Histopathology of acanthosis nigricans classically shows hyperkeratosis and epidermal papillomatosis. There is only slight acanthosis and in some places, atrophy can be seen. Other features that can be observed include pseudocyst formation and increased melanin pigmentation. The dermis is usually devoid of inflammatory cells with the exception of mucosal acanthosis nigricans, which may have a mixed infiltrate of lymphocytes, plasma cells, and occasional neutrophils. The pathologic differential diagnosis includes confluent and reticulated papillomatosis of Gougerot and Carteaud, seborrheic keratosis, and epidermal nevus.

COMPLICATIONS. The cutaneous complications of acanthosis nigricans are most often of cosmetic concern. With time, severe papillomatosis and acrochordon formation can lead to frictional irritation and can be quite problematic. Of most concern with these patients, however, is an undiagnosed endocrinopathy or malignancy.

PROGNOSIS AND CLINICAL COURSE. The malignant form may also parallel the course of the underlying malignancy. Unfortunately, most associated malignancies present at an advanced stage, and thus the median survival rate for those with malignant acanthosis nigricans has been reported to be from 10–24 months.[9]

TREATMENT. Management of any co-occurring disease or malignancy often improves and may even resolve acanthosis nigricans. Topical keratolytics, including the retinoids, and oral retinoids can reduce the appearance of acanthosis nigricans. Other oral medications reported to show improvement include dietary fish oil, metformin, and cyproheptadine, possibly by inhibition of tumor secreted growth factors in the case of the latter.[10]

PREVENTION. Unfortunately for those with acanthosis nigricans associated with inherited conditions and malignancy, there is no effective prevention.

ACQUIRED ICHTHYOSIS

(See also Chapter 49)

The sudden onset of ichthyosis in an adult may indicate an occult malignant tumor, most often Hodgkin's lymphoma. However, patients with AIDS can represent up to 30% of patients with acquired ichthyosis.[11] The ichthyosiform variant of mycosis fungoides should also be considered as it can rarely be the sole manifestation.[12] Diffuse rhomboidal scaling is observed on extensor surfaces and typically spares skin folds, palms, and soles. Erythema is often present in the ichthyotic fissures. Although the ichthyosis usually occurs as a late manifestation of a lymphoma, it may precede the diagnosis by several years and typically parallels the course of the malignancy.

Pityriasis rotunda may be considered a variant that presents as strikingly discrete circular patches with ichthyosiform scale. Individual lesions are usually less

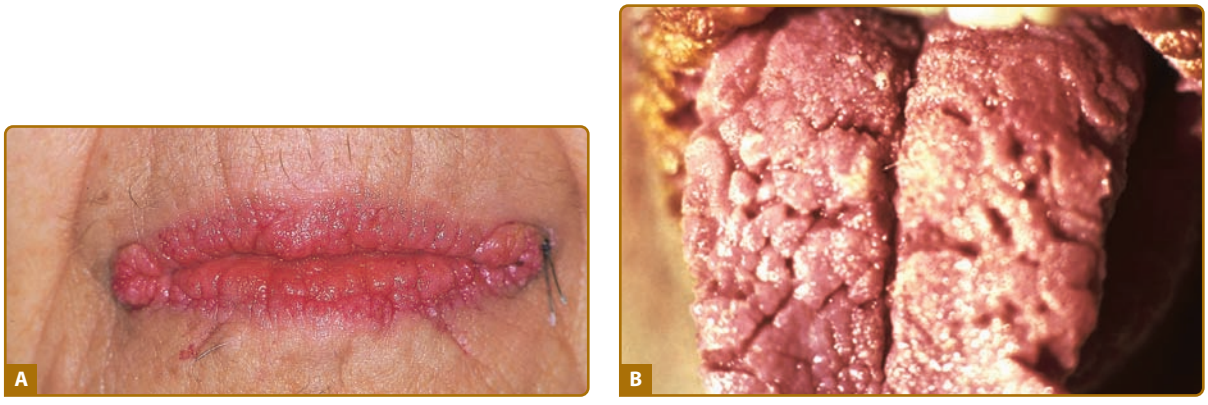

Figure 153-2 Acanthosis nigricans. **A.** Verrucous and papillomatous growths of the vermillion border of the lip. **B.** Velvety thickening of the tongue. (**A** and **B** are not the same patient.) (**A** and **B:** From Wolff K, Johnson RA: *Fitzpatrick's Color Atlas and Synopsis of Clinical Dermatology*, 6th edition. New York, McGraw-Hill, 2009)

than 3 cm but may become confluent and most often involve the trunk and proximal extremities. Paraneoplastic pityriasis rotunda is most commonly associated with hepatocellular and gastric carcinoma. There also exists a familial variant that is not reported to be associated with malignancy.[13,14] The pathogenesis is felt to be related to malabsorption resulting in a hypovitaminosis A and a possible contribution by tumor-secreted EGFs. Treatment is with emollients, retinoids, and α-hydroxy acids.

TRIPE PALMS

EPIDEMIOLOGY. Tripe palms are a rare paraneoplastic dermatosis with approximately 100 cases reported in the literature. The association with malignancy is high with a greater than 90% occurrence.

ETIOLOGY AND PATHOGENESIS. Specific mechanisms of development have not been fully elucidated. Similar to acanthosis nigricans, there is limited evidence for the role of TGF-α inducing cellular proliferation in the pathogenesis of tripe palms, and that normalization of this cytokine results in clinical improvement.[15]

Other investigations have shown melanocortin-1 and EGFs to be upregulated in malignancy-associated tripe palm.[16,17] However, these are not uniformly present.[18]

CLINICAL FINDINGS. The name originated from the description in the first reported case in 1963 whereby the patient suggested his hands looked similar to the rugose surface of the bovine stomach (Fig. 153-3).[19] Based on clinical similarities and frequency of co-occurrence, many consider this to be a form of palmar acanthosis nigricans. Indeed, tripe palms have also been called "*acanthosis nigricans of the palms*" and "*acanthosis palmaris*." The honeycombed and corrugated thickening of the palms may be associated with periungual tenderness. Normal dermatoglyphic ridges are accentuated. As a clinical differential diagnosis, the palmar morphology can be similar in keratitis–ichthyosis–deafness (KID) syndrome (see Chapter 49).

Histopathology of tripe palms includes hyperkeratosis, acanthosis, and papillomatosis. These features closely resemble those pathologic findings observed in acanthosis nigricans and seborrheic keratoses. Additional findings can include dermal mucin and mast cells in approximately 20% of specimens.

The majority (75%) of patients will have concomitant acanthosis nigricans. In patients with only tripe palms, pulmonary carcinoma (53%) is the most frequent malignancy, especially squamous cell type. In patients with both tripe palms and acanthosis nigricans, gastric carcinoma (35%) is the most common followed by lung carcinoma (11%).[20]

COMPLICATIONS. This is often a complication itself of underlying malignancy.

Figure 153-3 Tripe palm. The palmar ridges show maximal accentuation, thus mimicking the mucosa of the stomach of a ruminant.

PROGNOSIS AND CLINICAL COURSE. A complete malignancy work up should be performed in patients with tripe palms due to the high association and because the appearance precedes the diagnosis of malignancy in approximately 40% of cases.[20]

TREATMENT. There is no specific therapy for tripe palms. Similar to acanthosis nigricans, there are anecdotal reports of improvement with oral retinoids alone and in combination with metformin.[21] Approximately 30% will resolve with treatment of the underlying tumor.[22] However, there are many cases whereby a remission of the cancer has had no effect.

PREVENTION. There is no way to prevent the development of tripe palms. Patients should be up-to-date with standard cancer screenings. An expanded cancer investigation is warranted if no coexistence of malignancy is noted at the time of diagnosis.

LESER-TRÉLAT SIGN

LESER-TRÉLAT SIGN AT A GLANCE

- Rapid and eruptive increase in numbers and size of seborrheic keratoses.
- Pruritus common.
- Often with malignant acanthosis nigricans.
- Adenocarcinomas of the gastrointestinal tract are most common malignancy followed by lymphoproliferative malignancies.
- Differential diagnosis includes "regular" seborrheic keratoses, verrucae vulgares, dermatosis papulosa nigra, melanocytic nevi, and warty dyskeratomas.

EPIDEMIOLOGY. The sign of Leser-Trélat is a rare paraneoplastic dermatosis that occurs with equal frequency between men and women and among different races. Similar to the occurrence of malignancy, this sign is more common in older individuals.

Controversy has surrounded this as a true diagnosis due to the extremely common nature of benign seborrheic keratoses and furthermore, occurring in the age group most susceptible to malignancy. In a large population based study of 1,752 consecutive cases of seborrheic keratoses, there was no statistical evidence of an increased incidence of internal malignancy compared to the general population. Subanalysis of those presenting with eruptive seborrheic keratoses also failed to demonstrate an increased risk of internal malignancy.[23] In other large studies of patients with seborrheic keratoses and a recent solid tumor, a comparison with age- and sex-matched controls have not demonstrated a difference in either the clinical features or numbers of seborrheic keratoses.[24,25] As such, large epidemiologic studies have not provided the evidence needed to conclusively define this sign as a true paraneoplastic dermatosis.

Although large studies have not shown a statistical difference, there exists evidence to demonstrate that this sign may signify an internal malignancy. First, there are cases of eruptive seborrheic keratoses in patients in their 20s, an age group that rarely exhibits these lesions. Further workup in both cases led to a diagnosis of an internal malignancy.[26,27] Clinically, Leser-Trélat sign often coexists with malignant acanthosis nigricans, a more established paraneoplastic phenomenon. Additionally, alterations in growth factor expression differ from control patients. Together, this provides evidence that the Leser-Trélat sign is a legitimate but extremely uncommon paraneoplastic dermatosis.

ETIOLOGY AND PATHOGENESIS. An exact pathogenesis has yet to be elucidated. However, similar to acanthosis nigricans and tripe palms, evidence also exists with the Leser-Trélat sign that an alteration in growth factor homeostasis is contributory. In several instances, a state of increased growth factor expression has been observed with increased urinary levels of the growth factors EGF and TGF-α detected in patients with an underlying malignancy and eruptive seborrheic keratoses. Subsequently, growth factor levels decreased following primary tumor resection.[28]

It is not known if the tumors are the primary source or are inducing a secondary secretion of such growth factors as TGF-α and EGF. In an analysis of a patient with pancreatic carcinoma and the Leser-Trélat sign, the tumor cells expressed low levels of EGF while the hyperkeratotic lesions of seborrheic keratoses expressed increased EGF.[29] In a comparison of Leser-Trélat lesional skin and that of control seborrheic keratoses, increased levels of the growth factor homologs EGF and HER-2/neu were detected in the downward branching epithelial strands.[30] In addition to increased levels of growth factor expression, lesional skin in paraneoplastic acanthosis nigricans and seborrheic keratoses has alterations in the extracellular matrix.[31] It is unknown what the direct impact of growth factor signaling has on the skin. Proposed ideas include either inducing a hyperproliferative state primarily or by altering the surrounding environment such as via the extracellular matrix. These similar mechanisms further support the idea of a continuum between acanthosis nigricans and the Leser-Trélat sign.

CLINICAL FINDINGS. Clinical features signifying a paraneoplastic phenomenon include patients with widespread eruptive seborrheic keratoses. Pruritus is a significant feature occurring in 43%.[1] Co-occurrence with other hyperkeratotic paraneoplastic dermatoses is common with 20% having acanthosis nigricans. There are several reports of Leser-Trélat sign and tripe palms coexisting in the same patient.[8,32–34] The rapid occurrence of pruritic eruptive seborrheic keratoses, especially in a setting of acanthosis nigricans should

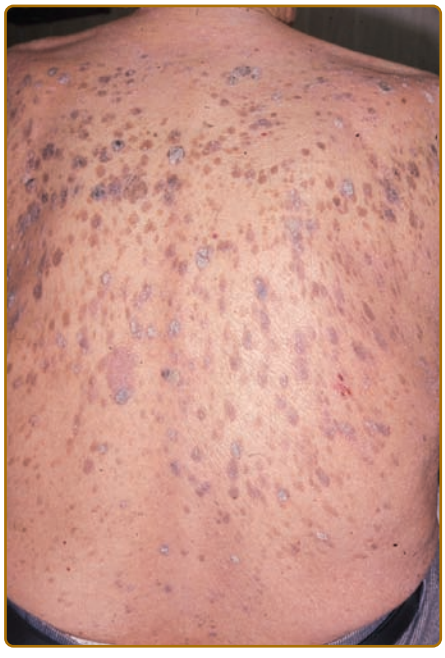

Figure 153-4 Leser-Trélat sign consisting of multiple pruritic eruptive seborrheic keratoses.

alert the clinician to a potential internal malignancy (Fig. 153-4). For the differential diagnosis, see Box 153-2.

Adenocarcinomas account for the majority of malignancies described with the sign of Leser-Trélat. Of 130 malignancies reported with this sign, 47.7% involve the gastrointestinal tract.[29] The second most common malignancy is lymphoproliferative disorders, and includes leukemias, lymphomas, Sézary syndrome and mycosis fungoides. Involvement of other organs such as the pancreas, kidneys, ovaries, and lungs has been reported in several cases as well. In a series of 44 patients with lung cancer, the sign of Leser-Trélat was observed in 2.27%.[35]

Typically defined by a concurrent malignancy, the sign of Leser-Trélat has also been reported in non-neoplastic tumors, HIV, conditions of erythroderma and in association with the chemotherapeutic drug cytaribine.[36–39] The term "pseudosign of Leser-Trélat" has been used to designate nonmalignancy associated eruptive seborrheic keratoses that presents identically to its paraneoplastic counterpart. Unfortunately, these examples do not help to further define an already confusing and controversial clinical entity.

BOX 153-2 DIFFERENTIAL DIAGNOSIS OF THE SIGN OF LESER TRELAT

Most Likely
- Seborrheic keratoses
- Verruca vulgaris
- Dermatosis papulosa nigra
- Melanocytic nevi
- Warty dyskeratoma

Consider
- Confluent and reticulate
- Cytaribine-induced irritation of seborrheic keratoses
- Cowden's syndrome
- Tuberous sclerosis
- Gorlin's syndrome

Always Rule Out
- Internal malignancy
- Erythroderma-induced irritation of seborrheic keratoses
- Pregnancy
- HIV

COMPLICATIONS. As with many paraneoplastic dermatoses, sudden reappearance may herald tumor recurrence, although this particular sign only occasionally parallels the malignancy.

PROGNOSIS AND CLINICAL COURSE. This sign can develop from 5 months prior to 9.8 months after the diagnosis of malignancy and once diagnosed, the prognosis is poor with an average survival time of 10.6 months.[40] This eruption parallels the course of the underlying malignancy in some cases, but not as a general rule.

TREATMENT. Treatment should be directed toward the underlying tumor. If the lesions are symptomatic or cosmetically concerning to the patient, other options for treatment include standard therapies for seborrheic keratoses such as α-hydroxy acids, retinoids, trichloracetic acid, cryosurgery with or without curettage, dermabrasion, laser, and shave excision.

PREVENTION. There is no effective prevention other than keeping up with age-appropriate cancer screenings.

ACROKERATOSIS PARANEOPLASTICA OF BAZEX

ACROKERATOSIS PARANEOPLASTICA OF BAZEX AT A GLANCE

- Distribution of cutaneous lesions is symmetrical and characteristically involves the helices, nose, cheeks, digits, and nails.
- Lesions evolve from nonspecific dermatitis and paronychia to inflammatory plaques, acral keratoderma, and nail plate changes.
- Skin lesions often predate detection of internal malignancy.
- Upper aerodigestive tract malignancy most common.

EPIDEMIOLOGY. Bazex established an association between this uniquely distributed papulosquamous eruption and underlying malignancy.[41] There have been over 100 cases reported in the medical literature. Patients are typically men over the age of 40. Acrokeratosis paraneoplastica is unrelated to Bazex-Dupre-Christol which is a genodermatosis characterized by congenital hypotrichosis, follicular atrophoderma, and basal cell carcinomas arising at an early age.

ETIOLOGY AND PATHOGENESIS. The mechanism by which this characteristic eruption occurs is still speculative. One theory proposes that antibodies mounted against the tumor cross react with keratinocyte or basement membrane antigens (similar to those found in paraneoplastic bullous pemphigoid).[41] Other theories include a T-cell-mediated immune response to tumor-like antigens in the epidermis or by excessive expression of autocrine growth factors from the tumor resulting in epidermal hyperplasia.[42–44] Other hypotheses include low serum levels of vitamin A and zinc.

CLINICAL FINDINGS. The name, acrokeratosis paraneoplastica, is aptly descriptive because characteristic lesions are located acrally and exhibit hyperkeratosis. The plaques are usually erythematous to violaceous with overlying scale. Almost all patients have lesions affecting the ears and nails during the disease. Nearly two-thirds will demonstrate involvement of the nose and fingers, and over half have lesions on the hands and feet, especially volar surfaces.[45] Other clinical findings include hyperpigmentation and bullae. Bullae, when present, are most common on the hands and feet.

Three stages of skin lesions parallel the growth and dissemination of the underlying tumor. In the first stage, the helices, nose, fingers, and toes are usually affected in a symmetrical fashion. Early lesions are macular and not clearly demarcated, simulating a nonspecific dermatitis. They may exhibit crust in addition to scale. The eruption is classically asymptomatic, but pruritus may be a problem. Paronychia is the first sign of nail involvement (Fig. 153-5). In most cases, the responsible tumor is occult at this stage and remains so for an average of 11 months.[45]

Figure 153-5 Distal edema of toes, painful generalized paronychia, and distal subungual hyperkeratosis in early acrokeratosis paraneoplastica.

Figure 153-6 Keratoderma characteristically spares central aspects of plantar (and palmar) surfaces in acrokeratosis paraneoplastica.

During the second stage the tumor exhibits symptoms, due to local extension or metastatic spread, and the skin eruption becomes more extensive. The cheeks display the typical red to purple scaly or crusted plaques. The palms and soles develop a keratoderma that often spares the central volar surfaces but may lead to painful fissures (Fig. 153-6). Nail plate changes include yellowing, thickening, onycholysis and ridging, both horizontal and vertical.

The final stage is observed when the tumor goes untreated or fails to respond to treatment. All of the above signs and symptoms persist while the papulosquamous lesions begin to appear on the trunk, elbows, knees, and dorsal hands and feet. Rarely, vesicles and bullae may be present, most commonly on the fingers, hands, and feet. Nail changes can be quite variable, ranging from the typical thickening to nail atrophy and loss.

The main differentiation to be made in diagnosis is psoriasis, especially acral variants. The distinguishing clinical feature, which is nearly always present in acrokeratosis paraneoplastica, is involvement of the helices of the ears (Fig. 153-7) and the tip of the nose. Knees and elbows may develop plaques but it occurs late in the disease. Typically, Bazex is treatment resistant unlike other diseases considered in the differential (see Box 153-3).

Mucosal squamous cell carcinoma of the head and neck is the most frequently associated malignancy in acrokeratosis paraneoplastica and is markedly overrepresented when compared to the cancer statistics in the general population. Tumors in the oropharynx or larynx and cervical squamous cell lymph node metastases of an occult primary malignancy make up more than 60% of cancers associated with Bazex

Figure 153-7 Characteristic helical inflammation with scale in acrokeratosis paraneoplastica.[45]

syndrome but only 7% of cancer patients without Bazex. The lung[46] and esophagus were the next most frequent site of tumors (15% and 10%, respectively), though not always squamous cell carcinomas.[45] If the classically associated malignancies are excluded on workup, other less common locations such as genitourinary or lower gastrointestinal tract, should be considered.

Histologically, some psoriasiform features are present including hyperkeratosis, parakeratosis and a superficial lymphohistiocytic infiltrate, but other nonpsoriasiform changes also exist. These include vacuolar degeneration with melanin-containing macrophages in the dermis and dyskeratotic keratinocytes.

BOX 153-3 DIFFERENTIAL DIAGNOSIS OF ACROKERATOSIS PARANEOPLASTICA

Most Likely
- Psoriasis
- Dermatitis (seborrheic, eczematous, or contact)
- Dermatophytosis/Onychomycosis

Consider
- Mycosis fungoides
- Drug eruption
- Cutaneous lupus erythematosus
- Keratoderma blenorrhagicum
- Arsenical keratoses

Always Rule Out
- Internal malignancy
- Dermatophyte infection

COMPLICATIONS. The keratoderma affecting volar surfaces may develop fissures. On the feet, this can lead to painful ambulation. Secondary infection occurs. Paronychia is usually painful and may be debilitating.

PROGNOSIS AND CLINICAL COURSE. The skin eruption is expected to resolve with treatment of the underlying malignancy and can reappear with tumor recurrence. For some patients, the cutaneous lesions, but more commonly the nail dystrophy (ridging and subungual hyperkeratosis), may persist despite (presumed) successful tumor eradication.

TREATMENT. Adequate treatment of the underlying malignancy usually results in improvement of acrokeratosis paraneoplastica and recurrence of the eruption heralds tumor recurrence. The skin lesions are typically resistant to standard therapies for hyperkeratotic conditions and few treatments specific for the cutaneous component of acrokeratosis paraneoplastica have been reported. Retinoids have been used with variable success. Isolated reports suggest benefit from oral psoralen and ultraviolet A phototherapy, topical salicylic acid, and corticosteroids.[47]

PREVENTION. There is no effective prevention other than keeping up with age-appropriate cancer screenings.

COLLAGEN-VASCULAR DISEASE

DERMATOMYOSITIS

(See Chapter 156)

Dermatomyositis can be a marker for internal neoplasia, and the development of the dermatomyositis can predate the diagnosis of the cancer. The clinical manifestations of dermatomyositis appear to be the same with and without a malignant tumor, although Basset-Sequin et al[48] noted that cutaneous necrosis and an elevated erythrocyte sedimentation rate appeared to be markers for those with cancer and a reduced survival. Up to 30% of adults with a new diagnosis may have an associated malignancy with men over the age of 50 having the greatest risk of malignancy. The most common cancers are ovarian, lung, pancreatic, stomach, colorectal, and lymphoma.[49] While dermatomyositis in an adult is strongly associated with concurrent cancer, polymyositis alone is much less strongly associated.[50]

The cancers are usually identifiable by history and physical examination. Adults with dermatomyositis should be examined thoroughly for evidence of an associated malignant tumor including all recommended cancer screenings. The diagnosis of malignancy is usually made within a year, but can be several years later. In children, dermatomyositis is not statistically linked to malignancy.

PROGRESSIVE SYSTEMIC SCLEROSIS

(See Chapter 157)

Systemic scleroderma is not commonly associated with internal malignancy. In a Japanese review of 8,327 patients with systemic sclerosis, the frequency of malignancy was 5.4% in men and 2.8% in women (overall 3.1%).[51] Several population based studies have been performed to determine the incidence of malignancy with mixed results. Some have detected no increase in overall malignancy incidence as compared to the general population, while others have detected a small, but statistically significant increased risk.[52] In a nested cohort comparing patients diagnosed with systemic sclerosis before the age of 60 and after the age of 75, not surprisingly there was an increased frequency of all malignancies in the older age, but especially esophageal and oropharyngeal cancer.[53,54]

Lung cancer has been the most often associated malignancy, but there is also a nearly 25-fold increased risk of squamous cell carcinoma of the tongue.[55] Almost all patients with associated lung tumors have very advanced systemic scleroderma, particularly older patients with advanced interstitial lung disease. Evidence suggests the association is most likely one of a lung tumor developing secondary to the chronic pulmonary fibrosis.

REACTIVE ERYTHEMAS

ERYTHEMA GYRATUM REPENS

(See Chapter 43)

This particular annular ("gyratum" is Latin for circle) erythema is nearly always indicative of internal malignancy and is one of the most dramatic skin diseases in both its appearance and evolution. Affected individuals are often Caucasian men (2:1) in their 60s. Numerous serpiginous bands are arranged in a parallel configuration of concentric red swirls over most of the body. This presentation is occasionally referred to as a "wood-grained" appearance (Fig. 153-8). Even more striking is the relatively rapid rate at which lesions migrate ("repens" is Latin for creeping), estimated at one centimeter per day.[56] A slight scale may be found along the trailing edge of erythema (Fig 153-9). The hands, feet, and face are commonly spared, except for occasional volar hyperkeratosis. Ichthyosis is present in many cases. Pruritus is universal and may be severe.

An underlying malignancy is associated with erythema gyratum repens over 80% of the time. This distinctive migratory eruption appears 4–9 months before the diagnosis of malignancy in approximately 80% of cases. Approximately one-third of patients will manifest a lung cancer, whereas 8% have esophageal cancer and 6% have breast cancer. Individual case reports of many other types of associated tumors are published, as well as 6% of cases with an unknown primary. In those individuals with erythema gyratum repens who did not have a detectible underlying malignancy; concurrent conditions included tuberculosis, pregnancy, and bullous dermatoses, among others.[56]

Figure 153-8 Erythema gyratum repens. Serpiginous parallel bands on axilla and arm. (Used with permission from Michael Adler.)

The exact etiology of erythema gyratum repens is unknown, but it has been suggested that the tumor may induce a chemical alteration of the normal components of the surrounding tissue. Molecular mimicry ensues as the inflammatory response directed against the tumor cross reacts with benign cutaneous proteins. This theory is supported by documentation of IgG and C3 deposition at the basement membrane of affected skin and bronchial basement membrane in one case associated with lung cancer.[56] Migration characterizes all of the figurate erythemas, but is notably rapid in erythema gyratum repens and the mechanism for this is not clear, although recent studies have focused on fibroblast activity. Inflammatory cells and/or fibroblasts may mediate ground substance alterations which may localize the inflammation that orchestrates the movement of the infiltrate in a patterned mode.[57,58]

Figure 153-9 Erythema gyratum repens. Characteristic "wood-grained" pattern of erythema and slight scale in a woman with breast cancer. (Used with permission from Jill McKenzie, MD.)

The treatment for erythema gyratum repens is to locate and treat the primary malignancy. With adequate control of the cancer the rash usually abates, but this may not be possible in cases that are widely metastatic at the time of diagnosis. Otherwise, the eruption is often treatment resistant, although variable results occur with systemic steroids.[59] Topical steroids, vitamin A, and azathioprine have not been beneficial.[60–62] The eruption has been known to resolve immediately before death, possibly due to generalized ante mortem immunosuppression.

NECROLYTIC MIGRATORY ERYTHEMA

NECROLYTIC MIGRATORY ERYTHEMA AT A GLANCE

- Painful, eroded, crusted intertriginous, and facial skin eruption.
- Highly suggestive of pancreatic malignancy (glucagonoma).
- Half of tumors are metastatic at the time of diagnosis.
- Pseudoglucagonoma syndrome occurs in absence of glucagonoma.
- Skin improves with treatment of underlying nutritional aberrations.

EPIDEMIOLOGY. NME is virtually pathognomonic for pancreatic glucagonoma and is present in more than two thirds of patients at the time of tumor diagnosis.[63] When the characteristic eruption occurs without underlying pancreatic malignancy the condition is referred to as pseudoglucagonoma syndrome. Glucagonomas are rare, with an estimated 400 cases cited in the literature. There is no sexual predilection and it most commonly affects people in their sixth decade.

ETIOLOGY AND PATHOGENESIS. Most of the signs and symptoms can be attributed to the metabolic effects of excess glucagon. Amino acid levels are depressed due to glucagon stimulating consumption of amino acid substrates for gluconeogenesis and increasing amino acid oxidation.[64] With insufficient amino acids epidermal protein deficiency and necrolysis ensues. Reduced amino acid levels (histidine and tryptophan) can cause painful, erythematous eroded skin, especially in intertriginous areas in several nutritional disorders. Glucagon also increases cutaneous levels of arachadonic acid, which likely increases downstream inflammatory mediators (prostaglandins and leukotrienes).

CLINICAL FINDINGS. The skin lesions of NME are polymorphous, but erosions and crusts are usually apparent. Primary lesions are erythematous patches that eventuate into plaques that develop central bullae. The blisters erode rapidly, form crust and eventually resolve. The erythematous and eroded annular patches and plaques coalesce into large geographic areas. The eruption disappears and reappears spontaneously over the course of weeks. Pruritus and pain are common symptoms. The distribution of NME is characteristic and includes intertriginous areas (groin, perineum, buttocks, and lower abdomen), the central face (especially perioral), and distal extremities (Fig. 153-10). Mucosal involvement manifests as angular cheilitis, atrophic glossitis, and stomatitis. Dystrophic nails may accompany the syndrome. For the differential diagnosis, see Box 153-4.

The features of glucagonoma syndrome are weight loss, sore mouth, diarrhea, weakness, mental status changes, and diabetes mellitus. Weight loss is the most common presenting sign. Laboratory abnormalities include a dramatically elevated

Figure 153-10 The glucagonoma syndrome, necrolytic migratory erythema. Flaccid and papulovesicular lesions (**A**) with erosions, crusting, and fissures around the orifices, and (**B**) appearing as geographic, circinate "necrolytic migratory erythema" in the groin. (**A** and **B** are not the same patient.)

BOX 153-4 DIFFERENTIAL DIAGNOSIS OF NECROLYTIC MIGRATORY ERYTHEMA

Most Likely
- Dermatitis (seborrheic, eczematous, or contact)
- Drug eruption

Consider
- Pemphigus (foliaceus, erythematosus)
- Acrodermatitis enteropathica
- Essential fatty acid deficiency
- Vitamin deficiency (especially B2, B3, B6)
- Amino acid deficiency (histidine, tryptophan)
- Cutaneous lupus erythematosus

Always Rule Out
- Glucagonoma (abdominal CT)
- Liver disease
- Pancreatitis
- Nutritional deficiencies (zinc, vitamin, amino and fatty acids)
- Malabsorption
- Inflammatory bowel disease

serum glucagon, usually well over 1,000 pg/mL (normal range 50–150 pg/mL). Most patients have hyperglycemia and a normochromic normocytic anemia. Abnormal liver function is present and serum levels of amino acids, total protein, albumin, and cholesterol are low. Occasionally, zinc levels are deficient. For individuals suspected of having an underlying glucagonoma, somatostatin receptor scintigraphy is positive in approximately 95% of patients.[65]

Pseudoglucagonoma syndrome presents identically, but the α-cell pancreatic tumor is not present, which may explain why the serum glucagon levels are not elevated. Underlying diseases identified in patients with the pseudosyndrome are: liver disease, pancreatitis, celiac sprue, inflammatory bowel disease, acrodermatitis enteropathica, pellagra, and nonpancreatic malignancies.

The histology of NME is characteristic. Acute lesions demonstrate a striking degree of epidermal necrosis in the upper layers of the stratum spinosum. Neutrophils may be abundant in the necrotic layer and frank separation from the underlying intact epidermis may occur. Chronic lesions also show a psoriasiform dermatitis with parakeratosis and loss of the granular layer. The constellation of hyperkeratosis, architectural disorder and scattered degenerating keratinocytes may be seen in other nutritional deficiencies, graft-versus-host disease, connective tissue disorders, and phototoxic drug eruptions.[66]

COMPLICATIONS. Nearly all patients suffer from weight loss, malaise, and anemia as a result of the catabolic effects of glucagon. Gastrointestinal symptoms such as abdominal pain, diarrhea, and anorexia may be debilitating. Neuropsychiatric features occur in approximately 20% of patients and may present as depression, dementia, psychosis, agitation, ataxia, and decreased cognitive function.[67] Venous thrombosis occurs in up to 30% of patients with glucagonoma.[68]

PROGNOSIS AND CLINICAL COURSE. If the glucagonoma is not metastatic and can be completely resected at the time of diagnosis, symptoms of the syndrome will resolve. Unfortunately, by the time of diagnosis, tumors are frequently large and metastatic in most cases. Fortunately, the tumors are slow growing and patients may experience symptom improvement with surgically decreasing the tumor burden, although survival may not be affected by the procedure. Chemotherapy has been disappointingly ineffective.

TREATMENT. The underlying cause for hyperglucagonemia must be addressed to eradicate the painful skin disease. For patients with glucagonoma, resection of the tumor is important for symptom relief. Measures to correct nutritional deficiencies and glucagon levels have provided relief for many patients. Given the high incidence of venous thromboses, deep vein thrombosis prophylaxis should be instituted. Intravenous somatostatin (a glucagon antagonist) has been shown to improve the cutaneous symptoms of the syndrome, however this does not affect the growth of the underlying tumor.[69] Supplementation to correct zinc, amino acid or fatty acid deficiencies has been shown to be beneficial in some cases when a deficiency is observed.

PREVENTION. None known.

NEUTROPHILIC DERMATOSES

SWEET SYNDROME

(See Chapter 32)

Many authors have suggested that the neutrophilic dermatoses Sweet syndrome and pyoderma gangrenosum represent a continuum when associated with an underlying malignancy. In approximately 40% of patients with malignancy-associated Sweet's syndrome, a diagnosis of cancer is made within one month of the dermatoses.[70] Two-thirds of the time cutaneous manifestations occur prior to the diagnosis of malignancy and is seen most commonly with acute myelocytic leukemia but also may be associated with other leukemias, myelodysplastic syndrome, multiple myeloma, and lymphoma.[71] Of note, patients with an underlying hematologic malignancy may have a normal neutrophil count but is in actuality a relative neutrophilia.

Much less commonly, associations have also been reported with solid tumors such as cancers of the genitourinary tract, embryonal carcinoma of the testes, ovarian carcinoma, gastric carcinoma, and adenocarcinoma of the breast, prostate, and rectum.[72] Unlike

many of the other paraneoplastic dermatoses, the neutrophilic dermatoses respond to systemic corticosteroids and other standard treatments regardless of the course of the underlying malignancy.

PYODERMA GANGRENOSUM

(See Chapter 33)

Overall, there is a low incidence of malignancy in patients with pyoderma gangrenosum but the incidence increases up to 27% in those presenting with atypical features such as hemorrhagic bullae, superficial and/or rapid appearance, involvement of the upper extremities/hands, and scaring. Similar to Sweet syndrome, the most common underlying malignancy is hematologic with acute myelogenous leukemia the most common followed by multiple myeloma.[73]

Another unexplained co-occurrence in patients with pyoderma gangrenosum is an IgA paraproteinemia, occurring in 10%–18% of patients. By itself, this is not a malignancy. However, studies of individuals with monoclonal gammopathy of undetermined significance show an increased risk of malignant transformation occurring at a rate of approximately 1%, and can be as high as 40% at 25 years. Those with IgA gammopathies have a higher probability of malignant transformation.[74,75] Therefore, careful monitoring is warranted in these patients as well. A parallel course to the underlying malignancy has not been well established with this paraneoplastic dermatosis.

DERMAL PROLIFERATIVE DISORDERS

MULTICENTRIC RETICULOHISTIOCYTOSIS

(See Chapter 148)

Though malignancy has been diagnosed in many patients with multicentric reticulohistiocytosis, no one malignancy predominates. Neoplasms that have been reported most commonly include melanoma, hematologic malignancies and carcinomas of the breast, colon, ovaries, cervix, and stomach.[11] The natural course of the disease is generally one of spontaneous remission after several years of activity that resides with permanent joint destruction. While active though, treatment options for multicentric reticulohistiocytosis have only been partially effective and the course of the disease does not consistently parallel the activity of the underlying malignancy.

NECROBIOTIC XANTHOGRANULOMA

(See Chapter 148)

This non-Langerhans cell histiocytosis is a rare disease that has a high association with hematologic abnormalities. In the majority (80%) of patients with necrobiotic xanthogranuloma, an IgG paraproteinemia can be detected with an approximate 10% conversion to multiple myeloma. Periorbital involvement is seen in 85% of patients and ulceration is more common in this particular xanthoma.[76] Other malignant associations include chronic lymphocytic leukemia, Hodgkin disease, and non-Hodgkins lymphoma.[1]

DERMAL DEPOSITION

SCLEROMYXEDEMA

(See Chapter 158)

Scleromyxedema is the generalized form of papular mucinosis (lichen myxedematosus) and has a particular predilection for face, arm, and hand involvement. Systemic organ involvement is common, and the majority (80%) of patients with scleromyxedema has an IgG-λ light chain monoclonal gammopathy of undetermined significance. Serum protein electrophoresis should be performed in conjunction with thyroid studies to rule out thyroid dysfunction and myxedema. Fortunately, the paraproteinemia only rarely converts to multiple myeloma, but when it occurs portends a poor prognosis. Other rare malignancies to co-occur include *Waldenstrom* macroglobulinemia, leukemia, or Hodgkin or non-Hodgkin lymphoma.[1] It is uncertain if treatment of scleromyxedema with agents such as melphalan triggers malignant transformation.[77] The course of the disease is usually progressive with major cardiac and pulmonary involvement and there is no established marker for those most likely to progress to malignancy.

SYSTEMIC AMYLOIDOSIS

(See Chapter 133)

Systemic amyloidosis can be classified as primary, secondary to inflammation and/or infection, familial, or idiopathic. It is important to differentiate skin lesions of primary systemic amyloidosis from the far more commonly seen purely cutaneous variants. With primary systemic amyloidosis, the integumentary system (cardiac, renal, carpal tunnel syndrome, macroglossia, etc.) is more commonly involved. The amyloid subtype in primary systemic amyloidosis most commonly associated with internal malignancy is the amyloid light chain (amyloid AL).

Multiple myeloma is the most common malignancy, seen in 13%–26% of patients, and once diagnosed has an extremely poor prognosis with a mean survival of 1 year. Other malignancies reported include Hodgkin disease and gastric, breast, and renal cell carcinoma.[11,78,79] Familial cutaneous lichenoid amyloidosis has been reported in association with multiple endocrine neoplasia (MEN) type 2A.[80] All patients with skin lesions of systemic amyloidosis should have a serum and urine electrophoresis performed.

BULLOUS DISORDERS

PARANEOPLASTIC PEMPHIGUS

(See Chapter 55)

The signature clinical finding is the early onset of severe refractory oral mucosal involvement. Other sites of involvement can include the ocular, respiratory, and gastrointestinal epithelium. Because nearly every patient with paraneoplastic pemphigus has an associated malignancy, if there is no diagnosed malignancy at the time of presentation, an extensive workup is required. There are occasional instances whereby the association is with a benign tumor. The most common malignancy associated is non-Hodgkin lymphoma. The next most common malignancies in frequency are chronic lymphocytic leukemia, Castleman disease, and thymoma.

DERMATITIS HERPETIFORMIS

(See Chapter 61)

Dermatitis herpetiformis and celiac disease are independent risk factors for gastrointestinal lymphoma. There is no indication that there is a greater than expected number of patients with dermatitis herpetiformis developing tumors other than intestinal lymphoma.[81] The incidence of lymphoma has been reported as between 1%–4% developing 2–31 years after the diagnosis.[82,83] Interestingly, the increased risk is observed only in adults and the incidence ratio decreases with every calendar year after diagnosis, ultimately reaching null.[84]

The most commonly associated malignancy is enteropathy-associated T-cell lymphoma of the gastrointestinal tract but patients are also at risk to develop B-cell lymphoma both in and out of the gastrointestinal tract and non-Hodgkin lymphoma.[82,85] The relative risk of non-Hodgkin lymphoma associated with dermatitis herpetiformis is 5.4 (95%, CI 2.2–11.1) in males, less in females.[85] It is often observed that affected patients with lymphoma are less compliant with a gluten free diet as compared to those without malignancy.

BULLOUS PEMPHIGOID

(See Chapter 56)

Case-control studies have failed to show a significant increased risk of a malignant tumor in patients with bullous pemphigoid, other than that associated with the age of the patient.[86] However, a Japanese cohort of patients with bullous pemphigoid had a 5.8% prevalence of neoplasia versus 0.61% of controls.[87] In younger patients, bullous pemphigoid under the age of 60 was observed in 9.5% of patients in a retrospective review of 74 patients and there are anecdotal reports of patients clearing when the concomitant tumor is treated.[88]

MISCELLANEOUS

HYPERTRICHOSIS LANUGINOSA ACQUISITA

Acquired hypertrichosis lanuginosa (described by Fretzin[89] as *malignant down*) is a rare condition characterized by the relatively sudden appearance of long, fine, nonpigmented lanugo (Latin for "down") hairs. The lanugo most frequently appears on the face and ears early in the course (Fig. 153-10). The hairs may grow to an extraordinary length; eyebrows and eyelashes may grow to inches long. The long fine hairs may also be seen on the trunk and limbs including the axillae. Epithelial proliferation of the oral mucosa may cause glossodynia, hypertrophy of the papillae of the tongue, mucosal pigmentation, and disturbances of taste or smell.[90,91] Symptoms in the mouth are similar to those seen in various vitamin deficiencies and one case has been reported with decreased vitamins A and B_1 and niacinamide levels.[92]

This condition is frequently paraneoplastic and nearly always predates the diagnosis of malignancy. The most commonly associated malignancies are located in the lung and colon. Breast and uterine adenocarcinomas, lymphoma and urinary bladder transitional carcinomas have also been found in patients with acquired hypertrichosis lanuginosa as have other malignancies.[90,91] Unfortunately, tumors are usually widespread by the time hypertrichosis manifests and thus this paraneoplastic condition portends a poor prognosis.

Hypertrichosis lanuginosa may also be seen in other disorders. These include acquired immunodeficiency syndrome (most characteristically hypertrichosis and trichomegaly of the eyelashes),[93] anorexia nervosa, thyrotoxicosis, porphyria cutanea tarda (see Chapter 132). The condition may be a consequence of medications such as cyclosporin, phenytoin, penicillin, spironolactone, corticosteroids, or minoxidil.

TROUSSEAU SYNDROME

In general, malignancy predisposes to alterations in the clotting cascade resulting in a combined state of hemorrhage and hypercoagubility. Approximately 11% of all cancer patients will develop migratory thrombophlebitis during the course of their disease and up to 23% will have evidence at autopsy.[94,95] Trousseau syndrome is an acquired coagulopathy presenting as migratory thrombophlebitis often in a setting of underlying malignancy. Both the arterial and venous vasculature can be affected and can lead to devastating complications such as pulmonary embolism, stroke, limb necrosis, and organ ischemia.

The human oncogene MET induces increased production of plasminogen activator inhibitor type 1 (PAI-1) and cyclooxygenase-2 (COX-2) in some models and may be part of the mechanism linking the hypercoagulable and hemorrhagic state with malignancy.[96]

The most common malignancy reported with Trousseau syndrome is lung carcinoma. However, this most likely reflects the frequency with which it occurs in the general population. The less common pancreatic cancer has a more striking association with 42% having evidence of pulmonary embolism. Furthermore, certain characteristics of tumors have been shown to correlate with an increased risk for the development of Trousseau syndrome. These features include adenocarcinoma, metastatic progression, and involvement of the gall bladder, gastrointestinal, and/or pulmonary systems.[95]

Treatment is best achieved with eradication of the underlying malignancy. To manage the embolic sequelae in Trousseau syndrome, anticoagulation can be achieved with the use of heparin. Low-molecular weight heparin is the treatment of choice, as unfractionated heparin exhibits strong neutralization in the presence of tumor cells.[97]

FAMILIAL CANCER SYNDROMES

It is important for clinicians to recognize cutaneous features of genetic conditions that predispose to internal malignancy. In several cases, cutaneous features predate the development of malignancy and increased surveillance may improve the survivability in these patients.

For malignancies associated with a genodermatosis, there may be an increased risk for family members to develop cancer. Appropriate genetic testing may elicit the carrier state of each relative in question, and can assist with genetic counseling of the patient and the patient's family.

The characteristic cutaneous findings and the major associated internal malignancy for the genodermatoses with cancer susceptibility are listed in Table 153-2.[98–104]

DIRECT TUMOR INVOLVEMENT OF THE SKIN

CUTANEOUS METASTASES

Direct involvement of the skin by metastatic spread from a distant primary tumor is perhaps the most unquestioned sign of internal malignancy. The overall incidence of cutaneous involvement is approximately 5%.[105] In a review of over 100,000 cancer patients, skin involvement was the first sign of internal malignancy in 7.8%.[106] The most common malignancies to metastases to the skin in women are breast, colon, and melanoma. In men, the most common are lungs, colon, and melanoma.

Figure 153-11 Hypertrichosis lanuginosa acquisita in a 19-year-old woman with pancreatic carcinoma.

Several clinical and pathologic features can aid in determining the source of the metastasis. Metastatic breast cancer can present as an erysipelas-like eruption known as *carcinoma erysipelatodes* (Fig. 153-12A). Usually asymptomatic, this type of breast cancer can be painful. Another clinical variant is the leather-like skin change of sclerosing metastatic breast cancer known as *carcinoma en cuirasse,* which may later present as nodules and ulceration (Fig. 153-12B and C). Carcinoma en cuirasse can be progressive for many years, even decades, in the absence of any apparent systemic involvement.

Metastases from malignant melanoma are usually pigmented (Fig. 153-13). Often there is a bluish tint to

Figure 153-12 **A.** Carcinoma erysipelatoides. Intralymphatic spread of mammary carcinoma that manifests as erysipelas-like erythema. **B.** Bilateral cutaneous metastases from underlying breast carcinoma. **C.** Carcinoma en cuirasse involving both breasts and thoracic wall.

TABLE 153-2
Genetic Syndromes Involving Skin and/or Mucous Membranes and Associated with Malignancy

Syndrome	Gene/Protein Defect	Cutaneous Findings	Other Characteristic Features	Major Associated Internal Malignancy	Minor Associated Internal Malignancy
Autosomal Dominant					
Birt-Hogg-Dube syndrome[99]	BHD (folliculin)	Fibrofolliculomas, trichodiscomas, acrochordons	Lung cysts, emphysema, recurrent spontaneous pneumothoraces	**Renal carcinoma** (12%)	
Carney complex[107]	PRKAR1-α (regulatory subunit type 1A protein kinase A)	Mucocutaneous myxomas, nevi, ephelides, blue nevi	Primary pigmented nodular adrenocortical disease (26%-benign, causes Cushing's syndrome)	**Myxomas** (cardiac- 53%, skin-33%) **Sertoli cell testicular cancer** (33% of males)	Other testicular cancers, breast and thyroid tumors, pituitary adenoma, and melanotic schwannomas
Cowden disease[98]	PTEN (tyrosine phosphatase)	Trichilemmomas, acral papules and keratoses, oral papillomas, sclerotic fibromas	Ovarian cysts, adenoid facies	**Breast cancer** (22%) **Hamartomatous intestinal polyps** (60%) **Thyroid abnormalities** (62%, includes follicular thyroid carcinoma, goiter, and adenoma)	Transitional cell and renal cell carcinomas, glioblastoma multiforme, liposarcoma, lung, hepatocellular, pancreatic, uterine, and ovarian cancer
Gardner disease[98]	APC (regulator of β-catenin)	Epidermoid cysts, fibromas, pilomatricomas	Congenital hypertrophy of retinal pigment epithelium (CHRPE), supernumerary teeth, osteomas	**Intestinal polyposis and colorectal adenocarcinoma** (near 100%)	Thyroid cancer, adrenal adenomas and adenocarcinomas, hepatoblastoma; bone and CNS tumors
Gorlin syndrome[98]	PTCH1 (patched 1)	Multiple BCCs, epidermoid cysts, milia, palmar and plantar pits	Calcified falx cerebri, bifid ribs, odontogenic cysts, kyphoscoliosis	**Medulloblastoma** (10%), **meningiomas** (5%)	Ovarian fibromas, fibrosarcomas, cardiac fibromas, ovarian desmoids
Howel-Evans syndrome[101]	TOC (tylosis and esophageal cancer gene)	Palmoplantar keratoderma (nontransgrediens)	Oral leukoplakia	**Esophageal carcinoma** (up to 90%)	
MEN I syndrome[98,100]	MEN1 (menin)	Angiofibromas, collagenomas, CALMs, lipomas, hypopigmented macules, gingival papules; necrolytic migratory erythema	Various endocrine sequelae based on underlying tumor	**Parathyroid adenomas** (90%) **Pancreatic islet cell tumors** (80%) **Gastrinomas** (54%, includes Zollinger-Ellison syndrome) **Anterior pituitary tumors** (10%–30%)	Foregut and thymic carcinoids, pheochromocytoma, thyroid adenomas
MEN IIa syndrome[98,100]	RET (tyrosine kinase receptor)	Scapular macular or lichen amyloidosis	No mucosal neuromas or marfanoid habitus	**Medullary thyroid carcinoma** (90%) **Pheochromocytomas** (50%) **Parathyroid tumors** (20%–30%)	

MEN IIb/III syndrome[98,100]	RET (tyrosine kinase receptor)	Mucosal neuromas, CALMs, thickened eyelids and lips	Marfanoid habitus, no parathyroid tumors	**Medullary thyroid carcinoma** (90%) **Pheochromocytoma** (50%)	Conjunctival neuromas, intestinal ganglioneuromas
Muir-Torre syndrome[98]	MSH1/2 (DNA mismatch repair)	Sebaceous tumors (epitheliomas, hyperplasias, and adenomas), keratoacanthomas		**Colorectal carcinomas** (51%) **Genitourinary cancers** (25%)	Breast, head and neck, and small intestine carcinomas, hematologic malignancies
Neurofibromatosis I[98]	NF1 (neurofibromin)	CALMs, NF, plexiform NF, axillary freckling	Lisch nodules, glaucoma, sphenoid wing dysplasia, pseudoarthrosis of tibia, learning disability	**Optic gliomas** (66%) **Neurofibrosarcoma** (3.5%) **Chronic myelomonocytic leukemia** (if associated with juvenile xanthogranuloma-increased risk)	Astrocytomas, ependymoma, meningioma, non-Hodgkins lymphoma, acute lymphoblastic leukemia, pheochromocytoma
Neurofibromatosis II[98]	NF2 (schwannomin/merlin)	Schwannomas, NF, CALMs, plexiform NF	Juvenile posterior subcapsular cataract, deafness	**Bilateral vestibular schwannomas** (near 100%) **Spinal tumors** (90%, usually schwannomas) **Meningiomas** (50%)	Gliomas, astrocytomas, intramedullary ependymomas
Peutz-Jeghers syndrome[98]	STK11 (serine/threonine kinase 11)	Perioral and mucosal lentigenes	Intussusception, bowel obstruction	**Polyps** (near 100%) **Gastrointestinal carcinoma** (13%)	Pancreatic, esophageal, breast, and ovarian carcinoma
Reed syndrome[102] (hereditary leiomyomatosis and renal cell carcinoma)	FH (fumarate hydratase)	Cutaneous leiomyomas		**Uterine leiomyoma** (98%) **Renal carcinoma*** (type II papillary renal cell)	
Tuberous sclerosis	TSC1 (hamartin) TSC2 (tuberin)	Ash leaf macules, shagreen patches, CALMs, facial angiofibromas, periungual fibromas	Tonic-clonic seizures, paraventricular calcification, subependymal nodules, retinal hamartomas	**Intracranial cortical/subcortical tubers** (near 100%) **Cardiac rhabdomyomas** (50%) **Renal angiomyolipomas** (49%) **Lung lymphangiomyomatosis**	Wilms tumor, pancreatic carcinoma, parathyroid adenoma
Autosomal Recessive Ataxia-Telangiectasia	ATM (DNA repair)	Telangiectasias (skin and conjunctiva), masklike progeric facies, CALMs, poikiloderma	Ataxia, nystagmus, choreathetosis, recurrent respiratory infections, radiosensitive	**Leukemia/lymphomas** (38%) **Breast cancer** (increased risk in heterozygotes)	Various solids tumors
Bloom syndrome[98,103]	RecQL3 (helicase)	Cheilitis, CALMs, malar poikiloderma	Immunodeficiency, short stature, hypogonadism, high-pitched voice	**Acute leukemia*** **Lymphoma*** **GI adenocarcinoma***	Wilms tumor, medulloblastoma, osteogenic sarcoma
Chediak-Higashi syndrome[103]	LYST (lysosomal trafficking)	Silver hair, slate-gray skin, ecchymoses	Immunodeficiency, pyogenic infections (staph), photophobia, cytopenia, neurodegeneration	**Lymphoma-like accelerated phase** (85%)	
Fanconi anemia[104]	FANC (multiple proteins that form a nuclear complex)	Short stature, CALMs microcephaly, thumb, and/or radial ray anomalies	Short stature, multiple birth anomalies, pancytopenia, infection, radial anomalies	**Acute myeloid leukemia** (9%) **Liver tumors** (5%) **Mucosal SCC** (5%)	Myelodysplastic syndrome, gynecologic, head/neck, and esophageal malignancies

(continued)

TABLE 153-2
Genetic Syndromes Involving Skin and/or Mucous Membranes and Associated with Malignancy (Continued)

Syndrome	Gene/Protein Defect	Cutaneous Findings	Other Characteristic Features	Major Associated Internal Malignancy	Minor Associated Internal Malignancy
Griscelli syndrome	RAB27A (GTP-binding protein) MYO5A (myosin)	Silver hair, partial albinism	Immunodeficiency, pancytopenia, neurodegeneration (MYO5A), hemophagocytic syndrome (RAB27A)	**Lymphoma-like accelerated phase** (in the majority)*	
Rothmund-Thomson syndrome[98]	RecQL4 (helicase)	Poikiloderma nail dystrophy, acral keratoses, photosensitivity, hypotrichosis	Short stature, radial anomalies, juvenile cataracts, hypogonadism	**Osteogenic sarcomas***	Fibrosarcoma, gastric carcinoma, SCCs
Werner syndrome[98,103]	RecQL2 (helicase)	Premature aging, birdlike facies, sclerodermoid changes, ulcers	Short stature, cataracts, diabetes, osteoporosis, high-pitched voice, hypogonadism	**Sarcomas** (10%, soft tissue, bone) **Thyroid cancer***	Mengiomas, adenocarcinomas; acrolentiginous melanoma in Japan
Xeroderma pigmentosum[98]	XP (multiple proteins that form DNA repair complex)	Photosensitivity, actinic keratoses, lentigenes, poikiloderma	Photophobia, multiple ocular complications, neurodegeneration (XPA, XPD)	**Ocular cancers** **Lung and gastric carcinomas** (10–20× incr. risk) **Cutaneous cancers** (BCC, SCC, and melanoma 100%)	Sarcomas, leukemia
X-linked Recessive					
Dyskeratosis congenita	DKC1 (XLR; dyskerin-telomerase component) TERT/TERD (AD; telomerase component) NOP10 (AR; telomerase component)	Leukoplakia, nail dystrophy, reticulate pigmentation, alopecia, palmoplantar hyperkeratosis, adermatoglyphia, hyperhidrosis	Pancytopenia, various ocular complications, mental retardation, pulmonary complications	**Cutaneous and mucosal squamous cell carcinoma***	Hodgkins lymphoma, gastrointestinal carcinoma
Wiskott-Aldrich syndrome	WASP (actin assembly in hematopoietic cells)	Eczema, petechiae/purpura	Immunodeficiency (decreased IgM), recurrent infections, thrombocytopenia	**Lymphoreticular malignancy** (20%, non-Hodgkins disease)	
X-linked ichthyosis[103]	STS (steroid sulfatase)	Adherent brown scales that spares face, palms, soles and flexural creases	Failure of maternal labor, comma-shaped corneal opacities	**Testicular cancer** (from associated cryptoorchidism)	
Sporadic					
Beckwith-Wiedemann syndrome	P57 (cyclin-dependent kinase inhibitor)	Capillary malformation, macroglossia, earlobe creases, helical pits	Omphalocele, hypoglycemia, mental retardation, hemihypertrophy	**Wilms tumor**[a] **Hepatoblastoma**[a]	Adrenocortical tumors, rhabdomyosarcoma
Epidermal nevus syndrome	Unknown, may be related to FGF-23	Epidermal nevi, hemangiomas, CALMs, capillary malformation	Mental retardation, neurologic deficits, ocular complications, rickets (Vit D resistant)	**Wilms' tumor** **Cutaneous cancers** (BCC, SCC, keratoacanthoma, syringocystadenoma papilleferum)	Astrocytoma, rhabdomyosarcoma
Famililial melanoma (dysplastic nevus syndrome)[98]	CDKN2A (cyclin-dependent kinase)	Multiple dysplastic nevi, melanomas		**Pancreatic cancer** (22× incr. risk)	Lung, laryngeal, and breast carcinomas
Mafucci syndrome	Unknown	Venous malformations	Encondromas, secondary fractures	**Chondrosarcoma** (20%)	Angio- and lymphangio-sarcoma, fibrosarcoma, osteosarcoma

[a]Frequency unable to be reported due to rarity of the genodermatosis and/or a specific malignancy.

Figure 153-13 Deeply pigmented cutaneous metastases from melanoma.

the lesion, even if it is deep in the skin. However, even if the primary tumor was pigmented, the metastases can be amelanotic. The reverse is also true.

Other tumors that commonly metastasize to skin include tumors of the lung (Fig. 153-14), stomach, kidney, and ovary. The scalp, is quite commonly involved by metastases from lung, kidney, and breast tumors. Alopecia may result. The face and neck may be involved by metastases from oropharyngeal carcinomas. Metastases from renal and thyroid carcinoma may be pulsatile and may have a bruit.

Figure 153-14 Metastatic lung cancer presenting as a forehead nodules.

A proposed diagnostic truncated immunohistochemical battery includes CK-7, CK-20, and S-100. When administered to a cohort of patients with lung, colorectal, bladder, renal cell carcinoma, and melanoma, there was an overall diagnostic accuracy of 83.3%. Other useful markers include antithyroid transcription factor (lung), HMB-45 (melanoma), PSA (prostate), estrogen/progesterone receptors (breast), and mucicarmine (salivary gland).[106]

Generally, though, cutaneous metastases herald a poor prognosis because evidence of systemic spread to other sites is usually quickly apparent. The average survival time of patients with cutaneous metastases is approximately 7.5 months.[106]

LEUKEMIA/LYMPHOMA CUTIS

(See Chapters 144 and 145)

Involvement of the skin with lymphoma cells is quite common, particularly in the case of a T-cell lymphoma. T-cell leukemias frequently have skin involvement, and this involvement may manifest itself as a diffuse erythroderma, as is seen in Sézary syndrome.

B-cell lymphomas also can involve the skin, with Hodgkin disease being the most common. B-cell lymphoma involvement of the skin is usually manifested by the development of one or more papules or nodules that may be ulcerated and form arcuate lesions. Alopecia also can be caused by lymphoma. Alopecia mucinosa is involvement of the hair follicles by lymphoma, with associated mucin deposition.

Aside from the erythroderma seen in T-cell leukemia, other lymphocytic, myeloid, and myelomonocytic leukemias can have cutaneous manifestations. The most common of these are the infiltrations of the skin produced by monocytic or myelomonocytic leukemia, which can produce a leonine facies in addition to other infiltrative plaques. Involvement of the skin can be a presenting feature in myelomonocytic leukemia, although it generally occurs late in the course of the disease.

When assessing a solitary nodule that is histologically lymphoma but in the absence of any definable systemic disease, it is important to consider benign cutaneous lymphoid infiltrates in the differential diagnosis.

PAGET AND EXTRAMAMMARY PAGET DISEASE

(See Chapter 121)

Paget disease of the nipple is an erythematous scaling eruption indicating ductal carcinoma of the underlying breast. Extramammary Paget disease, which can occur in the anogenital skin, similarly may be associated with an underlying adenocarcinoma. The underlying carcinoma may be of apocrine or

eccrine sweat gland origin, or can be from the rectum or urethra.

The Skin in Vascular and Connective Tissue and Other Autoimmune Disorders

Chapter 154 :: Mechanisms of Autoimmune Disease

:: Insoo Kang & Joseph Craft

MECHANISMS FOR AUTOIMMUNE DISEASES AT A GLANCE

- Autoimmune diseases are relatively common disorders and can be divided into organ-specific and systemic autoimmune diseases based on the autoantigens targeted by immune cells.
- Although the underlying etiologies of these illnesses are still elusive, they arise in the context of a break in the immune tolerance to self.
- The mechanisms for abrogation of immune self-tolerance appear to be multifactorial, including genetic and environmental, that lead to unregulated immune activation against self-antigens and subsequent tissue destruction.
- B cells and T cells recognize self-antigens and dominate the phenotype of the patient with autoimmunity, although other immune components including antigen-presenting cells and complement are involved in various steps from initiation of the autoimmune response to tissue destruction.

INTRODUCTION

Autoimmune diseases including rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE) are relatively common disorders.[1] Although the underlying etiologies of these illnesses are still elusive, they arise in the context of a break in the immune tolerance to self.[2,3] The mechanisms for abrogation of immune self-tolerance appear to be multifactorial, including genetic and environmental, that work in concert to initiate the eventual hallmarks of disease: unregulated immune activation against self-antigens and subsequent tissue destruction. Immune activation against self-antigens is clinically manifest by the presence of autoantibodies and autoreactive T cells.[1,2] Based upon their autoantigenic targets, autoimmune diseases can be classified into organ-specific and systemic autoimmune processes. For example, Grave's disease, with its autoantibodies against the thyroid-stimulating hormone (TSH) receptor, is a typical example of organ-specific autoimmune disease, as is type I diabetes mellitus (DM) with its autoantibodies and autoreactive T cells directed against components of pancreatic β cells, whereas SLE with its characteristic autoantibodies against ubiquitous nuclear antigens is a good example of a systemic autoimmune disease. Although adaptive immune cells such as B cells and T cells recognize self-antigens and hence dominate the phenotype of the patient with autoimmunity, other immune components including antigen-presenting cells (APC) and complement are involved in various steps from initiation of the autoimmune response to tissue destruction.[4–6] In this chapter, the contributions of these components to the development of autoimmune diseases will be discussed, focusing on the latest discoveries.

GENETICS

AUTOIMMUNE DISEASES ARE POLYGENIC

Autoimmune diseases are polygenic, involving both major histocompatibility complex (MHC) and non-MHC genes.[7,8] Yet, the concordance rate of autoimmune diseases in monozygotic twins is not 100%, ranging from 10% to 50%, including in RA and SLE,[7,9] indicating a significant role for nongenetic factors in the development of these disorders. Nevertheless, genetic influences are strong. For instance, the contribution of alleles of MHC to the development of autoimmunity has been known for more than 30 years. An increased frequency of HLA (human leukocyte antigen)-DR4 has been observed in some patients with RA.[8] Using more sophisticated molecular techniques, the sequence of genetic alleles encoding HLA loci have been typed, with the resultant demonstration that the *HLA-DRB1* gene is highly polymorphic and such polymorphisms can affect the binding of peptides to HLA molecules and the contacts between the T-cell receptor (TCR) and

the HLA molecule.[8] Thus, the associations between autoimmune diseases and particular HLA molecules can be explained by a model where disease susceptibility is determined by differences in the ability of different HLA alleles to present autoantigenic peptides to autoreactive T cells.[2,8] However, the genetic effect of MHC on disease propensity is broader. As an example, a recent study genotyped a panel of 1,472 single nucleotide polymorphisms (SNPs) across the 3.44 megabase (Mb) classic MHC region in 10,576 DNA samples from patients with autoimmune diseases including SLE, RA, and multiple sclerosis, and from appropriate controls.[10] The results of this study showed multiple risk alleles across MHC class I, II, and III in these autoimmune diseases, indicating complex, multilocus effects that span the entire region.

NON-MHC ASSOCIATIONS WITH AUTOIMMUNE DISEASES

The association of non-MHC genes with autoimmune diseases is now well established,[1,7,11] with the recent advent of genome-wide association (GWA) scans that are powerful tools for identifying new genes in autoimmunity.[11] These genes include those involved in antigen clearance, apoptosis, cell signaling, and cytokine production as well as in the expression of costimulatory molecules and cytokine receptors.[1,2,7,11] For instance, complement components are required for proper clearance of immune complexes, and an increased incidence of homozygous C4 deficiency is found in patients with SLE who have immune complex deposits in damaged organs such as the kidneys.[9]

AUTOIMMUNE REGULATOR

Recently, a gene called *autoimmune regulator* (*AIRE*) gene has been identified as a candidate gene responsible for the development of autoimmune diseases.[12,13] AIRE is a transcription factor that regulates the ectopic expression of proteins, normally expressed in peripheral tissues, in the thymus, allowing for thymic expression of the latter and subsequent negative selection of self-reactive thymocytes before they migrate as mature T cells to the secondary lymphoid organs such as the spleen and lymph nodes. An alteration in thymic expression of *AIRE* can lead to increased generation of autoreactive T cells due to their impaired negative selection.[14] Indeed, patients with mutations of the *AIRE* gene develop a syndrome called autoimmune polyendocrinopathy candidiasis ectodermal dystrophy (APECED) or autoimmune polyglandular syndrome 1 (APS-1) that is characterized by chronic mucocutaneous candidiasis, hypoparathyroidism, and Addison's disease.[15] In addition, patients with this condition often have other organ-specific autoimmune diseases including type 1 DM, autoimmune thyroid diseases, gonadal failure, vitiligo, alopecia, dystrophy of dental enamel and nails, and pernicious anemia.[15]

CYTOTOXIC T-LYMPHOCYTE ANTIGEN-4

An increased incidence of autoimmune diseases has been reported in individuals with a particular variant of genes that affect T-cell activation. These include the cytotoxic T-lymphocyte antigen-4 (*CTLA-4*) gene and the protein tyrosine phosphatase 22 gene (*PTPN22*)[1,11,16] (see below). CTLA-4 is a key immunoregulatory molecule that restrains T-cell activation. It is expressed on T cells upon TCR stimulation by antigen on APC and competes with CD28, a positive costimulatory molecule also on T cells, for binding to CD80 and CD86 expressed on APC.[17] By contrast to CD28 engagement by CD80 and CD86, binding of CTLA-4 to the latter molecules inhibits T-cell activation. The association of SLE and RA with SNPs in the *CTLA-4* promoter and coding region has been reported. These polymorphic sites include –1722 position of the *CTLA-4* promoter and +49 position of exon-1,[18,19] although the functional consequence of such gene polymorphisms is not clear yet. CTLA-4 polymorphisms also have been linked to autoimmune endocrinopathies; for example, a decrease in the alternate splice product of *CTLA-4* that is the soluble form of CTLA-4 is found in individuals with CTLA-4 SNP CT60 G/G which is linked with increased susceptibility to Grave's disease, autoimmune hypothyroidism, and type 1 DM.[20] This finding suggests a possible functional role for CTLA-4 polymorphisms in autoimmune diseases.

PROGRAMMED CELL DEATH 1

In a manner analogous to CTLA-4, a protein called programmed cell death 1 (PD-1) is expressed on T cells providing an inhibitory signal upon their activation. This molecule is also expressed on other immune cells including B cells and myeloid cells.[1,21] PD-1 is encoded by the *PDCD1* gene, with a SNP in its fourth intron associated with autoimmunity, including SLE and RA.[22–24] Of interest, this disease-associated SNP impairs the binding of the hematopoietic runt-related transcription factor 1 (RUNX1), leading to aberrant expression of *PDCD1* gene and subsequently uncontrolled T-cell activation.[22] The association of genetic polymorphisms of CTLA-4 and PD-1, molecules involved in regulating T-cell activation, with autoimmune diseases supports the notion that regulation of T-cell activation by these costimulatory molecules is a critical checkpoint for the development of autoimmunity.

PROTEIN TYROSINE PHOSPHATASE 22

The protein tyrosine phosphatase 22 (*PTPN22*) gene is another recently identified gene that is associated with autoimmune diseases.[1] A variant of the *PTPN22* gene, which encodes a tryptophan at codon 620 (620W) instead of an arginine (wild-type), has been found to be associated with an increased risk of RA, SLE, type 1 DM, and Grave's disease.[1] Such a mutation appears to have functional consequences, since the *PTPN22* gene encodes lymphoid tyrosine phosphatase (LYP) that modulates the activation of Lck and other kinases

involved in TCR signaling.[25] Indeed, the *PTPN22* 620W allele appears to potentially increase the inhibition of TCR activation by downregulating Lck activation.[25] Thus, it still needs to be clarified how this allele promotes the development of autoimmunity.

TUMOR NECROSIS FACTOR RECEPTOR SIGNALING PATHWAY

Recently, multiple genes encoding molecules involved in tumor necrosis factor (TNF) receptor signaling have been found to be associated with autoimmunity.[11] The best known is *TNFAIP3* that encodes TNF inducible protein A20 that is a negative regulator of TNF-induced NF-*k*B signaling pathways. SNP markers in the gene region near the *TNFAIP3* locus have been associated with RA, psoriasis, and SLE.[26–28] The gene encoding *TNFAIP3*-interacting protein 1 (*TNIP1*) that interacts with TNFAIP3 is associated with psoriasis and SLE,[27,29] with an association of the *TRAF1* (TNF receptor-associated factor 1) gene with RA also reported.[30]

CYTOKINE RECEPTORS

Polymorphisms in several cytokine receptors are associated with autoimmunity.[11] The IL-23 receptor complex consists of IL-23R and IL-12Rβ1 subunits, with the latter shared with the IL-12 receptor complex that is composed of IL-12Rβ1 and IL-12Rβ2 subunits. The *IL23R* receptor gene is associated with inflammatory bowel disease and psoriasis.[31,32] This is an intriguing point since IL-23 is involved in regulating the development of T helper 17 (Th17) cells that produce the potent proinflammatory cytokine IL-17. In fact, IL-17 is found in psoriatic skin lesions.[33] Likewise, the *IL12B* gene that encodes IL-12β (the p40 subunit of IL-12) has been found to associated with psoriasis.[34]

RECEPTORS FOR IMMUNOGLOBULIN G Fc PORTION (FcγR)

In addition to genes expressed by T cells, those involved in humoral immune responses also appear to be associated with autoimmunity. The receptors for immunoglobulin G (IgG) Fc portion (FcγR) are expressed on B cells, macrophages, monocytes, granulocytes, and dendritic cells (DCs). There are eight genes identified for the human FcγR: *FCGRIA, FCGRIB, FCGRIC, FCGRIIA, FCGRIIB, FCGRIIC, FCGRIIIA,* and *FCGRIIIB*.[35] The binding of FcγRs to IgG, except for that to FcγRIIb, results in a broad spectrum of activating cellular responses including phagocytosis, cytolysis, cytokine production, and degranulation that lead to inflammation. By contrast, FcγRIIb physiologically serves as an inhibitory receptor that downregulates the effector function of cells.[35] An increased frequency of some variants of *FCGR* genes has been reported in humans with autoimmune diseases including SLE and RA.[35–39] FcγRIIa with an arginine at position 131 has greater signaling in response to IgG1 engagement than FcγRIIa with a histidine at the same position, suggesting that FcγRIIa gene polymorphisms have physiologic relevance.[39] Of interest, FcγRIIa with an arginine has been reported as a susceptibility factor for SLE in some ethnic groups.[35,40] Similarly, a variant of FcγRIIIa with a phenylalanine at position 158 may be a susceptibility factor for SLE and RA.[36,38] In addition, genetic polymorphisms of the inhibitory FcγRIIb have been reported in patients with SLE.[37,41,42] The best known such polymorphism is a substitution of an isoleucine at position 232 (187 by counting from the *N*-terminus of the mature protein) with a threonine.[37,41,42] The latter genotype is more commonly reported in patients with SLE. While the biologic implication of such an alteration on the development of SLE is as yet unclear, functioning inhibitory FcR are necessary for dampening autoimmunity in murine lupus.[43]

Overall, genetic studies on MHC genes and non-MHC genes support the notion that some patients with autoimmune diseases have an increased genetic risk for the development of autoimmune diseases secondary to genetic alterations affecting immune cell function. However, such alterations are not always observed in patients with autoimmune diseases and ethnic differences in genetic susceptibility are not uncommon. These findings support the idea that autoimmune diseases are polygenic and that environment factors are also involved in their development (Fig. 154-1).

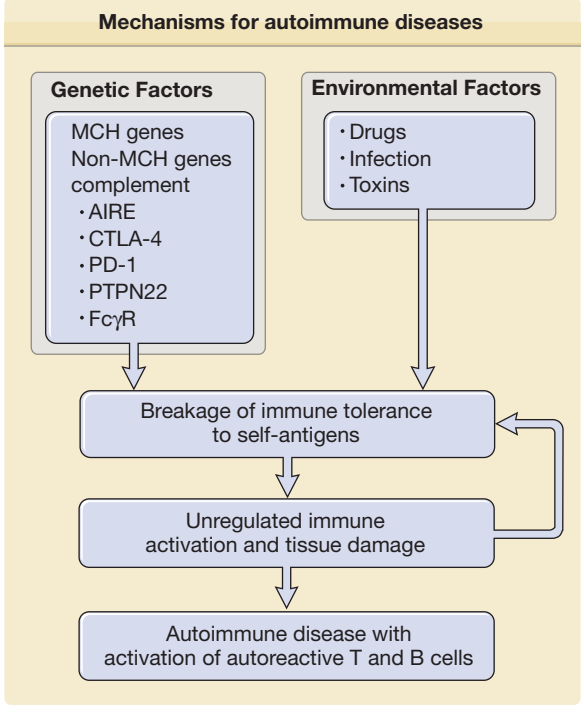

Figure 154-1 Mechanisms for autoimmune diseases. The figure shows potential mechanisms for initiation of autoimmune diseases including genetic and environmental factors that work in concert to initiate breakage of immune tolerance to self-antigens. Subsequently, unregulated immune activation and tissue damage arise, leading to the development of autoimmune disease with activation of autoreactive T cells and B cells with autoantibody production. Abbreviations: AIRE (autoimmune regulator), CTLA-4 (cytotoxic T-lymphocyte antigen-4), PD-1 (programmed cell death 1), PTPN22 (protein tyrosine phosphatase 22), and FcγR (receptor for immunoglobulin G (IgG) Fc portion). See details in text.

TOLERANCE AND AUTOIMMUNITY

CENTRAL TOLERANCE

Intact mechanisms of self-tolerance are necessary to prevent the development of autoimmune diseases.[2] Self-tolerance is generated and maintained through the capacity of the immune system to distinguish self-reactive B and T cells from nonself-reactive cells. These processes begin during the development of lymphocytes in the bone marrow and thymus, respectively.[3] Such selective processes are controlled by the binding affinity of antigen receptors to self-antigens during lymphocyte development. B and T cells expressing antigen receptors with affinity for self-antigens are altered, either becoming nonreactive to antigenic stimuli (through a process called anergy induction) or changing their antigen receptors so that they no longer bind self-antigens (a process called receptor editing, operative in self-reactive B cells), or if they bind too strongly to self, they are simply killed via apoptosis. These interventions lead to central tolerance to self-antigens.[3] A defect in central tolerance can cause autoimmune diseases as evidenced by the development of APS-1 in humans with an alteration in the *AIRE* gene (see Section "Genetics") that is involved in negatively selecting autoreactive T cells.[44,45]

PERIPHERAL TOLERANCE

Despite removing or modifying autoreactive lymphocytes in the thymus and bone marrow by selective processes, some lymphocytes reactive to self-antigens still mature and enter the peripheral immune system; i.e., negative selection is not perfect, probably because if it were, potentially beneficial T and B cells would never make it past central selection in the thymus and bone marrow, respectively. The autoreactive T and B cells that escape central selection can potentially be activated upon recognition of self-antigens; thus, peripheral tolerance mechanisms need to be available to avoid the development of autoimmunity. Such mechanisms are several, and involve minimizing contacts of autoreactive cells with self-antigens (ignorance of the self-reactive lymphocyte), not providing appropriate signals for their activation, terminating activated autoreactive cells by regulatory molecules such as PD-1 or CTLA4, and/or actively suppressing autoimmune responses by other T cells.[2] In critical organs like the brain, eyes, and gonads, immunological ignorance is a principal mechanism for avoidance of autoreactivity via the provision of anatomical barriers separating the tissue and lymphocytes. Activation of the latter can be further prevented by the relative paucity of APCs in these organs and the minimal expression of MHC molecules in these tissues.[46,47] These sites are termed immunologically privileged since even tissue grafts do not elicit immune responses therein. Immunologically privileged sites have additional mechanisms that prevent immune activation, including production of TGF-β, which can suppress immune responses such as in the anterior chamber of the eyes, and constitutive expression of Fas ligand that induces apoptosis of infiltrating activated lymphocytes.[46,47]

Nevertheless, since autoantigens are expressed on some tissues and autoreactive T (and B) lymphocytes are present in the circulation, there is still a reasonable chance for the latter to recognize autoantigens expressed by MHC molecules on APC. However, such an autoantigenic signal through potentially self-reactive antigen receptors is not enough to activate lymphocytes, as additional signals (second signals) provided by APCs, such as CD80 and CD86, to CD28 on T cells are required for proper activation.[17,48] When proper costimulation is not provided by antigen presenting cells, autoreactive T cells that are only signaled through the TCR undergo apoptosis or become anergized. As CD80 and CD86 upregulation on APCs requires an inflammatory stimulus provided to the APC such as that provided by a pathogen during infection, presentation of self-antigens in the absence of inflammation does not lead to autoreactive T cell activation. By contrast, peptides of pathogens lead to cellular activation as they are presented to the immune system in the appropriate inflammatory context. Of course, this regulatory control on autoimmunity may be bypassed if in a similar manner self-antigens are presented at a site of inflammation. Fortunately, this appears to be a relatively unusual event, and autoimmunity invoked by this mechanism is typically avoided.

Autoreactive lymphocytes that manage to get activated in the periphery can be also deleted by apoptosis (programmed cell death) and/or their activation terminated by inhibitory molecules expressed on autoreactive lymphocytes. Fas ligand, or Fas, expressed on T cells is largely responsible for the former.[49,50] The latter process can be achieved through CTLA-4 and PD-1 expressed on activated T cells that inhibit and downregulate T cell activation.[17,21] The potential roles for CTLA-4 and PD-1 in controlling autoimmunity have been demonstrated by mouse studies where these genes have been genetically eliminated, for example, with resultant autoimmunity.[51,52] In addition, genetic polymorphisms in these molecules have been reported to be associated with autoimmune diseases including SLE and RA (see Section "Genetics"). More importantly, there have been attempts to treat autoimmune diseases by modulating CTLA-4 and PD-1 inhibitory pathways.[53,54] Indeed, abatacept, a recombinant fusion protein comprising the extracellular domain of human CTLA4 and a fragment of the Fc domain of human IgG1, is available for the treatment of RA.[53] This drug, like CTLA4, competes with CD28 for CD80 and CD86 binding; however, in contrast to CTLA4 engagement that leads to downregulation of T cell activation, it blocks T cell activation and thus selectively modulates T cell activation.

The activation of autoreactive lymphocytes is also actively suppressed through other mechanisms. The most appealing such mechanism is immune suppression through subsets of T cells called regulatory T cells (Tregs), discussed below.

REGULATORY T CELLS

The concept that certain T cells can regulate immune responses dates back to early 1970s. These cells, that Gershon initially called "suppressor cells,"[55] remained largely undefined and their mechanism of suppression not identified. After their original discovery, they remained out of vogue until over a decade later when others including Sakaguchi reported modulation of immune responses by $CD4^+$ T cells expressing CD25 (IL-2 receptor alpha chain)[56] as well as by T cells producing TGF-β and IL-10.[57–59] Cells with immune regulatory functions are now called regulatory T cells (Tregs). Several subsets of Tregs have been identified thus far, including: (1) naturally occurring $CD4^+$ $CD25^+$ Tregs expressing the transcription factor protein forkhead box P3 (Foxp3); (2) $CD4^+$ T cells producing IL-10 called type 1 regulatory T cells (Tr1); (3) $CD4^+$ T cells producing TGF-β named T helper 3 cells (Th3); and (4) $CD8^+$ T cells producing IL-10 or TGF-β.[60,61]

CD4+ CD25+ REGULATORY T CELLS

Among the best characterized Tregs are naturally occurring $CD4^+$ $CD25^+$ $Foxp3^+$ cells ($FOXP3^+$ Treg) that are produced in the thymus. The potential role for these Tregs in controlling the development of autoimmunity was initially demonstrated by studies where mouse T cell suspensions were transferred into congenic athymic nude mice. If the latter animals received such suspensions depleted of $CD4^+$ $CD25^+$ T cells, they developed an autoimmune syndrome including thyroiditis, gastritis, insulitis, sialoadenitis, adrenalitis, oophoritis, glomerulonephritis, and polyarthritis.[56] By contrast, athymic nude mice that received whole T-cell suspensions did not develop autoimmunity, indicating a role for $CD4^+$ $CD25^+$ T cells in preventing autoimmune diseases.[56] Subsequently, the inhibitory effects of $CD4^+$ $CD25^+$ Tregs in different types of animal models of autoimmune diseases including collagen-induced arthritis (CIA) and autoimmune diabetes were documented.[62,63] Yet, not all $CD4^+$ $CD25^+$ T cells have immunoregulatory functions as CD25 is upregulated upon T-cell activation. Thus, the search for other markers that specifically identify these cells has been extensive, and has led to the identification of CD39, CD103, CTLA-4, glucocorticoid-induced TNF receptor (GITR), lymphocyte activation gene 3 (LAG-3), interleukin 7 receptor, and Foxp3[64,65] as potential markers. The most promising of this group is Foxp3. Disruption of its gene in mice results in autoimmune diseases,[66,67] whereas overexpression of Foxp3 in T cells induces expansion of $CD4^+$ T cells with immunosuppressive function.[66–68] Furthermore, $CD4^+$ $CD25^-$ T cells transfected with FoxP3 acquire immunosuppressive function.[66,67] Although it was originally thought that $FoxP^+$ Tregs develop only in the thymus, studies indicate that $CD25^-$ $CD4^+$ T cells in the periphery can become $FoxP3^+$ Treg-like cells with immune regulatory function in the presence of T-cell receptor triggering, IL-2, and TGF-β.[69] The latter cells are now called adaptive or inducible $FoxP3^+$ Treg ($FOXP3^+$ iTreg) whereas the former cells are called naturally occurring FoxP3 Treg (nTreg).[69]

Although the exact mechanism(s) by which naturally occurring $FoxP3^+$ Tregs suppress autoreactive T cells is not fully understood, cell-to-cell contact is necessary and CTLA-4 appears to be required.[70,71] CTLA-4 expressed on Tregs interacts with CD80 and CD86 expressed on APC as well as on the target T cells[72,73]; while CD80 and CD86, ligands for CTLA-4, are conventionally expressed on APC as noted above, they have also been found on activated $CD4^+$ T cells.[72,73] These molecules likely interact with CTLA-4 expressed on $FoxP3^+$ Treg, providing "outside-in" signaling leading to immune suppression. IL-2 appears to be involved in inducing and maintaining these cells.[71] IL-2 can upregulate FoxP3 expression through activating STAT5.[74,75] Of interest, CD25, the IL-2 receptor α chain, could be involved as a suppressive mechanism of $FoxP3^+$ Tregs by absorbing IL-2 and subsequently reducing the availability of this cytokine to other T cells.[76] These Tregs also express CD39 (ectonucleoside triphosphate diphosphohydrolase 1) and CD73 (ecto-5-nucleotidase). These molecules generate pericellular adenosine with immunosuppressive activity by catalyzing extracellular nucleotides.[77] $FoxP3^+$ Tregs can suppress T cell function by inducing the production of the enzyme indoleamine 2,3-dioxygenase (IDO) from DCs. IDO catabolizes conversion of the essential amino acid tryptophan to kynurenine that is harmful to T cells.[71,78] Overall, FoxP3 Tregs likely employ multiple mechanisms in suppressing other T cell function.

By contrast to animal studies, the data on $CD4^+$ $CD25^+$ Tregs in human autoimmune diseases is relatively minimal. In patients with type 1 DM, a typical example of an organ-specific autoimmune disease, the frequency of $CD4^+$ $CD25^+$ Tregs has been shown to be significantly lower than in healthy controls and patients with type 2 DM, suggesting a role for these cells in disease development.[79] However, in separate studies, no difference in the frequency of $CD4^+$ $CD25^+$ Tregs and *FOXP3* gene allelic variation has been reported in patients with type 1 DM compared to healthy controls,[80,81] although the inhibitory function of such cells was impaired.[81] Similarly, there was no difference in the frequency of $CD4^+$ $CD25^+$ T cells and their functional markers including Foxp3 among patients with APS-II characterized by Addison's disease, type I diabetes and autoimmune thyroid disease as well as control patients with single autoimmune endocrinopathies and normal healthy donors.[82] However, $CD4^+$ $CD25^+$ Tregs from APS-II patients were defective in their suppressive capacity.[82] These findings suggest that patients with autoimmune endocrinopathies including type 1 DM and APS-II may have an alteration in the suppressive function of $CD4^+$ $CD25^+$ Tregs.

A role for $CD4^+$ $CD25^+$ Tregs in the development of SLE and RA, typical systemic autoimmune diseases, has also been explored. Most studies on $CD4^+$ $CD25^+$ Tregs in human lupus reported a decreased frequency of this cell subset,[83] suggesting their potential role in

the development of SLE. In RA, $CD4^+$ $CD25^+$ Tregs from both peripheral blood and synovial fluid have been studied.[84–86] The frequency of $CD25^+$ $CD4^+$ Tregs in the latter fluid was higher than that in peripheral blood,[85,86] although there was no significant difference in the numbers of $CD4^+$ $CD25^+$ Tregs in peripheral blood between patients and controls.[85,86] Of interest, compromised function of $CD4^+$ $CD25^+$ Treg cells in suppressing inflammatory cytokines from $CD4^+$ $CD25^-$ T cells was reported in RA.[87] Furthermore, such impairment was reversed after treating patients with anti-TNF-α therapy. These findings suggest that patients with RA have a functional, but not a numerical, defect in $CD4^+$ $CD25^+$ Tregs.

OTHER REGULATORY T CELLS

In contrast to $CD4^+$ $CD25^+$ Tregs that naturally occur, other regulatory T cells can be induced in vivo and in vitro.[61] These cells include Tr1, Th3 ($CD4^+$ T cells producing large amounts of TGF-β) and $CD8^+$ $CD28^-$ T cells that develop in the setting of immune stimulation such as that initiated by chronic infections. For instance, humans chronically infected with hepatitis C or Epstein Barr viruses, or with *M. tuberculosis* or the nematode *Onchocerca volvulus,* may develop pathogen-specific Tr1 cells that produce large amounts of IL-10 that can suppress antigen-specific or nonspecific T-cell responses.[88–91] These cells can also be generated after ingestion of a foreign antigen via the oral route.[57] The immunosuppressive mechanisms employed by Tr1 and Th3 cells are dependent on IL-10 and TGF-β production rather than direct cell-to-cell contact as in natural Tregs.[61]

$CD8^+$ T cells may also have immunosuppressive activity.[60] Mice deficient in $CD8^+$ T cells develop experimental autoimmune encephalomyelitis (EAE), an animal model of multiple sclerosis.[92] However, EAE in the same animals was milder when they received adoptive transfers of $CD8^+$ $CD28^-$ T cells. Moreover, $CD8^+$ $CD28^-$, but not $CD8^+$ $CD28^+$, T cells suppressed in vitro IFN-γ production by $CD4^+$ T cells specific for myelin oligodendrocyte glycoprotein, an autoantigen in EAE. Such suppression required cell-to-cell contact and was mediated by inhibition of upregulation of costimulatory molecules on APCs that led to decreased costimulation of $CD4^+$ T cells. Of interest, a recent study suggested a potential role for $CD8^+$ T cells with suppressor activity in improving lupus-like disease in mice.[93] Decreased levels of pathogenic anti-dsDNA antibodies with a resultant increase in survival were found in lupus-prone (NZB × NZW)F_1 mice when injected with an artificial peptide called pConsensus (pCons) that was developed based on T cell stimulatory V_H sequences found in (NZB × NZW)F_1 anti-DNA antibodies. This protection depended in part on the generation of peripheral $TGF\beta^-$ and Foxp3-expressing inhibitory $CD8^+$ T cells, and suggested that $CD8^+$ T cells with regulatory activity could be a potential way to modulate autoimmune diseases.

T HELPER 17 (Th17) CELLS

IL-17 (IL-17A), a potent pro-inflammatory cytokine, has an important role in defending the mammalian host against challenge with extracellular bacteria and fungi. IL-17 is made primarily by a unique $CD4^+$ T cell subset called T helper 17 (Th17) cells, although it is also produced by $CD8^+$ and γδ T cells[94–96] as well as by $CD3^+CD4^-CD8^-$ (double negative or DN) T cells and NK cells.[97,98] Cytokines including IL-1β, IL-6, TGF-β, IL-21, and IL-23 are critical for the development and expansion of Th17 cells.[99–102] In fact, studies reported that $CD4^+$ T cells expressing IL-1 receptor I or IL-23 receptor had the strong capacity to produce IL-17.[103,104] The development of Th17 cells is regulated by the transcription factors RORγt (retinoic-acid related orphan receptor) (the human ortholog is RORC), RORα,[105] and IRF4.[106] In addition to IL-17, Th17 cells produce IL-17F, IL-22, and IL-26 as well as chemokine CCL20.[104,107,108] Th17 cells characteristically express CD161, a c-type lectin receptor associated with natural killer cells, as well as chemokine receptors CCR4 and CCR6.[109] These molecules have been used to purify Th17 cells.

IL-17 induces cytokines (IL-6, IL-8, GM-CSF, and G-CSF), chemokines (CXCL1 and CXCL10), and metalloproteinases from target cells including epithelial cells and fibroblasts.[110] IL-17 potently recruits and activates neutrophils through inducing GM-CSF and IL-8 production,[110] leading to neutrophil-mediated inflammatory responses. A potential role for IL-17 in autoimmunity has been demonstrated through mouse studies of EAE and CIA, models for multiple sclerosis and RA, respectively,[111–113] as well as murine lupus models.[114,115] Increased levels of IL-17 in blood and tissues as well as an increased frequency of peripheral Th17 cells were reported in patients with psoriasis, inflammatory bowel disease, and SLE,[97,116–121] suggesting a pathogenic role in human inflammatory diseases. A recent study reported that IL-17 could promote the survival and proliferation of human B cells in conjunction with B-cell activating factor (BAFF).[122] This can be an additional mechanism of how IL-17 promotes inflammatory autoimmune diseases like lupus and MS where autoantibodies have a pathogenic role.

INNATE IMMUNITY AND AUTOIMMUNITY

DENDRITIC CELLS AND TOLL-LIKE RECEPTORS

Various cells of the innate immune system appear to be involved in the regulation of autoimmunity, including DCs, natural killer cells, γδ T cells, natural killer T cells, and even mast cells.[123–128] Among the best characterized are DCs, or professional APCs.[129] DCs present antigens to T cells for their activation, but their requirement to provide costimulation via CD80

and CD86 limits autoreactive T-cell activation in the absence of inflammatory signals. Interaction of CD80 on DCs and CD28 on T cells polarizes TCR-triggered naive T cells into T helper 1 cells producing IFN-γ. In addition, activated DCs produce multiple cytokines including IL-12, TNF-α, and IL-6 that can promote inflammation. DCs express Toll-like receptors (TLRs), or pattern recognition receptors that recognize various pathogen-associated molecular structures including lipopolysaccharide, dsRNA, ssRNA, and hypomethylated cytosine and guanosine sequence (CpG) DNA.[130] Thus, microorganisms can potentially promote autoimmunity and inflammation through these receptors by activating DCs.[129] Activated DC can also affect $CD4^+$ $CD25^+$ Treg function. Microbial activation of TLRs blocks the suppressive effect of $CD4^+$ $CD25^+$ Treg cells, allowing activation of pathogen-specific adaptive immune responses.[131] This block of suppressor activity is dependent in part on interleukin-6, which was induced by TLRs upon recognition of microbial products.

DCs and TLRs are also likely involved in the development of SLE. Rönnblom and Alm have demonstrated that immune complexes in lupus serum containing autoantibodies associated with apoptotic fragments of cells including DNA or RNA can stimulate plasmacytoid DCs (pDCs) to produce interferon-α (IFN-α) with resultant autoimmune inflammation.[5,132] Such events can be mediated by TLRs.[133,134] pDCs express TLR9 that recognize CpG DNA[130]; thus, immune complexes in lupus serum containing CpG DNA and anti-DNA antibodies can stimulate pDC to produce IFN-α, which promotes autoimmunity (see below). This notion is supported by two studies showing that engagement of B cell receptors binding self-Ig (rheumatoid factor) complexes with DNA or DNA per se with their cognate ligand activates B cells by subsequent delivery of the nucleic acid TLR9 in endosomes.[135,136] A similar concept has been raised by recent studies demonstrating the role of TLR7 and TLR8 in cellular responses to ssRNA[137,138] since antibodies against small nuclear RNA and protein complexes are often found in lupus patients.[133,134]

ENVIRONMENTAL FACTORS AND AUTOIMMUNITY

DRUGS AND AUTOIMMUNITY

Certain drugs can induce autoimmune diseases, with potentially protean clinical manifestations.[139] Among the best-known inducers of autoimmunity are procainamide and hydralazine that can lead to drug-induced lupus in a minority of patients who take these agents. Although the exact mechanisms that promote procainamide- and hydralazine-induced lupus are not fully understood, recent studies suggest that alterations in DNA methylation, a process critically involved in gene regulation, by these drugs could be responsible for the development of lupus.[140,141] Procainamide and hydralazine can decrease DNA methylation in T cells, resulting in increased expression of genes such as lymphocyte function-associated antigen (LFA-1) which can potentially promote autoimmunity.[142,143] Evidence from mice also suggests that procainamide may alter central (thymic) tolerance in T-cell selection, leading to escape of autoreactive T cells into the periphery.[144]

INTERFERON-α AND AUTOIMMUNITY

Ironically drugs that modulate the immune system, for example IFN-α, can also induce autoimmunity. In patients treated with IFN-α for hepatitis C or for malignancies, drug-induced lupus with nephritis and antineutrophil cytoplasmic antibodies (c-ANCA)-associated vasculitis have been reported.[133,134,139] In fact, the potential role of IFN-α in the pathogenesis of lupus was suggested in late 1970s by a study reporting increased serum levels of IFN-α in lupus patients.[145] This notion has been recently revived by several groups that have demonstrated increased expression of interferon-induced genes in peripheral blood cells from lupus patients, using microarray analyses.[146,147]

IFN-α can affect innate and adaptive immune cell function. While it has antiproliferative effects on T cells,[148] at the same time it enhances immunoglobulin isotype switching by stimulating DCs.[149] IFN-α also induces maturation of DCs and drives monocytes to become more effective in stimulating T cells, including those that are potentially autoreactive.[150–152] The results of studies in mice also provide evidence for a role of this cytokine in the development of lupus. Administration of poly(inosine-cytosine), a synthetic dsRNA and strong IFN-α inducer, accelerated development of disease in lupus-prone $(NZB \times NZW)F_1$ mice.[153] Lupus-prone mice lacking receptors for type I IFN including IFN-α had reduced anti-dsDNA antibodies and disease activity.[154]

TOXINS AND AUTOIMMUNITY

Environmental chemicals and toxins also have been reported as a potential cause for autoimmune diseases.[155] Probably the best-known chemical is crystalline silica that has been reported to be associated with the development of systemic sclerosis.[155] In addition to this condition, there are patients with SLE and RA who were exposed to crystalline silica,[155] although such epidemiologic data is difficult to provide evidence for causation. On the other hand, lupus-prone $(NZB \times NZW)F_1$ mice exposed to silica have increased levels of antinuclear antibodies, with decreased survival compared to mice not exposed to this chemical.[156] Although the exact mechanism for the development of autoimmune diseases after crystalline silica exposure is unknown, this chemical could serve as an adjuvant promoting immune responses with an increase in the production of proinflammatory cytokines such as

TNF-α.[157] Although there are case reports of autoimmune diseases associated with the exposure to toxic chemicals as well as animals with autoimmune diseases aggravated by such chemicals, additional studies are needed to define the causal relationship between chemical exposure and autoimmunity.

