis instead of their normal location in the epidermis. Differentiation toward hair follicular melanocytes is possible. A specific mutation in the *GNAQ* gene has been identified in blue nevi.[63] Some varieties of cellular blue nevi stain for CD34,[64] suggesting a potential "stem cell" origin. Bednar's tumors (dermatofibrosarcoma protuberans including cells with melanocytic marker expression) also express $CD34^+$ suggesting a similar stem cell origin for these tumors with different differentiation pathways.[65] Nevus of Ito/Ota is related to common blue nevi but represents an extensive localized acquired proliferation. The extension of these neoplasms along specific neural pathways may provide insight into the etiology of these dermal proliferations, including the possible role of certain neural factors.

CLINICAL FINDINGS

(Fig. 122-12)

HISTORY. Common blue nevi are usually acquired, and once developed should remain stable. Nevus of Ota and Ito may share similar underlying defects to blue nevi and are also often acquired (in early childhood, often before age 1 year or around puberty) but are far more extensive, encompassing a portion of trigeminal (ophthalmic and maxillary) and brachial (posterior supraclavicular and lateral cutaneous) nerve distributions, respectively. Dermal melanocytosis (Mongolian spot) may also be related to blue nevi but is usually present at birth or within the first few weeks of life and centered over the lumbosacral area. Lesions of dermal melanocytosis usually regress in early childhood but may persist in approximately 10% of cases.