INFECTIONS AND AUTOIMMUNITY

Infection has been suggested as a possible causative factor for autoimmunity. Postulated mechanisms include: (1) release of inflammatory cytokines such as IFN-α by APC that can modulate immune responses; (2) production of cross-reactive antibodies or T cells that can recognize both autoantigens and foreign antigens (molecular mimicry); and (3) polyclonal activation of autoreactive T cells by superantigens.[2] However, these possible mechanisms are not yet proven. Nevertheless, a variety of infectious organisms including virus and bacteria have been linked to autoimmune diseases,[158] including Epstein Barr virus (EBV) as a trigger for SLE. The prevalence of EBV infection as determined by measuring anti-EBV antibodies is higher in patients with SLE compared to healthy controls,[159,160] and patients with SLE have increased EBV viral loads in peripheral blood and altered T-cell immune responses to EBV compared to healthy controls.[161] These findings suggest that the immune control of EBV is altered in SLE although it is not clear whether such an alteration is the cause or the consequence of SLE. Of interest, a recent study showed that EBV-encoded small RNA (EBER) and EBV double-stranded DNA (dsDNA) could induce IFN-α production from human plasmacytoid DC via binding to TLR7 and 9, respectively, suggesting a potential pathologic role for increased viral loads of EBV in human lupus.[162] An intriguing question is why only a small fraction of individuals develop autoimmunity even though infections that may be associated with autoimmunity such as EBV are very common in the population. One likely answer is diversity in the genetic background among individuals, which can lead to different immune responses to the same infectious organisms and possible development of autoimmune diseases.

PATHOGENESIS OF TISSUE DAMAGE IN AUTOIMMUNITY

The mechanisms involved in tissue damages in autoimmune diseases are similar to those that are used in eradicating invading foreign organisms. Autoantibodies can directly bind to autoantigens that are expressed on cells, which results in destruction of cells (type II antibody-mediated hypersensitivity reaction).[2] Autoimmune hemolytic anemia and autoimmune thrombocytopenia, which can be seen in SLE, are good examples of cell destruction by this mechanism.[9] Some autoantibodies can bind autoantigens and activate the complement cascade, which leads to the recruitment of inflammatory cells and subsequent tissue damage (type III immune complex-mediated hypersensitivity reaction).[163] For instance, autoantibodies against chromatin and ribonucleoproteins appear to have a pathogenic role in lupus.[164] The deposition of immune complexes of these autoantibodies with their respective autoantigens in target organs, such as in the kidney, leads to activation of complement and Fc receptor binding with subsequent tissue injury.[165,166] Although autoreactive T cells are required for the development of autoimmune diseases and autoantibodies,[167,168] it is still unclear whether autoreactive T cells are directly involved in damaging tissues in systemic autoimmune syndromes such as SLE, whereas their role in directly promoting tissue injury in organ-specific autoimmune syndromes, such as type 1 DM and multiple sclerosis, are much better established.

Chapter 155 :: Lupus Erythematosus

:: Melissa I. Costner &
Richard D. Sontheimer

LUPUS AT A GLANCE

- A group of heterogeneous illnesses that have in common the development of immunity to self-nucleic acids and their associated proteins, with skin-only disease at one end of the spectrum and severe visceral involvement at the other.
- Skin lesions may be specific to lupus or nonspecific and are seen in other conditions as well.
- Acute cutaneous lupus erythematosus (malar rash) is almost always associated with underlying visceral involvement, subacute cutaneous lupus patients meet systemic lupus erythematosus criteria about 50% of the time (but typically express only mild systemic clinical manifestations), and chronic cutaneous lupus (discoid lupus erythematosus, lupus panniculitis, chilblain lupus, and tumid lupus erythematosus) patients most often have skin-only or skin-predominant disease.
- Discoid lupus erythematosus causes scarring and can be permanently disfiguring. Subacute cutaneous lupus and acute cutaneous lupus erythematosus are highly photosensitive and are characteristically nonscarring.
- Lupus erythematosus-nonspecific skin lesions include nonscarring alopecia, mouth ulcers, photosensitivity, Raynaud's phenomenon, and vasculitis/vasculopathy, among others. They often herald a systemic lupus erythematosus flare.
- Treatment consists of sunscreens, local and systemic (short-term) glucocorticoids, antimalarials, retinoids, immunosuppressives, thalidomide, and biologic therapies.
- Lupus erythematosus occurs much more commonly in women (9:1 female-male ratio).
- Both systemic lupus erythematosus and cutaneous lupus erythematosus are associated with upregulation of class I interferon signaling.

LUPUS ERYTHEMATOSUS: A CHALLENGE TO DEFINE, CLASSIFY, AND TREAT

Lupus erythematosus (LE) is the root designation for a diverse array of illnesses that are linked together by the development of autoimmunity directed predominantly at the molecular constituents of nucleosomes and ribonucleoproteins. Some patients present with life-threatening manifestations of systemic LE (SLE); whereas others, who are affected with what likely represents the same basic underlying disease process, express little more than discoid LE (DLE) skin lesions throughout their illness. It is convenient to conceptualize LE as a clinical spectrum ranging from mildly affected patients with only localized DLE skin lesions to those at risk of dying from the systemic manifestations of LE such as nephritis, central nervous system disease, or vasculitis. The pattern of skin involvement expressed by an individual patient with LE can provide insight about the position on the spectrum where the patient's illness might best be placed.

The nomenclature and classification system originally devised by James N. Gilliam divides the cutaneous manifestations of LE into those lesions that show characteristic histologic changes of LE (LE-specific skin disease) and those that are not histopathologically distinct for LE and/or may be seen as a feature of another disease process (LE-nonspecific skin disease). Within this context, the term "LE-specific" relates to those lesions displaying an interface dermatitis. The term *cutaneous LE* (CLE) is often used synonymously with "LE-specific skin disease" as an umbrella designation for the three major categories of LE-specific skin disease: acute cutaneous LE (ACLE), subacute cutaneous LE (SCLE), and chronic cutaneous LE (CCLE). This will be the framework used in our discussion of the extraordinarily diverse set of cutaneous lesions that occur in patients with LE (Table 155-1).

The essence of LE is in its heterogeneity, and the challenge for those who treat it is to recognize clinically useful patterns within the mosaic of features that constitute this protean illness. An overview of the systemic manifestations of LE can be seen in the American College of Rheumatology's (ACR) classification criteria for SLE,[1] which are presented in Table 155-2, and from the outline of the systemic manifestations of SLE presented in Table 155-3.

EPIDEMIOLOGY

The epidemiology and socioeconomic impact of LE in general,[2] and CLE specifically,[3] have been reviewed.

TABLE 155-1
The Gilliam Classification of Skin Lesions Associated with Lupus Erythematosus

LE-Specific Skin Disease [Cutaneous LE (CLE)]	LE-Nonspecific Skin Disease
A. Acute cutaneous LE (ACLE) 1. Localized ACLE (malar rash; butterfly rash) 2. Generalized ACLE (lupus maculopapular lupus rash, SLE rash, rash, photosensitive lupus dermatitis) B. Subacute cutaneous LE (SCLE) 1. Annular SCLE (syn. lupus marginatus, symmetric erythema centrifugum, autoimmune annular erythema, lupus erythematosus gyratus repens) 2. Papulosquamous SCLE (syn. disseminated DLE, subacute disseminated LE, superficial disseminated LE, psoriasiform LE, pityriasiform LE, and maculopapular photosensitive LE) C. Chronic cutaneous LE (CCLE) 1. Classic discoid LE (DLE) a. Localized DLE b. Generalized DLE 2. Hypertrophic/verrucous DLE 3. Lupus profundus/lupus panniculitis 4. Mucosal DLE a. Oral DLE b. Conjunctival DLE 5. Lupus tumidus (urticarial plaque of LE) 6. Chilblain LE (chilblain lupus) 7. Lichenoid DLE (LE/lichen planus overlap, lupus planus)	A. Cutaneous vascular disease 1. Vasculitis a. Leukocytoclastic (1) Palpable purpura (2) Urticarial vasculitis b. Periarteritis nodosa-like cutaneous lesions 2. Vasculopathy a. Degos disease-like lesions b. Secondary atrophie blanche (syn. livedoid vasculitis, livedo vasculitis) 3. Periungual telangiectasia 4. Livedo reticularis 5. Thrombophlebitis 6. Raynaud phenomenon 7. Erythromelalgia (erythermalgia) B. Nonscarring alopecia 1. "Lupus hair" 2. Telogen effluvium 3. Alopecia areata C. Sclerodactyly D. Rheumatoid nodules E. Calcinosis cutis F. LE-nonspecific bullous lesions G. Urticaria H. Papulonodular mucinosis I. Cutis laxa/anetoderma J. Acanthosis nigricans (type B insulin resistance) K. Erythema multiforme L. Leg ulcers M. Lichen planus

LE, lupus erythematosus; SLE, systemic lupus erythematosus.
From Sontheimer RD: The lexicon of cutaneous lupus erythematosus—A review and personal perspective on the nomenclature and classification of the cutaneous manifestations of lupus erythematosus. *Lupus* **6**:84, 1997, with permission from Stockton Journals, Macmillan Press, Ltd.

Skin disease is the second most frequent clinical manifestation of LE after joint inflammation. As many as 45% of patients with CLE experience some degree of vocational handicap. A recent quality of life study suggested that the impact of skin manifestations in patients with SLE was preceded only by pain and fatigue related to their disease.[4] The Dermatology Life Quality Index and SF-36 have been used to measure quality of life in patients with CLE. Both questionnaires showed that patients with active skin lesions had lower quality of life and that patients with associated alopecia were particularly impacted.[5]

Malar, or butterfly rash (localized ACLE), has been reported in 20%–60% of large cohorts of patients with LE. Limited data suggest that the maculopapular or SLE rash of generalized ACLE is present in about 35%–60% of patients with SLE. ACLE, like SLE in general, is much more common in women than men (8:1). All races are affected; however, the early clinical manifestations of ACLE can be overlooked in a dark-skinned individual.

Patients presenting with SCLE lesions constitute 7%–27% of LE patient populations. SCLE is primarily a disease of white females, with the mean age of onset in the fifth decade. Drug-induced SCLE patients are somewhat older at disease onset, perhaps reflecting greater exposure to drugs for age-related medical problems (hypertension, cardiovascular disease).

The most common form of CCLE, a classic DLE skin lesion, is present in 15%–30% of SLE populations selected in various ways. Approximately 5% of patients presenting with isolated localized DLE subsequently develop SLE. Rheumatologists have estimated that SLE patients are sevenfold more common than isolated cutaneous LE patients. However, dermatologists have estimated that isolated cutaneous LE patients may be 2-3 times more common that SLE patients. Recently published population-based data have argued strongly that the incidence and prevalence of isolated forms of cutaneous LE are equivalent to those of SLE.[6] Although DLE can occur in infants and the elderly, it is most common in individuals between 20 and 40 years of age. DLE has a female-male ratio of 3:2 to 3:1, which is much lower than that of SLE. All races are affected, but investigations suggest that DLE might be more prevalent in blacks.

TABLE 155-2
The 1982 Revised Criteria for Classification of Systemic Lupus Erythematosus[a]

Criterion	Definition
1. Malar rash	Fixed erythema, flat or raised, over the malar eminences, tending the spare the nasolabial folds
2. Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
3. Photosensitivity	Skin rash as a result of unusual reaction to sunlight, by patient history or physician observation
4. Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by a physician
5. Arthritis	Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
6. Serositis	a. Pleuritis—convincing history of pleuritic pain or rub heard by a physician or evidence of pleural effusion *Or* b. Pericarditis—documented by electrocardiogram or rub or evidence of pericardial effusion
7. Renal disorder	a. Persistent proteinuria— >0.5 g/day or greater than 3+ if quantitation not performed *Or* b. Cellular casts—may be red cell, hemoglobin, granular, tubular, or mixed
8. Neurologic disorder	a. Seizures—in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, or electrolyte imbalance) *Or* b. Psychosis—in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, or electrolyte imbalance)
9. Hematologic disorder	a. Hemolytic anemia—with reticulocytosis *Or* b. Leukopenia— <4,000 µL total on two or more occasions *Or* c. Lymphopenia— <1,500/µL on two or more occasions *Or* d. Thrombocytopenia— <100,000 µL in the absence of offending drugs
10. Immunologic disorder	a. Anti-DNA—antibody to native DNA in abnormal titer *Or* b. Anti-Sm—presence of antibody to Sm nuclear antigen *Or* c. Positive finding of antiphospholipid antibodies based on (1) an abnormal serum level of immunoglobulin G or immunoglobulin M anticardiolipin antibodies, (2) a positive test result for lupus anticoagulant using a standard method, or (3) a false-positive serologic test for syphilis known to be positive for at least 6 months and confirmed by *Treponema pallidum* immobilization or fluorescent treponemal antibody absorption test
11. Antinuclear antibody	An abnormal titer of antinuclear antibody by immunofluorescence of an equivalent assay at any point in time and in the absence of drugs known to be associated with "drug-induced lupus" syndrome

[a]The proposed classification is based on 11 criteria. For the purpose of identifying patients in clinical studies, a person shall be said to have systemic lupus erythematosus if any 4 or more of the 11 criteria are present, serially or simultaneously, during any interval or observation.
From Tan EM et al: The 1982 revised criteria for the classification of systemic lupus erythematosus. *Arthritis Rheum* **25**:1271, 1982, copyright 1982, with permission of the American College of Rheumatology.

ETIOLOGY AND PATHOGENESIS

The cause(s) of and pathogenetic mechanisms responsible for LE-specific skin disease are not fully understood, although recent work has provided many new insights. The pathogenesis of LE-specific skin disease is inextricably intertwined with SLE pathogenesis. Simply put, SLE is a disorder in which the interplay between host factors (susceptibility genes, hormonal milieu, etc.) and environmental factors [ultraviolet (UV) radiation, viruses, and drugs] leads to loss of self-tolerance, and induction of autoimmunity. This is followed by activation and expansion of the immune system, and eventuates in immunologic injury to end organs and clinical expression of disease[7] (eFig. 155-0.1 in online edition). Recent work has highlighted the important role of interferon-α signaling in the pathogenesis of both SLE and LE-specific skin disease.

ENVIRONMENTAL FACTORS

Genetic predisposition for a lupus diathesis does not, in itself, produce disease. Rather, it appears that induction of autoimmunity in such patients is triggered by some inciting event, likely an environmental exposure. Drugs, viruses, UV light, and, possibly, tobacco, have been shown to induce development of SLE.

Ultraviolet radiation (UVR) is probably the most important environmental factor in the induction phase of SLE and especially of LE-specific skin disease. UV

TABLE 155-3
Overview of the Extracutaneous Manifestations of Systemic Lupus Erythematosus

- General
  - Fever, fatigue, malaise, weight loss
- Musculoskeletal
  - Symmetric small joint arthralgia, arthritis, (nondeforming and deforming), morning stiffness
  - Myalgia, myositis
  - Tendinitis
  - Avascular (aseptic) bone necrosis
- Hematologic
  - Anemia
    - Normocytic, normochromic
    - Hemolytic
  - Leukopenia
    - Lymphopenia
    - Granulocytopenia
  - Thrombocytopenia
- Cardiopulmonary
  - Pleurisy, pleural effusions, aseptic pneumonitis, pulmonary, hemorrhage
  - Pericarditis, tachycardia, cardiomegaly, congestive heart failure, arrhythmias, conduction defects, coronary arteritis, Libman-Sacks endocarditis
- Renal
  - Mesangial glomerulitis (WHO class II)
    - Mild proteinuria
  - Focal proliferative glomerulonephritis (WHO class III)
    - Proteinuria, hematuria, occasionally nephrotic syndrome, hypertension
  - Diffuse proliferative glomerulonephritis (WHO class IV)
    - Proteinuria, hematuria, red cell casts, renal insufficiency, nephrotic syndrome, hypertension
  - Membranous glomerulonephritis (WHO class V)
    - Severe proteinuria, nephrotic syndrome
- Neuropsychiatric
  - Peripheral neuropathy, transverse myelitis, Guillain-Barré syndrome
  - Chorea, choreoathetosis
  - Seizures
  - Headaches (severe, migraine-like)
  - Brain infarcts secondary to cerebral arteritis
  - Organic brain syndrome
    - Psychosis due to diffuse cerebritis
  - Psychological
    - Depression
- Gastrointestinal
  - Anorexia, nausea, vomiting, abdominal pain
  - Bowel infarction/perforation secondary to mesenteric vasculitis
  - Pancreatitis
  - Peritonitis, ascites
  - Hepatomegaly, chronic active hepatitis
- Ocular
  - Conjunctivitis, episcleritis
  - Blindness secondary to central retinal artery occlusion
  - Cytoid bodies
  - Keratoconjunctivitis sicca
- Lymphatic system
  - Lymphadenopathy
  - Splenomegaly

WHO = World Health Organization.

light likely leads to self-immunity and loss of tolerance because it causes apoptosis of keratinocytes, which in turn, makes previously cryptic peptides available for immunosurveillance. UVB radiation has been shown to displace autoantigens such as Ro/SS-A and related autoantigens, La/SS-B, and calreticulin, from their normal locations inside epidermal keratinocytes to the cell surface.[13] UVB irradiation induces the release of CCL27 (cutaneous T cell-attracting chemokine), which upregulates the expression of chemokines that activate autoreactive T cells and interferon-α (IFN-α), producing dendritic cells (DCs), which likely play a central role in lupus pathogenesis.[14,15]

A recent, large, case-control study reported that smokers are at a greater risk of developing SLE than are nonsmokers and former smokers. A cross-sectional analysis of a collaborative Web-based database established by Werth and colleagues documented that patients with treatment resistant CLE were much more likely to smoke.[16] Several authors have shown that patients with LE-specific skin disease who smoke are less responsive to antimalarial treatment.[17–19]

Numerous drugs have been implicated in inducing various features of SLE (Table 155-3). The drugs that induce CLE can be linked by their photosensitizing properties. It has been suggested that these drugs cause an increase in keratinocyte apoptosis, exposure of previously intracellular peptides on epidermal cell surfaces, and enhance proinflammatory cytokines such as TNF-α and IFN-α.[20,21]

There has been much speculation about the role of infectious agents, particularly viruses, in the induction of SLE and CLE. Seroconversion to Epstein-Barr virus (EBV) among patients with SLE is nearly universal, and recent data have demonstrated that patients with SLE have defective control of latent EBV infection that probably stems from altered T-cell responses against EBV.

CLINICAL FINDINGS

(eFig. 155-0.2 in online edition)

CUTANEOUS LESIONS

eTable 155-3.1 in online edition compares the key clinical, histopathologic, and laboratory features of patients presenting with ACLE, SCLE, and CCLE (classic DLE)

Figure 155-1 Localized acute cutaneous lupus erythematosus. Erythematous, slightly edematous, sharply demarcated erythema is seen on the malar areas in a "butterfly" distribution.

skin lesions. It is important to distinguish among the subtypes of LE-specific skin disease, because the type of skin involvement in LE can reflect the underlying pattern of SLE activity. In fact, the designations acute, subacute, and chronic, in regard to CLE, refer to the pace and severity of any associated SLE and are not necessarily related to how long individual lesions have been present. For example, ACLE almost always occurs in the setting of acutely flaring SLE, whereas CCLE often occurs in the absence of SLE or in the presence of mild smoldering SLE. SCLE occupies an intermediate position in this clinical spectrum. Subclassification, although important for assigning risk, is sometimes difficult, as it is not uncommon to see more than one subtype of LE-specific skin disease in the same patient, especially in patients with SLE.

ACUTE CUTANEOUS LUPUS ERYTHEMATOSUS. Although ACLE localized to the face is the usual pattern of presentation, ACLE can assume a generalized distribution. Localized ACLE has commonly been referred to as the *classic butterfly rash* or *malar rash of SLE* (Fig. 155-1). In localized ACLE, confluent symmetric erythema and edema are centered over the malar eminences and bridges over the nose (unilateral involvement with ACLE has been described). The nasolabial folds are characteristically spared. The forehead, chin, and V area of the neck can be involved, and severe facial swelling may occur. Occasionally, ACLE begins as small macules and/or papules on the face that later may become confluent and hyperkeratotic. Generalized ACLE presents as a widespread morbilliform or exanthematous eruption often focused over the extensor aspects of the arms and hands and characteristically sparing the knuckles (Fig. 155-2A). Although perivascular nail fold erythema and telangiectasia can occur (see Fig. 155-2B), they are considerably more common and occur in more exaggerated forms in dermatomyositis (see Fig. 157-5). Generalized ACLE has been indiscriminately referred to as the *maculopapular rash of SLE*, *photosensitive lupus dermatitis*, and *SLE rash*. An extremely acute form of ACLE is rarely seen that can simulate toxic epidermal necrolysis (TEN). This form of LE-specific vesiculobullous disease results from widespread apoptosis of epidermal keratinocytes, and eventuates in areas of full-thickness epidermal skin necrosis, which is subsequently denuded. It can be differentiated between true TEN because it

Figure 155-2 Generalized acute cutaneous lupus erythematosus. **A.** Well-demarcated patches of erythema with fine overlying scale on the dorsal aspect of the hands, fingers, and periungual areas. Note the characteristic sparing of the knuckles, which are preferentially involved in dermatomyositis. **B.** Closeup view of periungual erythema and grossly visible telangiectasia. Although these lesions can be seen in lupus erythematosus, they are more typical of dermatomyositis.

Figure 155-3 Subacute cutaneous lupus erythematosus (SCLE). **A.** Annular SCLE on the upper back of a 38-year-old woman. Note the central areas of hypopigmentation in which no dermal atrophy is present. **B.** Papulosquamous SCLE over the extensor aspect of the forearm of a 26-year-old woman.

occurs on predominantly sun-exposed skin and has a more insidious onset.[30] The mucosa may or may not be involved, as in TEN.

ACLE is typically precipitated or exacerbated by exposure to UV light. This form of CLE can be quite ephemeral, lasting only hours, days, or weeks; however, some patients experience more prolonged periods of activity. Postinflammatory pigmentary change is most prominent in patients with heavily pigmented skin. Scarring does not occur in ACLE unless the process is complicated by secondary bacterial infection.

SUBACUTE CUTANEOUS LUPUS ERYTHEMATOSUS. A disease presentation dominated by SCLE lesions marks the presence of a distinct subset of LE having characteristic clinical, serologic, and genetic features. Although a finding of circulating autoantibodies to the Ro/SS-A ribonucleoprotein particle strongly supports a diagnosis of SCLE, the presence of this autoantibody specificity is not required to make a diagnosis of SCLE.

SCLE initially presents as erythematous macules and/or papules that evolve into hyperkeratotic papulosquamous or annular/polycyclic plaques (Fig. 155-3). Whereas most patients have either annular or papulosquamous SCLE, a few develop elements of both morphologic varieties. SCLE lesions are characteristically photosensitive and occur in predominantly sun-exposed areas (i.e., upper back, shoulders, extensor aspects of the arms, V area of the neck, and, less commonly, the face). SCLE lesions typically heal without scarring but can resolve with long-lasting, if not permanent, vitiligo-like leukoderma, and telangiectasias.

Several variants of SCLE have been described. On occasion, SCLE lesions present initially with an appearance of erythema multiforme. Such cases are similar to Rowell syndrome (erythema multiforme-like lesions occurring in patients with SLE in the presence of La/SS-B autoantibodies). As a result of intense injury to epidermal basal cells, the active edge of an annular SCLE lesion occasionally undergoes a vesiculobullous change that can subsequently produce a strikingly crusted appearance. Such lesions can mimic Stevens-Johnson syndrome/TEN. Pathogenesis is similar to that described above for TEN-like ACLE. Rarely, SCLE presents with exfoliative erythroderma or displays a curious acral distribution of annular lesions. Pityriasiform and exanthematous variants of SCLE have been reported. The skin lesions of neonatal LE (transient, photosensitive, nonscarring LE-specific skin lesions in neonates who have received IgG anti-Ro/SS-A, and, occasionally, other autoantibody specificities transplacentally) share many features with SCLE.

Unlike ACLE skin lesions, SCLE lesions tend to be less transient than ACLE lesions and heal with more pigmentary change. They are also less edematous and more hyperkeratotic than ACLE lesions. SCLE more commonly involves the neck, shoulders, upper extremities, and trunk, whereas ACLE more commonly affects the malar areas of the face. When the face is involved with SCLE, it is most often the lateral face, with sparing of the central, malar regions. In comparison to SCLE lesions, DLE lesions are generally associated with a greater degree of hyper- and hypopigmentation, atrophic dermal scarring, follicular plugging, and adherent scale. A consistent clinical difference is that DLE lesions are characteristically indurated, whereas SCLE lesions are not; this difference reflects the greater depth of inflammation seen histopathologically in DLE lesions.

Approximately one-half of patients with SCLE meet the ACR's revised criteria for the classification of SLE. However, manifestations of severe SLE, such as nephritis, central nervous system disease, and systemic vasculitis, develop in only 10%–15% of patients with SCLE. It has been suggested that the papulosquamous type of SCLE, leu-kopenia, high titer of antinuclear antibody (ANA) (>1:640), and anti-dsDNA antibodies are risk factors for the development of SLE in a patient presenting with SCLE lesions.

SCLE can overlap with other autoimmune diseases, including Sjögren's syndrome, rheumatoid arthritis, and Hashimoto's thyroiditis. Other disorders that have been anecdotally related to SCLE are Sweet syndrome, porphyria cutanea tarda, gluten-sensitive enteropathy, and Crohn's disease. There has also been the suggestion that SCLE can be associated with internal malignancy (breast, lung, gastric, uterine, hepatocellular, and laryngeal carcinomas as well as with Hodgkin lymphoma).[31]

CHRONIC CUTANEOUS LUPUS ERYTHEMATOSUS

Classic DLE. Classic DLE lesions, the most common form of CCLE, begin as red-purple macules, papules, or small plaques and rapidly develop a hyperkeratotic surface. Early classic DLE lesions typically evolve into sharply demarcated, coin-shaped (i.e., discoid) erythematous plaques covered by a prominent, adherent scale that extends into the orifices of dilated hair follicles (Fig. 155-4).

DLE lesions typically expand with erythema and hyperpigmentation at the periphery, leaving hallmark atrophic central scarring, telangiectasia, and hypopigmentation (Fig. 155-5). DLE lesions at this stage can merge to form large, confluent, disfiguring plaques. DLE in persons of certain ethnic backgrounds, such as Asian Indians, can present clinically as isolated areas of macular hyperpigmentation. When present on hair-bearing skin (scalp, eyelid margins, and eyebrows), DLE causes scarring alopecia, which can lead to disfigurement and markedly impact quality of life. Follicular involvement in DLE is a prominent feature. Keratotic plugs accumulate in dilated follicles that soon become devoid of hair. When the adherent scale is lifted from more advanced lesions, keratotic spikes similar in appearance to carpet tacks can be seen to project from the undersurface of the scale (i.e., the "carpet tack" sign). DLE lesions can be difficult to diagnose in Caucasian patients because the characteristic peripheral hyperpigmentation is often absent. Such lesions are often confused with actinic keratoses, squamous cell carcinoma, or acne.

DLE lesions are most frequently encountered on the face, scalp, ears, V area of the neck, and extensor aspects of the arms. Any area of the face, including the eyebrows, eyelids, nose, and lips, can be affected. A symmetric, hyperkeratotic, butterfly-shaped DLE plaque is occasionally found over the malar areas of the face and bridge of the nose. Such lesions should not be confused with the more transient, edematous, minimally scaling ACLE erythema reactions that occur in the same areas. Facial DLE, like ACLE and SCLE, usually spares the nasolabial folds. It may be difficult to distinguish early lesions of malar DLE from ACLE, but induration and recalcitrance to topical steroids/calcineurin inhibitors favors the former diagnosis. When DLE lesions occur periorally, they resolve with a striking acneiform pattern of pitted scarring. DLE characteristically affects the external ear, including the outer portion of the external auditory canal (Fig. 155-6A). Such lesions often present

Figure 155-4 Classic discoid lupus erythematosus. Typical early erythematous plaque on the forehead demonstrating hyperkeratosis and accentuation of follicle orifices in a 60-year-old man with a 25-year history of cutaneous lupus erythematosus. The lesion had been present for 3 months; no dermal atrophy was present at this stage.

Figure 155-5 Classic discoid lupus erythematosus. Sharply demarcated, round-to-ovoid slightly indurated, erythematous plaques on the neck and face. Most plaques show a mild degree of hyperkeratosis, and some show dermal atrophy. Noninflamed areas of hypopigmentation and scarring mark the sites of prior lesions that have resolved.

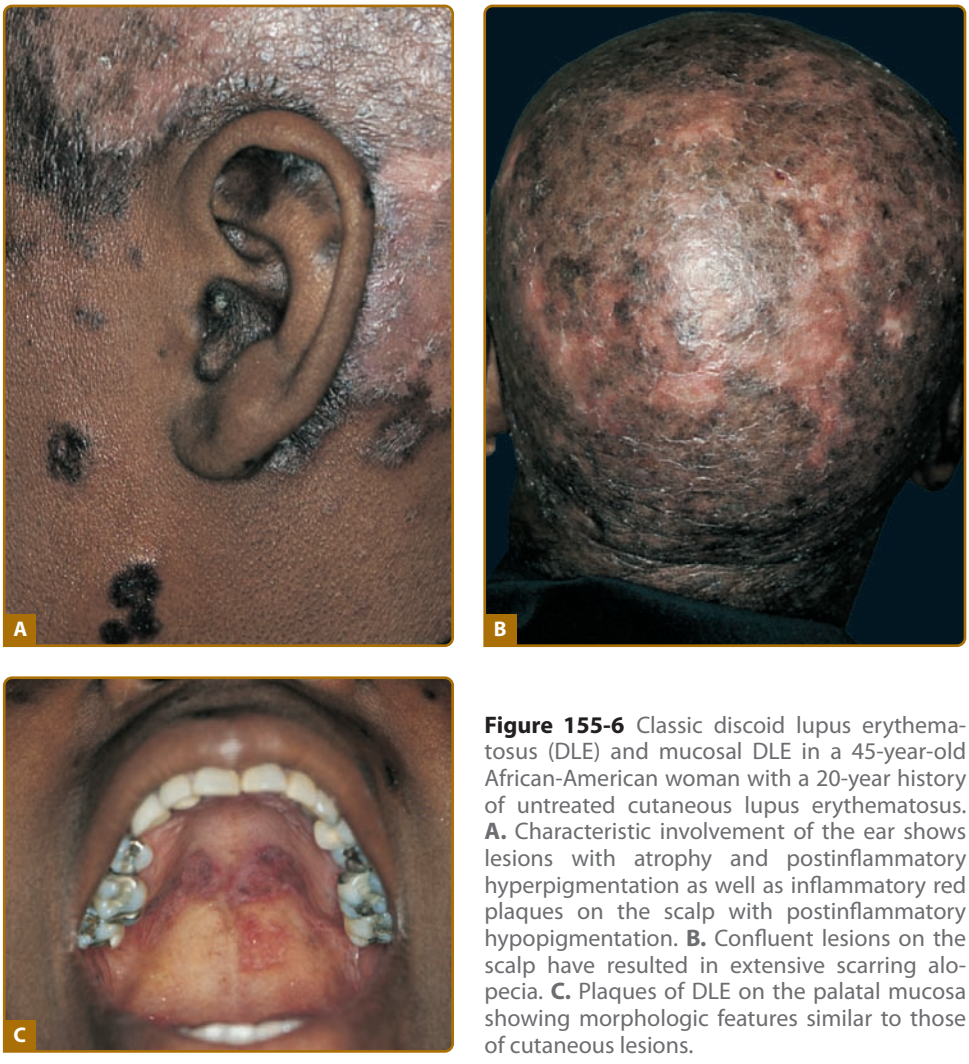

Figure 155-6 Classic discoid lupus erythematosus (DLE) and mucosal DLE in a 45-year-old African-American woman with a 20-year history of untreated cutaneous lupus erythematosus. **A.** Characteristic involvement of the ear shows lesions with atrophy and postinflammatory hyperpigmentation as well as inflammatory red plaques on the scalp with postinflammatory hypopigmentation. **B.** Confluent lesions on the scalp have resulted in extensive scarring alopecia. **C.** Plaques of DLE on the palatal mucosa showing morphologic features similar to those of cutaneous lesions.

initially as dilated, hyperpigmented follicles. The scalp is involved in 60% of patients with DLE; irreversible, scarring alopecia resulting from such involvement has been reported in one-third of patients (see Fig. 155-6B). The irreversible, scarring alopecia resulting from DLE differs from the reversible, nonscarring alopecia that patients with SLE often develop during periods of systemic disease activity. This type of hair loss, so-called *lupus hair*, may be telogen effluvium occurring as the result of flaring systemic disease.

Localized DLE lesions occur only on the head or neck, whereas *generalized DLE* lesions occur both above and below the neck. Generalized DLE is more commonly associated with underlying SLE and is often more recalcitrant to standard therapy, frequently requiring layering of antimalarial and immunosuppressive medications. DLE lesions below the neck most commonly occur on the extensor aspects of the arms, forearms, and hands, although they can occur at virtually any site on the body. The palms and soles can be the sites of painful, and at times disabling, erosive DLE lesions. On occasion, small DLE lesions occurring only around follicular orifices appear at the elbow and elsewhere (follicular DLE). We have observed that elbow/extensor arm lesions seem to cooccur with acral finger lesions of DLE, and that patients with this combination of findings more frequently have active systemic disease. DLE activity can localize to the nail unit. The nail can be impacted by other forms of CLE as well as SLE, producing nail fold erythema and telangiectasia, red lunulae, clubbing, paronychia, pitting, leukonychia striata, and onycholysis.

DLE lesions can be potentiated by sunlight exposure but to a lesser extent than ACLE and SCLE lesions. DLE, as well as other forms of LE skin disease activity, can be precipitated by any form of cutaneous trauma (i.e., the Koebner phenomenon or isomorphic effect).

The relationship between classic DLE and SLE has been the subject of much debate.[32] The following summary points can be made: (1) 5% of patients presenting with classic DLE lesions subsequently develop unequivocal evidence of SLE and (2) patients with generalized DLE (i.e., lesions both above and below the neck) have somewhat higher rates of immunologic abnormalities, a higher risk for progressing to SLE, and a higher risk for developing more severe manifestations of SLE than patients with localized DLE.

Roughly one-fourth of patients with SLE develop DLE lesions at some point in the course of their

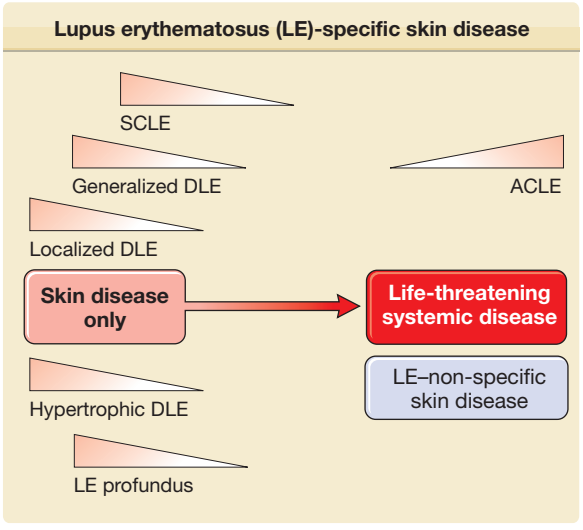

Figure 155-7 Relative risk for coexistence of or progression to systemic lupus erythematosus in patients presenting with various forms of lupus erythematosus (LE)-specific skin disease. The spectrum of LE is depicted as a disease continuum ranging from skin disease alone to life-threatening systemic disease. ACLE = acute cutaneous lupus erythematosus; DLE = discoid lupus erythematosus; SCLE = subacute cutaneous lupus erythematosus.

disease, and such patients tend to have less severe forms of SLE. Figure 155-7 illustrates the relative risks for systemic disease activity that are associated with the clinical varieties of LE-specific skin disease.

Aside from Classic DLE, there are several other less common variants of CCLE, which are subclasssified as such because of their overlapping histologies and tendency to occur in a low frequency in association with underlying SLE.

Hypertrophic DLE. Hypertrophic DLE, also referred to as *hyperkeratotic* or *verrucous DLE,* is a rare variant of CCLE in which the hyperkeratosis normally found in classic DLE lesions is greatly exaggerated. The extensor aspects of the arms, the upper back, and the face are the areas most frequently affected. Overlapping features of hypertrophic LE and lichen planus have been described under the rubric *lupus planus.* The entity *lupus erythematosus hypertrophicus et profundus* appears to represent a rare form of hypertrophic DLE, affecting the face with the additional features of violaceous/dull red, indurated, rolled borders and striking central, crateriform atrophy. The name for this clinical entity is ambiguous because LE panniculitis is not characteristic of its histopathology. Patients with hypertrophic DLE probably do not have a greater risk for developing SLE than do patients with classic DLE lesions.

Mucosal DLE. Mucosal DLE occurs in approximately 25% of patients with CCLE. The oral mucosa is most frequently affected; however, nasal, conjunctival, and genital mucosal surfaces can be targeted. In the mouth, the buccal mucosal surfaces are most commonly involved, with the palate (see Fig. 155-6C), alveolar processes, and tongue being sites of less frequent involvement. Lesions begin as painless, erythematous patches that evolve to chronic plaques that can be confused with lichen planus. Chronic buccal mucosal plaques are sharply marginated and have irregularly scalloped, white borders with radiating white striae and telangiectasia. The surfaces of these plaques overlying the palatal mucosa often have a honeycomb appearance. Central depression often occurs in older lesions, and painful ulceration can develop. Rarely, oral mucosal DLE lesions can degenerate into squamous cell carcinoma, similar to longstanding cutaneous DLE lesions. Any degree of nodular asymmetry within a mucosal DLE lesion should be evaluated for the possibility of malignant degeneration. Chronic DLE plaques also appear on the vermilion border of the lips. At times, DLE involvement of the lips can present as a diffuse cheilitis, especially on the more sun-exposed lower lip.

DLE lesions may present on the nasal, conjunctival, and anogenital mucosa. Perforation of the nasal septum is more often associated with SLE than DLE. Conjunctival DLE lesions affect the lower lid more often than the upper lid. Lesions begin as focal areas of nondescript inflammation most commonly affecting the palpebral conjunctivae or the lid margin. Scarring becomes evident as lesions mature, and the permanent loss of eyelashes and ectropion can develop, producing considerable disability.

LE Profundus/LE Panniculitis. LE profundus/LE panniculitis (Kaposi-Irgang disease) is a rare form of CCLE typified by inflammatory lesions in the lower dermis and subcutaneous tissue. Approximately 70% of patients with this type of CCLE also have typical DLE lesions, often overlying the panniculitis lesions. Some have used the term *LE profundus* to designate those patients who have both LE panniculitis and DLE lesions, and *LE panniculitis* to refer to those having only subcutaneous involvement. Typical subcutaneous lesions present as firm nodules, 1–3 cm in diameter. The overlying skin often becomes attached to the subcutaneous nodules and is drawn inward to produce deep, saucerized depressions (Fig. 155-8). The head,

Figure 155-8 Lupus erythematosus panniculitis. Lupus panniculitis has resulted in large, sunken areas of overlying skin; erythema and atrophy of the skin are present.

proximal upper arms, chest, back, breasts, buttocks, and thighs are the sites frequently affected. LE panniculitis, in the absence of overlying DLE, may produce breast nodules that can mimic carcinoma clinically and radiologically (lupus mastitis). Confluent facial involvement can simulate the appearance of lipoatrophy. Dystrophic calcification frequently occurs in older lesions of LE profundus/LE panniculitis, and pain associated with such calcification can, at times, be the dominant clinical problem. Roughly 50% of patients with LE profundus/panniculitis have evidence of SLE. However, the systemic features of patients with LE panniculitis/profundus tend to be less severe, similar to those of patients with SLE who have DLE skin lesions.

Chilblain LE. Chilblain LE lesions initially develop as purple-red patches, papules, and plaques on the toes, fingers, and face, which are precipitated by cold, damp climates and are clinically and histologically similar to idiopathic chilblains (pernio) (see Chapter 94). As they evolve, these lesions usually assume the appearance of scarred atrophic plaques with associated telangiectases. They may resemble old lesions of DLE or may mimic acral lesions of small vessel vasculitis. Histologic findings include a superficial and deep lymphocytic vascular reaction in addition to fibrin deposition in reticular, dermal-based blood vessels. Patients with chilblain LE often have typical DLE lesions on the face and head. It is possible that chilblain LE begins as a classic acral, cold-induced lesion that then koebnerizes DLE lesions, thus explaining the spectrum of clinico-histologic findings, which seem to vary based on when, in the course of the lesion, the biopsy sample is taken.

Chilblain LE appears to be associated with anti-Ro/SS-A antibodies,[33] and is linked to Raynaud's phenomenon in many cases.[34] Persistence of lesions beyond the cold months, a positive ANA, or presence of one of the other ACR criteria for SLE at the time of diagnosis of chilblain lesions helps to distinguish chilblain LE from idiopathic chilblains.[35] Approximately 20% of patients presenting with chilblain LE later develop SLE. Chilblain LE is an underrecognized entity, yet it is likely that it is one of the most common causes of digital lesions in patients with LE. It is sometimes misdiagnosed as vasculitis and may overlap with acral DLE as mentioned above. An autosomal dominant, familial form of Chilbalin LE has recently been described, and is caused by a missense mutation in the *TREX 1* (endonuclease repair) gene.[36]

Lupus Erythematosus Tumidus. Lupus erythematosus tumidus (LET; tumid LE) is a variant of CCLE in which the dermal findings of DLE, namely, excessive mucin deposition and superficial perivascular and periadnexal inflammation, are found on histologic evaluation. The characteristic epidermal histologic changes of LE-specific skin disease are only minimally expressed, if at all. This results in succulent, edematous, urticaria-like plaques with little surface change (Fig. 155-9). Annular urticaria-like plaques can also be seen. The paucity of epidermal change often produces confusion concerning the diagnosis of LET as a form of CCLE.[37,38]

Figure 155-9 Lupus erythematosus tumidus. Note succulent, indurated plaques.

There have been several recent reports that support this subclassification and further characterize this subtype of CCLE.[39–44] Although described to occur in some patients with SLE, most patients with LET have a negative ANA and a benign disease course. LET appears to be the most photosensitive subtype of cutaneous lupus, and typically demonstrates a good response to antimalarials. Additionaly, LET lesions tend to resolve completely without either scarring or atrophy.

There continues to be debate about the validity of LET as an authentic form of LE-skin disease. Some argue that LET lesions may in fact not be a form of CLE[45] while others feel that LET deserves to be recognized as a distinct type of CLE (intermittent cutaneous LE) equivalent in importance to acute cutaneous LE, subacute cutaneous LE, and chronic cutaneous LE.[46]

Other Variants. Other rare forms of chronic cutaneous LE have been described. These include LE hypertrophicus et profundus, lichenoid DLE, LE vermiculatus, LE telangiectaticus, linear CLE, and LE edematous (probably a historical designation for urticaria-like plaque DLE. Further information on these clinical entities has recently been presented.[47]

LABORATORY TESTS

eTable 155-3.1 in online edition summarizes the major laboratory findings associated with the varieties of LE-specific skin disease, and Table 155-5 presents the autoantibody associations of SLE. Because of the strong association between ACLE and SLE, the laboratory features of ACLE are those associated with SLE (high-titer ANA, anti-dsDNA, anti-Sm, and hypocomplementemia).

The laboratory markers for SCLE are the presence of anti-Ro/SS-A (70%–90%) and, less commonly, anti-La/SS-B (30%–50%) autoantibodies. ANA are present in 60%–80% of patients with SCLE, and rheumatoid factor is present in approximately one-third. Other autoantibodies in patients with SCLE include false-positive serologic tests for syphilis (VDRL rapid plasma reagin) (7%–33%), anticardiolipin (10%–16%),

antithyroid (18%–44%), anti-Sm (10%), anti-ds-DNA (10%), and anti-U1 ribonucleoprotein (10%). Patients with SCLE, particularly those with systemic involvement, may have a number of laboratory abnormalities, including anemia, leukopenia, thrombocytopenia, elevated erythrocyte sedimentation rate, hypergammaglobulinemia, proteinuria, hematuria, urine casts, elevated serum creatine and blood urea nitrogen, and depressed complement levels (resulting from genetic deficiency or increased complement consumption).

ANA are present in low titer in 30%–40% of patients with DLE; however, fewer than 5% have the higher ANA levels that are characteristic of patients with overt SLE (>1:320). Antibodies to single-stranded DNA are not uncommon in DLE, but antibodies to dsDNA are distinctly uncommon. Precipitating antibodies to U1RNP are sometimes found in patients whose disease course is dominated by DLE lesions; however, such patients usually have only mild manifestations of SLE or overlapping connective tissue disorders such as mixed connective tissue disease. Precipitating Ro/SS-A and La/SS-B autoantibodies are rare in patients with DLE; low levels of anti-Ro/SS-A antibody detected by enzyme-linked immunoassay are more common. A small percentage of patients with DLE have low-grade anemia, biologic false-positive serologic tests for syphilis (VDRL rapid plasma reagent), positive rheumatoid factor tests, slight depressions in serum complement levels, modest elevations in γ globulin, and modest leukopenia. It has been suggested that such findings

are risk factors for the development of SLE. ANA are present in 70%–75% of patients with LE profundus/panniculitis, but anti-dsDNA antibodies are rare.

The laboratory findings associated with SLE, as well as with CLE, in both adults and newborns, have been reviewed.[71,72]

HISTOPATHOLOGY

The LE-specific skin disease histopathology is a distinctive constellation of hyperkeratosis, epidermal atrophy, vacuolar basal cell degeneration, dermal-epidermal junction basement membrane thickening, dermal edema, dermal mucin deposition, and mononuclear cell infiltration of the dermal-epidermal junction and dermis, focused in a perivascular and periappendageal distribution (eFig. 155-9.1 in online edition). Variable degrees of these features are encountered in the different forms of LE-specific skin disease (see Chapter 6). Differences of opinion exist as to whether ACLE, SCLE, and DLE lesions can be distinguished reliably on the basis of their histopathologic appearances alone.[72–74]

ACUTE CUTANEOUS LUPUS ERYTHEMATOSUS

The histopathologic changes in ACLE lesions are generally less impressive than those in SCLE and DLE lesions, and are mainly those of a cell-poor interface dermatitis. The lymphohistiocytic cellular infiltrate is relatively sparse. Some authors have noted an increase in the number of neutrophils in the infiltrate. A mild degree of focal vacuolar alteration of basal keratinocytes can be seen, in addition to telangiectases and extravasation of erythrocytes. One may see individually necrotic keratinocytes, and in its most severe form, ACLE can display extensive epidermal necrosis similar to TEN. The upper dermis usually shows pronounced mucinosis and may be very helpful in distinguishing ACLE from other causes of a cell-poor interface dermatitis. It is uncommon to see basement membrane zone thickening, follicular plugging, or alteration of epidermal thickness in ACLE, although epidermal atrophy is sometimes present.[73,74]

SUBACUTE CUTANEOUS LUPUS ERYTHEMATOSUS

SCLE also frequently presents as an interface dermatitis, with foci of vacuolar alteration of basal keratinocytes alternating with areas of lichenoid dermatitis. Pronounced epidermal atrophy is often present. SCLE is in the differential diagnosis of atrophic lichenoid dermatitis, along with atrophic lichen planus and lichenoid drug eruptions. Dermal changes include edema, prominent mucin deposition, and sparse mononuclear cell infiltration usually limited to areas around blood vessels and periadnexal structures in the upper one-third of the dermis. Lesser degrees of hyperkeratosis, follicular plugging, mononuclear cell infiltration of adnexal structures, and dermal melanophages might help distinguish SCLE lesions from DLE lesions. It has not been possible to differentiate papulosquamous from annular SCLE by histopathologic criteria alone.[72]

CHRONIC CUTANEOUS LUPUS ERYTHEMATOSUS

In classic DLE lesions, epidermal changes include hyperkeratosis, variable atrophy, and interface changes similar to those described for SCLE. The epidermal basement membrane is markedly thickened. Dermal changes include a dense mononuclear cell infiltrate composed primarily of CD4 T lymphocytes and macrophages predominantly in the periappendageal and perivascular areas, melanophages, and dermal mucin deposition. The infiltrate is often quite dense and typically extends well into the deeper reticular dermis and/or subcutis, which may help to distinguish it from ACLE or SCLE. In chronic scarring DLE lesions, the dense inflammatory cell infiltrate subsides and is replaced by dermal fibroplasia. A folliculotropic variant of DLE, in which the inflammatory infiltrate is predominantly around hair follicles, has been described, as have lymphomatoid variants, in which there are extremely dense infiltrates that may contain atypical lymphoid cells.[73]

IMMUNOHISTOLOGY

Immunohistology is often helpful in confirming a diagnosis of LE-specific skin disease and has been shown to boost the sensitivity and specificity of diagnosis.[73] Because it is not uncommon to see negative immunofluorescence studies in patients with acute, subacute, and chronic LE, and false-positive studies in healthy individuals, immunohistology must be interpreted in the context of clinical and histologic findings in a given patient.

IgG, IgA, IgM, and complement components (C3, C4, Clq, properdin, factor B, and the membrane attack complex C5b-C9) deposited in a continuous granular or linear band-like array at the dermal-epidermal junction have been observed in the lesional and nonlesional skin of patients with LE since the early 1960s (Fig. 155-10). However, debate about terminology in this area continues to cloud the field. Some restrict the use of the term *lupus band test* to refer to the examination of nonlesional skin biopsies for the presence of this band-like array of immunoreactants at the dermal-epidermal junction. Others qualify the LBT as being either "lesional" or "nonlesional." Less confusion might exist if the terms *lesional LBT* (lesional lupus band) and *nonlesional LBT* (nonlesional lupus band) were uniformly adopted.

ACUTE CUTANEOUS LUPUS ERYTHEMATOSUS

The sparse data that exist suggest that 60%–100% of ACLE lesions display a lesional lupus band. However,

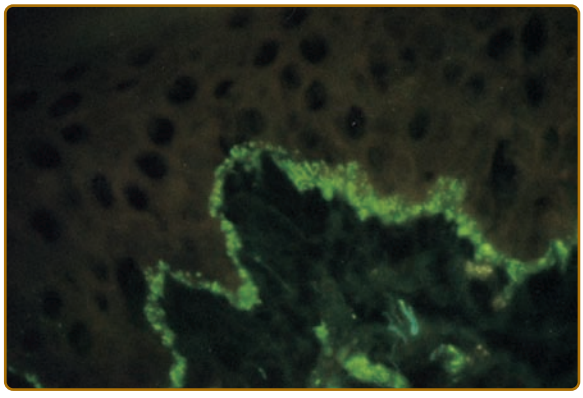

Figure 155-10 Immunopathology of lupus erythematosus-specific skin disease. Direct immunofluorescence examination of a discoid lupus erythematosus lesional skin biopsy showing a continuous band of granular fluorescence at the dermal-epidermal junction as a result of staining with fluorescein isothiocyanate-conjugated goat anti-immunoglobulin G.

the realization that sun-damaged skin from otherwise healthy individuals can display similar immunopathology has diluted the clinical value of this finding.

SUBACUTE CUTANEOUS LUPUS ERYTHEMATOSUS

Initial studies indicated that approximately 60% of patients with SCLE had lesional lupus bands. A "dust-like particle" pattern of IgG deposition focused around epidermal basal keratinocytes has been suggested to be more specific for SCLE by reflecting the presence of *in vivo* bound Ro/SS-A autoantibody.

CHRONIC CUTANEOUS LUPUS ERYTHEMATOSUS

Early reports suggested that more than 90% of classic DLE lesions had lesional immunoreactants at the dermal-epidermal junction, often extending along the basement membrane of the hair follicle, but subsequent studies report somewhat lower rates. Lesions on the head, neck, and arms are positive more frequently (80%) than those on the trunk (20%). The lesional lupus band also appears to be a function of the age of the lesion being examined, with older lesions (>3 months) being positive more often than younger ones. Ultrastructural localization of immunoglobulin at the dermal-epidermal junction confirms that these proteins are deposited on the upper dermal collagen fibers and along the lamina densa of the epidermal basement membrane zone.

In LE profundus, immunoglobulin and complement deposits are usually found in blood vessel walls of the deep dermis and subcutis. Immunoglobulin deposits at the dermal-epidermal junction may or may not be present, depending on the site biopsied, the presence or absence of accompanying SLE, and the presence or absence of overlying changes of DLE at the dermal-epidermal junction.

NONLESIONAL LUPUS BAND TEST

There has been much debate over the past three decades regarding the diagnostic and prognostic significance of an immunoglobulin/complement band at the dermal-epidermal junction of nonlesional skin taken from patients with LE.[72] When totally sun-protected nonlesional skin (e.g., buttocks) is sampled, the diagnostic specificity for SLE appears to be very high when three or more immunoreactants are present at the dermal-epidermal junction. Prospectively ascertained follow-up data also suggest that the presence of a nonlesional LBT correlates positively with risk for developing LE nephritis. However, the nonlesional LBT has fallen out of favor as a clinical tool largely because the information gained has not been proven to be of significantly greater value than the results of more readily available serologic assays such as antibody to dsDNA.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of CLE is outlined in Box 155-1 and eBox 155-1.1 in online edition. In addition, reticulated erythematosus mucinosis (REM) has been suggested by some to be a form of photosensitive cutaneous LE perhaps related to LE tumidus. REM presents as a reticulated array of macules and/or papules on the upper chest and back.

PROGNOSIS AND CLINICAL COURSE

ACUTE CUTANEOUS LUPUS ERYTHEMATOSUS

Both localized and generalized forms of ACLE lesions flare and abate in parallel with underlying SLE disease activity. Therefore, the prognosis for any given patient with ACLE is dictated by the pattern of the underlying SLE. Both 5-year (80%–95%) and 10-year (70%–90%) survival rates for SLE have progressively improved over the past four decades as a result of earlier diagnosis made possible by more sensitive laboratory testing and improved immunosuppressive treatment regimens. Ominous prognostic signs in SLE are hypertension, nephritis, systemic vasculitis, and central nervous system disease.

SUBACUTE CUTANEOUS LUPUS ERYTHEMATOSUS

Because SCLE has been recognized as a separate disease entity for only two decades, the long-term outcome associated with SCLE lesions has yet to be determined. It is the authors' experience that most patients with SCLE have intermittent recurrences

of skin disease activity over long periods of time without significant progression of systemic involvement (we are aware of only one death directly attributable to SLE in approximately 150 patients with SCLE). Other patients enjoy long-term if not permanent remissions of their skin disease activity. A few patients have experienced unremitting cutaneous disease activity.

It has also been the authors' experience that approximately 15% of the patients with SCLE develop active SLE, including lupus nephritis. This subgroup of patients is marked by the presence of papulosquamous SCLE, localized ACLE, high-titer ANA, leukopenia, and/or antibodies to dsDNA. Long-term follow-up studies of SCLE are required to determine the true risk of severe systemic disease progression in patients presenting with SCLE skin lesions. CCLE lesions, typically classic DLE, have also arisen in patients initially presenting with SCLE.

Evidence suggests that overlap occurs between SCLE and Sjögren's syndrome. Patients with SCLE who develop Sjögren's syndrome are at risk for developing the extraglandular systemic complications associated with Sjögren's syndrome, including vasculitis, peripheral neuropathy, autoimmune thyroiditis, renal tubular acidosis, myositis, chronic hepatitis, primary biliary cirrhosis, psychosis, lymphadenopathy, splenomegaly, and B-cell lymphoma.

CHRONIC CUTANEOUS LUPUS ERYTHEMATOSUS

Most patients with untreated classic DLE lesions suffer indolent progression to large areas of cutaneous dystrophy and scarring alopecia that can be psychosocially devastating and occupationally disabling. However, with treatment, skin disease can be largely controlled. Spontaneous remission occurs occasionally, and the disease activity can recrudesce at the sites of older, inactive lesions. Rebound after discontinuation of treatment is typical, and slower taper of medications during periods of inactivity is recommended. Squamous cell carcinoma occasionally develops in chronic smoldering DLE lesions.

Death from SLE is distinctly uncommon in patients who present initially with localized DLE. As discussed in Section "Epidemiology," patients presenting with localized DLE have only a 5% chance of subsequently developing clinically significant SLE disease activity. Generalized DLE and persistent, low-grade laboratory abnormalities appear to be risk factors for such disease progression. Unrecognized squamous-cell carcinoma developing within a longstanding DLE skin lesion could be a cause of morbidity and mortality.

OUTCOMES MEASURES

The recent development of a validated instrument to measure activity of CLE, the Cutaneous Lupus Erythematosus Area and Severity Index (CLASI), has made it possible to objectively follow patients' disease course and response to therapy. The instrument has separate scores for damage (scarring) and activity which is important, because one would not expect a "burned-out" scarred area to normalize with drugs that were meant to abate LE activity.[76] It has been validated as a useful tool to measure clinical response.[77]

TREATMENT

The initial management of patients with any form of CLE should include an evaluation to rule out underlying SLE disease activity at the time of diagnosis. All patients with CLE should receive instruction about protection from sunlight and artificial sources of UVR and should be advised to avoid the use of potentially photosensitizing drugs such as hydrochlorothiazide, tetracycline, griseofulvin, and piroxicam. With regard to specific medical therapy, local measures should be maximized and systemic agents used if significant local disease activity persists or systemic activity is superimposed.

ACLE lesions usually respond to the systemic immunosuppressive measures required to treat the underlying SLE disease activity that so frequently accompanies this form of CLE (e.g., systemic glucocorticoids, azathioprine, and cyclophosphamide). Increasing evidence suggests that aminoquinoline antimalarial agents such as hydroxychloroquine can have a steroid-sparing effect on SLE, and these drugs can be of value in ACLE. The local measures discussed in Local Therapy below can also be of value in treating ACLE. Because the lesions of SCLE and CCLE are often found in patients who have little or no evidence of underlying systemic disease activity, unlike the lesions of ACLE, nonimmunosuppressive treatment modalities are preferred for SCLE and CCLE (Table 155-6). For the most part, SCLE and CCLE lesions respond equally to such agents.

LOCAL THERAPY

SUN PROTECTION. Advise patients to avoid direct sun exposure, wear tightly woven clothing and broad-brimmed hats, and regularly use broad-spectrum, water-resistant sunscreens [SPF ≥30 with an efficient UVA blocking agent such as a photostabilized form of avobenzone (Parsol 1789), micronized titanium dioxide, micronized zinc oxide, or Mexoryl SX]. UV-blocking films should be applied to home and automobile windows, and acrylic diffusion shields should be placed over fluorescent lighting. Corrective camouflage cosmetics such as Dermablend® and Covermark® offer the dual benefit of being highly effective physical sunscreens as well as aesthetically pleasing cosmetic masking agents. An in-depth discussion of practical and theoretical photoprotection and local therapy for autoimmune connective tissue skin disease has been discussed in detail (see Chapter 223).[78]

LOCAL GLUCOCORTICOIDS. Although some prefer intermediate-strength preparations, such as triamcinolone acetonide 0.1%, for sensitive areas such as the face, superpotent topical class I agents, such as clobetasol propionate 0.05% or betamethasone dipropionate 0.05%, produce the greatest benefit in CLE. Twice-daily application of the superpotent preparations to lesional skin for 2 weeks followed by a 2-week rest period can minimize the risk of local complications such as steroid atrophy and telangiectasia. Alternatively, a topical calcineurin inhibitor can be used daily during the 2-week rest period from topical corticosteroids. Ointments are more effective than creams for more hyperkeratotic lesions such as hypertrophic DLE. Occlusive therapy with glucocorticoid-impregnated tape (e.g., flurandrenolide) or glucocorticoids with plastic food wrap (e.g., Saran or Glad Press-N-Seal) can potentiate the beneficial effects of topical glucocorticoids but also carries a higher risk of local side effects. Class I or class II topical glucocorticoid solutions and gels are best for treating the scalp. Unfortunately, even the most aggressive regimen of topical glucocorticoids by itself does not provide adequate improvement for most patients with SCLE and CCLE.

TOPICAL CALCINEURIN INHIBITORS. Pimecrolimus 1% cream and tacrolimus 0.1% ointment have demonstrated efficacy in the treatment of ACLE, DLE, and SCLE.[79–81] A double blind, placebo controlled pilot study showed that pimecrolimus 1% cream had equal efficacy with betamethasone valerate 0.1% cream in treating facial DLE,[82] and a different study demonstrated

TABLE 155-6
Therapeutic Options for Lupus Erythematosus-Specific Skin Disease

	Drug	Dose
First line	Topical glucocorticoids Topical calcineurin inhibitor Intralesional triamcinolone acetonide	Class I steroid qd–bid for 2 weeks alternating with pimecrolimus 1% or tacrolimus 0.1% bid for 2 weeks; 2.5–10.0 mg/cc
Second line (low threshold for use if scarring, widespread lesions, systemic symptoms)	Hydroxychloroquine Chloroquine Quinacrine (if monotherapy fails, add quinacrine to either hydroxychloroquine or chloroquine)	6.5 mg/kg/day ideal body weight 3.0–3.5 mg/kg/day ideal body weight 100 mg daily (available at compounding pharmacies)
Short courses only (2–16 weeks) (must have patient on concomitant alternative agent to prevent rebound on discontinuation)	Prednisone Thalidomide	5–60 mg/day 50 mg qd–200 mg/day; taper to 50 mg qod on response
Third line (safer immunosuppressives)	Azathioprine Mycophenolate mofetil Methotrexate	1.5–2.5 mg/kg/day PO 2.5–3.5 g/day PO 7.5–25 mg PO or SQ/wk
Worth consideration	Dapsone Accutane Acitretin Gold	50–200 mg/day 0.5–2 mg/kg/day 10–50 mg/day Work up to 50 mg weekly, taper after 1 g
Fourth line (limited by side effects)	Cyclophosphamide Clofazimine	1.5–2.0 PO mg/kg/day
Investigational (some currently available)	Efalizumab (Raptiva) Leflunomide (Arava) Antitumor necrosis factor agents Rituximab (Rituxan) Abatacept Epratuzumab Anti-interferon-α agents	

the efficacy of topical tacrolimus 0.3% compound in clobetasol propionate 0.05% for recalcitrant CLE.[83]

INTRALESIONAL GLUCOCORTICOIDS. Intralesional glucocorticoids (e.g., triamcinolone acetonide suspension, 2.5–5.0 mg/mL for the face with higher concentrations allowable in less sensitive sites) are more useful in the management of DLE than SCLE. Intralesional glucocorticoids themselves can produce cutaneous and subcutaneous atrophy (deep injections into the subcutaneous tissue enhances this risk). A 30-gauge needle is preferred because it produces only mild discomfort on penetration, especially when injected perpendicularly to the skin. The active borders of lesions should be thoroughly infiltrated. Intralesional therapy is indicated for particularly hyperkeratotic lesions or lesions that are unresponsive to topical glucocorticoids, but most patients with CLE have too many lesions to be managed exclusively by intralesional glucocorticoid injections.

SYSTEMIC THERAPY

ANTIMALARIALS. One or a combination of the aminoquinoline antimalarials can be effective for approximately 75% of patients with CLE who have failed to benefit adequately from the local measures described in Section "Local Therapy."[84] The risks of retinal toxicity should be discussed with the patient, and a pretreatment ophthalmologic examination should be performed. However, the risk of antimalarial retinopathy is extremely rare, particularly in the first 10 years of therapy, if recommended daily dose maximum levels of these agents are not exceeded (hydroxychloroquine, 6.5 mg/kg/day based on ideal body weight; chloroquine, 3 mg/kg/day). Patients should have follow-up ophthalmologic evaluations every 6–12 months while on therapy.

Hydroxychloroquine sulfate (Plaquenil), 6–6.5 mg/kg, should be given daily, either once daily or in two divided doses to prevent GI side effects. Patients should be informed about 2–3 month delayed onset of therapeutic benefit. If no response is seen after 8–12 weeks, quinacrine hydrochloride, 100 mg/day (currently available in the United States only through compounding pharmacies), can be added to the hydroxychloroquine without enhancing the risk of retinopathy (quinacrine does not cause retinopathy). If, after 4–6 weeks, adequate clinical control has not been achieved, consideration should be given to replacing the hydroxychloroquine with chloroquine diphosphate (Aralen), 3 mg/kg to prevent retinopathy. Doses may need to be adjusted for patients with decreased renal or hepatic function. In Europe, chloroquine is generally felt to be more efficacious than hydroxychloroquine in treating CLE, perhaps due to the earlier therapeutic

responses that might occur as a result of the shorter time period required to reach steady state blood levels with chloroquine as compared to hydroxychloroquine. Hydroxychloroquine and chloroquine should not be used simultaneously because of enhanced risk for retinal toxicity. There is some evidence that chloroquine may be more retinotoxic than hydroxychloroquine.

Multiple side effects other than retinal toxicity are associated with the use of antimalarials. Quinacrine is associated with a higher incidence of side effects, such as headache, gastrointestinal intolerance, hematologic toxicity, pruritus, lichenoid drug eruptions, and mucosal or cutaneous pigmentary deposition, than is either hydroxychloroquine or chloroquine. Quinacrine commonly produces a yellow discoloration of the entire skin and sclera in fair-skinned individuals, which is completely reversible when the drug is discontinued. Quinacrine can produce significant hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency (this adverse effect has also been reported to occur rarely with hydroxychloroquine and chloroquine). Each of the aminoquinoline antimalarials can produce bone marrow suppression, including aplastic anemia, although this effect is exceedingly rare with the current dosage regimens. Toxic psychosis, grand mal seizures, neuromyopathy, and cardiac arrhythmias occurred with the use of high doses of these drugs in the past; these reactions are uncommon with the lower daily dose regimens used today.

Before therapy with hydroxychloroquine and chloroquine is begun, complete blood cell counts, as well as liver and renal function tests, should be performed; these tests should be repeated 4–6 weeks after therapy has been initiated, and every 4–6 months thereafter. A screen for hematologic toxicity when quinacrine is used is recommended more often. Patients with overt or subclinical porphyria cutanea tarda are at particularly high risk for developing acute hepatotoxicity, which often simulates an acute surgical abdomen, when treated with therapeutic doses of antimalarials for CLE. It is also recommended to check urine levels of β-human chorionic gonadotropin initially in women with childbearing potential, although recent evidence indicates that the risk to pregnant women of currently recommended dose regimens of antimalarials is minimal.

NONIMMUNOSUPPRESSIVE OPTIONS FOR ANTIMALARIAL-REFRACTORY DISEASE.

Some patients with refractory CLE (SCLE more than DLE) respond to diaminodiphenylsulfone (dapsone).[85] An initial dose of 25 mg by mouth twice daily can be increased up to 200–400 mg/day, if necessary. Significant dose-related hemolysis and/or methemoglobinemia can result from the use of dapsone, especially in individuals deficient in glucose-6-phosphate dehydrogenase activity, and, therefore, complete blood counts and liver function tests should be performed regularly. Isotretinoin, 0.5–2.0 mg/kg/day, and acitretin, 10–50 mg/day, have also been used in this setting, but their efficacy is limited by their side effects (teratogenicity, mucocutaneous dryness, and hyperlipidemia). In addition, breakthrough of CLE activity has been a problem with the long-term use of retinoids.

Thalidomide (see Chapter 235) (50–200 mg/day) is strikingly effective for CLE that is refractory to other medications. Numerous studies have cited response rates between 85% and 100%, with many patients experiencing complete remission.[86] However, strict prescribing regulations put in place in the United States in 1998 because of severe teratogenicity, make thalidomide challenging to dispense to women of childbearing potential. Sensory neuropathy is another toxicity associated with thalidomide, and 25%–75% of patients with CLE develop peripheral neuropathy while taking the drug. Most cases are reversible when therapy is stopped. Neuropathy seems to correlate with total treatment times so that short courses are preferred. Relapses after the drug is stopped are common. Excess somnolence as well as constipation and other minor side effects sometimes limit its use, although these effects usually abate with lower daily doses.[87] Thromboembolism is a serious adverse event that may occur in patients with a preexisting hypercoagulable state (e.g., presence of antiphospholipid antibodies). Oncologists who use thalidomide for multiple myeloma frequently initiate concomitant anticoagulation therapy to prevent this side effect. Lenalidomide (Revlamid, Celgene) is a thalidomide analog that is more efficacious but has similar rates of teratogenicity, peripheral neuropathy, thromboembolism, and also has the additional potential side effect of profound leukopenia.[88]

Other drugs reported to be of value in the treatment of refractory CLE are gold and clofazimine; however, the benefit varies from case to case and both of these agents are associated with the risk of significant side effects. Vitamin E, phenytoin, sulfasalazine, danazol, DHEA, and phototherapy (UVAI phototherapy, photopheresis) have also been reported in uncontrolled trials to be of value in CLE.

SYSTEMIC GLUCOCORTICOIDS.

Every effort should be made to avoid the use of systemic glucocorticoids in patients with LE limited to the skin. However, in occasional patients who have especially severe and symptomatic skin disease, intravenous pulse methylprednisolone has been used. In less acute cases, moderate daily doses of oral glucocorticoids (prednisone, 20–40 mg/day, given as a single morning dose) can be used as supplemental therapy during the loading phase of therapy with an antimalarial agent. The dose should be reduced at the earliest possible time because of the complications of long-term glucocorticoid therapy, especially avascular (aseptic) bone necrosis, a side effect to which patients with LE are particularly susceptible.

Because steroid-induced bone loss occurs most rapidly in the first 6 months of use, all patients who do not have contraindications should begin agents to prevent osteoporosis with the initiation of steroid therapy. An excellent review describing current recommendations for prevention of bone loss and other side effects of systemic glucocorticoids has been published.[89] When the disease activity is controlled, the daily dosage should be reduced by 5- to 10-mg decrements until activity flares again or until a daily dosage of 20 mg/day is achieved. The daily dose should then be lowered by 2.5-mg decrements (some physicians prefer to use 1-mg

dose decrements below 10 mg/day). Alternate-day glucocorticoid therapy has not been successful in suppressing disease activity in most patients with CLE or SLE. Prednisolone rather than prednisone should be used in patients who have significant underlying liver disease, because prednisone requires hydroxylation in the liver to become biologically active. Any amount of prednisone given as a single oral dose in the morning has less adrenal-suppressing activity than the same amount given in divided doses throughout the day. However, any given amount of this drug, taken in divided doses, has a greater LE-suppressing activity than does the same amount of drug given as a single morning dose.

PREVENTION

Predicting and preventing the initial clinical manifestation of LE, whether it is skin disease or systemic, is not feasible at this time. However, as many LE patients exhibit worsening of their skin disease activity with UV light exposure, physical protection from sunlight and artificial sources of UV light as well as the regular use of broad-spectrum sunscreens having a SPF of 30 or greater should be encouraged.

Chapter 156 :: Dermatomyositis

:: Richard D. Sontheimer, Christopher B. Hansen & Melissa I. Costner

DERMATOMYOSITIS AT A GLANCE

- Dermatomyositis (DM) is thought to evolve through multiple sequential phases: (1) a genetically determined susceptibility phase, (2) an induction phase triggered by an environmental stimulus (e.g., ultraviolet light, infection) involving loss of tolerance to self-antigens in skin and skeletal muscle, (3) an autoimmune expansion phase, and (4) an injury phase involving multiple immunologic effector mechanisms.
- All clinical types of the idiopathic inflammatory dermatomyositis are rare orphan diseases.
- Some clinical subphenotypes of DM such as clinically amyopathic DM have been underdiagnosed in the past, often being confused with isolated forms of cutaneous lupus erythematosus.
- Clinical features are a function of age of onset (e.g., juvenile-onset classic DM: vasculopathy, dystrophic calcification; adult-onset classic DM: associated occult malignancy, interstitial lung disease).
- The sine qua non of DM is a hallmark constellation of inflammatory skin changes presenting as patchy or confluent, macular, violaceous erythema that assumes a highly characteristic anatomic distribution and is often photoaccentuated. With time, additional diagnostic skin changes appear, including Gottron papules, prominent periungual nail fold microvascular changes, and poikiloderma atrophicans vasculare.
- Joint disease (arthritis/arthralgia), pulmonary disease (interstitial lung disease, aspiration pneumonia), esophageal disease (dysphagia), vasculopathic injury of multiple organ systems (gastrointestinal system, central nervous system, eye), and cardiac disease (conduction defects, cardiomyopathy) may be related features.
- Pathologic features include the following: in skin—a cell-poor interface dermatitis with dermal mucin accumulation; in muscles—a characteristic pattern of myositis.

The idiopathic inflammatory myopathies (IIDMs) are a heterogeneous group of genetically determined autoimmune disorders that predominately target the skeletal musculature and/or skin and typically result in symptomatic skeletal muscle weakness and/or cutaneous inflammatory disease. Some physicians continue to refer to this group of clinical disorders by an earlier designation, idiopathic inflammatory myopathies. Among the IIDM, dermatomyositis (DM) is of special interest to the dermatologist due the universal presence of a hallmark pattern of cutaneous inflammation. DM is the only idiopathic inflammatory myopathy (IIM) that expresses a characteristic pattern of primary cutaneous inflammation.

In this chapter, the term *classic DM* is used to refer to DM as traditionally defined (i.e., the concurrence of myositis resulting in clinically significant proximal muscle weakness and a set of hallmark inflammatory skin lesions occurring in a specific anatomical distribution). Also of interest to the dermatologist is the subgroup of patients who express the hallmark cutaneous manifestations of DM for prolonged periods (6 months or longer) without developing clinically evident muscle weakness. This pattern of DM expression is referred to as *clinically amyopathic DM* (CADM); this term is synonymous with the historical designation, *dermatomyositis sine myositis*.

On occasion, other organ systems, such as the lungs (interstitial lung disease), joints (arthritis), and heart (cardiomyopathy, conduction defects), are targeted by inflammatory injury in IIM patients. In addition, differences exist between classic DM presenting in adults and that presenting in children. For example, juvenile-onset classic DM is associated with higher rates of vasculopathy/vasculitis resulting in the complication of dystrophic calcification, whereas adult-onset classic DM is associated with a significantly increased risk of internal malignancy and interstitial lung disease.

The diagnostic criteria for DM under the current consensus IIM classification system have not allowed for the inclusion of cutaneous-only or cutaneous-predominant subsets of DM, such as amyopathic DM and hypomyopathic DM, which together are referred to here as CADM (see eTable 156-0.1 in online edition). A more inclusive disease category designation, "idiopathic inflammatory dermatomyositis, " has been proposed by one of the authors (Richard D. Sontheimer) as an alternative to the "IIM" designation because it allows for the inclusion of these cutaneous subsets of DM[1–16] (eTable 156-0.2 in online edition). Other rheumatologic disorders such as lupus erythematous (LE) and scleroderma are broadly recognized to include skin-only subsets (e.g., discoid LE, morphea). However, the group designation "idiopathic inflammatory dermatomyopathies" has yet to be broadly embraced.

Thus, IIDM represents a heterogeneous group of clinical disorders that can be conveniently conceptualized as a continuum of illness with subgroups of patients who share common clinical and immunologic features at distinct positions along this spectrum (Fig. 156-1).

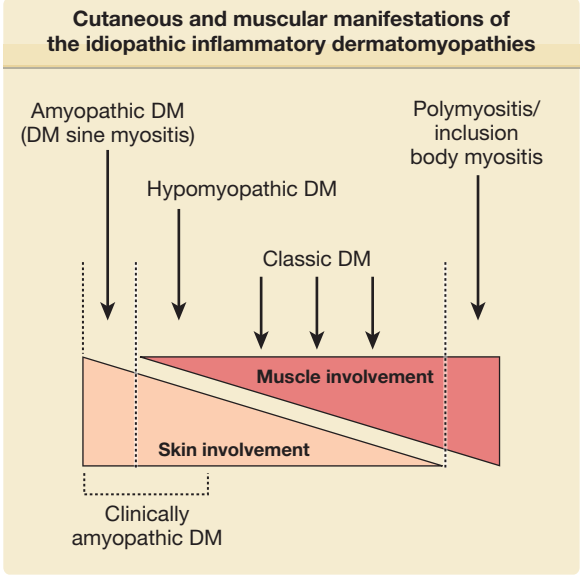

Figure 156-1 Graphic representation of the relationships between the cutaneous and muscular manifestations of the idiopathic inflammatory dermatomyositis, including the nosologic entities within this spectrum of illness. DM = dermatomyositis.

EPIDEMIOLOGY

CLASSIC DERMATOMYOSITIS

Cutaneous involvement occurs in 30% to 40% of adults and in 95% of children with IIDM. By definition, skin disease is absent in patients with PM and present in 100% of patients with classic DM and CADM. Skin disease activity can precede muscle disease activity in classic DM by weeks to several months.

Classic DM can occur from infancy to adulthood and most frequently presents in the fifth and sixth decades (PM is extremely rare in children). The incidence of classic IIDM between 1963 and 1982 was estimated to be 5.5 cases per million. The incidence probably is higher, inasmuch as this study[17] was based only on hospital inpatient-ascertained diagnoses and did not include cases of CADM. Familial concordance occurs rarely, and concordant disease expression has been reported in identical twins.

The epidemiology of juvenile-onset classic DM in the United States has been reviewed.[18] For children 2–17 years of age, the estimated annual incidence rates from 1995 to 1998 in the United States ranged from 2.5 to 4.1 cases per million children, and the 4-year average annual rate was 3.2 per million children. Estimated annual incidence rates by race were 3.4 for white non-Hispanics, 3.3 for African American non-Hispanics, and 2.7 for Hispanics. Girls were affected more than boys (ratio of 2.3:1). Cutaneous ulceration occurring as a result of infarctive vasculopathy and subsequent calcification is more common in the childhood form of the disease.

Environmental factors have been implicated as disease triggers. Seasonality has been noted in both juvenile-onset and adult-onset DM, which suggests the possibility of an infectious etiology. DM- and PM-like syndromes have been reported in patients infected with coxsackievirus, parvovirus B19, Epstein–Barr virus, human immunodeficiency virus, and human T-cell leukemia virus type 1.

CLINICALLY AMYOPATHIC DERMATOMYOSITIS

A population-based study in Olmsted County, Minnesota identified 29 patients over a 30-year period with dermatomyositis of which 21% had the clinically amyopathic subtype. The incidence of CADM in the study was 2.08 per million persons.[19–24] In Europe, a similar incidence has been observed,[25] whereas in Asia, CADM appears to be relatively more common. A retrospective analysis of 28 patients with DM at the National Skin Center in Singapore between 1996 and 1998 revealed that 13 (46%) had CADM.[26] In another cohort of 143 Taiwanese patients with IIDM treated in a veterans hospital system, CADM was the second most commonly encountered type of IIDM (14%) after classic adult-onset DM (64%). CADM was somewhat more common than juvenile-onset IIDM (13%) and PM (10%) in this study.[27] In Asian patients, adult-onset CADM appears to be more common in males.[27] One of the authors (Richard D. Sontheimer) has personally observed an unreported familial constellation of CADM in a father and his only children—two adult daughters. Indirect evidence suggests that CADM has human leukocyte antigen (HLA) associations similar to those found in patients with classic DM (i.e., HLA-DQA1).[28]

DRUG-INDUCED DERMATOMYOSITIS

An increasing number of cases of DM are reported to be caused or exacerbated by systemic medications. A number of different drug classes have been implicated including statin-type cholesterol-lowering agents.[31,32] The average incubation time is approximately 2 months. The majority of these cases present with both myositis and pathognomonic cutaneous findings and resolve with discontinuation of the medication. Pulmonary involvement appears to be uncommon in drug-induced DM.[33] Long-term hydroxyurea therapy for chronic myelogenous leukemia can produce a DM-like cutaneous eruption that is clinically and histopathologically similar to that of idiopathic DM-specific skin disease.[21] This subtype of drug-induced DM is unique in that muscle weakness and other systemic symptoms are absent. Painful leg ulcers are often seen in association, as are xerosis and cutaneous atrophy. This symptom complex usually occurs only after the patient has been treated with hydroxyurea for long periods (2–10 years). The presence of concurrent therapy with hydroxyurea has been proposed as the exclusion criterion for CADM.[1]

ETIOLOGY AND PATHOGENESIS

The inflammatory nature of the muscle and skin manifestations coupled with the characteristic humoral autoimmune abnormalities has led to the hypothesis that DM results from a genetically determined, aberrant autoimmune response to environmental agents. Figure 156-2 presents a summary overview of current thought in this area. Like other systemic autoimmune diseases involving autoantibody production such as systemic lupus erythematosus (SLE), DM is thought to evolve through multiple sequential phases: the susceptibility phase, the induction phase, the expansion phase, and the injury phase.

The susceptibility phase of DM is thought to result largely from a genetic predisposition. DM is one of the human autoimmune diseases that is linked to the 8.1 ancestral haplotype (HLA-A1, C7, B8, C4AQ0, C4B1, DR3, DQ2).[22] PM and DM have been specifically associated with HLA-B8, DR3, and DRw52, especially in white patients. This association is likely a result of linkage disequilibrium with HLA-DQA1*0501. The production of antisynthetase antibodies such as Jo-1 is strongly linked to HLA-DR3 and even more strongly linked to its supertypic specificity HLA-DRw52.

A single nucleotide polymorphism in the tumor necrosis factor-α promoter (TNF-α-308A), which is also a component of the 8.1 ancestral haplotype, has been associated with disease chronicity, calcinosis, and high levels of TNF-α in a cohort of white patients with juvenile-onset classic DM.[23] This same TNF-α promoter polymorphism has been associated with photosensitive subacute cutaneous LE.[34] This same TNF-α promoter polymorphism has been associated with photosensitive subacute cutaneous LE.[24,35] Several gene polymorphisms associated with low production of mannose-binding protein, a molecule involved in the physiologic clearance of apoptotic cells, have been associated with adult DM.[24] There has also been a single case report of adult-onset CADM that evolved to classic DM in a young Japanese woman who was shown to be genetically deficient in the fifth component of complement.[36]

The cutaneous manifestations of DM are precipitated or exacerbated by natural and artificial sources of ultraviolet (UV) light.[37] Approximately 50% of patients with DM experience photosensitivity. The action spectrum appears to include both UVB and UVA light. UV radiation intensity has been shown to associate with the proportional incidence of DM compared to other IIMs and correlate with the detection of anti-Mi-2 antibodies in women.[38] Environmental stimuli, including UV radiation and infection, could represent inductive factors in DM leading to loss of self-tolerance. Various types of infections have been circumstantially implicated as causative factors in DM. These include infection with RNA viruses such as coxsackievirus, echovirus, and human retroviruses (i.e., human T-cell leukemia/lymphoma virus type 1 and human immunodeficiency virus). Nonviral pathogens such as *Toxoplasma gondii* have also been implicated. However,

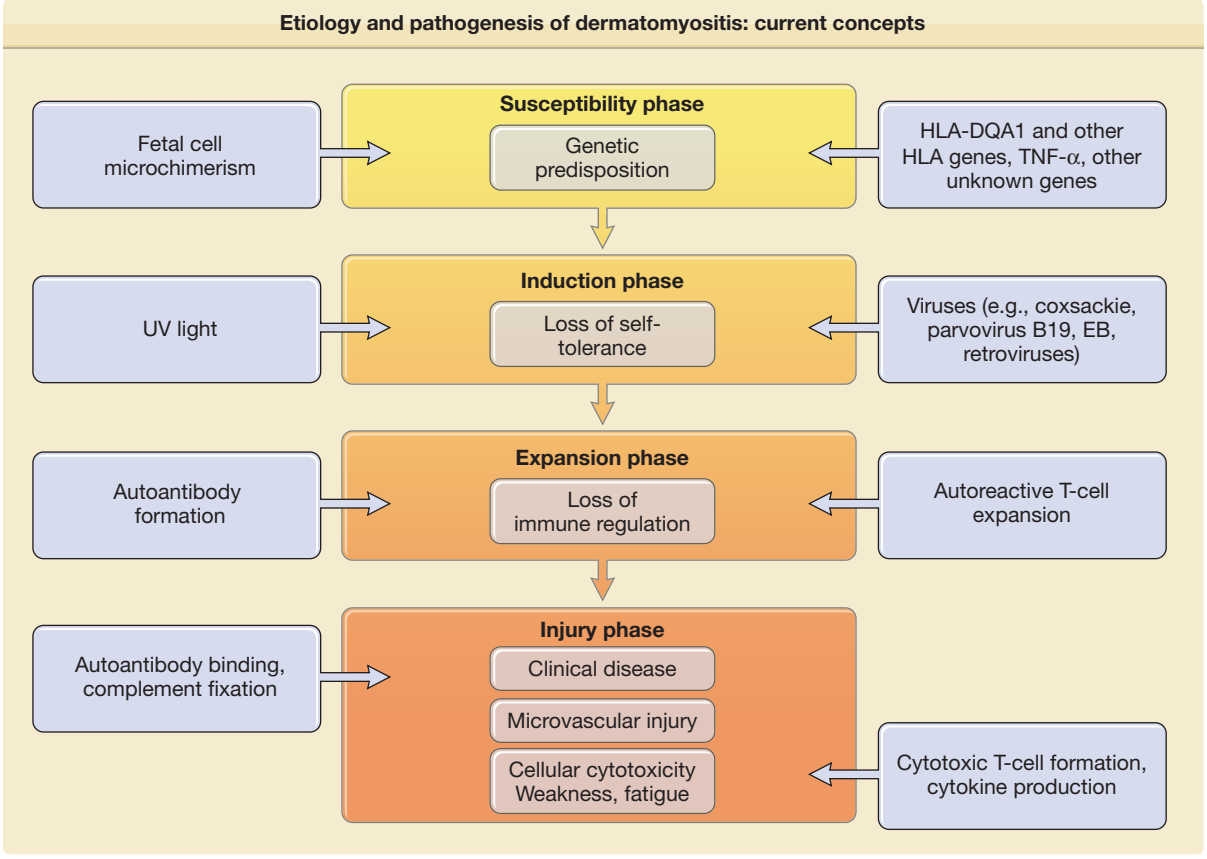

Figure 156-2 Etiology and pathogenesis of dermatomyositis: current concepts. See text for discussion. EB = Epstein–Barr; TNF-α = tumor necrosis factor-α; UV = ultraviolet.

repeated attempts to confirm persistent myotropic infection by viruses or other pathogens have not been successful.

The expansion phase of DM is marked by autoantibody production signaling the loss of normal immune regulation. DM is associated with the production of a number of specific autoantibodies that probably predates by some period the first evidence of clinical disease activity (Table 156-1). Whether these autoantibodies are truly pathogenetic or represent only a by-product of muscle injury is unknown. It has been suggested that CADM might be associated with a specific autoantibody profile (antibodies to 140-kDa, 155-kDa, and Se antigens).[39,40]

It is thought that autoantibodies, immune complexes, and/or autoreactive T cells play a major role in the tissue injury phase of DM. Cell-mediated immune activity against muscle autoantigens is thought to be primarily responsible for the muscle injury that occurs in PM. Both myocytotoxic $CD3^+$ T-cell clones and non-HLA-restricted myocytotoxic cells of other lineages have been identified in the peripheral blood of patients with inflammatory myopathies.[41] Little has been done in the past experimentally to date to probe for T-cell-mediated cytotoxic epidermal or dermal cell injury in DM skin lesions.

Predominantly humoral autoimmune mechanisms targeting the microvasculature have been implicated in the pathogenesis of muscle injury in DM. Microvascular ischemia is an early feature of DM muscle involvement. Components of the C5 to C9 membrane attack complex are regularly found in the walls of microvessels in muscle biopsy specimens from DM patients.

There is not always good agreement between the degree of muscle weakness or fatigue experienced by patients with classic DM and the degree of inflammation noted in muscle biopsy specimens and the elevation of serum muscle enzyme levels. This observation has led to the idea that inflammatory cytokines might be capable of mediating metabolic disturbances within muscle that can exacerbate muscle weakness and fatigue.[42] As with other rheumatic diseases such as systemic sclerosis, maternal microchimerism has been observed in children with juvenile classic DM.[43] The pathogenetic significance of the presence of alloreactive maternal lymphoid cells in the circulation, muscle, and skin of patients with juvenile DM is unknown.

The pathogenesis of cutaneous inflammation in classic DM and CADM and has received little attention, owing in part to the lack of an experimental animal model of this pattern of cutaneous inflammation. Histopathologic analysis of cutaneous DM reveals three general abnormalities: (1) a cell-poor interface dermatitis, (2) a vasculopathy of dermal microvessels, and (3) prominent dermal mucin deposition. These histopathologic elements can be precipitated or exacerbated by exposure to UV radiation.

TABLE 156-1
Autoantibodies in the Idiopathic Inflammatory Dermatomyositis

Autoantibody	Median Prevalence[a]	Molecular Specificity	Clinical Association
High Specificity for DM/PM			
155 kDa and/or Se	20%–80%	transcriptional intermediary factor-1γ	Classic DM, clinically amyopathic DM with increased risk of internal malignancy
140 kDa	53%	helicase C domain protein 1 (IFIH1)/melanoma differentiation-associated gene 5 (*MDA-5*)	Clinically amyopathic DM with increased risk for interstitial lung disease
Jo-1	20%	Histidyl-tRNA synthetase	PM, antisynthetase syndrome
Mi-2	15%	Helicase nuclear proteins	Shawl sign, cuticular overgrowth
SRP	5%	Signal-recognition particle	Fulminant DM/PM, cardiac involvement
PL-7	3%	Threonyl-tRNA synthetase	Antisynthetase syndrome
PL-12	3%	Alanyl-tRNA synthetase	Antisynthetase syndrome
OJ	Rare	Isoleucyl-tRNA synthetase	Antisynthetase syndrome
EJ	Rare	Glycyl-tRNA synthetase	Antisynthetase syndrome, possibly increased frequency of skin changes
Fer	Rare	Elongation factor 1α	—
Mas	Rare	Small RNA	—
KJ	Rare	Translation factor	—
Low Specificity for DM/PM			
ANA (most common nuclear immunofluorescence patterns—specked and nucleolar)	40%		Clinically amyopathic DM (80%)
SsDNA	40%		SLE, SSc
PM-Scl (PM-1)	40%	Ribosomal RNA processing enzyme	Overlap with scleroderma
Ro (52-kDa Ro)	15%	RNP	Overlap with SSJ, SCLE, neonatal LE/CHB, SLE
U1RNP	10%	U1RNP	Overlap connective tissue disease
Ku	3%	DNA end-binding repair protein complex	Overlap with scleroderma
U2RNP	1%	U2RNP	Overlap with scleroderma

ANA = antinuclear antibody; CHB = chronic hepatitis B; DM = dermatomyositis; LE = lupus erythematosus; PM = polymyositis; ssDNA = single-stranded DNA; SLE = systemic lupus erythematosus; SRP = signal recognition particle; SSc = systemic sclerosis; SSJ = Sjögren syndrome; tRNA = transfer RNA.
[a]Using current assay techniques.

CLINICAL FINDINGS

APPROACH TO THE PATIENT

The approach to a new patient with cutaneous DM is presented in eFig. 156-2.1 in online edition.

HISTORY

In 60% of patients with classic DM, the cutaneous lesions and muscle weakness present simultaneously. In 30% of patients, the cutaneous findings appear before the onset of muscle weakness. In 10%, muscle weakness precedes the appearance of skin lesions. The onset of cutaneous disease is typically accompanied by pruritus and/or a burning skin sensation. Sensitivity to sunlight or artificial sources of UV light is often present. Muscle weakness initially affects the shoulder and hip girdle musculature, presenting clinically as difficulty raising the arms above the head and arising from a sitting position. Weakness can be accompanied by muscle pain and tenderness.

CUTANEOUS LESIONS

HALLMARK SKIN LESIONS. eTable 156-1.1 in online edition presents the hallmark cutaneous manifestations of DM (to date, no recognizable differences in the clinical, histopathologic, and immunopathologic manifestations of classic DM and CADM have been reported). Some of these lesions, such as Gottron sign of DM (Fig. 156-3) and Gottron papules (see Fig. 156-4; Fig. 156-5), are pathognomonic of this disease, whereas others, such as periorbital, confluent, macular, violaceous (heliotrope) erythema/edema and grossly visible periungual telangiectasia associated with dystrophic cuticles, are highly characteristic.

Figure 156-3 Hand of a 30-year-old woman with a 15-year history of amyopathic dermatomyositis (DM). Note the confluent macular violaceous erythema, most pronounced over the metacarpophalangeal/interphalangeal joints, extending in a linear array overlying the extensor tendons of the hand and fingers. These changes, referred to as *Gottron sign,* are a hallmark cutaneous feature of DM. Early Gottron papules, an extension of Gottron sign, can be seen over the distal interphalangeal joints along with periungual erythema and dystrophic cuticles. In DM, the violaceous erythema is centered over the metacarpophalangeal/interphalangeal joints, whereas in lupus erythematosus these areas are relatively spared.

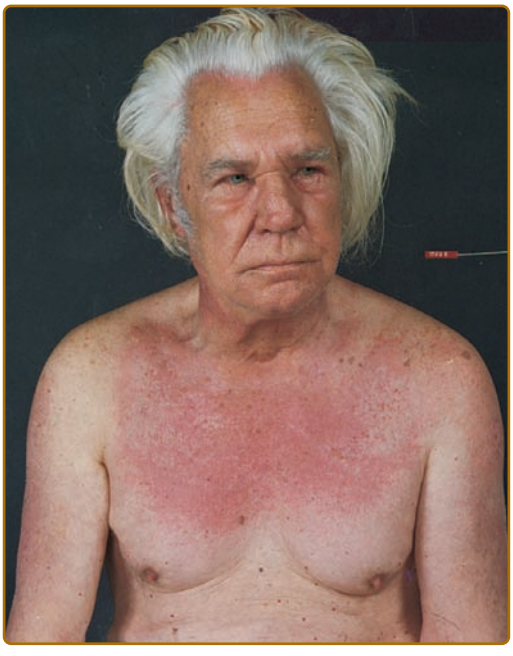

Figure 156-5 The confluent, macular, violaceous erythema of the V area of the upper chest and neck (V sign), when persistent over time, can evolve into poikilodermatous skin changes. Less evident in this photograph are periorbital edema and confluent, macular, violaceous (heliotrope) erythema of the upper eyelids. Note the absence of involvement of the malar areas, which are often involved in lupus erythematosus.

The primary skin change of DM is a highly characteristic, often pruritic, symmetric, confluent, macular violaceous erythema variably affecting the skin overlying the extensor aspect of the fingers, hands, and forearms; the arms, deltoid areas, posterior shoulders, and neck (the shawl sign); the V area of the anterior neck and upper chest; and the central aspect of the face, periorbital areas, forehead, and scalp (Fig. 156-6). Central facial involvement can occasionally simulate the appearance of seborrheic dermatitis with nasolabial fold involvement. The lateral aspects of the hips and thighs (holster sign) are also frequently involved.[50] Lesions such as poikiloderma atrophicans vasculare (poikilodermatomyositis) and calcinosis cutis are often present in patients with DM but may also appear in patients with cutaneous T-cell lymphoma (poikiloderma atrophicans vasculare) and scleroderma (SCL; calcinosis cutis). In addition, overlapping features of

Figure 156-4 Fingers of an elderly woman with classic dermatomyositis (DM). Note the fully formed Gottron papules over the distal interphalangeal joints, a hallmark cutaneous feature of DM. Prominent grossly visible nailfold telangiectasias are also present, along with dystrophic cuticles. The combination of Gottron papules and nail fold changes such as these is pathognomonic for DM. Such changes are seen to an equal degree in classic DM and amyopathic DM.

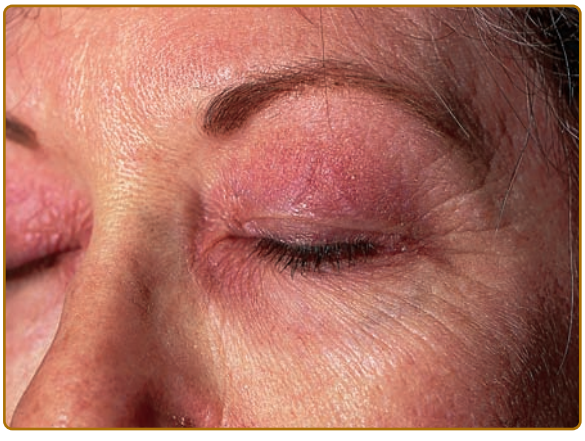

Figure 156-6 Periorbital confluent, macular, violaceous (heliotrope) erythema most prominent on the upper eyelids. Like Gottron papules and Gottron sign, this is a hallmark cutaneous feature of dermatomyositis.

cutaneous DM and cutaneous SCL (see Chapter 155) can occur in the same individual (sclerodermatomyositis).

Several other types of skin lesions have been suggested to be characteristic of IIDM; however, there is not yet enough published experience to determine their true disease specificity or prevalence. The mechanic's hand lesion consists of a nonpruritic, hyperkeratotic eruption accompanied by scaling, fissuring, and hyperpigmentation, which give the false appearance of the callused hands of a laborer. These changes are bilaterally symmetric and distributed along the medial aspect of the thumb and lateral aspect of the index and middle fingers. These hyperkeratotic changes can extend onto the palmar surface. A strong association between this skin lesion and the presence of active myositis and antisynthetase antibodies such as Jo-1 was originally suggested. However, subsequent observations indicate that this same skin change occurs in classic DM without all the elements of the antisynthetase syndrome, as well as in CADM.[51–53]

Table 156-2 presents the characteristic anatomic distribution of the hallmark cutaneous manifestations of DM. There is very little published information on the prevalence of involvement in these different anatomic locations. In some series reported by dermatologists, Gottron papules have been more commonly seen than periorbital heliotrope erythema, which by many outside of dermatology is felt to be the hallmark cutaneous manifestation of DM.

The violaceous hue of the cutaneous inflammation in lightly pigmented individuals is a striking clinical finding that usually is evident from the outset of disease activity. This hue helps to distinguish cutaneous DM from cutaneous LE, in which it is a late finding when present. It has been suggested that edema associated with the DM skin disease indirectly produces the violaceous hue by displacing the hyperemic cutaneous vasculature more deeply into the dermis. One might also speculate that this could result from the deoxygenation of blood flowing through an abnormal dermal microvascular bed. In this regard, it is interesting to note that cutaneous DM often presents in the skin over joints that is frequently stretched and thus often made to become transiently ischemic under normal physiologic conditions.

A striking clinical feature that helps to distinguish cutaneous DM from cutaneous LE is pruritus, which can be so severe in DM as to be disabling, even in the absence of systemic involvement. In addition to pruritus, DM patients often described severe burning, painful sensations associated with the DM skin inflammation. Some work has suggested that severe DM skin disease can have a greater impact on quality of life than other skin diseases such as psoriasis and atopic dermatitis for which aggressive systemic immunomodulatory therapies are often used.[54]

A number of other skin changes can be encountered in patients with DM. Hyperkeratosis may follow the onset of the confluent, macular, violaceous erythema;

TABLE 156-2
Anatomic Distribution of Hallmark Cutaneous Manifestations of Dermatomyositis

Anatomic Location	Lesions
Scalp	CMVE; nonscarring diffuse alopecia
Face	
Periorbital region	CMVE (usually most intense on the upper eyelids), edema
Malar eminences	CMVE sparing or involving the nasolabial fold[114]
Forehead, chin	CMVE
Neck and shoulders	
Anterior	CMVE evolving to poikiloderma
Posterior	CMVE (shawl sign)
Upper extremities	
Arms, forearms	CMVE on the extensor aspects
Elbows	CMVE usually most intense in this location (Gottron sign of dermatomyositis)
Hands, fingers	
Dorsal aspect	CMVE usually most intense over the extensor tendons and metacarpophalangeal/interphalangeal joints (Gottron sign), Gottron papules overlying the dorsal–lateral aspect of the metacarpophalangeal/interphalangeal joints, relative sparing of the dorsal aspects of the phalanges, periungual nail fold telangiectasia (often grossly visible), cuticular microvascular hemorrhage, dystrophic/ragged cuticles
Palmar aspect	Mechanic's hand lesion, mucinous plaques centered over the flexural creases
Trunk	CMVE evolving to large unilateral areas of poikiloderma (poikiloderma atrophicans vasculare) commonly seen over the flanks and lower back
Lower extremities	
Thighs	CMVE (holster sign)
Knees	CMVE (Gottron sign)
Lower legs, feet	CMVE, often focal, centered over the medial malleoli; Gottron sign overlying the medial malleoli

however, the scale in DM skin lesions is usually less prominent than that in subacute cutaneous LE and discoid LE. Secondary skin changes in DM skin lesions include excoriation with secondary infection and ulceration. Subepidermal vesicles and/or bullae occasionally occur in areas of particularly intense cutaneous inflammation. Postinflammatory pigmentary changes, both hyperpigmentation and hypopigmentation, occur. Older lesions may have white lacy markings somewhat similar to those of Wickham's striae in lichen planus. Another similarity between cutaneous DM and lichen planus is the characteristic violaceous hue. Mucinous infiltration, a common histologic finding in the dermis of DM skin lesions, can be clinically prominent, producing an infiltrated, glistening appearance. Superficial erosions and ulcers can subsequently develop over the face and eyelids as well as in other areas affected by intense and protracted inflammation. Deep, irregular, retiform ulcers can also develop in areas of poikiloderma in both adults and children. It has been suggested that the penetrating ulcers reflecting vasculopathy can be a bad prognostic sign in both juvenile-onset and adult-onset DM.

Clinical experience suggests that, as with cutaneous LE/SLE, the activity of IIDM can be precipitated or exacerbated by emotional and physical stress, although there is scant published evidence. Strenuous physical exertion can be detrimental to patients who have active myositis.

Magnetic resonance imaging (MRI) may identify edema/inflammation in skin, subcutaneous tissue, and fascia resulting from vasculopathy and vasculitis in patients with classic juvenile DM.[55] In approximately 80% of the 26 children studied, MRI abnormalities indicating skin, subcutaneous, and/or fascial edema were observed. Clinical skin disease activity scores correlated positively with MRI skin edema scores. Five children developed soft tissue calcification in areas previously found to be edematous by MRI after 4–9-month follow-up intervals. These observations suggest that the assessment of soft tissue by MRI could be of value in predicting risk for developing calcification and in monitoring treatment to prevent or minimize it.

DM can develop as a component of an overlap connective tissue disorder. Most common are overlaps with SLE (see Chapter 155) and systemic sclerosis (see Chapter 157). Raynaud phenomenon, sclerodactyly, sclerosis of the skin, and the characteristic hyperpigmentation can all be present in the latter setting. The term *sclerodermatomyositis* describes the disorder in patients who present with DM and who develop striking features of SCL 6 months to 3 years later. In addition, myositis occurs in approximately 5% of patients who test positive for anti-Ro/SSA autoantibody (most of whom have Sjögren's syndrome (see Chapter 161). The cutaneous manifestations of DM are not usually found in this setting.

The highly pruritic/burning scaling scalp involvement in patients with adult-onset classic DM and CADM that can be associated with nonscarring alopecia[56] has also been found to occur in approximately 25% of patients with juvenile-onset DM.[30] Localized scalp involvement can at times be the presenting manifestation of DM.

SYSTEMIC FEATURES

Table 156-3 outlines the systemic manifestations and associations of classic IIDM. Most of the extramuscular systemic features associated with classic DM have not been reported in CADM except for arthritis and interstitial lung disease.

MUSCLE DISEASE. Muscle involvement typically presents as symmetric weakness of the proximal muscles of the extremities. Lower-extremity weakness manifested as difficulty in performing routine activities of daily living, such as rising from a chair or bathtub and climbing stairs, is often the initial clinical finding. Weakness of the upper extremities soon follows, often manifested by difficulty in raising the arms above the head to perform routine activities such as combing the hair. Pain or tenderness in the affected muscle groups commonly occurs. Some patients experience a fulminant disease course that results in disabling weakness within a few weeks. Weakness involving the upper one-third of the esophagus and/or the laryngopharyngeal muscles may present as dysphagia or a hoarse voice (dysphonia), respectively.

Confirmation that proximal muscle weakness is caused by the inflammatory myositis of IIDM can be difficult, because so many other clinical disorders produce proximal muscle weakness (eTable 156-3.1 in online edition). The diagnosis can be supported by demonstration of characteristic elevations in serum levels of muscle enzymes (CK, aldolase) as well as identification of

diagnostic changes in electromyography (EMG) results, muscle imaging, and muscle biopsy specimens. Some patients with CADM have low-grade, subclinical muscle disease (i.e., hypomyopathic DM). However, in some patients who express the hallmark cutaneous manifestations of DM, no symptoms of muscular weakness have developed for up to 28 years (unpublished personal observation, Richard D. Sontheimer).

Inclusion-body myositis is a pathologically distinctive type of steroid-resistant myositis that more commonly affects the distal muscle groups of men in an asymmetric pattern. Cutaneous involvement is not seen with this disorder or with classic PM.

A retrospective analysis encompassing all patients with DM seen at the Mayo Clinic between 1976 and 1994 revealed that 32 (4%) of 746 patients conformed to the definition of CADM[63]; 27 had amyopathic DM and 5 had what can be classified as hypomyopathic DM. Follow-up information was available on 16 of the patients with amyopathic DM. Ten had no muscle weakness after 2–10 years, four had no weakness at 1 year, and two developed weakness within 5 years after diagnosis. None of the three patients classified as having hypomyopathic DM showed evidence of muscle weakness 8–17 years after diagnosis. Thus, of these 19 patients with CADM, only 2 developed clinical evidence of myositis after prolonged periods of time. Therefore, the presence of subclinical muscle abnormalities at the time of diagnosis of CADM does not necessarily portend the subsequent development of clinically significant muscle disease.

Although fatigue and/or myalgia without objective evidence of muscle inflammation have been described in a number of CADM case reports, a single case report of documented fibromyalgia occurring in amyopathic DM has now appeared.[64] The symptoms of fatigue, muscle pain, and muscle tenderness associated with fibromyalgia could falsely imply the development of myositis in a patient with CADM. There continues to be debate concerning the risk that patients with juvenile-onset CADM will ultimately develop clinically significant myositis. Some groups see a relatively low risk,[65] whereas others see a relatively high risk.[66] For the definition of CADM to be fulfilled, clinical evidence of muscle weakness should not be present. Muscle strength testing is graded on a scale of 1–5, where 0 = no muscle action; 1 = trace contraction; 2 = visible contraction but with inability to overcome gravity; 3 = fair contraction with ability to overcome gravity; 4 = contraction with ability to offer some resistance; 5 = muscle contraction that cannot be overcome by the evaluator. The examination should focus on the proximal muscle groups that control the neck, shoulders, and hips. Manual muscle testing is reproducible; variables such as pain, contractures, voluntary effort, and motivation may influence the ability of an individual to exert maximal muscle effort.

PULMONARY DISEASE. Among the most feared nonmuscular systemic manifestations of IIDM is pulmonary disease. Lung function can be compromised in a number of ways in patients with classic DM: by a restrictive lung defect resulting from respiratory muscle weakness; by aspiration pneumonia secondary to gastrointestinal reflux and impaired esophageal muscle function; by opportunistic infections; or by interstitial pneumonitis related to the underlying autoimmune disease process. In addition, some systemic drugs used to treat DM can produce pulmonary complications (e.g., methotrexate hypersensitivity pneumonitis).

Interstitial pneumonitis resulting from both classic DM and CADM has been reviewed.[67,68] Between 5% and 40% of patients with classic DM develop interstitial lung disease [high-resolution chest computed tomographic (CT) scan can identify lung involvement earlier than can routine chest radiography]. This complication presents clinically with symptoms of nonproductive cough and exertional dyspnea that are accompanied by bibasilar fine crackling rales. Pulmonary function test results show a restrictive pattern with reduced diffusion capacity. Several clinical patterns of interstitial lung disease have been described: usual interstitial pneumonia, nonspecific interstitial pneumonia, diffuse alveolar damage, and bronchiolitis obliterans with organizing pneumonia.

Interstitial lung disease can present clinically as an acute/subacute type or a chronic type. In the acute/subacute type, patients experience severe, rapidly progressive dyspnea and progressive hypoxemia within a month of the onset of lung involvement. In such cases, the lung disease is often resistant to treatment, and patients are at risk for death. In the chronic type, patients experience a much slower pace of progressive dyspnea. Interstitial lung disease can also be identified by chest CT and/or pulmonary function tests in the complete absence of symptoms. It has been suggested that interstitial lung disease associated with the myositis-specific autoantibodies (antisynthetases) can occasionally occur in the absence of skin and muscle disease.[69] In some individuals, interstitial lung disease occurs before the clinical appearance of myositis. Patients with classic DM who have the antisynthetase syndrome (the presence of Jo-1, PL-7, PL-12, or other synthetase autoantibodies; arthritis; Raynaud phenomenon) have increased risk of developing interstitial lung disease. The antisynthetase syndrome and interstitial pneumonitis occur also in children with classic DM. Interstitial pneumonitis and air leakage were observed in one child with classic juvenile DM.[70]

Interstitial pneumonitis of various subtypes is increasingly being recognized as a potential complication of CADM.[29,71] Published data indicate that the prevalence of interstitial pneumonitis in CADM is approximately 13%.[29] A disproportionately high percentage of patients with CADM and interstitial lung disease has been reported in Japan related to the fact that interstitial pneumonitis appears to be an especially common complication of classic DM in the Japanese. Curiously, the acute/subacute pattern of disease presentation with rapidly progressive dyspnea, progressive hypoxemia, treatment resistance, and fatal outcome has been observed in CADM patients who develop interstitial pneumonitis and is less common in classic DM patients.[72] A recent study from Japan

demonstrated a 45% mortality rate in patients with CADM and interstitial lung disease vs. 6% in classic DM with interstitial lung disease.[73] However, this difference in mortality has not yet been demonstrated in other patient populations.[72]

In most cases, interstitial pneumonitis has occurred in patients with CADM in the absence of antisynthetase autoantibodies such as Jo-1, which are considered to be markers for interstitial lung disease risk in patients with classic DM and the antisynthetase syndrome. However, it has been suggested that newly observed autoantibodies to 140-kDa and 155-kDa autoantigens that appear to be highly specific for classic DM and CADM might serve as a marker for interstitial lung disease in Japanese CADM patients.[40]

The appearance of symptoms of interstitial pneumonitis, especially the acute/subacute type, in a patient with any form of DM should be considered a medical emergency, and the assistance of a pulmonary medicine specialist should be obtained as soon as possible to ensure proper diagnosis and therapy. Aggressive multidrug systemic immunosuppressive therapy is typically required in such cases, and the patient is often admitted to a pulmonary intensive care unit.[74]

ARTHRITIS. Arthritis occurs in 20% to 65% of patients with juvenile-onset classic DM.[75] Typically, this is a nonerosive arthritis involving knees, wrists, elbows, and fingers. It is seen early in the course of the disease. For some patients, arthritis can be a major symptomatic problem. Arthritis also occurs in some patients with juvenile-onset CADM. In one study, three of five patients with juvenile CADM followed over an average of 4.9 years were reported to have arthritis, whereas 49 of 80 children with classic DM had arthritis.[75]

LABORATORY TESTS

CLASSIC DERMATOMYOSITIS

MUSCLE ENZYMES. An elevation in the serum level of CK is the most sensitive and specific laboratory indicator of muscle disease activity in IIDM. Ninety percent of patients with classic IIDM have elevated levels of CK at some point. The elevated CK activity is caused primarily by the CK-MM isoenzyme (muscle form of CK); however, elevations caused by the CK-MB isoenzyme (muscle and brain form of CK) are also seen. Elevated levels of CK can be associated with some of the disorders listed in eTable 156-3.1 in online edition (e.g., other myopathies, hypothyroidism, and ingestion of certain drugs), as well as with strenuous physical exertion and needle trauma (intramuscular injection, EMG needle insertion). Enzymatic detection of CK activity can at times be inhibited by serum factors. Levels of CK may become elevated before the development of weakness and can normalize several weeks before the return of normal strength during treatment. Patients with IIDM who have normal CK levels may have a worse prognosis with respect to pulmonary disease and associated malignancy. Levels of CK are usually normal in patients with glucocorticoid-induced myopathy.

Serum aldolase level is a somewhat less sensitive indicator than CK for active myositis in IIDM. However, aldolase level is occasionally elevated in the presence of a normal CK level, especially in juvenile DM. Levels of transaminases (aspartate aminotransferase, alanine aminotransferase) and lactic dehydrogenase can also be elevated in active myositis, but these values are less useful clinically because of their low degree of specificity. Elevations of transaminase levels during treatment with methotrexate may reflect the activity of myositis as well as drug-induced hepatotoxicity. Urinary creatine excretion can also be used to monitor the status of myositis. However, the specificity is low because urinary creatine excretion can also be elevated in steroid myopathy. Serum myoglobin levels can also be elevated in severe IIDM.

AUTOANTIBODIES. Elevated antinuclear antibody (ANA) levels with human tumor cell substrates are found in 60% to 80% of patients with both classic DM and CADM.[29] Autoantibodies of known molecular specificity in DM are now categorized into two groups: (1) myositis-specific autoantibodies and (2) myositis-associated autoantibodies.[77,78] Myositis-specific autoantibodies include the antisynthetases [Jo-1, PL-7, PL-12, OJ, Mi-2, and signal-recognition particle (SRP)]. PM/Scl, Ro/SSA (Ro52, Ro60), and U1RNP represent the major myositis-associated autoantibodies. Table 156-1 lists the molecular specificities and clinical correlations of these autoantibodies. The fact that none of the myositis-specific autoantibodies occurs with a prevalence greater than one in five patients with DM makes routine testing for these autoantibodies of little clinical use.

Among the most frequently encountered myositis-specific autoantibodies are those that target the various aminoacyl-transfer RNA synthetases. Of these antisynthetase autoantibodies, autoantibodies to Jo-1 (histidyl-transfer RNA synthetase) are the most common and are found in 20% of patients with classic IIDM overall and 30% to 40% of adult patients with PM. Fever, interstitial lung disease, polyarthritis, Raynaud phenomenon, and incomplete response to therapy occur more often in patients who produce these antibodies (antisynthetase syndrome), as does the mechanic's hand skin lesion. Patients who produce Jo-1 antibodies less frequently display the classic cutaneous manifestations of DM.

SRP antibodies occur in 5% of patients with PM and are more common in those who exhibit acute-onset, severe, treatment-resistant forms of classic IIDM with cardiac involvement. Such patients rarely have any type of skin involvement. Autoantibodies to Mi-2, a nuclear protein complex containing histone deacetylase and nucleosome remodeling activities, are seen almost exclusively in patients with classic DM. Mi-2 antibody is found in 5% to 10% of patients with classic IIDM overall and in 15% to 20% of patients with classic DM. This autoantibody is associated with more treatment-responsive forms of classic DM as well as with the shawl sign and prominent cuticular changes.

The clinical correlations of the myositis-specific autoantibodies found in adults (e.g., Jo-1) also occur in children with classic IIDM. IIDM autoantibodies that currently have less clinical significance are also listed in Table 156-1. An autoantibody to a 155-kDa nuclear antigen (transcriptional intermediary factor-1γ)[7] has recently been reported to be highly specific for classic DM and CADM. In classic DM patients, this antibody has been suggested to be associated with an increased risk for internal malignancy.[79]

SPECIAL TESTS (INCLUDING IMAGING STUDIES)

ELECTROMYOGRAPHY. The EMG changes of myositis include a myopathic pattern of the motor unit action potential, a myopathic recruitment pattern, increased insertional activity, and increased spontaneous activity. EMG changes of myositis can be erratically distributed. EMG recordings from the paraspinous muscles can be abnormal when those from the limb girdle musculature are normal. As many as 10% of patients with biopsy-documented myositis have normal EMG findings.

MUSCLE BIOPSY. Muscle fiber degeneration/regeneration, perifascicular atrophy, and capillary injury are frequently present in the muscle biopsy specimens of patients with IIDM. A perivascular infiltrate of T lymphocytes and histiocytes and, occasionally, of B lymphocytes, plasma cells, and eosinophils is also seen. Biopsy specimens from patients with DM often show CD4 T cells and B cells in the perivascular areas, whereas CD8 T cells preferentially associate with damaged muscle fibers in patients with PM. The capillary density in muscle specimens from patients with DM is decreased. Inflammation may be absent in up to 25% of biopsy specimens from patients with otherwise typical muscle disease by clinical, EMG, or biochemical criteria.

An occlusive vasculopathy is a striking aspect of the pathology of juvenile-onset classic DM. Phlebitis and arteritis leading to intimal hyperplasia, fibrinous occlusion of vessels, and infarction of the involved tissues can be seen. The muscles, gastrointestinal tract, and nerves are particularly affected. This vasculopathy in muscles is noninflammatory and occurs predominately in the capillaries. There is a spectrum of endothelial changes from swelling to obliteration to necrosis. In muscles this occlusive vasculopathy is most commonly seen in small vessels, resulting in microvascular ischemia. The local production of interferon-induced angiostatic ELR-negative CXC chemokines has been implicated as a pathogenetic factor in the vasculopathy of juvenile-onset DM.[85]

MUSCLE IMAGING. Myositic inflammation can be highly focal. A number of noninvasive techniques are currently being examined for their ability to localize affected muscle groups. MRI is the method of choice for diagnostic imaging of muscle abnormalities in patients with myositis.[86] However, the MRI signal associated with myositis is not specific for IIDM muscle involvement. The possibility that MRI-guided needle biopsy could obviate the need for the more costly and invasive open muscle biopsy is being explored. In addition, MRI and phosphorus-31 magnetic resonance spectroscopy are also useful in assessing the status of muscle disease activity during treatment with systemic glucocorticoids and other immunosuppressive drugs. These procedures are expensive and cannot be used in some individuals with metallic implants. Less costly approaches to monitoring muscle disease activity, such as power Doppler and grayscale ultrasonography and ultrasonography with contrast material are being examined.[87]

Functional metabolic changes in muscles identified by magnetic resonance spectroscopy have been especially evident on exercise in some patients with amyopathic DM (such patients would better be

BOX 156-1 DIFFERENTIAL DIAGNOSIS OF DERMATOMYOSITIS (DM)

CLASSIC DM

Most Likely

- Few illnesses can be confused with the fully expressed combination of hallmark skin changes and proximal weakness seen in classic DM. However, treatment with certain drugs, such as statin lipid-lowering agents, has been reported to be capable of triggering the appearance of both the cutaneous and muscle manifestations of DM.

Consider

- There are a number of causes of proximal muscle weakness other than myositis (see eTable 156-3.1 in online edition). It is possible that co-occurrence of one of these other causes of proximal muscle weakness with a common dermatologic condition mimicking the early manifestations of cutaneous DM could be confused with classic DM.

CLINICALLY AMYOPATHIC DM

Most Likely

- Cutaneous lupus erythematosus (acute cutaneous lupus erythematosus or subacute cutaneous lupus erythematosus, but not discoid lupus erythematosus)

Consider

- Seborrheic dermatitis
- Contact dermatitis
- Lichen planus
- Psoriasis
- Polymorphic light eruption
- Atopic dermatitis
- Overlap connective tissue disease
- DM-like skin changes induced by drugs (e.g., hydroxyurea, statins)

classified as having hypomyopathic DM). Artificial neural networks have been proposed as an effective way to analyze the multichannel functional data that result from phosphorus-31 magnetic resonance spectroscopy examination.[88] A central issue in this area is whether the subtle muscular abnormalities that can be identified with these sensitive imaging systems have true prognostic value.

DIFFERENTIAL DIAGNOSIS

(Box 156-1)

In the earlier stages, cutaneous DM might be confused with contact dermatitis, seborrheic dermatitis, lichen planus, psoriasis, polymorphic light eruption, and atopic dermatitis. In the later stages, when the more typical cutaneous manifestations of DM have evolved, the greatest challenge can be to distinguish the skin involvement of DM from that of cutaneous LE, especially acute cutaneous LE and subacute cutaneous LE (Table 156-4).

Periorbital heliotrope erythema and edema can occasionally be observed in SLE, but fully formed Gottron papules are never seen as a cutaneous manifestation of LE. It has been the authors' experience that, excluding the rare occurrence of hydroxyurea- or statin-induced DM-like skin changes, the concurrent presence of Gottron papules and grossly visible periungual nail fold telangiectasia is pathognomonic of DM skin disease. Pruritus or related dysesthetic symptoms such as burning pain are typical of DM skin inflammation, whereas the various forms of LE-specific skin disease are characteristically not pruritic.

From Euwer RL, Sontheimer RD: Dermatomyositis. In: *Cutaneous Manifestations of Rheumatic Disease,* edited by Sontheimer RD, Provost TT Baltimore, Lippincott Williams & Wilkins, 1996, p. 73, with the permission of Lippincott Williams & Wilkins.

The pattern of involvement over the hands also differs; in LE the skin over the dorsal interphalangeal and metacarpophalangeal joints is spared, and the hair-bearing skin between these joints is preferentially involved. The opposite is true for DM: the skin overlying the dorsal interphalangeal and metacarpophalangeal joints is preferentially affected (see Fig. 156-4). However, when extensive, the linear streaking of violaceous erythema that tracks over the extensor tendons of the hands and fingers can sometimes obscure this point of differential diagnosis.

Poikiloderma commonly occurs in DM patients. Various forms of "poikilodermatous" cutaneous LE have also been reported. However, it has been the authors' personal experience that most of the patients with "poikilodermatous LE" that have been referred to them have turned out to have CADM. For most physicians outside of dermatology, the absence of clinically evident muscle weakness reflexively prevents further consideration of cutaneous DM, no matter how typical the skin features might be. This confusion is exacerbated by the fact that the majority of CADM patients test positive for ANA.

In addition, multicentric reticulohistiocytosis (see Chapter 148) has been reported to masquerade as DM. However, the "string of pearls" papules that occur in the periungual areas in multicentric reticulohistiocytosis can be clearly distinguished from the periungual inflammatory changes of DM by clinical and pathologic examination. Many conditions other than IIDM can be associated with proximal muscle weakness.[89] eTable 156-3.1 in online edition outlines these disorders.

As previously noted (see Section "Epidemiology"), drugs such as hydroxyurea, penicillamine, niflumic acid/diclofenac, phenytoin, tryptophan, and practolol have been reported in rare cases to produce an eruption with clinical similarities to the hallmark cutaneous features of DM. In addition, statin-type lipid-lowering drugs (atorvastatin, fluvastatin, lovastatin, pravastatin, rosuvastatin, simvastatin) and other classes of lipid-lowering drugs (fenofibrate, gemfibrozil) are well known to produce a drug-induced myositis and/or rhabdomyolysis that can simulate the myositis seen in DM. However, considering the high rate of usage of these drugs, confirmed reports of statins and other lipid-lowering drugs triggering the hallmark cutaneous manifestations of DM are quite rare. To prove that a case of classic DM or CADM is drug induced would require a rechallenge with the suspected drug once the cutaneous and/or muscle manifestations of DM have remitted. Few patients or physicians would be willing to do this, and the ethics of such an attempt could be questioned.

COMPLICATIONS

CUTANEOUS ULCERATION

Cutaneous ulcers are more common in juvenile than in adult classic DM and appear to be quite rare in both juvenile and adult CADM. The skin can ulcerate in DM as a result of a number of different mechanisms. Superficial erosion/ulceration can develop from vesiculobullous changes occurring within intensely inflamed DM skin lesions. Retiform ulcers can result from skin breakdown in poikilodermal areas. Deep penetrating ulcers can result from cutaneous infarction secondary to vasculopathy. The skin can ulcerate as a result of pressure from underlying calcium deposits. In addition, leg ulcers are a component of the clinical constellation of hydroxyurea-induced DM skin changes. Because of their frequent association with vasculopathy, deeply penetrating cutaneous ulcers have traditionally been thought to be a poor prognostic sign. One of the authors (Melissa I. Costner) has noted that deeply penetrating ulcers may correlate with pulmonary involvement in DM.

SYSTEMIC VASCULOPATHY

Clinical manifestations of systemic vasculopathy are seen most often in patients with juvenile-onset classic DM. This can result in perforation of the gastrointestinal tract, ocular damage, and central nervous system damage.

CALCINOSIS

Extraosseous calcification is also more common in children than in adults with classic DM. As with cutaneous ulceration and systemic vasculopathy, calcinosis is seen less commonly in both children and adults with CADM. The higher rate of vasculopathy that occurs in juvenile DM is thought to be a forerunner of dystrophic calcification. Approximately 25% of children with classic DM have dystrophic calcification at the time of diagnosis, and 40% to 50% develop calcinosis sometime during the course of their illness.

DM patients experience several different patterns of calcinosis. In adults, cutaneous calcification often presents as firm dermal and/or subcutaneous papules or nodules that are often most prominent around the elbows and hands. Large subcutaneous tumoral deposits can also occur over the trunk of adults. Such lesions can be filled with a liquid suspension of calcium crystals (i.e., "milk of calcium"). Four types of calcification have been described in children with DM: (1) a superficial pattern consisting of small, firm nodules and plaques in the skin; (2) periarticular subcutaneous nodules (calcinosis circumscripta); (3) deposition along fascial planes in muscles (calcinosis universalis); and (4) a severe "exoskeleton" pattern of deposition in the subcutaneous tissue. Calcinosis cutis or calcium deposition in muscles and tendons is more common in the late phases of the disease in children. The TNF-α-308A promoter polymorphism might represent a risk factor for developing calcinosis.[8] The complications of calcinosis, such as ulceration and sepsis, are a significant cause of both morbidity and mortality in patients with juvenile classic DM.

INTERNAL MALIGNANCY

Population-based studies document that adult-onset classic DM is associated with a higher than expected risk for internal malignancy.[90–94] Relative risks for malignancy range from 2.4 in males with DM to 3.4 in females with DM. The risk for malignancies was negligible in patients with PM. During the 5-year period after the diagnosis of DM, the risk of a woman developing ovarian cancer in these studies was 16.7-fold higher than the risk for women without DM. In a more recent study, the standardized incidence ratio for malignancy in adult patients with DM was 6.5.[91] In the first year after diagnosis, the relative risk for malignancy in patients with DM was 26.0. Females with DM in this study had a 32-fold higher risk of developing ovarian carcinoma. This study also found that PM was not associated with an increased risk of cancer and that the treatment of DM with cytotoxic drugs did not increase the risk of malignancy. Because of the risk of ovarian cancer in females with DM, it has been suggested that all women with DM (classic DM and CADM) undergo an initial comprehensive gynecologic examination and repeat examinations at 6–12-month intervals for at least the first 2 years after the diagnosis. Determination of serum levels of cancer antigen-125 and transvaginal ultrasonography have been recommended for females with DM who have intact ovaries. However, it is an unfortunate fact that there is no foolproof way to screen for early ovarian cancer.

Tumors other than ovarian carcinoma have been reported with DM, including melanoma, mycosis fungoides, and Kaposi sarcoma. Carcinomas are more frequent than sarcomas, and lymphoproliferative malignancies are uncommon. Except for ovarian cancer in women, no preponderance of specific types of cancer is seen in whites with IIDM. Asian males most frequently develop nasopharyngeal carcinoma.[90,91]

The diagnosis of cancer is most often made by history, review of systems, physical examination, and routine laboratory and radiologic testing. Debate exists about the routine use of surveillance imaging techniques, such as chest, abdominal, and pelvic CT and/or MRI in this setting. Age appears to be a factor in malignancy risk. There is not a significant risk of occult malignancy in patients with juvenile-onset classic DM,[95] whereas individuals 50 years of age or older at the time of onset of classic DM appear to have a definite increased risk of malignancy (20% to 30%). The leading cause of death in patients with IIDM who have malignancy is metastatic spread of the malignancy rather than complications directly related to myositis. In patients with malignancy, the myositis and cutaneous manifestations are less responsive to systemic glucocorticoid therapy. In a few well-documented cases, definitive therapy for the malignancy resulted in resolution of the DM disease activity, and a recurrence of the cancer was associated with the reappearance of DM activity.

Older age, greater extent and severity of skin disease [i.e., intense generalized erythema ("malignancy suffusion"), blistering, ulceration], and elevated CK levels appear to enhance the risk of malignancy in adults with classic DM. It has been suggested that other systemic manifestations of DM, such as interstitial lung disease, are negatively correlated with risk for internal malignancy.[27] All routine age- and sex-directed malignancy surveillance guidelines should be followed.

OPPORTUNISTIC INFECTIONS AND LYMPHOMA

Early initiation of aggressive systemic immunosuppression is required for both juvenile-onset and adult-onset classic DM. Because DM frequently pursues a chronic and/or recurring course, such patients frequently are exposed to the consequences of long-term use of specific immunosuppressive regimens, including a panoply of opportunistic systemic infections (bacterial, mycobacterial, viral, fungal) and opportunistic infection-induced lymphoma (Epstein–Barr virus infection).[96,97]

PROGNOSIS AND CLINICAL COURSE

CLASSIC DERMATOMYOSITIS

GENERAL CONSIDERATIONS. Reported mortality rates vary from 25% to 80%, depending on the case mix and the medical era in which the cases were collected.[98,99] The 5- and 8-year survival rates for 76 patients with IIDM studied in the 1980s were 80% and 73%, respectively. Global survival rates for the IIDMs have been more reported to be 95%, 92%, and 89% for 1, 5, and 10 years, respectively. Pulmonary and cardiac complications were the most frequent causes of death. Cancer-associated myositis had the worst prognosis, whereas juvenile-onset and overlap myositis had the best. Five- and 10-year survival rates were 94.2% and 89.4% for patients with primary PM and 90.1% and 86.4% for those with primary DM.[100] Individuals who receive early systemic treatment for their disease have a better prognosis. The early, aggressive use of glucocorticoids has reduced the mortality rate in children to less than 10%.

CLINICALLY AMYOPATHIC DERMATOMYOSITIS

Data are not available to allow adequate discussion of mortality in either adult-onset or juvenile-onset CADM. Individual reports of death from occult malignancy and interstitial lung disease in adult-onset CADM have appeared.[29]

Insufficient long-term follow-up data are available to assess prognosis and clinical course in adults or children with CADM. All six patients in one cohort with adult-onset disease who initially had only skin disease and who were treated conservatively ultimately

developed muscle disease.[101] In another cohort, none of the five adults with CADM treated aggressively with high-dose systemic glucocorticoids developed clinical evidence of myositis.[102] Both of these small case series could have suffered from case selection/publication bias.

A systematic review of adult-onset CADM identified 291 cases among which there was a 13% incidence of interstitial lung disease and 14% incidence of associated internal malignancy.[29] However, this compilation of individual case reports and small case series is likely to have also been affected by reporter bias. Population-based studies of the epidemiology and management of CADM are greatly needed to address this and other clinical issues relating to this subtype of DM.

One study has suggested that patients with juvenile-onset DM who have only the cutaneous manifestations are usually not treated aggressively and may frequently develop pathologic calcifications.[66] This report is contrary to the findings of other studies of CADM in both children[65] and adults,[25,63] which have indicated that this mode of presentation is usually not associated with a high rate of subsequent dystrophic calcification. One study, indicating that both rheumatologists and dermatologists tend to be conservative in treating patients with CADM,[65] also reported that a high percentage of patients with juvenile-onset CADM enjoy spontaneous remission without systemic immunosuppressive treatment.

TREATMENT

The following discussion of the clinical management of DM skin disease is the product of published anecdotal observation by others, expert opinion by others, and the personal clinical experience of the authors. The goals of treatment of DM are to arrest inflammation in the skin and muscles and obtain a clinical remission. Improvement of both the clinical and laboratory features of the disease should be objectively monitored incrementally over time during treatment. The Cutaneous Dermatomyositis Disease Area and Severity Index (CDASI) appears to be a reproducible assessment tool to measure change in the cutaneous features of DM during treatment.[103]

The treatment of CADM patients differs from that of classic DM patients only in the absence of the need to treat symptomatic inflammatory myositis. The cutaneous manifestations of classic DM and CADM respond similarly to aggressive systemic immunosuppressive therapy; however, this therapy is difficult to justify in some cases of CADM when nonimmunosuppressive topical and systemic measures might be of benefit.

LOCAL TREATMENT

Patients with either classic DM or CADM should avoid excessive sun exposure and use effective broad-spectrum sunscreens. An in-depth discussion of practical and theoretical photoprotection and local therapy for autoimmune connective tissue skin disease such as DM has been presented elsewhere.[104] However, efforts should be made to insure that vitamin D deficiency does not occur.

Topical glucocorticoids (classes I and II) can dampen cutaneous inflammation and pruritus, and such agents can be used safely for prolonged periods of time when administered cyclically (2 weeks of daily treatment followed by 2 weeks off treatment). However, these agents alone usually cannot fully suppress DM skin disease activity. Daily use of a medicated shampoo followed by application of a topical class I and II glucocorticoid solution, gel, spray, or foam to the affected areas can provide relief for scalp pruritus. Xerosis is often present, especially in the elderly, and effective moisturization regimens can be of value in managing the pruritus often experienced by patients with DM. Topical antipruritic agents such as combinations of menthol/phenol/camphor, pramoxine, and doxepin can provide short-term relief.

Pulsed dye laser therapy has been advocated for the cosmetic treatment of the residual poikilodermatous skin changes that can follow in the wake of active cutaneous DM.[105]

SYSTEMIC TREATMENT

When nonimmunosuppressive systemic therapy is possible, its use should be maximized. Nonsedating or sedating antihistamines can be used during the day as appropriate. Doxepin, a tricyclic antidepressant, is a potent H_1 and H_2 receptor-blocking antihistamine. When given at bedtime in doses of 10–50 mg titrated to the degree of somnolence the next morning, this long-acting antihistamine can ameliorate the pruritus and excoriation that often occur during sleep. The addition of cimetidine 200–400 mg four times daily for its histamine H_2 receptor-blocking ability can also be helpful. With the appropriate precautions, oral naltrexone and mirtazapine may be used to treat the intractable pruritus and burning sensations that can be seen in this setting.

ANTIMALARIALS. Hydroxychloroquine sulfate (6 mg/kg given as two divided doses per day) has been used to treat DM skin disease. Hypersensitivity reactions to hydroxychloroquine may occur at higher frequencies in DM patients than in other patient groups.[106]

Some DM patients will respond better to a combination of hydroxychloroquine and quinacrine, 100 mg/day, or to chloroquine (3.5 mg/kg/day) and quinacrine (100 mg/day)[107] than to hydroxychloroquine alone (see Fig. 156-3). However, even combination antimalarial therapy will not adequately control the cutaneous symptoms of many DM patients. Precautions should be taken to minimize the risk of retinal toxicity with hydroxychloroquine or chloroquine and of hematologic toxicity with quinacrine. If extrapolation from the experience gained from patients with cutaneous LE is valid, patients with DM who smoke cigarettes may be less responsive to antimalarial therapy than those

who do not smoke. On rare occasion, antimalarials can contribute to muscular weakness by causing a toxic vacuolar myopathy. Other nonimmunosuppressive systemic therapies may benefit in cutaneous DM include dapsone[108,109] and antiestrogen therapy.[110]

SYSTEMIC GLUCOCORTICOIDS. Systemic glucocorticoids remain the traditional first-line therapy for classic DM. Early intervention with systemic glucocorticoids is associated with a better overall prognosis. In adults, prednisone (prednisolone for those with decreased liver function) is given orally in divided doses of 1.0–1.5 mg/kg/day, whereas in children the dosage is 1–2 mg/kg/day. Significant improvement of muscle strength, normalization of muscle enzyme levels, and improvement in cutaneous inflammation are the endpoints of therapy. Most patients require 1–3 months of full-dose treatment with prednisone. When symptoms improve, the dose can be consolidated from a divided dose to a single daily dose given in the morning to reduce the risk of adrenal suppression and other glucocorticoid side effects. The glucocorticoid dosage can then be progressively decreased. Treatment should be continued for 12 to 24 consecutive months to minimize the chance for recurrence. Attention should be paid from the outset to managing the side effects of long-term systemic glucocorticoid use such as osteoporosis. Calcium loss from bones starts within the first 3 months after initiation of systemic corticosteroid therapy.

In acutely ill patients, intravenous pulse therapy with methylprednisolone can be used. This approach has become increasingly popular in the management of juvenile DM. Alternate-day glucocorticoid administration usually does not provide adequate relief during active phases of the disease. The cutaneous lesions of DM can be refractory to high-dose, long-term glucocorticoid therapy in some patients. Other patients have recrudescent disease activity only in the skin after complete suppression of muscle disease with systemic immunosuppressive therapy.

Systemic glucocorticoids and other systemic immunosuppressives can be used to treat disabling skin disease activity in patients with CADM. However, it remains to be determined whether early aggressive immunosuppressive treatment of CADM might prevent the subsequent development of clinically significant myositis in the minority of CADM patients in whom this occurs.

Approximately 25% of patients with classic DM do not respond adequately to systemic glucocorticoids within the first 2 months of treatment. Azathioprine (2–3 mg/kg/day), cyclophosphamide (1–2 mg/kg/day), methotrexate (7.5–50 mg/week), chlorambucil (2–6 mg/day), cyclosporine (3–5 mg/kg/day), and mycophenolate (1–3 g/day) have been used in this setting in patients who cannot tolerate the side effects of prolonged high-dose glucocorticoid therapy.

METHOTREXATE, CYCLOSPORINE, MYCOPHENOLATE MOFETEL, AND CYCLOPHOSPHAMIDE. Methotrexate (7.5–25.0 mg) given once weekly by mouth has been successful in the treatment of patients with classic DM and some patients affected primarily by the cutaneous manifestations of DM. Higher dosages can be given subcutaneously or intravenously; administration by the intramuscular route may cause spurious elevation of muscle enzyme levels. Cyclosporine and cyclophosphamide have each been reported to be of benefit in treating severe complications of interstitial lung disease in patients with CADM, especially when started before frank respiratory failure has developed.[111,112] In children, oral cyclophosphamide (2–4 mg/kg/day) has traditionally been used in cases that could not be managed satisfactorily with systemic glucocorticoids. Mycophenolate mofetil has been tried with some effectiveness in recalcitrant DM.[113] There are also early indications that it may be beneficial in the setting of interstitial lung disease.[114] High-dose intravenous γ globulin therapy has been used in both children and adults in this setting and has the advantage of low toxicity. Plasmapheresis and leukapheresis appear to have little additional value in the management of IIDM.

ANTITUMOR NECROSIS FACTOR-α AND OTHER IMMUNOBIOLOGIC AGENTS. Based on experimental evidence indicating a role for TNF-α in the pathogenesis of the muscle inflammation in classic DM, anti-TNF-α therapy has been used anecdotally to treat both the muscular and cutaneous manifestations of DM. A small number of cases of severe, therapy-resistant DM have been successfully treated with etanercept (Enbrel) or infliximab (Remicade).[115] More systematic study is needed to define the value of this treatment. Such therapy would have to be used with caution because of the possibility of its uncovering other patterns of systemic autoimmunity (e.g., SLE). In addition, anecdotal reports have appeared suggesting benefit from the use of rituximab, a depletor of memory B cells, in patients with therapeutically refractory DM.[116,117]

B cells have also been implicated in the pathophysiology of DM. Studies of therapy with rituximab (a CD20 B cell-depleting antibody) have provided encouraging results in patients whose disease responded poorly to other treatments.[117,118]

TREATMENT OF CLINICALLY AMYOPATHIC DERMATOMYOSITIS

Current approaches to the treatment of adults and children with CADM are based on anecdotal observations of individual cases or a relatively small case series. One approach has been to treat patients with CADM aggressively from the outset with systemic glucocorticoids in the hope that progression to systemic involvement might be delayed or prevented.[102] This approach is supported by studies of patients with both juvenile- and adult-onset classic DM, which indicate that early systemic immunosuppressive treatment can lessen long-term disability from muscle dysfunction and complications such as calcification. However, in the large majority of published reports to date, a more

conservative approach has been taken to the treatment of CADM.[20,29,124] This approach is validated by reports of patients with CADM who go 10 to 28 years and longer without any sign of disease activity or damage other than in the skin.[1,63,64,125]

Until it is confirmed that adult patients with CADM do not have a significantly increased risk of internal malignancy, they should be evaluated for this potential complication in a manner similar to for patients with classic DM. Because internal malignancy has not been reported to be associated with juvenile-onset classic DM or CADM, it can be assumed that routine evaluation for internal malignancy is not indicated in this population.

Chapter 157 :: Scleroderma

:: P. Moinzadeh, Christopher P. Denton, T. Krieg, & Carol M. Black

SYNOPSIS AT A GLANCE

- Systemic sclerosis (SSc) is a multisystemic disease, characterized by excessive fibrosis, inflammation, and vasculopathy.
- The pathogenesis of this autoimmune process remains unclear.
- Differential diagnosis of SSc includes severe forms of localized scleroderma as well as many other scleroderma-like conditions.
- Patients with SSc are classified into two major subtypes depending on the extent of skin sclerosis [diffuse systemic sclerosis (dSSc) and limited systemic sclerosis (lSSc)]. Patients with an overlap syndrome, are characterized by additional clinical features of other rheumatic diseases.
- Raynaud phenomenon (RP) and skin sclerosis are almost always present.
- SSc is defined by sclerotic/fibrotic alterations of the skin and internal organs (digestive tract, lung, kidney, and heart), which can lead to severe dysfunction of almost any visceral organ.
- The heterogeneity and clinical course of SSc requires the urgent need of interdisciplinary collaborations and regular, at least yearly, follow-up visits.
- Although the disease is still not curable, there have been substantial advances in therapy for organ-based complications of SSc.

DEFINITION AND EPIDEMIOLOGY

Systemic sclerosis (SSc) is a rare, multisystem disease, based on autoimmunological processes, vascular endothelial cell injury and an extensive activation of fibroblasts. It is characterized by a large individual variability in the extent of skin and organ involvement, as well as in disease progression and prognosis. The skin, esophagus, lung, heart and kidneys are the most frequently affected organs.

Women are more frequently affected by SSc, with a female-to-male ratio between 3:1 up to 14:1.[1–4] The age of disease onset ranges between 30 and 50 years.[4] However, male patients have earlier onset than female patients. Blacks with SSc are frequently younger than whites. Published data about incidence rates increased from 0.6 to 16 patients per million inhabitants, which is also true for the prevalence rates, which rose from 2 to 233 patients per million inhabitants per year,[1–3,5] depending on methodological differences in case definition and ascertainment as well as the investigated time period.

SSc has the highest case-specific mortality of any of the autoimmune rheumatic diseases, but it varies individually depending on racial or ethnic differences, presence and severity of organ involvement, SSc subsets, age at diagnosis and gender differences. Although not curable, there have been substantial advances in treatment options for organ-based complications of SSc.

ETIOLOGY AND PATHOGENESIS

The pathogenesis of this complex disease involves multiple cell types (endothelial cells, epithelial cells, fibroblasts, and lymphocytic cells) interacting through a variety of mechanisms that are dependent on their microenvironment and key mediators.

Major facets of the disease include inflammation, vasculature, and connective tissue-producing cells. The clinical heterogeneity of SSc makes it likely that distinct pathogenetic mechanisms predominate in particular patients or subsets of disease. Similarly, it is likely that the mechanisms are not the same at different stages of SSc. Although a genetic component to etiopathogenesis is likely and evidence supports genetic factors in severity and susceptibility, there is also strong evidence supporting environmental and chemical factors as triggers for the disease.

GENETIC FACTORS

The best evidence for a genetic contribution to SSc comes from studies that report familial clustering and from the limited twin studies that have been undertaken. Although the absolute risk for familial occurring SSc is relative low, the relative risk for first-degree relatives is 13-fold higher compared to the normal population.[6] Several studies suggest that a positive family history for SSc is the strongest risk factor, but ethnicity also contributes.[6] Assassi et al suggest that members of SSc-affected families tend to show concordant scleroderma-specific autoantibodies.[7] Studies of the whole-genome microarray expression studies of skin biopsies and circulating blood cells support the involvement of multiple and complex pathways in the development of SSc.[6] Further support is provided from genetic association studies with candidate gene approaches. Most success has been observed in genetic analysis of individual components of the disease such as autoantibody profiles. These appear to have a strong genetic determinant, and this may underlie the apparent mutual exclusivity of the SSc hallmark reactivities. It has been demonstrated that the ability to mount an immune response to a particular SSc-associated antigen is restricted by major histocompatibility complex haplotype. Several studies suggest an association of HLA-DRB1*1302, DQB1*0604/0605 haplotypes with antifibrillarin positive patients,[8] while HLA SRB1*0301 occurs in patients with anti-Pm-Scl antibodies.[9] Observation from a large number of studies examining genetic markers has identified a number of candidate genes (AIF-1, CD19, CD22, CD86, CTLA-4, CCL-2, CCl-5, CXCL-8, CXCR-2, IL-1α, IL-1β, IL-2, IL-10, IL-13, MIF, PTPN22, TNF-α).[6,10] However, as with other complex diseases, in very many instances, it has not always possible to replicate initially promising data. Studies of genetically homogeneous populations have been especially informative, including those of the Choctaw nation of Native Americans. However, it is of interest that some of the associations are very plausible in terms of molecular pathogenesis. It is likely that epistasis and the effect of multiple modifier genes confound simple genetic association studies in SSc, just as in other complex diseases.[11]

IMMUNE EVENTS

There is substantial evidence of inflammatory changes in the skin and lung of patients with SSc. One example is the presence of highly specific hallmark autoantibodies, which are summarized in Table 157-1. The first inflammatory infiltrates in lesional skin are predominantly cells of the monocyte lineage[13] (T cells, macrophages, B cells, and mast cells). Later, T lymphocytes predominate and are detectable in both the circulation and affected organs. These T cells are predominantly $CD4^+$, bear markers of activation, exhibit oligoclonal expansion, suggesting an antigen-driven proliferation, and show a predominant Th2-helper phenotype.[14,15] Consequently, increased serum levels of Th2 cell-derived cytokines, i.e., IL-2, IL-4, IL-10, IL-13, and IL-17, have been observed in scleroderma patients.[16,17] Besides T cells, B cells are also found in involved skin. Several studies suggest that B cells are able to induce extracellular matrix (ECM) production through secretion of IL-6 and transforming growth factor-β (TGF-β) and are involved in the production of autoantibodies.

Several of these autoantibodies are associated with defined subsets of the disease and are important diagnostic markers (see Table 157-1). The potential role of autoantibodies in pathogenesis is a fascinating and

TABLE 157-1
Clinical Association of Hallmark Autoantibodies in Systemic Sclerosis (SSc)[12]

Reactivity	Target Antigen	Frequency in SSc (%)	HLA Association	Clinical Association
Centromere	CENP proteins speckled pattern	20–30	HLA-DRB1 HLA-DQB1	Limited skin sclerosis, severe gut disease, isolated PAH, calcinosis
Scl-70	Topoisomerase-1 speckled pattern	15–20	HLA-DRB1 HLA-DQB1 HLA-DPB1	Diffuse skin sclerosis, pulmonary fibrosis and secondary PAH, increased SSc-related mortality rate
RNAP III	RNA polymerase III speckled pattern	20	HLA-DQB1	Diffuse skin sclerosis, hypertensive renal crisis, correlated with a higher mortality rate
nRNP	U1-RNP speckled pattern	15	HLA-DR2, -DR4 HLA-DQw5, -DQw8	Overlap features of SLE, arthritis
PM-Scl	Polymyositis/Scl nuclear staining pattern	3	HLA-DQA1 HLA-DRB1	Limited skin sclerosis, myositis–sclerosis overlap, calcinosis
Fibrillarin	U3-RNP nuclear staining pattern	4	HLA-DQB1	Diffuse skin sclerosis, myositis, PAH, renal disease
Th/To	7–2RNP nuclear staining pattern	2–5	HLA-DRB1	Limited skin sclerosis, pulmonary fibrosis

exciting area. The majority of SSc cases have circulating antibodies. These include a number of hallmark reactivities, as well as autoantibodies, that occur in other autoimmune rheumatic diseases (e.g., anticyclic citrullinated peptide, rheumatoid factor) but also antibodies that may have functional significance, since they are directed against cell surface antigens [antiendothelial cell antibodies (AECA), antifibrillin antibodies, anti-PDGF receptor antibodies, etc.]. However, functional impact of these antibodies remains an area of investigation. The best evidence of functional significance is for antiendothelial cell autoantibodies and for antifibroblast-reacting antibodies. Recent reports suggest the presence of antifibrillin autoantibodies and stimulatory autoantibodies reacting with platelet-derived growth factor (PDGF) receptors, although this observation requires further confirmation.

Microchimerism and graft-versus-host disease mechanisms have been suggested in some cases, although the relatively high frequency of microchimerism in healthy individuals or other disease states suggests that this may be contributory rather than causal if it has a role in SSc.

VASCULOPATHY

Vasculopathy in SSc is based on inappropriate vascular remodeling and repair processes. It involves the microcirculation and arterioles and is very likely a primary event in the pathogenetic processes of the disease and precedes fibrosis. Vascular abnormalities are characterized by vasoconstriction, adventitial and intimal proliferation, inflammation, and thrombosis.[18] The earliest signs of vascular dysfunction are represented by enhanced vascular permeability with an imbalance between vasodilatory (NO, prostacyclin, calcitonin gene-related peptide) and vasoconstrictive mediators [endothelin 1 (ET 1), angiotensin II, α2-adrenoreceptors]. Consequently, the impaired blood-flow leads to tissue hypoxia, which induces strong expression of vascular endothelial growth factor (VEGF) and its receptors, associated with a defect of vasculogenesis. However, inflammatory cytokines like TNF-α may stimulate or inhibit angiogenesis depending on the duration of the stimulus.[19]

In addition to these functional abnormalities, intravascular and structural changes contribute to overt Raynaud phenomenon (RP), and in the course of time to progressive reduction of vessels and blood flow. These vasculopathies clinically manifest in all vessels of virtually all organs. Early lesions in the microcirculation because of structural damage are initially seen in the nail fold capillaries and as vasospastic responses in RP. Furthermore, vascular changes, i.e., overgrowth of the endothelium and deposition of scar tissue produce some of the major complications of SSc, including pulmonary arterial hypertension (PAH), scleroderma renal crisis (SRC), and digital vasculopathy.

FIBROSIS

SSc is a multisystem fibrotic disease. The initial inflammation and hypoxia in fibroblasts induces the production of several proteins that are involved in ECM remodeling as, for example, thrombospondin 1, fibronectin 1, lysylhydroxylase-2, TGF-β-induced proteins.[20] Deposition of excessive ECM in specialized organs is responsible for much of the morbidity and mortality of the disease. Fibrous connective tissue is deposited by activated fibroblasts and myofibroblasts. From an early stage in the disease, an autonomous population of fibroblasts appears to be established

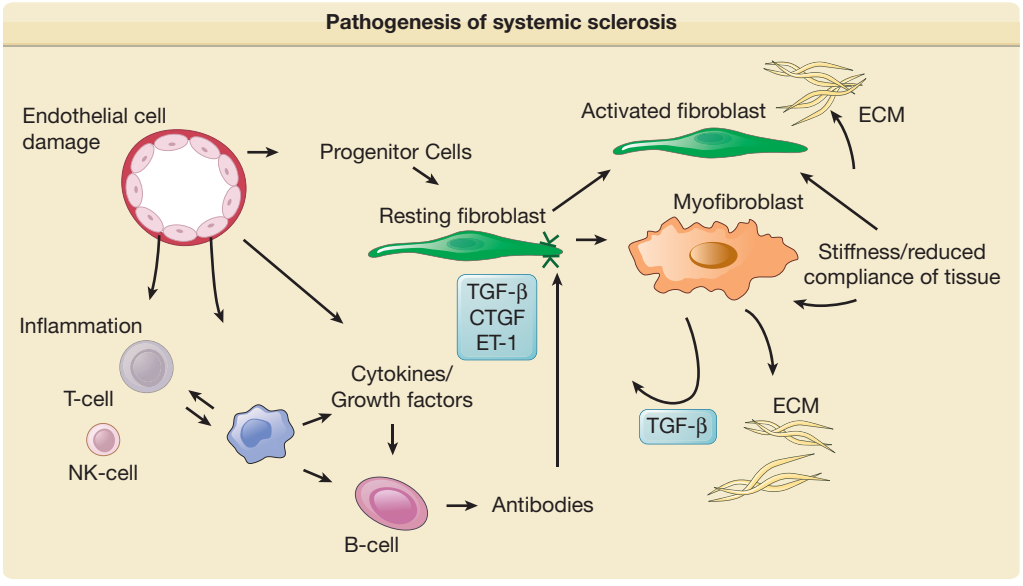

Figure 157-1 Pathogenesis of systemic sclerosis. The schematic shows how the development of systemic sclerosis results from a complex interplay between cells within the immune system, including adaptive and innate compartments, the vasculature, and the connective tissue. Cell–matrix interactions are important regulators of cellular functions. Early vascular events lead to later development of an autonomous population of activated fibroblasts and myofibroblasts that contract soft tissue and deposit excessive ECM. These cells may develop from resident connective tissue fibroblasts; transdifferentiation from other cell types, including activated microvascular pericytes; and recruitment of circulating progenitor cells (fibrocytes). The contribution of each lineage to the fibrotic lesion is still unclear. Many growth factors and cytokines are implicated as mediators of this process, and complex reciprocal networks may lead to a profibrotic microenvironment. Potential disease-modifying therapies could target individual mediators alone or in combination [e.g., tumor growth factor-β (TGF-β), endothelin (ET-1), connective tissue growth factor (CTGF), platelet-derived growth factor (PDGF)] or modulate immune cells (e.g., cyclophosphamide) or the endothelial cell (e.g., prostacyclin analogues). The extracellular matrix is an important repository for mediators that are later released and play a key role in pathogenesis. CCL = CC chemokine ligand; Ig = immunoglobulin; IL = interleukin.

that are responsible for the excessive production and accumulation of ECM. The initiators of this process include a number of key cytokines and growth factors that may represent logical therapeutic targets. The key factor seems to be a disturbed balance between synthetic and degradative mechanisms. Quiescent fibroblasts may be activated by TGF-β, connective tissue growth factor (CTGF), PDGF, or ET-1.[21–24] There is increasing evidence that fibroblasts are induced to differentiate into myofibroblasts, which are characterized by a high contractility, ECM production, and cytokine release. Together with altered biophysical properties of the resulting connective tissue this leads to persistent activation of fibroblasts leading to the excessive deposition of ECM components.

A schematic summarizing pathogenetic mechanisms is shown in Fig. 157-1.

ENVIRONMENTAL FACTORS

Scleroderma-like syndromes have been reported in association with numerous environmental toxins and drugs. These agents include solvents (vinyl chloride, benzene, toluene, epoxy resins), drugs (bleomycin, cardiopa, pentazocine, cocaine, docetaxel, metaphenylenediamine), and miscellaneous substances.[25]

SSc was reported to occur in underground coal and gold miners. In male patients with silicosis who were older than 40 years of age, the likelihood of developing SSc was approximately 190 times greater than in males not exposed to silica, and 50 times greater than in males without silicosis but exposed to silica dust.[26] The role of silicone gel implants and other silicone products in the development of scleroderma has been questioned.[27] However, most epidemiologic studies have failed to show a significant association. An unusual form of scleroderma characterized by RP, morphea-like skin changes, capillary abnormalities of the nail fold (similar to those in SSc), osteolysis of the distal phalanges, and hepatic and pulmonary fibrosis (PF) may occur in workers exposed to polyvinyl chloride. Bleomycin also produces PF, RP, and cutaneous changes indistinguishable from those of SSc.[27] The development of these changes appears to be dose-dependent and is reversible on discontinuation of the drug. Collectively, chemical exposures account for a small fraction of scleroderma-like diseases. Large epidemiologic studies have not yet revealed a significant role for toxins and drugs in scleroderma.

CLINICAL FEATURES OF SYSTEMIC SCLEROSIS

The clinical manifestations of SSc depend to a large extent on the subset and stage of disease. The clinical features of established SSc are diverse, include severe fibrosis of the skin with all additional cutaneous manifestations and reflect the multiple patterns of internal organ involvement and the consequences of progression of the underlying pathologic processes of vasculopathy, inflammation, and fibrosis. Particular consideration must be given to the hallmark complications of hypertensive SRC, PAH, PF, and gastrointestinal (GI) dysmotility.

CLASSIFICATION AND DEFINITION OF DIFFERENT SSC SUBSETS

The heterogeneity of SSc arises from the range of disease manifestations that vary in extent and severity of organ involvement between patients. However, some clinical features that are almost always present are RP and skin sclerosis. The extent of skin sclerosis defines each major disease subset. Each subset has particular features, although there are common features to each.

The American College of Rheumatology (ACR) published in 1980 preliminary classification criteria for SSc to classify patients with established disease,[28] showing 97% sensitivity and 98% specificity for SSc. The diagnosis is proven, if either one major criterion or at least two or more minor criteria are found. As major criterion are chosen scleroderma proximal to the metacarpophalangeal or metatarsophalangeal joints, and the minor criteria included sclerodactyly, digital ulcerations and/or pitting digital scars, and bibasilar PF.

Furthermore, in 1988 a descriptive subclassification of limited versus diffuse SSc by LeRoy,[29] which was primarily associated with the extent of cutaneous involvement, has been widely accepted and used in clinical practice. In 2001, LeRoy and Medsger[30] published amended criteria, with the additional presence of autoantibodies and nail fold capillaroscopic alterations. Furthermore, these criteria include a separate group of patients with early onset of SSc, with minimal skin thickening. It was mandatory that patients with early (limited) SSc have evidence of RP plus scleroderma-specific autoantibodies and/or nail fold capillaroscopic manifestations.[31,32] However, there are several other classifications published, for example, by Nadashkevich O et al, Maricq and Valter, etc.[32,33]

Diffuse cutaneous SSc (dcSSc) is defined as a progressive form with an early onset of RP, usually within 1 year of onset of skin thickening. This subset is characterized by rapid skin involvement of trunk, face, upper arms, and thighs, showing very frequently, anti-Scl 70 (antitopoisomerase-I) or anti-RNAPIII antibodies.[29] Furthermore, there is a higher propensity to develop PF, cardiac involvement, and SRC.

Limited cutaneous SSc is characterized by a long preexisting history of RP and skin changes of the extremities distal to the knee and elbow joints, including facial skin.[29] This variant of SSc-subset often (50%–70%) presents with anticentromere-antibodies (ACA) and is frequently associated with isolated PAH. The traditional acronym CREST (calcinosis, RP, esophageal dysmotility, sclerodactyly, and telangiectasias) is nowadays obsolete and assigned to the limited form of SSc.

Patients with features of scleroderma together with those of another autoimmune rheumatic disease are combined; are designated overlap syndromes. This is defined as a disease occurring with clinical aspects of SSc (according to the ACR-criteria) or main symptoms of SSc simultaneously with those of other connective tissue diseases or other autoimmune diseases such as dermatomyositis, Sjögren's syndrome, systemic lupus erythematosus, vasculitis, or polyarthritis. These patients present mostly high titers of anti-U1-RNP-, anti-nRNP-, antifibrillarin-, or anti-PmScl-antibodies.[34]

Patients suffering from early SSc, also known as undifferentiated SSc, are defined by positive RP and at least one further feature of SSc (positive nail fold capillary alterations, puffy fingers, pulmonary hypertension) and/or detectable scleroderma-associated autoantibodies without fulfilling the ACR-criteria.[35]

A very small proportion of cases (1.5%) develop vascular (RP and/or PAH), immunologic (most commonly anticentromere antibodies), and organ-based fibrotic features of SSc but do not show skin sclerosis.[36] Patients suffering from this subset are classified as SSc sine scleroderma.

In addition, the frequency and timing of different visceral manifestations of SSc differs between major subsets. However, there is some overlap between subsets in terms of organ-based disease and the extent and severity of skin sclerosis. In all patients, the extent and severity of skin sclerosis can be assessed by the modified Rodnan skin score (mRSS). Skin score at baseline correlates with disease severity and outcome in dcSSc. Thickening and fibrosis of the skin as one of the first recognized phenomenon in SSc still forms the basis of most classification criteria and proposed subsets of the disease.

Autoantibody-based classification of SSc has been proposed, and there is evidence from association studies that this may be clinically meaningful, as indicated in Table 157-1. Moreover, genetic association analysis using a candidate gene approach has demonstrated an association between serologically based subsets of SSc that are stronger than with SSc overall. The significance of this is uncertain, and it should be noted that a genetic basis for autoantibody reactivity has been well described, leading to the suggestion that the serologic subsets may be more genetically homogeneous than unselected SSc cases or clinically defined subsets of SSc.

ORGAN MANIFESTATION

VASCULOPATHY. Distinctive for this disease is the initial onset of RP, which appears in more than 90% of SSc-patients. It is defined by recurrent attacks of vasospasm of small digital arterioles/arteries at fingers and toes, usually caused by cold and/or other stimuli, for example, emotional stress. RP clinically appears suddenly and is clearly restricted and is accompanied by painful pallor/ischemia of single or several digits/toes, followed by reactive hyperemia after reheating at

Figure 157-2 Clinical feature of patients with early disease. **A.** Raynaud phenomenon with typical discoloration (white–blue pallor), localized mostly at fingers and/or toes as the result of vasospasm. Coldness and emotional stress are the most frequently triggers for these attacks. **B.** Limited disease with puffy fingers.

the end of a RP attack, in severe cases cyanosis (tricolore phenomenon) also ensues (see Fig. 157-2).

Patients presenting only with RP should be studied for capillary alterations as well as autoantibody-status. To identify and visualize vascular-cutaneous alterations due to SSc, nail fold capillaroscopy is a noninvasive, simple, and one of the most useful diagnostic and prognostic methods (see Table 157-2). Furthermore, it is

TABLE 157-2
Recommended Diagnostic Procedures in SSc[48]

Organ Involvement	Clinical Feature	Diagnostic Procedures
Vascular system	Raynaud phenomenon	■ Coldness provocation ■ Nail fold capillaroscopy ■ Antinuclear antibody levels
Skin	Scleroderma Calcinosis cutis	■ Clinical assessment regarding puffy fingers, telangiectasias, mechanic hands, hypo-/hyperpigmentations, digital ulcerations, dermatogenous contractures ■ Modified Rodnan skin score ■ 20-MHz ultrasound ■ Radiography (X-ray, MRI, CT)
Musculoskeletal system	Arthralgia/Synovitis Muscle weakness	■ Clinical assessment regarding fist closure-deficiency, joint contractures, tendon friction rub, muscle weakness ■ Laboratory parameters: erythrocyte sedimentation rate, rheumatoid factor, antinuclear autoantibodies ■ Creatine kinase (>threefold?) ■ MRI, electromyography ■ Muscle biopsy
Gastrointestinal tract	Reflux Dysphagia Diarrhoea, obstipation	■ Gastro-/Esophageal-endoscopy ■ Oesophageal-szintigraphy ■ Oesophagus-manometry ■ Coloscopy
Respiratory system	Dyspnoea	■ Lung function test (TLCOc SB, TLC, FVC) ■ Radiography (X-ray or HR-CT) ■ Bronchioalveolar Lavage (BAL) (optional)
Cardiac system	Dyspnoea, arrhythmia	■ Electrocardiography (conduction blocks?) ■ Echocardiography (mPAP, diastolic dysfunction?, ventricular ejection fraction) ■ (Spiro-)Ergometry ■ 24-hour blood pressure controls ■ Right-heart catheterization
Kidney	Renal function failure	■ Regular blood pressure controls (>140/90 mm Hg) ■ Ultrasound ■ Serum levels of creatinine, urine-analyses (protein-, albuminuria, microelectrophoresis)

Figure 157-3 Extensive skin involvement in patients with dSSc. **A.** Sclerodactyly with dermatogenous contractures (restricted mobility of digital joints) as well as salt-and-pepper typical hyper- and hypopigmentations. **B.** Microstomia (radial furrowing around the mouth) with the typical frenulum sclerosis. **C.** Skin hardening/thickening proximal of the metacarpophalangeal-joints. **D.** Scleroderma-typical facial physiognomy with hypermimia, microstomia, telangiectasias and a beaked nose.

a useful tool to categorize capillary changes into early, active, and late patterns. Furthermore, laser Doppler perfusion imaging (LDPI) is also a noninvasive microvascular imaging technique able to provide maps of the cutaneous blood flow.[37]

SKIN INVOLVEMENT

Skin involvement is a cardinal feature of SSc and usually appears first in the fingers and hands. Within time, patients develop nonpitting oedema of the fingers (puffy fingers) (see Fig. 157-2), hands, and extremities, whereupon an increasing induration and skin thickening appear (sclerodactyly). Depending on the localization of skin thickening, restricted mobility of joints (dermatogenous contractures), and/or restricted breath-excursion may be present. Typical facial features include telangiectasias, a beak-shaped nose as well as reduced mouth-aperture (microstomy). The typical physiognomy of FSSc patients is characterized by a radial furrowing around the mouth, no expression, a stiff and mask-like facial appearance, and sclerosis of the frenulum. Besides cosmetic/aesthetic problems, skin sclerosis causes considerable difficulties regarding eating and oral hygiene (summarized in Fig. 157-3).

The abnormal deposition of cutaneous and/or subcutaneous calcium (calcinosis cutis), usually occurs over pressure points (acral, joints) (see Fig. 157-4). Calcinosis cutis next to joints is designated as Thieberge–Weissenbach syndrome. Further skin manifestations include hypo- and hyperpigmented skin (salt and pepper) (see Fig. 157-3), loss of hair follicles and sweat glands (hypo-/anhydrosis).

Figure 157-4 Digital alterations with complications. **A.** Digital ulcerations at the fingertips. **B.** Digital ulcerations and necrosis of the fingertips. **C.** Severe calcifications with deposition of subcutaneous masses. **D.** Multiple ulcerations at bone protuberantes with inflammation in the surrounding sclerotic skin.

Skin involvement/scleroderma should be evaluated using mRSS. Usually, 17 sites are assessed and skin thickness is categorized to grade 1, 2, or 3, corresponding to mild, medium, and severe, according to palpation of the skin by a trained examiner (see Fig. 157-5). Furthermore, new techniques for calculating skin thickening have been evaluated. Besides mRSS[38] also 20-MHz ultrasound,[39] MRI,[40] and Plicometer[41] are useful methods to assess skin thickening (recommended diagnostic procedures are listed in Table 157-2). Further physical procedures to monitor skin fibrosis are Durometer,[42] Cutometer,[43] and Elastometer.[44] Besides all these non-invasive methods, a further appropriate but invasive method includes skin biopsy with histological evaluation of the dermal skin thickness. This also allows the characterization of the inflammatory infiltrates.

Approximately 50% of patients with SSc are affected by digital ulceration associated with vasculopathy at some point in their disease. This is the major external feature of structural vessel disease, probably due to thickened intima and lumen-occluded vessels. Tender and painful pitting scars are very frequent and, on occasion, progress to ulcers. These occur on the finger- or toe-tips, over the extensor surfaces of the joints due to microtrauma or in association with the above-mentioned calcinosis cutis. Digital ulcers are associated with strong, local pain and a major impact on quality of life regarding all-day functions, i.e., dressing, eating, etc. Other complications include critical digital ischaemia, paronychia, infections, gangrene, osteomyelitis, and finger pulp loss or amputation.

CARDIOPULMONARY MANIFESTATIONS

There are different ways that the cardiopulmonary system may be involved, most often appearing as fibrosis and PAH. The differentiation between these manifestations is often clinically difficult because of similar, overlapping clinical features, such as dyspnea, non-productive cough, disturbed diffusion-capacity, and cyanoses. PAH is currently the most common cause of disease-related death in SSc. It occurs in both limited and diffuse cutaneous subsets, although the most typical cases are those of limited SSc (lSSc) associated with isolated PAH. This condition has substantial similarities to idiopathic PAH. Thus, two patterns of disease occur in SSc. Most cases have PAH, but there are some patients with late-stage extensive interstitial lung fibrosis in SSc that develop a true secondary PH. Besides the right-heart worsening due to PAH, the heart could also be involved because of diffuse interstitial myocardio-fibrosis. This could lead to a diastolic dysfunction as well as a restricted contractibility of the myocardium. These patients clinically present cardiac arrhythmia, paroxysmal tachycardia, incomplete or complete right-heart blocks, and heart insufficiency.

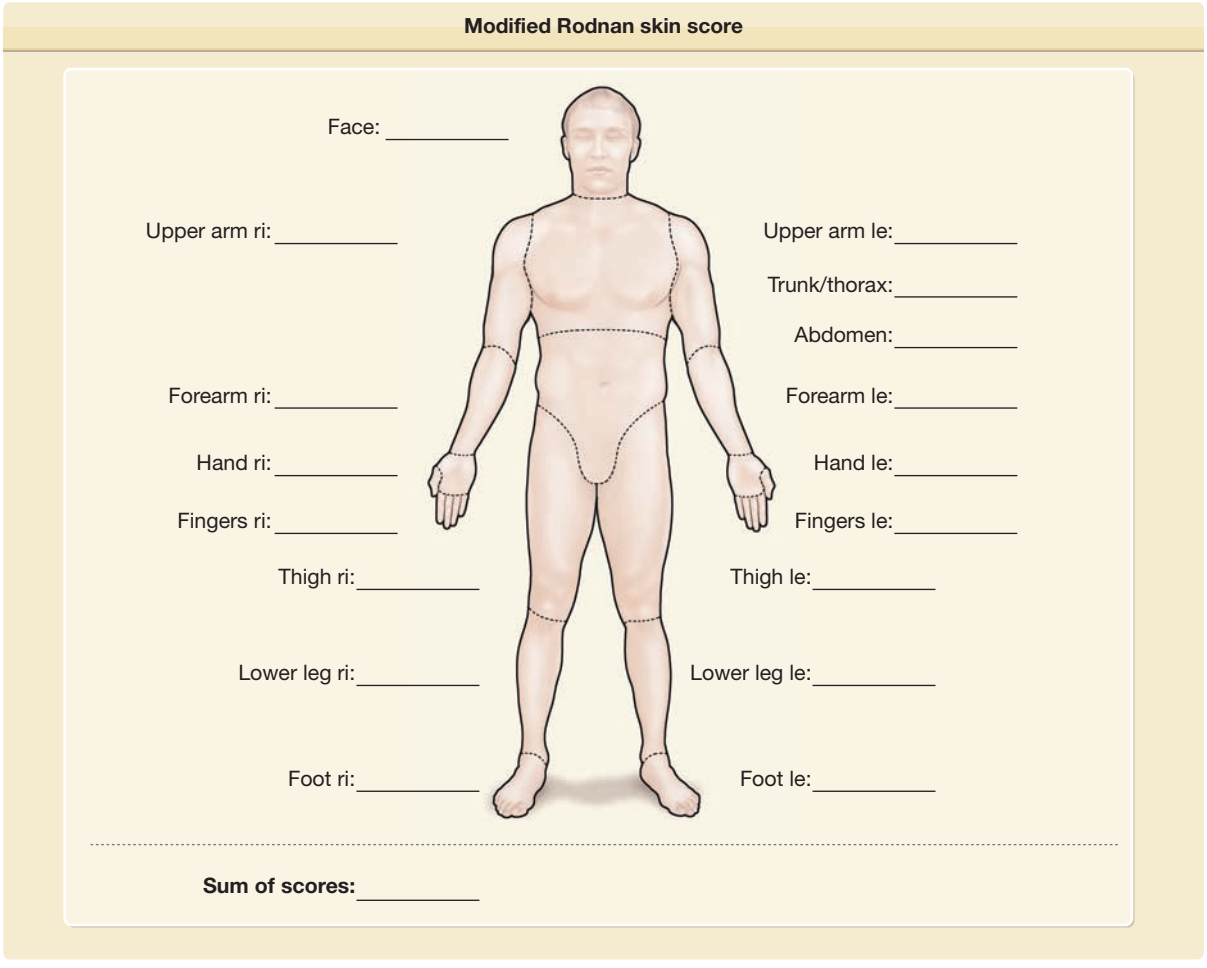

Figure 157-5 Modified Rodnan skin score (mRSS). Skin hardening will be evaluated with the modified mRSS that is usually performed by assessing the skin thickness at 17 different areas. The skin sclerosis is categorized by palpation to grade 1, corresponding to mild, 2, moderate, and 3, corresponding to severe ri = right, le = left.

Individuals with SSc should be followed up at least annually using pulmonary function tests, echocardiography, a 6-minutes walk test, and high-resolution computer tomography (HRCT). Pulmonary function tests are the most important techniques to determine possible cardiopulmonary involvement, because of impaired diffusion capacity (DLCO ≤75%) being an early marker of both lung fibrosis and PAH.

To determine the presence of interstitial lung involvement, i.e., subpleural localized line opacities, ground-glass opacities, and subpleural cysts with honeycomb formations, HRCT and/or thoracic X-ray should be used.

Follow-up should also include transthoracal-executed Doppler echocardiography, a noninvasive procedure, which can indicate a hypertrophy with or without enlargement of the right ventricle, paradoxical motion of the interventricular septum, tricuspid valve insufficiency, and pericardial effusion. Right-heart catheterization is indeed the gold standard, but an invasive diagnostic procedure for certain determination of PAH. Pulmonary arterial hypertension (PAH) is defined as a mean pulmonary pressure (mPAP) of >25 mm Hg at rest together with a pulmonary capillary wedge pressure of <15 mm Hg as determined by right-heart catheterization.[45,46]

Cardiac magnetic resonance imaging is also a further potential strategy for assessing myocardiac involvement in SSc. Besides imaging procedures, there is also some promise for the use of *N*-terminal brain natriuretic peptide (NTproBNP) to detect right ventricular impairment (see Table 157-2).

GASTROINTESTINAL INVOLVEMENT

GI involvement is the most common internal organ involvement in patients suffering from both, limited and diffuse SSc (>60%).[4] Many parts of the GI-tract may be impaired, affecting motility, digestion, absorption, and excretion.[47]

Esophageal involvement includes symptoms like dysphagia, heartburn due to reflux, nausea, and/or vomiting. A weakened lower esophageal sphincter and impaired peristalsis increase the risk for esophagitis. If untreated, this could lead to peptic esophagitis,

gastric/esophageal ulcerations, peptic stricture formations, and fistulae. Chronic gastroesophageal reflux can be complicated after a time by a higher risk of Barrett's esophagus, which may progress into an adenocarcinoma.

Possible gastric manifestations include atrophy of the mucous membrane associated with anacidity, ulcerations, and delayed gastric emptying.

SSc can also affect the intestine, and includes atonic dilatation, constrictions, malabsorption, pseudoobstructions, diarrhea, fecal incontinence, and severe malnutrition.

The presence of esophagitis can be determined by upper GI endoscopy with histological evaluations. Impaired motility of the esophagus can usually be diagnosed by scintigraphic evaluation following a radiolabeled meal or 24 hours ph-manometry (see Table 157-2).

KIDNEY INVOLVEMENT

SRC appears in 5%–10% of SSc patients, and may cause an abrupt onset of significant systemic hypertension (>150/85 mm Hg), proteinuria (>200 mg/g urine-creatinine), followed by an acute renal failure (≥30% reduction in estimated glomerular filtration rate). Studies suggest that a chronic vasculopathy with reduced glomerular filtration rate is frequent. In addition, there is evidence of an increase in fibrillar collagen deposition within the renal interstitium in SSc. Many cases occur within the first 12 months of disease, and in up to one-fourth of patients with SRC the diagnosis of SSc is made at the time of the renal presentation. End-organ damage can result in encephalopathy with generalized seizures or flash pulmonary edema. Microangiopathic anemia is common, and sometimes disseminated, intravascular coagulation develops. Nephrotoxic drugs and high-dose prednisolone (>7.5 mg/day) should be avoided in patients suffering from SSc. Early diagnosis is the key role in improving the outcome of SRC using regular blood pressure monitoring, urine-analyses microelectrophoresis, and determination of creatinine clearance (see Table 157-2).

HISTOPATHOLOGY

The histopathology of SSc shows fibrosis of the lower two-thirds of the dermis and the subcutaneous fibrous trabeculae, because of excessive deposition of ECM proteins, most notably collagen type I and III (Fig. 157-6).

Panniculitis and mucoid edema may also be prominent features in the early stages, whereby subcutaneous fat is replaced by a fibrous connective tissue. It is possible to differentiate histologically an early cellular stage on the one hand and a later fibrotic stage on the other hand. In the early stages, the dermis presents pathologically collagen bundles within the reticular dermis, and appear pale, homogenous, running parallel to the skin surface, and swollen, and there is often a perivascular lymphocytic infiltrate. These inflammatory cell infiltrates are localized between the collagen bundles but mainly around the vessels, and can also spread into subcutaneous fat tissue. The infiltrate can also entrap sweat glands. The epidermis often becomes atrophic in the overlying areas. Vessels of all sizes may be involved in SSc. In the early stages, there may only be dilatation of capillaries, then endothelial proliferation and complete occlusion of vessels occur. With the progression of scleroderma, the involved skin becomes more avascular and inflammation decreases. In later stages, pilosebaceous units and eccrine glands disappear, collagen bundles appear to be packed closely, and there may be an effacement of the rete ridges.

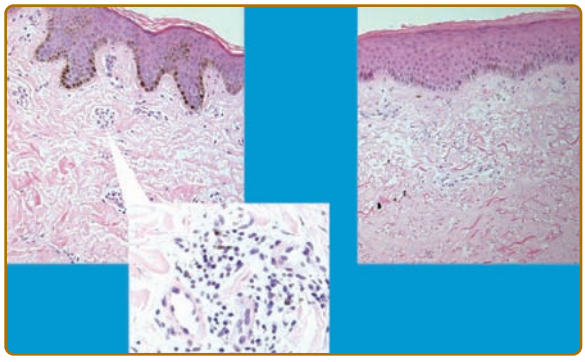

Figure 157-6 Histologic appearance of skin in early and late-stage diffuse cutaneous systemic sclerosis (dcSSc). In SSc, there is perivascular mononuclear cell infiltrate at the early stages of disease. This precedes the development of skin sclerosis. Perivascular changes are shown at high power in the left panel. Later stage disease is accompanied by skin sclerosis, a low density of blood vessels, and absence of inflammatory cells. At this stage, there may be associated epidermal changes with thickening and loss of secondary skin structures, including hair follicles and sweat glands. Absence of the rete ridges is also characteristic at the later stages of dcSSc. Similar changes are predicted in localized cutaneous SSc, but this is rarely biopsied due to limited skin sclerosis and concerns about healing.

DIFFERENTIAL DIAGNOSIS

The diagnosis of SSc is clinical. Although there are classification criteria that were developed to facilitate the distinction of SSc from other connective tissue diseases, no formal diagnostic criteria have been developed. The main differential diagnosis is with other conditions within the scleroderma spectrum and with the scleroderma overlap syndromes. There are several differential diagnoses, which imitate scleroderma, i.e., circumscript (localized) scleroderma, eosinophilic fasciitis, sclerodermiform genodermatoses, acrodermatitis chronica atrophicans, scleroderma-like syndromes induced by environmental factors, scleroderma adultorum Buschke, scleroderma diabeticorum, sclero-myxoedema, nephrogenic fibrosing dermopathy, porphyria cutanea tarda, graft-versus-host disease, and scleroderma-like lesions in malignancies. More details are summarized in Table 157-3).

TABLE 157-3
Differential Diagnosis of Systemic Sclerosis (SSc)

Differential Diagnosis
- Other disorders within the scleroderma spectrum
- Circumscript (localized) scleroderma (morphea)
- Eosinophilic fasciitis
- Lichen sclerosus et atrophicans
- Acral Vasospasm
  - Raynaud phenomenon (primary versus secondary)
  - Other autoimmune rheumatic diseases
    - Systemic lupus erythematodes
    - Rheumatic diseases
    - Dermato-/polymyositis
  - Other vascular diseases
    - Hematologic
      - Cryoglobulinemia
      - Cold agglutinin disease
      - Hyperviscosity syndrome
- Systemic vasculitis
- Buerger disease (thromboangiitis obliterans)
- Macrovascular disease
- Other Causes For Skin Sclerosis
  - Sclerodermiform genodermatoses (e.g., progeria, acrogeria)
  - Sclerodermiform acrodermatitis chronica atrophicans
  - Scleroderma adultorum Buschke
  - Scleroderma diabeticorum
  - Scleroderma amyloidosum
  - Scleromyxedema
  - Nephrogenic fibrosing dermopathy
  - Porphyria cutanea tarda
  - Sclerodermiform chronic graft-versus-host disease
  - Eosinophilia–Myalgia syndrome

DISEASE-MODIFYING TREATMENT

Three facets of SSc are potentially amenable to therapeutic modulation, and this raises the possibility of true disease-modifying treatment. At present, vascular therapies and immunomodulation have the widest range of candidate therapies. These approaches are summarized in Tables 157-4 and 157-5. Antifibrotic treatment remains much more of a challenge. Some encouragement is provided by recent clinical trials of idiopathic PF. However, at present there is no proven antifibrotic agent. Further details about possible treatment approaches are provided in Table 157-6. A simplified schematic for integrating putative disease-modifying therapy with programs of screening and surveillance that permit timely intervention in SSc is shown in Figure 157-7 with organ-based strategies that currently form the basis of the majority of SSc therapeutics. Possibilities for targeted disease modifying therapy depend on the availability of therapeutic agents and a clear understanding of their role in pathogenesis.

There has been much more success in the field of organ-based therapeutics in SSc.

DIGITAL VASCULOPATHY AND ITS COMPLICATIONS

Simple but important recommendations include the reduction of vasoconstriction by avoiding precipitating factors like nicotine, sympathomimetics, emotional

TABLE 157-4
Immunomodulatory Strategies for Treatment of Systemic Sclerosis

Agent	Clinical Trial Data
Cyclosporin A (CyA)	■ Open study, 10 patients. Improvement in skin score.[49] ■ RCT, combination of low-dose CyA with iloprost; 20 patients. Improvement of skin, microvascular, and esophageal parameters.[50]
Methotrexate (MTX)	■ RCT, placebo-controlled trial, 29 patients; Significant improvement in skin score ($p = 0.06$).[51] ■ RCT, placebo-controlled trial, 73 patients; improvement of mRSS.[52] ■ Placebo-controlled, 18 patients; clinical improvement in the MTX group.[53]
Cyclophosphamide (CyC)	■ Minor effect on lung function tests but significant benefit for skin and disability in Scleroderma Lung Study of oral cyclophosphamide for 12 month.[54] ■ Randomized, unblended trial, 30 patients; significant improvement in mRSS, attack frequency of RP and erythrocyte sedimentation rate.[55] ■ Scleroderma lung study, 153 patients; one year of treatment leads to an improvement in health-related quality of life.[56]
Immunoablation/stem cell transplantation	■ Ongoing studies in United States and Europe.[57]
Extracorporeal photopheresis	■ Multicenter, RCT, placebo-controlled and double-blind; 64 patients. Significant improvement of skin and joint manifestation.[58]
Antithymocyte globulin oral tolerization to type I collagen	■ Pilot study of 13 patients; combination with mycophenolate mofetil in dSSc; improvement of skin score.[59] ■ Open pilot study, ten patients with early SSc no improvement in skin and pulmonary features.[60]
Mycophenolat mofetil (MMF)	■ Retrospective chart review of 17 patients, show stable pulmonary function.[61] ■ Retrospective analysis of 109 patients, well tolerated and seems to be at least as effective as other current treatment options.[62]
Rapamycin	■ Single-blind pilot study, 18 patients with dSSc; mRSS improved significantly as well as the patient's global assessment.[63]

TABLE 157-5
Therapies for Raynaud Phenomenon and Digital Ischemia in Systemic Sclerosis

Intervention	Evidence
Calcium channel blockers (nifedipine) Diltiazem	■ Several studies confirm benefit of this class of drug for Raynaud phenomenon.[64,65] ■ Two RCTs gave contradictory results.[64,66]
Angiotensin-converting enzyme inhibitors	■ Anecdotal support for benefit in Raynaud phenomenon and proven efficacy in scleroderma renal crisis.[67]
Angiotensin receptor blockers	■ Study suggests superiority over nifedipine in small trial.[68]
Antioxidant agents	■ Study suggests benefit for probucol, a synthetic antioxidant, in Raynaud phenomenon. Antioxidant vitamins not helpful in clinical trials.[69,70]
Prostacyclin analogues	■ RCT, placebo-controlled trials, intravenous iloprost effective for Raynaud phenomenon ■ RCT, placebo-controlled trial; oral iloprost not effective at low dose, and side effects limit higher dose treatment.[71] ■ RCT, placebo-controlled trial; intravenous iloprost significantly effective for healing digital ulcers.[72]
α-Adrenergic blockers	■ Preliminary studies suggest benefit compared with placebo.[73]
Endothelin receptor blockade	■ Two large placebo-controlled studies show reduction in new digital ulcer formation on bosentan. No effect on healing of established ulcers.[74]
Anticoagulants	■ One study suggests benefit for low-molecular-weight heparin.[74]
Serotonin reuptake inhibitors	■ Small study suggested benefit over nifedipine and favorable side-effect profile.[75]
Phosphodiesterase type 5 inhibitors	■ Uncontrolled studies of sildenafil and tadalafil suggest benefit for Raynaud phenomenon.[76]
Nitrate formulations	■ Uncontrolled trials suggest benefit for Raynaud phenomenon. Vasodilator side effects may limit usefulness.[84]

TABLE 157-6
Recommended Therapeutic Strategies for Internal Organ Involvement in SSc

Organ Involvement	Clinical Feature	Therapeutic Options
Vasculopathy	RP DU	Consistent warm keeping, Paraffin-bath Calcium channel blockers (nifedipine, creeping) p.o. Iloprost i.v. Bosentan p.o. Sildenafil p.o. (off-label) Wound dressing (hydrocolloid membrane, mepilex)
Musculoskeletal system	Synovitis/myositis	Methotrexate (p.o., i.m.)
Gastrointestinal tract	Reflux Dysphagia Diarrhea, obstipation	PPI, procinetica H_2-receptor-antagonists Change habit of eating Antibiotics (Erythromycin)
Respiratory system	Dyspnoea Alveolitis/lung fibrosis	Oxygen Cyclophosphamide p.o. or i.v. Azathioprine p.o. Glukokortikoide (short dated)
Cardiac system	PAH	Oxygen Diuretics Bosentan p.o. Sildenafil p.o. Epoprostenol p.o.
Kidney	SRC	ACE-Hemmer (high-dosed)

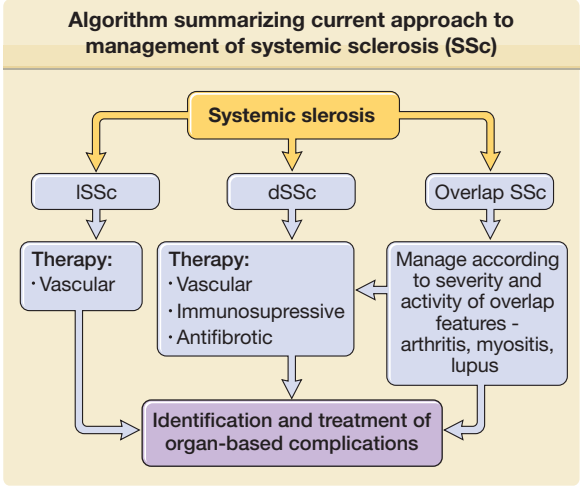

Figure 157-7 Algorithm summarizing current approach to management of systemic sclerosis (SSc). The principles of therapy for SSc include accurate diagnosis and treatment according to the disease subset, the presence of overlap features, and the likely predominant pathologic process according to the stage of disease. In all cases, screening for and treatment of organ-based complications has a major role in successful management. Education of patients and a multidisciplinary team, including specialist nurses, physiotherapists, occupational therapists and many subspecialty physicians, and surgeons, are central to providing appropriate care for severe cases of SSc. dSSc = diffuse systemic sclerosis; lSSc = limited systemic sclerosis.

stress and coldness, and instead to pay attention to have a heated home, thick and airtight clothes, heatable gloves, soles, or infrared hyperthermy, regular paraffin bath treatments, and minimal trauma.

Current local management of digital ulcers includes a combination of nonpharmacological care, antibiotics (in case of infection), analgesia, and individually applied wound dressings, if necessary.

Potential pharmacological treatment requires optimal therapy for RP, including agents that may have the potential for vascular remodeling and/or dilatation, such as calcium channel blockers, i.e., nifedipine, that should be considered as first-line therapy, while experience with other treatment options such as diltiazem, ACE-inhibitors, etc, have given contractory results.[64,65,66,67,77]

Parenteral prostacyclin derivatives, in particular iloprost, are widely used, and help to heal digital ulcers and may prevent recurrent lesions. Prostacyclin derivatives by intravenous infusion are the mainstay of therapy for critical digital ischaemia.[71,72] Antiplatelet agents such as aspirin or clopidogrel are used especially in critical digital ischaemia.

More recently, there has been enthusiasm about therapies that are effective for PAH in digital vasculopathy. Thus, Bosentan, an oral dual specificity endothelin receptor antagonist, has been demonstrated in two large controlled trials to significantly reduce the number of new digital ulcers, compared with placebo.[78] No positive effect on healing of established ulcers has been demonstrated. Other agents, such as phosphodiesterase type 5 inhibitors sildenafil and tadalafil, have also been used for treatment of RP and digital ulcers, but prospective clinical trial data are not available.[76] Surgical treatments include digital microarteriolysis, which can benefit single fingers with refractory ulcers. Whenever possible, surgical amputation of digits is avoided, and prolonged treatment with parenteral prostacyclin and potent analgesia may help with this. Lumbar sympathectomy may be helpful for lower limb RP or ulceration. Generally, a temporary procedure is performed initially to determine the likely benefit from a definitive sympathectomy. In cases of critical digital ischemia, antiplatelet therapies are often given, with anecdotal reports of the benefit of clopidogrel in preventing digital infarction (see Table 157-5 and 157-6).

SKIN INVOLVEMENT

A key element in the management of skin manifestations of SSc physical therapy and regular exercise to maintain circulation, joint mobility, and muscle strength to improve the quality of life of SSc patients. Skin affected by scleroderma tends to be very dry, taut, and susceptible for trauma.

Skin hardening may be improved by physical therapy and exercise, lymphatic drainage, topical treatment with steroids, calcineurin inhibitors, and moisturizing crèmes. Systemic therapies include immunosuppressive drugs, systemic steroids (for just a short time), and phototherapy (UVA1 or PUVA). UVA1-irradiation appears to inhibit fibrotic and inflammatory processes and reduce the amount of sclerotic skin.

Dry and itching skin should be treated topically with steroids, cannabinoid agonists, capsaicin, emollients, and phototherapy (see above). Local steroid injections and laser or surgical therapies could also be tried for the treatment of calcinosis cutis.

Laser therapies or noninvasive methods like camouflage have been used for telangiectases. Bleaching agents, salicylic acids, and chemical peels as well as camouflage, retinoids, or corticosteroids may have the potential to improve hyper- or hypopigmentations[79] (see Table 157-7).

Two randomized clinical trials have shown that methotrexate improves the skin score in early diffuse SSc, while positive effects on other organ manifestations have not been established.[51–53] On the other hand, cyclophosphamide has been shown to improve skin sclerosis in two randomized clinical trial.[54,55] All other systemic treatment options have not demonstrated success (see Table 157-4). Protein kinase-inhibitors (e.g., imatinib) have recently been used but controlled clinical trials have not yet been reported.

CARDIOPULMONARY MANIFESTATIONS

It is increasingly appreciated that a group of patients with some lung fibrosis have predominantly PAH and that this group may respond to standard PAH therapies. There have been substantial advances in the treatment of PAH over the past decade. Most cases are treated with oral agents: either an endothelin receptor antagonists (e.g., bosentan, ambrisentan) or a phosphodiesterase

TABLE 157-7
Therapeutic options for Skin Involvement in SSc[79]

Clinical Feature	Therapeutic Options
Skin hardening	■ Lymphatic drainage ■ Physiotherapy ■ Topical treatment with steroids or calcineurin inhibitors ■ Systemic treatment with steroids (short dated) and/or immunosuppressants ■ Phototherapy (PUVA, UVA1, ECP)
Dryness and itching	■ Topical treatment with steroids, capsaicin ■ Cannabinoid agonists ■ Emollients ■ Phototherapy (PUVA, UVA1) ■ Systemic treatment with antihistamines or gabapentin
Digital ulcerations	■ Intravenous iloprost ■ Bosentan p.o. ■ Hydrocolloid dressings ■ Skin substitutes ■ Physical therapy
Calcifications	■ Bisphosphonate p.o. ■ Local corticosteroid injection ■ Laser therapy ■ Surgery
Telangiectases	■ Laser therapy ■ Camouflage
Hyper- and hypopigmentation	■ Bleaching agents, camouflage, sunscreens ■ Salicylic acid and chemical peelings ■ Hydroquinone, retinoids, corticosteroids

5 inhibitor (e.g., sildenafil, tadalafil) once they are significantly functionally limited (New York Heart Association class III). Later, if progression takes place, combination of oral treatment or introduction of parenteral prostacyclin is used, by either the intravenous or subcutaneous route. Inhaled delivery systems for iloprost are available.

Although PAH is probably responsible for more deaths than lung fibrosis in SSc, lung fibrosis remains an important complication. Treatment of SSc-PF remains challenging.[80] Adding to a substantial body of uncontrolled or retrospective data suggesting benefit for cyclophosphamide in SSc-PF, the results of two randomized double-blind placebo-controlled trials have recently been reported. Both show a modest placebo-subtracted benefit for cyclophosphamide.[56,81,82] For change in forced vital capacity (percent predicted), this was statistically significant for the Scleroderma Lung Study comparing oral cyclophosphamide with placebo, showing a strong trend ($p = 0.06$) in the trial of intravenous cyclophosphamide followed by oral azathioprine. At present, most centers use cyclophosphamide as treatment for severe or progressive SSc-PF, defining the extent and severity by pulmonary function tests and HRCT. The extent of disease by HRCT and a history of progressive restrictive abnormality on pulmonary function tests is the best predictor of future decline in lung function and is generally used to make decisions about therapy. Other therapies that are in use include carbocysteine and low-dose corticosteroids. The place of other immunosuppressive strategies remains uncertain and requires evaluation in prospective multicenter clinical trials. It is noteworthy that despite strong theoretic rationale as a treatment for lung fibrosis, the endothelin receptor antagonist bosentan was not superior to placebo in a recent large multicenter study of SSc-PF cases.

Cardiac involvement from SSc is also an important contributor to mortality but remains one of the least

TABLE 157-8
Frequency of Organ Involvement in Two Networks for Systemic Sclerosis (Germany and United Kingdom)

	Diffuse SSc		Limited SSc	
Clinical Features	**Germany ($n = 780$)**	**United Kingdom ($n = 741$)**	**Germany ($n = 1190$)**	**United Kingdom ($n = 1505$)**
Raynaud phenomenon	95.3%	97.0%	96.3%	99.0%
Skin Hardening	95.9%	100.0%	90.0%	90.0%
Digital ulcerations	36.0%	28.0%	24.3%	13.0%
PAH	20.2%	12.0%	14.0%	15.0%
Lung fibrosis	62.9%	38.0%	26.7%	16.0%
GIT involvement	65.2%	90.0%	60.7%	90.0%
Heart involvement	20.0%	3.0%	9.9%	1.0%
Kidney involvement	15.9%	19.0%	9.7%	3.0%
Musculoskeletal inv.	48.8%	45.0%	38.8%	35.0%

well understood and poorly recognized of the internal organ complications of SSc. A large number of studies confirm that radionuclide imaging, electrophysiologic, and functional abnormalities are frequent in SSc, but the significance of these findings is uncertain. Hemodynamically significant cardiac involvement occurs in up to 10% of cases of dcSSc. An inflammatory component of myocarditis may respond to immunosuppression, and so an operational approach to management of cardiac scleroderma is indicated in Fig. 157-7. This is not based on data but could form the basis for prospective evaluation of the significance of impaired left ventricular ejection fraction and elevated circulating troponin levels in SSc.

There have been many advances in SSc, including a better appreciation of the diversity of the condition, improved understanding of the underlying pathologic mechanisms, and major progress in treating organ-based complications. This includes the accumulation of robust clinical trial data that demonstrate effectiveness or lack of benefit of individual therapies and in validation of measures of disease assessment.[83]

GASTROINTESTINAL INVOLVEMENT

Involvement of the GI tract is very frequent in SSc. Esophageal symptoms can respond very well to proton pump inhibitors and agents that increase lower esophageal sphincter tone such as domperidone. Midgut involvement takes many forms. Pseudo-obstruction requires conservative management initially but may require parenteral nutritional supplementation. Small intestinal bacterial overgrowth can be treated using broad-spectrum antibiotics, and pancreatic insufficiency may require enzyme supplements. Large bowel involvement is a major challenge. Anorectal incontinence sometimes responds well to an implanted sacral nerve stimulator or to less elaborate approaches such as bioplastic injection to increase the internal anal sphincter bulk. Associated rectal prolapse may require additional surgical intervention. Chronic constipation, sometimes with overflow diarrhea, is a common problem. An adjustment to diet and judicious use of stimulating, softening, or bulking aperients is recommended, but an individualized approach with substantial patient involvement is generally the most successful approach. On occasion, defunctioning colostomy is needed, but this is only appropriate in a very limited number of cases.

SCLERODERMA RENAL CRISIS

Overall, approximately two-thirds of cases of SRC presenting to a specialist center require renal replacement therapy. Of these, approximately one-half of cases eventually recover sufficiently to discontinue dialysis. This can occur over 24 months after the crisis, and so decisions about renal transplantation should be postponed until that time. The possibility of late recovery distinguishes SRC from other causes of end-stage renal failure. These outcomes are possible through the use of angiotensin-converting enzyme inhibition as routine therapy for SRC. Before their availability, the mortality from established SRC was more than 90% at 12 months. The most critical aspect of management of SRC is prompt identification and treatment of significant hypertension in the context of scleroderma, with initiation of ACEi. This is a medical emergency and any features of renal impairment or end-organ damage should prompt hospitalization.

The frequency of organ involvement in two networks for SSc (Germany and United Kingdom) are seen in Table 157-8.

Chapter 158 :: Scleredema and Scleromyxedema

:: Roger H. Weenig & Mark R. Pittelkow

Disorders characterized by excessive mucin deposition, increased collagen production, or fibrocyte hyperplasia are historically categorized as mucinoses, sclerosing disorders, and fibrosing disorders, respectively. The fibroblast is central in each of these conditions. Thus, shifting our focus from the fibroblast product (mucin, collagen, and fibrosis) to the cell of origin, the fibroblast and the mechanisms that stimulate specific fibroblast activities will provide better understanding of the histopathogenesis of these diseases and also lays a foundation for the development of more effective treatments for these incapacitating conditions. In some disorders, a singular fibroblast activity predominates, such as excessive mucin or collagen production [pretibial myxedema (see Chapter 151) and sclerodermoid disorders respectively (see Chapter 157)]. In others, a combination of excessive mucin and collagen production is observed (scleredema) or excessive mucin production and fibroblast hyperplasia occurs [scleromyxedema and nephrogenic systemic fibrosis (see Chapter 150)].

Fibroblasts are derived from CD34-positive hematopoietic precursors that originate in the bone marrow and populate the skin during development and wound repair. The chief role of the skin fibroblast is to deposit collagen, elastin, and ground substance, the major constituents of the dermis and pannicular septae and the substrate to which the epidermis and skin appendages attach (see Chapter 63).

The stimuli that cause fibroblasts to overproduce mucin or collagen or to proliferate or aberrantly immigrate into skin are varied. Infectious triggers, inflammatory states, diabetes mellitus, drugs, genetic mutations, and toxins as well as specific mediators such as eicosanoids, growth factors, cytokines, immunoglobulin-paraproteins, and other circulating factors have been implicated, but the precise mechanisms that result in fibroblast pathology (fibropathy) are poorly characterized. Some of these stimuli may recruit bone-marrow-derived fibroblast precursors to the skin; others may act directly on fibroblasts already residing in the skin.

This chapter will discuss scleredema and scleromyxedema. Other diseases relevant to cutaneous fibroblasts are discussed elsewhere in this textbook and listed in Table 158-1.

SCLEREDEMA

HISTORICAL ASPECTS

Scleredema was described by Buschke in 1902[1] and is also designated as scleredema of Buschke and scleredema adultorum, although the latter is a misleading term because children or adolescents can develop the condition.

SCLEREDEMA AT A GLANCE

- Acute skin induration characterized by dermal mucinosis and mild sclerosis
- Disease associations:
  - Postinfectious scleredema of youth
  - Diabetes mellitus-associated scleredema of adulthood
  - Paraproteinemia-associated scleredema
  - Rare associations: hyperparathyroidism, connective tissue disease, human immunodeficiency virus infection
- Histopathology: pandermal thickening with broad collagen bundles separated by mucin deposits, chiefly hyaluronate.
- Clinical course:
  - Postinfectious: usually resolves in 1–2 years
  - Diabetes mellitus-associated: may improve with better control of diabetes, but a prolonged course is expected
  - Paraprotein associated: often more chronic although remissions observed with specific treatments
  - Treatment: treat underlying disease; UVA-1; psoralen plus ultraviolet A light

EPIDEMIOLOGY

Scleredema is rare, although the precise incidence and prevalence are unknown. Men and women are affected with equal frequency. More than half of cases of scleredema occur in childhood or adolescence, most commonly after an upper respiratory tract infection.[2] Streptococcal infection is most commonly identified, but other infectious agents have also been implicated. Disease development in adulthood in association with adult-onset diabetes mellitus is the second most common presentation of scleredema. Uncommonly, scleredema occurs in association with paraproteinemia or multiple myeloma, and this association possibly is becoming more common as other causes diminish in frequency with better treatment and management of underlying disease.

■ Degos disease	171

PATHOGENESIS

Type 1 collagen and hyaluronate appear to be the major fibroblast products that are increased in scleredema-affected skin.[3–5] The precise mechanism(s) for increased collagen and glycosaminoglycan production in scleredema is not known. Stimulation of fibroblasts by serum factors or immunoglobulin may be related to the pathogenesis of scleredema, particularly cases associated with infectious agents or a paraproteinemia. Serum from a patient with scleredema associated with paraproteinemia was able to increase collagen production by cultured fibroblasts in vitro.[6] However, the factor(s) involved has not been elucidated. Other soluble circulating cytokines and small molecule mediators likely also play critical roles.

Figure 158-1 Scleredema. Waxy, nonpitting induration of back skin.

CLINICAL FINDINGS

The clinical findings of scleredema are distinctive. An acute onset of nonpitting induration of neck, shoulders, and upper back skin may be followed by involvement of the face and arms. Characteristically, the affected skin appears smooth and waxy, with tense dermal induration and prominent follicular ostia, at times imparting a "peau d'orange" appearance (Fig. 158-1). In general, however, skin changes are better felt on palpation than seen. The skin of the upper trunk (especially the back) is a favored site for scleredema, but more widespread involvement may be observed. The affected and unaffected skin blend imperceptibly. Scleredema involving the esophagus, bone marrow, nerve, liver, or salivary glands has been described rarely.[7,8] However, investigations to identify internal organ involvement by scleredema are infrequently pursued. Patients may report symptoms of restricted motion of joints, the tongue, or eyes, as well as weak or tender muscles.

HISTOPATHOLOGY

Punch biopsies of affected skin reveal a nontapered (square) appearance on low power. The proportion of dermis in dramatically increased in comparison to adjacent nonaffected skin (Fig. 158-2A). A decreased number or higher placement of eccrine units may be appreciated. Fibroblasts are normal in number and morphology. The collagen bundles are slightly thickened and separated from each other by subtle deposits of mucin. Stains for mucin (alcian blue, colloidal iron) are often used to identify the mucin deposits (Fig. 158-2B).

PROGNOSIS AND CLINICAL COURSE

Postinfectious scleredema usually abates in 1–2 years. Scleredema associated with adult-onset diabetes tends

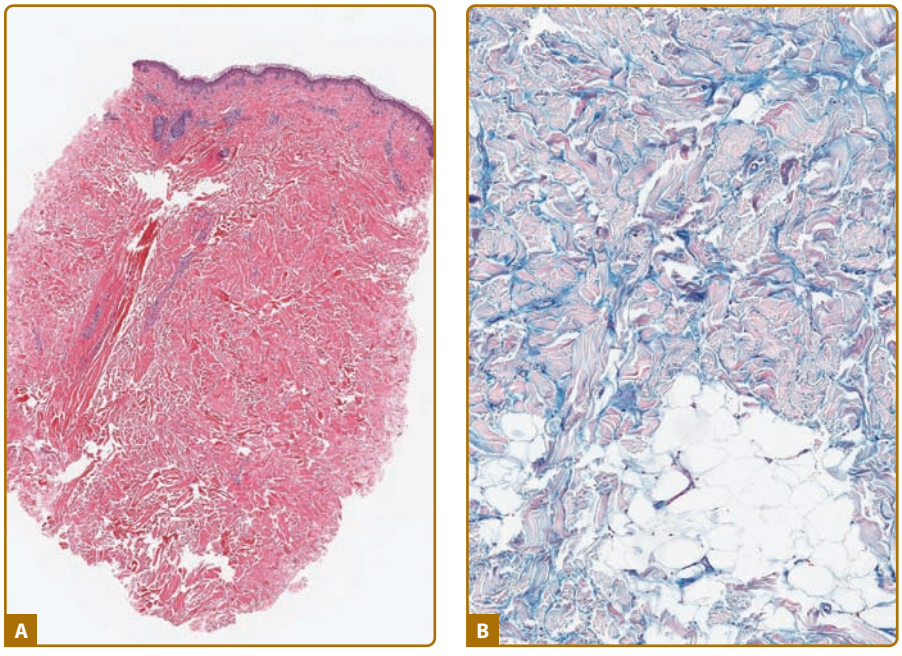

Figure 158-2 **A.** Scleredema. Thickened dermis characterized by enlarged collagen bundles separated by clear spaces (15 × original magnification). **B.** Scleredema. Mucin deposition identified in clear spaces by acid mucopolysaccharide stain (80 × original magnification).

to be protracted, although some patients appear to improve with better glucose control. Gammopathy-associated scleredema is more chronic and can be resistant to many therapies.

TREATMENT

Antibiotics do not appear to affect the course of postinfectious scleredema. Treatment of the associated disease (e.g., improved glucose control or treatment of paraproteinemia) may lead to improvement. Ultraviolet A1 phototherapy has been reported effective in a few adult patients,[9,10] as has psoralen plus ultraviolet A phototherapy.[11] Treatment with methotrexate did not provide benefit in a series of cases of scleredema. Scleredema has responded to local radiotherapy or electron-beam irradiation. Scleredema associated with monoclonal gammopathy has responded to extracorporeal photopheresis.

SCLEROMYXEDEMA

SCLEROMYXEDEMA AT A GLANCE

- Chronic, progressive condition characterized by dermal fibrosis and mucinosis and normal thyroid function
- Usually associated with paraproteinemia
- Clinical variants
  - Generalized, confluent lichenoid eruption (scleromyxedema)
  - Discrete papular (rarely nodular) eruption on the trunk or extremities (lichen myxedematosus)
    - Papular mucinosis of infancy
    - Papular mucinosis of adulthood
    - Self-healing papular mucinosis
    - Acral persistent papular mucinosis
    - Nodular variant
  - Localized or generalized lichenoid plaques (but distinct from plaque-like mucinosis/reticulated erythematous mucinosis)
  - Urticarial plaques
- Histopathology: superficial to mid-dermal fibroplasia and mucin deposition
- Clinical course: chronic progressive course and poor outcome in generalized cases; localized and self-healing forms have a better prognosis
- Treatment: correct paraproteinemia: through melphalan therapy, intravenous immune globulin, autologous stem-cell transplant

EPIDEMIOLOGY

Lichen myxedematosus/scleromyxedema is a rare disease afflicting men and women with equal frequency and symptom onset in mid to later life.

PATHOGENESIS

The pathogenesis of scleromyxedema is unknown. Most patients with scleromyxedema have a monoclonal paraproteinemia, typically designated as monoclonal gammopathy of undetermined significance (MGUS). Rare patients meet criteria for multiple myeloma. Excessive hyaluronate production and fibroblast proliferation are observed, but support for a direct effect of the monoclonal protein on fibroblasts is lacking.[15,16] Indirect mechanisms appear to include circulating cytokines, inflammatory mediators, and fibroblast precursor cell lineages that migrate from the blood, take up residence in the dermis and, in more extensive cases, in other tissues, and synthesize mucin.

CLINICAL FINDINGS

Several distinct clinical presentations, and hence nosologic designations have been recognized. Although there is considerable clinical overlap and patients may show progression from limited to widespread involvement, it is useful to distinguish localized from generalized disease as well as patients that present with discrete papules from those with confluent plaques. The generalized lichenoid eruption consists of numerous minute (1–3 mm) papules scattered on the extremities and the trunk. Scleromyxedema presents with confluent lichenoid plaques. Individual lesions and plaques may exhibit marked erythema or hyperpigmentation. The face is involved in most cases, resulting in significant deformity, "bovine facies" (Fig. 158-3). The trunk and extremities are usually affected (Fig. 158-4A) and often results in decreased flexibility and range of motion in the involved areas (Fig. 158-4B).

Figure 158-3 Scleromyxedema. Marked, nodular induration of facial skin with accentuation of skin folds.

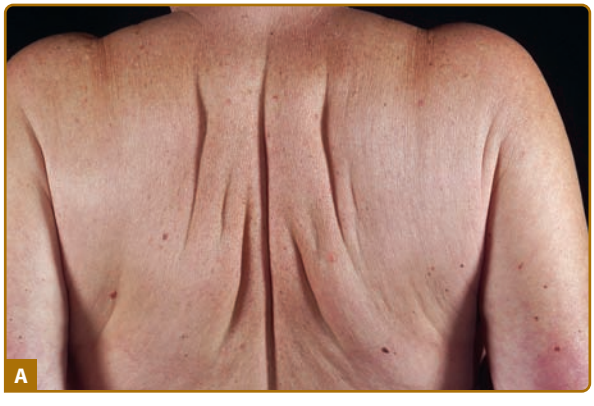

Figure 158-4 **A.** Scleromyxedema. Thickened bound-down skin of the back. **B.** Scleromyxedema. Confluent lichenoid papules and indurated skin of the hand and wrist.

A monoclonal paraproteinemia of undetermined significance, usually immunoglobulin-γ-κ type is identified in most patients. Paraproteinemia is less common in localized variants. Progression to multiple myeloma occurs rarely.

Muscle weakness, contractures, restrictive lung disease, upper airway involvement, pulmonary hypertension, esophageal dysmotility, and neurologic disorders (seizures, motor impairment, carpal tunnel syndrome, depression, memory loss, aphasia, peripheral neuropathy, and psychosis) have been reported in association with scleromyxedema. Thyroid function is normal by definition.

HISTOPATHOLOGY

Regardless of the clinical presentation, the histopathologic findings of scleromyxedema are identical and demonstrate superficial to mid-dermal mucin deposition with admixed fibroblast proliferation (Fig. 158-5). Moreover, scleromyxedema is histologically distinct from other mucinoses as well as sclerosing and fibrosing conditions. Nephrogenic systemic fibrosis [(NSF), formerly nephrogenic fibrosing dermopathy] shows close histologic resemblance to scleromyxedema. However, the pannicular septae are the focus for histologic distinction: they are always involved in NSF and never involved in scleromyxedema. Moreover, scleromyxedema tends to be restricted to the upper half of the dermis and nephrogenic fibrosing dermopathy becomes more prominent in the lower dermis and then extends to pannicular septae. Although occasional multinucleated histiocytes with or without elastophagocytosis may be identified in biopsies of scleromyxedema, there is typically minimal associated inflammation. A highly unusual histologic presentation with a marked dermal granulomatous infiltrate was observed in association with fibromucinous deposition in a 56-year-old male with scleromyxedema.[17] This unique case emphasizes the importance of correlating clinical and pathologic findings and raises the question if this patient may have had a second superimposed granulomatous disorder such as sarcoidosis in addition to scleromyxedema.

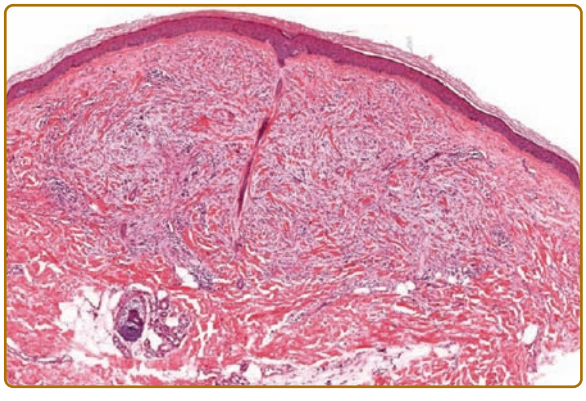

Figure 158-5 Scleromyxedema. Superficial to mid-dermal fibroplasia and increased mucin (40 × original magnification).

PROGNOSIS AND CLINICAL COURSE

Localized, "self-healing" variants are usually confined to the skin and self-limiting. However, prospective follow-up and caution is advised as some cases fitting criteria for localized disease have been associated with internal organ involvement or progression to more generalized disease (so called "atypical papular mucinosis"). Scleromyxedema usually follows a chronic and progressive clinical course and a poor outcome is expected. Respiratory failure, cerebral disease, and infection usually lead to a gradual decline and death.

TREATMENT

Melphalan had been used for decades to treat scleromyxedema with variable efficacy.[18–20] Other therapies directed towards quantitatively reducing or ameliorating the effects of the paraproteinemia have shown variable results. Agents or therapies with reported efficacy include: glucocorticoids,[21] intravenous immune globulin (IVIg),[22] thalidomide,[23] extracorporeal photophoresis,[24] interferon alpha,[25] combination chemotherapy,[26] and PUVA.[27] Partial to complete remission was achieved in 8 of 10 patients treated with IVIg.[28] Autologous peripheral blood stem cell transplantation has resulted in dramatic remission of scleromyxedema in a number of patients with severe disease.[29,30]

Chapter 159 :: Relapsing Polychondritis

:: Camille Francès

RELAPSING POLYCHONDRITIS AT A GLANCE

- Relapsing polychondritis is a rare multisystem autoimmune disease with both autoantibodies and cellular immune reactions to different cartilage proteins.
- More than 30% of patients have an associated autoimmune or hematologic disorder.
- Recurrent episodes of chondritis lead to progressive destruction of cartilaginous structures in joints, ears, and the nose.
- Other proteoglycan-rich structures such as eyes, blood vessels or inner ear are also affected.
- Dermatologic manifestations including nodules that may ulcerate; purpura and aphthae occur frequently.

EPIDEMIOLOGY

The incidence of RP has been estimated to be 3.5/million in Rochester, Minnesota.[1] The peak age for disease onset is the fifth decade; however, development of the disease may occur in young children and in the elderly.[2] The male to female ratio has been estimated from 1.1 to 1.3.[3] Although most cases have been reported in Caucasians, there is no evidence supporting the role of ethnic or geographical factors.

ETIOLOGY AND PATHOGENESIS

Several lines of evidence have been accumulated that suggest the role of autoimmunity in RP. More than 30% of patients have an associated disease, mainly of autoimmune origin.

The role of the humoral immune response was based on the presence of antibodies to collagen type II in the acute phase of RP. Antibody titers seemed to correlate with the severity of symptoms. Other antibodies were secondarily detected in patients with RP: antibodies to collagen type IX and type XI, minor collagens which represent 5–10% of cartilage collagens, antibodies to matrilin-1, an extracellular matrix protein, predominantly expressed in upper respiratory tract cartilage, and antibodies to cartilage oligomeric matrix protein, other cartilage proteins expressed in auricular, tracheal and nasal cartilage. Several animal models have been published in which immunization with these various cartilage proteins induced a variety of chondritis manifestations that mimic those seen in patients.[4] A role for immune complexes and subsequent activation of the complement system is suggested by examination of tissue lesions that usually show the presence of granular deposits of immunglobulins and the C3 component of complement associated with $CD4^+$ lymphocytes and plasma cells. The influence of T cells in RP pathogenesis, although less investigated, has also been demonstrated in patients and in animal models with specificity against the same cartilage proteins. T-cell clones isolated from an RP patient were found to be specific for a peptide corresponding to residues 261–273 of the type II collagen and were restricted to either the DRBI*0101 or the DRBI*0401 allele.[5] A significant near two fold increase in DR4 antigen frequency was found in RP patients as compared to that in healthy controls, but the genotyping of DR-4 positive patients and controls did not show a predominance of any DR4 subtype. Genetic susceptibility was also confirmed by animal models.[6]

CLINICAL FINDINGS

Disease onset is usually sudden with characteristic chondritis, and/or less frequently arthritis or ocular inflammation. Nonspecific initial symptoms such as fever or weight loss are rare.

Attacks of chondritis usually occur in a relapsing and remitting pattern. Inflammatory episodes generally last a few days or weeks and may subside spontaneously or after treatment is initiated; recurrences after weeks or months occur and result subsequently in cartilage destruction. Auricular chondritis is the most frequent (85%), causing pain, redness, and swelling of the cartilaginous portion of the pinna, sparing the noncartilaginous lobe (Fig. 159-1). Biopsy of the auricular cartilage is not usually necessary to

Figure 159-1 Relapsing polychondritis. Painful inflammation of the cartilaginous portion of ear.

Figure 159-2 Relapsing polychondritis. Soft and sloppy ear with a "cauliflower" aspect.

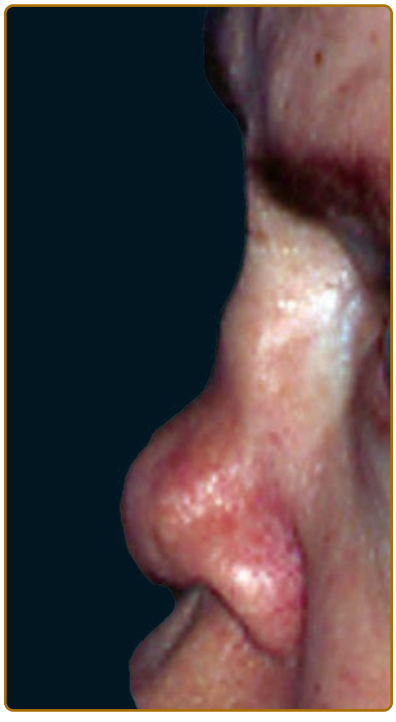

Figure 159-3 Relapsing polychondritis. Saddle nose deformity.

make a diagnosis. The histology shows perichondrial inflammation and the loss of the normal cartilaginous basophilia. After several attacks, the pinna may become soft and floppy with a cauliflower appearance (Fig. 159-2); sometimes it is stiff due to calcifications. Nasal chondritis (65%) is less inflammatory, presenting with nasal pain, stuffiness, rhinorrhea, and sometimes epistaxis. The characteristic saddle-nose deformity (Fig. 159-3) may appear secondarily or without previous inflammatory episodes. Respiratory tract chondritis, though uncommon at presentation, occurs in up to 50% of patients, and may be lethal. This results in complaints of hoarseness, nonproductive persistent cough, dyspnea, wheezing. Complications include upper airway collapse, obstructive respiratory insufficiency and secondary infections. Costochondritis (35%) induces parietal pains, which may also compromise respiration.

Joint pain is a common presenting feature (30%). Large and small joints of the peripheral or axial skeleton may all be affected (>70%). Arthritis is intermittent, migratory, asymmetric, seronegative, and usually nonerosive.

Nearly 60% of patients develop ocular inflammation. Episcleritis and scleritis (see eFig. 159-3.1 in online edition) are the most common manifestations, followed by keratoconjunctivitis sicca, iritis, retinopathy, keratitis. Rarely corneal perforation, retinal vasculitis, and optic neuritis lead to blindness.

Conductive hearing loss is secondary to stenosis of the external auditory canal, Eustachian tube chondritis or serous otitis media while perception hearing loss may occur as a consequence of sensorineural involvement. Symptoms of vestibular dysfunction such as dizziness, ataxia, nausea, and vomiting are usually acute and improve with time.

The spectrum of cardiovascular manifestations is wide including different cardiac tissues (aortic and/or mitral regurgitation, impairment of the conduction system, pericarditis) and all types of vessels (thoracic and abdominal aortitis leading to aneurysms, Takayasu-like aortic arch syndrome, medium and large vessels vasculitis, leukocytoclastic vasculitis, thrombophlebitis). Lesions are inflammatory and/or thrombotic. Some but not all thrombotic manifestations have been linked to antiphospholipid syndrome. Large vessel vasculitis tends to occur after several years of smoldering and often occult disease, despite immunosuppressive therapy.

Dermatologic manifestations are sometimes the presenting feature of RP (12%), and become apparent in more than one-third of patients of a large series.[7] They are nonspecific including nodules on the limbs (see eFig. 159-3.2 in online edition), annular eruptions, purpura (see eFig. 159-3.3 in online edition), oral or complex aphthosis (see eFig. 159-3.4 in online edition), papules, sterile pustules (see eFig. 159-3.5 in online edition), superficial phlebitis, livedo reticularis, ulcerations on the limbs, distal necrosis (see eFig. 159-3.6 in online edition). They appear concomitantly or independent of attacks of chondritis. Pathological features include inflammatory or thrombotic vascular lesions, neutrophil infiltrates as in neutrophilic dermatoses, and inflammation of the dermis or subcutis. Patients with and without dermatologic manifestations have similar clinical manifestations of RP. However, the frequency of dermatologic manifestations (>90%), age at first chondritis and male/female ratio seems higher

BOX 159-1 EMPIRICAL DIAGNOSTIC CRITERIA

1. Bilateral auricular chondritis
2. Nonerosive seronegative inflammatory polyarthritis
3. Nasal chondritis
4. Ocular inflammation
5. Respiratory chondritis
6. Audiovestibular damage

For the diagnosis of RP, patients must have one of the following:

(a) At least three of the above clinical criteria
(b) One or more of the above clinical criteria + biopsy confirmation of cartilage inflammation
(c) Chondritis at two or more separate anatomic locations with response to steroids and/or dapsone

when RP is associated with myelodysplasia[7]; so, their presence in an old man warrants repeated blood counts to detect a smoldering myelodysplasia.

Laboratory findings in RP are nonspecific, consistent with acute or chronic inflammation. Urinalysis may be abnormal in the presence of renal involvement (mesangial expansion, IgA nephropathy, tubulointerstitial nephritis, or necrotizing glomerulonephritis).

Pulmonary function tests, including inspiratory and expiratory flow volume curves, should be performed systematically to detect occult pulmonary involvement, which may be confirmed by computed tomography of the respiratory tract. Three-dimensional or spiral magnetic resonance imaging may provide better resolution. Although not routinely available, autoantibodies to collagen type II, IX, XI and to matrilin I can be found in patients with RP. Urinary type II collagen neoepitope measurement may be a useful tool to follow evolution of disease.[8]

(Box 159-2)

PROGNOSIS AND CLINICAL COURSE

The clinical course of RP is progressive with intermittent flares. The number of different organ manifestations, their severity, and the response to treatment are unpredictable. Common causes of death are respiratory or cardiovascular complications and secondary infections. Patients have an increased risk of developing lethal myelodysplastic malignancies.

TREATMENT

Because of the highly variable course of relapsing polychondritis, individualized therapy is the key to optimum management. General therapeutic guidelines are based on retrospective analyses of series of patients or isolated case reports. Nonsteroidal anti-inflammatory drugs, colchicine or dapsone may be useful for patients with mild auricular or nasal chondritis, arthralgia or mild arthritis. More serious manifestations require oral corticosteroids in a dose of 0.3–1 mg/kg of body weight according to severity. Pulse intravenous steroids are prescribed for acute airway obstruction, sudden hearing loss and/or before surgical intervention (tracheostomy, aortic aneurysm repair, cardiac valve replacement). Long-term corticosteroids decrease the frequency and severity of recurrences although it has no preventive effect of vital organ involvement. Many kinds of immunosuppressants have been used with some success as disease-modifying and steroid-sparing agents. Methotrexate, azathioprine, cyclophosphamide, and cyclosporine A are the more commonly

used. The beneficial effects of new biological therapies such as antitumor necrosis factor agents, anti-interleukin-1 or -6 receptor, and of autologous stem cell transplantation have been reported in isolated cases.

Chapter 160 :: Rheumatoid Arthritis, Rheumatic Fever, and Gout

:: Warren W. Piette

RHEUMATOID ARTHRITIS AT A GLANCE

- Affects roughly 1% of the world population.
- Chronic disfiguring inflammatory condition.
- Genetics and environment play a role in etiology.
- Symmetric arthritis of the proximal interphalangeal and metacarpophalangeal joints.
- Skin findings include granulomatous dermatitis, vasculitis, rheumatoid nodules, pyoderma gangrenosum, and Bywater lesions.
- Treatment based on severity of disease.

This chapter discusses common rheumatologic diseases that have predominantly musculoskeletal presentations; however, all of these conditions have cutaneous manifestations.

RHEUMATOID ARTHRITIS

Rheumatoid arthritis (RA) is a systemic inflammatory autoimmune disease that is characterized by a debilitating chronic, symmetric polyarthritis with significant extra-articular manifestations, which include rheumatoid nodules, pyoderma gangrenosum, granulomatous dermatitis, vasculitis, and internal organ involvement. The disease process is often progressive, resulting in limitation of joint function. Ultimately, there may be a resultant decline in functional status, possibly leading to premature death. Permanent remission is unusual.

EPIDEMIOLOGY

Rheumatoid arthritis has an annual incidence of approximately 0.4 per 1,000 in females and 0.2 per 1,000 in males, with a prevalence of approximately 0.4% to 1% of the adult population in diverse populations worldwide.[1–3] Approximately 70% of patients follow a chronic disease course with exacerbations and remissions; 25% have intermittent disease with brief attacks of inflammation followed by remissions; approximately, 5% have an aggressive, malignant form with multiple extra-articular manifestations.[4] RA has a peak onset at 50 years of age.[1,2]

ETIOLOGY AND PATHOGENESIS

The exact etiology of RA remains unknown. Genetics plays at least some role in the development, severity, and outcome of the disease in certain patients.[5] Furthermore, an association between extra-articular disease and *HLA-DR1* and *-DR4* genes has been noted in some populations.[6]

Mechanical stress on joints may initiate an inflammatory response creating an imbalance between the rapid response to trauma and the need to protect self from damage. Patients with seropositive RA (positive rheumatoid factor) have circulating and tissue-bound immune complexes. B cells produce autoantibodies in

some RA patients. After binding to antigen, these autoantibodies result in complement fixation and recruitment of polymorphonuclear leukocytes, which result in joint destruction. Possible antigens in RA include heat shock proteins, collagen, and cyclic citrullinated peptides.[7] Indeed, antibodies to several citrullinated peptides are enriched in the joints of patients with RA.[8]

Patients with negative rheumatoid factor (seronegative RA) may not create autoantibodies, but other immune mechanisms are involved. This theory led to the recognition that T cells are important players in the etiology of this disease. In the SKG mouse model, autoreactive T cells are preferentially selected, leading to inflammatory arthritis similar to RA. T cells also activate other cells via cytokines, including osteoclasts, which play a major role in the bone resorption seen in RA. Effector cytokines of the T cell include interferon-γ, interleukin 1, interleukin 17, and tumor necrosis factor-α (TNF-α), many of which have been, or are being, used as therapeutic targets to treat RA.[4,7]

Lastly, joints have unique anatomic and physiologic qualities that render them targets for immune and inflammatory assault. Cartilage is subject to repetitive mechanical stress, retains antigens and proinflammatory cytokines, and has a limited capacity for regeneration. Only two groups of enzymes found in the joint are capable of degrading native type I and II collagen fibrils: (1) cysteine cathepsins and (2) matrix metalloproteinases.[9]

CLINICAL FEATURES

RA often begins with general constitutional symptoms such as fatigue, anorexia, vague musculoskeletal complaints, and generalized weakness. It may be weeks or months before the characteristic synovitis presents. It is in these early stages that definite diagnosis is most difficult, despite a thorough patient evaluation. However, early diagnosis and treatment are essential because most of joint damage is thought to occur early in the disease process. The American College of Rheumatology has guidelines for the diagnosis of RA (Table 160-1).[10] For a patient to be diagnosed with RA, four of the seven criteria must be present, and the first four criteria listed must be present for at least 6 weeks. Extra-articular manifestations may help to delineate the disease process early and may signify a more serious disease process requiring the initiation of aggressive therapy.[11,12] Several conditions can mimic RA, and must be considered in the differential diagnosis of early disease: viral syndromes (especially parvovirus B19, rubella, hepatitis B and C), polymyalgia rheumatica, remitting seronegative symmetric synovitis with pitting edema (RSSSPE), palindromic rheumatism, adult Still's disease, systemic lupus erythematosus, and multicentric reticulohistiocytosis.[13]

ARTICULAR MANIFESTATIONS. The articular manifestations of RA relate to an inflammatory synovitis that can affect the synovial lining of joints, tendons, and bursae. Synovial inflammation usually results in warmth but not erythema of the affected area. There is significant pain in association with stretching of the joint capsule. Hand and foot involvement forms the basis of the disease in most patients. Although the initial manifestations in the hand may be asymmetric, the clinical course subsequently takes on a symmetric and diffuse pattern. There is a characteristic involvement

TABLE 160-1
1987 American College of Rheumatology Revised Criteria for the Classification of Rheumatoid Arthritis (Modified)

Criterion	Definition
Morning stiffness	Morning stiffness in and around the joints, lasting at least 1 hour before maximal improvement
Arthritis of three or more joint areas	At least three joint areas simultaneously afflicted with soft-tissue swelling or joint fluid observed by a physician. The possible areas are (right or left): PIP, MCP, wrist, elbow, knee, ankle, and MTP joints
Arthritis of hand joints	At least one area swollen in a wrist, MCP, or PIP joint
Symmetric arthritis	Simultaneous involvement of the same joint areas on both sides of the body (bilateral involvement of PIP, MCP, or MTP acceptable without perfect symmetry)
Rheumatoid nodules	Subcutaneous nodules over bony prominences or extensor surfaces or in juxta-articular regions (observed by a physician)
Serum rheumatoid factor	Abnormal amount of serum rheumatoid factor by any method while the result has been positive in 5% of control subjects
Radiographic changes	Erosions or unequivocal bony decalcification localized in or most marked adjacent to the involved joints

MCP = metacarpophalangeal; MTP = metatarsophalangeal; PIP = proximal interphalangeal.
From Arnett FC et al: The American Rheumatism Association 1987 revised criteria for the classification of rheumatoid arthritis. *Arthritis Rheum* **31**:315, 1988.

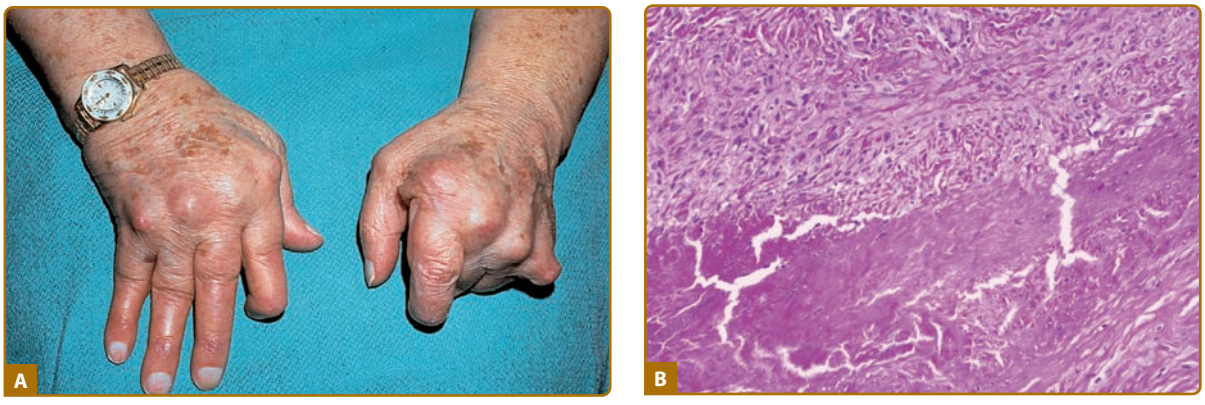

Figure 160-1 Rheumatoid nodules. **A.** Severely affected joints of a patient with rheumatoid arthritis with overlying rheumatoid nodules. **B.** Histopathologically, rheumatoid nodules are palisaded granulomas in the deep reticular dermis surrounding degenerated collagen.

of the proximal interphalangeal (PIP) and metacarpophalangeal joints with sparing of the distal interphalangeal (DIP) joints. The pattern of joint involvement is highly suggestive of the diagnosis.

Chronic inflammation may result in irreversible structural damage of the joint, including cartilage destruction and bony erosion. Late structural deformities may result from soft-tissue contractures or from bony ankylosis. Characteristic deformities include radial deviation of the hand with ulnar deviation of the digits, the "swan neck" deformity from hyperextension of the PIP joint and compensatory flexion of the DIP joint, and the boutonnière deformity from flexion contracture of the PIP joint and extension of the DIP joint. Similar structural deformities can occur in the feet, and all can be debilitating. Involvement of the thoracic and lumbar spine in RA is exceptional. Although the shoulder joint is often affected, it is soft-tissue structures, which include the rotator cuff tendons and muscles and the subacromial bursa that are usually involved in the patient's symptomatology.

DERMATOLOGIC MANIFESTATIONS. Extra-articular manifestations occur in more aggressive or extensive forms of RA.[11,12] The most common dermatologic finding in RA is the rheumatoid nodule. The classic rheumatoid nodule is a subcutaneous nodule that occurs in approximately one-fourth of patients with RA (Fig. 160-1A). More than 90% of patients with rheumatoid nodules have seropositive RA. The usual location is over pressure points such as the olecranon, the extensor surface of the forearms, and the Achilles tendon; but they have been described in almost every location, including viscera.[12] The main histologic findings (see Fig. 160-1B) are palisaded granulomas in the deep dermis or subcutaneous tissues with fibrinoid degeneration of collagen, a multitude of neutrophils, and neutrophilic dust, with surrounding fibrosis and proliferation of vessels. The main differential diagnoses histopathologically include subcutaneous granuloma annulare, necrobiosis lipoidica, foreign body or infectious granulomatous reaction, and epithelioid sarcoid.[14]

Though rheumatoid nodules are benign, they can lead to complications, including ulceration, infection, joint effusion (rheumatoid chyliform bursitis), and fistulas (fistulous rheumatism). All conditions may lead to the need for surgical excision.[12]

Rheumatoid vasculitis has an estimated annual incidence of less than 1%, most often affects patients with seropositive disease, and is believed to affect 1 in 8 males with RA, versus 1 in 38 females.[15] A study of 30-year cumulative incidence of extra-articular manifestations, major cutaneous vasculitis occurred in 5.1% of the study population.[16] Small- to medium-sized vessels are primarily affected, often with associated peripheral neuropathy (including motor), digital gangrene, nail fold infarcts, and palpable purpura (see Chapter 163 and 164).[12,17] Some patients may have nail fold telangiectasias, with minute digital ulcerations or petechiae and digital pulp papules (Bywaters lesions) (Fig. 160-2). These papules are a manifestation of mild vasculitis and typically occur without systemic signs of vasculitis. Histopathology of skin biopsy specimens usually shows leukocytoclastic vasculitis with neutrophilic infiltration of the vessel wall, fibrinoid necrosis, and hemorrhage without palisaded granulomatous

Figure 160-2 Bywaters lesions. Note the purpuric papule on the dorsal finger.

Figure 160-3 Felty syndrome. A refractory ulcer on the foot of a patient with rheumatoid arthritis and hypersplenism.

reaction.[14] Cutaneous small-vessel vasculitis mostly involves postcapillary venules and may affect arterioles and larger vessels of the viscera, heart, and central nervous system. The spectrum of clinical lesions reported in rheumatoid vasculitis is wide and varies with the size and location of the vessels involved and with the extent of the disease (see Chapters 163 and 164). Unfortunately, the presence of vasculitis, especially at the onset of the disease, portends a poor outcome.[18] Vasculitis, along with certain other extra-articular manifestations of RA (pericarditis, pleuritis, amyloidosis, and Felty syndrome), are associated with a diminished lifespan.[16] Rheumatoid vasculitis can present as lower-extremity ulcers; however, pyoderma gangrenosum (see Chapter 33) should be suspected if deep liquefying ulcers with a characteristic purple, undermined border occur in patients with RA. The ulcers may occur at any site but are most common on the lower extremities and abdomen. Pyoderma gangrenosum occurs more frequently and more severely in females and may take years to heal. Leg ulcers may also appear in patients with Felty syndrome, a combination of chronic RA, hypersplenism, and leukopenia (Fig. 160-3).[12] In some instances, the ulcers of Felty syndrome exhibit the same morphologic characteristics and behavior of pyoderma gangrensoum ulcers, suggesting that these ulcers are not necessarily a manifestation of rheumatoid vasculitis.

Rheumatoid neutrophilic dermatosis is a very rare cutaneous manifestation in patients with severe RA. First described by Ackerman in 1978, these lesions are usually chronic, erythematous, and urticaria-like plaques and papules that are sharply marginated (Fig. 160-4A). Histopathologically, these lesions have a dense infiltrate of neutrophils without leukocytoclasia, in the setting of a mixed infiltrate and papillary edema (see Fig. 160-4B).[14] It may be difficult to differentiate rheumatoid neutrophilic dermatosis from acute febrile neutrophilic dermatosis (Sweet syndrome) (see Chapter 32). Some authors accept palisaded neutrophilic granulomatous dermatitis as a histologic finding consistent with rheumatoid neutrophilic dermatitis.[19] However, in the absence of granuloma formation, it seems reasonable to separate rheumatoid neutrophilic dermatitis from multiple named entities, which would seem to be now included under the term interstitial granulomatous dermatitis.

Other vasculitis syndromes, such as erythema elevatum diutinum (see Chapter 165) and livedo vasculitis (segmental hyalinizing vasculitis), have also been described in patients with RA. Skin manifestations such as palmar erythema, erythromelalgia, autoimmune bullous diseases such as epidermolysis bullosa acquisita (see Chapter 60), yellow nail syndrome (see Chapter 89), erythema multiforme (see Chapter 39), erythema nodosum (see Chapter 70), and urticaria (see Chapter 38) also have been reported in patients with RA.[20]

Low-dose methotrexate, often used for the treatment of rheumatoid arthritis, may precipitate erythema and enlargement of preexisting rheumatoid nodules, known as accelerated nodulosis.[21] Regression of these changes is expected when the methotrexate dose is decreased or discontinued. A second reaction to methotrexate has also been reported as a syndrome of clustered, erythematous, indurated papules arising most commonly on the proximal extremities and buttocks. This has been reported not only in patients

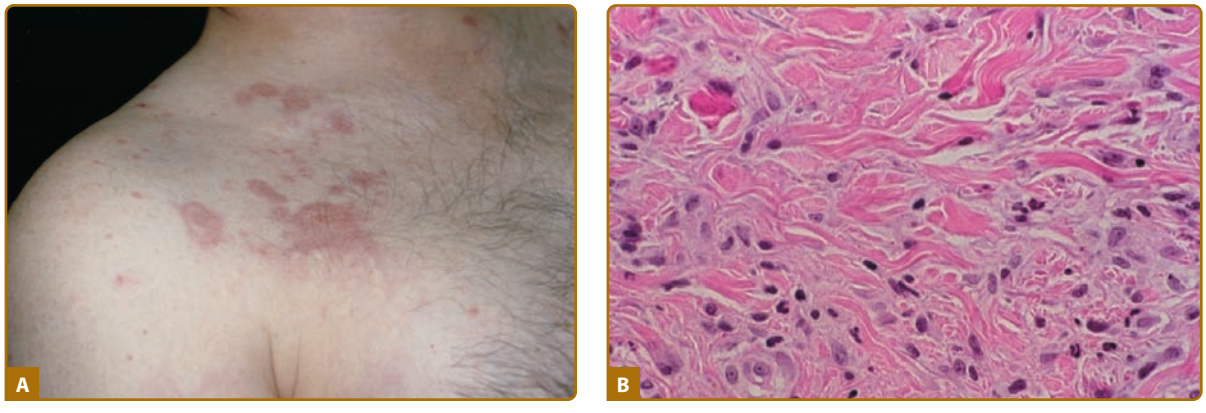

Figure 160-4 Rheumatoid neutrophilic dermatosis. **A.** Lesions are erythematous urticarial papules often coalescing into plaques in a patient with rheumatoid arthritis. **B.** Histopathologically, there is an interstitial mixed dermal infiltrate predominated by neutrophils without leukocytoclasis. This is often accompanied by papillary edema.

with rheumatoid arthritis, but also in association with other diseases as well, especially collagen vascular diseases.[22,23] In rare instances, some lesions may develop erosions or surrounding livedo. The histologic pattern seen in the popular eruption is that of a mostly histiocytic infiltrate arranged interstitially between collagen bundles in the dermis, intermixed with a few neutrophils. Small rosettes of histiocytes may surround thick collagen bundles in the reticular dermis. Yet another possible cutaneous complication of methotrexate therapy in rheumatoid arthritis is the development of Epstein–Barr virus-associated multifocal cutaneous lymphoproliferative disease, which may regress on discontinuation of therapy.[24]

A histologically related eruption of interstitial granulomatous dermatitis has been described in association with a number of disorders, including rheumatoid arthritis.[23] Cutaneous lesions consist of linear slightly red or skin-colored cords, most often extending from the upper back to the axillae.[23,25] Histopathologic findings include a dense, diffuse infiltrate of histiocytes arranged in a band-like configuration in middle or deep reticular dermis. There may be foci of basophilic collagen surrounded by palisaded histiocytes. These cells may also exhibit large and pleomorphic nuclei, and scattered mitotic figures are readily seen. Neutrophils and eosinophils are present, most notably in areas of degenerated collagen.

Indurated erythema, livedo-like erythema, and papules over the elbows have been reported as clinical findings of intravascular or intralymphatic histiocytosis in rheumatoid arthritis.[25]

NONDERMATOLOGIC EXTRA-ARTICULAR MANIFESTATIONS. In addition to systemic vasculitis, which can affect numerous organ systems, there are multiple nondermatologic extra-articular manifestations of RA. Table 160-2 lists the more common ones.

TABLE 160-2
Nondermatologic Extra-Articular Manifestations of Rheumatoid Arthritis

Type	Manifestations
Ocular	Keratoconjunctivitis sicca, scleritis, episcleritis, scleromalacia
Renal	Amyloidosis and vasculitis
Hematologic	Anemia, thrombocytosis, lymphadenopathy, Felty syndrome
Neurologic	Entrapment neuropathy, cervical myelopathy, mononeuritis multiplex (vasculitis), peripheral neuropathy
Lung	Pleural effusions, pulmonary fibrosis, bronchiolitis obliterans, rheumatoid nodules, vasculitis
Cardiac	Pericarditis, premature atherosclerosis, vasculitis, nodules, aortic root dilatation

DIFFERENTIAL DIAGNOSIS OF RHEUMATOID NODULES

(Box 160-1)

LABORATORY FINDINGS

There is no one specific histologic, radiographic, or laboratory test that conclusively permits the diagnosis of RA. Rheumatoid factor, an autoantibody that reacts with the Fc portion of immunoglobulin G (IgG), is found in sera of 85% of patients with RA. Rheumatoid factor should not be used as a definitive screening tool because it can be found in other disease processes (sarcoidosis, liver diseases, pulmonary fibrotic processes, and cryoglobulinemia). It is also found in approximately 5% of the unaffected population.[17] A false-positive rheumatoid factor can be caused by many factors, including chronic bacterial infections such as infective endocarditis, tuberculosis, and Lyme disease, as well as by viral diseases such as rubella and infectious mononucleosis.[26] Anticitrullinated protein antibodies have been shown to be a more specific marker than rheumatoid factor, particularly in early disease where specificity ranges from 94% to 100%, compared to 23% to 94% for rheumatoid factor, with roughly equivalent sensitivities.[3]

TREATMENT

Because the exact cause of RA is unknown, treatment has been directed against various components of the inflammatory process. No single therapy is the treatment of choice. In the past, most patients with early disease were started on nonsteroidal anti-inflammatory drugs until joint erosions were evident.

These medications are useful to alleviate symptoms. They do not alter disease progression.

Furthermore, new understanding of disease mechanism and the chronic disabling nature of RA have resulted in a shift to earlier use of disease-modifying

BOX 160-1 DIFFERENTIAL DIAGNOSIS OF RHEUMATOID NODULES

Consider
- Subcutaneous granuloma annulare
- Foreign body granuloma
- Infectious granuloma

- Leflunomide
- D-penicillamine

antirheumatic drugs (DMARDs). New guidelines released by the American College of Rheumatology in 2002[18] advocate this switch.[27] DMARDs decrease inflammation (confirmed by a reduction in acute-phase reactants), reduce or prevent joint damage, and modify the disease process. The use of DMARDs is now recommended early in the disease course, when joint damage has already occurred or is imminent. Multiple medications fall into this category (Table 160-3). They may be used alone or in combination, but their use may be limited by loss of efficacy or systemic toxicity. Medications are often used in combination, but the decision about which drug to use is often individualized and determined by the clinical severity and loss of function and resultant disability, along with concerns about the safety profile of each given patient.

Systemic glucocorticoids are potent anti-inflammatory agents but have a serious side-effect profile when used in large doses over long periods of time. They are not a good option alone for RA, but are sometimes used in a low dose with other DMARDs. Methotrexate has been used as a very effective DMARD for many years, and is often the standard of care for initial DMARD therapy of RA.[28,29] Other nonbiologic DMARDs include hydroxychloroquine sulfate, sulfasalazine, leflunomide, gold salts, azathioprine, cyclosporine, and minocycline.

The newest additions to the antirheumatic armamentarium are the biologic response modifiers, which act to inhibit the proinflammatory cytokines that play a role in RA. The best known commercially available members of this category are the anti-TNF-α agents. TNF-α is a proinflammatory agent released by macrophages and T cells contributing to synovitis and joint destruction.

There are five anti-TNF-α drugs currently approved by the US Food and Drug Administration, which have been used in the treatment of RA: (1) etanercept, (2) infliximab, (3) adalimumab, (4) golimumab, (each approved for use in RA), and (5) certolizumab (approved for use in Crohn disease).[28] Etanercept is a recombinant human TNF dimeric receptor fusion protein consisting of the ligand-binding portion of the human 75-kDa TNF receptor linked to the Fc portion of human IgG1. This treatment is given as a subcutaneous injection twice per week. Infliximab is a chimeric (mouse/human) *IgG1* monoclonal antibody to TNF-α. It is given intravenously every 6 to 8 weeks. Adalimumab is a human IgG1 monoclonal antibody that binds membrane bound and soluble TNF-α. Adalimumab, like other TNF inhibitors, commonly induces autoantibodies, but only rarely induces autoimmune diseases, such as lupus.[30] Golimumab, a human monoclonal antibody, is the newest TNF inhibitor approved for use in rheumatoid arthritis, administered as a once monthly subcutaneous injection.[31] Certolizumab is a humanized, pegylated, Fc-free anti-TNF monoclonal antibody, which has been used alone or in combination with methotrexate in rheumatoid arthritis. These agents render TNF-α biologically inactive, thereby significantly decreasing the synovitis and retarding the progression of joint destruction.[32] Cutaneous vasculitis presumed secondary to RA has been reported in three patients treated with anti-TNF agents.[33] An apparent rare class effect of TNF inhibitors is the development of sarcoidosis in patients with psoriatic or rheumatoid arthritis.[34]

Other biologic DMARDs include rituximab (CD20 monoclonal antibody), abatacept (T-cell activation inhibitor, anakinra (IL-1 receptor antagonist), and tocilizumab (an IL-6 receptor antagonist).[28] Rituximab is commonly given with methotrexate or another nonbiologic DMARD, and is administered as two 1,000-mg intravenous infusions given 2 weeks apart.[28] Rituximab has been helpful in patients refractory to TNF blockade.[35] Pretreatment with methylprednisolone 50–100 mg infused 30 minutes beforehand may mitigate infusion reactions. Cutaneous vasculitis has been reported as a rare association with rituximab therapy.[36] Ofatumumab is also an anti-CD20 monoclonal antibody approved for use in chronic lymphocytic leukemia, which has been used in some patients with DMARD-resistant rheumatoid arthritis.[37] Abatacept is a fusion protein that interferes with T-cell activation, given as an initial IV dose, then at week 2 and 4, then monthly thereafter. Infusion reactions may occur within an hour after infusion. Increase in pneumonia, pyelonephritis, cellulitis, and diverticulosis is suspected, but increase in tuberculosis is not documented.[28,38] Anakinra competitively inhibits the interleukin-1 effects, but is currently felt to be the least effective biologic DMARD for RA.[28] Tocilizumab may achieve clinical improvement within a few weeks. Adverse effects include hypertension, neutropenia, elevated transaminases, dyslipidemia, and rarely GI perforation, serious infection, or anaphylaxis.

There are a number of limitations to the use of biologic response modifiers. They are expensive, ranging between 18,000 to 30,000 dollars per year, and both etanercept and adalimumab require the patient to self-administer injections. Not all patients are willing to do this. Injection site reactions are common with etanercept and adalimumab. Infliximab, on the other hand, is an infusion, which inherently requires that the patient has more time from work/home and lends itself to the possibility of infusion reactions, including fever, urticaria, dyspnea, and hypotension. In addition, there needs to be an infusion center nearby where the patient can receive therapy. Most patients receiving TNF-α-blocking agents have failed therapy with one or a combination of the previously mentioned DMARDs.

Inhibiting the normal host immune response has led to concern about reactivation of tuberculosis, increased susceptibility to other infections, and predisposition to the development of malignancy. The true risk of malignancy is difficult to establish because patients with RA are thought to have a higher incidence of lymphoid malignancy than the normal population, and some have shown that the incidence of lymphomas may in fact be increased in patients taking anti-TNF-α drugs.[39] As with all medications, knowing your patient's medical history is the key to proper use of these medications. They should not be used in patients with concurrent serious infection or in those predisposed to serious infections (patients with poorly controlled diabetes). Extreme caution and consultation with the hematologist-oncologist should be used before prescribing these medications to patients with a recent history of malignancy.

In conclusion, the dermatologist and rheumatologist must function as a cohesive team in the treatment of patients with cutaneous manifestations of RA, which often present during phases of intense disease activity. Patients need their underlying rheumatic disease to be treated aggressively, but proven treatments for these associated dermatologic processes, such as pyoderma gangrenosum, cryoglobulins, vasculitis, and others, should not be forgotten. These specific treatment regimens are beyond the scope of this chapter.

JUVENILE IDIOPATHIC ARTHRITIS, STILL'S DISEASE, ADULT-ONSET STILL'S DISEASE

In 1995, the International League of Associations for Rheumatology (ILAR) Task Force on the Classification of Childhood Arthritis proposed juvenile idiopathic arthritis (JIA) for all chronic childhood arthritides of unknown cause, beginning before age 16 and persisting for at least 6 weeks, and encompassing previous terms including juvenile rheumatoid arthritis and Still's disease.[40] Using their criteria, JIA can be diagnosed as early 6 weeks after the onset of symptoms, while the assignment to a specific JIA category requires a disease duration of up to 6 months These categories include systemic arthritis, oligoarthritis, RF-negative polyarthritis, RF-positive polyarthritis, psoriatic arthritis, enthesitis-related arthritis, and others.[40] The expression adult-onset Still's disease (AOSD) was introduced by Bywaters in 1971 to characterize 14 women with seronegative polyarthritis, rash, fever, and raised erythrocyte sedimentation rate.[41] This syndrome most often affects younger adults, and females more often in Eastern than in Western countries. The classical adult presentation includes high spiking fever, an evanescent salmon pink rash, and arthritis, often accompanied by sore throat, myalgias, lymphadenopathies, splenomegaly, and neutrophilic leukocytosis.[42] High fever of unknown origin (FUO) exceeding 39°C is the presenting sign of AOSD in 95% of patients, but only 5% of all persons with FUO have AOSD.[41] Classically, patients present with one to two daily fever spikes above 39°C occurring in the afternoon or evening and receding within hours. Musculoskeletal pain is often present, including myalgia (20%–90%), arthralgia (27%–100%), and arthritis (18%–82%).[41] Multiple arthritis patterns may occur, but polyarticular and symmetric involvement affecting knees, wrists, fingers, and ankles is most common.

A rash may be seen in 25% to 100% of patients.[41,42] It is seen more often in the febrile presentation than in the solely arthritic form of disease. It most characteristically occurs on the chest, abdomen, and extensor surfaces of the arms, and tends to peak with the fever in the late afternoon, and then disappears, only to recur with fever the following day.[41,43] The rash consists of discrete pink to red macules or slightly edematous papules ranging in size from 5 to 10 mm. The lesions tend to be relatively fixed in shape and site during their daily eruption and seldom itch. Koebner phenomena may be seen. Histologic findings include dermal edema, a mild mostly lymphocytic perivascular infiltrate that may include a few neutrophils. In some patients, the lesions may demonstrate prominent perivascular neutrophilic infiltrates, sometimes involving dermis but without the edema typical of Sweet lesions, with leukocytoclasia but without vasculitis. This finding has been reported as neutrophilic urticarial dermatosis, and found in association with autoinfammatory diseases, Schnitzler syndrome, hepatitis C, asthma, and adult-onset Still's disease.[44]

Two unusual syndromes appear to be associated with AOSD: (1) thrombotic thrombocytopenic purpura and (2) reactive hemophagocytic syndrome.[45,46] Both are rare, and the reason for association unclear, but each syndrome has multiple reports supporting these as a complication of AOSD.

Laboratory findings include an increased sedimentation rate, leukocytosis with neutrophilia, hypoalbuminemia elevated hepatic enzymes, anemia (<10 g/dL), and thrombocytosis, in decreasing order of frequency. Antinuclear antibody and rheumatoid factor are negative in most patients. More recently, a very elevated serum ferritin with a lowered concentration of glycosylated ferritin, has been seen as strongly suggestive of, but not specific for, this diagnosis.[41,42] Very high levels of serum ferritin between 3,000 and 30,000 ng/mL (normal range 40–200 ng/mL) are not uncommon, and levels above 250,000 ng/mL have been reported.[42] A threshold level of 1,000 ng/mL appears to offer an 80% to 82% sensitivity and 41% to 46% specificity for a diagnosis of AOSD. Perhaps more specific is the fraction of glycosylated ferritin. In healthy individuals, 50% to 80% of serum ferritin is glycosylated, but this drops to 20% to 50% in patients with inflammatory diseases.[42]

Acute disease is often treated with nonsteroidal anti-inflammatory agents, particularly enteric-coated aspirin, while some begin with corticosteroid and most would use corticosteroids if NSAID therapy is ineffective. A variety of second-line drugs has been used: intramuscular gold, D-penicillamine, sulfasalazine, hydroxychloroquine, methotrexate, thalidomide, azathioprine, cyclosporine, cyclophosphamide, intravenous immunoglobulins, anti-TNF agents, anakinra,

rituximab, and tocilizumab (an IL-6 receptor inhibitor) are reported as sometimes effective.[41,42,47]

RHEUMATIC FEVER

Acute rheumatic fever (ARF) is a delayed sequel to group A β-hemolytic streptococcal (GAS) infection of the oropharynx. It is an inflammatory disease that can affect the heart, joints, central nervous system, skin, and subcutaneous tissues. There are no specific diagnostic tests, rather it is a clinical diagnosis made on the basis of certain criteria. Treatment of the underlying infection leads to prevention of rheumatic fever.

EPIDEMIOLOGY

ARF is rare and most commonly occurs in children 5 to 15 years of age after clinically severe tonsillopharyngeal infections. However, it has been reported in patients of all ages and in those with asymptomatic disease. The incidence of rheumatic fever has decreased since the beginning of the twentieth century, and dropped precipitously since the 1950s with widespread recognition of disease and treatment with penicillin. It has been nearly eradicated from the developed world but remains a serious health problem in developing countries. Currently, the average incidence in most developed communities is less than 5/100,000 population.[48,49] Rates of 72 to 150/100,000 have been reported in countries with sizable less affluent populations, where overcrowding and poorer public hygiene may play a role. The World Health Organization estimates that 15.6 million people worldwide are affected by rheumatic heart disease, and that 233,000 people die annually either from rheumatic heart disease or acute renal failure as a result of complicated GAS infection.[48,49]

PATHOGENESIS

The exact mechanism by which ARF results from an infection with group A streptococcal bacteria is unclear, but it is thought to be an exaggerated immune response to infection. Some strains of streptococcus are more likely to cause ARF than others. For instance, pharyngeal strains are much more likely to cause ARF than extrapharyngeal strains responsible for impetigo or cellulitis.[48] Molecular mimicry has also been implicated in the etiology of ARF. M protein has structural similarity to cardiac myosin. Studies have demonstrated that rats immunized with streptococcal M protein develop myocarditis. Oddly, however, the morbidity and mortality of rheumatic fever results from valvular disease rather than acute carditis.[49] Familial clustering of disease, and the linkage of HLA-DR4 and -DR2 to ARF in Caucasian and African-American patients demonstrates that host properties also affect the susceptibility of individual patients in the development of disease.[48]

CLINICAL FEATURES

The clinical features of ARF vary widely and are largely outlined in the Jones criteria used to aid in diagnosis of the disease. The Jones criteria, updated in 1992,[50] emphasize five characteristic major manifestations: (1) polyarthritis, (2) carditis, (3) chorea, (4) subcutaneous nodules, and (5) erythema marginatum (Box 160-2). Nonspecific signs of systemic inflammation are considered minor criteria and include arthralgia, fever, elevated acute-phase reactants, and a prolonged P–R interval by echocardiogram.

Diagnosis is based on the presence of two major criteria and one minor criteria plus evidence of preceding infection with group A *Streptococcus*. If, however, chorea and carditis are present then demonstration of antecedent strep infection is not required to make the diagnosis.[50] There is some evidence that a revision of the Jones criteria should be considered, particularly in endemic areas.[51] These might include monoarthritis, subclinical carditis, and a low-grade fever, (≥37.5), in order to avoid an important subset of patients who develop cardiac complications but do not meet standard Jones criteria.

Rheumatic carditis usually involves the endocardium, myocardium, and pericardium and almost always is associated with a murmur, either mitral or aortic regurgitation.[49] Carditis, if present, usually presents in the first 3 weeks of the illness. There has been much debate about the use of echocardiography to aid in diagnosis of rheumatic heart disease without clinical evidence of a murmur; however, thus far its routine use has not been advocated. Its use has been accepted in patients with polyarthritis where other diagnostic criteria have not yet been met and in indistinguishable heart murmurs.[49]

BOX 160-2 THE JONES CRITERIA FOR RHEUMATIC FEVER, UPDATED 1992

Major Criteria

- Carditis
- Migratory polyarthritis
- Sydenham chorea
- Subcutaneous nodules
- Erythema marginatum

Minor Criteria

- Clinical
  - Fever
  - Arthralgia
- Laboratory
  - Elevated acute-phase reactants
  - Prolonged P–R interval

plus

Supportive evidence of a recent group A streptococcal infection (e.g., positive throat culture or rapid antigen detection test, and/or elevated or increasing streptococcal antibody test)

From Guidelines for the diagnosis of rheumatic fever. Jones Criteria, 1992 update. Special Writing Group of the Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease of the Council on Cardiovascular Disease in the Young of the American Heart Association. *JAMA* **268**:2069, 1992.

Figure 160-5 Erythema marginatum of rheumatic fever. Enlarging and shifting transient annular and polycyclic lesions.

Migratory polyarthritis can affect any joint but most often involves the large joints. Early administration of anti-inflammatory medications does mitigate the arthritis and may therefore mask it. In addition, post-streptococcal reactive arthritis exists and can confound the picture.[49] The diagnosis of chorea is based entirely on clinical signs, which include fleeting local muscular weakness, emotional lability, personality changes, and erratic, jerky, purposeless movements. Chorea does not occur in adult men.

The dermatologic manifestations of ARF are characteristic but rare. Subcutaneous nodules are small, painless, and localized over bony prominences and in tendon sheaths. They are usually smaller, more discrete, and less persistent than rheumatoid nodules, and are usually seen in children with prolonged active carditis, rather than in the early stages of rheumatic fever.[48] These resemble histologically the Aschoff nodules seen in the heart.[48] Typically, they last for 1 to 2 weeks and spontaneously resolve. Erythema marginatum begins as an erythematous macule or papule extending outward while the central skin returns to normal. The border is pink and serpiginous, is not indurated, and blanches with pressure (Fig. 160-5). Patients are often unaware of its presence. Histopathologically, there is a sparse superficial perivascular infiltrate of lymphocytes and neutrophils.[14,48]

TREATMENT

Treatment is directed at eradication of GAS from the oropharynx. Penicillin is the antibiotic of choice, is inexpensive, and can be administered orally or intramuscularly. Oral therapy should be continued for at least 10 days.[48] Penicillin-allergic patients can be treated with cephalosporins or macrolide antibiotics.[21] Due to the high rate of recurrence in previously affected people, antibiotic prophylaxis is recommended, especially in endemic areas.

The acute inflammatory process is largely treated symptomatically, including bed rest during the early phase of the syndrome.[48] Anti-inflammatory medications including salicylates and nonsteroidal agents are effective for the arthritis, fever, and arthralgia. However, salicylates alone have not been shown to be effective in decreasing the incidence of rheumatic heart disease after ARF. Corticosteroids are believed to be beneficial in the treatment of carditis; though this has never been shown in a randomized controlled trial. Lastly, intravenous Ig has also been tested but has not shown any benefit.[19] Approximately 80% of patients who fulfill the criteria for this disorder recover spontaneously.

GOUT

Gout is a clinical syndrome caused by a group of heterogeneous diseases characterized by deposition of monosodium urate crystals in synovial fluid and joints with or without hyperuricemia, renal disease, or nephrolithiasis.[52,53] It tends to occur in both acute and chronic forms. Classically, the acute presentation is that of an acute lower extremity peripheral joint inflammatory synovitis. The most commonly affected sites are the first metatarsophalangeal joint and the ankle. In the chronic form, aggregates of crystals are deposited in tissue, especially in skin and around joints. While skin disease is often asymptomatic, periarticular and osseous deposition may lead to bone destruction.

EPIDEMIOLOGY

Gout affects approximately 5 million Americans and has historically been described as a disease that affects men; however, it also affects women. Recent epidemiologic studies demonstrate that on average, women develop gout a decade later than men, and that female patients with gout are more likely to have renal insufficiency or to be taking diuretics.[22] Obesity has been linked to gout, and both diseases have increased in incidence over the past two decades. Alcohol has long been recognized as a risk factor for gout, but only recently consumption of purine rich foods such as meat and seafood has been shown to correlate positively with serum urate levels and gout. It has also been shown that eating low-fat dairy products may be protective.[23] Gouty attacks in children are so uncommon that this diagnosis should prompt an evaluation for a malignant or genetic cause.

PATHOGENESIS

Hyperuricemia is a risk factor for gout, but acute gouty arthritis can occur in patients with normal serum uric acid levels. Patients with serum uric acid levels greater than 7 mg/dL have a 22% chance of developing gout

TABLE 160-4
Classification of Hyperuricemia

- Overproduction of uric acid
  - Primary hyperuricemia
    - Idiopathic
    - Hypoxanthine-guanine phosphoribosyltransferase deficiency
    - Phosphoribosylpyrophosphate synthetase superactivity
  - Secondary hyperuricemia
    - Excessive dietary purine intake
    - Increased nucleotide turnover (e.g., myeloproliferative and lymphoproliferative disorders, hemolytic disease, psoriasis)
- Diminished excretion of uric acid
  - Primary hyperuricemia
    - Idiopathic
  - Secondary hyperuricemia
    - Diminished renal function
    - Inhibition of tubular urate secretion by competitive anions (e.g., keto- and lactic acidosis)
  - Enhanced tubular urate reabsorption
    - Dehydration, diuretics
  - Miscellaneous
    - Hypertension
    - Hyperparathyroidism
    - Certain drugs (e.g., cyclosporine, pyrazinamide, ethambutol, low-dose salicylates)
    - Lead nephropathy

over a 5-year period, demonstrating that many patients with elevated serum uric acid levels may never have gouty arthritis.[6]

Uric acid is the end product of purine catabolism. In most fish, amphibians, and nonprimate mammals, purine-generated uric acid is degraded through a uricase (a uric acid oxidase).[53] In primate mammals and humans, the *uricase* gene is silenced by two mutations. This absence of uricase, along with extensive reabsorption of filtered urate, results in plasma urate levels that are 10 times that of most other mammals.[53] Hyperuricemia results from either overproduction or underexcretion of uric acid. Ninety percent of affected patients are underexcreters.[6]

Table 160-4 presents a classification of hyperuricemia. Less than 10% of patients with hyperuricemia or gout excrete excessive quantities of uric acid in a 24-hour urine collection. It is usually in this group that identifiable and inherited derangements in mechanisms regulating protein nucleotide synthesis, specifically a deficiency of hypoxanthine-guanine phosphoribosyltransferase, glucose-6-phosphatase, or fructose-1-phosphatase, either partial or complete, can be found. These are genetically inherited by X-linked and autosomal recessive means (in the latter two); therefore, family history or early presentation may be a clue. The Lesch–Nyhan syndrome, well described but very rare, is an extremely severe form of hypoxanthine-guanine phosphoribosyltransferase deficiency associated with mental retardation, gout, and self-mutilation.[26]

Uric acid underexcretion is idiopathic in patients with hyperuricemia. The anatomic appearance and physiologic function of the kidney appear normal; however, alteration of renal tubular function in these patients by many drugs can precipitate gouty attacks. These pharmacologic agents include loop diuretics, low-dose cyclosporine, and salicylates.

Precipitating causes of an acute gouty attack are not well understood. Studies have shown the presence of intracellular monosodium urate crystals in synovial fluid of asymptomatic patients, suggesting that inflammation in gout is chronic. There must be an unidentified trigger in the acute attack that incites a more robust inflammatory response. Monocytes are present and secrete cytokines, including TNF-α, interleukin 1, interleukin 6, and interleukin 8. Neutrophils are then attracted to the site as well; they ingest the crystals, and release multiple inflammatory mediators, initiating further inflammation and tissue damage.[53]

CLINICAL MANIFESTATIONS

It is felt that gout occurs in four stages: (1) asymptomatic hyperuricemia, (2) acute gouty arthritis, (3) intercritical gout (between gouty attacks), and (4) chronic tophaceous gout.[26]

Patients are often asymptomatic for years, requiring no therapeutic intervention in the absence of other evidence of disease (e.g., nephrolithiasis or renal insufficiency).

Acute gouty arthritis usually occurs in middle age and primarily affects a single joint in the lower extremities, the first metatarsophalangeal being the most common site of initial involvement (podagra).[26,52] Clinically, the affected joint is erythematous and exquisitely tender to palpation. This may be confused with a sprain, a septic joint, or cellulites. Cytokine release can lead to fever and systemic symptoms, confounding the picture further. Further differential diagnoses include other forms of arthritis (psoriatic, reactive arthritis osteoarthritis, or RA) and pseudogout (chondrocalcinosis).[26]

Intercritical gout describes the interval that occurs between attacks of gout, an interval of between 6 months to 2 years. As attacks continue, they tend to be polyarticular, more severe, and of longer duration. Chronic tophaceous gout describes gout where patients rarely have asymptomatic periods. Urate crystals may be found in the soft tissues, cartilage, and tendons (Fig. 160-6A).[26] They have been reported in a variety of unusual places as well, including the nasal dorsum.[24] They may be confused with rheumatoid nodules, and aspiration or biopsy may prove useful.

LABORATORY PRESENTATION AND PATHOLOGY

Laboratory analysis may reveal elevated uric acid levels, but this finding is not necessary for the diagnosis. Leukocytosis and elevated sedimentation rate are often seen during acute arthritic attacks. Accurate diagnosis rests on the demonstration of intracellular,

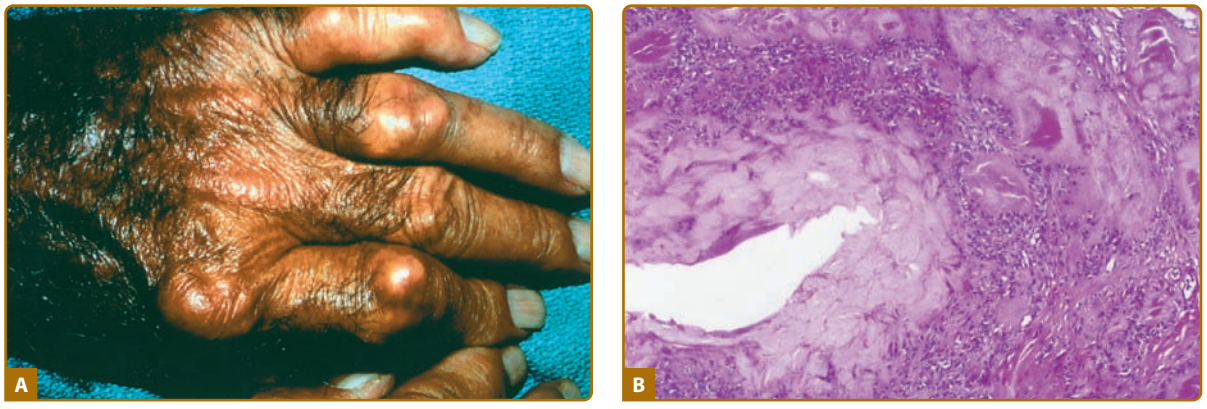

Figure 160-6 Gouty tophi. **A.** Tender nodules overlying joints and tendons, which may drain chalky white material. **B.** Histopathology shows granulomatous "fluffy" appearing infiltrate surrounding radially arranged needle-like spaces.

negatively birefringent, needle-shaped crystals by polarized microscopy. Histopathologic examination of a gouty tophus reveals granulomatous inflammation surrounding yellow–brown urate crystals or needle-like spaces in a radial arrangement, representing crystals dissolved during processing (see Figs. 160-6B and 160-7).[14]

TREATMENT

The goal of therapy in acute gouty attacks is analgesia and reduction in inflammation. The main options to choose from are the nonsteroidal anti-inflammatory drugs, colchicine, and corticosteroids. Indomethacin has been shown in randomized controlled trials to decrease pain, as has colchicine; however, the adverse gastrointestinal side effect of colchicine is often a deterrent for its use. However, a newer regimen for colchicine use in acute attacks appears to greatly reduce the incidence of gastrointestinal symptoms.[54] This regimen of 1.2 mg of colchicine followed in 1 hour by 0.6 mg, also is likely to reduce drug–drug interactions mediated by colchicine inhibition of *P*-glycoprotein and cytochrome 3A4 pathways. Severe adverse reaction and deaths have been reported when colchicine is combined with other strong inhibitors of one or both pathways (e.g., clarithromycin, erythromycin, and cyclosporine).[54] Indomethacin can precipitate acute renal failure in patients with underlying renal disease. Corticosteroids, both oral and intra-articular, are also believed to be effective. Because patients with gout are older and often have many comorbidities, therapy should be individualized. Treatment should continue for 7 to 10 days after the acute attack, and prophylactic therapy may be continued for 3 to 6 months.[26,52]

Figure 160-7 Gouty tophi on helix.

In patients with only one gouty attack, a conservative management approach can be used. This includes avoidance of drugs that decrease the excretion of uric acid such as thiazide or loop diuretics, aspirin, pyrazinamide, or niacin. Patients should maintain adequate hydration, lose weight, control hypertension and hyperlipidemia, and make diet adjustments by decreasing purine intake. Effectiveness of limiting cholesterol, fat, meat, and alcohol has never been studied, but should be advocated to avoid the need for lifelong oral therapy.[26,53]

Uric acid-lowering therapy is probably necessary in patients in whom the diagnosis of gout has been established, and who have had more than one gouty attack or are suffering from chronic tophaceous gout. It is also indicated in patients with history of gout and renal calculi, extremely high values of serum uric acid, high serum uric acid levels in the setting of a known familial history of gout (e.g., where there is a known deficiency of one of the relevant enzymes previously described), and prophylaxis for patients receiving acute courses of chemotherapy.

The goal of urate-lowering drugs is to maintain the serum urate level consistently at less than 6 mg/dL. Uricosuric therapy is ideal in younger patients

(age less than 60 years) with normal kidneys who are underexcreters of uric acid. Uricosurics include probenecid, sulfinpyrazone, and benzbromarone.[55,56] The major risks associated with these medicines include hypersensitivity reactions and increased risk of uric acid nephrolithiasis (avoided by alkalinizing the urine). Unfortunately, most patients with gout do not fit this "ideal" situation. Benzbromarone is not commercially available in the United States and many other countries; though potent, it is potentially hepatotoxic.[56]

For all other patients, the xanthine oxidase inhibitors are used. Allopurinol is the first-line drug for serum urate lowering.[55] It decreases production of uric acid, and is indicated for patients with nephrolithiasis, renal impairment, those who failed uricosuric agents, with myeloproliferative disorders on chemotherapy, and patients with hyperuricemia due to enzyme abnormalities. Dosages must be reduced in patients with renal failure. Twenty percent of patients taking allopurinol report side effects, and 5% discontinue medication as a result. Side effects include dyspepsia, headache, diarrhea, a pruritic papular eruption, thrombocytopenia, and hepatic function abnormalities. Allopurinol hypersensitivity syndrome is rare and includes fever, urticaria, leukocytosis, eosinophilia, interstitial nephritis, acute renal failure, granulomatous hepatitis, and toxic epidermal necrolysis. A second xanthine oxidase inhibitor is febuxostat, labeled for use at 40 mg once daily.[55,56] It appears to be roughly equivalent to allopurinol. However, it does show higher efficacy in the setting of renal impairment, when allopurinol, but not febuxostate, must be reduced.[56]

Uricases are an additional class of therapeutic agents used in treating urate disorders. The nonpegylated recombinant fungal enzyme rasburicase is Food and Drug Administration (FDA) approved for short-course therapy to prevent tumor lysis syndrome.[55] It is highly immunogenic, and its plasma half-life is less than 24 hours. Pegylation of uricases with production of PEG multimers has decreased the immunogenicity and increased the serum half-life to days or weeks. Infusion reactions may be seen, and include flushing, urticaria, hypotension, and anaphylaxis. All uricase therapies may induce oxidative stress, which can lead to methemoglobinemia or anemia, occurring more often but not confined to glucose-6-phosphate dehydrogenase-deficient (G6PD-deficient) individuals.[55] The role of pegylated uricases in treating urate disease remains to be determined.

Chapter 161 :: Sjögren's Syndrome

:: Gabor Illei & Stamatina Danielides

SJÖGREN'S SYNDROME AT A GLANCE

- Chronic autoimmune disease characterized by chronic inflammation involving the exocrine glands.
- Salivary and lachrymal glands are predominantly affected leading to dry mouth and dry eyes.
- May occur alone (primary Sjögren's syndrome), or may coexist with other systemic connective tissue disorders (secondary Sjögren's syndrome).
- Systemic manifestations, such as fatigue, arthritis, vasculitis, interstitial pulmonary disease, peripheral or central neuropathy, and autonomic nervous dysfunction may accompany glandular involvement.
- Patients with systemic manifestations are at higher risk of lymphoma.
- Treatment of sicca symptoms is mainly symptomatic, whereas management of extraglandular manifestations is similar to other autoimmune diseases.

EPIDEMIOLOGY

Sjögren's syndrome (SS) is one of the most common rheumatic autoimmune diseases. SS affects predominantly women with a female to male ratio of 9:1. Women are most commonly diagnosed in their fifth or sixth decade, but it can affect individuals of any age and sex.

SS has a worldwide distribution. In most studies done mainly in Caucasian populations the estimated prevalence rate in the adult general population is between 0.1% and 0.8%. However, one study in the United Kingdom showed a prevalence rate of 3.3%, whereas another study in Japan showed only a 0.02% prevalence rate. The estimated annual incidence rate was consistently approximately 0.005% in several studies.[1]

PATHOGENESIS

The pathogenesis of SS is still largely unknown. In a genetically predisposed individual, various environmental factors, such as viral infections, may lead to epithelial-cell activation and a protracted inflammatory response with features of autoimmunity. Autoreactive lymphocytes and autoantibodies are considered important in this process, although the pathogenic role of any particular autoantibody is still undefined. Abnormal apoptosis may be important in several ways. First, increased apoptosis of epithelial cells may lead to functional defects and provide autoantigens, whereas the prolonged survival of B and T cells through upregulation of antiapoptotic signals may be involved in sustaining a self-perpetuating autoimmune process. Decreased apoptosis of lymphocytes may also contribute to the increased frequency of lymphoma in SS patients.

IMMUNOGENETIC FACTORS

The role of genetic factors in SS was recognized in family studies where first-degree relatives of patients had an increased prevalence of SS.[2] Such family clustering was further observed among first-degree relatives of individuals with anti-Ro/SSA antibodies regardless of their clinical diagnoses (SS or systemic lupus erythematosus or even healthy controls).[3]

There is a well-established association between SS or anti-Ro/SSA and anti-La/SSB antibodies with HLA class II genes.[4] Genes other than those of the HLA loci may also be associated with an increased risk of disease. Associations with a number of cytokine gene polymorphisms, such as interleukin (IL) 6, IL-10, tumor necrosis factor-α (TNF-α) and the IL-1 receptor antagonist, have been reported, but none of these have been confirmed to date.[4] Several genetic polymorphisms previously linked to systemic lupus erythematosus and other autoimmune diseases are also associated with SS. From these, two transcription factors, (1) signal transducer and activator of transcription 4 (STAT4)[5] and (2) interferon regulatory factor 5 (IRF 5),[6] which were both independently associated with SS showed an additive effect in increasing the risk of Sjögren's syndrome from around 1.6–1.9 for one risk allele to 6.7 when both risk alleles were present.[7]

ENVIRONMENTAL FACTORS

The inciting event in the pathogenesis of SS is not known, and it may not be a single event. The strong predominance of females suggests gender-specific predisposing factors. Although sex hormones are obvious targets, there is no conclusive proof yet that the difference in the pathogenesis between males and females is due to sex hormones alone.[8,9] Viral infections have also been proposed as inciting events. This theory is strongly supported by the fact that chronic inflammation of the salivary glands has been observed with chronic hepatitis C and human immunodeficiency virus infections, and such infections cause a disease with a clinical spectrum very similar to SS. The fact that some viruses, such as Epstein–Barr virus (EBV), are known to replicate in oropharyngeal and lachrymal glands led to the hypothesis that these viruses may be involved in Sjögren's pathogenesis. In fact, genetic material from EBV was detected by DNA hybridization in SS salivary tissue, but it was also found in normal individuals. Further experiments have identified an unusual strain of EBV containing a deletion in the genome in salivary gland specimens from Chinese SS patients.[10] Similarly, in a Japanese cohort, defective human T-lymphotropic virus-I genome was isolated from salivary gland tissue.[11] Other viruses, such as coxsackievirus[12] or endogenous retroviruses have also been proposed as causative agents. However, there is no proof, to date, that any of these viruses play a pathogenic role in SS.

EPITHELIAL-CELL ACTIVATION AND CHRONIC INFLAMMATION

Sections of salivary and lachrymal glands in SS are characterized by periductal mononuclear infiltrates. The majority of the infiltrating cells are $CD4^+$ T lymphocytes, whereas $CD8^+$ cytotoxic T cells are found in smaller numbers. Activated B lymphocytes are also present, including immunoglobulin-secreting cells.

Inflammation seems to target glandular epithelial cells, and recent research has demonstrated the central role of epithelial-cell activation in initiating the recruitment of the inflammatory infiltrate.[13] In animal models, changes in epithelial cells occur before the appearance of lymphocytes in the salivary glands. Initial events include the expression of HLA class II molecules and various activation markers, such as the costimulatory molecules CD80 and CD86, on the surface of acinar and ductal[14] salivary epithelial cells. These molecules are crucial in regulating the interaction between antigen-presenting cells and lymphocytes. Their expression in acinar and ductal[15,16] epithelial cells suggests that epithelial cells in SS act as antigen-presenting

cells and actively participate in lymphocyte activation. Another important step is the upregulation of adhesion molecules and chemokines, all of which contribute to the recruitment of inflammatory cells, such as T and B lymphocytes, macrophages, and dendritic cells. The activation of lymphocytes leads to abnormal cytokine and chemokine expression,[17] perpetuating the chronic inflammatory process characterized by a complex interaction between activated epithelial cells, the innate and acquired immune system. Extraglandular manifestations occur as a result of similar lymphocytic infiltrations at other organs. This is described by some as *autoimmune epithelitis* to better reflect the systemic nature of the disease. Some epithelial cells express Fas and Fas ligand[18] and, as a consequence, undergo apoptosis; others may be destroyed by perforin, granzymes, and other cytotoxins produced by lymphocytes. However, in most patients, only partial destruction of the glands is noted. Local production of cytokines, autoantibodies, metalloproteinases, and other inflammatory mediators may contribute to the dysfunction of the remaining epithelial cells by various mechanisms. For example, it has been shown that TNF interferes with the intracellular trafficking of aquaporin-5, one of the water channels required for saliva production. Enhanced activity of the type-1 interferon system has been linked to multiple autoimmune diseases, including Sjögren's syndrome. Increased expression of interferon-regulated genes was described both in the salivary glands and peripheral blood.[19–21] One of the cytokines upregulated by interferon-α is B-cell activating factor (BAFF), which promotes B-cell survival and has also been found at higher levels in Sjögren's patients.[22,23] Interestingly, both of these cytokines can be upregulated by viruses.[24]

AUTOANTIBODIES

Autoantibodies are the hallmarks of systemic autoimmune diseases, including SS. The best-defined autoantibodies in SS are the anti-Ro/SSA and anti-La/SSB antibodies.[25] Both are targeted against ribonucleoprotein antigens. Anti-Ro/SSA recognizes two RNA-binding proteins (the 52-kDa or the 60-kDa protein), whereas anti-La/SSB antibodies recognize RNA polymerase III. Anti-Ro/SSA antibodies are found in over 70% of patients with SS, but are not specific for SS and are frequently found in SLE and other autoimmune diseases even when there are no symptoms or signs of oral or ocular dryness. Anti-La/SSB is more specific; it is present in 50% of patients with primary SS or SS/SLE but is rarely seen in other diseases. The pathogenic role of these antibodies is not yet defined, but, because Ro and La are expressed on the surface of apoptotic epithelial cells, it is possible that an immune response against these antigens contributes to inflammation in the gland. The most compelling in-vivo evidence for a pathogenic role of these autoantibodies comes from newborns with fetal heart block born to women with anti-Ro/SSA and/or anti-La/SSB antibodies. These antibodies can cross the placenta and bind to Ro and La antigens located on the cell surface of fetal myocardial tissue, leading to fetal heart block. Other autoantibodies, such as antinuclear antibodies and rheumatoid factor, are frequently present in patients with both primary and secondary SS. Although they lack specificity, they are markers of a systemic autoimmune response and thus can help distinguish SS from other causes of salivary or lachrymal gland dysfunction.

In recent years, research has focused on identifying antibodies more specific for SS, such as anti-α-fodrin and antimuscarinic acetylcholine receptor antibodies, but the results have been controversial. The major stimulus for saliva production is the binding of acetylcholine to muscarinic acetylcholine receptors. The hypothesis that oral and ocular dryness could result from antibodies antagonizing the muscarinic acetylcholine receptor-3 is intriguing. These antibodies have been demonstrated to play an essential role in eliciting glandular dysfunction in the nonobese diabetic (NOD) mouse model of SS, possibly through an inhibitory effect on the receptor.[26] In humans, however, results are still contradictory as multiple attempts to detect these antibodies with conventional immunologic methods have been fruitless.[27,28]

CLINICAL MANIFESTATIONS

EXOCRINE GLAND INVOLVEMENT

The dominating feature of SS is exocrine gland dysfunction, leading to the classic sicca symptoms of xerostomia (oral dryness) and xerophthalmia or keratoconjunctivitis sicca (dry eyes).

XEROSTOMIA. Oral dryness is the principal symptom of SS, caused by decreased saliva secretion, which is persistent and continuous throughout the day and night and can significantly compromise quality of life. Reduced salivation causes difficulty in chewing and swallowing dry foods. Dryness of the tongue and oral mucosa leads to an altered sense of taste and, at times, produces a burning discomfort, especially when eating acidic or spicy foods. Physical examination may reveal a red and fissured tongue with a characteristic atrophy of the filiform papillae or angular cheilitis. Ulcerations can be found, particularly in SS patients with dentures, usually in proximity to the mucosal surface that makes contact with the denture.

Saliva has antimicrobial properties, so lack of saliva can predispose to infections. Oral thrush is common and can be manifested as pseudomembranous or erythematous mucosal lesions. Furthermore, patients with SS have an increased incidence of caries. A characteristic feature of caries in SS is its primary location at the cervical and incisal regions of the teeth.

Bilateral salivary gland enlargement usually occurs in the parotid glands of SS patients. It is frequently nontender, and it can be recurrent or chronic (Box 161-1). Painful, unilateral parotid enlargement should raise the suspicion of an infection (Fig. 161-1) or a salivary gland stone. In cases of persistent unilateral

BILATERAL	**VIRAL INFECTIONS**	**MUMPS**
		Epstein's–Barr, cytomegalovirus, coxsackie
		Human immunodeficiency virus, human T-lymphotropic virus-I
		Hepatitis C
	Immune mediated	Sjögren's syndrome
		Sarcoidosis
		Amyloidosis
	Endocrine/metabolic	Diabetes mellitus
		Hyperlipoproteinemia
		Chronic pancreatitis
		Acromegaly
	Other	Alcohol
		Recurrent parotitis of the childhood
Unilateral	Bacterial infections	
	Neoplasms	Mainly lymphomas
	Sialolithiasis	

parotid gland enlargement, the presence of lymphoma should be excluded (see Box 161-1).

Medical causes of oral dryness, such as dehydration, diabetes, viral infections, or drug treatment, should be considered when evaluating a patient for Sjögren's syndrome.

KERATOCONJUNCTIVITIS SICCA. Ocular dryness is the other dominant feature of SS. A burning and itching sensation in the eyes, commonly exacerbated by smoke, is caused by lack of tear production. Patients frequently complain of intolerance to contact lenses. Paradoxically, the quantity of tears produced during crying may not be affected. Physical evaluation shows corneal injection and mucous discharge in the lower fornix. Enlarged lachrymal glands have been described in Sjögren's patients, but occur less commonly than enlarged salivary glands. The constellation of symptoms and signs indicating dry eyes constitutes keratoconjunctivitis sicca.

OTHER SICCA MANIFESTATIONS. *Cutaneous xerosis*, a term used to describe dryness of the skin, is very common in SS, with a frequency varying between 23% to 68%. The most common symptoms of xerosis are nonspecific pruritus, burning sensation and a pinprick-like feeling. Physical examination reveals roughness, fine scaling, and loss of elasticity of the skin. The pathogenesis of xerosis is unknown. Impairment of the sweat glands is considered an important factor because decreased sweating has been reported in SS patients. A recent study has indicated that xerosis may be related to increased epidermal proliferation with disturbed epidermal differentiation.[29]

Dryness of the upper respiratory tract can cause epistaxis, hoarseness, and bronchial hyper-responsiveness. Another common complaint in women with SS is vaginal dryness, which may lead to an increased incidence of vaginal infections and dyspareunia.

NONEXOCRINE GLAND INVOLVEMENT

SKIN INVOLVEMENT. Cutaneous manifestations are common extraglandular features of SS (Table 161-1).[30] They are generally considered either vasculitic or nonvasculitic lesions.

Vascular Lesions. Raynaud's phenomenon is probably the most common abnormality. It can be seen in 15% to 35% of patients and can precede sicca symptoms by many years. Raynaud's phenomenon in Sjögren's syndrome is not accompanied by telangectasias as seen in systemic sclerosis. Calcifications have been described, but are uncommon. Although Raynaud's is usually mild in SS, it is a marker of a subgroup with increased risk of extraglandular manifestations.[31]

Hypergammaglobulinemic Purpura. Purpuric macules are very common in Sjögren's. Flat, nonpalpable, blanching purpura has been associated with an entity called benign hyperglobulinemic purpura, characterized by polyclonal hypergammaglobulinemia and a positive rheumatoid factor. The skin biopsies reveal ruptured blood vessels with complement deposition.[32]

TABLE 161-1
Cutaneous Manifestations of Sjögren's Syndrome

Vascular	■ Raynaud's phenomenon ■ Cutaneous vasculitis ■ Nonpalpable purpura ■ Palpable purpura ■ Urticarial vasculitis ■ Necrotizing vasculitis ■ Annular erythema ■ Erythema multiforme ■ Erythema perstans ■ Erythema nodosum
Nonvascular	■ Oral ■ Dry mucous membranes ■ Papillary atrophy of the tongue ■ Candidiasis ■ Angular cheilosis ■ Eyelid dermatitis ■ Alopecia ■ Vitiligo

Figure 161-2 Cutaneous vasculitis in primary Sjögren's syndrome. Biopsy showed leukocytoclastic vasculitis.

Cutaneous vasculitis (CV) can present as palpable purpura or urticarial vasculitis.

Palpable purpura, which does not blanch when pressure is applied to the skin is due to dermal vasculitis with extravasation of red blood cells, and typically involves the lower extremities and buttocks (see Chapter 164). It represents an important marker of more severe disease, and is associated with an increased risk of lymphoma development and mortality. Histopathologically, palpable purpurae can be divided into two groups. Neutrophilic inflammatory vascular disease is characterized by a predominantly neutrophilic infiltrate, fibrinoid necrosis, occlusion of the lumen, and extravasation of red blood cells, and is indistinguishable from the classical leukocytoclastic vasculitis (Fig. 161-2) (see Chapter 163). On the other hand, mononuclear inflammatory vascular disease is characterized by a mononuclear inflammatory infiltrate with invasion of the blood vessel walls. Fibrinoid necrosis is present but less prominent. The clinical presentation of these two forms are indistinguishable, but neutrophilic inflammatory vascular disease is associated more strongly with markers of systemic autoimmunity, such as antinuclear antibodies and anti-Ro/SSA and anti-La/SSB antibodies, hypergammaglobulinemia, rheumatoid factor, and hypocomplementemia. Cryoglobulinemic vasculitis can also be seen among Sjögren's patients and has the same cutaneous manifestations (see Chapter 169).

Urticarial vasculitis is the second most frequent form of CV in SS and presents as pruritic wheals with erythema (see Chapter 38). In contrast to true urticaria, individual lesions last for more than 24 hours and often resolve with hyperpigmentation. Biopsy of the skin lesions demonstrates a perivascular neutrophilic infiltrate accompanied by leukocytoclasia. Necrotizing vasculitis is not commonly seen in Sjögren's syndrome. It can present as palpable purpuric lesions of the lower extremities, which may ulcerate, finally resolving within 1–4 weeks. They heal with atrophy or scar tissue formation. This form of vasculitis has been observed more frequently among patients with more active disease; it has been associated with arthritis, Raynaud's phenomenon, peripheral neuropathy, fever, and pulmonary or glomerular involvement. Antineutrophil cytoplasmic antibodies with perinuclear fluorescence can be found, but are uncommon in Sjögren's syndrome.

Annular erythema is found primarily among Asian patients who have anti-Ro/SSA antibodies. Characteristic lesions are annular erythematous plaques with elevated borders and central clearing. They are localized on the face, arms, back, trunk, and proximal thighs. Lesions are similar to subacute cutaneous lupus but seem to represent a distinct clinical and histopathologic entity.

A painful nodular eruption of the anterior surface of the lower extremities, suggesting erythema nodosum (see Chapter 70) may occur in patients with sicca manifestations. Because erythema nodosum in SS patients is rare, its presence should raise suspicion for sarcoidosis. Erythema multiforme-like lesions and superficial ill-defined patches (erythema perstans) have also been described in SS.

Nonvascular Cutaneous Manifestations. Xerostomia predisposes to angular cheilitis, which presents as recurrent, symmetric, itching fissures. Eyelid dermatitis is defined by the presence of erythematous, infiltrated and lichenificated lesions of the eyelids associated with itching and foreign body sensation. Alopecia and vitiligo can also be seen in SS, albeit infrequently. Despite multiple case reports describing

cutaneous B- and T-cell lymphomas in SS patients, they are, in fact, rare.

NONCUTANEOUS EXTRAGLANDULAR MANIFESTATIONS

Musculoskeletal Manifestations. A symmetric nonerosive polyarthritis can frequently be seen in primary SS. The distinction from rheumatoid arthritis may be difficult; the absence of rheumatoid factor and anti-CCP antibodies and the absence of erosions on X-rays would favor SS over RA. Arthralgias and myalgias are common complaints but true myositis is rare in primary SS.

Visceral Manifestations. Dry cough due to dryness of the tracheal mucosa is common (tracheobronchitis sicca). Rarely, patients can develop interstitial pneumonitis. Patients may also develop mucosa-associated lymphoid tissue (MALT) lymphoma in the lungs.

Genitourinary manifestations include interstitial cystitis, renal tubular acidosis, interstitial nephritis, and, rarely, glomerulonephritis.

Dysphagia due to xerostomia and esophageal dysmotility is common. *Helicobacter pylori* is associated with an increased risk of MALT lymphomas, therefore, SS patient with gastritis should be checked for *H. pylori* and treated if found positive. An asymptomatic, chemical pancreatitis with high-serum amylase concentrations has been reported in 25% of patients.

SS is associated with various other diseases, such as celiac disease, primary biliary cirrhosis, and hypothyroidism. Because of these associations, a high index of diagnostic suspicion is warranted to identify and treat these conditions.

Neurologic Manifestations. Neurologic manifestations can be divided into those that involve the central nervous system, and those that involve the peripheral nervous system and autonomic dysfunction.

The peripheral nervous system is involved in approximately 20% of patients with SS.[33] The most common manifestations are peripheral axonal polyneuropathies, which are mostly sensory. Another entity that has been described is a ganglionopathy involving the sensory ganglia of the posterior column. This starts with unilateral peripheral paresthesias evolving over months to years to deep sensory impairment, positive Romberg sign, generalized areflexia, and ataxia.[34] Cranial neuropathies are also frequent among SS patients. The most common form is unilateral trigeminal neuropathy; it usually spares the ophthalmic division, thus preserving the corneal reflex. Other cranial neuropathies may lead to Bell's palsy (facial nerve), neural deafness and vestibular dysfunction (vestibulecochlear), and diplopia (oculomotor, trochlear, abducent nerve).

The central nervous system can be involved, although the prevalence and the spectrum of manifestations are still controversial. Manifestations similar to multiple sclerosis as well as transverse myelitis have been described. The latter is frequently associated with antiaquaporin-4 autoantibodies.

Lymphoproliferative Disease. The incidence of lymphoma in Sjögren's patients is increased 15- to 44-fold, according to various studies,[35] and 4% to 8% of SS patients develop lymphoma. Most of these are indolent, extranodal, marginal-zone B-cell lymphomas of MALT, but higher grade lymphomas are also seen.

A variety of clinical and laboratory features have been correlated to an increased risk of lymphoma development. Recurrent or persistent salivary gland swelling, palpable purpura, low complement levels, low CD4 counts, and persistently elevated inflammatory markers indicate an increased disease activity and increased risk for lymphoma development.[36,37]

Pregnancy. In Sjögren's syndrome, pregnancy outcomes are similar to those in healthy women. Carriers of the SSA antibody, however, can transmit it through the placental circulation to the fetus. These antibodies can cause congenital heart block or neonatal lupus, characterized by an annular rash with central scarring in the scalp and around the eyes, as well as, liver inflammation and transaminitis. This syndrome develops around the sixth week postpartum. Although the rash spontaneously resolves around the sixth to eighth months of age, the heart block is permanent and requires placement of a pacemaker. Expectant mothers with anti-SSA antibodies should be counseled about this risk and their fetuses should be followed closely for the development of fetal heart block.

DIAGNOSIS

The diagnosis of SS in a patient with complaints of oral and ocular dryness requires evaluation by a dentist or salivary gland specialist (such as a otorhinolaryngologist) and an ophthalmologist for specialized tests to quantify mucosal dryness, as well as laboratory evidence of autoantibodies and salivary gland biopsy for evidence of inflammation within the gland itself.

Several sets of diagnostic criteria were developed, and used by various groups over time, creating some confusion about how to define SS. Recently, an international consensus group agreed on a set of criteria, and this revised American–European classification system has been widely accepted (Table 161-2).[38] Six features are taken into consideration: subjective complaints and objective evidence of dry eyes or dry mouth, objective evidence of salivary gland inflammation, and the presence of specific autoantibodies in the serum. For the diagnosis of primary SS, at least four criteria should be present, and at least one of them should be either evidence of lymphocytic infiltration or the presence of autoantibodies. Patients with a coexisting connective tissue disease are labeled secondary SS. Exclusions include other diseases and medications that may cause sicca symptoms.

To establish subjective symptoms of dry eyes and dry mouth, a validated uniform questionnaire is used. A variety of noninvasive methods can be used to diagnose reduced salivary flow in clinical practice.

TABLE 161-2
Revised International Classification Criteria for Sjögren's Syndrome

I. **Ocular symptoms:** A positive response to at least one of the following questions:
   1. Have you had daily, persistent, troublesome dry eyes for more than 3 months?
   2. Do you have a recurrent sensation of sand or gravel in the eyes?
   3. Do you use tear substitutes more than three times a day?

II. **Oral symptoms:** A positive response to at least one of the following questions:
   1. Have you had a daily feeling of dry mouth for more than 3 months?
   2. Have you had recurrently or persistently swollen salivary glands as an adult?
   3. Do you frequently drink liquids to aid in swallowing dry food?

III. **Ocular signs:** Objective evidence of ocular involvement defined as a positive result for at least one of the following two tests:
   1. Schirmer's test, performed without anesthesia (≤ 5 mm in 5 minutes)
   2. Rose Bengal score or other ocular dye score (≥ 4 according to van Bijsterveld's scoring system)

IV. **Histopathology:** In minor salivary glands (obtained through normal appearing mucosa) focal lymphocytic sialoadenitis, evaluated by an expert histopathologist, with a focus score ≥ 1, defined as a number of lymphocytic foci (which are adjacent to normal appearing mucous acini and contain more than 50 lymphocytes) per 4 mm^3 per glandular tissue

V. **Salivary gland involvement:** Objective evidence of salivary gland involvement defined as a positive result for at least one of the following diagnostic tests:
   1. Unstimulated whole salivary flow (<1.5 mL/15 min)
   2. Parotid sialography showing the presence of diffuse sialectasias (punctuate, cavitary or destructive pattern), without evidence of obstruction in the major ducts
   3. Salivary scintigraphy showing delayed uptake, reduced concentration and/or reduced excretion of tracer

VI. **Autoantibodies:** Presence in the serum of the following autoantibodies: antibodies to Ro/SSA, La/SSB or both

Modified from Vitali C et al: Classification criteria for Sjögren's syndrome: A revised version of the European criteria proposed by the American-European Consensus Group. *Ann Rheum Dis* **61**:554, 2002.

ORAL DRYNESS

SIALOMETRY. Sialometry involves measurement of the total saliva produced from all salivary glands in a time period of 15 minutes. The whole unstimulated salivary flow is considered suggestive of SS if it is less than 1.5 mL in 15 minutes. A "stimulated" salivary flow can be measured after administration of lemon juice or citric acid, and low values are also suggestive of SS.

SALIVARY GLAND SCINTIGRAPHY. Salivary gland scintigraphy is a functional study to assess saliva production by measuring the secretion of a radioisotope (^{99m}technetium-sodium pertechnetate) into the oral cavity. Salivary gland scintigraphy (SGS) provides functional information about individual salivary glands and can potentially distinguish between decreased production and/or decreased excretion of saliva. The past decade has seen a shift towards the quantitative evaluation of SGS based on various parameters generated from time–activity curves.[39] Given the high cost and the exposure to radiation, their routine use may not yet be justified but it is a useful diagnostic tool in selected cases. Sialography is an imaging method based on retrograde injection of contrast media into the parotid duct. Dilatations of salivary ducts and sialolithiases are the most common findings.

OCULAR DRYNESS

The diagnosis of keratoconjuctivitis sicca is based on the demonstration of decreased tear production, corneal damage, or both. Tear production is measured by Schirmer's test. This is performed by placing a standardized paper strip in the inferior fornix of each eye and measuring the length of filter paper that becomes wet after 5 minutes. The American–European classification system uses a cut-off value of 5 mm in 5 minutes, below which the diagnosis of dry eyes is made. An alternative method is staining with a dye (rose Bengal or lissamine green) that preferentially stains the devitalized cornea and conjunctiva. This staining is evaluated through the van Bijsterveld scoring system; a score of 4 or more indicates keratoconjunctivitis sicca. These tests have a high sensitivity but low specificity; they identify ocular dryness, but cannot attribute abnormal findings to SS.

LABORATORY TESTS. High inflammatory markers, such as high sedimentation rates and signs of chronic inflammation (anemia, hypoalbuminemia) are common in SS patients.

Serologies can demonstrate hyperglobulinemia, in as high as 80% of primary SS patients. Autoantibodies include Ro (SSA) and La (SSB) antibodies, as well as rheumatoid factors and ANA.

PATHOLOGY

None of the above diagnostic procedures is specific for SS. The most reliable objective diagnostic feature is seen on biopsy of the minor salivary gland. A small incision is made on the inner surface of the lip, and a minor salivary gland tissue sample is collected. Evidence of a focal, periductal infiltrate composed of T and B lymphocytes and few plasma cells is the histologic hallmark of SS (Fig. 161-3). The degree of lymphocytic infiltration is evaluated semiquantitatively by means of a focus

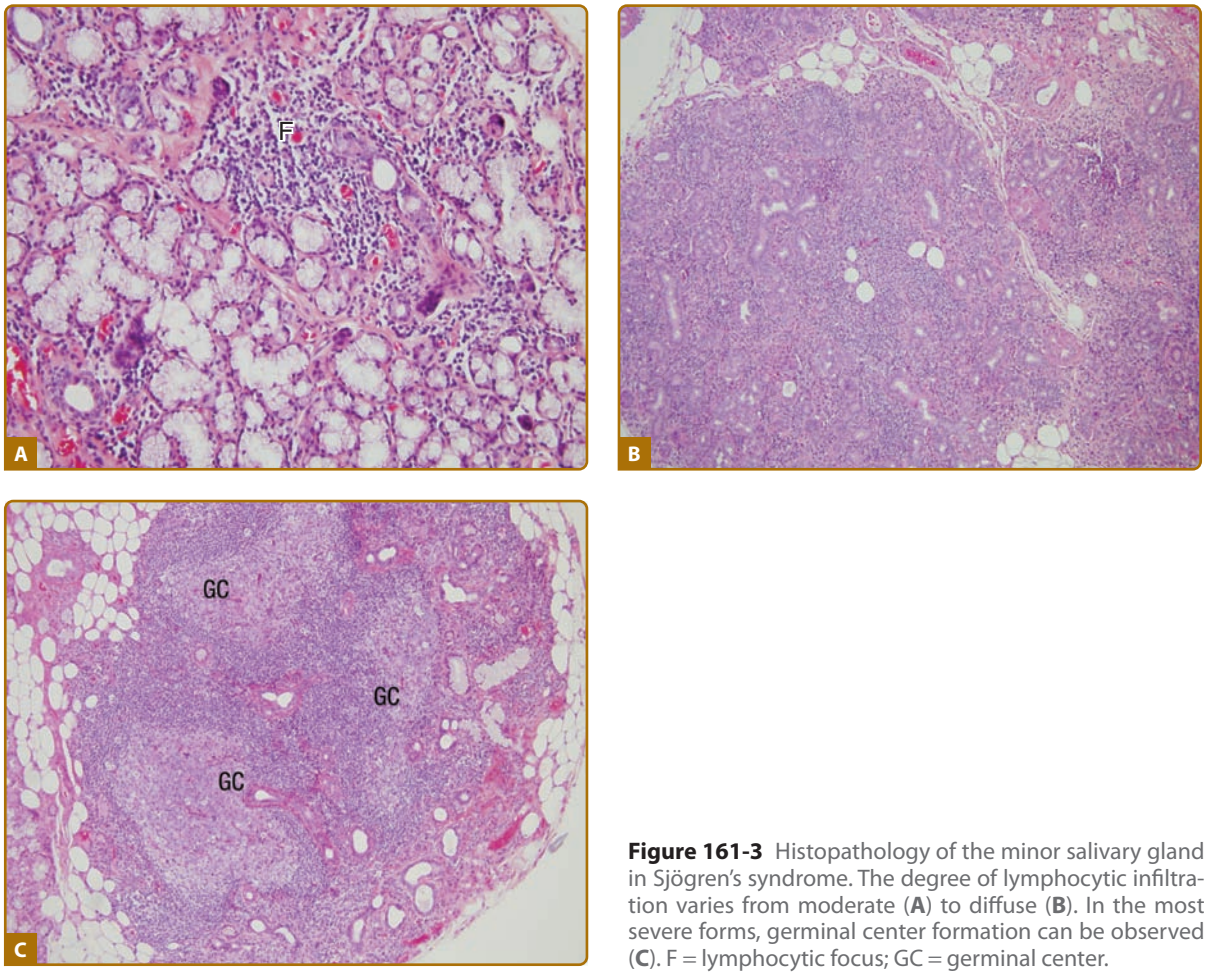

Figure 161-3 Histopathology of the minor salivary gland in Sjögren's syndrome. The degree of lymphocytic infiltration varies from moderate (**A**) to diffuse (**B**). In the most severe forms, germinal center formation can be observed (**C**). F = lymphocytic focus; GC = germinal center.

scoring system. Evidence of one or more focus is considered indicative of SS, and a focus is considered a conglomeration of at least 50 lymphocytes per 4 mm^2 of glandular tissue. Atrophy and fat tissue are other findings that may be present in SS patients, but are also present among healthy, elderly individuals. Although salivary gland biopsy provides important clues that may lead to definitive diagnosis, some controversy still exists regarding its sensitivity and specificity. Some patients with primary SS diagnosed on the basis of reduced salivary flow and evidence of anti-SSA and anti-SSB antibodies have no lymphocytic infiltration in biopsy specimens of minor salivary glands. In addition, some healthy individuals may demonstrate lymphocytic foci in their salivary glands.

PROGNOSIS

There are two patterns of primary SS that define two distinct disease categories with very different clinical risks. Patients with low complement C4 levels and/or palpable purpura early in their disease course may be classified as a high-risk disease syndrome (type I). This group comprises approximately 20% of the primary SS diagnoses and carries a significantly increased risk of lymphoproliferative disease and also has an increased mortality rate. Most severe extraglandular manifestations also occur in this group. Patients without these two predictors (80% of all primary SS diagnoses) may be reassured that they have a low-risk (type II) form of primary SS that carries no increased risk of death and in general has a more benign course dominated by sicca symptoms.[37]

TREATMENT

TREATMENT OF DRY MOUTH

(Table 161-3)

The treatment of oral dryness is largely symptomatic.[40]

Nonpharmacologic strategies are the mainstay of treatment.

Adequate hydration, and reduction of irritants like coffee, alcohol and nicotine as well as substitution of drugs that can lead to dry mouth when possible (diuretics, tricyclics, antihistamines, β-blockers) is essential.

Frequent sips of water are recommended initially to maintain moisture. Patients should also be encouraged to use sugar-free candies and chewing gums to

TABLE 161-3
Management of Sicca Symptoms in Sjögren's Syndrome

Xerostomia	■ Frequent water ■ Mechanical stimulation of saliva secretion (sugar-free gum and candies) ■ Artificial saliva ■ Meticulous oral hygiene ■ Caries prevention with fluoride-containing toothpaste and rinses ■ Aggressive treatment of candidiasis with topical and systemic antifungals ■ Sialogogues: pilocarpine (5 mg orally three times/day) or cevimeline (30 mg orally three times/day)
Xerophthalmia	■ Frequent use of preservative-free artificial tears ■ Nighttime use of moisturizing ointments ■ Topical cyclosporine A ophthalmic solution (0.05%, one drop every 12 hours) ■ Surgical: punctal plug placement ■ Sialogogues

increase saliva production. Saliva substitutes are available in the form of gels, oils or sprays, but the need for frequent application is inconvenient for many patients.

Sugar-containing foods should be avoided because they contribute to the increased risk of dental caries and oral candidiasis. Meticulous dental hygiene is essential for SS patients to prevent or treat dental caries.

Caries prevention with fluoride applications including prescription-strength toothpaste, fluoride gels, and oral rinses is further recommended.

Oral candidiasis is treated with oral and systemic antifungal therapy. To prevent candidiasis, patients should not wear dentures at night, and the dentures should be soaked in 2% chlorhexidine. Nystatin or clotrimazole cream can be used to treat angular cheilitis.

If dry mouth is not adequately controlled with replacement methods, pharmacologic therapy with secretagogue drugs is an option. Two drugs are approved for this indication: (1) pilocarpine (5 mg four times a day)[41] and (2) cevimeline (30 three times/day).[42] Both act on muscarinic receptors and increase exocrine gland secretion. They are contraindicated in narrow-angle glaucoma and uncontrolled asthma. Cholinergic side effects, such as excessive sweating, urinary frequency, flushing, and headaches, are common for both agents. Tolerability can be increased if treatment is started at a lower dose, which is then gradually increased (see Table 161-3).

TREATMENT OF DRY EYES

(See Table 161-3)

Non pharmacologic measures are very important therapeutic interventions; avoidance of dry, smoky and windy environments, avoiding contact lenses or opting for those higher in water content, and minimizing medications that inhibit tear production (diuretics, β-blockers, tricyclic antidepressants, antihistamines) are first-line measures.

Many tear substitutes are available and are commonly used by patients to alleviate ocular dryness. Preservative-free preparations are preferred, especially if used more than four times a day. Methylcellulose-containing ointments may provide longer relief, but their use is limited to nighttime use by the risk for blurred vision.

A frequently used surgical option is the occlusion of the puncta to block tear drainage and consequently increase moisture. The occlusion can be transient by the insertion of collagen or silicone plugs, or permanent by electrocautery.

Cyclosporine A 0.05% ophthalmic solution has been approved by the FDA for the treatment of keratoconjunctivitis sicca.[43] Topical corticosteroids are rarely needed and should probably only be prescribed after ophthalmic examination. Infections may present with aggravation of symptoms or increased mucus secretion, and should be promptly treated with topical antibiotics.

Pilocarpine and cevimeline can be effective for dry eyes, too, especially in patients with the most severe dryness.[42]

TREATMENT OF EXTRAGLANDULAR MANIFESTATIONS

The treatment of musculoskeletal manifestations of SS is similar to those of other systemic rheumatologic diseases.[44] Because of reduced saliva production and esophageal dysmotility, these patients have reduced tolerance to nonsteroidal anti-inflammatory drugs. Antimalarial drugs, such as hydroxychloroquine, are effective for arthralgia/arthritis, myalgia, and fatigue.[45] Dryness of eyes and mouth may also improve slightly in some cases.[46] Visceral manifestations such as vasculitis, pneumonitis, glomerulonephritis, and neurologic manifestations are treated with corticosteroids and immunosuppressive drugs, in doses similar to those used in systemic lupus erythematosus.

Treatment of lymphoma in SS is the same as in the general population. Most SS-associated lymphomas are low-grade B-cell lymphomas localized to the exocrine glands. For these, watchful waiting may be the most appropriate approach. Higher grade lymphomas require more aggressive treatment with a rituximab, cytotoxic regimen, and/or radiation therapy.

TARGETED THERAPY

Several randomized case-control studies have focused on therapy for SS using biologic agents, such as the TNF-blocking agents infliximab[47] and etanercept,[48] but none of the studies showed clinical benefit. There is increasing interest in therapies targeting B cells, such

as monoclonal antibodies against CD20 (rituximab) or CD22 (epratuzumab). A recent randomized placebo-controlled study demonstrated efficacy of rituximab over placebo in patients with active primary SS.[49] Rituximab improved stimulated salivary flows, laboratory parameters of inflammation and subjective symptoms. This clinical efficacy was supported by reduced glandular infiltration and morphologic improvements of epithelial cells on salivary gland biopsies.[50] Other potential targets for biologic therapy include cytokines such as IL-6 and BlyS (BAFF), interferons, adhesion molecules, and chemokines. However, even if effective, systemic immunomodulatory therapy may be associated with unwanted side effects and may not be justified in patients with primary SS whose disease is limited to exocrine glands. An alternative approach is to develop a localized form of immunotherapy by using gene therapy restricted to the salivary and lachrymal glands. This approach would most likely alter the abnormal immune response locally but may avoid the systemic side effects.[51]

SECTION 28

The Skin in Inflammatory and Other Vascular Disorders

Chapter 162 :: Endothelium in Inflammation and Angiogenesis

:: Peter Petzelbauer, Robert Loewe, & Jordan S. Pober

ENDOTHELIUM AT A GLANCE

- All blood vessel endothelial cells (ECs) perform three important constitutive functions:
  - Maintaining homeostasis of the blood.
  - Forming a barrier that separates circulating blood from the tissue.
  - Regulating the extent of local blood flow.
- The cutaneous vasculature is divided into a superficial vascular plexus and a deep vascular plexus. The superficial vascular plexus is formed by parallel pairs of arterioles and venules connected via capillary loops that extend into the dermal papillae.
- ECs participate in innate and adaptive immune responses.
- Tumor necrosis factor-α and interleukin-1β are important modulators of EC function.
- Vascular ECs contribute to inflammation through distinctive patterns of adhesion molecule expression. In the skin, E-selectin, vascular adhesion molecule 1, and intercellular adhesion molecule 1 may be particularly important.
- Microvessels of the skin in situ basally express major histocompatibility complex (MHC) class I and II molecules at their luminal surfaces and may present antigen in an MHC-restricted manner to T cells.
- In the healthy adult, blood vessels are stable structures with very slow turnover of ECs. In chronic inflammation, tissue injury, wound healing, and tumor growth, new vessels are formed (angiogenesis) and existing vessels undergo remodeling.
- Keratinocytes produce a wide range of angiogenic factors, including members of the fibroblast or transforming growth factor protein family, platelet-derived growth factor, and vascular endothelial growth factor, as well as chemokines like cutaneous T cell-attracting chemokine. Vascular remodeling is a prominent feature of psoriasis.

OVERVIEW OF THE VASCULAR SYSTEM

The blood vascular system is a continuous series of hollow tubes that carry blood from the heart to the tissues and back again. Blood exits the heart through the aorta that gives rise to a series of diverging, progressively narrower muscular arteries and arterioles, delivering blood to all organs of the body. The terminal arterioles arborize into an interconnecting network of microvessels, mostly capillaries that nourish and cleanse the peripheral tissues. The capillary network empties into a series of converging venules and progressively larger veins that ultimately return the blood to the heart. All segments of this vascular system are lined by a one-cell-thick layer of epithelium-like cells called *endothelium* (Fig. 162-1). All vascular endothelial cells (ECs) share common features and functions, and hence may be collectively described as one cell type. However, ECs from one segment of the vascular system may differ in significant ways from the ECs

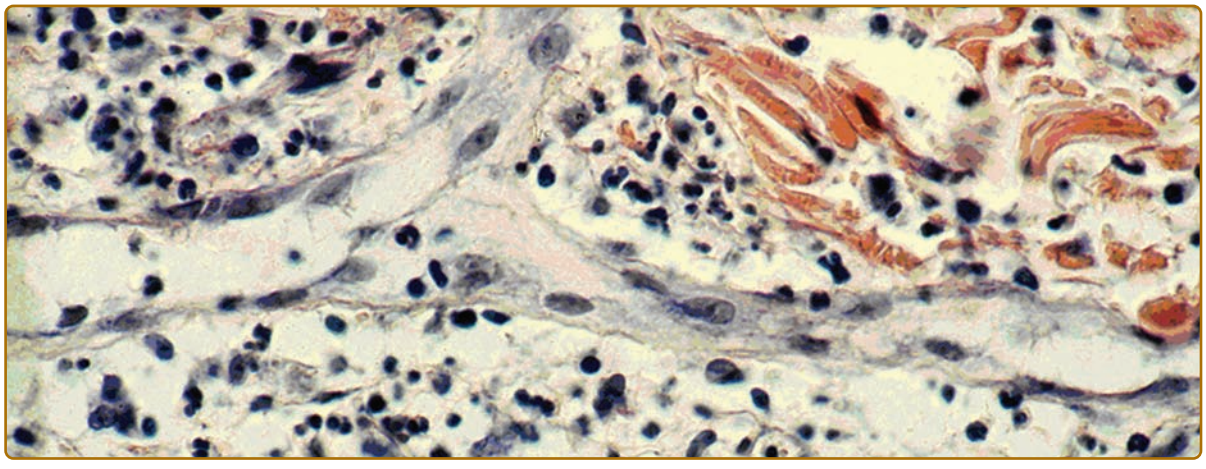

Figure 162-1 Endothelium. In this postcapillary venule, endothelial cells are seen to line a channel. Nuclei are seen en face and in cross-section, and activated endothelial cells appear to have an edematous cytoplasm, which increases their visibility. This specimen is from an inflammatory lesion (Sweet syndrome; see Chapter 32) without signs of vessel damage.

at other anatomic sites. Blood vessel ECs differ from lymphatic ECs, which are not discussed in this chapter.

Blood vessel ECs must perform three important constitutive functions. First, vascular ECs must maintain homeostasis of the blood, which consists of roughly equal volumes of fluid (plasma) and cellular elements (erythrocytes, leukocytes, and platelets). The plasma contains the proteins of the coagulation system. In addition, both leukocytes and platelets have membrane receptors that trigger cellular activation on contact with the extravascular environment. The EC lining prevents intravascular activation both of the coagulation system and of these responsive cellular elements, yet keeps both systems poised respond to wounding or infection.

Second, ECs must separate circulating blood from the tissues. The barrier formed by ECs permits limited passage of fluid and solutes, allowing the blood to nourish the tissues while displaying "permselectivity" for macromolecules and presenting a virtually impenetrable barrier for blood cells (except at specialized sites of high permeability and leukocyte trafficking). In other words, vascular ECs regulate rather than prevent interactions between blood and tissues.

Third, ECs must regulate local blood flow. Because ECs are arranged in alignment with flow, their contraction opens gaps between cells, enhancing permeability without altering flow (see Fig. 162-1). However, ECs indirectly regulate flow by acting on smooth muscle cells (SMCs), which are oriented almost parallel to the vessel's circumferential or radial axis.

ECs do so principally by the generation of SMC relaxants [e.g., nitric oxide (NO), prostaglandin E_2 or prostaglandin I_2 (PGI_2), and endothelium-derived hyperpolarizing factor] or contractants (e.g., endothelin) or by catalyzing the generation of vasoconstrictors from plasma protein-derived mediators (e.g., angiotensin II through the action of EC-expressed angiotensin-converting enzyme, which also inactivates bradykinin, a plasma protein-derived agonist that acts on ECs to generate NO.

In addition to these constitutive functions, ECs may be activated to induce additional functions, a topic discussed later in the chapter.

STRUCTURE AND FUNCTION OF THE SKIN VASCULATURE

Approximately three decades ago Irwin Braverman described the organization of the vascular network of human skin, which he summarized in 1989.[1] The human dermal vasculature consists of two interconnected systems—(1) a superficial and (2) a deep vascular plexus—with additional vascular networks surrounding sweat glands and hair follicles[2,3] (Fig. 162-2). The superficial vascular plexus (SVP) is comprised of paired arterioles and venules that form an interconnected network of vessels coursing on a plane parallel to and just beneath the epidermal surface.[3] Capillaries arise from the arterioles, extend upward within the papillary dermis at sites between the epidermal rete ridges, and then loop back down to the venules

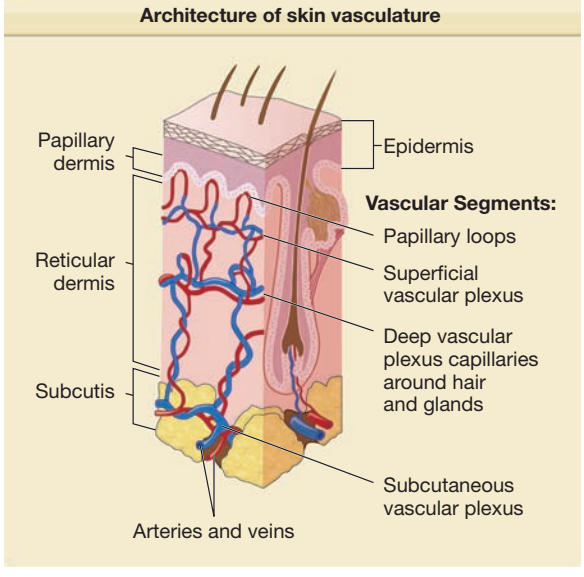

Figure 162-2 Schematic diagram of the architecture of the skin vasculature.

forming arcade-like structures. The basement membrane of the arterioles appears homogeneous by electron microscopy whereas that of the venules is multilayered. In normal skin, most of the capillary loop is invested with a basement membrane that resembles that of the arteriole, acquiring a venule-like investiture only at the level of the deepest rete just proximal to the anastomosis with the venule of the SVP.[2] There are no ultrastructural differences between capillary loops at different sites of the skin. Inflammatory leukocytes extravasate through the venule-like portions of the capillary and the venule proper but only rarely infiltrate through the arteriole-like portions of the capillary or the arteriole itself.

The arterioles and venules of the SVP are connected by short, straight vessels to the arterioles and venules of a deeper planar network of anatomizing vessels called the *deep vascular plexus* (DVP) (see Fig. 162-2). The plane of the DVP is parallel to that of the SVP and courses above the boundary between the reticular dermis and the underlying subcutis (see Fig. 162-2). The DVP is fed through penetrating vessels from the subcutis. The DVP is drained by valve-containing veins into the subcutaneous fat. The vessel wall in the SVP consists of discontinuous layers of elastic fibers and SMCs. The DVP contains arterioles and venules of larger caliber consisting of three layers: (1) an intima, (2) a media, and (3) an adventitia. Capillary networks connecting the arterioles and venules of the DVP provide nourishment for the adnexal structures within the reticular dermis. The venules of the DVP serve as portals of entry for leukocytes associated with inflammation of the adnexa or for inflammation within the reticular dermis itself, as occurs in erysipelas.

Dermal microvessels are surrounded by flat adventitial cells, ultrastructurally most closely resembling a fibroblast, called *veil cells*.[1] Veil cells are external to the wall, demarcating the vessel from the surrounding dermis. These cells lack leukocyte markers and are negative for HLA-DR and CD1a expression. They express glycoprotein Ib α, von Willebrand factor (vWF) receptor, and factor XIIIa, a coagulation transglutaminase, and are sometimes called *XIIIa-positive dendrocytes*. Factor XIIIa-positive dendrocyte rarefaction is found in the classic type of Ehlers–Danlos syndrome, but the significance of this finding is not clear. They should be distinguished from dermal dendritic cells, a population of specialized antigen-presenting leukocytes resident within the dermis.

Dermal microvessels, especially capillaries, contain, in addition to ECs, a population of contractile mesenchymal cells called *pericytes (PCs)*. Unlike veil cells, PCs are an integral component of the vessel wall. They extend long cytoplasmic processes over the abluminal surface of the ECs and make interdigitating contacts. The coverage of ECs by PCs varies considerably among different microvessel types. Communicating gap junctions, tight junctions, and adhesion plaques are present at these points of contact.

Because PCs are rich in contractile proteins and have complex interdigitations with ECs in postcapillary venules, it is assumed that they are responsible, at least in part, for gap formation in response to, for example, histamine or bradykinin (although cultured ECs are capable of contraction in the absence of PCs). Moreover, interaction between PCs and ECs is important for the maturation, remodeling, and maintenance of the vascular system via the secretion of growth factors or modulation of the extracellular matrix. There is also evidence that PCs are involved in the transport across the blood–brain barrier and the regulation of vascular permeability.

MORPHOLOGY AND MOLECULAR MARKERS

GENERAL MORPHOLOGY

ECs usually appear as flattened epithelium-like cells, with a thickness typically less than 10 μm and a surface area covering up to 1,000 μm^2 (see Fig. 162-1). In large vessels, ECs have an elongated shape, especially in regions of laminar flow, and have their long axis oriented in the direction of blood flow. ECs located in regions of disturbed flow (i.e., at branch points of the arterial tree) are often polygonal rather than elongated. Cultured ECs are typically polygonal but elongate when flowing medium is passed over them for periods of 24 hours or more.[4] Shear stress, the force imparted by viscous drag of flowing liquid, is responsible for inducing a cytoskeletal rearrangement and the change of shape from polygonal to elongated. Interestingly, the microtubular organizing center of ECs, located near the nucleus, is always oriented toward the heart (i.e., upstream of the nucleus in arteries and downstream of the nucleus in veins) regardless of the direction of blood flow.[5] Moreover, ECs have an apical/luminal polarization, integrin receptors for matrix macromolecules are concentrated on the basal/abluminal surface, and adhesion molecules for leukocytes are almost exclusively displayed on their apical surface, which faces the lumen of the blood vessel.[6]

SPECIALIZED ORGANELLES OF ENDOTHELIAL CELLS

The ultrastructure of a postcapillary venule is shown in Fig. 162-3. ECs have a number of characteristic organelles. The best described are Weibel–Palade bodies (WPBs), fenestrae, and the caveolar system. WPBs are elongated, membrane-bound organelles that display longitudinal striations by electron microscopy. WPBs are distributed randomly throughout the cytoplasm in vascular ECs of most vertebrates. WPBs constitutively contain vWF (also called *factor VIII-related antigen*), P-selectin (CD62P),[7] lysosomal membrane-associated glycoprotein 3 (or CD63),[8] 1,3-fucosyltransferase VI,[9] interleukin 8 (IL-8),[10] and angiopoietin 2 (Ang-2).[11] The longitudinal striations within the WPBs are formed by highly polymerized forms of vWF, reaching sizes of up to 20,000 kDa. On release, vWF polymers may attach to the basement membrane and stabilize platelet adhesion to the subendothelial matrix, particularly in

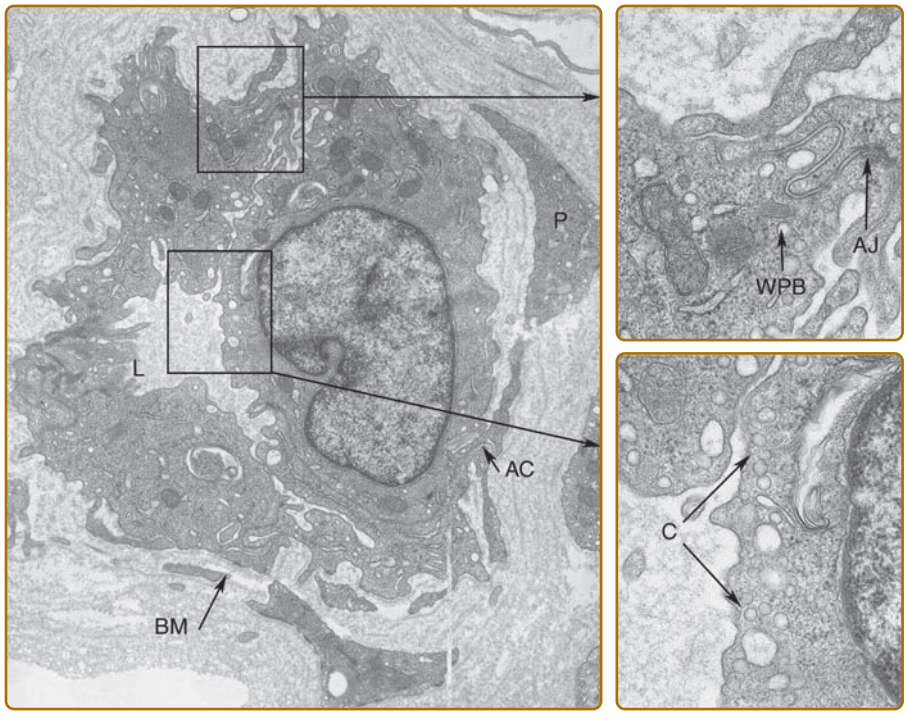

Figure 162-3 Ultrastructure of a postcapillary venule. AC = area of contact between endothelial cell and pericyte; AJ = adherens junction; BM = basement membrane; C = caveolae; L = lumen; P = pericyte; WPB = Weibel–Palade body.

high-velocity arterial flow. Although vWF is commonly used as an EC marker (see Section "Molecular Markers of Endothelial Cells"), it is also found in megakaryocytes, which appear to lack a physiologic mechanism of release, synthesizing vWF only for storage within the α granules of their platelet progeny. P-selectin is rapidly translocated to the cell surface as the WPB fuses with the plasma membrane, where it mediates leukocyte adhesion to ECs (see Section "Leukocyte Adhesion"). CD63 is a 53-kDa lysosomal membrane glycoprotein belonging to the tetraspanin superfamily; its function in the WPB is unknown.

Blood vascular ECs usually form a continuous monolayer, and most transendothelial transport takes place in the junctions between cells. One important exception is in the fenestrae of capillaries in lymph nodes, capillaries in the intestinal mucosa, renal glomerular ECs, and hepatic and bone marrow sinusoids. Fenestrae, uniquely found in ECs, are specialized annular patches of attenuated cytoplasm and membrane, about 175 nm in diameter, characterized by an increased concentration of anionic lipids.[12] They group into structures resembling sieve plates that occupy 6% to 8% of the surface capillaries. Fenestrated capillaries are much more permeable to water and small-molecular-size solutes than those of the continuous type. The anionic charge probably precludes the transfenestral passage of anionic plasma proteins. Various factors, such as pressure, alcohol, serotonin, nicotine, and infection, change the number and diameter of fenestrae, and ECs of the continuous type may become transiently fenestrated.

All ECs appear to contain numerous vesicles subjacent to the plasmalemma, both luminal and abluminal. On careful examination, most of these vesicles turned out to have narrow tubular connections to the plasma membrane. Such flask-shaped invaginations are called *caveolae*, literally "little caves," and are part of the surface membrane, either as a single caveola or as more complex racemose invaginations. In situ, they may account for 50% or more of the plasma membrane surface area of ECs. Caveolae arise from a late Golgi compartment and represent a stable membrane unit built up around caveolins, cholesterol, and glycosphingolipids. ECs are rich in caveolins 1 and 2. Caveolins bind to cholesterol and are required for caveolae formation; ECs in caveolin 1 knockout mice fail to form caveolae. Expression of caveolin 1 in some cell types normally lacking caveolae can cause their formation, but cultured ECs normally retain expression of caveolins yet lose their caveolae, with cholesterol and glycosphingolipids dispersing into submicroscopic lipid rafts on the now simplified plasma membrane, implying a key role for an as yet unidentified factor.

Caveolae can mediate vesicular transport, internalize certain plasma membrane proteins and provide a platform for the assembly of signaling complexes at the surface of the cell. Caveolins interact with a variety of downstream signaling molecules, including Src-family of tyrosine kinases, p42/44 mitogen-activated protein kinase, and endothelial NO synthase (eNOS). They hold these signal transducers in the inactive conformation until activation by an appropriate stimulus. For example, the amount of caveolin is inversely related to NO production by eNOS.[13] Mice lacking caveolin 1 have impaired NO and calcium signaling in the cardiovascular system, which causes aberrations in EC-dependent relaxation, contractility, and maintenance of myogenic tone.[14]

Caveolin 1 is associated with a number of growth factor receptors, including the epidermal growth factor receptor, the high affinity nerve growth factor receptor (TrkA), the insulin receptor, the platelet-derived growth factor receptor and transforming growth factor receptors I and II.[15,16] In addition, cytokine receptors like the tumor necrosis factor (TNF) receptor 1 (CD120a) and interferon receptors also localize to caveolae. For these receptors, the invaginated structure of caveolae provides an optimal environment for receptor function, forming a more stable signaling complex and allowing for cross talk with other receptors.

The lipid constituents of caveolae are the same as those of lipid rafts, but rafts are regions without membrane indentations and they are flat. A key limitation in a clear distinction between rafts and caveolae is due to methodical limitations to clearly separate them. Moreover, rafts and caveolae should be considered as dynamic entities that form and dissipate in response to various stimuli, and both may facilitate transport of entities to other cellular regions and across the cell.

Another organelle that is present in venular endothelium is so called vesicular–vacuolar organelle, grapelike structures of interconnected vesicles that extend throughout the cytoplasm. They show a wide variation in size and most vesicles do not contain caveolin. Consistent with this finding, they are present in normal size and numbers in caveolin null mice.[17] These organelles appear to be critically involved in acute vascular hyperpermeability, which typically involves the postcapillary venules, where these vesicular–vacuolar organelles are typically situated.

ENDOTHELIAL JUNCTIONS

Neighboring ECs connect to each other by forming interdigitating protrusions connected by junctions. Junctions possess different degrees of complexity along the vascular tree, reflecting different permeability for proteins and cells. Intercellular tight (occluding) junctions constitute the anatomic basis for the tightly regulated interfaces of the blood–testis and blood–brain barriers.[18] They consist of a continuous belt-like meshwork of six anastomosing junctional strands, which prevent the transport of macromolecules into the tissue. Arterial ECs also possess tight junctions[19]; however, they consist of only one or two junctional strands, and tight junctions are difficult to find in postcapillary venules. Tight junctions contain a complex of transmembrane (junctional adhesion molecule-1, occludin, and claudins) and cytoplasmic (zonula occludens-1 and -2, cingulin, AF-6, and 7H6) proteins linked to the actin cytoskeleton. The claudin multigene family encodes tetraspan membrane proteins that are crucial structural and functional components of tight junctions. In mammals, the claudin family consists of 24 members, which exhibit complex tissue-specific patterns of expression. Their extracellular loops interact with each other to seal the cellular sheet and regulate paracellular transport between the luminal and basolateral spaces. The transmembrane protein occludin is linked to ZO-1, a cytoplasmic protein that interacts with the cytoskeleton and appears involved in opening and closing of the junctions. Junctional adhesion molecules, called *JAMs*, members of the immunoglobulin superfamily, form homophilic adhesion sites in tight junctions and play a role in the generation of cell polarity, keeping luminal proteins from diffusing to the abluminal cell surface and vice versa.

Adherens junctions are found in all vascular ECs (see Fig. 162-3). They are multimeric protein structures that mediate homotypic cell adhesion. In endothelial cells, they are distributed along the cleft between neighboring cells and are frequently intermingled with tight junctions. During embryonic development, this type of junction promotes adhesion of identical cells and is important for organization and separation of tissues. In the adult, they maintain tissue homeostasis and contribute to paracellular permeability. Moreover, they confer cell-to-cell signals such as contact inhibition of cell growth, or resistance to apoptosis. They also regulate cell shape and polarity. Endothelial adherens junctions are principally organized by VE-cadherin [also called *cadherin 5* or *vascular endothelial cadherin (CD 144)*]. VE-cadherin-negative ECs derived by gene targeting fail to organize in vessel-like structures, blocking VE-cadherin interactions with monoclonal antibodies inhibits vessel formation.[20,21] Whereas VE-cadherin appears critical for initial formation of blood vessels, for maintenance and remodeling of blood vessels, a receptor-type phosphotyrosine phosphatase (RPTP) called *VE-PTP* appears essential. VE-PTP binds to VE-cadherin via the extracellular domain and supports adhesive functions of VE-cadherin.[22] Intracellularly, VE-cadherin is linked to a large cytosolic protein complex. This complex contains catenins, β-catenin, p120ctn, plakoglobin (also called γ-catenin), and α-catenin. Catenins β-catenin, p120ctn and plakoglobin contain homologous Armadillo repeats, whereas α-catenin is homologous to vinculin, which is another actin-binding protein. Moreover, this complex contains src, fyn and src homology-containing phosphatase (SHP)-1, and RPTP-μ and may associate with neighboring transmembrane receptors such as vascular endothelial growth factor receptor (VEGF-R)-2, angiopoietin receptor 1 (also known as Tie-2) and protease activated receptors (PAR)-3 and -6. Thus, adherens junctions integrate signals from neighboring cells and neighboring transmembrane receptor molecules and link these signals to the cytoskeleton and through focal adhesion kinase with integrin receptors to the basal matrix. This signaling pathway also functions retrograde from integrin receptors to adherens junctions. This network gets further input through RhoGTPases signaling to Rho kinase (ROCK) and leading to contraction of the cytoskeleton.[17,23–29]

ECs form gap junctions, demonstrated by transfer of microinjected small-molecular-weight tracers between adjacent ECs. In ECs, the relevant gap junctional proteins are connexin-43, connexin-37, and connexin-40. Interestingly, ECs also may form heterogap junctions with PCs or SMCs in the vessel wall and sometimes with adherent leukocytes.

ENDOTHELIAL CELL–MATRIX INTERACTIONS

ECs rest on a basal lamina, which is formed by EC itself and by surrounding cells. It consists of laminins, collagens, fibronectin, nidogen (entactin), and heparan sulfate proteoglycans. Interaction with these matrix molecules is essential for maintaining normal endothelial function. For example, the laminin A chain peptide supports endothelial branching and formation of new capillaries.[30] Furthermore, a 20-kDa *C*-terminal fragment of collagen XVIII specifically inhibits endothelial proliferation and angiogenesis,[31] which suggests that collagen XVIII is also a positive regulator of vessel growth. On the other hand, EC–collagen V interactions inhibit endothelial attachment and growth. ECs interact with these components of the basal lamina by numerous transmembrane adhesion molecules. The complexities of these interactions have only been partially characterized. Members of the integrin family are particularly important for this function. For example, $\alpha_6\beta_1$-, $\alpha_2\beta_1$-, $\alpha_5\beta_1$-, and $\alpha_V\beta_3$-receptor complexes are important for endothelial attachment to, and migration on, laminin, collagen, and tenascin, and therefore serve important roles in angiogenesis. In addition, integrin binding to matrix proteins also has a multitude of intracellular effects on the organization of the endothelial actin skeleton and on signaling processes within the cell.[3] Endothelial-cell growth factors have been shown to differentially upregulate the biosynthesis of α_2, α_5, β_1, and β_3 integrins, serving the different needs of endothelium during growth, spreading, and new vessel formation. Moreover, integrins show certain tissue-and vessel-restricted expression; for example, $\alpha_1\beta_1$ is found only in small blood vessels and capillaries but not in large vessel ECs. Matrix proteins such as thrombospondin 1, may also serve as inhibitors of angiogenesis.[33]

MOLECULAR MARKERS OF ENDOTHELIAL CELLS

ECs display a number of molecular markers that result in a characteristic profile detectable with antibodies, lectins, and other ligands (Table 162-1). In addition to containing molecules expressed on all endothelium, the skin vasculature shows several site-specific characteristics. Postcapillary venules of the SVP are $CD36^-$ and thus distinct from capillaries of the DVP and from capillaries of other tissues, which are $CD36^+$.[34] CD36 antigen is a cellular receptor for thrombospondin, collagen, low-density lipoproteins, long-chain fatty acids, and platelet-agglutinating protein p37.[35] Moreover, CD36 functions as one of the receptors that mediate the adhesion of *Plasmodium falciparum*-infected erythrocytes to microvascular EC. The functional consequences of the disparate CD36 expression on SVP and DVP endothelium are unknown. Microvessels are best characterized by expression of the pathologische anatomie Leiden-endothelium (PAL-E) antigen (which is identical with plasmalemmal vesicle 1 or fenestrated endothelial-linked structure protein),[36] N-cadherin, and CXC chemokine receptor 4 (CXCR4), and by their surrounding by smooth muscle actin-positive cells (which may be SMCs or PCs). Blood vascular ECs normally lack the lymphatic EC markers lymphatic vessel endothelial-1 [LYVE-1, (a hyaluronan receptor) and podoplanin], but may express these molecules when inflamed.[37,38] ECs express receptors for binding members of the VEGF family. Blood endothelial cells express VEGFR-2 and VEGFR-1, whereas lymphatic vessel endothelial cells express VEGFR-2 and VEGFR-3.[39–42] Neuropilins, another group of VEGF-binding membrane-bound receptors, are also differentially expressed in various types of vasculature. Whereas neuropilin-1 is strongly expressed in arterial endothelial cells, neuropilin-2 is expressed in veins and visceral lymphatic vessels.[43] Another important signaling system is the angiopoietin/Tie receptor system (see Section "Regulation of Angiogenesis and Vasculogenesis").

Postcapillary venules of the skin express toll-like receptor (TLR) family members and CD32 molecules (FcγRIIa).[44] CD32 binds complexed immunoglobulin G and is thought to function in the elicitation of type III (immune complex-mediated) hypersensitivity as well as in immune complex clearing. ECs of postcapillary venules express significantly higher levels of the histamine H_1 receptor than other ECs. Histamine produces increased albumin leakage and induces rolling of leukocytes, mediated in part by P-selectin expressed on the EC surface. PAR 2 expression at this site also plays a role in inflammatory reactions. PAR 2-activating peptides increase leukocyte rolling and adhesion to postcapillary venules. Finally, postcapillary vessels of the skin in situ constitutively express major histocompatibility complex (MHC) class I and II molecules at their luminal surfaces, which implies that ECs may directly participate in the elicitation of antigen-driven immune responses. As discussed later (see Section "Role of Endothelium in Adaptive Immunity"), skin microvessels in cell culture appear able to process and present antigen in an MHC-restricted manner to T cells.[45]

ENDOTHELIUM IN INFLAMMATION

INNATE IMMUNITY

Innate immunity, also called *natural* or *native immunity*, comprises the host's defense systems against microbes that are independent of T and B lymphocytes and their receptors for specific antigens (see Chapter 10). The innate immune system is much older in evolutionary terms than the T- and B-cell-specific immune system (often called *adaptive immunity* to distinguish it from innate immunity). The humoral component primarily involves the complement system. The primary cellular effectors of innate immunity in humans are neutrophils, mononuclear phagocytes, and natural killer cells, but ECs also participate.

Endothelial cells represent the initial target in many different types of infection.[46] For example, exposure to lipopolysaccharide, a major cell-wall constituent

TABLE 162-1
Molecular Markers of Endothelium

Marker	Location/Function	Expression Profile
VWF	WPB, biosynthetic organelles (Golgi, ER)	EC, megakaryocytes, platelets
CD31	Adhesion molecule, transmigration	EC, platelets, leukocytes
CD143 (angiotensin-converting enzyme)	Secreted then bound to cell surface	EC, macrophages
CD141	Anticoagulant thrombomodulin	EC, trophoblast of the placenta
Reactivity with the lectin UEA-1	Blood group H antigens	EC, erythrocytes, specialized epithelia
VEGFR-1 and VEGFR-2	Receptor tyrosine kinase	EC, macrophages, hematopoietic stem cells, motor neurons (R2)
Tie-1 and Tie-2	Receptor tyrosine kinase	EC, hematopoietic stem cells, peripheral nervous tissue (Tie-2)
ICAM-2	Adhesion molecule	EC
CD40, CD54, CD58, CD105	–	EC, broad expression pattern
CD9, CD13, CD31, C1q and C5a receptors, complement regulatory proteins	Common embryologic origin of the angioblast and the hematopoietic stem cell	EC, hematopoietic cells
CD26, CD40, CD44, CD47, CD54, CD58, CD146	—	EC, broadly expressed on other cell types
Class II MHC molecules	Antigen presentation	Constitutive on skin and kidney microvessels
Endoglin (CD105)	Surface receptor	EC, stromal cells
PAL-E antigen	Fenestrae	Microvessels and veins
CD34	Proteoglycan, adhesion molecule	Microvessels, hematopoietic cells
CD36	Proteoglycan	Microvessels except brain and some skin ECs
CD32	Fc receptor	Liver and skin microvessels, leukocytes
P-selectin	Prestored in WPB	EC
VCAM-1 (CD106)	Inducible adhesion molecule	EC, macrophages, follicular-dendritic cells
E-selectin (CD62E)	Inducible adhesion protein	EC
MAdCAM-1	Adhesion molecule, sialomucin	Microvessels of intestine and breast
GlyCAM-1	Adhesion molecule, sialomucin	Lymph nodes, high endothelial venules
Peripheral node addressing (antibody MECA-79)	L-selectin ligands	EC of peripheral nodes and skin
ICAM-3	Adhesion molecule	Tumor vessels

EC = endothelial cell; ER = endoplasmic reticulum; GlyCAM = glycosylation-dependent cell adhesion molecule; ICAM = intercellular adhesion molecule; MAdCAM = mucosal addressin cell adhesion molecule; MHC = major histocompatibility complex; PAL-E = pathologische anatomie Leiden-endothelium; UEA = ulex europaeus agglutinin; VCAM = vascular adhesion molecule; VEGFR = vascular endothelial growth factor receptor; vWF = von Willebrand factor; WPB = Weibel–Palade body.

of Gram-negative bacteria, results in endothelial activation through a receptor complex consisting of TLR-4, CD14, and MD2. Then, recruitment of the adaptor protein myeloid differentiation factor (MyD) 88 to the ligand-activated TLR-4 receptor initiates an MyD88-dependent pathway that culminates in the early activation of nuclear factor-κ B and the mitogen-activated protein kinases. In parallel, an MyD88-independent pathway using an alternative adaptor protein called TRIF results in a late-phase activation of nuclear factor-κ B as well as generation of interferons.[47,48] ECs also express TLR-2, which serves as a signaling receptor for Gram-positive cell-wall components, and intracellular TLRs that respond to various types of nucleic acids typically encountered during infections by viruses. Stimulation of TLR 2/6

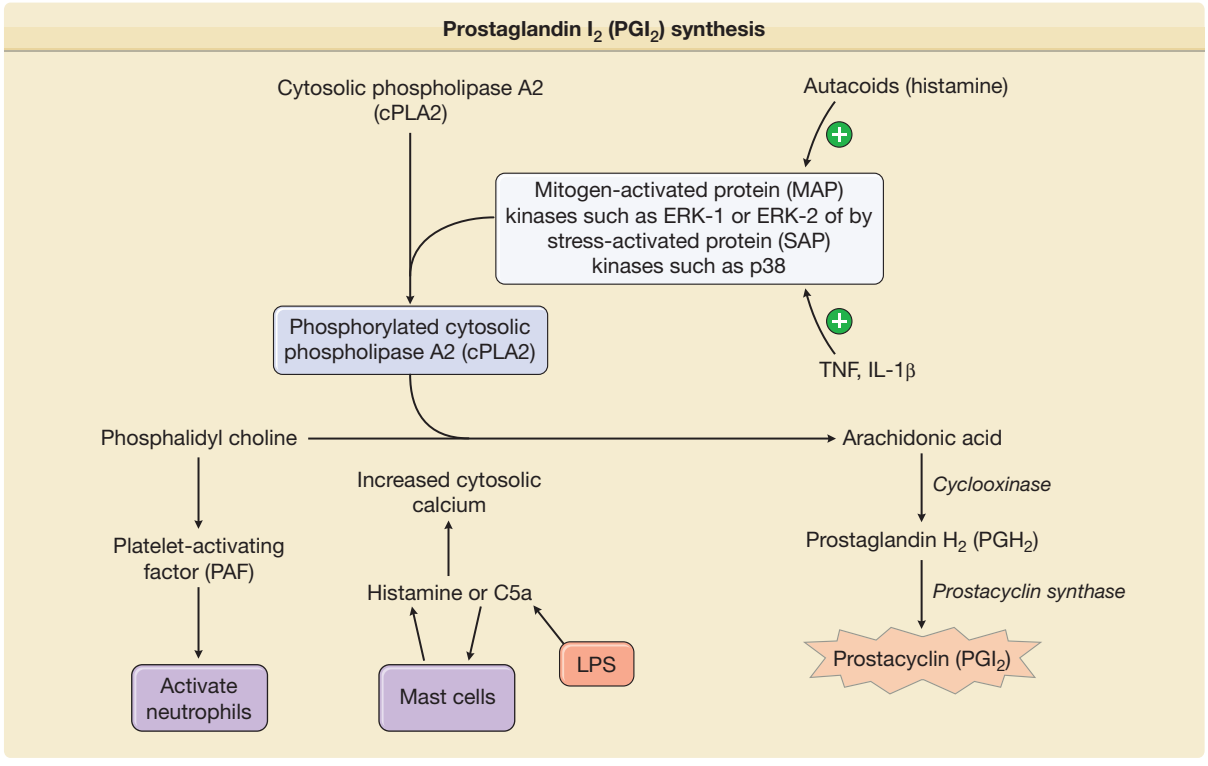

Figure 162-4 Prostaglandin I_2 (PGI_2) synthesis. ERK = extracellular signal-regulated kinase; IL = interleukin; LPS = lipopolysaccharide; TNF = tumor necrosis factor.

by bacterial lipopeptides also may promote angiogenesis and results in the secretion of GM-CSF.[49] Certain vascular beds express the macrophage mannose receptor (CD206), a receptor for oligosaccharides on the cell wall of bacteria, yeasts, and parasites. Other receptors of the innate immune system include a variety of lectin-type molecules, such as mannose-binding protein or galectins that recognize bacterial carbohydrates. Mannose-binding protein may stimulate the alternative pathway of complement activation.

TNF and IL-1 are the principal effector cytokines of the innate immune response to bacteria. In general, endothelial responses to TNF and IL-1 are similar and are considered together. The major isoform of IL-1 that is produced during innate immune responses is IL-1β, but IL-1α, the major isoform made by ECs, has indistinguishable actions, and we will simply refer to both isoforms as IL-1. At least five changes in the phenotype of ECs that promote inflammation, collectively called *endothelial activation*, have been described.

SYNTHESIS OF VASODILATORS.

TNF- or IL-1-treated ECs increase production of vasodilators, such as PGI_2 and NO, that relax smooth muscle cell tension, thereby producing vasodilation and increasing tissue perfusion. PGI_2, also called *prostacyclin*, is synthesized in ECs by a series of three sequential enzyme-catalyzed reactions.[52] ECs express one isoform of prostaglandin H synthase, PGHS-1, also called *cyclooxygenase 1*, that is constitutively active. Treatment of ECs with TNF or IL-1 dramatically increases PGHS activity by inducing de novo expression of a second isoform, PGHS-2, which is also called *cyclooxygenase 2*. This response markedly increases the capacity to make prostaglandin (PG)H_2 from arachidonic acid, and the increased PGH_2 is subsequently converted into PGI_2 (Fig. 162-4). Pharmacologic inhibition of the synthesis of PGH_2 is thought to contribute to the anti-inflammatory actions of aspirin and nonsteroidal anti-inflammatory drugs. NO is produced by conversion of arginine to citrulline through eNOS (Fig. 162-5). TNF exhibits opposing effects on vasodilation. Initially, it enhances eNOS function and NO synthesis through activation of Akt and by increasing the synthesis of tetrahydrobiopterin, a limiting cofactor for eNOS function.[53] At later times, TNF destabilizes eNOS mRNA and thereby inhibits NO production.

LEUKOCYTE ADHESION.

(Tables 162-2 and 162-3). TNF- or IL-1-treated ECs exhibit changes in the cell surface that favor the initial capture, rolling, and, ultimately, firm adhesion and spreading of leukocytes (Fig. 162-6). Adhesion is a necessary prelude to extravasation of leukocytes into the tissues. Capture and rolling are typically mediated by selectins expressed on the leukocyte or on the EC.[54] There are three structurally related selectin proteins: (1) L-selectin (CD62L), (2) E-selectin (CD62E), and (3) P-selectin (CD62P). In the presence of flowing blood, the leukocyte is propelled in the direction of blood flow, rapidly breaking and reforming selectin-mediated attachments. This

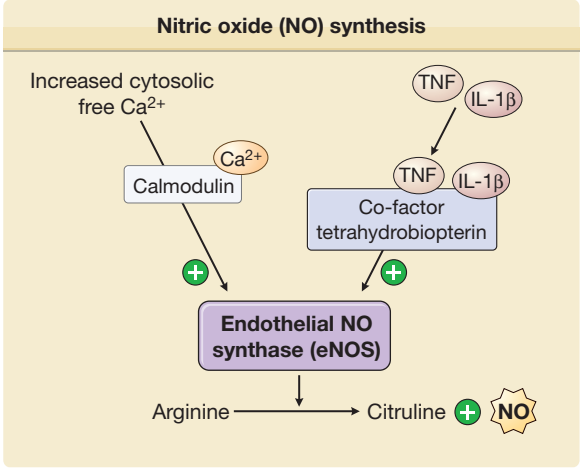

Figure 162-5 Nitric oxide (NO) synthesis. IL = interleukin; TNF = tumor necrosis factor.

results in rolling of the leukocyte along the EC surface (see Fig. 162-6). Ligands involved in selectin-mediated capture may not be the same as those involved in selectin-mediated rolling; for example, neutrophils may switch from L-selectin to E-selectin ligand (ESL)-1 as the principal E-selectin ligand during these two phases of the interaction.[55,56] Studies using blocking monoclonal antibodies or selectin knockout mice have confirmed that selectins are required for neutrophil rolling and subsequent recruitment in vivo. In mice, E- and P-selectin functions may be redundant (i.e., both molecules must be knocked out or inhibited for complete loss of rolling). Of note, whereas IL-1 and TNF upregulate both P- and E-selectin in mice, they induce only E- but not P-selectin in humans. In humans, E-selectin expression is largely regulated by de novo synthesis induced by cytokines whereas P-selectin is preformed and mobilized from WPBs to the cell surface in response to stimuli like thrombin, histamine, reactive oxygen species, and the like. Consequently, E- and P-selectin may not be redundant in humans. Selectin expression is rapid, within 5 min for P-selectin and 1 to 2 hours for E-selectin, but is often transient, peaking at 15 minutes for P-selectin and 4 to 6 hours for E-selectin, but may persist much longer on skin ECs. Another important mechanism initiating rolling of T lymphocytes on ECs is the interaction of the hyaluronan receptor CD44. CD44 is expressed on

TABLE 162-2
Adhesion Molecules

Adhesion Molecule	Expression	Ligand	Function
Selectins			
L-selectin (CD62L)	Leukocytes	Sialylated and fucosylated carbohydrates displayed on, for example, CD34, MAdCAM-1, or GlyCAM-1	Tether, rolling
E-selectin (CD62E)	EC	Sialylated Lewis X or A moieties such as CLA displayed on ESL-1, L-selectin or PSGL-1[58]	Tether, rolling
P-selectin (CD62P)	EC, platelets	Glycans and sulfated sialomucins displayed onPSGL-1[95]	Tether, rolling
Integrins			
LFA-1 ($\alpha_L\beta_2$ or CD11a/CD18)	Leukocytes	ICAM-1, ICAM-2[96]	Firm adhesion, diapedesis

endothelial cells and, under inflammatory conditions, binds hyaluronan, which then binds CD44 expressed on activated T lymphocytes and macrophages.[57]

Firm adhesion of leukocytes to ECs is generally mediated by leukocyte integrins. Leukocytes use two different types of integrins to interact with ECs. The first of these are the CD18 or β_2 integrins, including lymphocyte function-associated antigen-1 ($\alpha_L\beta_2$ or CD11a/CD18) and Mac-1 ($\alpha_M\beta_2$ or CD11b/CD18). The adhesion mediated by LFA-1 or Mac-1 recognition of intercellular adhesion molecule-1 (ICAM-1) is much stronger than that mediated by selectins, so that once these molecules have engaged ICAM-1, leukocytes no longer roll. In the case of neutrophils, integrin engagement results in a gradual slowing of rolling velocity. In contrast, lymphocytes abruptly convert from rolling to firm adhesion. Once adherent, leukocytes spread out and then slowly crawl along the EC surface until they reach a cell junction, where they undergo diapedesis through the vessel wall into the tissues (see Fig. 162-6). It is likely that LFA-1-mediated attachment, disengagement, and reattachment to ICAM-1 play a role in the spreading, crawling, and diapedesis of leukocytes. ICAM-1 is induced at slightly later times than E-selectin, but it remains elevated for days; it is initially (at 4 hours after treatment with TNF) upregulated diffusely on the luminal surface of the EC but then preferentially localizes to the intercellular junctions over the first few days.[6] Studies with blocking antibodies and in knockout mice confirm that β_2 integrins and ICAM-1 play a major role in leukocyte adhesion to ECs and in subsequent recruitment.

The second group of integrins on leukocytes that mediate attachment to ECs are the α_4 integrins (CD49d), which may pair with either β_1 (CD29) to form very late activation antigen-4 (VLA-4) ($\alpha_4\beta_1$) or with β_7 to form

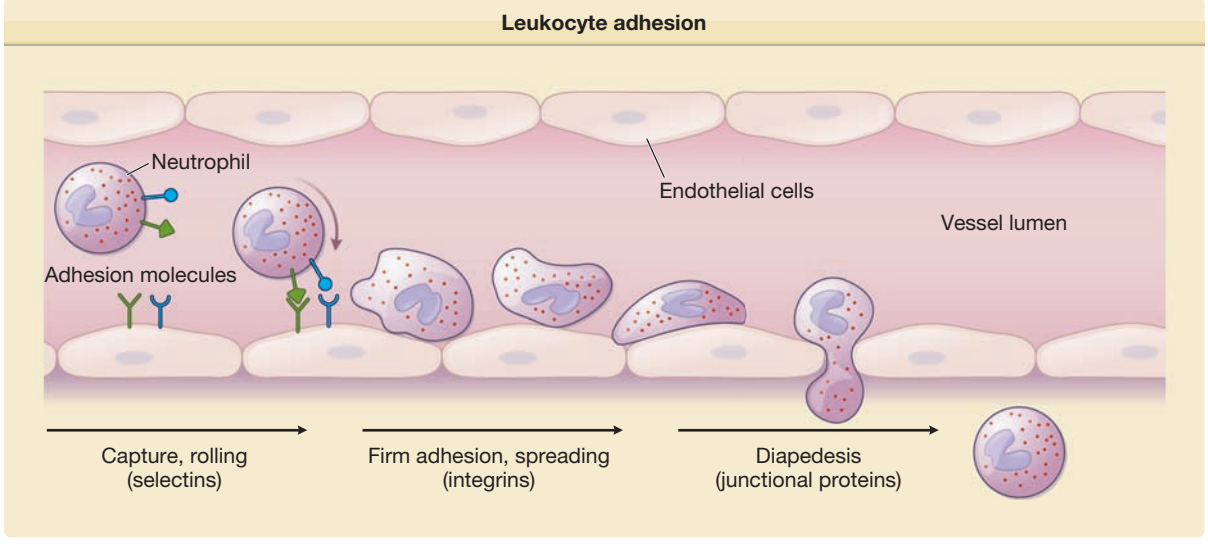

Figure 162-6 Leukocyte adhesion.

lymphocyte Peyer patch adhesion molecule-1 (LPAM-1) (integrin $\alpha_4\beta_7$). The principal EC ligand for VLA-4 is vascular adhesion molecule 1 (VCAM-1). This immunoglobulin superfamily member is not expressed on resting ECs under normal circumstances but is upregulated by TNF or IL-1 with a time course that peaks at about 24 hours. VCAM-1 may be selectively upregulated by IL-4, a cytokine associated with certain types of adaptive immunity, and IL-4 can act synergistically with TNF or IL-1. Although VCAM-1 expression is not responsive to interferon-γ (IFN-γ) itself, IFN-γ intensifies TNF-induced VCAM-1 expression.[60] Interestingly, VCAM-1 may support initial tethering and rolling of some leukocytes (e.g., of T cells but not of neutrophils), as well as firm adhesion, depending on whether the affinity/avidity of the leukocyte VLA-4 is increased by leukocyte activation. Antibody-blocking experiments confirm a role for these molecules in leukocyte recruitment in vivo.[61] True VCAM-1 knockout mice are embryonic lethals due to failure of placentation. Some VCAM-1 "knockouts" were made by disrupting the first exon. These animals make a truncated VCAM-1 protein, lacking the first Ig domain but express it at reduced ("hypomorphic") levels. These animals also confirm a role for VCAM-1 in leukocyte recruitment.

LEUKOCYTE ACTIVATION. TNF- or IL-1-treated ECs promote the activation of tethered or rolling leukocytes, triggering the transition from selectin-mediated low-affinity attachment to integrin-mediated firm adhesion and the transition from spherical, immotile leukocytes to spreading, migrating forms. In some experiments, engagement of selectins appears to be adequate by itself to trigger some of these changes, but most experiments indicate the requirement for a distinct signal. One candidate activator is the lipid mediator platelet-activating factor (PAF), which can be displayed in the EC plasma membrane. PAF synthesis is initiated by cytosolic phospholipase A2 activation, which is the same reaction that provides arachidonic acid for PGI_2 synthesis. It has been reported that IL-1β may promote PAF synthesis in ECs, but most studies emphasize the role of autacoids (e.g., histamine), rather than cytokines, as inducers of PAF synthesis.

The chemokines constitute an important group of TNF- or IL-1β-induced leukocyte activators that are defined by the presence and number of amino acids between two *N*-terminal cysteine residues (i.e., CC, CXC, etc.) (see Chapter 12). Chemokines induce migration and/or activation of various types of leukocytes through interaction with a group of seven transmembrane G protein-coupled receptors. The CXC chemokines (such as IL-8) are particularly important for neutrophil activation, and CC chemokines (such as MCP-1) are important for monocyte activation. IL-8 is stored in WPBs and released on stimulation with histamine or thrombin. Both IL-8 and MCP-1 are synthesized and secreted by TNF- or IL-1β-treated ECs. Furthermore, ECs can display their secreted chemokines in a complex with cell surface proteoglycans in a manner that renders them bioavailable to tethered or rolling leukocytes. The bound chemokines displayed by ECs could be made by ECs or could be captured and displayed once made by tissue cells or leukocytes. In addition, there is a transmembrane protein form of a chemokine called *fractalkine* that has its chemokine domain presented at the top of a mucinlike stalk. Fractalkine can be induced in vascular ECs and functions as an adhesion molecule. Accumulating evidence suggests that fractalkine mediates vascular injury in glomerulonephritis, allograft rejection, and atherosclerotic disease.[63–65] Chemokines may also play a role in activation and recruitment of specific lymphocyte subsets, as discussed later.

EXTRAVASATION OF LEUKOCYTES. The extravasation of leukocytes requires the preceding steps of tethering, rolling and adhesion followed by locomotion to junctions. Junctional proteins such as PECAM-1 (CD31), CD99 and junctional adhesion molecules (JAMs) contribute to leukocyte transmigration, and as noted earlier, activated ECs also concentrate adhesive ligands, such as E-selectin, ICAM-1, and VCAM-1, at these same junctions. The details of interaction between leukocytes and ECs during diapedesis in vivo are incompletely defined. The principal pathway for extravasation appears to be through the intercellular junctions (see Table 162-2). Antibodies to PECAM-1 and to CD99 inhibit this process. Of note, in PECAM-1 knockout mice, effects on leukocyte transmigration appear to be mouse strain specific. PECAM-1 at the border of endothelium forms homophilic interaction between PECAM-1 on leukocytes and triggers targeted recycling of membrane from a reticulum localized compartment close to the endothelial cell lateral border and is called lateral border recycling compartment. This compartment constitutively recycles and is mobilized to sites of junctions and surrounds the transmigrating leukocyte. This compartment also contains CD99 and JAM-1 but not VE-cadherin.[66] JAM proteins interact with leukocytes by binding to integrins. The integrin LFA-1 mediates neutrophil and T-cell adhesion to JAM-A; the integrin $\alpha_4\beta_1$ mediates leukocyte adhesion to JAM-B. JAM-2–$\alpha_4\beta_1$ interactions appear to be dependent on interactions between JAM-B and JAM-B. JAM-B binds to CD11b/CD18 on neutrophils, and this interaction is thought to be important for neutrophil transendothelial migration. It has been shown that VE-cadherin gap formation is required for leukocyte transmigration and p120 is a critical intracellular mediator of this process through its regulation of VE-cadherin expression at junctions.[67] In addition, VE-cadherin may interact with leukocytes through an interposed fragment of fibrin, which is formed through thrombin-induced fibrinogen activation followed by plasmin or urokinase digestion.[68]

In certain instances, leukocytes may extravasate through the EC body. The factors that determine whether leukocytes use the intercellular or transcellular pathway are unknown. The early stages of this process appear to involve phagocytosis of the leukocyte through membrane extensions enriched in ICAM-1 and VCAM-1. The transcellular diapedesis of monocytes and neutrophils also involves the lateral border recycling compartment within which PECAM-1, CD99

and JAM-A are the critically involved adhesion molecules. In addition, the rapid transmigration of T cells, but not other leukocyte subsets, appears to depend on the presence of venular levels of shear stress, which contribute by signaling to the T cell by "stretching" tethered adhesion molecules such as LFA-1. TNF- or IL-1-treated ECs secrete and activate matrix metalloproteinases (MMPs), which degrade the condensed region of connective tissue matrix, that is, the basement membrane that underlies the endothelial monolayer. ECs may also trigger leukocytes to synthesize or release MMPs, and the signals for this release may be cytokine-inducible molecules such as VCAM-1 or chemokines.[69]

T cells in the circulation are heterogeneous. Some have never encountered their cognate antigen and are said to be naïve. Memory T cells arise following encounters with antigen and may be divided into central memory and effector memory subpopulations. Effector memory $CD45RO^{+}$ $CCR7^{low}$ L-$selectin^{low}$ $CD4^{+}$ T cells transmigrate across endothelial monolayers in flow chambers in the presence of the IFN-γ-inducible protein-10 (IP-10) (CXCL10) whereas naive T cells or central memory T cells do not, despite the expression of CXCR3 on the latter cell type. In vitro assays established that the recognition of endothelial MHC class II by T cells blocks the response to IP-10 but causes delayed transendothelial migration of effector memory, but not of naïve or central memory $CD4^{(+)}$ T cells. Fractalkine, induced by TNF or IL-1 on microvessel EC, also contributes to the TCR-initiated response.[70] The TCR pathway also involves PECAM-1, which is not used by T cells responding to IP-10.

VASCULAR LEAKAGE AND PROVISIONAL MATRIX. Extravasation of plasma proteins into the tissue is a hallmark of inflammation. Autacoids such as histamine allow this to occur rapidly and transiently by causing ECs to contract their actin cytoskeleton, opening gaps between cells. VEGF may function similarly but also appears to have its primary effects on increasing fluid transit through vesiculovacuolar organelles. In contrast, TNF- or IL-1-treated ECs permit the nonspecific extravasation of fluid and plasma proteins, commonly called *vascular leak*, only after a delay of several hours in a process that depends on new protein synthesis. The loss of permselectivity (vascular leak) is a hallmark of inflammation. The principal purpose of this response is to allow plasma proteins, such as fibronectin and fibrinogen, to deposit in the tissues, where they form a provisional matrix that can be used by motile leukocytes. This is important because circulating leukocytes typically lack receptors that allow them to interact with the normal extracellular matrix, composed largely of interstitial collagens.

Collectively, these five TNF- or IL-1-mediated responses of ECs promote the development of an inflammatory infiltrate initially comprised of neutrophils and later of mononuclear phagocytes. The infiltrating leukocytes serve to phagocytose the eliciting microbes and clean up damaged tissue. Infiltrating phagocytes also can cause tissue damage through the same mediators and enzymes they use to eradicate microbes. These mechanisms can and often do injure local ECs, which is manifested by EC retraction and/or denudation and often accompanied by intravascular thrombosis. Intravascular thrombi exacerbate tissue ischemia and injury. Fortunately, TNF- or IL-1-treated ECs become more resistant to injury through expression of protective gene products such as detoxifying agents for reactive oxygen intermediates like manganese-superoxide dismutase and hemoxygenase, protease inhibitors like plasminogen activator inhibitor-1 and tissue inhibitors of metalloproteinases, and cytoprotective genes such as the zinc finger protein ubiquitinase/de-ubiquitinase enzyme A20 and Bcl-related antiapoptotic genes such as *A1*. These protective responses allow ECs to survive many inflammatory reactions without triggering thrombosis and consequent tissue infarction.

The acquisition of cytoprotective features has been observed in the ECs of organ grafts that have evaded transplant rejection.[71] However, these protective responses are not always adequate. Moreover, some other TNF- or IL-1-mediated endothelial responses, for example, induction of procoagulant proteins such as tissue factor coupled with loss of anticoagulant proteins such as thrombomodulin, may actually exacerbate tissue and vascular injury. This combination of neutrophil recruitment and alterations in the endothelial coagulation system may underlie the tissue injury seen in the local Shwartzman reaction or in Gram-negative septicemia.

In summary, ECs, through their responses to cytokines, can contribute to host defense reactions mediated by the innate immune system. However, these same effector mechanisms may lead to endothelial injury and exacerbate tissue damage.

ROLE OF ENDOTHELIUM IN ADAPTIVE IMMUNITY

ECs of microvessels constitutively express MHC molecules. To date, the only well-established function of class I and class II MHC molecules is to present peptides to T cells. Vascular ECs not only express MHC molecules but also express the proteins involved in generating peptides and loading these peptides into nascent class I and class II molecules.[72] The expression of class I genes (and the gene encoding the associated β_2-microglobulin molecule), as well as the proteins involved in peptide generation and class I MHC molecule peptide loading, are all upregulated by cytokines, particularly by IFNs, and by TNF.[73] Under basal culture conditions human ECs do not express class II MHC molecules or the proteins responsible for peptide loading of class II molecules, but these proteins are induced by IFN-γ. In humans, class II molecules are basally expressed on microvascular cells in vivo.[73,74] It is unclear whether this "constitutive" expression depends on low levels of circulating IFN-γ or is truly constitutive.

The typical diameter of a capillary lumen is less than 10 μm, i.e., narrower than the diameter of a circulating lymphocyte. Consequently, circulating T cells are

forced to encounter antigenic peptides complexed to both class I and class II MHC molecules displayed on the endothelial surface during the course of normal circulation. A key question is what effect this encounter has on the T cell. Studies of the consequences of T-cell recognition of antigen presented by ECs have largely used cell culture systems. Naive T cells ignore antigens presented by ECs whereas resting memory T cells or recently activated T blasts respond by cytokine gene expression and a limited degree of proliferation. This limitation correlates with the observation that human ECs are deficient in expressing certain costimulatory molecules, for example, CD80 and CD86, and primarily costimulate T cells with LFA-3 (CD58).[76] Naive T cells poorly express CD2, the receptor for LFA-3. Another factor may be that naive T cells lack the expression of adhesion molecules necessary to attach firmly to ECs. In addition to constitutive expression of LFA-3, human ECs display inducible expression of ligands for inducible T-cell costimulator, CD137, and CD134 that are typically associated with the stimulation or reactivation of memory T cells, as well as expression of molecules that inhibit T-cell activation, such as ligands for PD-1.[77–79]

Several nonexclusive roles have been proposed for presentation of antigen by ECs if it were to occur in vivo. The first is the maintenance of immunologic memory. Long-lived memory T cells may require periodic low-affinity signaling to survive, and the expression of MHC molecules bearing self-peptides by ECs may provide such low-affinity signals as these cells pass through the microcirculation. Recent data indicate that human blood ECs are able to present self-antigens in vivo[75], which may help sustain the viability of memory-cell populations. A second role might come into play when there is reinfection by a particular pathogen. In this case, ECs may present microbe-derived peptides in association with MHC molecules, providing an antigen-specific signal to circulating memory T cells that pathogen is present. This mechanism would contribute to the efficiency of immune surveillance. This is a potentially important function, because T cells specific for any one antigen, even among memory T cells expanded by prior encounter with antigen, are rare (less than 1 in 10,000–100,000). Presentation of antigen by ECs could markedly increase the likelihood that antigen is recognized in a timely manner and that memory T cells are recruited to sites of danger. A third possibility involves the postthymic induction and activation of $CD4^+25^+$forkhead box P3 regulatory T cells.[80] It has been shown that, in mice, alloantigen presentation by vascular ECs to $CD4^+$ T cells induces such regulatory T cells, which could be important for induction of tolerance. However, it must be noted that mouse ECs usually do not express class II MHC molecules in vivo and that cultured human T cells preferentially activate $CD4^+$ effector cells rather than regulatory T cells.

T cells may differentiate into specialized cytokine-producing subsets. For $CD4^+$ T cells, such responses may become polarized into T helper 1 (Th1, they produce IFN and lymphotoxin), or into T helper 2 (Th2, they produce IL-4 and IL-5). More recently, it has been appreciated that some effector $CD4^+$ T cells may selectively secrete IL-17, a proinflammatory cytokine. IL-17 producing helper T (Th17) cells bind via LFA-1 to ICAM-1, which is expressed on EC. IL-17 has been identified as an important proinflammatory mediator in various diseases like atopic dermatitis or bronchial asthma. In various models, IL-17 was also able to directly disrupt the blood–brain barrier as a direct effect of Th17 cells on ECs. Disruption of blood–brain barrier is an important step for the development of central nervous system inflammation as observed in diseases like multiple sclerosis.[81,82] On HUVEC, IL-17 induces expression of adhesion molecules like ICAM-1, VCAM-1, E-selectin[83] but the potency of IL-17 is markedly less than that of TNF or IL-1. Another subclass of specialized T cells, regulatory T cells (Treg; $CD4^+$/$CD25^+$/$FOXP3^+$) play an important role in inflammatory and neoplastic diseases.[84,85] ECs of tumor vessels express a specific addressin signature to guide Tregs into the tumor.[86]

Cytokines released by Th1 or Th2 cells may differentially shape EC activation patterns. For example, IFN-γ combined with lymphotoxin causes prolonged expression of E-selectin, an important ligand for Th1 T cells. Th1 cells, but not Th2 cells, are able to bind to P-selectin and E-selectin, and migration of Th1 cells into inflamed skin is blocked by antibodies against P- and E-selectin.[87] P-selectin glycoprotein ligand 1 appears to function as P- and E-selectin ligands for Th1 cells, which correlates with increased expression of the α_3-fucosyltransferases in Th1 cells.[87,88] In contrast, Th2-derived IL-4 increases VCAM-1 expression while suppressing E-selectin, a cell surface molecule that favors eosinophil and possibly also Th2-cell recruitment. In other words, T cell-derived cytokines may modify the innate EC responses in a way that biases leukocyte recruitment toward recruitment of specific effector cells. Finally, differential expression of chemokine receptors may also account for selective recruitment of T-cell subsets. For example, CCR5 and, to a lesser degree, CXCR3 are preferentially found on Th1 cells, whereas CCR4, CCR8, and, more controversially, CCR3 and CXCR4 are preferentially found on Th2 cells.

SKIN MICROVESSELS IN INFLAMMATION AND REPAIR

SKIN MICROVESSELS IN CUTANEOUS INFLAMMATION

It is clear that vascular ECs are important participants in the development of inflammatory responses and that ECs may be partially responsible for tissue-specific differences in inflammation. One mechanism by which vascular ECs may contribute to tissue-specific inflammatory patterns is through distinctive patterns of adhesion molecule expression, which results in selective recruitment and diapedesis of circulating leukocytes bearing the proper ligands. In the skin, E-selectin, VCAM-1, and ICAM-1 may be particularly important in this process, and they have

been extensively evaluated in normal and disease states[34,89–91] (see Table 162-3).

The induction of E-selectin appears to be particularly important in cutaneous inflammatory reactions. In addition to being readily inducible by cytokines and uniformly associated with leukocytic infiltration, E-selectin may play a role in the selective recruitment of lymphocytes to cutaneous sites of inflammation through binding to the cutaneous lymphocyte antigen (CLA).[92,93] CLA is a carbohydrate moiety on the surface of T cells closely related to sialylated Lewis X, which has homology to the core structure of P-selectin glycoprotein-1.[94] By using the identifying monoclonal antibody HECA-452, CLA has been found on 80% to 90% of skin infiltrating lymphocytes compared with 5% to 10% at other peripheral sites. CLA is also present on circulating precursor Langerhans cells and presumably plays a role in their eventual localization to the skin. The expression of E-selectin in cultured dermal microvascular ECs is relatively persistent compared to endothelium derived from other sources. This persistent expression of E-selectin in vivo has been proposed to be responsible for the preferential homing of CLA-positive lymphocytes to the skin. Work in a chimeric human mouse model of inflammation suggests that CLA-positive lymphocytes specifically migrate through the superficial, as opposed to the deep, vascular plexus.[95] It is unlikely that E-selectin–CLA interactions alone are sufficient to account for the homing of lymphocytes to the skin. The transmigration of CLA-positive lymphocytes across activated ECs is dependent on interactions with VCAM-1 and ICAM-1, in addition to E-selectin.

The induction of E-selectin on cutaneous microvessels also appears to play a role in immediate hypersensitivity reactions in atopic individuals. These reactions are characterized by an immunoglobulin E-dependent biphasic response. Within minutes after exposure, the relevant antigen cross-links immunoglobulin E, which is bound to the high-affinity FcRε receptors on the surface of mast cells, and results in histamine release. Histamine-dependent stimulation of ECs leads to vasodilation and increased vascular permeability, which produces the classic wheal-and-flare response that typically resolves within 30 to 90 minutes. This reaction, known as the *early-phase response*, is not accompanied by endothelial E-selectin upregulation or inflammatory cell recruitment. The late-phase reaction begins 3 to 4 hours after antigen challenge and is characterized by the infiltration of eosinophils, neutrophils, and mononuclear cells into the inflamed area. Granulocytes are most prominent at 6 to 8 hours, and, by 24 to 48 hours, the cellular infiltrate consists largely of mononuclear cells. The expression of E-selectin, which indicates endothelial activation, is detectable at the onset of infiltration. Although this E-selectin induction may simply be due to cytokine release from infiltrating inflammatory cells, there is evidence that the necessary mediators are first released from skin-resident cells. In skin organ culture, the addition of antigen either before or during the culture period results in significant E-selectin expression without inflammatory infiltrate.[96]

VCAM-1 may play a role in the specific homing of leukocytes to the skin through binding to the integrin $\alpha_4\beta_7$ on the surface of lymphocytes. This integrin is associated with the specific localization of lymphocytes to the gut through binding to mucosal addressin cell adhesion molecule 1 (Madcam-1) on ECs of intestinal microvessels.[91] Another ligand for $\alpha_4\beta_7$ includes fibronectin. $\alpha_4\beta_7$ has been found to be expressed on a high percentage of intraepidermal lymphocytes, particularly in cutaneous T-cell lymphoma (CTCL) and, to a lesser degree, in spongiotic dermatitis.[91] Interestingly, in CTCL, the expression of $\alpha_4\beta_7$ strongly correlated with the expression of integrin $\alpha_E\beta_7$. $\alpha_E\beta_7$ is also found on a high percentage of gut (intraepithelial) and intraepidermal lymphocytes.

In chronic inflammatory conditions such as psoriasis and CTCL, the cutaneous microvascular endothelium develops a "high endothelial venule" morphology similar to that seen in peripheral lymph nodes. This is accompanied by the expression of peripheral lymph node addressin identified by the antibody MECA-79, which serves as an L-selectin ligand. This has led to the speculation that peripheral node addressins in chronic T cell-mediated skin diseases are responsible for sustained lymphocyte recruitment. Interestingly, there is MECA-79 reactivity in the perifollicular vessels in non-inflamed skin.[97] This constitutive expression in normal skin may serve a function in continuous lymphocyte recirculation.[98]

Chemokines also play a role in the selective homing of T cells to the skin. CCR4 is expressed at high levels by CLA-positive memory T cells. The CCR4 receptor TARC is constitutively expressed on ECs in cutaneous postcapillary venules. In vitro TARC triggers CLA-positive T cells that are rolling on E-selectin to firmly adhere ICAM-1. Another skin-associated chemokine, CCL27 (cutaneous T cell-attracting chemokine), is produced by keratinocytes and also preferentially attracts CLA-positive memory T cells.[99]

NEW VESSEL FORMATION IN THE SKIN

DEFINITION OF ANGIOGENESIS AND VASCULOGENESIS.

In the healthy adult, blood vessels are stable structures with very slow turnover of ECs. In settings of chronic inflammation, tissue injury, or tumor growth, new vessels may be formed and existing vessels may undergo remodeling. Much of the process of vessel formation has been learned by the study of the formation of the vascular system during embryogenesis. In the embryo, ECs arise from angioblasts,[100,101] which migrate from their site of origin (initially blood islands, later liver, and ultimately bone marrow) to peripheral tissues, where they form primitive blood vessels (vasculogenesis). Subsequently, new blood vessels arise from preexisting ones (angiogenesis). Mesenchymal cells are then recruited into the vessel wall, where they subsequently differentiate into smooth muscle cells and pericytes, as part of a process called *vascular remodeling*. New vessels can be formed in the adult as part of chronic inflammation, as part of the repair of injured tissues or during tumor growth. In the adult,

new blood vessels develop through adult angiogenesis (sprouting from preexisting, mature blood vessels); it has been proposed that there may also be a contribution through recruitment of circulating endothelial progenitor cells, mesoangioblasts, and multipotent adult progenitor cells derived from the adult bone marrow (adult vasculogenesis).[102,103] However, it is unclear that such cells give rise to stable ECs and many such observations have now been reinterpreted to imply a role for monocytes that express EC markers, promote angiogenesis, and then disappear as the new vessels become stable. Stem cells and endothelial progenitor cells have been identified in vessel walls as resident cells. Such cells are thought to reside in a niche, awaiting appropriate stimuli like vessel injury to take part in the repair of damaged and the formation of new blood vessels. Among such vascular wall progenitor cells are $CD34^+/CD31^-$ cells that differentiate into endothelial cells.[108] Other resident vascular wall progenitor cells are smooth muscle-cell progenitors and mesenchymal stromal cells,[109] which may arise from PCs.

REGULATION OF ANGIOGENESIS AND VASCULOGENESIS. (Table 162-4). Molecules of the VEGF family, VEGF A through E, and their receptors, VEGFR-1 (Flt-1), VEGFR-2 (KDR or Flk-1), and VEGFR-3 (Flt-4), are required to initiate the formation of primitive vessels. Mice with a targeted disruption of *VEGF* or *VEGFR-2* genes fail to develop a vasculature. VEGFR-1 knockout mice have immature leaky vessels. Disruption of VEGFR-3 results in the disorganization of large vessels and lymphatic hypoplasia. A missense mutation in VEGFR-3 occurs in primary human lymphedema.[107,110,111] Fibroblast growth factors 1 and 2 (FGF-1 and FGF-2, also called *acidic* and *basic FGF*, respectively) mainly signal through FGF receptor I.[112] Knockout mice die before vasculogenesis starts; thus, specific evaluation of FGF function in vascular development is not possible in these animals. Both FGF-1 and FGF-2 are potent EC mitogens but they also act on SMCs, PCs and fibroblasts. FGFs "synergize" with VEGF in stimulation of cultured EC mitogenesis and in bioassays of angiogenesis. In the adult, FGF-1 and FGF-2 are stored in the cytoplasm of a variety of cells, which is consistent with the fact that these proteins lack the signal sequences required for efficient secretion. Stored FGFs are released when cells are injured, acting as "wound hormones" to stimulate local angiogenesis and connective tissue growth.[112] Other polypeptide factors have also been found to act on ECs in vivo and in vitro, including epidermal growth factor,[113] heparin-binding EGF-like growth

TABLE 162-4
Molecules Important in Vasculogenesis and Angiogenesis

Molecule	Function	Receptor
VEGF family ■ Five splice variants (VEGF A–E) ■ Homolog PlGF	Specific mitogen for ECs	Family of closely related receptor tyrosine kinases ■ VEGFR-1 (Flt-1) binds VEGF A and B, PlGF ■ VEGFR-2 (KDR or Flk-1), main mediator of VEGF-induced vascular development and angiogenesis, binds all isoforms of VEGF ■ VEGFR-3 (Flt-4) binds VEGF C and D
FGF-1 and FGF-2	Involved in vasculogenesis and angiogenesis in embryonic development	FGFR-I
Angiopoietins ■ Ang-1 ■ Ang-2 ■ Murine Ang-3 ■ Human Ang-4	Ang-1 positively affects vascular stability Ang-2 is a competitive inhibitor of Ang-1	Tie-1 and Tie-2 receptor tyrosine kinases ■ Tie-2 mediates dialog between primitive mesenchymal cells and EC of immature vessels ■ Tie-1 ligands not known
PDGF	Secreted by ECs, acts on mesenchymal cells to promote migration, matrix biosynthesis, and differentiation	Receptor tyrosine kinase
TGF-β	Secreted by ECs, acts on mesenchymal cells to promote migration, matrix biosynthesis, and differentiation	Protein serine/threonine kinase endoglin (CD105), important for vascular development
TSP-1	Antiangiogenic, inhibits MMP-9, activates TGF-β	Integrin $\alpha_v\beta_3$ CD36

Ang = angiopoietin; EC = endothelial cell; FGF = fibroblast growth factor; FGFR = fibroblast growth factor receptor; KDR = kinase insert domain protein receptor; MMP = matrix metalloproteinase; PDGF = platelet derived growth factor; PlGF = placental growth factor; TGF = transforming growth factor; TSP = thrombospondin; VEGF = vascular endothelial growth factor; VEGFR = vascular endothelial growth factor receptor.

factor,[114] and hepatocyte growth factor (HGF)/scatter factor (SF).[115] For vascular remodeling and stabilization, tyrosine kinase receptors 1 (Tie-1) and 2 (Tie-2; Tek) are required. Tie-2 mediates the dialogue between mesenchymal cells and the endothelium of the immature blood vessel through binding to angiopoietins (Ang-1, Ang-2, murine Ang-3, and its human ortholog Ang-4). In humans, Tie-2 mutations cause venous malformations typified by enlarged vascular channels lacking smooth muscle cells. Ang-2 appears to be a competitive inhibitor of Ang-1, and Ang-2 overexpression results in a phenotype resembling an Ang-1 knockout animal.[116] Ligands for Tie-1 are not known, but knockout of this receptor results in defective vascular maturation later in embryonic development.[107,117] The eph family of receptor tyrosine kinases (ephA1 to ephA8 and ephB1 to ephB6) and their corresponding ephrin ligands (ephrin-A1 to ephrin-A5 and ephrin-B1 to ephrin-B3) are membrane bound and appear to mediate bidirectional cell-to-cell signaling. Mice lacking ephrin-B2 and its ephB4 receptor have lethal defects in early angiogenic remodeling.[118] During vascular development ephrin-B2 marks the ECs of early arterial vessels and ephB4 marks the ECs of early veins.[119]

PDGF and TGF-β are secreted by ECs and promote migration of mesenchymal cells, matrix biosynthesis, and differentiation.[120] PDGF and TGF-β act through receptors equipped with tyrosine and serine/threonine kinase activities. TGF-β also uses nonsignaling receptors that present TGF-β to the signaling receptor, for example, endoglin (CD105). A truncation mutation in the *endoglin* gene in humans causes a hereditary form of vascular malformations (hereditary hemorrhagic telangiectasia type I),[121] and endoglin knockout mice die of defective vascular development.

Matrix glycoproteins such as fibronectin and laminin and receptors for matrix glycoproteins such as β_1 and β_3 integrins are also believed to play a role in vasculogenesis and angiogenesis.[122] This seems intuitive, because neither ECs nor mesenchymal cells can survive unless they interact with matrix proteins via integrin receptors. Knockout of most of these molecules causes early embryonic death, which prevents a direct test of their role in vascular embryology. An exception is the β_3-integrin knockout mouse, which shows normal development but enhanced tumor angiogenesis. Coagulation factors, like tissue factor or coagulation factor V, are implicated in vasculogenesis by observations of defective vascular development in knockout mice.[123] It is thought that these defects are an indirect result of defective thrombin production, because knockout of the thrombin receptor PAR-1 produces similar phenotypes.

CUTANEOUS ANGIOGENESIS AND VASCULOGENESIS. Cutaneous angiogenesis and vasculogenesis occur in wound healing, inflammation, and tumorigenesis. New vessel formation in the skin differs in several ways from that in other organs. Skin harbors hair follicles, which, besides having a role in forming hair shafts, appear to play a role in new vessel formation. The follicle contains a distinct population of presumptive follicular stem cells that express nestin, also a marker for neural stem cells. These nestin-expressing follicle cells are located in the follicular bulge region. During the follicular growth cycle, they differentiate into the various cell types of the hair follicle and, in addition, can form a variety of epidermal cells. It has been shown that these nestin-positive cells can also develop into cutaneous blood vessels that originate from hair follicles and form a follicle-linked vascular network. The quantitative contribution of hair follicle-derived angiogenesis compared with conventional angiogenesis through local sprouting is unknown.

Skin endothelium is also unique by virtue of its close proximity to keratinocytes, which form the overlying epidermis coating. Keratinocytes have been shown to express a wide range of angiogenic factors, including members of the fibroblast or TGF protein family, platelet PDGF, or VEGF.[124,125] Of note, not only ECs respond to VEGF, but also epithelial cancer cells possess receptors for and respond to VEGF.[126] Under conditions of injury, hypoxia, or inflammation, keratinocytes produce and release these growth factors. Concomitantly, VEGFR-2 is upregulated on ECs, which augments endothelial responses to VEGF.[127] Ang-1 and Ang-2 are also upregulated during injury, which is consistent with the role they are thought to play in the destabilization, followed by stabilization, of the vasculature. This allows a window for VEGF-mediated sprouting and elongation, followed by Ang-1-mediated remodeling.[68] FGF-2 is released in cutaneous wounds and is derived from ECs and from infiltrating macrophages. Antibodies against FGF-2 inhibit wound angiogenesis nearly completely.[128]

Adhesion molecules are necessary for physiologic angiogenesis in the skin. The expression of integrin $\alpha_V\beta_3$ on the tips of growing capillaries appears to facilitate endothelial migration and to be required for wound healing. In an in-vivo model in which human skin placed on immunodeficient mice was wounded, blocking antibodies directed to CD31 and VE-cadherin reduced wound vascularization and healing.[20] In a similar model, blocking antibodies directed against $\alpha_V\beta_3$ inhibited angiogenesis and wound healing.[129] Administering $\alpha_V\beta_3$ inhibitors reduce granulation tissue formation and wound-induced angiogenesis, which suggests that $\alpha_V\beta_3$ is required for proper wound healing. In contrast, mice lacking β_3 integrins show enhanced wound healing with complete reepithelialization several days earlier than do wild-type mice,[130] apparently due to an increase in TGF-β1 and enhanced dermal fibroblast infiltration into wounds of β_3-null mice. This suggests that the role of β_3 integrins is complex and that these molecules may influence both angiogenic and antiangiogenic effects.

Angiogenesis is also necessary in skin tumorigenesis to maintain adequate nutritive supply. Skin tumors are known to produce angiogenic factors such as VEGF, FGF-2, EGF, and HGF/SF.[131] Some of these growth factors play a role in the pathogenesis of both benign and malignant skin tumors. There is a significant vascular contribution to the growth and metastasis of cutaneous melanoma and increased number of vessels in primary melanomas compared with severely atypical nevi. This vascular proliferative response appears to

be in part mediated by FGF-2, which is produced by melanoma cells. Antisense oligonucleotides directed against FGF-2 inhibit the proliferation of both primary and metastatic melanoma.[132] HGF/SF and VEGF are also produced by melanoma cells and also contribute to vascularization. Peptide growth factors also appear to play a role in the pathogenesis of vascular tumors. The spindle cells of Kaposi sarcoma also produce large amounts of VEGF (see Chapter 128). When human ECs are cultured in the presence of HGF/SF, they acquire a Kaposi sarcoma cell-like morphology. In hemangiomas, high levels of FGF-2 and VEGF characterize the proliferative phase. However, there is also abundant FGF-2 expression in the involuting phase.

VASCULAR REMODELING IN THE SKIN. Vascular remodeling plays a role in the pathogenesis of some inflammatory skin diseases, notably psoriasis (see Chapter 18). Psoriatic vessels become tortuous and elongated, and the normally well-defined boundary between capillary ECs resting on an arteriole-like homogenous basement membrane and ECs on a venule-like laminated basement membrane becomes unclear. The intrapapillary portions of capillaries acquire a venular phenotype.[133] It is unknown whether this is due to metaplasia from arteriolar to a venular endothelium or to an elongation of the postcapillary venule. The first ultrastructurally visible alterations in eruptive guttate psoriasis lesions consist of gap formation within postcapillary venules, EC hypertrophy with a cuboidal shape similar to that seen in high endothelial venules, and compression of the vascular lumen, all of which precedes the invasion of inflammatory cells into the tissue.[133] This morphologic alteration is accompanied by altered endothelial function. For example, there is increased blood flow in perilesional psoriatic skin even in the absence of any microscopically detectable changes.[134] It has been suggested that these vascular alterations may, in part, be mediated by increased production of VEGF by keratinocytes. There is also increased expression of VEGFR-1 and VEGFR-2 on the papillary dermal microvascular ECs.[135] VEGF appears to directly upregulate expression of ICAM-1, VCAM-1, and E-selectin. The VEGF-mediated vascular leak and adhesion molecule upregulation can be inhibited by concurrent overexpression of Ang-1. The role of angiogenesis in inflammatory processes has been further exemplified by the anti-inflammatory effects of angiogenesis inhibitors.[136]

The skin is prone to frequent trauma. Therefore, vascular remodeling, angiogenesis, and vasculogenesis in the skin are most often caused by wound healing processes. Wound healing requires a complex interplay between resident cells (endothelial cells, fibroblasts, and smooth muscle-like cells), soluble mediators, infiltrating leukocytes, and extracellular matrix molecules.[137] The most important soluble factors in wound healing are members of the VEGF family of growth factors. VEGF acts as an EC mitogen, a regulator of vascular permeability, and a chemotactic agent.[138] VEGF in the wound healing situation is mainly produced by stromal fibroblasts. In situations where the VEGF production cannot be appropriately adjusted to the increased demands, as is the case in elderly or diabetic patients, vessel formation is strongly reduced and wound healing impaired.[139,140]

CONCLUSION

The skin vascular system is unique in several respects. It is organized into functionally distinct vascular segments: the loops within the tips of the papillae, the SVP and the DVP, and the subcutaneous vascular plexus. These segments may individually or conjointly respond to exogenous or endogenous stimuli, thereby influencing skin disease expression. Due to their proximity to the epidermis, ECs of the SVP may directly respond to keratinocyte-derived factors like cutaneous T cell-attracting chemokine or VEGF, which results in an altered vascular architecture, phenotype, and function. Moreover, skin EC may be directly exposed to environmental antigens. In this context, the constitutive expression of HLA class II molecules by postcapillary venules implies that ECs play a role in antigen presentation, which may increase the likelihood that antigen is recognized in a timely manner to efficiently recruit memory T cells to sites of danger.

Chapter 163 :: Cutaneous Necrotizing Venulitis

:: Nicholas A. Soter

CUTANEOUS NECROTIZING VENULITIS AT A GLANCE

- Signature lesions are erythematous papules that do not blanch when the skin is pressed and are known as *palpable purpura.*
- Palpable purpura persists for 1 to 4 weeks and resolves at times with transient hyperpigmentation and/or atrophic scars.
- Macules, papules, urticaria/angioedema, pustules, vesicles, ulcers, necrosis, and livedo reticularis also may be present.
- May be characterized by episodes of recurrent and chronic urticaria and angioedema.
- Lesions may occur anywhere on the skin but are most common on the lower extremities or over dependent areas such as the back and gluteal regions.
- May be associated with connective-tissue diseases, notably rheumatoid arthritis, Sjögren syndrome, systemic lupus erythematous, and hypergammaglobulinemic purpura.
- There may be many precipitating causes but infections and drugs are most common.
- The most widely recognized subgroup of idiopathic cutaneous necrotizing vasculitis in children is Henoch–Schönlein purpura.
- Histopathologic criteria include necrosis of the blood vessels with the 'deposition of fibrinoid material and dermal cellular infiltrates that consist of neutrophils with nuclear debris, mononuclear cells, and extravasated erythrocytes.

Necrotizing angiitis or vasculitis comprises a diverse group of disorders that combine segmental inflammation with necrosis of the blood vessels. The vascular damage may result from immunologic and/or inflammatory mechanisms. Clinical syndromes are based on criteria that include the gross appearance and the histopathologic alterations of the vascular lesions, the caliber of the affected blood vessels, the frequency of involvement of specific organs, and laboratory abnormalities. Necrotizing vasculitis may be a primary disease, may develop as a feature of a systemic disorder, or may be idiopathic. There is no standard classification of the vasculitides; the American College of Rheumatology classification and the Chapel Hill consensus criteria are widely used.[1,2] These classifications are limited in clinical practice, owing to the lack of recognition of certain disorders, the overlap of clinical manifestations, and the lack of precision in the description of cutaneous features.

Necrotizing vasculitis in the skin predominantly involves venules and is known as *cutaneous necrotizing venulitis/vasculitis* (CNV), *cutaneous small-vessel vasculitis*, and *leukocytoclastic vasculitis.* The occurrence of CNV in association with systemic involvement of the small blood vessels has been termed *hypersensitivity angiitis/vasculitis, systemic polyangiitis,* and *microscopic polyangiitis* (see Chapter 164). CNV may be restricted to the skin, may occur in association with an underlying chronic disease, may be precipitated by infections or drugs, or may develop for unknown reasons (Table 163-1). Systemic forms of necrotizing vasculitis that affect larger blood vessels are considered in Chapter 164.

EPIDEMIOLOGY

The age of patients has a limited influence on CNV. An associated chronic disorder usually determines the age of the affected individual. CNV is most commonly described in children as Henoch–Schönlein purpura, with an incidence of 20/100,000 individuals less than age 17 in the United Kingdom.[3] CNV was the most common type of vasculitis presenting to a dermatology ambulatory department in India.[4] Antineutrophil cytoplasmic antibody (ANCA)-associated vasculitides are most common in patients older than 50 years of age. Geographic variations in vasculitis may reflect an environmental influence, and seasonal variations in the incidence of vasculitis may suggest an infectious etiology.[5]

ETIOLOGY AND PATHOGENESIS

Experimental studies in animal models and observations in humans implicate immune complexes as a major pathobiologic mechanism in the production of CNV. Data obtained in animal models suggest that the localization of immune complexes in venules is related to vasoactive amines and subsequent vasopermeability alterations. Additional factors that are operative in the localization of immune complexes include endothelial-cell surface receptors and the defective clearance of immune complexes by the reticuloendothelial system.

The most frequently postulated mechanisms in the production of CNV are the local deposition of circulating immune complexes that are formed during antigen excess or the formation of immune complexes in situ in the skin. Immune complexes may activate

  - Eosinophilic vasculitis
  - Idiopathic

the complement system and lead to the generation of C5a anaphylatoxin that degranulates mast cells and attracts neutrophils, which release lysosomal enzymes that damage tissue. The neutrophil superoxide-generating system may produce reactive oxygen products, which also cause tissue injury. The generation of the chemoattractant leukotriene (LT) B_4 from infiltrating neutrophils enhances the influx of neutrophils. An infiltrate composed predominantly of neutrophils in the lesional skin of patients with CNV is consistent with tissue damage, which is induced by immune complexes that activate the complement system. The initial neutrophilic process contains few CD3, CD4, CD1a, and CD36 cells whereas these cells are prominent in the later phase, with the adhesion receptors intercellular adhesion molecule-1 (ICAM-1) and lymphocyte function-associated antigen-1 (LFA-1).[6] In Henoch–Schönlein purpura, the fragmentation of neutrophils was attributed to apoptosis on the basis of the detection of inducible nitric oxide synthase and nitrotyrosine in the infiltrates and the detection of interleukin-8 (IL-8) on vascular endothelial cells.[7] Long penetration PTX3, which inhibits phagocytosis of apoptotic neutrophils by macrophages, was detected in skin biopsy specimens of idiopathic CNV and of Henoch–Schönlein purpura about blood vessels and at sites of infiltrates with leukocytoclasia.[8]

In CNV, circulating immune complexes have been demonstrated in serum as mixed-type cryoglobulins and indirectly by assays that detect C1q precipitins, materials that bind to complement receptors on human lymphocytoid (Raji) cells, materials that bind to monoclonal rheumatoid factor, and substances that function in the antibody-dependent cellular cytotoxicity inhibition assay. The presence of immune complexes is inferred from the occurrence of serum hypocomplementemia with activation of the classic activating pathway and by the detection of increased plasma levels of C4a and C3a anaphylatoxins.

In CNV, immune complexes have been detected in lesional tissues by their ultrastructural observation as electron-dense subendothelial deposits; the membrane-attack complex, C5b-9, of the complement system has been detected on the surface of endothelial cells and infiltrating neutrophils. Decay-accelerating factor, a regulatory complement protein that prevents the assembly of the membrane-attack complex, was not present on the surface of endothelial cells of the superficial dermal microvasculature. Tissue immune complexes also have been detected by direct immunofluorescence techniques as deposited immunoglobulins and complement proteins. In time–course studies of the evolution of cutaneous vascular lesions, immune reactants have been identified in lesions that are less than 24 hours old. Antigens have been identified only in a few instances as bacterial, viral, mycobacterial, or rickettsial proteins by direct immunofluorescence techniques or by the polymerase chain reaction.

A role for lymphocytes, mononuclear cells, and Langerhans cells in the production of CNV is suggested by a perivenular infiltrate in skin lesions that is rich in lymphocytes with large and hyperchromatic nuclei and by a prominence of other types of mononuclear cells in the vascular skin lesions of patients with CNV and Sjögren syndrome. The lymphocytes express CD3, CD4, CD1a, CD36, ICAM-1, and LFA-1. Lymphocytes may be activated by immune complexes, by cellular immune mechanisms, and by primary activation in autoimmune disease to produce lymphokines. In cell-mediated immune responses in lymphocytic vasculitis, dendritic cells and lymphocytes contribute to the perpetuation of CNV.[9] In CNV, there were increased numbers of factor XIIIa+ derived dendrocytes, which are involved in antigen presentation to T cells.[10] Endothelial cells also can present antigens to and activate T lymphocytes. Activated macrophages secrete chemokines and lysosomal enzymes. γ/δ T cells have been detected in CNV with a neutrophil-rich pattern and with an infectious etiology.[11] In these specimens, a 72-kDa heat shock protein was expressed by endothelial cells and antigen-presenting cells.

The participation of mast cells in CNV is suggested by hypogranulated mast cells with shed extracellular granules and by the development of vascular lesions after the intracutaneous injection of histamine in patients with active episodes of CNV. Mast cells can be activated directly by immune complexes through FcγRIII or by C5a. Through the production of histamine, prostaglandin D_2, and cysteinyl LTs, the mast cell could alter venular permeability; interendothelial cell gaps have been noted in venules in patients with CNV. Eosinophils and neutrophils could be recruited by mast cell-derived chemotactic factors. The neutral proteases and acid hydrolases of mast cells may facilitate tissue damage, and the release of tumor necrosis factor-α (TNF-α) may increase expression of E-selectin on endothelial cells and facilitate neutrophil recruitment.

Evidence for the role of the mast cell also is provided by time–course analyses of the sequential histopathologic changes in individuals with physical urticaria. In a patient with circulating immune complexes and hypocomplementemia, in whom cold and trauma elicited CNV, initial mast cell degranulation was followed by the infiltration of neutrophils, the deposition of fibrin, and venular endothelial-cell necrosis. A postulated sequence of events would be the activation of the mast cell by physical stimuli, the release of vasoactive mediators, the deposition of circulating immune complexes with activation of the complement system, the influx of neutrophils, and the development of CNV.[12] Another example of the time–course analysis of CNV in human skin was provided by an individual with exercise-induced vasculitis.[13] At 3 hours, the number of mast cells decreased, and the eosinophil was the first cell to appear around the venules with the deposition of eosinophil peroxidase. TNF-α levels were elevated, E-selectin was expressed on endothelial cells, and an influx of neutrophils appeared with the deposition of neutrophil elastase and the development of CNV.

Early in the course of necrotizing venulitis, endothelial cells show increased expression of ICAM-1 and E-selectin without the expression of vascular cell adhesion molecule-1 (VCAM-1) in response to TNF-α (see Chapter 162). Because E-selectin is an adhesion molecule for neutrophils and for skin-homing, memory T lymphocytes, the increase in E-selectin is consistent with the appearance of an infiltrate of neutrophils that express CD11b within the first 24 hours.[14]

In the acute phase of Henoch–Schönein purpura, endothelin-1, serum insulin-like growth factor-1 (IGF-1), IGF-binding protein-3, plasma matrix metalloproteinase-9 (MMP-9), ICAM-1, VCAM-1, TNF- α, IL-I-β, IL-2 receptor, IL-6, IL-8, transforming growth factor-β, vascular endothelial-cell growth factor (VEGF), and urine leukotriene E4 levels were elevated,[15–20] and the interferon-γ-inducible protein 10 level was low.[21] However, the pathogenic roles of these mediators remain undefined. IgA antiendothelial cell antibodies bind to endothelial cells and enhance endothelial cell production of IL-8 via the mitogen-activated protein kinase (MEK)/extracellular signal-regulated kinase (ERK) pathway.[22]

In skin biopsy specimens from patients with idiopathic CNV, hypersensitivity vasculitis, urticarial vasculitis, and Henoch–Schönlein purpura, E-selectin was detected on endothelial cells of lesions that were less than 48 hours old and was associated with an infiltrate of neutrophils that expressed CD11b. The endothelial cells expressed human leukocyte antigen DR (HLA-DR) and very late activating antigen-1 but not P-selectin, and the perivascular cells expressed VCAM-1 and HLA-DR. Diminished cutaneous fibrinolytic activity with reduced release of plasminogen activator from venular endothelial cells occurs in patients with CNV; the subsequent reduction in fibrinolytic activity leads to fibrin deposition. Increased levels of plasma thrombomodulin, tissue-type plasminogen activator, and plasminogen activator inhibitor-1 were detected in patients with Henoch–Schönlein purpura.[23,24]

Cutaneous nerve fibers can release neuropeptides, such as substance P, neurokinin A, and calcitonin gene-related peptide (CGRP), that cause vasodilation (see Chapter 102). Substance P activates mast cells and macrophages and increases fibrinolytic activity that is mediated by plasminogen activator. CGRP induces expression of E-selectin on endothelial cells and is chemotactic for T lymphocytes.

Eosinophils are minor infiltrating cells in CNV except in eosinophilic vasculitis and drug-induced CNV.[25] Eosinophils produce LTC_4 and platelet-activating factor, which increase vascular permeability. Eosinophil granule proteins are toxic to endothelial cells and cause the release of mediators from mast cells.

Associations have been recognized between small-vessel necrotizing vasculitis and ANCAs, which have specificity for proteins of the cytoplasmic granules of neutrophils and the lysosomes of monocytes. Two forms are recognized: (1) cytoplasmic (c-ANCAs) that are directed against proteinase 3(PR3) and (2) perinuclear (p-ANCAs) that are directed against myeloperoxidase (MPO). TNF-α facilitates neutrophil activation and cell surface expression of PR3 and MPO, which bind to ANCAs and increase the adherence of neutrophils to endothelial cells resulting in endothelial cell injury. Antiendothelial-cell antibodies have been detected in the sera of patients with systemic vasculitis, rheumatoid arthritis with vasculitis, microscopic polyangiitis, and Sneddon syndrome.

An increased prevalence of the HLA haplotype HLA-A11, Bw35 in patients with CNV and associated connective-tissue disorders suggests that genetic factors may be operative. HLA-DRB1 genotype associations were detected in patients with CNV and Henoch–Schönlein purpura in Spain.[26]

CLINICAL FINDINGS

The skin lesions of CNV are polymorphous; however, erythematous papules that do not blanch when the skin is pressed, which are known as *palpable purpura*, are the signature lesions (Fig. 163-1A). Macules, papules, urticaria/angioedema, pustules, vesicles, hemorrhagic blisters (Fig. 163-1B), necrosis and ulcers (Fig. 163-1C), and livedo reticularis may be present. Occasionally, there is subcutaneous edema below the area of the dermal lesions.

The eruption most often appears on the lower extremities or over dependent areas, such as the back and gluteal regions. The lesions may occur anywhere on the skin but are uncommon on the face, palms, soles, and mucous membranes. The clinical lesions are episodic and may recur over weeks to years. Palpable purpura persists for 1 to 4 weeks and resolves at times with transient hyperpigmentation and/or atrophic scars. Lesional symptoms include pruritus or burning and, less commonly, pain.

An episode of cutaneous vascular lesions may be attended by fever, malaise, arthralgias, or myalgias irrespective of a defined underlying or associated disease. Systemic involvement of the small blood vessels most commonly occurs in the synovia, gastrointestinal

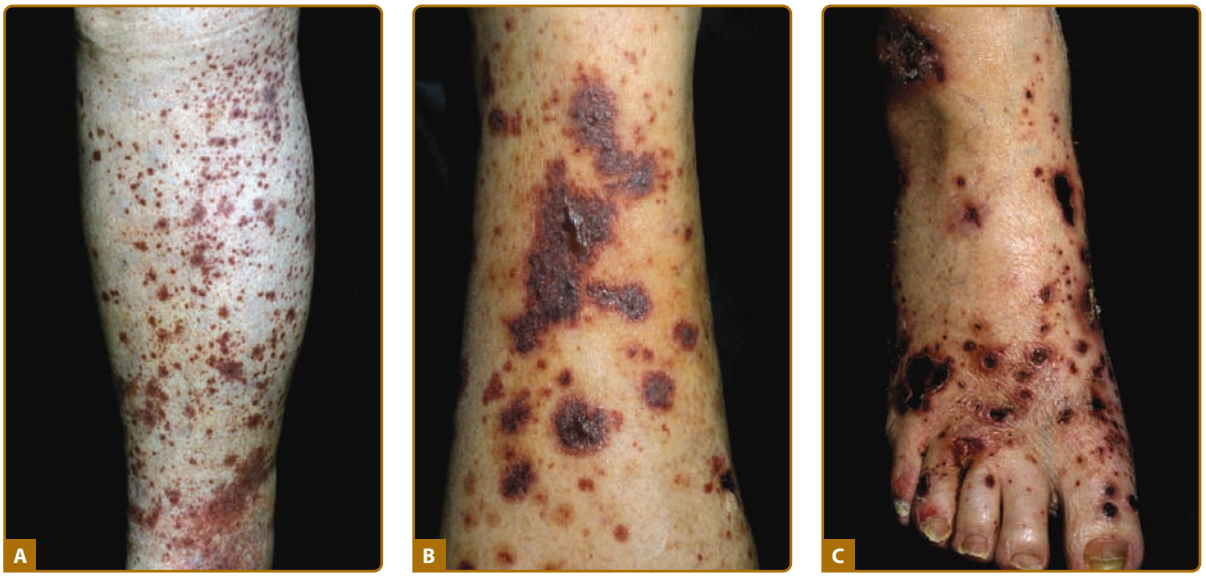

Figure 163-1 **A.** Palpable purpura on the lower leg in a patient with Henoch–Schönlein purpura. **B.** Palpable purpura with more severe tissue damage with hemorrhagic vesicles and bullae. **C.** With even more tissue damage, multiple necrosis, and ulcers.

tract, voluntary muscles, peripheral nerves, and kidneys.

ASSOCIATED CHRONIC DISORDERS

CNV is associated with connective-tissue diseases, notably rheumatoid arthritis, Sjögren syndrome, systemic lupus erythematosus (SLE), and hypergammaglobulinemic purpura. It rarely occurs in mixed connective-tissue disease, relapsing polychondritis, and scleroderma. In patients with rheumatoid arthritis and CNV, the development of vascular lesions is related to the severity of the disease, which is generally but not always seropositive, and the presence of anti-Ro antibodies. Subcutaneous nodules and cutaneous ulcers may be present. Patients with rheumatoid arthritis often have involvement of larger vessels with associated peripheral neuropathy, nail-fold infarcts, and digital gangrene.

In patients with SLE, CNV is a frequent manifestation[27] and is associated with exacerbations of the underlying disease. Patients with anti-Ro antibody have a greater risk for the development of CNV, with an Odds ratio 1.63.[28] Vasculitis, however, is rare in patients with subacute cutaneous lupus erythematosus. Some women with necrotizing vasculitis without connective-tissue disease have anti-Ro antibodies, and their infants may be born with neonatal lupus erythematosus.

In patients with Sjögren syndrome, the vascular lesions are located predominantly on the lower extremities and appear after exercise. Both hyperpigmentation and cutaneous ulcers are common features. Patients with Sjögren syndrome and CNV have a higher prevalence of articular involvement, peripheral neuropathy, Raynaud phenomenon, and renal involvement[29] as well as the presence of anti-Ro antibody. Hypergammaglobulinemic purpura occurs in older women and may be associated with Sjögren syndrome, SLE, or a lymphoproliferative disorder. Dermatomyositis in children, but not in adults, may be associated with vasculitis of the gastrointestinal tract.

Paraneoplastic vasculitis describes CNV with associated malignant conditions, which include Hodgkin lymphoma, lymphosarcoma, adult T-cell leukemia, mycosis fungoides, myelofibrosis, acute and chronic myelogenous forms of leukemia, B-cell chronic lymphocytic leukemia, multiple myeloma, IgA myeloma, diffuse large-cell leukemia, hairy-cell leukemia, squamous-cell bronchiogenic carcinoma, adenocarcinoma of the lung, prostatic carcinoma, renal carcinoma, bladder carcinoma, and colon carcinoma.[30] However, the association between CNV and neoplasia is rare. It is not necessary to evaluate all patients with CNV for associated malignant conditions.

Cryoglobulins (see Chapter 169), especially mixed types II and III, may be found in patients with idiopathic CNV and in patients with CNV that is associated with connective-tissue diseases, lymphoproliferative disorders, and hepatitis A, B, and C virus infections. Hepatitis C virus is the most common infection, especially when it is associated with cryoglobulinemia.[31,32] CNV occurs in patients with cystic fibrosis, inflammatory bowel diseases of the colon, and Behçet disease.[33]

ANCAs are associated with various forms of necrotizing vasculitis. ANCAs are present in patients with microscopic polyangiitis and cutaneous vasculitis with hepatitis C virus infection (see Chapter 164). The most common cutaneous feature in patients with ANCAs is palpable purpura. Microscopic polyangiitis is associated with small-vessel systemic vasculitis that involves the cutaneous venules and arterioles, the kidneys with necrotizing and crescentic glomerulonephritis,

the lungs with pulmonary hemorrhage or interstitial pneumonia, and p-ANCAs. Erythematous macules, purpura, and livedo reticularis are cutaneous manifestations in microscopic polyangiitis.[34,35] A male patient has experienced microscopic polyangiitis restricted to the skin and p-ANCAs for 20 years without progression to systemic vascular disease.[36] IgA ANCAs are present in acute Henoch–Schönlein purpura in children.

Anticardiolipin antibodies occur in patients with various forms of necrotizing vasculitis. IgA cardiolipin antibodies of the IgA class were detected in 6 of 10 patients with idiopathic CNV.[37] IgA anticardiolipin and IgA and IgM antiphosphatidyl serine–prothrombin complex antibody levels are elevated in adults with Henoch–Schönlein purpura and CNV that is restricted to the skin.[38] IgG and IgM anticardiolipin antibodies have been detected in some individuals with livedoid vasculitis.[39]

PRECIPITATING INFECTIONS AND DRUGS

Infections and drugs may precipitate episodes of CNV. The most commonly recognized infectious agents are β-hemolytic *Streptococcus*, *Staphylococcus aureus*, *Mycobacterium leprae,* and hepatitis B and C viruses. Transient episodes of urticaria may occur early in the course of hepatitis B virus infection and represent immune complex-induced vasculitis; episodes of palpable purpura may occur in patients with chronic active hepatitis. Cutaneous vasculitis has been recognized in a limited number of individuals with human immunodeficiency virus infection; the skin lesions consisted of palpable purpura, which at times had a follicular localization, and cutaneous ulcers.

Erythema nodosum leprosum (see Chapter 186), which appears as cutaneous nodules in lepromatous leprosy, is a form of necrotizing vasculitis that involves capillaries, venules, arterioles, small-to-medium-sized arteries, and veins. The vascular lesions occur spontaneously or are precipitated by the administration of chemotherapeutic agents. They may be accompanied by fever, malaise, arthralgias, lymphadenopathy, and polyneuritis.

Necrotizing vasculitis caused by the direct invasion of the blood-vessel wall occurs in septicemia due to *Neisseria meningitidis, Neisseria gonorrhoeae, Pseudomonas, Hemophilus influenzae*, rickettsia, candida, and infectious endocarditis; in Rocky Mountain spotted fever; and in infections localized at the site of a catheter.

Palpable purpura is one of the less common forms of drug reactions (see Chapter 41). The most commonly incriminated therapeutic agents were propylthiouracil, hydralazine, granulocyte colony-stimulating factor (G-CSF)/granulocyte-macrophage colony-stimulating factor (GM-CSF), allopurinol, cephaclor, minocycline, penicillamine, phenytoin, isotretinoin, and methotrexate in a Medline database search from 1965 to 1999.[40] Propylthiouracil[41] and hydralazine may cause vasculitis in association with ANCAs. Cutaneous vasculitis also has occurred after the administration of streptokinase, radiocontrast media, staphylococcal protein A column immunoadsorption therapy, drug additives, infliximab, etanercept, adalimumab, and rituximab.[42,43]

IDIOPATHIC DISORDERS

HENOCH–SCHÖNLEIN PURPURA. The most widely recognized subgroup of idiopathic CNV is Henoch–Schönlein purpura, which was formerly known as *anaphylactoid purpura*. It occurs predominantly in children, with a peak incidence at 5 to 6 years of age, but it may occur in adults.[44,45] Most cases occur in the autumn and winter and often are preceded by a history of a recent upper respiratory tract infections, especially with β-hemolytic *Streptococcus*, in up to 75% of individuals; however, Henoch–Schönlein syndrome has been associated with other infections.[46] Sites of involvement include the skin, synovia, gastrointestinal tract, and kidneys. Symptoms may include colicky abdominal pain, melena, arthralgia, and hematuria. Long-term morbidity from progressive renal disease depends on the degree of initial renal damage. The spread of purpura to the upper parts of the trunk is a predictive factor for renal involvement. Adults have a worse prognosis, owing to an increased risk of renal disease.

ACUTE HEMORRHAGIC EDEMA OF INFANCY. This uncommon disorder, which often goes unrecognized or has been confused with Henoch–Schönlein purpura, affects infants and children younger than 2 years of age. The lesions appear as painful, edematous petechiae and ecchymoses that affect the head and distal portions of the extremities. Facial edema may be the initial sign. The skin lesions may be associated with a target-like appearance and may develop bullae and necrosis. Infection, drugs, or immunization may be triggering factors. Acute hemorrhagic edema of infancy is distinguished from Henoch–Schönlein purpura by its occurrence in children aged 4 months to 2 years, by its lack of systemic features, and by its resolution within 1 to 3 weeks without sequelae.[47]

URTICARIAL VENULITIS. Episodes of recurrent and chronic urticaria and angioedema may be a clinical manifestation of CNV.[48,49] Known as *urticarial vasculitis/venulitis*, this edematous form of necrotizing venulitis occurs in patients with serum sickness, connective-tissue disorders, hematologic and other malignant conditions, an IgM_K M component, infections, and physical urticarias; after the administration of a variety of therapeutic agents; and as an idiopathic disorder. The term *hypocomplementemic urticarial vasculitis syndrome* (HUVS) has been used to describe patients with more severe systemic manifestations, hypocomplementemia, and an autoantibody to the collagen-like region of Clq.

The skin lesions appear as erythematous, occasionally indurated, wheals that may contain foci of purpura (Fig. 163-2; see Fig. 164-3 and Chapter 164). Other skin manifestations include angioedema,

Figure 163-2 Urticarial venulitis. Some of the wheals have been marked 24 hours previously to demonstrate persistent character of the urticaria.

macular erythema, livedo reticularis, nodules, and bullae. Although the individual urticarial lesions may last for fewer than 24 hours, they often persist for up to 3 to 5 days. The lesions are pruritic or possess a burning or painful quality; they usually resolve without residua although some individuals may develop contusions or hyperpigmentation. The episodes of urticaria are chronic, range in duration from months to years, and vary in frequency. Approximately 70% of affected individuals are women. The prevalence of this disorder remains unknown. General features include fever, malaise, and myalgia; the lymph nodes, liver, and spleen may be enlarged. Extracutaneous features involve the synovial, kidneys, gastrointestinal tract, lungs, eyes, heart, central nervous system, peripheral nerves, and blood vessels (Table 163-2). These extracutaneous features are more extensive in patients with HUVS.

The natural history of urticarial vasculitis is unknown although individuals have been described with historic episodes of cutaneous lesions for up to 25 years. In one series of patients followed for 1 year, 40% experienced complete resolution of skin lesions; in another series of individuals followed for as long as 14 years, resolution occurred in only one patient. Sjögren syndrome and SLE have developed. Deaths have been reported from pulmonary disease, sepsis, and myocardial infarction.

The prevalence of urticarial vasculitis in individuals with chronic idiopathic urticaria is unknown, although series have reported rates ranging from 1% to 50%. Most of these data have been reported from histopathologic studies in tertiary referral centers. The prevalence of urticarial vasculitis in a prospective clinical study in a university hospital in India was 11.4%.[50]

Necrotizing vasculitis of cutaneous venules has been described in isolated instances of dermographism, cold urticaria, delayed pressure urticaria, solar urticaria, and exercise-induced urticaria. However, the prevalence of necrotizing vasculitis in patients with physical urticaria is unknown, and the importance of this histopathologic finding for prognosis and therapy remains to be elucidated. Individuals with these physical urticarias have provided experimental models for time–course studies of the evolution of necrotizing vasculitis in human skin.

Schnitzler syndrome consists of episodes of urticarial vasculitis that occur in association with a monoclonal IgM_K M component. Associated features include fever, lymphadenopathy, hepatosplenomegaly, bone pain, a sensorimotor neuropathy, and renal failure. Evolution into hematologic malignant conditions has been reported in 15% of patients.[51]

TABLE 163-2
Extracutaneous Manifestations of Urticarial Venulitis

- General features
  - Fever
  - Malaise
  - Myalgia
- Specific organ involvement
  - Lymphadenopathy
  - Hepatosplenomegaly
  - Synovia (arthralgia, arthritis, Jaccoud arthropathy)
  - Kidneys (glomerulitis; glomerulonephritis with mesangioproliferative, membranoproliferative, or crescentic changes; interstitial nephritis; nephrotic syndrome; end-stage renal diseases)
  - Gastrointestinal tract (nausea, vomiting, pain, diarrhea)
  - Respiratory tract (laryngeal edema; dyspnea; chronic obstructive, restrictive, or interstitial pulmonary disease; emphysema; pulmonary hemosiderosis; tracheal stenosis; pleural effusion; pulmonary hemorrhage; vasculitis of the pulmonary venules)
  - Eyes (conjunctivitis, episcleritis, iridocyclitis, uveitis, vasculitis of the optic nerve and retina, blindness)
  - Central nervous system (headache, benign intracranial hypertension, seizures)
  - Peripheral nerves (neuropathy, cranial nerve paralysis)
  - Heart (arrhythmias, valvular heart disease, congestive heart failure, pericardial effusion, myocardial infarct)
  - Blood vessels (Raynaud phenomenon)

ERYTHEMA ELEVATUM DIUTINUM. Erythema elevatum diutinum occurs as symmetric, persistent, red–purple or red–brown plaques that are predominantly disposed over the joints of extensor surfaces and over the gluteal area (see Chapter 165).

NODULAR VASCULITIS. Nodular vasculitis (see Chapter 70) appears as tender, red, subcutaneous nodules over the lower extremities, especially the calves, without systemic manifestations (Fig. 163-3; see Fig. 70-5 and Chapter 70). At times, lesions develop on the thighs, buttocks, trunk, and arms, and ulcerated nodules may be present. Recurrent episodes are common. It is more common in women and has a peak incidence in individuals between 30 and 40 years of age. *Erythema induratum* is a form of nodular vasculitis, which has been

Figure 163-3 Nodular vasculitis with ulcers on lower legs (see Fig. 68-5).

associated with *Mycobacterium tuberculosis* infection, as demonstrated by polymerase chain reaction amplification for *M. tuberculosis* DNA in skin biopsy specimens.[52] Various sizes of blood vessels, which include venules, are affected.[53] Erythema induratum has been associated with hepatitis C virus infection.[54]

LIVEDOID VASCULOPATHY. Livedoid vasculopathy (Fig. 163-4), known also as *livedoid vasculitis*, *livedo vasculitis*, *segmental hyalinizing vasculitis*, and *atrophie blanche*, occurs as recurrent, painful ulcers of the lower extremities in association with a persistent livedo reticularis (*livedo racemosa*) that often is deep purple in color (see Fig. 164-11 and Chapter 164). Healing results in sclerotic pale areas that are surrounded by telangiectasias and designated atrophie blanche (Fig. 163-5). Many patients have arteriosclerosis or stasis of the lower extremities. Livedoid vasculitis is more common

Figure 163-4 Livedoid vasculitis with recurrent, painful ulcers and livedo reticularis.

Figure 163-5 Atrophie blanche over the medial malleolus with porcelain-white atrophy, telangiectases, and ulcers.

in women and may occur in patients with connective-tissue disorders, such as SLE, who develop central nervous system features; in malignant conditions; in hypercoagluable states; in thrombophilia; and as an idiopathic disorder. Protein C and S deficiencies,[55] factor V Leiden gene mutation, activated protein C resistance, prothrombin gene mutation, hyperhomocysteinemia, and antithrombin deficiency have been reported. Atrophie blanche, however, probably represents the end stage of a variety of forms of vascular damage in the skin (see Chapter 173). Elevated levels of fibrinopeptide A, homocystein, and plasminogen activator inhibitor[56] may occur in blood. Pathogenesis has focused on a hypercoagulable state with fibrin thrombi in the lumina of the superficial blood vessels. Some consider this condition to be a thrombogenic vasculopathy rather than a small-vessel vasculitis.[57] Antiphospholipid antibodies have been detected in a few individuals.[39]

Sneddon syndrome[58,59] is a condition in which livedo racemosa and livedoid vasculitis are associated with ischemic cerebrovascular lesions, hypotension, and extracerebral arterial and venous thromboses (see Fig. 173-9 in Chapter 173). Antiendothelial cell antibodies were detected in the serum in 35% of individuals; antiphospholipid antibodies, anti-β_2-glycoprotein antibodies, and antiprothrombin antibodies[60] were detected in some patients.

GENETIC COMPLEMENT DEFICIENCIES. Genetic C2 deficiency has been recognized in association with CNV in three children and in two siblings with HLA-A25, B18, DR2 (w15) haplotype. C4 deficiency was present in one child with CNV. Deficiencies of C4A and C4B isotypes were found in some children and adults with Henoch–Schönlein purpura. A partial C4B deficiency with C4 A1, A3, B1, and a null allele B*QO was reported in a 51-year-old woman with CNV.

EOSINOPHILIC VASCULITIS. Eosinophilic vasculitis has been described as an idiopathic syndrome in individuals with recurrent, pruritic, and purpuric papular skin lesions, urticarial plaques, and angioedema. Skin biopsy specimens showed an infiltrate composed of eosinophils expressing CD40[61] and VCAM-1 on endothelial cells of involved vessels. Eosinophilic vasculitis also has been described in some individuals with the hypereosinophilic syndrome (see Chapter 36) and in others with connective-tissue disorders.[62] There may be depressed complement levels, peripheral eosinophilia, elevated major basic protein levels, and a prolonged eosinophil survival time.

IDIOPATHIC. Individuals with CNV who do not meet the criteria for recognized syndromes are classified as idiopathic.

LABORATORY FINDINGS

The laboratory evaluation of patients with CNV depends on information obtained from the history and physical examination (Table 163-3). An elevated erythrocyte sedimentation rate is the most consistent abnormal laboratory finding. The platelet count is usually normal. Other abnormalities reflect either a coexistent chronic disorder or the involvement of additional organ systems. Occasionally, leukocytosis, anemia, thrombocytosis, an abnormal urine sediment, circulating immune complexes, rheumatoid factor, and antinuclear antibodies have been reported in idiopathic disease.

Serum complement levels are usually normal. Hypocomplementemia may develop in patients with concomitant connective-tissue diseases or cryoglobulinemia and reflects the associated disease or the composition of the cryoglobulin. Hypocomplementemia also occurs in some individuals with idiopathic CNV and in 40% of individuals with urticarial venulitis.

In patients with the HUVS, a low-molecular-weight 7s C1q precipitin, which has been identified as an IgG autoantibody against the collagen-like region of C1q, was detected. Autoantibodies to vascular endothelial cells were detected in patients with HUVS, in patients with SLE and urticarial vasculitis, and in patients with urticarial vasculitis alone.[63] In Henoch–Schönlein purpura, serum IgA1 levels are elevated, IgA ANCAs may be present, and urinary endothelin-1 levels may be elevated. In patients with CNV, various types of circulating immune complexes and IgA ANCAs[64] have been described. IgG autoantibodies to IgE and to FcεRIα also have been identified in some patients with urticarial venulitis.

- Antiphospholipid antibodies
- Circulating immune complexes
- Stool guaiac test
- Skin biopsy

HISTOPATHOLOGY

In skin biopsy specimens of palpable purpura and urticarial vasculitis stained with hematoxylin and eosin (Fig. 163-6A), the histopathologic criteria requisite for

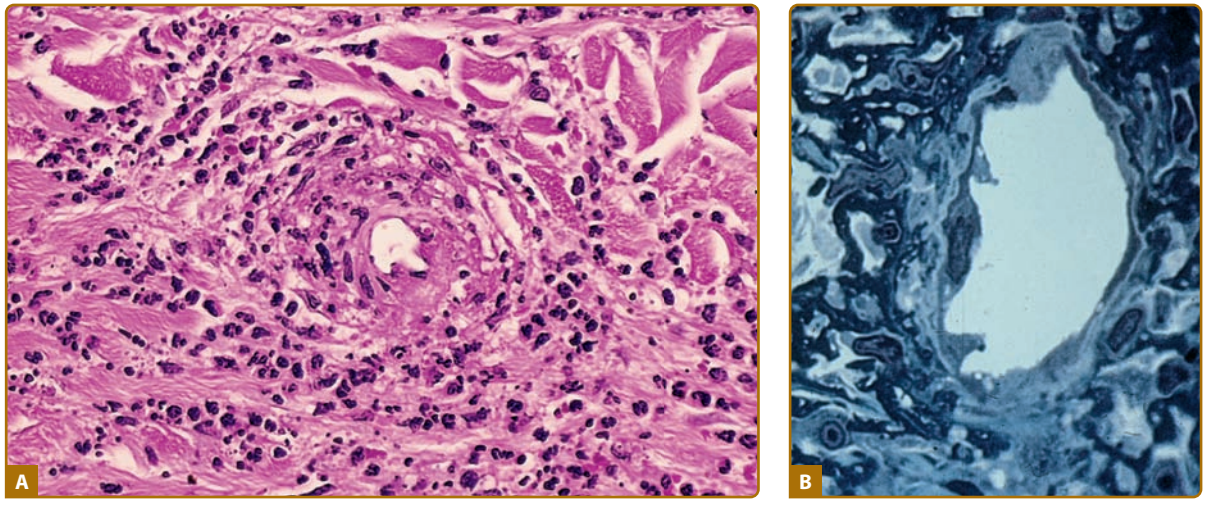

Figure 163-6 **A.** Perivenular infiltrate of neutrophils with fibrin deposition. (Hematoxylin and eosin stain, ×50 in the original magnification.) **B.** Endothelial-cell necrosis of a venule with perivenular fibrin and neutrophils. (1-µm section, Giemsa stain, ×1000 in the original magnification.)

the diagnosis of CNV include necrosis of the blood vessels with the deposition of fibrinoid material and dermal cellular infiltrates that consist of neutrophils with nuclear debris, mononuclear cells, and extravasated erythrocytes. The dermal inflammatory infiltrates vary in intensity and are usually perivenular in location, but at times they are dispersed widely. Some patients with connective-tissue disorders and cutaneous vasculitis have an infiltrate of inflammatory cells composed of eosinophils with deposited major basic protein and decreased numbers of mast cells.[62] Eosinophils may be present in increased numbers in drug-induced CNV.[25] The fibrinoid material consists of fibrin, necrotic endothelial cells, immunoreactants, and antigens.

Studies with 1-µm-thick sections (Fig. 164-6B) show two distinct cellular patterns in CNV: one rich in neutrophils and the other in lymphocytes.[65] The infiltrate of neutrophils regresses with the persistence of an infiltrate of mononuclear cells; repeat biopsy specimens in some patients consistently demonstrated an infiltrate of mononuclear cells. In a time–course study over 6 days of the evolution of experimentally induced CNV in a patient with physical urticarias,[12] the number of infiltrating neutrophils decreased without a concomitant increase in lymphocytes although the number of monocyte-macrophages was increased at 48 hours and 72 hours. Other features in both cell patterns of CNV include hypogranulated mast cells, macrophages containing debris, and the perivenular and interstitial deposition of fibrin. Venular alterations in both cell patterns consist of endothelial-cell swelling, activation of nuclei, wrinkling of nuclear membranes, necrosis (Fig. 163-6B), and basement-membrane reduplication and thickening. The arterioles are not affected.

By direct immunofluorescence techniques, fibrin deposition in venules is routinely identified in biopsy specimens, whereas the deposition of immunoglobulins and complement proteins varies widely. IgG is the most commonly deposited immunoglobulin although IgM and IgA also have been detected. IgA is deposited about blood vessels in the skin, intestines, and kidneys in Henoch–Schönlein purpura and has become an immunopathologic marker of this condition. In the skin in Henoch–Schönlein purpura, IgA1 is the dominant subclass deposited.[66] C3 is the only complement protein that has been sought with frequency in CNV.

DIFFERENTIAL DIAGNOSIS

Thrombocytopenia may result in purpura; however, these lesions are flat. Other causes of nonpalpable cutaneous purpura include local trauma to the skin of aged individuals with vascular fragility, chronic sun exposure, and endogenous or iatrogenic hypercorticism. Erythema elevatum diutinum may resemble Kaposi sarcoma (see Chapter 128) or multicentric reticulohistiocytosis (see Chapter 148). Scurvy may appear as hemorrhagic, follicular papules over the lower extremities. Various infectious agents may be associated with hemorrhagic skin lesions that arise from disseminated intravascular coagulation or septic emboli. The cutaneous manifestation of disseminated intravascular coagulation, which is known as *purpura fulminans,* appears as extensive areas of purpura with a slate-gray color (see Chapter 144). These lesions occur in patients with acute meningococcemia but also with Gram-positive coccal sepsis; skin biopsy specimens show thrombosis but not necrotizing venulitis. Septic emboli occur as finite numbers of hemorrhagic pustules, papules, and vesicles that are distributed over acral areas. Rarely, echo and coxsackievirus infections may cause purpuric papules. Rocky Mountain spotted fever typically begins as purpuric papules over the ankles and wrists that spread to include the trunk. Cholesterol embolization includes purpura, livedo reticularis, ulcers, and nodules. Calciphylaxis may appear as painful plaques with a reticulated or stellate pattern, induration, eschars, and ulcers.

The progressive pigmentary purpuric dermatoses (purpura simplex) (see Chapter 168), which include a number of disorders, appear as macular, petechial, pigmented, or lichenoid lesions.

The differential diagnosis of cutaneous nodules includes erythema nodosum, panniculitis, superficial forms of thrombophlebitis, fat necrosis associated with pancreatic disease, and systemic vasculitides, such as polyarteritis nodosa, granulomatosis with polyangiitis (Wegener's), and Churg–Strauss syndrome.

TREATMENT

Therapeutic approaches may be divided into removal of the antigen, treatment of an underlying disease, and treatment of CNV. Therapeutic approaches in the treatment of necrotizing vasculitis consist of prevention of the deposition of immune complexes, suppression of the inflammatory response, modulation of underlying immunopathologic mechanisms, and local therapy. When the eruption is associated with a precipitating event, withdrawal of the medication or treatment of the infection results in resolution of the cutaneous lesions. If a coexistent chronic disease is present, treatment of the underlying disease may be associated with improvement in the cutaneous vascular lesions. In many cases, CNV is a self-limited condition, and double-blind, placebo-controlled, prospective trials of therapeutic agents are usually lacking.

The treatment of CNV (Table 163-4) depends on an analysis of the cutaneous disability as well as on the toxicity and side effects of the therapeutic agents. H_1 antihistamines are used in patients with palpable purpura to alleviate lesional symptoms and perhaps to reduce tissue deposition of circulating immune complexes. Nonsteroidal anti-inflammatory agents are combined with the H_1 antihistamine. Depending on the therapeutic response, colchicine can be added to or substituted for these agents. However, colchicine was shown to have no significant therapeutic effect in a prospective, randomized, controlled trial. If there is no benefit, dapsone or hydroxychloroquine sulfate

TABLE 163-4
Treatment of Cutaneous Necrotizing Venulitis

- H_1 Antihistamines
- Nonsteroidal anti-inflammatory agents
- Colchicine
- Dapsone
- Hydroxychloroquine sulfate
- Systemic glucocorticoids
- Azathioprine
- Methotrexate
- Cyclosporin
- Mycophenolate mofetil
- Cyclophosphamide
- Intravenous gammaglobulin
- Plasmapheresis
- Infliximab
- Rituximab

can be used. If there still is no therapeutic response, a major decision must be made because the medications systemic glucocorticoids, azathioprine, methotrexate, cyclosporine, mycophenolate mofetil, cyclophosphamide, plasmapheresis, intravenous immunoglobulin,[67] infliximab,[68] and rituximab[69,70] are associated with serious side effects. Although all of these agents have been reported to benefit some patients, controlled clinical trials are not available. The administration of interferon-α is associated with clearing of cutaneous vasculitis in patients with hepatitis C virus infection.

The treatment of patients with urticarial vasculitis is similar to those with palpable purpura. Additional case reports exist on the treatment of patients with intramuscular gold therapy, cyclophosphamide-dexamethasone pulse therapy, mycophenolate mofetil,[71] thalidomide, anakinra, cinnarizine, and psoralen plus ultraviolet A (PUVA) photochemotherapy.

In patients with erythema elevatum diutinum, dapsone is the drug of choice. The treatment of nodular vasculitis consists of empiric trials of a variety of therapeutic agents that include a saturated solution of potassium iodide, nonsteroidal anti-inflammatory drugs, colchicine, and systemic glucocorticoids. Thalidomide is the treatment of choice for erythema nodosum leprosum.

In the treatment of livedoid vasculitis, support stockings are useful. Empiric trials of aspirin and dipyridamole, colchicine, dapsone, danazol, low-dose heparin, systemic glucocorticoids, nicotinic acid, low-molecular-weight dextran, phenformin and ethylestrenol, nifedipine, and pentoxifylline have been used. Infusions of prostacyclin, prostaglandin E_1, intravenous immunoglobulin, rituximab,[72] tissue plasminogen activator,[73] hyperbaric oxygen therapy,[74] and PUVA photochemotherapy have been used successfully in a few patients.

Chapter 164 :: Systemic Necrotizing Arteritis

:: Peter A. Merkel & Paul A. Monach

SYSTEMIC VASCULITIS AT A GLANCE

- Heterogenous group of rare inflammatory conditions in which blood vessel walls are primarily targeted by an inflammatory reaction.
- Etiology unknown; geographic, environmental, and genetic factors may be important.
- Incidence up to 42 cases per million per year.
- Diagnosis often established in patients with multiple but variable organ involvement; supported by laboratory or radiologic studies and histologic evidence of inflammatory reaction in blood vessels.
- Cutaneous involvement can occur in any of the primary systemic vasculitic syndromes.
- Cutaneous features are often not sufficient to provide complete diagnosis and staging.
- Classification of the vasculitides is based on several factors including known etiology or disease association (primary vs. secondary forms), predominant size of involved vessels (small, medium, or large arteries), and additional clinical and laboratory data.
- Primary vasculitis is a diagnosis of exclusion after causes of secondary vascular inflammation have been ruled out.
- Determinants of prognosis and treatment include the specific vasculitic syndrome, whether critical organs are involved, the severity of involvement, and the rate of disease progression.
- Treatment often requires glucocorticoids and the use of other immunosuppressive drugs.

INTRODUCTION

The term "vasculitis" can be defined broadly to mean inflammation of blood vessels. However, from the perspective of the practicing clinician, "vasculitis" is most commonly used to describe a group of diseases in which inflammation of the blood vessels is the major, but not only, pathologic process. The vasculitides are a wide-ranging set of diseases that are mostly idiopathic, rare, and multisystemic. These diseases involve such a variety of clinical presentations and pathologies that all clinicians in every medical and surgical specialty will encounter such patients.

Vasculitis of the skin is a frequent manifestation in many forms of vasculitis, especially small- and medium-vessel arteritis where skin lesions may be the presenting symptom of a systemic illness.

This chapter will focus on skin disease in the systemic vasculitides. Isolated forms of skin vasculitis and some of the systemic vasculitides are covered in Chapter 163. In addition to outlining the skin manifestations of vasculitis in general and for specific types of vasculitis, this chapter will provide an approach to patients with skin disease in which vasculitis is a diagnostic consideration.

EPIDEMIOLOGY OF VASCULITIS

With the probable exception of drug/toxin-induced vasculitis, all forms of idiopathic vasculitis are considered rare, "orphan" diseases in the United States (prevalences of less than 200,000 people); similar designations exist in Europe and elsewhere.

Vasculitis occurs in people of both sexes, all ages, and all major racial/ethnic groups. However, some forms are more common in certain groups. For example, Takayasu arteritis is substantially more common in women than men, Kawasaki disease is almost exclusively a disease of young children, and giant cell arteritis is limited to older adults. Granulomatosis with polyangilis (GPA) mostly occurs in Caucasians and Behçet disease is markedly more common in countries in the Eastern Mediterranean as well as Japan and Korea. The demographic differences among the vasculitides are of scientific interest as clues to etiology and can be helpful diagnostically.[1] However, the epidemiologic tendencies are generally not so strong as to fully exclude the diagnosis of a specific form of vasculitis in any one person and exceptions to the typical epidemiology occur regularly.

CLASSIFICATION OF VASCULITIS

Multiple systems for classifying vasculitis exist, a situation that reflects a lack of clear understanding of the underlying pathophysiology and the overlap of clinical features among many types of vasculitis.[2–7] The most commonly accepted approach to classifying the vasculitides is to sort them by the size(s) of the predominant vessel involved (small, medium, or large) and then subdivide or group diseases, as appropriate (Fig. 164-1).

Classification criteria and definitions have been developed for many, but not all, specific types of vasculitis. These systems were designed for use in

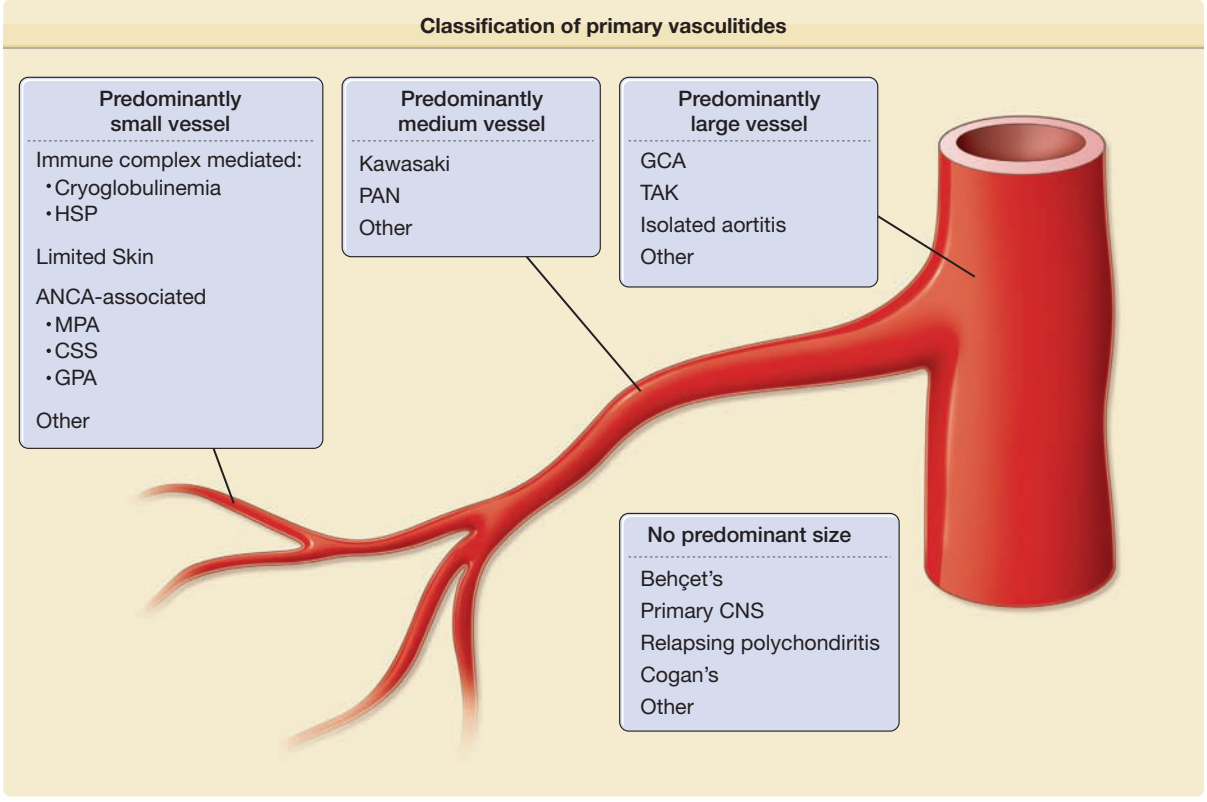

Figure 164-1 Classification of the primary vasculitides. ANCA = antineutrophil cytoplasmic antibodies; CSS = Churg–Strauss syndrome; GCA = giant cell arteritis; GPA = granulomatosis with polyangiitis (Wegener's); HSP = Henoch–Shönlein purpura; MPA = microscopic polyangiitis; PAN = polyarteritis nodosa; TAK = Takayasu's arteritis. (Redrawn from: Watts RA et al: Systemic vasculitis—Is it time to reclassify? *Rheumatology (Oxford)* Jul 20;2010.)

clinical research to create fairly homogenous study cohorts and were not meant to be used as "diagnostic" criteria.[3] Nonetheless, clinicians will find these criteria helpful. The most widely used criteria for vasculitis are from the classification criteria of the American College of Rheumatology[5–6] and the disease definitions of the Chapel Hill Consensus Conference.[7] However, these systems do not contain several forms of vasculitis, including some with frequent skin manifestations, such as Behçet disease and cryoglobulinemia, nor any "secondary" vasculitides (associated with another underlying disease such as systemic lupus erythematosus or an infection). Furthermore, some classes are no longer advised for use (e.g., "hypersensitivity vasculitis" is a term that has lost specific meaning). It should be emphasized that the term "leukocytoclastic vasculitis" does not refer to a specific disease but is a pathological description that often, but not always, applies to vasculitis in the skin or other organs. Similarly, "cutaneous vasculitis" is a vague name that could apply to any of several skin lesions seen in vasculitis and is not a distinct entity. There are also some separate sets of criteria for pediatric patients.[8]

A new international initiative is underway to reconsider the classification of the vasculitides and take into consideration data regarding the clinical and pathophysiological aspects of vasculitis not available when the prior systems were created; such new elements include testing for antineutrophil cytoplasmic autoantibodies (ANCA) and greater availability of advanced imaging techniques for large arterial disease.[3]

EVALUATION OF A PATIENT WITH POSSIBLE CUTANEOUS VASCULITIS

When a patient presents with skin lesions that are concerning for possible vasculitis, answers to three questions should be sought quickly:

1. Is the lesion due to vasculitis?
2. Are other organ systems involved in the illness?
3. Are there additional findings on medical interview, physical examination, laboratory testing, or radiographic imaging that can help establish a specific diagnosis?

   If a diagnosis of vasculitis is obtained, then it is imperative to ask two more questions:
4. Is it possible to make a diagnosis of a specific type of vasculitis for the patient?
5. Does the patient need immediate treatment and/or hospitalization?

A suggested approach to patients with skin lesions suspected of being due to vasculitis is shown in Fig. 164-2. The answer to the first question is often obtained by a skin biopsy, which is indicated in many cases of palpable purpura or other lesions when a diagnosis of vasculitis is not otherwise easily established. The second question is addressed by a thorough review of systems and physical exam and routine laboratory testing that can usually be completed rapidly. The third question is addressed

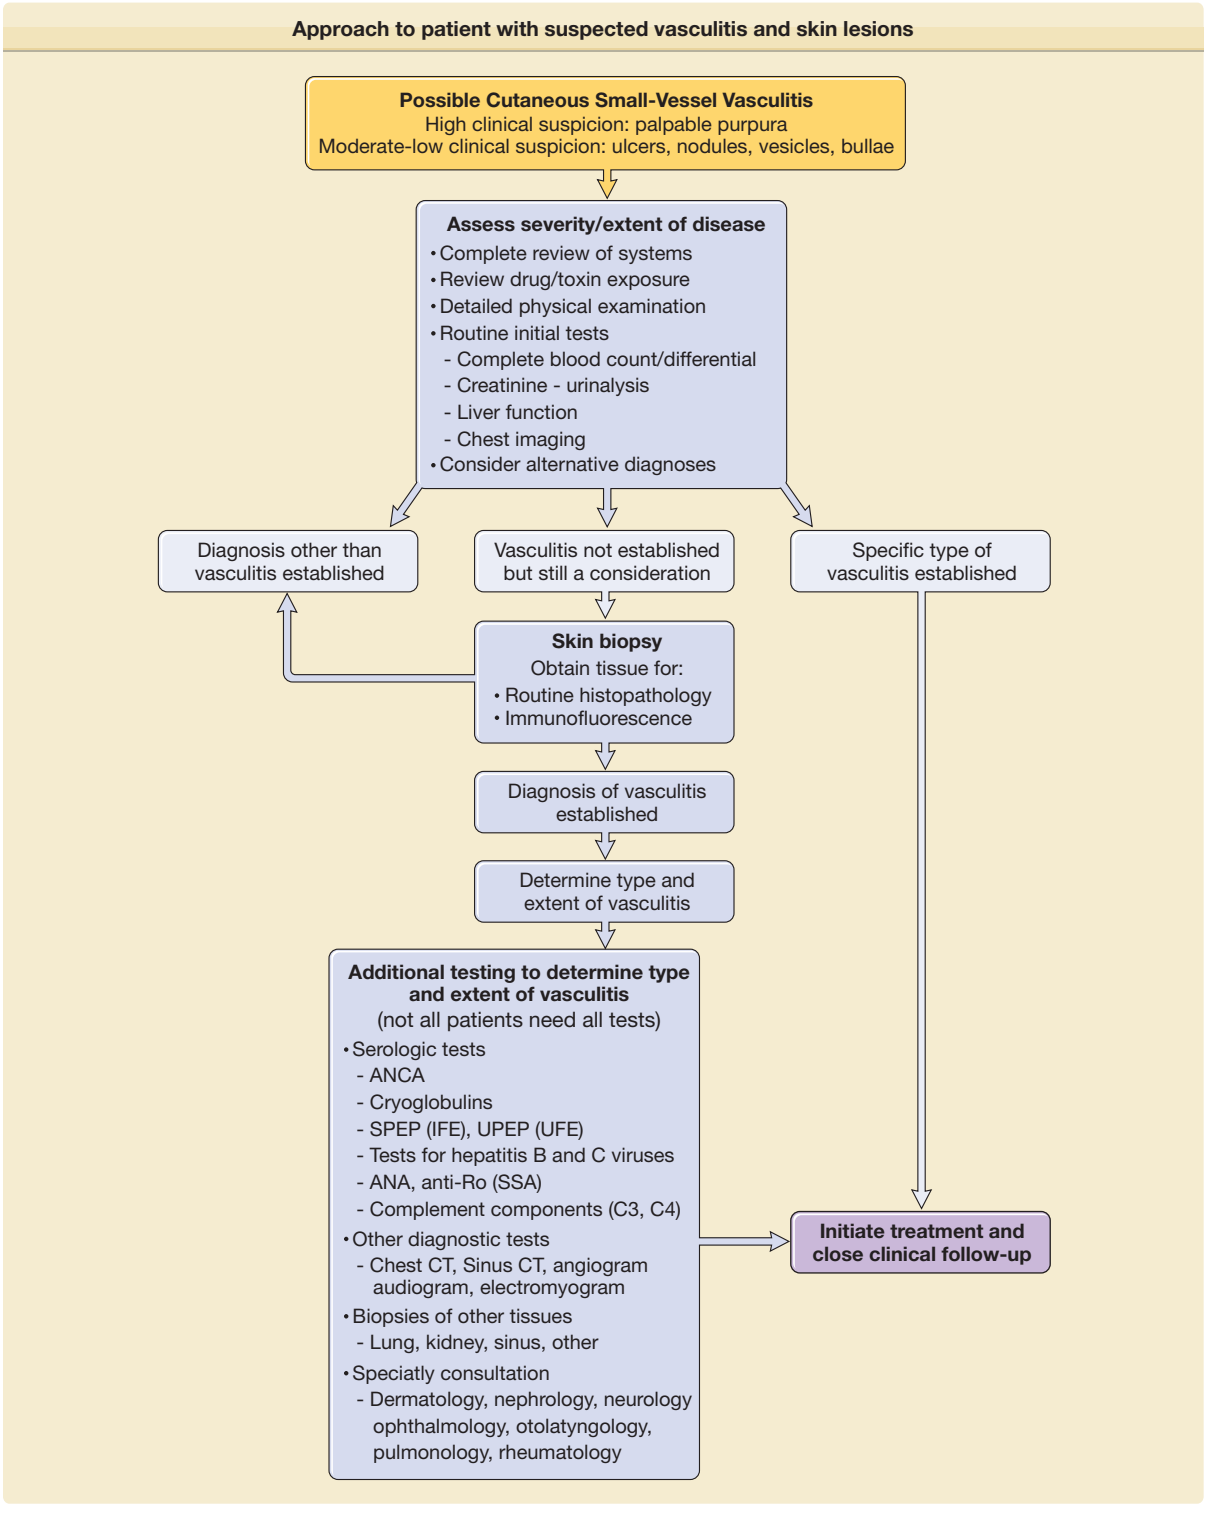

Figure 164-2 Approach to the patient with suspected vasculitis and skin lesions. ANCA = antineutrophil cytoplasmic antibodies; ANA = antinuclear antibodies; CT = computed tomography; IFE = immunofixation electrophoresis; SPEP = serum protein electrophoresis; SSA = susceptible *S. aureus*; UFE = uterine fibroid embolization; UPEP = urine protein electrophoresis.

by more specialized laboratory tests for which results typically take several days to return. It is important to quickly identify organ system involvement and how "sick" the patient is (or might soon be), since some causes of cutaneous vasculitis require no treatment, but others require immediate hospitalization for initiation of immunosuppressive and supportive therapy.

REVIEW OF SYSTEMS

A full review of systems with assessment of the overall severity of illness is the single most important component of the early evaluation of a patient suspected of having vasculitis. Together, the diseases that cause

TABLE 164-1
Major Signs, Symptoms, and Disease Processes of the Primary Vasculitides[a]

Organ System	Signs and Symptoms	Disease Process	Type of Vasculitis
General			
	Fever	Systemic inflammation	Many of the systemic vasculitides
	Fatigue/malaise,	Systemic inflammation	Most of the systemic vasculitides
	Weight loss	Systemic inflammation	Most of the systemic vasculitides
Eye			
	Red eye	Episcleritis, scleritis, uveitis, conjunctivitis	GPA, MPA, RPC, BD, others
	Acute visual loss or amaurosis fugax	Arterial insufficiency	GCA, TAK
	Proptosis	Orbital granuloma ("pseudotumor")	GPA
	Tearing	Dacrocystitis with lacrimal duct occlusion	GPA, CSS
Ear			
	Hearing loss	Sensorineural hearing loss	GPA, MPA, CSS, GCA
		Conductive hearing loss	GPA, CSS, RPC
	Ear pain and fullness	Mastoiditis and/or other inflammation of upper airway, auditory tube, middle ear	GPA, CSS
	External ear redness, tenderness, swelling	Chondritis	RPC, GPA, CSS
Nose and sinuses			
	Epistaxis, nasal crusting and discharge	Nasal mucosal inflammation	GPA, CSS
	Nasal bridge collapse (saddle nose deformity)	Nasal cartilage inflammation	GPA, RPC
	Nasal polyps	Eosinophilic nasal inflammation	CSS
	Facial pain/tooth pain	Sinusitis	GPA, CSS
	Anosmia	Olfactory epithelium/cells damage	GPA, CSS
Oral cavity			
	Painful oral ulcers	Aphthous ulcers	BD, GPA
	Gingival pain and swelling	Gingival inflammation	GPA
	Jaw claudication	Arterial insufficiency to muscles of mastication	GCA
Pulmonary			
	Hemoptysis	Alveolar hemorrhage	GPA, MPA
		Pulmonary artery rupture	BD
		Pulmonary embolus	GPA, MPA, CSS, BD
		Pulmonary nodules	GPA, CSS
		(See also causes of "Hemoptysis")	
	Dyspnea/cough	Pulmonary infiltrates	GPA, MPA, CSS
		Bronchitis/large airway collapse	GPA, RPC
		Pleuritis	GPA, CSS
		Subglottic stenosis	GPA, RPC
	Stridor/dyspnea	Asthma	CSS
	Wheezing	Large airway collapse	GPA, RPC
Cardiovascular			
	Angina	Coronary arteritis	TAK
	Congestive heart failure	Aortic root/valvular disease	TAK, GCA, BD, RPC
		Myocarditis	CSS, GPA
	Limb claudication	Aortic valve insufficiency	TAK, GCA
		Large artery stenosis	TAK, GCA
Gastrointestinal			
	Abdominal ischemic pain	Arterial insufficiency	PAN, HSP, GCA, TAK
	Lower GI bleeding	Muscoal ulcers or infarction	HSP, CSS, GPA, MPA, PAN
Renal			
	Gross hematuria	Renal infarction	PAN
		Glomerulonephritis (rare cause of gross hematuria)	GPA, MPA, CSS, HSP, Cryo

TABLE 164-1
Major Signs, Symptoms, and Disease Processes of the Primary Vasculitides[a] (Continued)

Organ System	Signs and Symptoms	Disease Process	Type of Vasculitis
Central nervous system	Headache, scalp tenderness	Cranial arteritis	GCA, TAK
	Lightheadedness/syncope	Arterial insufficiency to brain	GCA, TAK
	Cranial neuropathy	Inflammation of nerves; rarely mass lesion	GCA, GPA, MPA
Peripheral nervous system	Sensory/motor dysfunction	Inflammation of nerves; rarely mass lesion	CSS, GPA, MPA, PAN, Cryo
Musculoskeletal	Polyarthralgia	Polyarthritis	GPA, GCA, TAK, Cryo, HSP, BD
	Shoulder and hip girdle pain	Polymyalgia rheumatica	GCA
	Muscle weakness	Myositis	CSS
Skin	Purpura	Small-vessel vasculitis	GPA, MPA, CSS, PAN, HSP, Cryo
	Painful nodules, deep ulcers	Medium-vessel vasculitis	PAN, GPA, MPA, Cryo
	Digital ischemia/gangrene	Medium-large artery stenosis	GCA, TAK, PAN, GPA, MPA, Cryo
	Superficial nodules	Granulomas	GPA, CSS
	Papules, acne-like lesions	Papulopustular lesions	BD
	Painful, red nodules	Erythema nodosum	BD, TAK
	Peripheral edema	Deep vein thrombosis	GPA, MPA, CSS, BD

[a]This list is not inclusive of all manifestations for all diseases.
GPA = granulomatosis with polyangiitis (Wegener's), MPA = microscopic polyangiitis, CSS = Churg–Strauss syndrome, Cryo = cryoglobulinemic vasculitis, HSP = Henoch–Shönlein purpura; PAN = polyarteritis nodosa; BD = Behçet disease; RPC = relapsing polychondritis; GCA = giant cell arteritis; TAK = Takayasu's arteritis.

cutaneous vasculitis can affect all organ systems and, in most cases, that involvement will cause symptoms—renal disease being a prominent exception. Although some symptoms are clearly more concerning than others (hemoptysis vs. dry cough, painful red eye vs. mild arthralgias), even relatively mild symptoms can be a clue that disease is not limited to the skin. A list of important signs and symptoms of vasculitis is shown in Table 164-1.

PAST MEDICAL HISTORY, MEDICATION USE, AND EXPOSURES TO TOXINS OR INFECTIOUS DISEASES

It is critical to know the full medical history of any patient suspected of having vasculitis. Other diseases may either have vasculitis as a component of the illness (e.g., lupus) or may cause skin lesions that mimic vasculitis. Drug-induced vasculitis (DIV) is common and skin lesions, usually but not always purpura, are the most common manifestation of DIV.[9] The list of drugs reported to cause vasculitis is enormous with almost every class of medication implicated in possible cases of DIV. It is useful to ask about prescription, nonprescription, and "alternative" or herbal mediation use in the prior 6–12 months since the effect of some medications may persist after usage ends. Patients should also be asked about use of illegal or recreational drugs since several such agents, including methamphetamines, cocaine, and others have been implicated in cases of vasculitis. Occupational or other exposure to nondrug toxins should be asked about.

The patient should be asked about not only usual signs and symptoms of infection, but also recent travel, contacts with sick individuals, and risks for sexually transmitted diseases.

PHYSICAL EXAMINATION

Beyond a careful and full assessment of the skin, a multisystem examination is useful to determine whether symptoms are associated with objective abnormalities, or whether there are findings that a patient has not noticed. Vital signs are essential, but a patient with normal blood pressure can still have severe glomerulonephritis. The eyes should be inspected for redness and proptosis. The anterior nasal cavity can be easily visualized with an otoscope. Evidence of lymphadenopathy should be sought. Cardiac, lung, and abdominal examinations can give clues to underlying disease, but normal examinations do not rule out pathology. Similarly, absent pulses, asymmetric blood pressure readings, and bruits are helpful but imperfect measures to screen for large-vessel vasculitis. A complete joint examination is important and any findings suggestive of synovitis (joint swelling, warmth, redness) must be further investigated; however, many patients with vasculitis will have arthralgias without joint effusions. A full neurological examination is one of the most valuable components of the evaluation and

triage of a patient suspected of having vasculitis; subtle sensory and even motor abnormalities may be missed on initial evaluation.

The more detailed and expert examinations that can be performed by ophthalmologists and otolaryngologists are often extremely helpful in evaluating patients suspected of having vasculitis. Urgent referral is often indicated in patients with concerning symptoms such as new visual impairment, painful or red eyes, hoarseness or stridor, or hearing loss.

DIAGNOSTIC TESTING FOR SUSPECTED VASCULITIS

Given the broad range of entities that fall under the category "vasculitis", and the even larger number of diseases that are also reasonably considered when evaluating a patient suspected of having vasculitis, a vast number and range of diagnostic tests are often considered in such cases. However, obtaining a thorough medical history and conducting a detailed physical examination should enable the clinician to limit the types of vasculitis under consideration and prioritize the ordering of diagnostic tests. Not all tests need be ordered for all patients suspected of having vasculitis. This approach must of course be balanced by the possibility of atypical presentations of vasculitis as well as a range of infections, malignancies, and other diseases in the differential diagnosis of such patients. Evaluation for possible vasculitis usually occurs in parallel to evaluation for other processes.

SKIN BIOPSY. The method for diagnosing vasculitis depends on the type of vasculitis suspected, which is often based on the size of vessel involved. Vasculitides affecting the skin usually involve small- and medium-sized vessels and these vessels are amenable to biopsy (Fig. 164-3). Given the ease and low risk of skin biopsies, they play an important role in diagnosing vasculitis, and an equally important role in establishing a diagnosis other than vasculitis. A standard punch biopsy is sufficient to diagnose small-vessel vasculitis but a deeper and wider excision may be necessary to capture information on medium-sized vessels.[10,11] Lesions that should be approached with a deeper biopsy include subcutaneous nodules, livedo reticularis, or deep ulcers (Fig. 164-4). Many types of small-vessel vasculitis may also involve medium-sized skin vessels. It is important to realize that the difference between "small" and "medium" vessels is somewhat subjective and skin pathologists make such distinctions more often than might other pathologists who see larger biopsy specimens.

Sometimes the presence of a typical clinical syndrome makes biopsy unnecessary. For example, Henoch–Schönlein purpura in children is often

Figure 164-3 Different skin manifestations of systemic vasculitis. **A.** Purpura. **B.** Bullae. **C.** Ulcer.

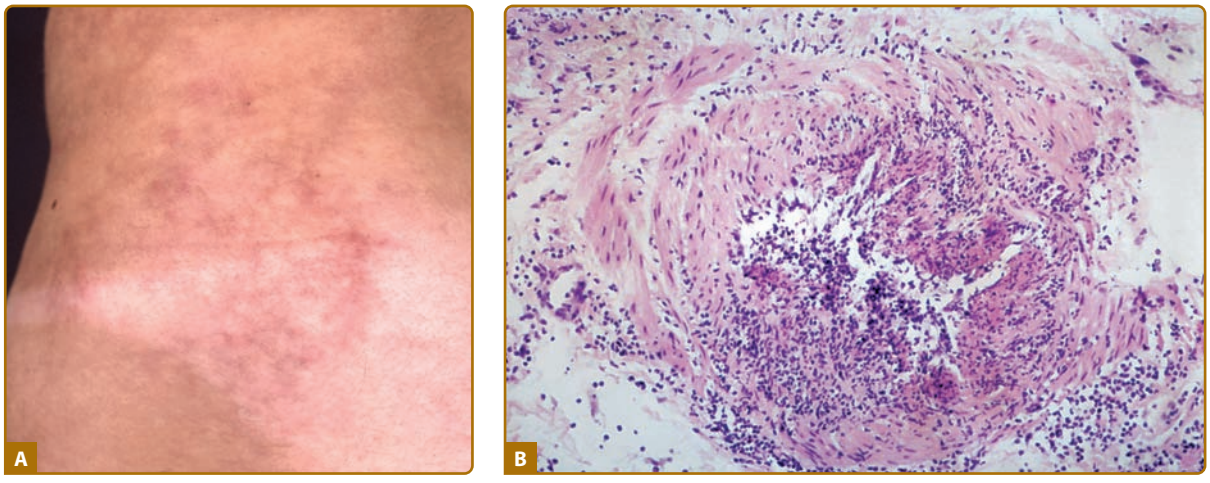

Figure 164-4 **A.** A patient with polyarteritis nodosa with "starburst" livedo made up of a cluster of nodular lesions. **B.** Histopathology of skin lesions in polyarteritis nodosa showing segmental necrotizing arteritis.

diagnosed on clinical grounds alone and some cases of ANCA-associated or cryoglobulinemic vasculitis can be diagnosed confidently by combining clinical features with specific serologic tests. Behçet disease and Kawasaki disease are diagnosed based on the clinical syndromes; biopsy is usually not performed on the skin lesions that are common in these diseases, and such biopsies are often nondiagnostic.

It is generally recommended to biopsy a skin lesion that has been clinically apparent for less than 48 hours, if possible, to maximize the chance of finding the typical features of acute neutrophilic vasculitis, including fibrinoid necrosis, extravasation of erythrocytes, extravasation of neutrophils with release of nuclear debris (leukocytoclasia), and the presence of immune deposits.[10,11] Processing of tissue is different for conventional histopathology or immunofluorescence testing; if immunofluorescence is desired, then either two specimens need to be obtained, or a single specimen needs to be divided before processing. The latter approach may however damage the tissue.[10]

As discussed throughout this chapter, the histologic finding of leukocytoclastic vasculitis is helpful in confirming the diagnosis of vasculitis but does nothing to establish an etiology from among the broad number of possibilities. Microscopy sometimes reveals features that are suggestive but not diagnostic of vasculitis, such as leukocytoclasia without fibrinoid necrosis. The finding of a perivascular infiltrate, particularly if it consists predominantly of mononuclear cells but even if it is neutrophilic, is also nonspecific. Certain features, when seen in addition to leukocytoclastic vasculitis, are strongly suggestive of particular diseases, such as extravascular granulomas with geographic necrosis (GPA), or eosinophil-rich extravascular granulomas (Churg–Strauss syndrome; CSS),[12] but these features are seen in a minority of biopsies in these diseases.

A predominance of IgA over IgG/IgM by immunofluorescence is suggestive but not diagnostic of Henoch–Schönlein purpura. The presence of deposits of IgG, IgM, and/or complement is suggestive of one of several immune-complex-mediated etiologies, including drug hypersensitivity, postinfectious vasculitis, cryoglobulinemia, and vasculitis secondary to systemic lupus erythematosus, Sjögren syndrome, or rheumatoid arthritis.[12]

OTHER BIOPSIES. Vasculitis is often diagnosed by biopsy of other organs, such as kidney, lung, muscle, or peripheral nerve or even from surgical specimens (Fig. 164-5). Kidney or lung biopsies are more likely than skin biopsies to show pathology diagnostic of a particular disease. Nonetheless, a skin biopsy establishing the diagnosis of vasculitis may preclude the need for more invasive biopsies.

LABORATORY TESTING. Although individual laboratory tests on their own are almost never diagnostic for vasculitis, such tests are essential in the evaluation of a patient in whom cutaneous vasculitis is being considered. Laboratory testing may identify organ systems involved in the disease process, especially renal disease. Furthermore, in the proper setting, selected serologic tests may establish an etiology for vasculitis. However, serologic tests usually complement rather than substitute for biopsy, particularly in a patient with skin lesions that can be readily biopsied.

Tests of Renal Function. Tests for renal disease are the most important laboratory tests to order in evaluating a patient suspected of having vasculitis since renal disease is common in many vasculitides and is rarely accompanied by signs or symptoms until end-stage renal failure occurs. Urinalysis, including both dipstick and microscopic examinations, should be performed on all patients in whom vasculitis is suspected, and repeatedly in patients in whom vasculitis of small- or medium-sized vessels is established in another organ system. The presence of any blood on the routine dipstick tests needs to be followed by an examination for red blood cell casts by someone specifically trained to look for casts (many nephrologists, some rheumatologists, but few laboratory technicians in North America). Measurement of serum creatinine

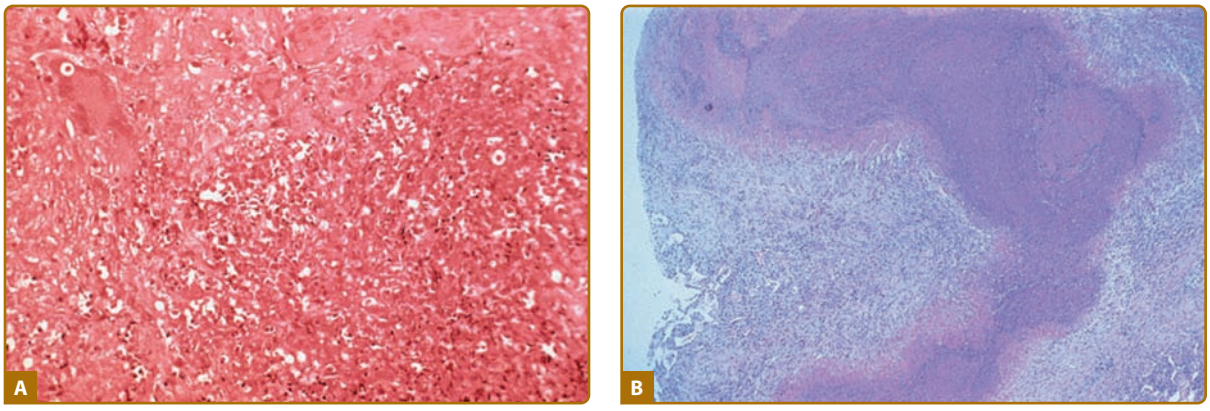

Figure 164-5 **A.** Lung histopathology from a patient with granulomatosis with polyangiitis (Wegener's) demonstrating necrosis, giant cells, and mixed cellular inflammation. **B.** "Geographic necrosis" in a low-power view of an open lung biopsy specimen from a patient with granulomatosis with polyangiitis (Wegener's).

is critical to estimate the glomerular filtration rate (GFR). Small changes in creatinine, even within the normal range, may be early evidence of decline in GFR. Although small-vessel vasculitis affecting the glomeruli is expected to produce hematuria, usually accompanied by red blood cell casts and proteinuria, vasculitis affecting only medium-sized vessels (e.g., polyarteritis nodosa) typically produces either isolated hematuria or a normal urinalysis. Urinalysis and serum creatinine are equally important tests and are complementary; neither alone is sufficient to exclude renal disease in vasculitis.

Tests of Liver Function. Vasculitis, particularly polyarteritis nodosa, can involve the liver, but significant hepatic dysfunction is rare. Liver function tests are thus of limited value in diagnosing vasculitis, but they do provide a baseline against which future values can be compared if, as is often the case, potentially hepatotoxic drugs are to be used for treatment. Liver function tests can also provide an early hint at infection with hepatitis B or C viruses, both of which are associated with vasculitis, but do not substitute for serologic testing for these infections. Normal liver function tests do not rule out infectious hepatitis.

Complete Blood Count. A complete blood count should be ordered on all patients suspected of having vasculitis. Many patients with active vasculitis have anemia and/or thrombocytosis, but the same is true of a wide range of inflammatory diseases. Severe anemia can be a clue to serious gastrointestinal involvement from various forms of vasculitis. The white blood cell count and differential can also be clues to the presence of infection or hematologic malignancy. However, leucocytosis is usually nonspecific and is also commonly caused by use of glucocorticoids. An elevated absolute eosinophil count is found in most untreated patients with CSS and a count greater than 1,000 cells/μL helps differentiate this disease from asthma and atopy.

Acute Phase Reactants. The erythrocyte sedimentation rate (ESR) and levels of C-reactive protein (CRP) are elevated in many patients with vasculitis, but the diagnostic sensitivity and specificity of these tests are not particularly high and thus these tests are not particularly helpful in either establishing or excluding a diagnosis of vasculitis. Furthermore, the levels of ESR and CRP do not correlate well with stage or severity of disease. ESR and CRP are often elevated in conditions that mimic vasculitis in the skin, as well as in many serious systemic diseases, including infections and malignancies. Patients with active vasculitis can have normal ESR and CRP values and patients may remain in clinical remission despite persistent elevation of these markers after treatment.

Autoimmune Serologies. Testing for autoantibodies is often a critical component of establishing the type of vasculitis present but it is important to recognize that serologic testing on its own is never diagnostic and should never substitute for clinical judgment.

Testing for ANCA and antiglomerular basement membrane (anti-GBM) antibodies, as well as antinuclear antibodies (ANA) to address the alternative possibility of systemic lupus erythematosus, is advised for any patient presenting with pulmonary hemorrhage and/or acute renal insufficiency with an active urinary sediment. ANCA-associated vasculitis and lupus can present with vasculitis of the skin, but anti-GBM disease does not, so the latter topic will not be discussed further.

Antineutrophil Cytoplasmic Antibodies. Approximately 90% of patients with microscopic polyangiitis, 75% of patients with GPA, and 40% of patients with CSS will test positive for ANCA.[13–16] Modern ANCA testing includes both immunofluorescence staining of neutrophils for the cytoplasmic (c-ANCA) or perinuclear (p-ANCA) patterns and ELISAs for specific autoantigens [proteinase-3 (PR3) and myeloperoxidase (MPO)].[16–18] Specificity of positive testing for anti-PR3 and anti-MPO antibodies for ANCA-associated vasculitis is quite high,[17–19] but specificity of p-ANCA staining in the absence of anti-MPO antibodies is low. Thus, positive tests for ANCA by ELISA are essential to consider ANCA testing positive for purposes of diagnosing vasculitis.

The predictive value of positive ANCA testing depends on the setting. In cases of biopsy-proven vasculitis or clinical "surrogates" of a biopsy of vasculitis, such as diffuse alveolar hemorrhage or acute renal failure with an "active" urinary sediment, positive testing for anti-PR3/MPO ANCA is highly specific. In the setting of nonspecific constitutional and musculoskeletal symptoms, the positive predictive value of ANCA testing is lower.

Anti-Nuclear Antibodies. Testing for ANA and related autoantibodies is useful when there is suspicion of systemic lupus or Sjögren syndrome. ANA testing is extremely sensitive (>95%) but not specific for the diagnosis of lupus. With the exception of anti-Ro (SSA) antibodies, additional tests for specific nuclear antigens, including double-stranded DNA, Smith, RNP, and La (SSB), should only be ordered if the ANA is positive and lupus is still under consideration. Only 80% of patients with Sjögren syndrome test positive for rheumatoid factor (RF), anti-Ro (SSA), or anti-La (SSB) antibodies, so negative tests do not rule out this diagnosis.

Rheumatoid Factor. Testing for rheumatoid factor is rarely useful in establishing either the diagnosis or specific type of vasculitis. The sensitivity and specificity of rheumatoid factor for Sjögren syndrome or cryoglobulinemic vasculitis are low. While at least 70% of patients with rheumatoid arthritis test positive for rheumatoid factor, the test is positive in more than 95% of patients with rheumatoid vasculitis.[20] However, since rheumatoid vasculitis typically occurs in patients with longstanding, severe rheumatoid arthritis, such testing has little additive value.

Paraproteins (Abnormal Immunoglobulins, Including Cryoglobulins). Cryoglobulins are immune complexes (immunoglobulins and their target antigens) that precipitate in the cold and are associated with clinical syndromes in which vasculitis is a prominent component (see Chapter 169). Cryoglobulinemia most commonly results from chronic infection with hepatitis C virus, but rheumatoid arthritis, systemic lupus erythematosus, Sjögren syndrome, and hematologic malignancies are also all associated with cryoglobulinemia. Testing for cryoglobulins requires careful attention to specimen handling and processing since incorrect practice at any one of several steps results in a high false-negative rate. Similarly, standard serum protein electrophoresis testing may not pick up some immunoglobulin clones, and immunofixation electrophoresis is a more comprehensive screen for clonal immunoglobulins.

Vasculitis has also been associated with monoclonal gammopathies (myeloma, plasmacytoma, or lymphoma) in the absence of cryoglobulinemia.[21]

Complement. Total hemolytic complement is measured using the CH50, but since this assay is cumbersome and suffers from variability between laboratories, measurement in serum of the complement proteins C3 and C4 is usually sufficient, and is useful for assessing patients with cutaneous vasculitis in several settings. In patients with cryoglobulinemic vasculitis C4 levels are usually severely depleted whereas C3 levels are less depleted or even normal.[22,23] One or both of these components are low in 70% of patients with rheumatoid vasculitis,[20] which is useful because rheumatoid arthritis is generally not associated with low circulating complement. In contrast, because systemic lupus erythematosus is commonly associated with low complement in a variety of settings, low complement helps raise the suspicion for lupus but is not specific for vasculitis in SLE. A subset of patients whose cutaneous vasculitis presents as urticaria (hence the term "urticarial vasculitis"), but who cannot be diagnosed with lupus or another underlying disease, have depletion of complement (see Chapter 163).

Selected Testing for Infectious Diseases. Many infections can cause skin lesions that either include vasculitis or mimic vasculitis. Chronic infection with hepatitis C virus is strongly associated with cryoglobulinemic vasculitis, and it can also be associated with polyarteritis nodosa in the absence of cryoglobulins.[24] Chronic hepatitis B virus infection was the cause of many cases of polyarteritis nodosa prior to the widespread adoption of vaccination programs.[25] Thus, patients with known or suspected vasculitis affecting small- or medium-sized arteries should be screened for hepatitis B and C infections.

Endocarditis can cause both true vasculitis, presumably through deposition of immune complexes, and lesions that mimic vasculitis, through septic emboli. Blood cultures are therefore appropriate to order for some patients suspected of small-vessel vasculitis.

Numerous and diverse infections have been implicated in causing secondary vasculitis, usually of small vessels and limited to the skin. Testing for specific organisms should therefore be based on a history of exposure or a suspicious clinical syndrome (e.g., sore throat or acute diarrhea).

Several uncommon infections directly infect and damage vascular endothelial cells and thus produce lesions that can either be regarded as vasculitis or as mimics of vasculitis; numerous organisms have been implicated, mostly in the form of case reports.

Screening for Drugs of Abuse. Toxicology screens for commonly used drugs of abuse may be appropriate for some clinical situations where vasculitis is suspected. In particular, both cocaine and methamphetamines have been associated with cutaneous vasculitis and/or arterial vasospasm, and nasal inhalation of cocaine can produce destructive nasal disease as severe as that seen in ANCA-associated vasculitis, although certain clinical features may help distinguish the two causes.[26,27]

DIAGNOSTIC IMAGING STUDIES

Chest Imaging. A chest radiograph is an appropriate screening test for any patient suspected of having vasculitis. For a patient with pulmonary symptoms, computed tomography (CT) is usually indicated, since plain radiographs will frequently not detect small

nodules or subtle but significant infiltrates. In patients diagnosed with GPA, microscopic polyangiitis, or CSS, a screening CT is indicated for staging purposes and to establish a baseline, even in asymptomatic patients.

If subglottic stenosis is suspected, CT of the neck/trachea can be a helpful adjunct to direct laryngoscopy.

Sinus Imaging. Sinus involvement is extremely common in GPA and CSS, and the ability to evaluate the sinuses on physical examination is limited even for an otolaryngologist. CT of the sinuses can help assess the possibility of GPA or CSS and is useful in staging and restaging disease once one of those diagnoses is made and treatment is initiated. However, the CT appearance of sinus inflammation in these diseases does not allow discrimination from other causes of sinusitis, and patients with prior damage from vasculitis often have persistent abnormalities. Nasal inflammation may be better assessed by physical exam than by CT.

Angiography. Angiography has a central role in the diagnosis and management of large- and medium-vessel vasculitis. Conventional catheter-based dye angiography has the highest resolution but is an invasive procedure and still does not allow visualization of most small vessels. Angiography based on CT and magnetic resonance (MR) is increasingly replacing the use of catheter-based angiography in large-vessel vasculitis (GCA and Takayasu's).[28]

The role of angiography in the diagnosis of vasculitis of the skin is limited to either establishing the underlying type of vasculitis (e.g., abdominal angiography demonstrating multiple aneurysms and stenoses in polyarteritis nodosa) or evaluating the arterial supply in patients with gangrene.

OTHER DIAGNOSTIC STUDIES

Nerve Conduction Studies and Electromyography. Nerve conduction studies should never replace a full neurologic examination and most patients with neurologic manifestations of vasculitis do not need such testing. Thus, nerve conduction testing is not recommended for screening asymptomatic patients, but can be useful for providing objective evidence of neuropathy and for distinguishing between compressive (i.e., mechanical) and noncompressive neuropathy, with the latter type including neuropathy due to vasculitis and many other medical causes. Electromyography (EMG) can establish the presence of myopathy, but usually not the cause. Nerve conduction studies are painful and require expertise not always readily available.

Audiology Testing. An audiogram is critical in diagnosing and distinguishing between conductive and/or sensorineural hearing loss. Hearing loss is a commonly missed manifestation of small-vessel vasculitis, including among elderly patients.[29] Sensorineural hearing loss is a cranial neuropathy and may rapidly lead to irreversible hearing loss. Although an audiogram is not generally indicated for screening an asymptomatic patient, a baseline audiogram is advised for all patients with an established diagnosis of ANCA-associated vasculitis (GPA, microscopic polyangiitis, or CSS).

SUMMARIES OF THE VASCULITIDES

MICROSCOPIC POLYANGIITIS

Microscopic polyangiitis (MPA) is a multisystem vasculitis of small vessels and sometimes also of medium-sized vessels.[30,31] Pauciimmune glomerulonephritis develops in the majority of patients, and pulmonary hemorrhage, peripheral and cranial neuropathy, musculoskeletal, and constitutional symptoms are also common; cardiac and gastrointestinal involvement are less common. Most patients with MPA are positive for ANCA, usually with specificity for antibodies to myeloperoxidase (MPO).[32] Although rapidly progressive glomerulonephritis and/or diffuse alveolar hemorrhage commonly lead to diagnosis, MPA often features a prolonged prodrome limited to musculoskeletal and constitutional symptoms.[33]

The skin is frequently involved in MPA.[15] The most common cutaneous lesion is palpable purpura and the pathology is indistinguishable from other types of leukocytoclastic vasculitis[12,34] (Fig. 164-6). Vasculitis of medium-sized vessels, leading to digital ischemia, subcutaneous nodules, livedo reticularis, and deep ulcers, can rarely occur in MPA.

GRANULOMATOSIS WITH POLYANGIITIS (WEGENER'S)

GPA encompasses all the features of microscopic polyangiitis but also many additional manifestations caused by necrotizing granulomatous inflammation and the two syndromes are currently considered distinct entities. Chronic inflammation of the upper airway (nasal cavity, sinuses, auditory tube, and middle ear) is present in about 90% of patients, often but not always as the initial manifestation.[13,35,36] Cavitary

Figure 164-6 Purpura in a patient with microscopic polyangiitis.

Figure 164-7 Skin ulcer in a patient with granulomatosis with polyangitis (Wegener's).

pulmonary nodules, orbital pseudotumor, and subglottic stenosis are also common and important features. Vasculitis of the eye (scleritis and episcleritis) is also much more common in GPA than in MPA.[13,30,35–37] Most patients with GPA who have involvement of multiple organ systems will test positive for ANCA.[37,38] The majority ANCA type in this disease is C-ANCA/antiproteinase-3 (PR3); however, P-ANCA/antimyeloperoxidase (MPO) is also not uncommon. Patients with disease seemingly restricted to the upper airway are only ANCA-positive in about 70% of cases, which can make diagnosis more challenging.[16,37]

In addition to palpable purpura and other presentations typical of small-vessel vasculitis, additional skin lesions occur in GPA and reflect a combination of vasculitis and necrotizing granulomatous disease, including neutrophilic and granulomatous dermatitis with papules (particularly on the extensor surfaces of the elbows), subcutaneous nodules, and ulcers[12,39–42] (Figs. 164-7 and 164-8). Vasculitis and extravascular granulomatous disease are sometimes seen in the same biopsy, facilitating diagnosis. As with MPA, manifestations attributable to involvement of medium-sized vessels can also be seen (Fig. 164-9).

CHURG–STRAUSS SYNDROME

CSS is often included among the ANCA-associated vasculitides since approximately 40% of patients test positive for ANCA,[43] and there is considerable overlap in features of CSS with both GPA and microscopic polyangiitis. However, CSS has unique features, the most prominent being a history of asthma (often severe or poorly controlled), and blood eosinophilia. Nasal polyps, constitutional symptoms, and rashes, all typical of atopy, are also common. The presence of pulmonary infiltrates on chest imaging (eosinophilic pneumonia) provides an important distinction from asthma. The most common presentation of severe vasculitis in CSS is acute peripheral neuropathy with involvement of the heart, gastrointestinal tract, brain, and eyes less common. Glomerulonephritis and pulmonary hemorrhage occur in about 10% and less than 5%, respectively, of patients with CSS.[14,44,45]

Cutaneous disease is more common in CSS than in GPA or microscopic polyangiitis.[14,44,45] Palpable and nonpalpable purpura, reflecting vasculitis histologically, comprise about 50% of cutaneous lesions.[12] Eosinophilic dermatitis and granulomatous dermatitis rich in both neutrophils and eosinophils are also common and produce erythematous macules, papules, and nodules. As with GPA, small-vessel vasculitis and extravascular eosinophilic and/or granulomatous disease are sometimes seen in the same biopsy. While the skin lesions of CSS often contain eosinophils, with or without vasculitis, eosinphil-rich skin biopsies are not unique to this disease and can be seen in other types of vasculitis.

VASCULITIS ASSOCIATED WITH OTHER AUTOIMMUNE DISEASES

Vasculitis is seen relatively commonly in patients with systemic lupus (10%–36%)[46,47] and Sjögren syndrome (10%),[48] but is now extremely uncommon in rheumatoid arthritis.[49,50] Vasculitis in these diseases affects mostly small vessels, with some medium-vessel disease. The vasculitis may cause peripheral neuropathy, gastrointestinal ischemia, and central nervous system disease with other visceral involvement rare. Inflammatory bowel disease and relapsing polychondritis[51] have also been associated with vasculitis involving small, medium, or large vessels.

The cutaneous manifestations of systemic rheumatic diseases are covered in Chapters 155, 160, and 161. The cutaneous manifestations of small-vessel vasculitis (purpura, vesiculobullous lesions, shallow ulcers) and medium-vessel vasculitis (nodules, deep ulcers, digital gangrene) associated with connective-tissue diseases are generally similar to what is seen in other forms of cutaneous vasculitis (eFig. 164-9.1 in online edition).

MALIGNANCY-ASSOCIATED VASCULITIS

Vasculitis temporally associated with a solid malignancy has been reported in many case reports and in a few larger series.[52] A diverse set of malignancies has been implicated. Small-vessel vasculitis of the skin appears to be most common manifestation, and reports of remission of vasculitis after surgical resection of the tumor (and no other therapy) are suggestive of a causal relationship. Hematologic malignancies with or without associated paraproteinemias can result in vasculitis.[21] Furthermore, the often comprehensive medical testing and imaging associated with evaluating a patient with possible vasculitis can lead to discovery of a malignancy in a patient with vasculitis, and the two diagnoses may be unrelated.

CUTANEOUS LEUKOCYTOCLASTIC ANGIITIS

All of the diseases and syndromes described to this point are defined by a combination of clinical and laboratory parameters. Cutaneous leukocytoclastic angiitis, in contrast, is a histologic term defined by the absence of evidence of systemic disease and the term undoubtedly encompasses many etiologies, and appears in this list only to serve as a reminder that cutaneous vasculitis is not always a marker of systemic disease. If, and only if, a patient has biopsy-proven vasculitis, has no evidence of involvement of other organ systems by vasculitis, and has no clinical of laboratory evidence to support a specific form of vasculitis or a coexisting autoimmune inflammatory disease, should the diagnosis of cutaneous leukocytoclastic angiitis be tentatively made. This term appears in the nomenclature of the Chapel Hill Consensus Conference of 1994 to acknowledge that vasculitis limited to the skin is relatively common.[7] It has been estimated that about 20% of such cases follow infections, and another 20% are associated with drug exposure.[12] However, it is quite problematic to label skin-only vasculitis as a separate disease entity, and all such patients should be followed carefully for the possible evolution to a more systemic form of vasculitis.

DRUG-INDUCED VASCULITIS

Reactions to drugs have been implicated in about 20% of cases of cutaneous small-vessel vasculitis,[10] but the exact frequency of drug-induced disease is hard to establish due to incomplete reporting of cases and difficulty in firmly establishing causality of any one agent. Most categories of drugs have been implicated as causing vasculitis, but the number of reports for a given drug may represent reporting bias rather than relative risk.[9,53] Cutaneous small-vessel disease is the norm, but medium-vessel vasculitis and visceral involvement have been reported. The literature

Figure 164-10 Leukocytoclastic vasculitis after administration of granulocyte macrophage colony-stimulating factor for aplastic anemia.

is undoubtedly biased toward severe cases, but there are numerous reports of serious or fatal internal organ involvement (particularly renal, pulmonary, and hepatic). There is also a now well-accepted subset of drug-induced ANCA-associated vasculitis (antibodies usually directed against myeloperoxidase), especially involving propylthiouracil and related agents, hydralazine, but also other drugs.[54,55]

The cutaneous presentation of DIV is indistinguishable from other causes of small-vessel vasculitis (i.e., usually purpura but sometimes other lesions) (Fig. 164-10).

It is essential that a comprehensive review of all prescription, over-the-counter, illegal, and "alternative" drugs and supplements be undertaken for all patients suspected of having vasculitis.

Establishing a diagnosis of DIV may lead to avoidance of treatment with glucocorticoids and immunosuppressive agents in favor of clinical follow-up after drug discontinuation. However, two important caveats must be kept in mind in such cases: (1) drug discontinuation alone may not resolve the disease and severe disease may be present necessitating treatment; (2) the diagnosis of DIV may be wrong and the patient really has another form of vasculitis; thus, careful and prolonged follow-up of all patients is required.

BEHÇET DISEASE

See Chapter 166.

POLYARTERITIS NODOSA

Idiopathic vasculitis of medium-sized vessels (i.e., small- or medium-sized muscular arteries) can present in one or multiple organ systems. "Classic" polyarteritis nodosa involves multiple organ systems and presents with some combination of skin disease, myalgia, hypertension (from renal artery involvement), abdominal pain, neuropathy, and/or testicular pain. However, many patients do not present with the full set of manifestations, and diseases limited to muscle and nerve, single internal organs, or to the skin are

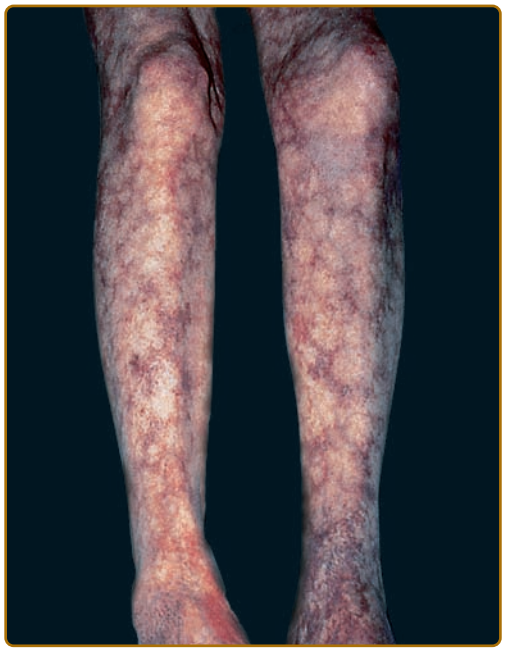

Figure 164-11 Livedo reticularis.

well-described variants. When the disease is limited to the skin, it is sometimes referred to as cutaneous poyarteritis nodosa; however, some of these patients will later manifest disease in other organs.

Interpreting the literature on poyarteritis nodosa is problematic since the term was formerly used to describe several forms of vasculitis now considered to be distinct diseases (particularly microscopic polyangiitis).[56,57] Historically, many cases of poyarteritis nodosa were associated with chronic infection with hepatitis B, but that association has declined markedly in countries in which vaccination against hepatitis B has become routine.[57] Whether the remaining, rare entity still known as poyarteritis nodosa represents one, a few, or many etiologies, or even whether there is a unified fundamental pathophysiology (e.g., immune complex disease), is unclear.

The most common cutaneous features of poyarteritis nodosa are livedo reticularis/racemosa (a lacy pattern of cutaneous blood vessels on the legs, and not always easy to distinguish from a benign consequence of vasoconstriction of more superficial vessels) (Fig. 164-11), painful cutaneous nodules or ulcers (Fig. 164-12), and digital ischemia.[58,59] These manifestations reflect vasculitis of "medium-sized" arteries in the subcutis, which are frequently too deep to be sampled in a routine punch biopsy.[10]

KAWASAKI DISEASE

See Chapter 167.

PRIMARY VASCULITIS OF THE CENTRAL NERVOUS SYSTEM

This rare disease is limited to the central nervous system (hence, no cutaneous findings) and presents with

Figure 164-12 Leg ulcer in a patient with polyarteritis nodosa.

symptoms of encephalopathy, multiple small strokes, and often headache.[60,61]

GIANT CELL ARTERITIS

Giant cell arteritis (GCA; temporal arteritis) is currently considered strictly a disease of adults older than 50 years of age that is markedly more common with advancing age. It is mostly a disease of people of Northern European ancestry. Cranial arteritis is a common feature with this term indicating stenosis or occlusion of one or more branches of the carotid artery to produce headache (70%–80%), jaw claudication (50%), and monocular (and rarely binocular) blindness (15%). Polymyalgia rheumatica, which includes pain and stiffness of the shoulder and hip girdles, is seen in at least 30%–40% of patients and may occur without cranial disease. Constitutional symptoms are common, including fever, malaise, and weight loss. Involvement of the aorta and its major branches produces symptoms similar to Takayasu arteritis in 15%–20% of patients. Diagnosis of GCA is usually confirmed by temporal artery biopsy (Fig. 164-13).

Palpable nodularity of the temporal artery is present in 30%–40% of cases and is the only cutaneous manifestation of GCA apparent on examination. Scalp necrosis and digital ischemia are rare complications.[62,63]

TAKAYASU ARTERITIS

Takayasu's is a rare form of vasculitis (prevalence <1:100,000) involving the aorta and its major branches.[64–69] Many patients are diagnosed as young adults, and 90% are female. The typical presentation of Takayasu's is limb claudication. Dizziness, constitutional symptoms, and severe hypertension (from renal artery stenosis) are also common. Cerebral infarction can occur. Coronary occlusions with angina or infarction and bowel ischemia are less common but life-threatening complication. Absent pulse(s), abnormal blood-pressure readings, and arterial bruits are common but not universal findings. Diagnosis is made by angiography.

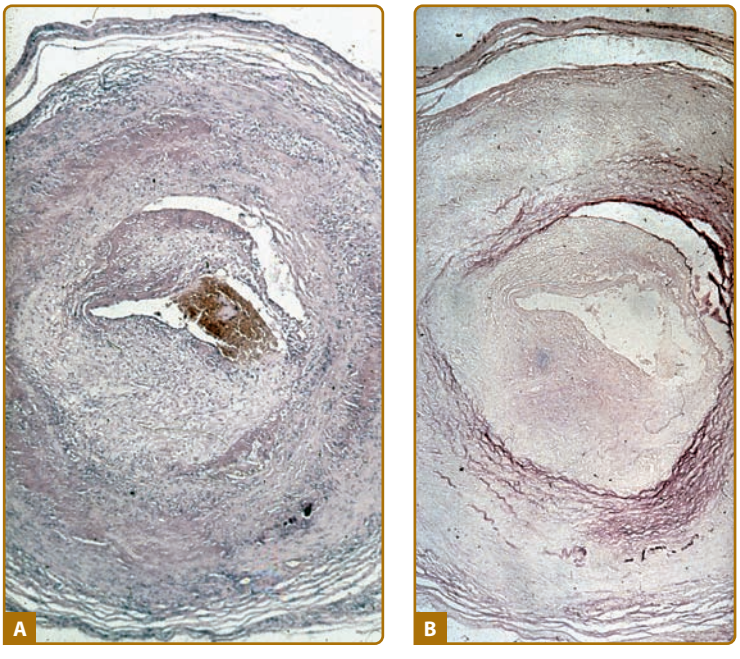

Figure 164-13 **A.** Histopathology of the temporal artery from a patient with giant cell arteritis shows necrosis of the media, inflammatory infiltrates consisting of lymphocytes, and giant cells. There is also subintimal proliferation of fibroblasts and fibrosis. **B.** Elastic tissue stain reveals destruction of the lamina interna and externa.

Lesions resembling erythema nodosum or pyoderma gangrenosum[70] have been described repeatedly in Takayasu's, with pathology of nodular lesions often, but not always, showing vasculitis and thereby differing from typical erythema nodosum.[71,72] Although complete occlusion of subclavian arteries is common, digital ischemia is rare.

TREATMENT AND MANAGEMENT OF VASCULITIS

GENERAL APPROACH TO TREATMENT OF SYSTEMIC VASCULITIS

When establishing a treatment regimen for a patient with vasculitis, consideration must be given to both the severity of the current presentation and the likelihood of disease progression and recurrence. For an increasing number of vasculitides, treatment is guided by results of relatively large, randomized, controlled trials. However, for many situations, clinicians still rely upon either extrapolation from trials in other diseases or empiric treatment based on small case series or personal experience.

For vasculitides expected to have extended courses and/or include severe manifestations, the general approach is to plan for two phases of treatment: remission induction and remission maintenance.[73,74] Remission induction usually involves use of high-dose glucocorticoids with steady dose taper combined with a short course (3–6 months) of a fairly rapid-acting and potent immunosuppressive agent. For example, cyclophosphamide, rituximab, and methotrexate all have roles in remission induction for ANCA-associated vasculitis. Remission maintenance usually involves prolonged use of non-cyclophosphamide-based regimens to allow for glucocorticoids to be either fully discontinued or maintained at a low dose (e.g., ≤10-mg prednisone daily). However, while the preceding approach is usual for the ANCA-associated vasculitides, polyarteritis nodosa, and some other forms of severe systemic disease for which there are data from clinical trials to guide treatment, it is less commonly used for other vasculitides in which glucocorticoids alone may suffice as therapy.

Clinicians must always remain alert to the possibilities of (1) a different diagnosis (either a different form of vasculitis or an entirely different disease); (2) development of additional manifestations of vasculitis; (3) treatment-related side effects, some of which can mimic vasculitis (infections, skin reactions, etc.).

An important aspect of caring for patients with vasculitis is determining who and when *not* to treat. "Watchful waiting" may be a reasonable management approach when (1) a diagnosis is not clear and no major organ system appears threatened; (2) there is an obvious cause or etiology for the vasculitis that is either reversible (toxin/drug) or self-limited (some infections); (3) uncertainly exists as to whether the patient's symptoms are due to a flare of disease or the result of either chronic damage or another process.

A critical component to the care of patients with vasculitis is close, regular clinical follow-up. Vasculitis often progresses rapidly and most forms of vasculitis have high rates of relapse. Depending on the form of vasculitis, regular office visits should be accompanied by laboratory and radiographic monitoring. Close follow-up should occur not only at the start of the disease process, but also for years following diagnosis.

TREATMENTS FOR SYSTEMIC VASCULITIS

A comprehensive list of drugs used in the treatment of the various systemic vasculitides and details of treatment regimens is beyond the scope of this chapter (additional information about specific agents is available in Chapters 224, 227, 233, and 234.

GLUCOCORTICOIDS. Glucocorticoids remain the mainstay of therapy for vasculitis given the rapidity of action, reliability of response, and physicians' familiarity with dosing and side effects. Glucocorticoids are usually the initial drug used to treat vasculitis and may be the only agent used for some forms of the disease. However, additional agents are often prescribed because either the dose of glucocorticoids needed to maintain disease control is unacceptably high or disease control is not attained by glucocorticoids alone. The acute and chronic toxicities are often underappreciated and the potential cumulative damage from chronic or recurrent use of glucocorticoids may be substantial.

OTHER IMMUNOSUPPRESSIVE AGENTS. A wide variety of additional immunosuppressive agents are used for treatment of the vasculitides. The proven effectiveness of the alkylating agent cyclophosphamide for the ANCA-associated vasculitides and, to a lesser extent, other forms of vasculitis, have helped establish this drug as the standard of care for initial treatment of severe forms of vasculitis.[35,75–77] Other alkylating agents are now rarely prescribed for vasculitis. Although effective in many, but certainly not all, cases, cyclophosphamide is also associated with serious toxicities, many of which are related to total cumulative dose (e.g., female and male infertility, bladder cancer). Therefore, the past three decades have seen the emergence of "cyclophosphamide-sparing" regimens[78] that usually have patients transition from an initial course of treatment with cyclophosphamide to a more prolonged course of a less toxic immunosuppressive agent, especially either methotrexate[79,80] or azathioprine[76,81]; mycophenolate, cyclosporine A, and other agents have also been used for maintenance therapy.

BIOLOGIC AGENTS. More recently, the so-called "biologic" agents, drugs created using recombinant DNA techniques to target specific components of the immune system, have been studied for use in treating vasculitis, often with a goal of being either cyclophosphamide

sparing or glucocorticoid sparing. The recent demonstration that rituximab, a B cell-depleting therapy, is as effective as cyclophosphamide for induction of remission in AAV is considered a major advance for the field.[82,83] However, studies examining the efficacy of anti-TNF agents for either GPA or giant cell arteritis have been highly disappointing.[84,85] There are many new biologic agents under consideration for use in the treatment of vasculitis, and clinical trials are needed to properly evaluate these new treatments.

OTHER TREATMENTS. Although a variety of other drug classes, including colchicine, antibiotics (dapsone and others), and "alternative" therapies have been promoted for treatment of various forms of vasculitis, good evidence is generally lacking for the efficacy of these agents.

The role of plasma exchange in the treatment of vasculitis remains controversial. There is some evidence for efficacy for plasma exchange for patients with AAV and severe renal disease[86] and possibly forms of cryoglobulinemic vasculitis. A large, international, randomized trial of plasma exchange for AAV is under way.

COMMON ERRORS IN THE DIAGNOSIS AND TREATMENT OF SYSTEMIC VASCULITIS

Given the huge spectrum of disease manifestations in vasculitis, the potential toxicities of treatments for vasculitis, and the serious ramifications of missing alternative diagnoses, especially infections, diagnostic misclassification is a major concern. Establishing a firm diagnosis of vasculitis based on physical examination and laboratory findings alone is a common problem. This is especially true for skin disease since not all purpura is due to vasculitis and not all skin disease in vasculitis is purpuric. Clinicians are cautioned against making a diagnosis of vasculitis in the skin without a biopsy; the exception to this guideline is if the patient has a clearly established diagnosis of vasculitis based on other evidence but, even then, it may be necessary to know what is causing a skin lesion. Many types of skin lesions improve with treatment with glucocorticoids; so, response to empiric use of this treatment is not diagnostically useful.

TABLE 164-2
Medical Emergencies Related to the Primary Vasculitides

Emergency Manifestations of Vasculitis	Type of Vasculitis
Ophthalmologic	
■ Threatened vision; monocular blindness	GCA, TAK
■ Scleritis	GPA, MPA, RPC
■ Uveitis	BD
Pulmonary	
■ Subglottic stenosis	GPA, RPC
■ Alveolar hemorrhage	GPA, MPA, CSS
■ Diffuse inflammatory infiltrates	GPA, MPA, CSS
■ Pulmonary embolus	GPA, MPA, CSS, BD
Cardiovascular	
■ Malignant hypertension–renal arterial stenoses	TAK, GCA, PAN
■ Rapid-onset cardiomyopathy/heart failure	CSS
■ Angina/myocardial infarction	TAK, GCA
■ Gangrene-digital ischemia	GCA, TAK, PAN, GPA, MPA
■ Aneurysm dissection (aorta or branches)	PAN, BD, GCA, TAK
Gastrointestinal	
■ Mesenteric ischemia	PAN, HSP, GCA, TAK
Renal	
■ Glomerulonephritis/rising creatinine/renal failure	GPA, MPA, CSS, HSP, PAN, Cryo
Neurologic	
■ Headache	GCA
■ Syncope	GCA, TAK
■ Stroke	GPA, MPA, CSS, BD, GCA, TAK
■ Sensorineural hearing loss or other cranial neuropathies	GPA, MPA
■ Mononeuritis multiplex	CSS, PAN, GPA, MPA
Other organ-threatening disease	Any systemic vasculitis

GPA = Granulomatosis with polyangiitis (Wegener's), MPA = microscopic polyangiitis, CSS = Churg–Strauss syndrome, Cryo = cryoglobulinemic vasculitis, HSP = Henoch Shönlein purpura; PAN = polyarteritis nodosa; BD = Behçet disease; RPC = relapsing polychondritis; GCA = giant cell arteritis; TAK = Takayasu's arteritis.

Undertreatment or delayed initiation of immunosuppressive therapy is a common problem for patients with systemic vasculitis. Undertreatment may take the form of failure to recognize multiorgan system disease, delay or reluctance to initiate immunosuppressive medications other than glucocorticoids for those forms of vasculitis for which such therapy has been shown to be useful, or underdosing of immunosuppressive agents.

Another common mistake is extending the course of treatment with medium–high doses of glucocorticoids beyond what is necessary to control an acute flare of vasculitis or the more serious manifestations.

MEDICAL EMERGENCIES RELATED TO THE PRIMARY VASCULITIDES

The systemic vasculitides vary greatly in their rate of progression and level of medical severity. However, it is imperative that all clinicians caring for patients with vasculitis understand that these diseases are often organ- and life-threatening and that progression to emergency situations may be rapid. Furthermore, vasculitis can accelerate rapidly even after a long period of slowly changing or even indolent disease. Table 164-2 outlines several of the most common situations in which patients require emergency care but this list is incomplete and clinicians must be vigilant about considering these and other potentially rapidly progressive problems.

Chapter 165 :: Erythema Elevatum Diutinum

:: Nneka I. Comfere & Lawrence E. Gibson

ERYTHEMA ELEVATUM DIUTINUM AT A GLANCE

- Rare disease; unknown incidence.
- A chronic leukocytoclastic vasculitis typified by a distinctive clinical pattern.
- Symmetric, erythematous, violaceous, or yellow–brown papules/nodules/plaques.
- Most common sites of involvement are the extensor surfaces of the hands, fingers, elbows, knees, legs, and Achilles tendon. Trunk is usually spared.
- Co-occurring diseases include monoclonal paraproteinemias, lymphoproliferative disorders, chronic infection, autoimmune conditions, and connective tissue diseases.
- Pathology consists of leukocytoclastic vasculitis in early stage lesions and a granulation-tissue-like response with fibrosis in later stages.

Erythema elevatum diutinum (EED) is a chronic leukocytoclastic vasculitis (LCV) that was initially described by Hutchinson in 1888 and subsequently by Bury in 1889. The name *EED* was first used by Radcliff-Crocker and Williams who separated it into two groups.[1–3] The Bury type tended to occur more commonly in younger women with a history of underlying rheumatologic disease, and the Hutchinson type tended to occur in elderly males.

EPIDEMIOLOGY

The incidence of EED is unknown; however, it appears to be a rare disease. There is no significant mortality associated with EED. It presents predominantly in males, in the fourth to sixth decade of life.

ETIOLOGY AND PATHOGENESIS

The pathogenesis of EED is not entirely clear; however, the prevailing and traditional theories are based on immune complex deposition within vessel walls, complement fixation, inflammation, and subsequent vascular destruction.[1] The various disease associations seen in EED (see Section "Associated Diseases") have

provided further understanding of the underlying pathomechanism of EED.

Antineutrophil cytoplasmic antibodies (ANCA) of the immunoglobulin G (IgG) type have proven useful for the diagnosis and monitoring of disease activity in various systemic vasculitides, including granulomatosis with polyangiitis (Wegener's), microscopic polyangiitis (MPO), polyarteritis nodosa, and Churg–Strauss syndrome.[4]

There are reports in the literature documenting the occurrence of IgA ANCAs in patients with neutrophil-driven dermatoses such as Henoch–Schönlein purpura, inflammatory bowel disease, and various cutaneous vasculitides, including EED.[5,6] It seems likely that abnormal functioning or activation of the neutrophil, which is the primary inflammatory cell in EED, may represent the central event. Most importantly, some of the neutrophilic dermatoses, including EED, have been associated with underlying paraproteinemias (monoclonal and polyclonal IgA gammopathies)[7] and hematologic malignancies. The severity of EED does not, however, appear to be dependent on the total paraprotein levels. Nevertheless, immunoelectrophoresis screening for monoclonal gammopathies as a marker of EED has been recommended.[8] Hence, IgA ANCAs against yet unidentified neutrophilic antigenic targets may prove to be useful clinical markers in EED.[9]

In a recent analysis of the clinical, histopathologic, and immunohistochemical features in six patients with EED by Wahl et al,[8] the vascular endothelium of EED was immunoreactive for CD31, CD34, vascular endothelial growth factor, and factor VIIIa but nonimmunoreactive for factor XIIIa, transforming growth factor-β, and latency-associated nuclear antigen of human herpesvirus 8. The staining properties of the endothelium in EED were compared to endothelial staining in similar lesions, including LCV, urticarial vasculitis, dermatofibromas, and capillary hemangiomas. No significant differences in the immunohistochemical staining properties were observed. The authors concluded that the chronic and recurrent nature of EED is the primary means of distinguishing it from other entities that are similar clinically and histologically.[8]

CLINICAL FINDINGS

EED typically presents as multiple, persistent, symmetric, and erythematous to violaceous papules/nodules/plaques on the extensor surfaces of the hands (Fig. 165-1), elbows (Fig. 165-2), wrists, knees (Fig. 165-3), ankles, Achilles tendons, fingers (Fig. 165-4) and toes, buttocks (see eFig. 165-4.1 in online edition), face, ears, legs, forearms, and genitals.[1] The trunk, however, is usually spared, but may be involved rarely.[10] Other atypical sites of involvement include the retroauricular and palmoplantar regions.[1,2,10] Overlying epidermal changes, such as vesicles, bullae or ulcers, may be present. Lesions may be exacerbated by cold exposure and may become more raised, erythematous, and firm in the evening.[11–13]

Figure 165-1 Erythema elevatum diutinum. Nodular lesions on dorsal hand present for several years.

With time, the lesions may become firmer and develop a yellowish-brown coloration, resembling xanthomata (see Fig. 165-2). These eventually heal with dyspigmentation. The onset of new lesions may be associated with symptoms of pruritus, burning, stinging sensations, paresthesias, or may be completely asymptomatic. Constitutional symptoms, including fever and arthralgias, are seen commonly.[1,14]

The clinical presentation of EED in human immunodeficiency virus-infected (HIV-infected) individuals is somewhat different and can mimic lesions of Kaposi sarcoma and bacillary angiomatosis usually seen in immunosuppressive states.[15] Nodular lesions have been reported in HIV-infected patients.

Figure 165-2 Multiple erythematous scaly papules coalescing into plaques on extensor elbow.

Figure 165-3 Crusted brown and violaceous papules over knee and anterior thigh.

LABORATORY FINDINGS

For histopathology see Figure 165-5.

OTHER LABORATORY FINDINGS

(See Section "Associated Diseases" and Table 165-1)

Figure 165-4 Smooth, flesh-colored to slightly erythematous papules on extensor fingers over proximal interphalangeal joints.

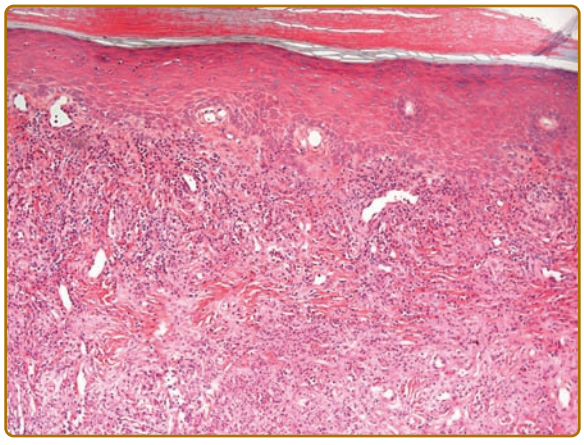

Figure 165-5 Early stage lesion of erythema elevatum diutinum: Focal leukocytoclastic vasculitis with a fairly dense perivascular and interstitial infiltrate composed of neutrophils, lymphocytes, histiocytes, and leukocytoclastic debris. Mild capillary proliferation is also evident.

ASSOCIATED DISEASES

EED has been reported in association with a wide range of disease processes (see Table 165-1). Notable associations include chronic bacterial infections, especially streptococcal infections; HIV infection; underlying monoclonal and polyclonal gammopathies; and connective tissue diseases. Some of these disease associations have provided further insight into the pathogenesis of EED.

The most frequent disease association with EED is IgA paraproteinemia. Lesions of EED have been noted to flare with increased IgA levels. Hence, IgA paraprotein levels have been proposed to be a useful clinical marker in EED.[23] Other notable associations have included chronic bacterial, viral, and parasitic infections. Bacterial infections, especially streptococcal infections, have been associated with EED, and typical skin lesions have been reproduced or exacerbated by the intradermal injection of streptococcal antigens.[1,3,23] Juxta-articular nodules of EED have been observed in patients with HIV infection. The histopathology of these nodules usually reveals a predominance of fibrosis rather than a neutrophilic infiltrate, probably secondary to the advanced/chronic stage of such lesions.[15,24,25] The role of infectious agents in the etiopathogenesis of EED is still unclear, but evidence suggests that perhaps these agents serve as antigenic triggers of a hypersensitivity response that manifests as EED.

Connective tissue diseases and autoimmune diseases have also been seen in association with EED.

TREATMENT

As is the case with cutaneous vasculitis, treatment is aimed at alleviating discomfort associated with the lesions, diminishing damage to the skin, and eradication/minimization of underlying/associated conditions. Reports in the literature on treatment options are primarily anecdotal or based on experience in small case

TABLE 165-1
Associated Entities

Infectious Diseases	Inflammatory Diseases	Connective Tissue Diseases/ Autoimmune Conditions	Malignancy	Medications	Miscellaneous
Chronic bacterial infections	Crohn disease	Cutaneous lupus erythematosus	Polycythemia vera	Rifampin	Pulmonary infiltrates
HIV, HIV-2	Mixed cryoglobulinemia	Relapsing polychondritis	Myelodysplasia	Pyrazinamide	Pleural effusions
Human herpesvirus 6	Pyoderma gangrenosum	Rheumatoid arthritis	IgA/IgG paraproteinemia (monoclonal gammopathy/ MGUS/myeloma)	Isoniazid	Mosquito bites
Measles virus		Systemic lupus erythematosus	Hairy-cell leukemia	Streptomycin	Insulin-dependent diabetes mellitus
Streptococcal infection/ rheumatic fever		Myasthenia gravis	Chronic lymphocytic leukemia		Hyperimmunoglobulinemia D syndrome
Syphilis		Celiac disease	B-cell lymphoma		Hypereosinophilic syndrome
Tuberculosis		Dermatitis herpetiformis	Lymphadenopathy-associated virus/ human T-cell lymphotrophic virus type 3		Acro-osteolysis
Hepatitis B		Autoimmune keratolysis of the eye			Hemophilia Peripheral ulcerative keratitis
		Sjogren syndrome[21]	Pulmonary lymphoepithelioma-like carcinoma[22]		

HIV = human immunodeficiency virus; Ig = immunoglobulin; MGUS = monoclonal gammopathy of undetermined significance.

series. Management of EED remains challenging due to the chronic and recurrent nature of the disease. In general, treatment of the underlying cause or infectious process may result in resolution of lesions.[1] Dapsone- and sulfone-based therapies are considered first-line treatment choices for EED.[1,3,14,26] Dramatic and rapid response is usually seen within 48 hours of initiation of therapy, with near complete resolution of lesions within weeks to months.[26] However, lesions may recur with discontinuation of therapy.[1,23] The responsiveness of EED and other neutrophil-driven dermatoses to dapsone and sulfonamides is not completely known but is thought to be secondary to its inhibitory effects on neutrophil chemotaxis and function.[13] In patients with HIV infection, treatment with a combination of antiretroviral agents and dapsone or sulfonamides may be beneficial.[1] Other reported treatments with variable success in EED include niacinamide and tetracycline,[27] colchicine,[28] intralesional, potent topical or oral corticosteroids,[3] phenformin,[29,30] clofazimine,[12] and cyclophosphamide.[31]

CONCLUSION

EED is a distinctive form of cutaneous vasculitis. It is the clinical pattern combined with the chronicity of this process that is unique to EED. Repeated antigenic stimulation or infection appears to play a key role in the pathogenesis. Although microscopic features of early lesions are shared with other cutaneous vasculitides, in the chronic phase of the disease, the microscopic pattern may resemble various other entities characterized by granulation response and healing skin. It is important to search for an underlying disease and to evaluate patients carefully for infection. Otherwise, treatment recommendations are anecdotal and similar to those used for other cutaneous vasculitides.

Chapter 166 :: Adamantiades–Behçet Disease

:: Christos C. Zouboulis

ADAMANTIADES–BEHÇET DISEASE AT A GLANCE

- Rare disease with worldwide distribution but strongly varying prevalence; certain ethnic groups are mainly affected.
- A genetically determined disorder with a probable environmental triggering factor.
- Multisystem occurrence, with oral aphthous ulcers, genital ulcers, papulopustules, erythema nodosum-like lesions, uveitis, and arthropathy as most common signs.
- Inflammatory disease representing a neutrophilic vascular reaction or vasculitis.
- Chronic relapsing progressive course and potentially poor prognosis (especially in males with systemic presenting signs; mortality, 0–6%).

Adamantiades–Behçet disease is a multisystem inflammatory disease of unknown etiology, classified as systemic vasculitis involving all types and sizes of blood vessels and characterized clinically by recurrent oral aphthous and genital ulcers, skin lesions, and iridocyclitis/posterior uveitis, occasionally accompanied by arthritis and vascular, gastrointestinal, neurologic, or other manifestations[1,2] (Fig. 166-1).

HISTORICAL ASPECTS

Hippocrates of Kos (460–377 BC) used the designation "στοματα αφθωδεα, ελκωδεα" (oral aphthous ulcers) in a probable first description of a patient with the disease (*Epidemion Book III*, Case 7). The disease is named after Benediktos Adamantiades, a Greek ophthalmologist and Hulûsi Behçet, a Turkish dermatologist, who, in 1931 and 1937, respectively, described patients with the characteristic clinical complex insisting for a single clinical entity.[3] The first international multidisciplinary conference was organized by two dermatologists, Drs. M. Monacelli and P. Nazarro, 1964 in Rome, Italy.

EPIDEMIOLOGY

Adamantiades–Behçet disease presents a worldwide occurrence with varying prevalence, being endemic in the Eastern and Central Asian and the Eastern Mediterranean countries (along the so-called Silk Road) and rare in Northern European countries, Central and Southern Africa, the Americas, and Australia.[4] A prevalence of 80 to 420 patients per 100,000 inhabitants has been reported in Turkey,[5] 7 to 30 patients per 100,000 inhabitants in the rest of the Asian continent (Japan, 14–31:100,000; Korea, 7.3:100,000; Northern China, 14:100,000; Saudi Arabia, 20:100,000; Iran, 17:100,000) and 1.5–7.5:100,000 in Southern Europe. In Northern Europe (0.27–1.18:100,000) and the United States (0.12–0.33:100,000), the disease is rare.[4] In countries with several ethnic populations, including of Turkmen and Mongol descents, the latter are mainly affected. The increasing prevalence of the disease is due to its chronic character. Its annual incidence is low; 0.75 to 1.0 new cases per 100,000 inhabitants were assessed in Japan (1990) and Germany (2005).[6] Adamantiades–Behçet disease most often affects patients in their 20s and 30s; however, early and late onsets (first year of life to 72 years) have been reported. Juvenile disease rates are 2 to 21% in different ethnic groups; its prevalence was estimated to be 0.17:100,000 in France. In contrast to old Japanese and Turkish reports of male predominance, the male-to-female ratio drastically decreased

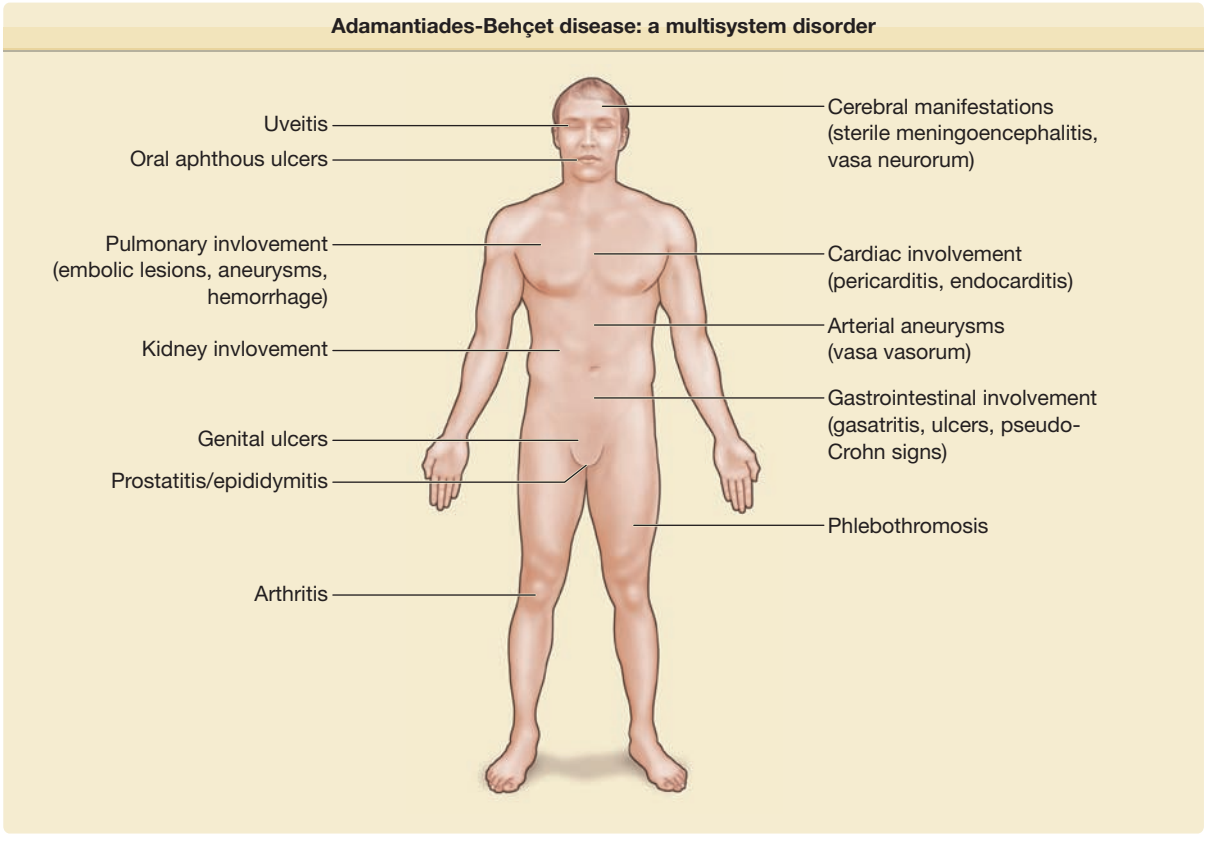

Figure 166-1 Adamantiades–Behçet disease: a multisystem disorder.

in the last 20 years. Currently, both genders are equally affected; a male predominance is still observed in Arab populations, whereas female predominance is evident in Korea, China, some Northern European countries, and the United States.

ETIOLOGY AND PATHOGENESIS

The etiology of the disease remains unknown, although genetic factors, infectious agents, environmental pollution, immunologic mechanisms, and endothelial and clotting factors have been implicated and studied intensively.[7,8] The endemic occurrence along the historical Silk Road, the major involvement of certain ethnic groups (mostly of Turkmen and Mongol descent), and associated immunogenetic data support the hypothesis that the disease followed the migration of these old nomadic tribes. On the other hand, the wide variation of the disease prevalence in the same ethnic group in association with different geographic areas of residence indicates an additional environmental triggering factor. Therefore, transfer of genetic material and/or of an unknown exogenous agent may have been responsible for the expansion of the disease.

GENETICS AND IMMUNOGENETICS

There is no specific mode of Mendelian transmission in Adamantiades–Behçet disease.[7,8] Familial occurrence with regional differences has been reported, being more frequent in Korea (15%) than in Japan or China (2–3%) and in Arab countries, Israel, and Turkey (2–18%) than in Europe (0–5%). An earlier disease onset in children compared with their parents and a higher frequency of familial cases in juveniles than in adults has been observed.

A significant association exists between the disease and human leukocyte antigen-B_{51} (HLA-B_{51}) in Japan, the Middle East, and the Mediterranean countries; however, this relationship is not as strong in Western countries.[9] The allele also seems to be associated with a more severe prognosis.[10] Its exact role in the disease mechanism is still unknown; however, it may be involved in the disease development through specific antigen presentation, molecular mimicry with microbial antigens, or participation in linkage disequilibrium with a presently unknown susceptibility gene.[11,12] Among the 24 currently described alleles, HLA-B_{5101} and -B_{5108} have most frequently been associated with Adamantiades–Behçet disease.[13] Shared amino acid residues (defining the Bw4 epitope) are crucial for antigen binding and natural killer cell interactions,[14] and Bw_4 was also reported to contribute to the severity of the disease.[15] Genes possibly associated with the disease have been localized on chromosome 6 in the region between the *tumor necrosis factor* gene and *HLA-B* or *HLA-C* genes, including the *major histocompatibility complex class I chain A* gene (A6 allele) and genes for heat shock proteins[8,11,13,16] (eFig. 166-1.1 in online edition). In addition, a novel susceptibility locus mapped to 6p22–23 was detected.[13] Lately, associations on chromosomes 1p31.3

[Interleukin (IL) 23R-IL12RB2] and 1q32.1 (IL10) were found by genome-wide association studies.[14,17] A haplotype association of *IL-8* gene with Adamantiades–Behçet disease was also detected.[18] Polymorphisms in gene encoding for host effector molecules may contribute to the disease susceptibility to and/or severity of the disease, such as in IL-23R reported in a Chinese Han population.[19]

INFECTIOUS PRECIPITANTS

Adamantiades–Behçet disease is not considered contagious as no horizontal transmission has ever been reported. However, viral and bacterial infections have been implicated in initiating immunopathologic pathways, leading to the onset of the disease.[7,8]

VIRAL AGENTS. Early theories of the pathogenesis of Adamantiades–Behçet disease proposed a viral or other infectious etiology.[3] Partial transcription of herpes simplex virus type 1 (HSV-1) DNA in patients' peripheral blood lymphocytes was reported.[7] HSV-1 DNA was detected in patients' saliva and oral and genital ulcers, and HSV-1 antibodies were found in patients' serum.

BACTERIAL AGENTS. The disease activity has been known to correlate with bacterial infection, particularly *Streptococci*.[7] *Streptococcus sanguinis (S. sanguinis)* dominates the flora of the oral mucosa in patients with the disease and appears to be the most relevant *Streptococcus* strain as a provoking factor for initiation of the disease.[20] *Streptococcus* antigens and antistreptococcal antibodies are frequently found in the oral mucosa and serum of patients. The involvement of immunoglobulin A protease-producing *S. sanguinis* is proposed as an explanation for a chronic infection leading to initiation of Adamantiades–Behçet disease. High titers of the immunogenic *S. sanguinis* antigen KTH-1 have been detected in patients. In addition, exposure of the patients to *Streptococcus* antigens may be a major provoking factor for disease activity. The lipoprotein of *Mycoplasma fermentans* MALP-404 was found in the serum of patients with Adamantiades–Behçet disease but not in healthy controls.[21] Interestingly, MALP-404 contains a peptide motif, which can be presented by HLA-B_{51}. A possible role for bacterial stimulation of monocytes via Toll-like receptor-2 producing neutrophil-stimulating proinflammatory factors in Adamantiades–Behçet disease was currently detected.[22]

IMMUNOLOGIC MECHANISMS

Immunologic mechanisms are considered to play a major role in the pathogenesis of Adamantiades–Behçet disease.[7,8,13,16] The disease has currently been classified among the autoinflammatory disorders,[23] which are caused by primary dysfunction of the innate immune system.

AUTOIMMUNE MECHANISMS. The major microscopic finding at most sites of active disease is an immune-mediated occlusive vasculitis. The pathergy reaction (see Section "Clinical Findings") is induced by the rapid accumulation of neutrophils (hyperchemotaxis) and later by T lymphocytes and monocytes/macrophages at the needle prick sites. T cells in the peripheral blood and in the involved tissues are increased, and a predominant T helper 1 immune response induced by IL-12 has been demonstrated.[24] Patients' lymphocytes also express CD29 molecules and bind to endothelial cells in active disease. In addition to defective T-cell immunity, B-cell activation is impaired. Circulating immune complexes, together with enhanced neutrophil migration, may be involved; diversity of T cells indicates that specific T-cell responses to several antigens may lead to the variety of symptoms.[25] Tropomyosins and the 160-kDa polypeptide kinectin have been detected as autoantigens in Adamantiades–Behçet disease.[26,27]

HEAT SHOCK PROTEINS. Increased levels of heat shock protein (HSP)-specific antibodies in serum have been found in Adamantiades–Behçet disease.[28,29] T cells respond to 60-kDa HSP, and four different peptide determinants within 60-kDa HSP identified by T-cell epitope mapping have been suggested to be involved in the pathogenesis of the disease.

CYTOKINE MEDIATORS. Various proinflammatory cytokines, such as IL-1, -8, -12, -17, -23, and tumor necrosis factor-α, are elevated in the sera of patients with Adamantiades–Behçet disease.[30–34] In particular, IL-8 seems to play an important role, can also be released by endothelial cells, has a potent effect on the inflammatory response, and is a sensitive marker of disease activity.[30–32] Cytokine release may be dependent on the involved organ.[30,31,33]

ENDOTHELIAL CELLS. The endothelium seems to be the primary target; however, it may just be subject to the bizarre behavior of the immune system.[35] An immunoglobulin M-type, 47-kDa cell surface HSP against endothelial α-enolase was identified in the serum of patients with Adamantiades–Behçet disease.[36] Plasma endothelin-1 concentrations were found significantly increased, perhaps indicating vasoconstriction and being the direct result of elevated synthesis by injured vascular endothelial cells. Thrombomodulin, a cell surface glycoprotein of vascular endothelium, which is also increased in the plasma of patients with active disease, potentially damages the endothelial cells.

CLINICAL FINDINGS

Adamantiades–Behçet disease is a chronic, recurrent, multisystem, and, occasionally, life-threatening disorder.[1,6] Recurrent oral aphthous ulcers, recurrent genital ulcers, skin manifestations, ocular lesions, and arthritis/arthropathy are the most frequent clinical manifestations. Vascular, gastrointestinal, neurologic, psychiatric, pulmonary, renal, and cardiac manifestations; epididymitis; and other findings can also occur. The clinical picture usually develops within a few months after the presenting sign; both an acute multisystem presentation and long-term development of the disease over years are possible.

APPROACH TO THE PATIENT WITH ORAL ULCERS, GENITAL ULCERS, OR IRIDOCYCLITIS/POSTERIOR UVEITIS

Diagnosis of Adamantiades–Behçet disease is based on clinical signs, as pathognomonic laboratory test or histologic characteristics are absent. There are several sets of diagnostic criteria, the most popular of them being the criteria of the International Study Group[37] and those of the Behçet Disease Research Committee of Japan.[38] However, there have been several problems with these criteria, including their performance in selectivity and specificity, so that both of them have currently been revised[2,39,40] (Tables 166-1, 166-2).

TABLE 166-1
Revised Diagnostic Criteria of the Behçet's Disease Research Committee of Japan[a]

- Main points
- Main symptoms
  - Recurrent oral aphthous ulcers
  - Skin lesions
    - a. Erythema nodosum (see eFig. 166-5.1B in online edition)
    - b. Superficial thrombophlebitis
    - c. Papules Skin hypersensitivity
  - Ocular lesions
    - a. Iridocyclitis or sequelae
    - b. Posterior uveitis or sequelae
- Genital ulcers
- Additional symptoms
  - Arthritis without deformity or sclerosis
  - Epididymitis
  - Gastrointestinal lesions represented by ileocecal ulcerations
  - Vascular lesions
  - Central nervous system lesions moderate or severe
- Criteria for diagnosis of disease types
  - Complete types: four main symptoms
  - Incomplete types: three main symptoms or two main and two additional symptoms or typical ocular lesions and another main symptom or two additional symptoms
  - Suspected disease: typical main symptoms not fulfilling the criteria for an incomplete type
  - Special lesions: certain gastrointestinal, vascular, and nervous system lesions
- Clinical laboratory data contributing to the diagnosis (not essential)
  - Negative or positive pathergy test
  - Negative or positive prick test to vaccinate for streptococci
  - Inflammatory response
  - Positive HLA-B51
  - Other pathologic findings
- Additional points
  - Nontypical symptoms should not be diagnosed as Behçet disease.
  - One of the criteria (a) to (c) of the skin lesions and (a) or (b) of the ocular lesions is enough for the diagnosis of the relevant symptom if the lesion occurs frequently

TABLE 166-2
Revised International Criteria for Behçet Disease (International Team for the Revision of ICBD; coordinator: F. Davatchi)[a]

Symptom	Points
Ocular lesions (recurrent)	2
Oral aphthosis (recurrent)	2
Genital aphthosis (recurrent)	2
Skin lesions (recurrent)	1
Central nervous system	1
Vascular manifestations	1
Positive pathergy test[b]	1

[a]BCD scoring: score ≥4 indicates Adamantiades–Behçet disease.
[b]Though the main scoring system does not include pathergy test, where pathergy testing *is* conducted, a positive result may be included for one extra point.
From Schirmer M et al: Evaluation and revision of the International Criteria for Behçet's Disease (ICBD). *Abstracts of the 14th International Conference on Behçet's Disease*, London, UK, 2010, p. 145, with permission.

MUCOCUTANEOUS LESIONS

Recurrent oral aphthous and genital ulcers are the most frequently observed mucosal manifestations. Oral aphthous ulcers are the presenting sign in more than 80% of the cases.[1,6,16] Although recurrent aphthous stomatitis is a common disorder, only a few patients progress to Adamantiades–Behçet disease, and it is not possible to determine in whom or when the transition may occur.[41] Typically, lesions are multiple, painful, 1–3 cm in diameter, and sharply margined with a fibrin-coated base and surrounding erythema (Fig. 166-2). Oral aphthous ulcers usually heal without scarring (92%). Genital ulcers may not recur as often and usually heal with a characteristic scar (64%–88%; Fig. 166-3). Spontaneous healing of aphthae occurs within 4 days to 1 month; genital ulcers may persist longer. Large oral ulcerations can also be associated with problems such as pharyngeal involvement, dysphagia, and dyspnea or fistulae involving the pharynx, larynx, trachea, or esophagus. Genital ulcers can occur on the penis, scrotum, vagina, labia, and urethra, and also in the anal, perineal, and inguinal regions.

Skin lesions that should be accepted as diagnostically relevant in Adamantiades–Behçet disease should be confined to pustular vasculitic lesions (including pathergy lesions), erythema nodosum-like lesions, Sweet-like lesions, pyoderma gangrenosum-like lesions, and palpable purpuric lesions of necrotizing venulitis (see Fig. 166-5). All of these lesions are characterized in their early stages by a neutrophilic vascular reaction. Acneiform lesions or follicle-based pustules should not be considered relevant.[42]

Figure 166-2 Single (**A**) and multiple (**B**) oral aphthous ulcers. (**A** from Altenburg A et al: Epidemiology and clinical manifestations of Adamantiades-Behçet disease in Germany—Current pathogenetic concepts and therapeutic possibilities. *J Dtsch Dermatol Ges* **4:** 49, 2006, with permission.)

SYSTEMIC LESIONS

Ocular involvement is the major cause of morbidity in patients with Adamantiades–Behçet disease. The most diagnostically relevant lesion is posterior uveitis (also called *retinal vasculitis*), which can lead to blindness (Fig. 166-4A). Other ocular lesions include anterior uveitis, hypopyon (pus in the anterior chamber of the eye, which is now—due to early treatment—uncommon; see Fig. 166-4B), and secondary complications such as cataract, glaucoma, and neovascular lesions.[43] Retinal inflammation can lead to vascular occlusion and, ultimately, tractional retinal detachment. Severe vitreous involvement, chronic cystoid macular edema, and possible—presumably also vasculitic—involvement of the optic nerve can result in vision loss. Recurrent vasculitic changes can ultimately lead to ischemic optic nerve atrophy.

The characteristic arthritis is a nonerosive, asymmetric, sterile, seronegative oligoarthritis; however, symmetric polyarticular involvement is common. Joint manifestations frequently occur first in one knee or ankle and then the other as migratory monoarthritis,

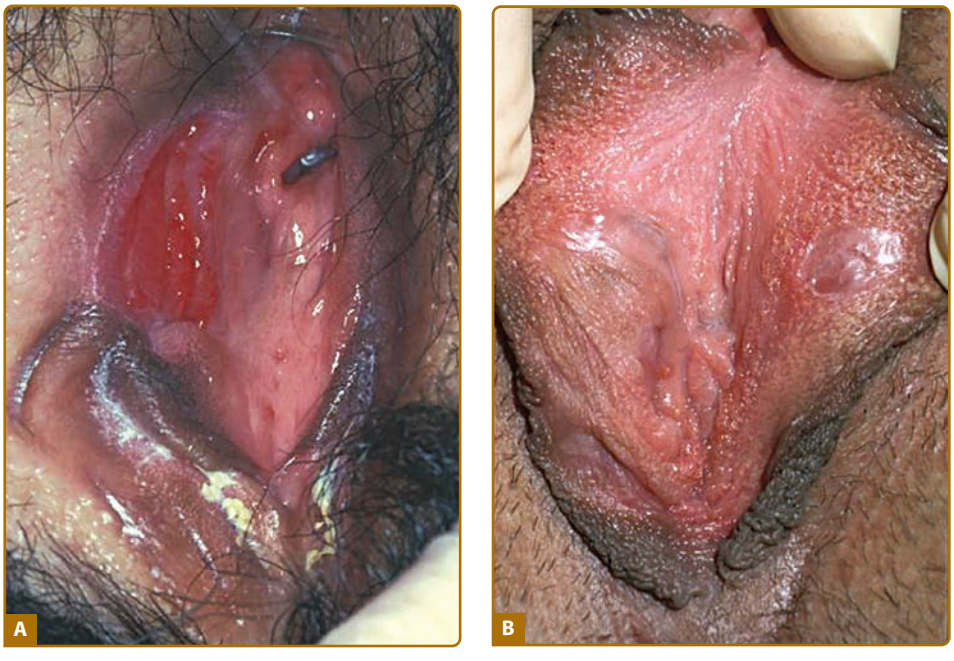

Figure 166-3 Genital ulcer (**A**) healing with a demarcated flat scar (**B**).

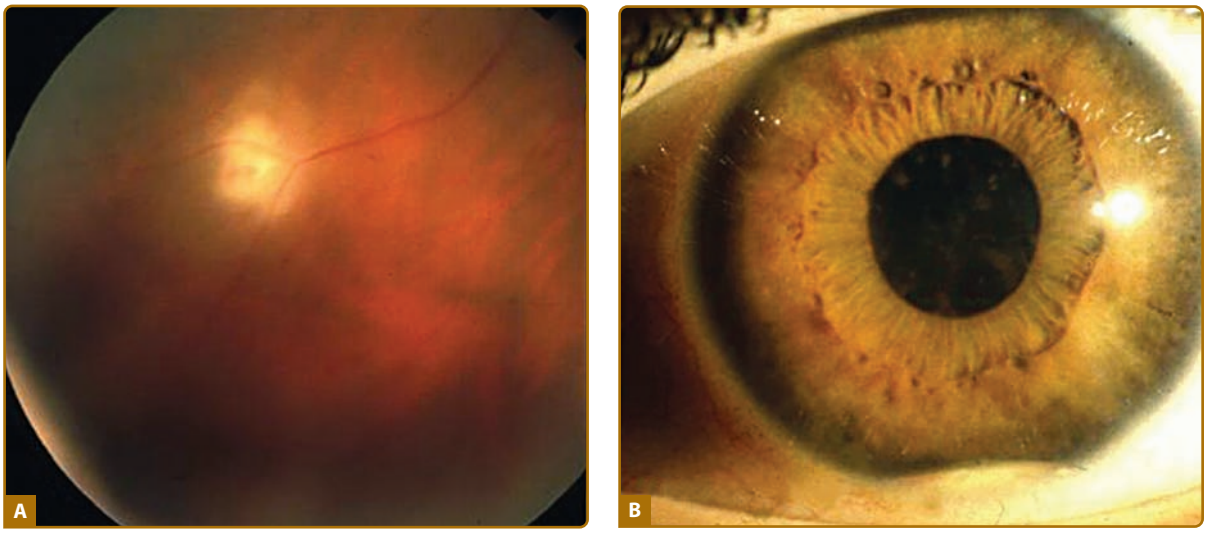

Figure 166-4 **A.** Posterior uveitis. **B.** Hypopyoniritis. (From Altenburg A et al: Epidemiology and clinical manifestations of Adamantiades-Behçet disease in Germany—Current pathogenetic concepts and therapeutic possibilities. *J Dtsch Dermatol Ges* **4:** 49, 2006, with permission.)

then in both joints simultaneously, and finally affecting nearly all joints. An HLA-B27-positive, erosive sacroiliitis has to be excluded.

Systemic vascular involvement can be significant and includes venous occlusions and varices, arterial occlusions, and aneurysms, often being migratory. Cases of large-vein thrombosis (inferior vena cava, cranial venous sinuses) or large-artery aneurysms are potentially fatal.[1,6] Arterial involvement is rather rare and usually presents in the form of thromboses and, less often, of aneurysms, resulting from multicentric arteritis. Pulmonary artery aneurysms are the principal feature of pulmonary involvement in Adamantiades–Behçet disease, occasionally resulting in coughing and hemoptysis. Cardiac involvement can include myocarditis, coronary arteritis, endocarditis, and valvular disease. A wide spectrum of renal manifestations can occur, varying from minimal change disease to proliferative glomerulonephritis and rapidly progressive crescentic glomerulonephritis. Immune complex deposition is thought to be responsible for the underlying pathogenesis in some cases of glomerulonephritis. Gastrointestinal complaints can be a symptom for aphthae throughout the gastrointestinal tract and can rarely result in perforation and peritonitis (0.5%). Inflammatory bowel disease has to be excluded. Sterile prostatitis and epididymitis can be present in male patients without genital ulcers.

Significant neurologic manifestations occur in approximately 10% of patients and may be delayed in onset. Meningoencephalitis, cerebral venous sinus thrombosis, benign intracranial hypertension, cranial nerve palsies, brainstem lesions, and pyramidal or extrapyramidal lesions have been described. Poor prognosis is associated with a progressive course, relapses after treatment, repeated attacks, and cerebellar symptoms or parenchymal disease. Neurologic manifestations usually present with severe headache. Further symptoms include gait disturbance, dysarthria, vertigo, and diplopia as well as hyperreflexia, epileptic seizures, hemiplegia, ataxia, or a positive Babinski reflex. Psychiatric symptoms, such as depression, insomnia, or memory impairment, are also signs of neurologic involvement.

HISTOPATHOLOGY

Characteristic histopathologic features of Adamantiades–Behçet disease are vasculitis and thrombosis (Fig. 166-5). Biopsies from early mucocutaneous lesions show a neutrophilic vascular reaction with endothelial swelling, extravasation of erythrocytes, and leukocytoclasia or a fully developed leukocytoclastic vasculitis with fibrinoid necrosis of blood vessel walls.[1,6] Although there are reports of lesions that consist primarily of a lymphocytic perivasculitis, most of these lesions are likely older. The neutrophilic vascular reaction should be considered the predominant histopathologic finding.[42] Aneurysms can also develop in large arteries as a result of vasculitis of the vasa vasorum with penetration of the lamina elastica.

SPECIAL TESTS

PATHERGY TEST

A positive pathergy test (hyperreactivity reaction) manifests within 48 hours as an erythematous papule (>2 mm) or pustule at the site of a skin needle prick or after intracutaneous injection of 0.1-mL isotonic salt solution using a 20-gauge needle without prior disinfection of the injection site (see eFig. 166-5.1A in online edition). The skin prick is generally placed at an angle of 45°, 3 to 5 mm intracutaneously on the volar forearm. Erythema without infiltration is considered a negative finding. Provoked oral aphthae and genital

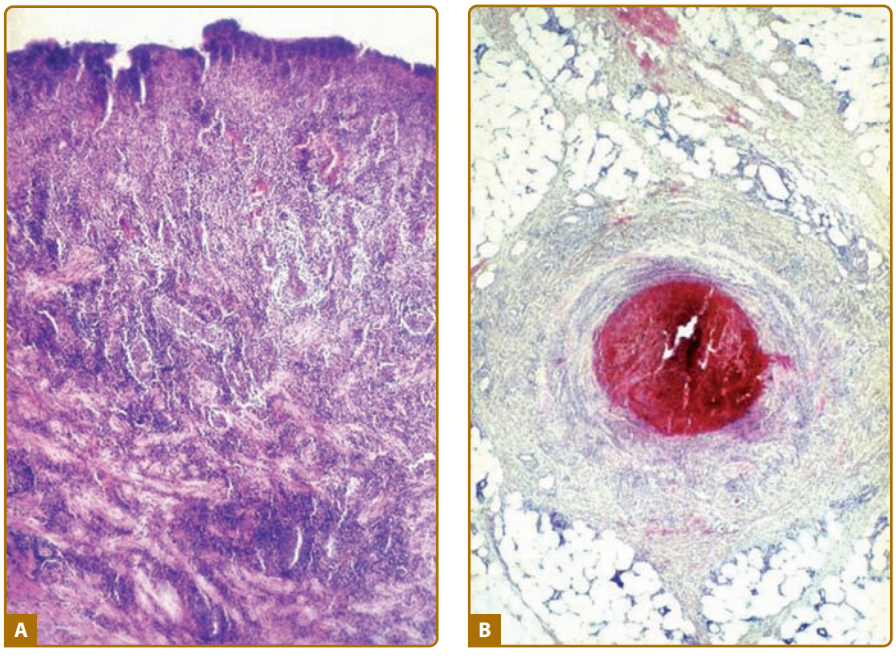

Figure 166-5 **A.** Abundant mixed inflammatory infiltrate dominated by neutrophils in an oral ulcer of Adamantiades–Behçet disease. **B.** Vessel thrombosis in an erythema nodosum-like lesion.

ulcers after injection or injury (such as chorioretinitis in the corneal region of the eye after photocoagulation of the ocular fundus region) can also be considered as positive pathergy phenomenon. Broader pathergy phenomena also include the occurrence of aneurysms around vascular anastomoses as well as local recurrence of ulcers after resection of affected bowel segments. Although a positive pathergy reaction is a sign of Adamantiades–Behçet disease, it is not pathognomic, as it can also occur in patients with pyoderma gangrenosum, rheumatoid arthritis, Crohn disease, and genital herpes infection.

RADIOLOGIC FINDINGS

Scintigraphic evidence of arthritis is found in 50% of the patients.[6] Cranial magnetic resonance imaging allows documentation of hypodense or atrophic changes in the brain. Electroencephalographic detection of diffuse α-waves is considered a positive finding. Vascular lesions can be detected by angiography.

DIFFERENTIAL DIAGNOSIS

(Box 166-1)[6,44]

CLINICAL COURSE AND PROGNOSIS

The clinical course of Adamantiades–Behçet disease is variable. There can be a delay of up to several years before the diagnosis is made, and this may influence the prognosis. Mucocutaneous and joint manifestations usually occur first. Recurrent erythema nodosum and $HLAB_{51}$ positivity are risk factors for the development of superficial thrombophlebitis and vision loss,[10,45,46] and superficial thrombophlebitis, ocular lesions, and male gender are risk factors for the development of systemic vessel involvement.[10,45,47] A severe course, including blindness, meningoencephalitis, hemoptysis, intestinal perforation, and severe arthritis, occurs in approximately 10% of patients. Blindness can often be prevented with early aggressive therapy of posterior uveitis. Lethal outcome has been seen in 0 to 6% of affected patients in different ethnic groups. Central nervous system and pulmonary and large vessel involvement, as well as bowel perforation, are the major life-threatening complications; death may also result as a complication of immunosuppressive therapy. Markers of severe prognosis include HLA-B_{51} positivity, male gender, and early development of systemic signs.[10] Onset in childhood does not necessarily predict a poor prognosis. Spontaneous remissions of certain or all manifestations of the disease have been observed. Ophthalmic and neurologic sequelae are leading causes of morbidity, followed by severe vascular and gastrointestinal manifestations, and their effects on morbidity may be cumulative.

TREATMENT

The choice of treatment for patients with Adamantiades–Behçet disease depends on the site and severity of the clinical manifestations of the disease. Recurrent aphthae are most often treated with palliative agents, such as mild diet, avoidance of irritating agents, and potent topical glucocorticoids and local anesthetics,[48,49] lately topical hyaluronic acid 0.2% gel 2 × /day over

BOX 166-2 TOPICAL TREATMENT OF ORAL APHTHOUS ULCERS

- Mild diet
- Avoidance of hard, spicy, or salty nutrients and irritating chemicals, such as toasted bread, nuts, oranges, lemons, tomatoes, spices (pepper, paprika, curry), alcohol- or CO_2-holding drinks, mouthwashes, toothpastes containing sodium lauryl sulfate[a]
- Topical treatment of the aphthous oral ulcers includes:
  - Caustic solutions (silver nitrate, 1%–2%; tinctura myrrha, 5–10% weight/volume; H_2O_2, 0.5%; methyl violet, 0.5%) 1–2 ×/day
  - Antiseptic and anti-inflammatory preparations (amlexanox, 5% in oral paste[a]; triclosan, 0.1% mouthwash solution and in toothpastes[a]; amyloglucosidase- and glucoseoxidase-containing toothpastes[a]; hexetidine, 1%, chlorhexidine, 1–2% mouthwash solutions; benzydamine; camomile extracts); 3% diclofenac in 2.5% hyaluronic acid[a]; hyaluronic acid 0.2% gel; tetracycline mouthwash (as glycerine solution 250 mg/5 mL glycerine) 2 min 4–6 ×/day[a] (caveat: pregnancy); doxymycine in isobutylcanoacrylate[a]
  - Corticosteroids (triamcinolone mucosal ointment, dexamethasone mucosal paste, betamethasone pastilles) 4 ×/day or during the night (ointment/paste) or intrafocal infiltrations with triamcinolone suspension 0.1–0.5 mL per lesion
  - Anesthetics (lidocaine, 2–5%; mepivacaine, 1.5%; tetracaine, 0.5–1% gels or mucosal ointments) 2–3 ×/day (caveat: allergy)
  - 5-Aminosalicylic acid (5% cream) 3 ×/day (reduces the duration of lesions and the pain intensity)
  - Cyclosporine A, 500 mg solution for mouthwash 3 ×/day (effective as topical immunosuppressive drug)
  - Sucralfate suspension, 5 mL × 4/day[a] (for oral aphthous and genital ulcers)
- A close association of smoking with a decrease of recurrences of oral aphthous ulcers has been described.

[a]Small, randomized, double-blind, placebo-controlled trial against placebo.

30 days was found effective (Box 166-2).[50] For the topical treatment of genital ulcers and skin lesions, corticosteroid and antiseptic creams can be applied for up to 7 days. Painful genital ulcerations can be managed by topical anesthetics in cream. Corticosteroid injections (triamcinolone acetonide, 0.1–0.5 mL/lesion) can be helpful in recalcitrant ulcerations. They can also be beneficial on panuveitis and cystoid macular edema as a single intravitreal injection (triamcinolone acetonide 4 mg).[51,52]

Patients with mucocutaneous lesions resistant to topical treatment, those with systemic involvement, and patients with markers of poor prognosis are candidates for systemic treatment.[53,54] Several compounds have been found effective in randomized, double-blind, placebo-

BOX 166-3 SYSTEMIC TREATMENT OF ADAMANTIADES–BEHÇET DISEASE[a]

DRUG	DOSE	INDICATION	RCT
Methylprednisolone	40 mg/every 3-week IM	Erythema nodosum (but not orogenital ulcers)	55
Rebamipide	300 mg/day PO (caveat: pregnancy, lactation)	Oral ulcers	56
Colchicine	1–2 mg/day PO (caveat: pregnancy, lactation—induces oligozoospermia)	Oral aphthous ulcers, genital ulcers, folliculitis, erythema nodosum	57
		Erythema nodosum, arthritis, genital ulcers, (oral ulcers in females)	58
	1.5 mg/day	Ineffective	59
Dapsone	100 mg/day PO (caveat: pregnancy, lactation—methemoglobin increase: ascorbic acid, 500 mg/day)	Oral ulcers, genital ulcers, skin lesions, pathergy test	60
Azathioprine	2.5 mg/kg/day (caveat: pregnancy, lactation, severe liver disease, bone marrow depression, severe infection, children)	Recent onset ocular disease	61
Interferon-α 2a	6×10^6 IU/3 ×/week SC (caveat: pregnancy, lactation—induces psychotic signs, psoriasis, myopathy)	Oral ulcers, genital ulcers, papulopustular lesions	62
Interferon-α	1,000 and 2,000 IU/day PO	Ineffective	63
Thalidomide	100 mg/day or 300 mg/day (caveat: pregnancy, lactation—induces polyneuropathy: minimized at 25 mg/day)	Oral ulcers, genital ulcers, papulopustular lesions	64
Cyclosporine A	10 mg/kg/day PO (against colchicine, 1 mg/day PO) (caveat: lactation, renal insufficiency—induces pathologic central nervous system findings)	Ocular manifestations, oral ulcers, skin lesions, genital ulcers	65
	5 mg/kg/day PO (against cyclophosphamide pulses)	Visual acuity	66
	5 mg/day PO (against conventional treatment)	Ocular attacks	67
Etanercept	25 mg/2 ×/week PO (caveat: pregnancy, lactation)	Oral ulcers, nodular lesions, papulopustular lesions (not pathergy test)	68
Aciclovir	5 × 800 mg for 1 week + 2 × 400 mg/day for 11 week	Ineffective	69
Azapropazone	900 mg/day over 3 weeks PO	Arthritis	70

[a]Evidence grade A—randomized, double-blind, placebo-controlled trial (RCT) against placebo except otherwise mentioned.

controlled trials[55–70] (Box 166-3). Additional treatments have been successful in studies with a lower grade of evidence (eBox 166-3.1 in online edition).[2,16,48,71–83] Oral and intravenous prednisolone can be combined with other immunosuppressants, colchicine, dapsone, sulfasalazine, or interferon-α. A synergistic effect with cyclosporine A has been described in patients with ocular involvement. Prednisolone is one of the few medications that can be used during pregnancy. Colchicine can be combined with immunosuppressants and interferon-α. A rapid relapse often occurs after discontinuing cyclosporine A, interferon-α, dapsone or infliximab.[73,76,78]

PREVENTION

- Patients with severe or progressive recurrent aphthous stomatitis should be followed up for years as potential candidates for Adamantiades–Behçet disease, particularly those patients with familial occurrence of the disease.
- Patients with suspected Adamantiades–Behçet disease should be referred early for specialist advice.
- Male patients with systemic involvement as a presenting sign and/or an early age of onset should be treated systemically because of the poor prognosis.

Chapter 167 :: Kawasaki Disease

:: Anne H. Rowley

KAWASAKI DISEASE AT A GLANCE

- Most common cause of acquired heart disease in children in developed nations.
- Highest incidence in Asian children; 1 in 100 Japanese children develops Kawasaki disease (KD) by age 5 years.
- KD is a multisystem inflammatory process of unknown but suspected infectious etiology.
- KD affects all blood vessels in the body, particularly medium-sized arteries such as the coronary arteries.
- Major symptoms are prolonged high fever, conjunctival injection, oral mucosal changes such as red lips and pharynx and strawberry tongue, redness and swelling of the hands and feet, erythematous polymorphic rash, and cervical lymphadenopathy.
- Inflammation in the coronary arteries can lead to aneurysms with subsequent myocardial infarction, aneurysm rupture, and sudden death.
- Treatment with intravenous immunoglobulin (IVIG) and aspirin, when given in the first 10 days of fever, reduces the prevalence of coronary artery abnormalities from 25% in those treated with aspirin alone, to 5% in those who receive IVIG with aspirin.
- Long-term complications are confined to the heart and vascular tree, primarily thrombosis and stenosis of the major coronary arteries with myocardial ischemia.

Kawasaki disease (KD), the leading cause of acquired heart disease in children in developed nations, is a multisystem inflammatory illness that particularly affects blood vessels, especially the coronary arteries. About 25% of untreated children develop coronary artery abnormalities, including dilatation and aneurysms that can lead to myocardial infarction and sudden death.[1,2] The etiology is unknown, but clinical and epidemiologic data support an infectious cause. In KD, an intense inflammatory cell response develops in a wide array of organs and tissues[3]; in medium-sized arteries such as the coronary arteries, this response can damage collagen and elastin fibers in the vessel walls and lead to loss of their normal structural integrity with resultant ballooning or aneurysm formation. Despite a limited understanding of KD pathogenesis, a very effective therapy exists in the form of IVIG and aspirin; when given in the first 10 days of fever, this therapy reduces the prevalence of coronary artery abnormalities from 25% in untreated patients to 5% in those who receive the therapy.[4] Because the etiology is unknown, no diagnostic test exists, and the diagnosis is made clinically. Classic KD is diagnosed in a patient with prolonged fever and four of five other clinical findings (Box 167-1). However, incomplete forms of illness are well-recognized, in which a child manifests prolonged fever with fewer than four other clinical features of the illness and subsequently develops coronary artery abnormalities. The existence of these incomplete forms of illness results in a major diagnostic dilemma for physicians in establishing the diagnosis accurately in children with prolonged fever of uncertain cause.

HISTORICAL ASPECTS

KD is named for Dr. Tomisaku Kawasaki, a Japanese pediatrician who first recognized the clinical features of the illness. He described 50 cases of a new illness in 1967 in the Japanese-language literature that he termed

BOX 167-1 DIAGNOSTIC CRITERIA FOR CLASSIC KAWASAKI DISEASE

Fever ≥5 days,[a] high spiking and intermittent, with at least four of the five clinical features[b]

1. Bilateral nonexudative conjunctival injection
2. Oral mucosal changes, including red, dry, cracked lips, pharyngeal erythema, and/or strawberry tongue
3. Changes of the hands and feet: erythema of palms and soles and/or swelling of the hands and feet during the acute phase, and/or periungual desquamation of the fingers and toes during the subacute phase
4. Rash: erythematous maculopapular, scarlatiniform, or erythema multiforme
5. Cervical lymphadenopathy ≥1.5 cm in diameter

[a]The diagnosis can be made before the fifth day of fever by experienced physicians if the patient has the other clinical features of the illness.
[b]In the absence of another explanation for the illness.

mucocutaneous lymph node syndrome.[5] It was not until later that some of the children with this newly described illness experienced sudden death; autopsy revealed myocardial infarction from thrombosis of coronary artery aneurysms. Prior to Dr. Kawasaki's description of the clinical features, KD was recognized only by pathologists at autopsy, who called the disease "infantile periarteritis nodosa."[6] Dr. Kawasaki described the illness in the English-language literature in 1974; this report was closely followed by a description of the same illness, observed independently in the early 1970s in Hawaii by Dr. Marian Melish and colleagues.[7,8] Since that time, it has become clear that although the attack rate of KD is highest in Asian, particularly Japanese, Korean, and Chinese children, all racial and ethnic groups around the world are affected by the illness.

EPIDEMIOLOGY

KD is predominantly an illness of young children, with 80% of cases occurring in children ages 6 months to 5 years.[9,10] However, infants less than 6 months of age can be affected, often manifest incomplete forms of the illness, and can have particularly severe KD.[11,12] Similarly, KD can occur in older children and teenagers, in whom the diagnosis is often delayed, and who may also have more severe KD with a higher prevalence of coronary artery abnormalities.[13–15] Therefore, the diagnosis must be considered in all pediatric age groups.

Boys are more commonly affected than girls at a ratio of 3:2. The incidence of KD is approximately tenfold higher in Japanese than in Caucasian children.[9,10] About 1 in 100 Japanese children develop KD by the age of 5 years; the peak age of illness is 9–11 months of age in both Japan and the United States.[9,16] The higher attack rate in Japanese children persists in those who adopt a Western diet and lifestyle, and is likely related to a genetic predisposition to KD among Asian children.[17] The risk of KD in siblings is tenfold higher than in the general population, and the incidence of KD in children born to parents who had KD is twice as high as in the general population.[18,19] Recurrence is rare, occurring in about 3% of cases in Japan.[16]

Many epidemiologic features of KD suggest an infectious agent is the cause. Among these are the well-described epidemics of illness[17,20–22] and the geographic wave-like spread of illness during an epidemic, compatible with spread of an infectious agent.[22] Cases in the United States are more common in the winter and spring.[9]

ETIOLOGY AND PATHOGENESIS

The etiology of KD remains unknown. The hypothesis that best fits the available clinical, immunologic, and epidemiologic data is that KD results from infection with a ubiquitous etiologic agent that usually results in asymptomatic infection, but causes KD in a small subset of genetically predisposed individuals. Genetic predisposition is a common theme in susceptibility and host response to infectious diseases. It is likely that KD is polygenic. Intensive investigation of genetic factors influencing susceptibility to KD is ongoing by several international collaborative groups. A functional polymorphism in the *ITPKC* gene, which is a negative regulator of T-cell activation, has been associated with KD susceptibility and risk of developing coronary artery abnormalities[23]; it is likely that other susceptibility genes will be discovered in the near future.

KD is often referred to as an autoimmune illness, but there is no compelling reason to classify it as such. The spontaneous resolution of the febrile phase of illness, the rarity of recurrent KD, and the fact that the highest incidence occurs in male infants, a group who rarely develop autoimmune diseases, all argue strongly against this possibility. Immune complexes, although detectable in serum in the subacute phase, are not deposited in tissues and do not appear to play a prominent role in pathogenesis. Although inflammation in KD results in tissue damage, the damage is likely to be primarily the result of an immune response targeting antigen(s) of an infectious agent in the tissue.

Many cytokines are upregulated in KD, which has led some investigators to propose a superantigen as the cause of the illness. However, cytokines are upregulated in many infectious diseases, and the cardinal feature of a superantigen-mediated illness, the paralysis of adaptive immunity,[24] is not observed in acute KD. Oligoclonal, antigen-driven CD8 T lymphocyte,[25] IgA plasma cell,[26] and IgM B lymphocyte[27] adaptive immune responses are detected in acute KD.

In KD, an intense inflammatory cell infiltrate is observed in many organs and tissues, particularly in the medium-sized arteries.[3] These inflammatory cells secrete matrix metalloproteinases and other enzymes that can disrupt collagen and elastin fibers in the coronary arteries, impairing the integrity of the arterial wall

and resulting in ballooning or aneurysm formation.[28] The initial insult that causes this immune response is unknown, but the nature of the inflammatory cell infiltrate provides clues. Although neutrophils contribute to the very early inflammatory-cell infiltrate in KD tissues, they are quickly replaced by large mononuclear cells and lymphocytes.[2] By two weeks after the onset of fever, the inflammatory infiltrate in the arterial walls largely consists of T lymphocytes (predominately CD8 T lymphocytes), macrophages, plasma cells (predominately of the IgA isotype), and eosinophils.[29,30] IgA plasma cells are increased in the respiratory tract, particularly in a peribronchial distribution.[31] The presence of IgA plasma cells and CD8 T cells as primary components of the inflammatory infiltrate in acute KD suggests an immune response to an intracellular pathogen with a respiratory portal of entry.[29] Sequencing of IgA genes in the arterial walls in acute KD shows an oligoclonal, or antigen-driven, response.[26] Synthetic versions of these oligoclonal IgA antibodies identify antigen in acute KD tissues.[32] Light and electron microscopic studies show that the antigen detected by KD synthetic antibodies resides in cytoplasmic inclusion bodies that are consistent with aggregates of viral protein and RNA.[33,34] Identification of the specific proteins and RNA in the inclusion bodies should lead to identification of the etiologic agent of KD. These studies are hampered by the lack of unfixed tissue specimens from fatal cases, and by the likelihood that the etiologic agent is an RNA virus without significant homology to known viruses, thereby making its RNA sequence difficult to identify.[34] It is hoped that advances in high throughput sequencing and bioinformatics analysis will yield the solution to the mystery of the etiology of KD in the near future.

CLINICAL FINDINGS

CLASSIC DIAGNOSTIC CRITERIA FOR KD

A diagnosis of classic KD is made in the presence of prolonged fever ≥5 days, with four of the following five clinical features in the absence of another explanation for the illness: (1) nonpurulent bulbar conjunctival injection (Fig. 167-1); (2) red, swollen, dry lips, which may crack and bleed (Fig. 167-1); (3) redness and swelling of the hands and feet; (4) rash; and (5) cervical lymphadenopathy, ≥1.5 cm in diameter. Experienced physicians can make a diagnosis of KD before the fifth day of fever in children with classic features. A patient with prolonged fever and fewer than four of the other features of the illness can be diagnosed with KD if coronary artery abnormalities develop. Incomplete (or atypical) KD refers to children with prolonged fever and fewer than four of the other features of illness who have a laboratory profile compatible with KD. Such patients should undergo echocardiography and be considered for treatment with IVIG because KD patients, particularly infants, do not always manifest classic diagnostic criteria during the acute febrile phase of illness, yet can develop coronary artery abnormalities (Box 167-1).

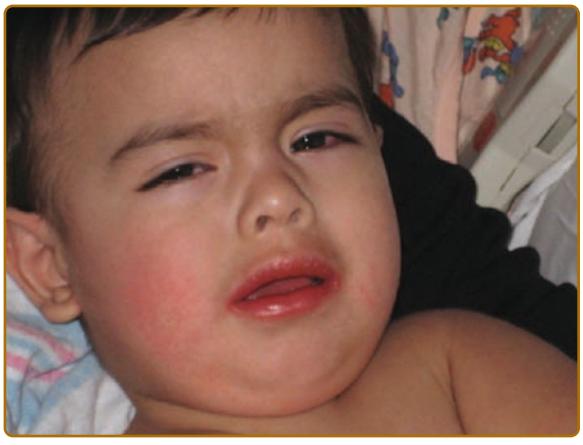

Figure 167-1 Typical facial features of acute Kawasaki disease showing conjunctival injection and red dry lips.

HISTORY

KD should be considered in the differential diagnosis of any child with prolonged fever without other explanation. In KD, all clinical features may not be present simultaneously. Therefore, it is important to query parents and physicians who saw the patient during the course of a prolonged febrile illness as to the presence of the other five clinical features of the illness: (1) conjunctival injection, (2) oral mucosal changes, (3) changes of the hands and feet, (4) rash, and (5) cervical adenopathy. Children with KD often have significant enough swelling and discomfort of the hands and feet that they will refuse to pick up objects or to walk. This is not commonly observed in children with most other illnesses in the differential diagnosis of KD and can provide an important clue to the diagnosis. Similarly, extreme irritability is common in KD and not as common in most other illnesses in the differential diagnosis. Without specific therapy, fever in KD is daily, high spiking, intermittent, and lasts for one to two weeks. The illness is often divided into three stages: (1) the acute febrile phase, (2) the subacute phase (that begins when fever resolves and continues until all clinical features have normalized), and (3) the convalescent phase (that follows the subacute phase and continues until the erythrocyte sedimentation rate (ESR) normalizes, usually at 6–8 weeks after the onset of fever).

CUTANEOUS FEATURES

Rash is commonly observed in KD, is most pronounced on the trunk and extremities, and generally takes one of three forms: (1) an erythematous maculopapular exanthema (Fig. 167-2), (2) erythema multiforme with typical target lesions, or (3) a scarlatiniform exanthema. Bullae, vesicles, and ulcerative lesions are not observed, but a fine micropustular rash, especially on the extensor surfaces, occasionally occurs. The rash may be pruritic. In the acute febrile phase of illness, groin erythema and desquamation are commonly observed (Fig. 167-3), and can be mistaken for candidal diaper dermatitis

Figure 167-2 Erythematous maculopapular exanthema observed in acute Kawasaki disease.

or even a staphylococcal scalded skin syndrome. The skin changes in the groin can be seen both in children in diapers and toilet-trained children. Classic periungual desquamation of the fingers and toes does not begin until the second to third week after fever begins, and can progress to involve the entire hand and foot (Fig. 167-4); treatment should be administered well before its appearance. In the third to sixth week after illness, transverse lines across the fingernails (Beau lines) are often apparent. These grow out with the nail.

In countries where BCG vaccine is routinely administered, such as in Japan, a common finding in children with KD is erythema and swelling at the site of BCG vaccine; the mechanism is unknown but the process resolves with treatment of KD. Although KD results in a vasculitis affecting all arteries and veins in the body, blood vessels in the skin are not prominently affected, and skin biopsy is not useful for diagnosis because pathologic findings are nonspecific.

RELATED PHYSICAL FINDINGS

Conjunctival injection in KD is bilateral and nonexudative. There may be limbal sparing (Fig. 167-5). Photophobia is a common accompanying feature. Oral findings include red, swollen, dry, cracked lips that may bleed, a "strawberry" tongue, and erythema of the mouth and throat. Oral ulcers are not a feature of KD. Palmar and plantar erythema is a common feature, and there can be an abrupt transition from marked erythema to normal skin at the wrists and ankles. The hands and feet can be edematous and painful. Cervical adenopathy is the least commonly observed clinical feature, occurring in only about 75% of children with classic KD, but can be the most prominent feature in a subset of patients, who are often treated with multiple different courses of antibiotic therapy without improvement before the correct diagnosis is made.[35] Cervical adenopathy is usually unilateral, may or may not be associated with superficial erythema and/or tenderness to palpation, and is nonfluctuant. Because KD is a multisystem inflammatory process, many organs and tissues are involved in the inflammatory process, leading to a variety of associated clinical features (Box 167-2). In particular, arthritis can occur during the acute febrile phase, involving the small interphalangeal joints and larger joints, or may occur during the subacute phase of illness, usually involving the larger joints such as the knees and ankles. Aseptic meningitis is a common finding in patients who undergo lumbar puncture.

Figure 167-3 Erythematous desquamating groin rash of acute Kawasaki disease.

Figure 167-4 Desquamation of the feet in the subacute phase of Kawasaki disease; this process began periungually and progressed to involve the entire soles.

Figure 167-5 Conjunctival injection with limbal sparing in acute Kawasaki disease.

BOX 167-2 ASSOCIATED CLINICAL FEATURES OF KAWASAKI DISEASE

CARDIOVASCULAR
- Coronary artery aneurysms
- Myocarditis
- Pericardial effusion
- Aneurysms of other medium-sized arteries (uncommon)
- Valvular disease (rare)
- Peripheral gangrene (rare)

RESPIRATORY
- Pneumonitis: interstitial or peribronchial infiltrates on chest X-ray, usually without respiratory distress
- Pulmonary nodules (rare)

GASTROINTESTINAL
- Hepatitis
- Obstructive jaundice
- Gallbladder hydrops
- Diarrhea

MUSCULOSKELETAL
- Arthritis

GENITOURINARY
- Urethritis
- Hydrocoele

NEUROLOGIC
- Marked irritability
- Aseptic meningitis
- Facial palsy (uncommon)
- Sensorineural hearing loss (uncommon)

OTHER
- Anterior uveitis
- Erythema and induration at the site of a Bacille Calmette-Guérin (BCG) vaccine

LABORATORY TESTS

In the absence of knowledge of the etiology of KD, a diagnostic test is not available. Laboratory findings in acute KD are nonspecific but quite characteristic. A complete blood count reveals either a normal or elevated white blood cell count with a neutrophil predominance. A low white blood cell count with lymphocyte predominance would be distinctly unusual in KD. A normochromic, normocytic anemia can be present, and resolves spontaneously with resolution of KD. The platelet count is normal in the first week of illness, although thrombocytopenia has been reported to be associated with a more severe outcome. Thrombocytosis, with platelet counts sometimes exceeding 1,000,000/mm^3, is characteristic of the subacute phase of KD, peaking in the second to third week after the onset of fever. This feature, like periungual desquamation, is not useful in making a diagnosis of KD in the first week of fever. Patients with anemia and low albumin levels may be at higher risk of developing coronary artery disease. A mild elevation of the liver transaminases is commonly observed in acute KD. Occasionally, obstructive jaundice occurs. Gallbladder hydrops, with accompanying right upper quadrant abdominal pain, resolves spontaneously and does not require surgical intervention. Sterile pyuria is also commonly observed. Acute-phase reactants such as the C-reactive protein (CRP) and the ESR are characteristically elevated in patients with acute KD, and the CRP is sometimes used to follow clinical response in patients refractory to IVIG therapy. Once IVIG is given, the ESR cannot be used to follow clinical response, because IVIG itself transiently increases the ESR.

SPECIAL TESTS

To determine whether a child with KD develops coronary artery dilatation, an echocardiogram should be performed at diagnosis, at 2–3 weeks after fever onset, and at 6–8 weeks after fever onset.[36] A complete blood count and CRP or ESR are also repeated at 2–3 weeks and 6–8 weeks after onset to monitor for resolution of inflammation. The peak time to detect coronary artery dilatation is 2–3 weeks after onset of fever, during the subacute phase of illness. Some centers perform an additional echocardiogram at 1 year after onset, but it is rare to find any evidence of coronary artery abnormalities at 1 year that were not present within the first two months after fever began. Electrocardiogram most often shows a prolonged PR interval and/or nonspecific ST- and T-wave changes.

DIFFERENTIAL DIAGNOSIS

The KD child with prolonged high fever, marked conjunctival injection, red, swollen hands and feet, erythematous rash, and red, cracked, bleeding lips who has a markedly elevated ESR and/or CRP and an elevated peripheral white blood cell count with a neutrophil predominance has a very distinctive illness and usually does not pose any difficulties in diagnosis. In other patients who have only some of the clinical features of KD, or in whom clinical findings are not as dramatic, other diagnoses must be carefully considered (Box 167-3).

In areas where measles is still prevalent, differentiating the two disorders can be difficult. Classically, patients with measles have rash that begins on the face behind the ears and Koplik spots in the mouth; neither of these features is observed in KD. Later in the course of measles infection, the rash becomes diffuse and Koplik spots are no longer visible. Conjunctival injection and edema of the hands and feet can be observed in both disorders. In uncomplicated measles, the peripheral white blood cell count and the erythrocyte sedimentation rate are generally low. The measles IgM antibody is virtually always

BOX 167-3 DIFFERENTIAL DIAGNOSIS OF KAWASAKI DISEASE

- Measles
- Adenovirus infection
- Enterovirus infection
- Scarlet fever
- Staphylococcal scalded skin syndrome
- Toxic shock syndrome
- Drug hypersensitivity reaction
- Juvenile rheumatoid arthritis

If Patient has Epidemiologic Risk Factor:

- Rocky Mountain spotted fever
- Leptospirosis

positive by the appearance of the measles rash, and is the best single test to differentiate the two conditions.

Group A streptococcal infection should be considered in the differential diagnosis of a KD patient with a scarlatiniform rash, and can be excluded by a negative throat culture. Diagnostic uncertainty could arise in a KD patient who is a group A streptococcal carrier. Administration of antibiotic therapy followed by reevaluation in 24–48 hours generally clarifies the diagnosis; children with group A streptococcal pharyngitis have a rapid response to therapy, while antibiotics are ineffective in KD. Adenovirus infection can mimic KD. The presence of exudative conjunctivitis and exudative pharyngitis suggests adenovirus as the most likely diagnosis. Other viruses can occasionally cause prolonged fever, such as enterovirus; in differentiating KD patients from those with uncomplicated viral infection, laboratory tests such as the ESR, CRP, and urinalysis can be helpful, as pyuria and markedly elevated acute-phase reactants are more typical of KD.

Drug hypersensitivity reactions can mimic KD. Oral and mucosal ulcers observed in Stevens–Johnson syndrome are absent in KD. Edema of the face, particularly around the eyes, is much more suggestive of drug reaction than KD. In general, the ESR and CRP are either normal or only mildly elevated in drug hypersensitivity reactions.

Staphylococcal scalded skin syndrome (SSSS) is easily distinguished by the classic finding of painful skin in SSSS, which is not observed in KD, and by Nikolsky sign, which is present in SSSS and absent in KD.

Although hypotension is unusual in KD, it occurs occasionally,[37,38] and toxic shock syndrome is in the differential diagnosis of such patients. Renal involvement and elevated creatinine phosphokinase are more likely to be observed in toxic shock syndrome than in KD. IVIG administered for a possible diagnosis of KD may serve as adjunctive therapy for toxic shock syndrome.

Juvenile rheumatoid arthritis is a diagnosis of exclusion, and an occasional patient with this disorder might initially be diagnosed with and treated for incomplete KD. The correct diagnosis may become apparent when fever recurs following reduction of high-dose aspirin therapy, implying an original clinical response to aspirin rather than to IVIG.

The following are in the differential diagnosis of KD in the appropriate epidemiologic context: (1) leptospirosis, which predominately occurs in tropical climates; (2) Rocky Mountain spotted fever, which tends to be highly regional in incidence; and (3) mercury poisoning, now quite rare.

DIAGNOSIS OF INCOMPLETE KD

The American Heart Association Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease has published an algorithm to assist the clinician in diagnosing incomplete KD.[36] This algorithm emphasizes the importance of combining clinical features, laboratory findings, and echocardiographic findings in making a diagnosis (see Box 167-4). In difficult cases, consultation with a KD expert should be considered. If the patient is not treated for KD but develops typical periungual desquamation after fever has resolved, and an alternative diagnosis that could explain this clinical finding has not been established (such as scarlet fever), an echocardiogram should be repeated. Infants ≤6 months of age can have mild or subtle clinical findings with KD, but have a high risk of developing coronary artery abnormalities. Therefore, infants with fever for a week or more without other explanation should have laboratory testing performed. If evidence of an inflammatory process is present, an echocardiogram should be ordered and KD considered, even in the absence of other clinical features of the illness.

COMPLICATIONS

KD can result in myocardial infarction, aneurysm rupture, and sudden death. Myocardial infarction can occur from thrombosis of an aneurysm, which is most common in the first few months after the onset, or from coronary artery stenosis, which occurs months to years following the illness. Aneurysm rupture is less common and usually occurs within the first month after the onset. More than 50% of KD patients have myocarditis during the acute febrile phase, manifested clinically as tachycardia out of proportion to fever, which generally improves rapidly with IVIG therapy. In the acute phase of illness, a pericardial effusion can be present; this resolves spontaneously. In patients with the most severe coronary artery aneurysms, aneurysms of other medium-sized arteries can also be observed, most commonly in the iliac, femoral, and axillary arteries. Rarely, valvulitis significant enough to require valve replacement has been reported. Although KD is a systemic inflammatory disease affecting multiple organs and tissues, there are no known long-term consequences of the disease outside of the heart and blood vessels.

PROGNOSIS/CLINICAL COURSE

About 85% of KD children treated with IVIG and aspirin within the first 10 days of illness respond with rapid

BOX 167-4 CRITERIA FOR DIAGNOSIS OF INCOMPLETE KAWASAKI DISEASE[a]

Fever for ≥5 days with two or three compatible clinical features of KD and

- ESR ≥40 mm/h and/or CRP ≥3.0 mg/dL
  - If patient has at least three compatible laboratory features,[b] perform echocardiogram and begin treatment
  - If patient has fewer than three compatible laboratory features,[b] but has dilated coronary arteries by echocardiogram (Z score of LAD or RCA ≥2.5), begin treatment
  - If patient has fewer than three compatible laboratory features[b] and LAD and RCA Z scores <2.5, but has at least three supportive echocardiographic features,[c] begin treatment.
  - If patient has fewer than three compatible laboratory features,[b] LAD and RCA Z scores <2.5, and fewer than three supportive echocardiographic features,[c] then follow patient and consider other diagnoses. If fevers persist and no other diagnosis is established, consider repeating laboratory tests and echocardiogram and consider consulting a KD expert. If fever resolves, KD is unlikely.
- ESR <40 mm/h and/or CRP <3.0 mg/dL
  - Follow patient. If fever continues, reevaluate clinically and consider repeating ESR and CRP. If fever resolves but patient develops typical periungual desquamation, perform echocardiogram.

[a]Adapted from Newburger JW et al: Diagnosis, treatment, and long-term management of Kawasaki disease: A statement for health professionals from the Committee on Rheumatic Fever, Endocarditis and Kawasaki Disease, Council on Cardiovascular Disease in the Young, American Heart Association. *Circulation* **110**(17):2747-2771, 2004

[b]Compatible laboratory features:
1. Albumin ≤3.0 g/dL
2. Anemia for age
3. Elevated alanine aminotransferase
4. Platelet count ≥450,000/mm^3 after the 7th day of illness
5. WBC ≥15,000/mm^3
6. Urinalysis with ≥10 WBC/high power field

[c]Supportive echocardiographic features:
1. Perivascular brightness
2. Lack of tapering
3. Decreased left ventricular function
4. Mitral regurgitation
5. Pericardial effusion
6. Z scores of LAD or RCA of 2–2.5

LAD = left anterior descending coronary artery
RCA = right coronary artery

resolution of fever and other clinical signs. Only 5% of KD patients treated within the first 10 days of fever develop coronary artery abnormalities.[4,39] Therefore, the vast majority of KD patients who are promptly diagnosed and treated do well, without developing cardiac complications. However, about 15% of KD children treated within the first 10 days of illness continue to have fever following a single infusion of IVIG with aspirin and require additional therapy; these patients have a higher risk of developing coronary artery abnormalities.[40,41] Long-term studies show that coronary artery abnormalities regress in 50% of patients by 1–2 years after the onset.[42] The larger the aneurysm, the less likely it is to regress. Giant coronary artery aneurysms, classically defined as those ≥8-mm internal diameter, almost never regress.[43] Regression of an aneurysm usually is accompanied by intimal proliferation, which can be significant enough in large aneurysms to lead to coronary artery stenosis and an increased risk of myocardial infarction.[44] In young infants and children, myocardial infarction usually presents as shock, emesis, and/or abdominal pain.[44] Patients with significant coronary artery disease may require catheter intervention procedures,[45] coronary artery bypass surgery,[46] or rarely, heart transplantation.[47] Cardiovascular risk assessment should be performed at intervals dependent upon the severity of coronary artery abnormalities.[36]

TREATMENT

A single infusion of 2 g/kg IVIG with aspirin (80–100 mg/kg/day given every 6 hours orally) should be administered to children with acute KD as soon as possible after diagnosis (Box 167-5).[39] This regimen, when administered to children with KD within the first 10 days of fever, reduces the prevalence of coronary artery abnormalities from 25% in untreated patients to 5% in those who receive the therapy. Most children experience rapid resolution of fever and other clinical signs following treatment, as well as improvement in acute-phase reactants. The mechanism of action of IVIG in KD is unknown.

Aspirin is given in high doses during acute KD for anti-inflammatory effect. It is generally continued at 80–100 mg/kg/day until the 14th illness day, or until the patient has been afebrile for at least 2–3 days. Aspirin is then reduced to 3–5 mg/kg/day given in a single daily dose, for its antithrombotic effect. Aspirin is discontinued at 6–8 weeks after onset if all echocardiograms have been normal and acute-phase reactants have normalized. If coronary artery abnormalities develop,

BOX 167-5 TREATMENT OF ACUTE KAWASAKI DISEASE

Intravenous gammaglobulin (IVIG) 2 g/kg infused over 10–12 hours; monitor vital signs carefully during infusion, with aspirin 80–100 mg/kg/day divided every 6 hours orally until the 14th illness day or until patient is afebrile for at least 2–3 days, then reduce dose to 3–5 mg/kg/day as a single daily dose. Aspirin is discontinued if echocardiograms at 2–3 weeks and 6–8 weeks are normal and when acute-phase reactants have normalized.

low-dose aspirin is continued. Depending upon the severity of coronary artery disease, other therapies such as clopidogrel or warfarin may be indicated[36]; such decisions should be made in consultation with a pediatric cardiologist. Intravenous methylprednisolone is not indicated for primary therapy of acute KD.[48]

IVIG and aspirin is also given to KD patients who present after the tenth day of illness if fever and/or clinical and laboratory signs of ongoing inflammation are present, although the efficacy of the therapy in this clinical situation is uncertain. About 15% of acute KD patients do not respond to initial therapy; optimal therapy for these patients with "refractory" KD is unknown. Most of these patients will respond to a second 2 g/kg IVIG infusion.[40,41] In those who remain febrile after a second IVIG infusion, intravenous methylprednisolone once daily for 3 days or infliximab have been given with apparent success.[49–51] More specific therapy awaits the identification of the cause of KD.

PREVENTION

Prevention of KD will not be possible until the etiology of the illness is identified.

Chapter 168 :: Pigmented Purpuric Dermatoses

:: Theresa Schroeder Devere, & Anisha B. Patel

PIGMENTED PURPURIC DERMATOSES AT A GLANCE

- A group of dermatoses characterized by petechiae, pigmentation, and, occasionally, telangiectasia.
- Are found most commonly on the lower extremities; however, the lesions may involve the upper body and rarely become generalized.
- Are benign, generally asymptomatic eruptions that tend to be chronic with remissions and flares.
- Share common histopathology features, including capillaritis, erythrocyte extravasation, and hemosiderin deposition.
- Clinical variation between eruptions led to their subclassification into eponymic groups.
- Frequent overlap may make differentiation difficult.

The pigmented purpuric eruptions are a group of dermatoses characterized by petechiae, pigmentation, and, occasionally, telangiectasia in the absence of associated venous insufficiency or hematologic disorders (Table 168-1). Synonyms include *persistent pigmented purpuric dermatitis*, *purpura simplex*, and *purpura pigmentosa chronica*. They are found most commonly on the lower extremities; however, the lesions may involve the upper body and rarely become generalized. There are reports of palm, sole, genital, and oral mucosal involvement. These benign, generally asymptomatic eruptions tend to be chronic, with remissions and flares. They share common histopathology features, including capillaritis, erythrocyte extravasation, and hemosiderin deposition.

EPIDEMIOLOGY

Pigmented purpuric eruptions are rare. There seems to be no ethnic or gender predisposition, and most patients are in their 30s and 40s (see Table 168-1), but children may be affected.

PATHOGENESIS

There are three different views of the pathogenesis of pigmented purpuric eruptions. The first is that they are

TABLE 168-1
Pigmented Purpuric Eruptions

	Schamberg	Majocchi	Gougerot and Blum	Doucas and Kapetanakis	Itching Purpura	Lichen Aureus
Average age	40s	30s	40s	40s	50s	20s–30s

F = female; M = male.

due to a disturbance or weakness of the cutaneous blood vessels, leading to capillary fragility and erythrocyte extravasation. However, this does not account for the inflammatory infiltrate common to these disorders. The second proposed mechanism is humoral immunity. This suggested pathogenesis is supported by direct immunofluorescent studies showing vascular deposition of C3, C1q, immunoglobulin M, or immunoglobulin A. However, several cases have not shown these deposits. The third proposed mechanism is cellular immunity.[1,2] The infiltrate in pigmented purpuric dermatoses consists of lymphocytes, macrophages, and Langerhans cells. This inflammatory infiltrate leads to vascular fragility and subsequent leakage of erythrocytes. Aiba and Tagami used immunohistologic studies in eight cases of Schamberg disease to demonstrate that the dermal infiltrate was predominantly composed of helper–inducer T cells and OKT6-reactive cells,[3] whereas the epidermis showed intercellular staining with human leukocyte antigen (HLA)-DR antibody and OKT6 antibody. Based on this study, they concluded that a cellular immune reaction, specifically the Langerhans cell, likely plays an important role in the pathogenesis.

Pigmented purpuric dermatoses may be induced by drugs (Table 168-2),[4–17] but other causes have also been implicated (Table 168-3).[18–25] The mechanism behind drug-induced or other causes may be immune-mediated; however, this is unproven. There could be familial involvement, as was shown in a handful of cases, with one report consistent with an autosomal dominant inheritance pattern.[26] Gravity and increased venous pressure may account for the lesions localizing to the lower extremities.

TYPES OF PIGMENTED PURPURIC DERMATOSES

PROGRESSIVE PIGMENTARY DERMATOSIS (SCHAMBERG DISEASE)

Schamberg first described in 1901 a pigmented eruption on the legs of a 15-year-old boy that consisted of irregularly shaped reddish-brown patches with "pin head sized reddish puncta, closely resembling grains of cayenne pepper."[27]

Although described in children and adolescents, the average age of onset of Schamberg disease is in the fifth decade.[28] The lesions tend to develop insidiously on either or both lower legs. Lesions can involve the trunk or the upper extremities (Figs. 168-1 and 168-2). Schamberg disease is generally asymptomatic and persistent. Remissions and flares can occur indefinitely.

PURPURA ANNULARIS TELANGIECTODES (MAJOCCHI PURPURA)

The original case of purpura annularis telangiectodes, described by Majocchi in 1896, was a 21-year-old man with annular patches of follicular and punctate

reddish-brown macules, with telangiectasias and purpura on the lower extremities.[29] The annular pattern is the distinctive characteristic of this subtype (Fig. 168-3). The individual lesions may have central hypopigmentation and slight atrophy, with peripheral telangiectasias. Linear and irregularly shaped patterns may also occur. The lesions most often present symmetrically on the lower extremities; however, the upper extremities and trunk may be involved. The lesions are asymptomatic and usually last several months with relapses and remissions. This subtype occurs more commonly in young adult females.

Figure 168-1 Pigmented purpuric dermatosis: Schamberg disease. Multiple, discrete, and confluent nonpalpable, nonblanching purpuric lesions of many months' duration on the legs. Acute microhemorrhages resolve with deposition of hemosiderin, creating a disfiguring dark-brown peppered stain.

Figure 168-3 Pigmented purpuric dermatosis: Majocchi disease. Multiple nonpalpable, nonblanching purpuric lesions arranged in annular configurations and associated with tiny telangiectasias. Note brownish discoloration of older lesions.

Figure 168-4 Lichenoid dermatosis of Gougerot and Blum. (Used with permission from S. Mallory, MD.)

PIGMENTED PURPURIC LICHENOID DERMATOSIS (GOUGEROT AND BLUM)

In 1925, Gougerot and Blum reported a pigmented eruption on the lower extremity of a 41-year-old man.[30] The distinguishing feature of this subtype is the primary lesion, a reddish-brown polygonal or round lichenoid papule, in association with purpura or telangiectasia. Individual papules frequently coalesce into plaques with or without overlying scale. The term *lichenoid* describes the clinical appearance rather than a histologic feature. The color and morphology of the lesions can be mistaken clinically for Kaposi sarcoma (Fig. 168-4). Like the other subtypes, this eruption is found on the lower extremities and, occasionally, the arms. It occurs in males more often than females and has a chronic course.

ECZEMATID-LIKE PURPURA OF DOUCAS AND KAPETANAKIS

Doucas and Kapetanakis reported a group of patients with an asymptomatic seasonal eruption occurring in the spring and summer.[31] Its distinguishing quality is the mild scale overlying the typical patches and pinpoint erythematous macules. These spread rapidly over a period of 15–30 days, involving the legs and, occasionally, the upper body. This eruption fades without treatment over several months to years.

Figure 168-5 Disseminated pruriginous angiodermatitis (itching purpura). (Used with permission from S. Mallory, MD.)

ITCHING PURPURA (DISSEMINATED PRURIGINOUS ANGIODERMATITIS)

The acute onset and widespread involvement of orange–brown to purpuric macules with severe pruritus distinguishes itching purpura (Fig. 168-5).[32,33] It usually appears first on the lower extremities and may become generalized. This disorder also has a chronic course, but there can be spontaneous remissions. Middle-aged men are most commonly affected.

LICHEN AUREUS (LICHEN PURPURICUS)

Marten first coined the term "lichen purpuricus" in 1958,[34] and Calnan later termed the same eruption "lichen aureus."[35] In this condition, *lichen* refers to the clinical and histopathologic descriptions. A dense, band-like, dermal, inflammatory infiltrate differentiates lichen aureus from the other pigmented purpuric dermatoses. Clinically, there are circumscribed areas of confluent gold to copper-orange to, less commonly, purple macules or papules (Fig. 168-6). Although these lesions may be intensely pruritic, they are typically asymptomatic. They are most commonly unilateral and localized on the lower extremities, but they can affect the forearms and trunk. This disorder has a predilection for young adults, with a peak incidence in the second and third decades. The lesions tend to be chronic, remaining stable or progressing slowly. Spontaneous resolution rarely occurs in adults, but in children the eruption may be self-limited.

Figure 168-6 Lichen aureus. (Used with permission from S. Mallory, MD.)

UNILATERAL LINEAR CAPILLARITIS (SEGMENTAL PIGMENTED PURPURA)

Riordan et al reported a linear and pseudodermatomal distribution of pigmented purpura in four young men (average age, 22 years), which they called "unilateral linear capillaritis."[36] Both "segmental pigmented purpura" and "quadrantic capillaropathy" are considered variants of this linear pigmented purpura.[37,38] The patients all had a macular, pigmented, unilateral eruption involving the foot, leg, or buttock. Clinically, the lesions most closely represented lichen aureus; however, the pathology did not show a lichenoid infiltrate. Furthermore, all four cases resolved spontaneously in approximately 2 years, unlike the typically chronic course of lichen aureus. Two more cases were reported in a young woman and man, both in their 20s and both with involvement of their arms. The lesion in the male was self-resolving, similar to previously reported cases, and the female's lesion resolved with PUVA.[39] There are also several reported cases of segmental or zosteriform lichen aureus and Schamberg disease. Two cases have been associated with trauma, and one case preceded the development of localized morphea.[38,40–51]

GRANULOMATOUS PIGMENTED PURPURA

Saito and Matsuoka first reported a granulomatous variant of pigmented purpuric dermatosis in 1996,[52] and Wong reported two additional cases.[53] The mean age of onset was 59 years; all patients were of Asian descent, and all occurred only on the dorsum of the feet. Additional cases have been reported in a Caucasian female with lesions on her lateral ankles[54] and four more patients of Asian descent with involvement of the hands and wrists.[55] The scope of this variant appears to be expanding. Histopathologic examination showed a dense mononuclear cell infiltrate with granulomas in the papillary dermis, thickened capillaries, vascular proliferation, melanophages, and hemosiderin deposits. The duration of the lesions ranged from 2 months to 20 years.

PIGMENTED PURPURIC DERMATOSIS/ MYCOSIS FUNGOIDES OVERLAP

The first cases of pigmented purpura-like eruptions progressing to mycosis fungoides were reported in 1988 by Barnhill and Braverman.[56] Further, the first patient diagnosed with lichen aureus in the United States was later diagnosed with mycosis fungoides. Some evidence supports the idea that lichenoid variants of pigmented purpuric dermatoses may be precursors of mycosis fungoides, with similar histologic findings and clonal populations of lymphocytes.[57–64] Is there a relationship between the two disorders, or are these cases of mycosis fungoides merely mimicking pigmented purpura clinically? Although there is no clear connection between the two diseases, three different relationships have been reported: mycosis fungoides presenting as pigmented purpura, pigmented purpura evolving into mycosis fungoides, and pigmented purpura that simulates mycosis fungoides histologically. The latter may explain why similar treatments are used for both.[65] In a study of T-cell clonality and markers, T-cell monoclonality of PPD was most likely to predict a progression to mycosis fungoides. The absence of certain T-cell markers was less reliable predictor. Histologic clues were subtle, including greater lymphoid atypia in the intraepidermal lymphocytes as opposed to the dermal lymphocytes, but both subsets of PPD had a degree of lymphoid atypia, lichenoid infiltrates, and epidermotropism.[66] Differentiating between the two can be difficult, and clinical and histologic information, as well as immunophenotypic and genetic studies may be necessary.[65,67] Pigmented purpuric dermatoses with large areas of confluence, reticular arrangements, a superimposed violaceous hue, or pruritus that have been present or relapsing for several years are suspicious for mycosis fungoides. There is predominance for adult males as well.[56,68] Long-term follow-up of these patients is needed to determine if their lesions will evolve into mycosis fungoides.

HISTOPATHOLOGY

The pigmented purpuric dermatoses share similar histopathology. In early lesions, a lymphocytic perivascular infiltrate is found in the papillary dermis with extravasated erythrocytes (Fig. 168-7). The epidermis may show spongiosis and parakeratosis, especially in the pigmented purpuric lichenoid dermatitis of

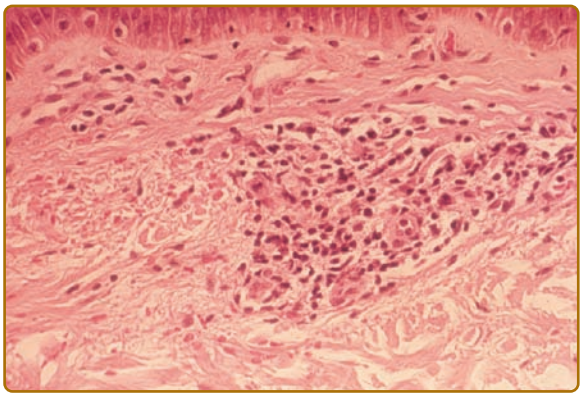

Figure 168-7 Pigmented purpuric dermatosis showing superficial perivascular lymphocytes and extravasated erythrocytes.

Gougerot–Blum and in the eczematid-like purpura of Doucas and Kapetanakis. In older lesions, there is less inflammation, and extravasated red cells may no longer be present. Hemosiderin is deposited primarily in macrophages. In lichen aureus, the mononuclear infiltrate in the upper dermis is distributed in a band-like fashion with a grenz zone.

DIAGNOSTIC STUDIES

Diagnosis is generally made clinically and supported by histopathologic examination. No consistent laboratory abnormalities have been identified. The clinical measurement of capillary fragility by application of a sphygmomanometer (Hess test) does not appear to be reliable, because some reports show an increased capillary fragility in pigmented purpuric eruptions, and others were normal. Review of the patient's medical history, medications, and potential contact allergens is advised. Skin biopsy may be indicated to rule out vasculitis, especially if the lesions are papular. Mycosis fungoides should be considered if the lesions are chronic and unremitting.

DIFFERENTIAL DIAGNOSIS

(Box 168-1)

BOX 168-1 DIFFERENTIAL DIAGNOSIS OF PIGMENTED PURPURIC DERMATOSES

- Contact dermatitis
- Cutaneous necrotizing vasculitis
- Stasis dermatitis and purpura
- Angioma serpiginosum
- Kaposi sarcoma (Gougerot–Blum)
- Mycosis fungoides

MANAGEMENT

Treatment is often ineffective, and most treatments are anecdotal. If the eruption is induced by a drug or contact allergen, discontinuation of the causative drug or contact allergen can lead to complete resolution. However, residual pigmentation may persist for years. Oral bioflavonoid (rutoside, 50 mg bid) and ascorbic acid (500 mg bid) given to three patients with chronic pigmented purpura in an open trial led to clearance in all three patients within 4 weeks.[69] Corticosteroids have been reported to be successful; in particular, triamcinolone spray or potent topical (fluorinated) steroids. Systemic corticosteroids and cyclosporine are often effective but are not indicated due to the benign nature of the disorder.[70] With both topical and systemic steroids, recurrence of the lesions is the rule when steroids are discontinued. Treatment with topical pimecrolimus twice daily cleared lichen aureus lesions in a 10-year-old boy.[71] In a pilot study, calcium dobesilate, 500 mg twice daily, was given to nine patients for 3 months.[72] Seven patients had some mild-to-moderate improvement that was sustained at 1 year after cessation of therapy. Griseofulvin, 500 mg to 750 mg daily, improved existing lesions within a week and stopped new lesions within a mean of 33 days in an open trial of six patients.[73] Colchicine, 0.5 mg twice daily, cleared a 28-year-old woman with recalcitrant Schamberg disease.[74] Minocycline has also been reported to be beneficial. Methotrexate was reported to clear a patient with Majocchi purpura with just 15 mg weekly dosing for 4 weeks, although she had recurrence when the medication was stopped. Again, aggressive therapy is not often warranted for this benign condition, but this patient was treated for her severe burning and pruritus.[75]

Pentoxifylline, which inhibits T-cell adherence to endothelial cells and keratinocytes, may be helpful. A randomized, investigator-blinded trial compared pentoxifylline, 400 mg thrice daily, with topical betamethasone dipropionate cream, 0.05 percent twice daily, for 2 months. Patients treated with pentoxifylline had significantly greater improvement than those treated with the topical steroid. However, the response was not sustained after discontinuation of the medication.[76] Psoralen and ultraviolet A light and narrow band ultraviolet B have both been reported to clear lesions.[77–80] In one case, phototherapy was used to maintain disease suppression while tapering oral prednisolone. The patient remained clear on once every 2-week dosing, but had recurrence when UVB was completely stopped.[81] In the second case, the patient cleared completely with just 30 UVB treatments and remained clear 8 months after stopping.[82] The phototherapy-induced immunosuppression of cell-mediated response is the proposed mechanism.[75] Photodynamic therapy has been reported as beneficial as it affects both immunomodulation and vascular destruction.[83] Supportive stockings should be worn when lesions are on lower extremities.

Chapter 169 :: Cryoglobulinemia and Cryofibrinogenemia

:: Holger Schmid & Gerald S. Braun

CRYOGLOBULINEMIA AT A GLANCE

- Cryoglobulins are circulating immunoglobulin complexes found in plasma or serum that reversibly precipitate in cold temperatures.
- Cryoglobulinemia may be symptomless or cause a clinical syndrome involving the skin: purpura at distal sites is the hallmark. Livedo reticularis, acrocyanosis, ulceration, or gangrene may also be seen.
- Cryoglobulins are classified based on molecular properties into types I, II, III (Brouet classification).
- Type I cryoglobulins consist of a single monoclonal immunoglobulin (typically IgG) or light chain. They occur with hematologic malignancies such as multiple myeloma. If symptomatic, they present with a noninflammatory occlusive vasculopathy.
- Type II cryoglobulins consist of a monoclonal immunoglobulin (typically IgM) complexed with a polyclonal immunoglobulin (typically IgG).
- Type III cryoglobulins consist of purely polyclonal immunoglobulin complexes; type II–III refers to an intermediate state with oligoclonal immunoglobulin.
- Types II and III are also referred to as mixed cryoglobulinemias. They are caused by chronic hepatitis C virus (HCV) infection in >90% of cases, while in a minority of cases no etiology can be identified, designating them as "essential mixed" cryoglobulinemias. They present as the cryoglobulinemic vasculitis syndrome, i.e., an immune complex vasculitis involving the skin, neural, and renal tissues.
- Therapy primarily consists of controlling the underlying malignancy or HCV infection. In addition, immunosuppressants, plasma exchange, or targeting of cryoglobulin-producing B-cell clones may alleviate the cryoglobulin burden.

CRYOGLOBULINEMIA

EPIDEMIOLOGY

Cryoglobulinemia may be a symptomless phenomenon that is incidentally found, or it may produce a clinical syndrome involving the skin as a primary organ. In a historic large-scale examination, 11% of patient sera were shown to have cyoglobulinemia, but detection rates vary greatly with the patient population studied.[1] Reliable figures on the incidence or prevalence of cryoglobulinemia or symptomatic cryoglobulinemic syndrome are lacking. The epidemiologic study is hampered by factors such as selection bias from the referral of patients to tertiary care hospitals,

by the heterogeneity of clinical presentations inclusion criteria, and by the different geographic distribution of underlying etiologies such as HCV infection. There is a geographic predominance of cryoglobulinemia in Southern Europe as compared to Northern Europe or the United States that might be explained by this latter fact. The frequency distribution of different cryoglobulinemia subtypes among all types of cryoglobulinemia is approximately type I 25%, type II 25%, type III 50%, making the mixed cryoglobulinemias (types II and III) the most abundant form.[2] The vast majority (>90%) of mixed cryoglobulinemias occurs in association with chronic HCV infection. Thus, HCV-associated mixed cryoglobulinemia is the form among all cryoglobulinemias that has been studied best. On average, 30% of chronically HCV-infected subjects develop cryoglobulinemia, and this proportion can go up to 90% when patients with very longstanding disease are examined.[3–5] Development of cryoglobulins is more frequent with HCV genotype 1 as compared to genotypes 2 and 3.[6] However, on average, the symptomatic cryoglobulinemic vasculitis syndrome is present in only 2% to 5% of chronically HCV-infected patients[7] though figures as high as 15% have been proposed.[8,9] With a conservatively estimated prevalence of chronic HCV infection of ~1% in mind,[10] the calculated prevalence of HCV-associated cryoglobulinemic vasculitis in the USA would be 20–50 per 100,000. The true prevalence is probably on the lower end of this estimation. Given the increasing proliferation of HCV infection worldwide, rising figures might be expected on a global perspective.[11] The prevalence of "essential mixed cryoglobulinemia," i.e., mixed cryoglobulinemia without an identifiable cause, has been estimated to be 1:100,000 in former studies, with a female-to-male ratio of 3:1. However, this number is difficult to interpret since many cases that are nowadays recognized to be associated with HCV or other viruses were formerly attributed to be "essential."[12]

ETIOLOGY AND PATHOGENESIS

In 1933, Wintrobe and Buell first noted the in vitro phenomenon of cryoprecipitation, i.e., the cold-induced precipitation of plasma or serum proteins that is reversible upon rewarming at 37°C (98.6°F).[13] In 1947, Lerner and Watson described immunoglobulins and mixtures of immunoglobulins with other proteins that precipitate in the cold and called them cryoglobulins.[1] In 1974, Brouet introduced the classification of cryoglobulins based on molecular properties that is currently used.[2] Cryoglobulinemia describes the presence of cryoglobulins in a patient's serum (see Fig. 169-1). It can be asymptomatic, meaning that its presence usually goes undetected outside academic study screening protocols, or it can cause occlusive vasculopathy or the so-called cryoglobulinemic syndrome, which is characterized by immune-complex deposition causing vasculitis that involves the skin and mainly neural and renal tissues.

The classification scheme of Brouet, estimated frequency and composition of cryoglobulins is depicted in Table 169-1. Type-I cryoglobulins consist of a single monoclonal immunoglobulin (Ig), typically IgM, less commonly IgG or IgA or free Ig light chains (Bence Jones proteins). Complement components are not routinely found in type I cryoprecipitates. Type I cryoglobulins are often present in substantial amounts, ranging from 1 to 30 mg/mL. The large molecular size of monoclonal IgM and other molecular characteristics, such as absence of sialic acid moieties, deficient carbohydrate side chains, and weak noncovalent factors may predispose these Igs to precipitation.[14] Type I cryoglobulinemia is associated with hematologic disorders, such as Waldenström macroglobulinemia, multiple myeloma, or lymphoproliferative diseases (e.g., B-cell lymphoma).

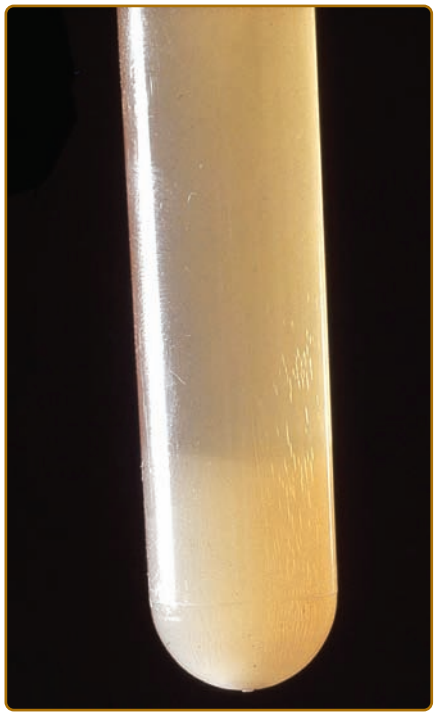

Figure 169-1 Whitish cryoprecipitates after keeping tube at 4°C (39.2°F) for 48 hours and centrifugation.

Type II and type III cryoglobulins are immune complexes composed of polyclonal IgGs and mono- or polyclonal IgMs. Type II and type III cryoglobulins are typically present in relatively small amounts and generally result from chronic inflammatory states. Type II and type III cryoglobulins may fix complement.

Type II cryoglobulins represent a mixture of two Ig components: polyclonal Igs are associated with a monoclonal Ig that exhibits rheumatoid factor (RF) activity. Typically, a monoclonal IgM RF is complexed with a polyclonal IgG. HCV infection is the classical underlying disease.

A mixture of polyclonal Igs or polyclonal Ig-nonimmunoglobulin cryoprecipitates results in detection of type III cryoglobulins. Polyclonal IgM–IgG cryoglobulins with complement as an integral component are the most frequent scenario in type III cryoglobulinemia that is commonly associated with HCV infection or connective tissue diseases.

TABLE 169-1
Types of Cryoglobulins, Composition of Cryoprecipitates and Disease Associations

Type of Cryoglobulinemia (Estimated Frequency)	Composition of Cryoprecipitates	Disease Associations
Type I (25%)	Monoclonal IgM (sometimes IgG, IgA), immunoglobulin light chain, complexed to other proteins	Haematological disorders ■ Multiple myeloma ■ Waldenström macroglobulinemia ■ Plasma cell dyscrasias, monoclonal gammopathy of undetermined significance (MGUS) ■ Other lymphoproliferative diseases with M components
Type II (25%)	Combination of monoclonal (usually IgM with rheumatoid factor activity) and polyclonal (usually IgG)	Chronic infection ■ Viral (HCV) Autoimmune diseases ■ Sjögren syndrome ■ Cold agglutinin disease Haematological disorders ■ Waldenström macroglobulinemia ■ Chronic lymphocytic leukemia ■ B-cell non-Hodgkin lymphoma
Type III (50%)	Polyclonal Igs	Chronic infection ■ Viral (e.g., HCV, HIV, HBV) ■ Bacterial (e.g., subacute bacterial endocarditis, leprosy, spirochetal) ■ Fungal, parasitic Autoimmune diseases ■ Systemic lupus erythematosus ■ Rheumatoid arthritis ■ Dermatomyositis/polymyositis ■ Inflammatory bowel diseases ■ Biliary cirrhosis
Type II–III (frequency unknown)	Oligoclonal IgM, intermediate state between the entirely polyclonal type III and the monoclonal, polyclonal type II	Chronic infection (e.g., HCV) Autoimmune diseases Lymphoproliferative diseases Chronic liver disease Proliferative glomerulonephritis

Data from Crowson AN et al: Cutaneous vasculitis: A review. *J Cutan Pathol* **30**:161-173, 2003; and Kallemuchikkal U, Gorevic PD: Evaluation of cryoglobulins. *Arch Pathol Lab Med* **123**:119-125, 1999

A new type of cryoglobulins, called type II–III cryoglobulin, containing polyclonal IgG associated with a mixture of polyclonal and monoclonal (oligoclonal) IgM has recently been described.[15] This type of cryoprecipitate describes an intermediate, developing state between types III and II, suggesting a continuous transition from a purely polyclonal to a partially monoclonal composition by a process of successive clonal selection.

Types II and III cryoglobulinemias are classically referred to as "mixed cryoglobulinemias". Circulating mixed cryoglobulins are commonly detected in a great number of infectious or systemic disorders (see Table 169-1). The term "essential" is originally reserved for instances of mixed cryoglobulinemia in the absence of a well-defined underlying disease and, given the striking association between mixed cryoglobulinemia and HCV, is actually referred to only a minority of cryoglobulinemic patients.

Prevalence of serum anti-HCV antibodies and/or HCV RNA in cryoglobulinemic patients ranges from 70% to 100%. Type II cryoglobulinemia is more strongly associated with HCV than type III (90% vs. 70%, respectively). Presence of cryoglobulins increases with duration of HCV infection: cryoglobulins are found in 55%–90% of patients with longstanding infection. However, overt cryoglobulinemic syndrome develops in only 2%–5% of these cases (see also Section "Epidemiology"). The precise role of viral or host factors contributing to this discrepancy remains largely unknown. Specific HCV genotypes or distinct HLA subtypes, like HLA-DR11 or HLA-DR6 may predispose to extrahepatic systemic manifestations of cryoglobulinemia.[16,17] Pathogenesis of mixed cryoglobulinemia is probably a multifactorial and multistep process. Viral HCV antigens exert a chronic stimulus on the host immune system, resulting in specific immune dysregulatory mechanisms with B-cell proliferation and autoantibody production. HCV-related B-cell lymphoproliferative disorders comprise a spectrum of disease, ranging from asymptomatic clonal B-cell expansions to pathogenic cryoglobulinemia and

lymphoma.[18] From that perspective, HCV-associated mixed cryoglobulinemia is a benign lymphoproliferative B-cell disease with a potential for subsequent development of B-cell lymphoma.[19,20] Development of HCV-associated cryoglobulinemic vasculitis syndrome is associated with longstanding infection, old age, type II cryoglobulins, higher cryoglobulin levels, and clonal B-cell expansion.[21,22]

The group of non-HCV-induced mixed cryoglobulinemias is small. The following associations have been described: An association of cryoglobulinemia with various other infectious viral agents, for example, hepatitis B virus, cited as a major causative agent,[23] and HIV with or without HCV coinfection has also been demonstrated.[24] Parvovirus B19 has been implicated in a mild form of cryoglobulinemic syndrome.[25] Another important association is the one with Sjögren syndrome. According to one study, 16% of patients with primary Sjögren syndrome had cryoglobulins, and of those, 56% had cryoglobulinemic syndrome.[26,27] A study by the same group found cryoglobulinemia in 25% of patients with systemic lupus erythematosus.[28]

CLINICAL FINDINGS

APPROACH TO THE PATIENT. In almost all cases, the possibility of a diagnosis of cryoglobulinemia or cryoglobulinemic syndrome is primarily suggested by the presence of purpura of the distal extremities or by acral cyanosis and necrosis, depending on the potential presence of type I or types II and III cryoglobulinemia. Alternatively, the potential diagnosis may be suggested by the presence of a candidate underlying disease. A targeted review of systems and subsequent clinical examination will guide the physician towards the entire picture of organ involvement or differential diagnoses. The laboratory panel must include parameters relevant to both cryoglobulinemia and important differential diagnoses. Box 169-1 presents an algorithm for the diagnostic approach to the patient, including laboratory testing. eTable 169-1.1 in online edition summarizes the symptoms, signs, cutaneous, extracutaneous and laboratory findings of cryoglobulinemia. Of note, there are still only preliminary diagnostic criteria for the classification of mixed cryoglobulinemic patients (see eTable 169-1.2 in online edition).

CUTANEOUS LESIONS. Cutaneous lesions are the most frequent manifestations (Fig. 169-2). Type I cryoglobulinemia per se is often asymptomatic and cutaneous signs are related to hyperviscosity and/or thrombosis that induce ischemic vasculopathy presenting as Raynaud phenomenon, digital ischemia, livedo reticularis, or purpura. Type II and III cryoglobulinemic vasculitis is mediated by deposition of antigen–antibody complexes in small- and medium-sized arteries, leading to inflammation of vessel walls. Intermittent orthostatic palpable purpura, frequently observed late in the afternoon when highest cryoglobulin concentrations are present, is the most common presentation and particularly affects the lower extremities.[29] Dimension and diffusion of purpuric lesions can vary from sporadic isolated petechias or erythematous macules to severe vasculitic lesions with ulcerations. Leukocytoclastic vasculitis is the histopathological hallmark of mixed cryoglobulinemia and is easily detectable by skin biopsy (see Chapter 163 see also eFig. 169-2.1 in online edition). Nail-fold capillary abnormalities are common and include dilatation, altered orientation, capillary shortening, and neoangiogenesis.

RELATED PHYSICAL FINDINGS. *Renal involvement* is a serious complication, typically manifests early in the course of the disease and can present as a broad range of clinical findings, including hematuria with or without renal insufficiency (41%), isolated proteinuria, nephrotic syndrome (21%) or acute nephritic syndrome.[30] Chronic renal insufficiency without significant renal abnormalities and acute renal failure are less common. The incidence of renal disease in cryoglobulinemia varies from 5% to 60% and is typically immune complex mediated (type II and III), but may also occur secondary to thrombosis (type I) (for details see eTable 169-1.3 in online edition).

Neurological manifestations, typically affecting the sensory peripheral nervous system secondary to epineural vasculitis frequently complicate the clinical course. Patients typically describe paresthesias with burning symptoms in the lower limbs, often with nocturnal exacerbation, leading to severely compromised quality of life. Electromyographic and nerve conduction studies demonstrated peripheral neuropathy in up to 80% of patients with mixed cryoglobulinemia, but many symptom-based demographic studies report prevalence of only 5% to 45%. Peripheral neurologic disease manifests as a progressive, chronic distal mild sensory neuritis and only rarely as acute mononeuritis. Clinically apparent central nervous system dysfunction is rare.

Musculoskeletal complaints, typically arthralgias and myalgias, are described in more than 70% of persons with cryoglobulinemia, predominantly in type II and III disease. The association of cryoglobulinemia with palpable purpura, arthralgia and myalgia was referred to as Meltzer triad in the late 1960s. Arthralgias classically affect the proximal interphalangeal and metacarpophalangeal joints of the hands, the knees, and ankles. Clear clinical signs of myositis or arthritis are rare.

Abnormal liver function tests, hepatomegaly including signs of cirrhosis or abnormal histological results in liver biopsy were reported in up to 90%. Also, thyroid disorders and diabetes mellitus seem to be associated with cryoglobulinemia.[39]

Unspecific abdominal pain can affect 2% to 22%. Intestinal vasculitis of the small mesenteric vessels leading to acute abdomen has been reported.

Approximately 40% of patients are symptomatic with dyspnea, cough, or pleuritic pain. Pulmonary function tests often reveal evidence of small airways disease and chest radiographs sometimes show interstitial infiltrates or signs of subclinical alveolitis. Severe pulmonary disease, for example, bronchiolitis obliterans organizing pneumonia (BOOP) or pulmonary vasculitis are very uncommon.

BOX 169-1 APPROACH TO THE PATIENT ALGORITHM FOR PATIENTS WITH SUSPECTED CRYOGLOBULINEMIA

HISTORY AND EXAMINATION (INCLUDING OPTIONAL TECHNICAL METHODS)

Ask for

- Cold sensitivity
- Weakness, musculoskeletal complaints, arthralgia
- Alcohol consumption, hereditary liver disease, history of hepatitis
- Known infections (HCV, HBV, HIV)
- Urine abnormalities (hematuria, foamy urine, edema; any one suggesting renal involvement)
- Paresthesias
- Difficulties in concentrating (suggesting central neuronal involvement)

Look for

- Acrocyanosis, Raynaud phenomenon (suggesting type I cryoglobulinemia)
- Purpura of distal extremities (suggesting type II and III cryoglobulinemia)
- Peripheral neuropathy (consider electromyographic testing)
- Joint swelling (suggestive for rheumatoid arthritis, SLE)
- Lymph node enlargement (suggesting lymphoma)

Technical examination (optional)

- Ultrasound: Liver abnormalities, splenomegaly (suggesting lymphoma)
- EKG, echocardiography: Rule out cardiac involvement, e.g., suggesting SLE
- Ophthalmology: Eye involvement, chorioretinitis (suggestive for Behçet disease or sarcoidosis)

MANDATORY LABORATORY TESTING IN CRYOGLOBULINEMIA

- Cryoglobulins (establishing the diagnosis when positive; stringent laboratory workup at 37°C is needed)
- Complete blood count including differential blood count
- Creatinine, BUN
- Complement (C4 and possibly both C4 and C3 diminished)
- IgA level (suggestive for liver disease or Henoch-Schönlein Purpura)
- ANA, SS-B, SS-A (positive in SLE and Sjögren syndrome associated cryoglobulinemia)
- ANCA (possibly positive, or suggesting granulomatosis with polyangiitis [Wegener's] or microscopic polyangiitis)
- Rheumatoid factor RF (positive in Type II cryoglobulinemia with a very high titer)
- Urinalysis, if positive additional microscopic examination of urinary sediment
- Hepatitis A, B, C serology
- Look for other viruses, e.g., parvovirus B19, HIV if suspicion
- Further workup for hepatic failure if appropriate

HISTOLOGY

- Consider skin biopsy
  - To confirm leukocytoclastic vasculitis (stain for complement and immune complexes)
  - To rule out other forms of vasculitis
- Consider renal biopsy (discern between MPGN I and other forms)
- Consider hepatic biopsy

Hyperviscosity due to high levels of monoclonal cryoglobulins, typically seen in Waldenström macroglobulinemia and less frequently in multiple myeloma, can induce microcirculation impairment and reduced platelet function, leading to skin and mucosal bleeding. A variety of neurologic symptoms have been reported in hyperviscosity syndrome: blurring or loss of vision, headache, vertigo, nystagmus, dizziness, sudden deafness, diplopia, ataxia, confusion, dementia, disturbances of consciousness, stroke, seizures, somnolence or coma. A characteristic retinal venous engorgement ("sausaging") on funduscopic inspection can serve as a diagnostic clue.

LABORATORY TESTS. In clinical practice, cryoglobulin testing is underutilized, most probably due to the expenditure of time and stringent temperature requirements.

Serum must be obtained in warm tubes (37°C) in the absence of anticoagulants. After clotting and centrifugation at 37°C, the separated serum is stored at 4°C and inspected daily for a precipitate. Type I cryoglobulins

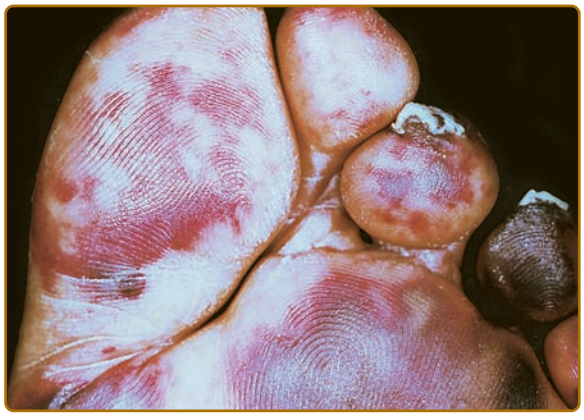

Figure 169-2 Leukocytoclastic vasculitis in a patient with mixed cryoglobulinemia manifested as palpable purpura and acrocyanosis. Patient with tuberculosis, positive antinuclear antibody, and hepatitis.

tend to precipitate within the first 24 hours (at concentrations >5 mg/mL), whereas type III cryoglobulins may require 7 days (see Fig. 169-1). For calculation of cryocrit (volume of packed cryoglobulins as percentage of original serum volume), the cryoprecipitate has to be spun in a graded (e.g., Wintrobe) tube. A cryocrit ≥2% is considered to be positive. Cryocrit levels usually do not correlate with severity and prognosis of disease.

Some authors recommend proof of reversibility of the cryoprecipitate by rewarming an aliquot at 37°C for 24 hours.[12] For phenotyping and identification of cryoglobulin components specific immunologic assays are performed at 37°C.

Clinical diagnosis of hyperviscosity can be established by measuring serum viscosity with an Oswald-type viscometer. Reference serum viscosity, measured as flow time through the viscometer of the patient's serum divided by that of water or saline, is between 1.4 and 1.8, while most symptomatic patients have values between 5 and 8. Again, clinical manifestations are often not proportional to serum viscosity.

As hypocomplementemia (with the typical pattern of low or undetectable C4 and normal or relatively normal C3 levels) occurs in up to 90% of patients with mixed cryoglobulinemia, C3 and C4 levels, usually measured in nephelometric immunoassays, should be routinely determined. A sudden increase in complement C4, raised to abnormally high levels can be observed in some patients developing a B-cell lymphoma.[40]

RF is often positive in type II and III cryoglobulinemia. Testing for antinuclear antibodies (ANAs, SS-A, SS-B) and other autoantibodies (e.g., anti-smooth-muscle Abs) is indicated upon clinical suspicion of underlying systemic connective tissue disease (e.g., SLE, Sjögren syndrome). Although the immunofluorescence ANA assay is the current diagnostic gold standard, titer and specificity of ANAs may vary considerably.

Particularly in patients with HCV-associated mixed cryoglobulinemia serum levels of IL-1β, IL-6, and TNF-α are significantly elevated.[41] Increased levels of the chemokines CXCL10 and CXCL13, also known as BCA-1 (B-cell-attracting chemokine-1), seem to be associated with active vasculitis.[42,43]

DIFFERENTIAL DIAGNOSIS

Starting from the symptom of purpura all small vessel cutaneous vasculitides, especially those involving the histopathological picture of leukocytoclastic vasculitis must be considered in the differential diagnosis of mixed cryoglobulinemia. Major differential diagnosis of vasculopathy, typical for type I cryoglobulinemia, includes diseases causing Raynaud syndrome, acrocyanosis, and acral ischemia.

See Box 169-2 for a complete overview on differential diagnosis of cryoglobulinemia (and cryofibrinogenemia).

COMPLICATIONS

Acute severe complications directly caused by cryoglobulins are rare with any type of cryoglobulinemia. The organs most vulnerable to complications are the nervous system and the kidneys. In Type I cryoglobulinemia, they are mostly related to an acute vaso-occlusive crisis caused by increased serum viscosity leading to acute acral ischemia and to cerebral and renal ischemia causing stroke or acute renal failure. In addition, the underlying hematologic disease of type I cryoglobulinemia can directly cause renal failure (e.g., myeloma kidney); see also eTable 169-1.3 in online edition. At advanced stages, complications are defined by the underlying hematologic disease itself: immunosuppression leading to infection and sepsis, coagulation disorders with severe bleeding, and side effects of hematologic disease-specific treatments. Mixed cryoglobulinemic vasculitis may involve the peripheral nerves leading to life-threatening situations or cause acute-on-chronic renal failure. Again, advanced stages of the underlying disease (mostly hepatitis C or other types of liver disease) can result in acute liver failure or problems associated with hepatic insufficiency, i.e., coagulation disorders, malnutrition, ascites, and the hepatorenal syndrome. Skin necrosis and vasculitic lesions can be entry sites for infection. Catastrophic individual patient courses have been described.[44]

PROGNOSIS AND CLINICAL COURSE

Prognosis is defined by the severity of the cryoglobulinemic syndrome and by the treatability of the underlying disease causing cryoglobulinemia. In type I cryoglobulinemia this will depend on the nature and stage of the hematological disease. A favorable prognosis in a patient with type I cryoglobulinemia can only be expected when control of the underlying disease can be achieved. In type II cryoglobulinemic vasculitis, data suggest that prognosis is generally benign in 50% of cases, but 30% have a moderate to severe course, especially because of renal and/or hepatic insufficiency.

BOX 169-2 DIFFERENTIAL DIAGNOSIS OF CRYOGLOBULINEMIA AND CRYOFIBRINOGENEMIA

Most likely

- Autoimmune disease
  - Lupus erythematosus
  - Dermatomyositis
  - Rheumatoid arthritis
  - Antiphospholipid antibody syndrome
- Vasculopathies
  - Thromboangiitis obliterans
  - Henoch-Schönlein purpura
  - *Atheroemboli*
  - Cholesterol emboli
  - Septic emboli
  - Calciphylaxis
- Primary cutaneous disorders
  - Urticaria
  - Livedo or livedoid vasculitis
  - Neutrophilic dermatoses
  - Lipodermatosclerosis panniculitis
  - Idiopathic perniosis (chilblains)
  - *Frostnip, pernio, frostbite*

Consider

- Autoimmune disease
  - Scleroderma
- Hematologic disorders
  - Inherited or acquired hypercoagulable states (e.g., protein C or S deficiency)
  - Thrombocytopenic disorders (e.g., thrombotic thrombocytopenic purpura, idiopathic thrombocytopenic purpura)
  - Disseminated intravascular coagulation
- Infection
  - Bacterial: *Rickettsia rickettsii* (Rocky Mountain spotted fever), *Neisseria meningitidis*
- Drug-related reactions
  - Raynaud (e.g., bleomycin, ergotamine)
  - Livedo reticularis (e.g., amantadine)
  - Purpura (e.g., heparin, warfarin)
- Other
  - Oxalosis

Always Rule Out

- Infection
  - Viral: HCV
- Vasculopathies
  - *Atherosclerotic peripheral vascular disease*

Consequently, 10-year-survival rates are significantly lower than in the normal population.[29,45,46] These data integrate a heterogeneous population that includes hepatitis C-associated cases that were treated by differing approaches ranging from symptomatic steroid therapy to antiviral treatment. It can be expected, however, that prognostic outlook will improve in the future since currently used antiviral treatment aimed at elimination of hepatitis C infection may cure or completely control HCV-associated mixed cryoglobulinemic vasculitis. In these patients, complications and side effects of antiviral treatment and the course of underlying hepatic disease will have a major impact on prognosis.[47]

Renal involvement is a poor prognostic sign in patients with cyroglobulinemic vasculitis with 15% progressing to end stage renal disease (ESRD).[29] MPGN I from any cause including noncyroglobulinemic ones has a poor prognosis: 50% of patients progress to ESRD within 10 years. Small studies report successful treatment of MPGN I by antiviral strategies.[48,49] The prognosis of cryoglobulinemia with no identified underlying disease (essential mixed cryoglobulinemia) is not well predictable, and, again, renal involvement is associated with poor prognosis (renal failure in 10% of patients).[50] The spectrum of renal disease in non-HCV mixed cryoglobulinemia has been recently studied.[51]

TREATMENT

Generally three levels of treatment can be considered when treating cryoglobulinemia: (1) etiologic treatment, which is aimed at the cure or safe containment of the underlying disease; (2) pathogenetic treatment, which is aimed at reducing the production of cryoglobulins while the underlying etiology remains untreated; and (3) symptomatic treatment that is aimed at reducing the cryoglobulin burden by removal from plasma or at mitigating the tissue's vasculitic reaction. Sometimes a combination of these approaches is used. The decision for initiation of a therapy should be informed by the severity of the symptoms with benefits outweighing risks. Cryoglobulinemia without symptoms does not justify treatment, unless there is an underlying condition that merits therapy. eTable 169-1.4 in online edition summarizes all available approaches, while integrated therapeutic concepts for typical clinical situations are presented here.

TYPE I CRYOGLOBULINEMIA

Etiologic treatment is the treatment of choice. The underlying hematologic disease, typically multiple myeloma, Waldenström macroglobulinemia or lymphoma must be treated with chemotherapy directed

by a hematologist according to current standards of care. In addition to this, severely symptomatic hyperviscosity syndrome of type I cryoglobulinemia can be reduced by repeated plasma exchange or by cryofiltration (see eFig. 169-2.3 in online edition). This may be necessary as a bridging therapy until therapy of the underlying disease shows an effect. In plasma exchange, the patient's plasma is removed by an apheresis membrane and substituted using approximately 3.5 L of donor plasma per session. Cryofiltration operates by passing the cooled patient's plasma through a specialized membrane unit designated at the removal of cryoprecipitates without necessitating plasma substitution. However, this latter approach may be hampered by rapid clogging of the membrane in the setting of high cryglobulin concentrations. In severe cases of type I cryoglobulinemia, it may be necessary that these removal procedures be performed daily over a period of two weeks or more. Intriguingly, the occurrence of plasmapheresis rebounds in disease activity has also been described.

HCV-ASSOCIATED TYPE II AND TYPE III CRYOGLOBULINEMIA IN PATIENTS WITH MILD-TO-MODERATE DISEASE

The primary therapeutic approach depends on disease severity. Patients with mild-to-moderate cryoglobulinemic vasculitis without major organ failure are best treated using antiviral agents. While the effects of the treatment exhibit some delay, the approach has the advantage of offering a potentially complete and sustained remission of the vasculitic syndrome. This has been shown by a series of pioneering studies employing regimens of interferon alone or in combination with ribavirin in patients with HCV and cryoglobulinemia.[55–63] Among those therapeutic regimens, the highest response rates were found using the current gold standard of therapy, PEGylated interferon α-2b and ribavirin[55,62]: recovery of purpura 87.5%, recovery of arthralgia 82%, recovery of peripheral neuropathy 74%, and recovery of nephropathy 50%. The rate of sustained viral response was similar to large patient study populations without cryoglobulinemia: 62.5%. The regimen is detailed in the current statements on the management of hepatitis C of the American Gastroenterological Association,[64,65] and it is briefly described in eTable 169-1.4 in online edition. There are several limitations of antiviral combination therapy. Applicability in renal insufficiency is reduced due to drug accumulation. Recommendations for dosage adjustment have been published in the current Kidney Disease: Improving Global Outcomes (KDIGO) guidelines of 2008[66] and are summarized in eTable 169-1.5 in online edition. While ribavirin is contraindicated at an estimated GFR <50 mL/min, it is a desirable drug rendering interferon therapy markedly more powerful.[62,64] Therefore a dosage regimen guided by plasma levels has been proposed that could allow for off-label administration in settings of a GFR <50 mL/min.[67] The contraindications and side effects of antiviral combination therapy are summarized in eTable 169-1.6 in online edition. Of note, ribavirin can cause hemolytic anemia requiring pausing or dosage adjustments. If in doubt, collaboration with a hepatologist and a nephrologist is recommended in order to apply this most promising of all approaches in HCV-related mixed cryoglobulinemic syndrome to as many eligible patients as possible.

HCV-ASSOCIATED TYPE II AND TYPE III CRYOGLOBULINEMIA IN PATIENTS WITH SEVERE DISEASE

In the case of organ failure such as overt renal failure, possibly accompanied by the nephrotic syndrome or neuropathy, initial pathophysiologic and symptomatic therapy are required in order to achieve a reasonably rapid response. Traditionally, an immunosuppressive combination therapy using steroids possibly followed by cyclophosphamide, azathioprine, or chlorambucil have been used.[68] Off-label use of the chimeric anti-CD20 (see also eTable 169-1.4 in online edition.) antibody, rituximab has recently emerged as a powerful alternative to classic immunosuppression.[69] The antibody targets B-lymphocytes leading to a depletion of 95% of the B-lymphocytic population. Thereby, the cryoglobulin-producing B lymphocytic clone is markedly reduced leading to marked cryoglobulin level reduction and consecutive remission. Taken together, this represents a pathophysiological approach to treatment (see eTable 169-1.4 in online edition). Since the B-cell depletion is only transient after one course, a relapse will usually occur.[70] As with classic immunosuppression, the therapy may lead to increased viral loads of HCV.[70] For long-term effects, repeated dosages of rituximab or maintenance therapy using classic immunosuppression would be required. The best option is to use these strategies to reduce acute cryoglobulinemic disease burden in order to bridge patients to a state where antiviral treatment, as outlined above, can be safely initiated.[68] Cases of successful remission of severe disease allowing for subsequent safe antiviral combination therapy have been reported.[71,72] As a bridging therapy, plasma exchange and cryofiltration can also be applied (see Section "Type I Cryoglobulinemia" for details). Though reported to be generally well tolerated in patients with cryoglobulinemic syndrome, rituximab has several limitations. It cannot be used in patients with overt skin ulceration due to interference with wound healing. Progressive multifocal leukencephalopathy under rituximab has been reported.[69] A recent report has pointed to a severe complication with worsening of cryoglobulinemic vasculitis syndrome on rituximab.[73] Yet, given the enormous potential of rituximab, the NIH has initiated a clinical research study on rituximab for the treatment of HCV-associated cryoglobulinemic vasculitis (Protocol number: 02-I-0096).

RELAPSE OF HCV-ASSOCIATED CRYOGLOBULINEMIC VASCULITIS

After initial successful antiviral treatment, relapses of HCV viremia with relapse of the vasculitic syndrome

have been described. The recent study by Cacoub and coworkers has concluded a protocol recommendation using another course of IFN + ribavirin in combination with rituximab to address this problem.[72] Another scenario of relapse after successful antiviral treatment has been described in one study where only the cryoglobulinemic vasculitis syndrome, but not the viremia reoccurred.[74] Such a scenario would call into question the concept of HCV as a cause for cryoglobulinemic vasculitis. However, in two-thirds of the study's patients, B-cell lymphoma was found on follow-up. This stresses the pivotal role of HCV in inducing B-cell lymphoma, as its occurrence is elevated 35-fold in patients with chronic HCV infection,[19,20] and stresses the importance of close medical follow-up in patients with a relapse of vasculitis despite successful clearance of the virus.

TYPE II AND TYPE III CRYOGLOBULINEMIC VASCULITIS NOT ASSOCIATED WITH HCV

In type II and III cryoglobulinemic vasculitis not associated with HCV classic immunosuppression using steroids and possibly steroid-sparing agents as outlined in eTable 169-1.4 in online edition continues to represent a major therapeutic approach. However, successful treatment has also been reported using rituximab.[69]

In any case, careful monitoring for development of B-cell lymphoma should be conducted which then would lead to specific treatment. Likewise specific treatment of the underlying disease remains key. Symptomatic therapy may also include nonsteroidal anti-inflammatory drugs.

CRYOFIBRINOGENEMIA

EPIDEMIOLOGY

CRYOFIBRINOGENEMIA AT A GLANCE

- Cryofibrinogenemia results from cryoprecipitation of patients native fibrinogen or fibrin by-products in plasma, but not serum.
- Cryofibrinogenemia is classified as essential or secondary (associated with malignancies, collagen vascular diseases, and thrombotic disorders).
- Cryofibrinogenemia is rare, but probably underestimated in clinical practice.
- Typical clinical features result from thrombosis (thrombotic phenomena of skin and viscera) and are often life threatening.

Cryofibrinogenemia is often clinically asymptomatic. Of note, 2% to 9% of healthy persons may have demonstrable amounts of cryofibrinogen, usually in concentrations less than 50 mg/L. In the past, cryofibrinogenemia was considered rare, but recent single-center studies indicate that this disorder is possibly underrecognized due to (1) the infrequency with which it causes symptoms and (2) inconsistencies in laboratory investigations producing falsely negative results. Initial studies noted the prevalence of cryofibrinogenemia among hospitalized patients between 3.4% and 13%, with a female (female–male ratio 4:1) but without age or racial prediction. In a study by Saadoun and coworkers, 2,312 hospitalized patients were tested for cryofibrinogenemia between 1996 and 2006.[75] A total of 515 (22.2%) patients had positive test results, of whom 88% had secondary and 12% had essential cryofibrinogenemia. Another retrospective single hospital 10-year report identified 61 patients having cryofibrinogenemia, which was essential in 18 (29.5%) and secondary in 43 (70.5%) patients.[76]

ETIOLOGY AND PATHOGENESIS

Precipitation of patients' native fibrinogen or fibrin by-products in plasma, but not serum, was first described by Korst and Kratochvil in 1955.[77] The so-called cryofibrinogenemia can be classified as primary (also named essential or idiopathic) or secondary. Diagnosis of primary cryofibrinogenemia requires the presence of cryofibrinogens in plasma, absence of cryoglobulins, and one or more compatible clinical features (e.g., cold-induced thromboses, increases in blood viscosity and/or vascular reactivity) in an otherwise healthy individual. Some authors hypothesize that essential cryofibrinogenemia might be a prerequisite for a secondary disease.

Secondary cryofibrinogenemia is diagnosed when an associated disease or drug is present. The most frequently associated disorders include malignancy, infections, connective tissue and autoimmune diseases (see Table 169-2).

Cryofibrinogen is characteristically composed of fibrinogen, fibrin, fibronectin and/or fibrin degradation products. Other components include albumin, cold insoluble globulin, factor VIII, and plasma proteins as well as the plasmin activity inhibitors α_1-antitrypsin, and α_2-macroglobulin. Pathology in cryofibrinogenemia is attributed to "in situ" thrombosis, leading to thrombotic occlusion of small- and medium-sized dermal vessels and resultant ischemia. Defects in the fibrinolysis process might lead to further clotting in small and medium arteries. Additional immunologic mechanisms may play a significant role in the pathophysiology of cryofibrinogenemia.

Some people with cryofibrinogenemia are asymptomatic, while others have clinical features resulting from thrombosis that can be life threatening when untreated.

Secondary forms of cryofibrinogenemia are significantly more frequent in patients with combined cryofibrinogenemia and cryoglobulinemia than in those with isolated cryofibrinogenemia (79 vs. 47%).[78] Among HCV-infected patients, cryofibrinogenemia is common, and closely correlated with cryoglobulinemia: in

TABLE 169-2
Cryofibrinogenemia Disease Associations

Endocrine Disorders
Diabetes mellitus
Hypothyroidism
Infection
Viral (e.g., VZV, EBV, HCV)

Dermatomyositis
Drugs
Oral contraceptive agents

VZV = varicella-zoster virus; EBV = Epstein-Barr virus; HCV = hepatitis C virus.

a study of 143 patients with HCV infection, 53 (37%) had cryofibrinogen levels >50 mg/L. Forty-seven of these cryofibrinogen-positive patients (89%) had positive tests for cryoglobulins.[79]

CLINICAL FINDINGS

APPROACH TO THE PATIENT AND HISTORY TAKING.

Patients with cryofibrinogenemia typically report a temporal association between cold exposure and onset of symptoms. Nonspecific general complaints of fever and malaise are common. For all patients with cryofibrinogenemia, age-appropriate malignancy screening and evaluation for possible underlying infection or systemic inflammatory disease are indicated. However, diagnostic workup should always be directed by the patient's clinical presentation.

CUTANEOUS LESIONS.

Clinical signs in cryofibrinogenemia are mostly cutaneous and are typically located on cold-exposed areas (hands, feet, buttocks, ear, nose). These cold-sensitive lesions often reflect cold-induced thromboses, increased viscosity, and/or vascular reactivity. Palpable purpura with underlying leucocytoclastic vasculitis is the most frequent clinical presentation. Other cutaneous features can include painful ulcerations, livedo racemosa, Raynaud phenomenon, segmental swelling, lower extremity nodules, painful or pruritic erythema (perniosis) of the extremities and cold urticaria. Cryofibrinogenemia may clinically simulate calciphylaxis, presenting normally in patients with end-stage renal disease (ESRD).

RELATED PHYSICAL FINDINGS.

Cryofibrinogenemia has a broad spectrum of clinical manifestations including vessel, kidney, musculoskeletal and/or neuronal involvement. Various thrombotic events, nephritic or nephrotic syndrome, arthralgia, myalgia, multineuritis, and fever have been reported.[80] In a recent study, main clinical manifestations included purpura (46.6%), skin necrosis (36.6%), and arthralgia (31.6%) with cold sensitivity in 40% and overall thrombotic events occurring in up to 40% of cases. A high cryofibrinogen plasma concentration was a significant predisposing factor for thrombotic events.[75] Thrombotic events include cerebrovascular accidents (stroke, ocular thrombi including retinal arterial and/or venous occlusions), myocardial infarction, limb and bowel ischemia or infarction, and pulmonary emboli, although a causal relationship has not been proven for all described cases.[81]

LABORATORY TESTS.

Laboratory workup is critical for the accuracy of cryofibrinogen detection, and ideally includes separation in a temperature controlled centrifuge (see also Section "Laboratory Tests" under "Cryoglobulinemia").

The warm blood specimen should be anticoagulated with citrate, EDTA or oxalate, but not heparin, that nonspecifically precipitates fibrinogen. After centrifugation at 37°C, the plasma is placed in a Wintrobe tube, refrigerated at 4°C and observed for the formation of a precipitate for 72 hours. The cryocrit is quantitated by centrifuging the specimen while it remains cooled to 4°C. Each millimeter of visible precipitate in the Wintrobe tube represents 1% of cryocrit.

In parallel, a cryoglobulin test is simultaneously performed in a sample without anticoagulants, to ensure that the plasma precipitate is cryofibrinogen and not cryoglobulin.

Affinity-chromatography, immunodiffusion and/or electrophoresis are used for quantitation and/or identification of the individual cryofibrinogen components.

SPECIAL TESTS

Histological Features. Irrespective of the anatomic site, cryofibrinogenemia shows an occlusive thrombotic diathesis comprising eosinophilic refractile deposits within vessel lumina with extension into the vessel intima, with or without an accompanying characteristic granulomatous vasculitic component.[76,82] Cryofibrinogen precipitates have a cylindrical configuration in ultrastructural analysis, which is often displayed within the vessel lumina. Examination of renal deposits showed fibrillary material within glomerular capillary lumina and tubules with unique morphologic features not previously described.[80]

COMPLICATIONS

Typical complications due to thrombotic events include gangrene (5%), septicemia (5%), and leg amputation (3.3%).[75] In some cases essential cryofibrinogenemia might be a prerequisite for a secondary disease, particularly lymphomas[83]: in a 2008 report, 27% of

patients with primary cryofibrinogenemia developed lymphoma after a 5-year follow-up period.[76]

PROGNOSIS/CLINICAL COURSE

Clinical data regarding prognosis in cryofibrinogenemia are limited. In one study, 3 out of 60 patients with essential cryofibrinogenemia died after a mean follow-up of 85 months.

TREATMENT

Smoking cessation, avoidance of cold exposure and eliminating the use of vasoconstricting drugs are nonpharmacologic interventions that are recommended, but are only partially effective. In secondary cryofibrinogenemia, specific treatment of the underlying disease can lead to improvement in related symptoms.

For essential cryofibrinogenemia, various pharmacological agents including fibrinolytic approaches and immunosuppressive agents have been proposed. Oral stanozolol (2–4 mg twice daily), a synthetic derivative of testosterone with substantial fibrinolytic properties, has been effective after several days of treatment.[84] Streptokinase (sometimes in combination with streptodornase), given intravenously (e.g., 25,000–200,000 U/day) has a more rapid onset of action than stanozolol. Recently, the use of colchicine (0.6 mg twice daily) in combination with high-dose pentoxifylline (800 mg three times daily) has been described.[85]

Combinations of glucocorticoids (e.g., prednisone 10–60 mg/day) with other immunosuppressive agents (e.g., azathioprine 150 mg/day or chlorambucil 10 mg/day) have also been used in small studies with some benefit, including successful treatment of acute attacks.

Plasmapheresis might be considered when high levels of cryofibrinogens are present, and are associated with monoclonal proteins (e.g., myeloma, Waldenström macroglobulinemia), hyperviscosity, or clinically significant thrombosis. Long-term repeated plasmaphereses and anti-immunoglobulin adsorption improved the symptoms in one patient with secondary cryofibrinogenemia.[86]

Chapter 170 :: Raynaud Phenomenon

:: John H. Klippel

RAYNAUD PHENOMENON AT A GLANCE

- Affects 10% of the population; 4:1 female–male ratio.
- Chronic episodic attacks of digital ischemia provoked by exposure to cold or emotional stress.
- Classified into primary (idiopathic) and secondary (underlying disease or cause present) forms; severity ranges from mild/benign to severe with loss of digital tissues.
- Connective tissue diseases—particularly systemic sclerosis—are the most common forms of secondary Raynaud.
- Both nonpharmacologic and drug therapies are used to reduce the frequency and severity of attacks.

EPIDEMIOLOGY

Studies of the epidemiology of Raynaud phenomenon are biased by underreporting (most patients with primary Raynaud never seek medical attention) and studies done by investigators interested in the secondary forms of the disorder. Surveys indicate that Raynaud phenomenon affects up to 10% of the general population.[1,2] Primary Raynaud phenomenon is estimated to be approximately twice as common as secondary Raynaud.[3] Symptoms most often first develop in the teenage years, and most series show a female predominance of the disorder (female–male = 4:1). Increases in the frequency and severity of attacks during menses suggest that female sex hormones may be involved in the pathogenesis.[4] Differences in seasonal skin temperatures, marital status, alcohol use, age, and smoking between women and men have also been suggested to contribute to the sex differences.[5,6] Familial aggregation has been identified in a number of studies and suggests the contribution of genetic factors.[7] Other associations reported in epidemiologic studies include

living in a cold climate, occupation, cardiovascular disease, low body–mass index, and use of vibratory tools.

ETIOLOGY AND PATHOGENESIS

The pathophysiology of the vasospasm is complex and only partially understood. Studies show significant reductions of peripheral blood flow throughout all phases of central body cooling and rewarming, suggesting impairments of central thermoregulatory control mechanisms.[8] Additional features which likely contribute to the development of Raynaud phenomenon include local defects of digital blood vessels causing abnormal vascular reactivity or reduced blood flow; an imbalance of locally produced vasoconstrictors or vasodilators; hyperreactivity of the sympathetic nervous system; and abnormal properties of the blood that compromise distal perfusion.

The gross histology of digital arteries in patients with primary Raynaud phenomenon is normal. Structural abnormalities of the digital microvasculature are frequently seen in patients with secondary forms of Raynaud phenomenon, particularly in the connective tissue diseases. Studies show a range of pathology, including intimal hyperplasia, narrowing or total occlusion of arteries, or thrombi. In most patients with systemic sclerosis, there exists evidence of activation and damage of the endothelium, fibrinolysis, and platelet activation.[9] Autoantibodies and microvascular damage appear to be independent predictive factors for the progression of Raynaud phenomenon to systemic sclerosis.[10]

Microcirculatory flow studies with laser Doppler in patients with scleroderma have shown marked reductions in blood flow and hand temperature during an attack, with prominent abnormalities during rewarming—findings that suggest a failure of the arteriovenous anastomoses to open.[11]

Serotonin is also incriminated as an important mediator in the induction of ischemic attacks of Raynaud phenomenon. Patients have an increased sensitivity to intra-arterial infusions of serotonin, and S2-serotonergic antagonists relieve but do not prevent the induction of attacks.

The evidence of direct central sympathetic nervous system hyperactivity is strongest in vibration-induced injury. The use of a vibration tool in one hand produces vasospasm in the other hand, and vasospasm can be inhibited by proximal nerve blockade.[12] In general, most studies of the sympathetic nervous system in patients with primary or other secondary forms of Raynaud phenomenon have failed to detect evidence of sympathetic hyperactivity. The results of microelectrode studies of skin sympathetic nervous activity during cold pressor tests are normal, and plasma levels of catecholamines are not increased in the venous drainage of the hands of patients with Raynaud phenomenon.

Consistent abnormalities in plasma fibrinogen, cold agglutinins, platelets, or cryoglobulins have not been demonstrated in primary Raynaud phenomenon, but are important in certain secondary cases, particularly scleroderma. Levels of von Willebrand's factor and soluble thrombomodulin, thromboxane B_2 and β-thromboglobulin, and tissue plasminogen activator inhibitor-1 are increased in patients with scleroderma, when compared to levels in patients with primary Raynaud phenomenon.[9]

Genetic studies with microsatellite markers of extended families affected with primary Raynaud phenomenon have identified several potential candidate genes.[13]

CLINICAL FINDINGS

A careful history and physical examination are important in the evaluation of a patient with suspected Raynaud phenomenon.

HISTORY

The history is important to elicit a clear description of the attacks and to screen for evidence of signs and symptoms suggestive of a secondary cause. Patients complain of episodic attacks of well-demarcated, white or blue digits induced by exposure to cold and sometimes by emotional stimuli (Fig. 170-1). Often only a portion of the digit is affected, and the thumbs are typically spared. A classic tricolor change of pallor, cyanosis, and hyperemia described in most textbooks is rarely volunteered by patients; most describe only blanching of the digits accompanied by numbness. During the attacks, one or more fingers or toes may be numb and be described as "dead." On rewarming, the digits may become bright red, and throbbing pain may occur. When pain is a prominent symptom in the ischemic phase, a secondary cause should be suspected. Attacks persist for minutes to hours. The fingers and toes are most commonly involved; however, the attacks may involve the nose, earlobes, or nipples.

A careful review of systems is important to screen for symptoms of connective tissue disease (arthralgias,

Figure 170-1 Ischemic phase of attack of Raynaud phenomenon with marked pallor of the ring and little fingers of the left hand and little finger of the right hand.

arthritis, dysphagia, heartburn, rash, photosensitivity, telangiectases, calcinosis, muscle weakness, shortness of breath, or sicca), a drug-related etiology, symptoms of obstructive arterial diseases (intermittent claudication), and exposure to vibratory tools or continuous finger trauma.

CUTANEOUS LESIONS

Attacks of Raynaud phenomenon, presumably stress induced, are commonly witnessed during the course of the history or physical examination. There is well-demarcated blanching or cyanosis of the digits extending from the tip to various levels of the digit (see Fig. 170-1). The skin distal to the line of ischemia is cold and pale, while the proximal skin is pink and warmer. On rewarming, blanched digits may become cyanotic, because of the low blood flow and deoxygenation, and then bright red, because of reactive hyperemia. Persistent ischemic discoloration of digits suggests a secondary cause.

The digits should be carefully examined for trophic or ischemic changes, which are signs of prolonged or severe attacks of Raynaud phenomenon. The skin may become atrophic, thin, and tight (sclerodactyly) and hair loss may occur over the dorsal surfaces. The nails may become brittle and deformed. Ulcerations, which can be extremely painful, particularly at night, may develop on the finger pads or around the nail bed. The ulcers heal slowly, leave characteristic small, pitted scars (Fig. 170-2), and may become infected. Gangrene of the distal aspects of the digit is rare.

RELATED PHYSICAL FINDINGS

The physical examination should pay attention to all pulses, and blood pressure should be obtained in both arms. Allen's test is useful to assess arterial and capillary function of the hands. Abnormal filling implies structural disease of the microcirculation and raises the suspicion of a secondary form of Raynaud phenomenon. In this test, the radial and ulnar arteries are simultaneously compressed by the examiner's thumbs, while the patient opens and closes the fist to induce blanching of the palm. Selective arterial filling is judged by the rate of color return as pressure is sequentially released from the radial and ulnar arteries. Vascular obstruction from the thoracic outlet syndrome should be assessed by the Adson maneuver, which tests for diminution in the radial pulse with exaggerated movements of the neck and shoulder. A careful neurologic examination should be performed to detect evidence of sympathetic hyperactivity, abnormal reflexes, muscular weakness or atrophy, or compression of the median nerve within the carpal tunnel. Skin changes, such as telangiectases, calcium deposits, changes in skin texture, rashes, or purpura, provide valuable clues to the presence of a connective tissue or hyperviscosity disorder.

Figure 170-2 Loss of pulp of the pad of the digit with pitting scars and ulcerations from chronic, severe Raynaud phenomenon.

LABORATORY TESTS

In all patients, a complete blood count, erythrocyte sedimentation rate, urinalysis, and antinuclear antibody test should be obtained. Additional laboratory studies should be directed by findings elicited by the history and physical examination. In patients with abnormal antinuclear antibody levels, tests for antibodies to specific nuclear antigens, such as Sm antigen or topoisomerase or centromere antigens, are helpful to detect early systemic lupus erythematosus or scleroderma (see Chapters 155 and 157). A routine chest radiograph should be obtained to look for a cervical rib or evidence of interstitial lung disease.

SPECIAL TESTS

Nail fold capillary microscopy is considered to be a useful procedure to distinguish primary from secondary Raynaud phenomenon.[14] Although mild capillary abnormalities may be observed in patients with primary Raynaud phenomenon, patients with connective tissue diseases may have enlarged, deformed capillary loops surrounded by avascular areas (Fig. 170-3).[15] Serial studies reveal progressive decreases in the total number of nail fold capillary loops in secondary, but not primary, forms of Raynaud phenomenon.[16] The patency of small arteries can be assessed by laser Doppler perfusion imaging.[17,18] Digital subtraction arteriography should be reserved for selected patients with prolonged, severe ischemia for whom arterial reconstruction is a consideration.

DIFFERENTIAL DIAGNOSIS

Raynaud phenomenon is subdivided into primary (idiopathic) and secondary forms based on whether an underlying cause or disease association can be identified.

PRIMARY RAYNAUD PHENOMENON

Primary Raynaud phenomenon is a disorder in which known causes of attacks of peripheral

Figure 170-3 Nail fold capillary microscopy, in a patient with scleroderma, showing capillary drop out with enlarged, dilated, tortuous capillary loops.

vasospasm cannot be found. Criteria for the diagnosis of primary Raynaud phenomenon have been developed by Allen and Brown[19] and LeRoy and Medsger[20] (Table 170-1).

Several studies have examined the long-term outcome of patients with primary Raynaud phenomenon.[3,21,22] Progression to a secondary form of Raynaud phenomenon, most commonly a connective tissue disease such as scleroderma, occurs in approximately 15% of patients during the first decade after onset. Variables predictive of a transition to a secondary form include nail fold capillary abnormalities, hand swelling, positive Allen's test, and antinuclear antibodies.

TABLE 170-1
Criteria for Primary Raynaud Phenomenon

- Vasospastic attacks precipitated by exposure to cold or emotional stimuli
- Bilateral involvement of extremities
- Normal vascular examination with symmetric peripheral pulses and normal nail fold capillary microscopy
- Absence of gangrene or, if present, limited to the skin of the fingertips
- No evidence of an underlying disease, drug, or occupational exposure that could be responsible for vasospastic attacks
- Negative antinuclear antibody test
- Normal erythrocyte sedimentation rate
- History of symptoms for at least 2 year

Combined criteria of Allen and Brown[19] and Le Roy and Medsger.[20]

SECONDARY RAYNAUD PHENOMENON

CONNECTIVE TISSUE DISEASES. The connective tissue diseases are the most common cause of secondary Raynaud phenomenon (Table 170-2). Among patients with scleroderma, 80%–90% manifest Raynaud phenomenon and/or persistent vasospasm. It is the presenting symptom in about one-third of patients and may be the only manifestation of the disease for years. Raynaud phenomenon occurs in about one-third of patients with systemic lupus erythematosus, idiopathic inflammatory myopathies, and systemic vasculitis. Although patients with rheumatoid arthritis often complain of cold hands with mottled red and white areas, true Raynaud phenomenon appears to be no more common in persons with rheumatoid arthritis than in the general population. Arteriograms of patients with connective tissue diseases usually show digital and sometimes, ulnar or radial artery obstructions.

OCCUPATIONAL. Raynaud phenomenon may be occupational in origin. It is especially common in

TABLE 170-2
Secondary Raynaud Phenomenon

  - Hypothyroidism
  - Infections (bacterial endocarditis, Lyme disease, viral hepatitis)
  - Neoplasms
  - Primary pulmonary hypertension
  - Arteriovenous fistula
  - Intra-arterial injections

individuals who use vibratory tools (e.g., air hammers, chain saws, rivet guns) and in those whose occupation requires prolonged exposure of the extremities to cold temperatures (e.g., butchers, ice cream workers, fish packers). Prevalence rates correlate with the vibration level of the tool and the duration of exposure; they can be as high as 90% in high-risk occupations such as logging or mining.[23]

NEUROLOGIC DISORDERS. Any neurologic condition that produces permanent disuse of a limb can be associated with sympathetic nervous system disturbances to that limb. Patients often develop persistent vasospasm with coldness, paleness or cyanosis, and even ulcerations of the limb, and Raynaud phenomenon may occur. Thermoregulatory abnormalities may be a prominent feature of reflex sympathetic dystrophy syndrome.[24] Nerve root pressure or nerve entrapment may produce Raynaud phenomenon. It is often present in patients with carpal tunnel syndrome and typically involves the first, index, and middle fingers, digits innervated by the median nerve. In addition, Raynaud phenomenon may occur as a result of neurovascular compression at the thoracic outlet. The compression may be caused by cervical ribs; abnormalities of the scalenus anticus muscle; bony abnormalities of the cervical vertebrae, clavicle, or first rib; or shoulder compression syndromes (the costoclavicular or hyperabduction syndrome).

DRUGS AND TOXINS. Propranolol, one of the most widely used β-adrenergic blockers for cardiovascular diseases and migraine headaches, is probably the most frequently used drug responsible for Raynaud phenomenon. Ergot preparations and methysergide used to treat migraine headaches may produce vasospasm. Intra-arterial use of many medications and recreational drugs can result in toxicity to endothelial cells with irreversible structural damage to the microvasculature of the extremities and be responsible for severe Raynaud phenomenon. The chemotherapeutic agents, bleomycin and vinblastine, also may cause the phenomenon.[25]

HYPERVISCOSITY. Patients with hyperviscosity from cryoglobulinemia, macroglobulins, cold agglutinins, and polycythemia can exhibit Raynaud phenomenon. Cryoglobulins are most commonly present in patients with multiple myeloma, but they also occur in patients with rheumatic diseases, chronic infections, leukemia, and lymphoma, and as an idiopathic condition.

MISCELLANEOUS. The most common endocrine disturbance associated with Raynaud phenomenon is hypothyroidism; symptoms usually remit with thyroid hormone replacement. Raynaud phenomenon may be a feature of various infectious disorders, including subacute bacterial endocarditis, Lyme disease, and viral hepatitis, presumably a reflection of systemic vasculitis. Peripheral vasospasm may also occur in association with malignant tumors, including pheochromocytoma, carcinoid, breast and ovarian carcinoma.

The major forms of vascular ischemia that must be distinguished from Raynaud phenomenon are cold digits, chilblain (pernio), livedo reticularis, and acrocyanosis (see Chapters 94 and 173). Many patients

complain of cold, sometimes painful digits without color changes. This condition likely represents one extreme of the spectrum of normal sympathetic nervous system activity. Chilblain is an inflammatory condition of the skin of the extremities induced by cold. Patients develop a bluish-red discoloration and edema, typically involving the lower limb and associated with warmth, erythema, and burning. In severe cases, hemorrhagic lesions, bullae, or ulcers may develop, and secondary infections may supervene. The lesions last from 7 to 10 days, often leaving a residual pigmentation of the skin. Livedo reticularis is a bluish discoloration of the skin of the extremities with a characteristic lacy, irregular appearance. The bluish discoloration becomes more intense on exposure to cold and may disappear in a warm environment. Most patients are entirely asymptomatic, although livedo reticularis may be a feature of the antiphospholipid syndrome, in which patients are at increased risk for venous and arterial thromboses, thrombocytopenia, and pregnancy losses. In acrocyanosis, the hands, and, less commonly, the feet, develop a persistent bluish discoloration. The blue color is intensified by exposure to cold and is converted into a purplish or red color by warming; a pallor phase is absent. The skin is cold, and the palms are often wet and clammy from sweat. Trophic changes or ulcerations are rarely observed.

TREATMENT

The management of Raynaud phenomenon is guided by the frequency and severity of attacks and the complications from ischemia (Table 170-3). Secondary forms of Raynaud phenomenon require treatment directed at the underlying medical disorder, discontinuation of drugs causing the vasospasm, or occupational modifications.

TABLE 170-3
Management of Raynaud Phenomenon

Infrequent or mild attacks	Preventive measures Cessation of smoking
Frequent or severe attacks	Calcium channel blockers (nifedipine, diltiazem) Antiadrenergic drugs (prazosin, reserpine) Topical nitroglycerin
Acute, severe ischemia	Intravenous prostaglandin E_1 or prostacyclin Digital sympathectomy Microvascular surgery
Digital ulcers	Antiseptic soaks, antibiotic ointments, occlusive dressing Calcium channel blockers (maximal doses) Intravenous prostaglandin E_1 or prostacyclin
Gangrenous, infected ulcers	Analgesics Antibiotics Surgical debridement Amputation

GENERAL MEASURES

Mild Raynaud phenomenon is generally easy to control with lifestyle changes to minimize exposure to the cold; dressing warmly with loose-fitting, layered clothing; and keeping the thermostat a few degrees higher than normal. Limiting time spent outdoors in winter, wearing insulated gloves, and using hand or foot warmers are usually helpful. Patients should be taught to recognize and terminate attacks promptly by returning to a warmer environment and applying local heat to the hands (e.g., by placing their hands in warm water or by using a hair dryer). Patients should be strongly encouraged to stop smoking and to avoid secondhand smoke, because nicotine induces cutaneous vasoconstriction. Stress modification and social support are valuable aspects of treatment to minimize vasoconstriction induced by hyperactivity of the sympathetic nervous system. Counseling, training in relaxation, or medications may be helpful. Some patients benefit from conditioning programs such as biofeedback training.

Digital ulcers from Raynaud phenomenon can be extremely painful and typically take weeks or months to heal completely. Pain control is an important part of therapy, because pain can lead to additional vasospasm and more ischemia. On occasion, narcotic pain medications may be necessary to control symptoms. The finger should be soaked in a tepid antiseptic solution (e.g., half-strength hydrogen peroxide) twice daily to soften or loosen the crust or eschar. After drying, an antibiotic ointment is applied to the ulcer, and the digit is covered with an occlusive dressing. Maximum drug therapy with a calcium channel blocker should be used throughout treatment. Infection is a common complication of digital ulcers and is typically manifest by increasing pain, erythema, swelling, or purulent drainage. Cultures usually demonstrate *Staphylococcus* sp., and treatment with dicloxacillin or cephalosporins is usually effective.

DRUG THERAPY

Various drugs have been used to treat Raynaud phenomenon, including vasodilators, platelet inhibitors, serotonin antagonists, and fibrinolytics. Drug therapy is usually reserved for patients with prolonged or frequent attacks that fail to respond to conservative measures. In general, improvements with drug therapy are more pronounced in patients with primary Raynaud phenomenon, presumably as a consequence of fixed, structural damage in patients with secondary forms.

The calcium channel blockers are by far the most widely used and effective drugs for treating Raynaud phenomenon.[26,27] Vasodilating properties vary among different agents. Nifedipine (10–20 mg tid or qid) reduces the severity and frequency of attacks; the

long-acting preparation of nifedipine is better tolerated but may be less effective. Diltiazem (60 mg tid or qid) may be substituted if nifedipine is ineffective or not well tolerated. Side effects of calcium channel blockers include fluid retention, light-headedness, and heartburn; these may limit therapy.

Sympatholytic drugs, including reserpine, methyldopa, phenoxybenzamine, and tolazoline, have been used in management, although they have not been well studied. In a pilot study, the selective serotonin reuptake inhibitor fluoxetine reduced the frequency and severity of Raynaud attacks.[28] Additional drug therapies reported to be beneficial in the treatment of Raynaud phenomenon include low molecular weight heparin,[29] prazosin,[30] the angiotensin II receptor antagonist losartan,[31] and stanozolol.[32] Topical nitroglycerin paste (2%) and a sustained-release transdermal glyceryl patch are helpful in selected patients[33]; although side effects such as headaches, dizziness, and skin irritation often limit therapy. Newer formulations of nitroglycerin appear to show promise.[34] Intravenous prostaglandin E_1 and prostacyclin (PGI_2) and iloprost (a PGI_2 analog) have been shown to have beneficial effects in patients with severe Raynaud phenomenon; however, the vasodilatory effects are not sustained and long-term therapy is required.[35–38] Oral prostaglandins are currently available only as investigational agents.

SYMPATHECTOMY

Sympathectomy may be a consideration for the management of patients with refractory, disabling attacks or with an acutely ischemic digit that is unresponsive to other measures.[39] A positive vasodilator response to a stellate ganglion block or epidural infusion should be documented before a permanent procedure is done. Lumbar sympathectomy has an important role in the management of severe Raynaud phenomenon of the feet, and selective digital sympathectomy may be used to relieve pain and heal digital ulcers in patients with ischemic digits.[40]

SEVERE VASOSPASM

Severe vasospasm with prolonged ischemia (dead-white finger) poses a threat of gangrene and amputation; it is considered a medical emergency. The patient should be hospitalized and the affected extremity put to rest. Nifedipine (10–20 mg tid) should be started immediately, as well as prostaglandin E_1 (6–10 ng/kg/minute) or PGI_2 (0.5–2 ng/kg), given by continuous intravenous infusion for several hours over three consecutive days. Intra-arterial phentolamine or tolazoline may reverse acute vasospasm, but monitoring of vital signs is essential, and these drugs need to be used with great caution. A digital (or stellate ganglion) block with lidocaine hydrochloride or bupivacaine hydrochloride (without epinephrine) relieves pain and produces a chemical sympathectomy that may reverse vasoconstriction. Sympathectomy (thoracic, lumbar, or digital) should be considered in patients who have a positive response. Arterial reconstruction should be reserved for patients with angiographically documented occlusive vascular disease.[40]

Chapter 171 :: Malignant Atrophic Papulosis (Degos Disease)

:: Dan Lipsker

MALIGNANT ATROPHIC PAPULOSIS AT A GLANCE

- A rare, primary vaso-occlusive disorder, affecting mainly the skin, the gastrointestinal tract, and the central nervous system.
- Diagnosis relies on clinicopathologic evaluation.
- Characterized by numerous typical porcelain-white, atrophic papules, with a rim of rosy erythema and/or telangiectases.
- Pathology shows a wedge-shaped area of dermal necrosis with edema and mucin deposition.
- Benign forms without extracutaneous involvement are possible.

In the early 1940s, Köhlmeier first described malignant atrophic papulosis, whereas Degos, Delort, and Tricot recognized it as a specific entity a year later.[1–3] We now know that the clinically distinctive lesion of the so-called *Degos disease* is a marker of a cutaneous thrombo-obliterative vasculopathy rather than of a specific disease per se. Indeed, such lesions can be found in at least two distinctive clinical settings: (1) as an apparent idiopathic disease, either classic Degos disease or its benign variant, or (2) as a surrogate clinical finding in some connective tissue diseases such as the antiphospholipid syndrome, lupus erythematosus, dermatomyositis, and systemic sclerosis.

EPIDEMIOLOGY

Classic Degos disease is rare, with about 200 reported cases. It almost always occurs in Caucasians, but cases have been observed in African-American patients and in Japan. The disease most commonly presents between the third and fourth decades, but can occur at any age. Men are more often affected than women (ratio, 3:1). The majority of cases are sporadic, but familial cases have been described, and most of these cases are consistent with an autosomal dominant pattern of inheritance.[4]

ETIOLOGY AND PATHOGENESIS

The etiology of Degos disease is unknown. The histopathologic findings in patients with malignant atrophic papulosis suggest a primary vaso-occlusive process. Thus, a vascular coagulopathy and/or endothelial cell damage should be considered as the major pathogenic mechanism. A combination of prothrombotic factors possibly plays a role in triggering the full-blown disease. Extensive studies of prothrombotic factors were performed in some patients with Degos disease, and no single abnormality was repeatedly identified. All patients should be screened for the presence of antiphospholipid antibodies/lupus anticoagulant and cryoglobulins, although Assier et al did not find the former in their series of 15 patients.[5] Inhibition of fibrinolysis and platelet abnormalities, including increased platelet adhesiveness and spontaneous aggregation, were reported in some patients.[5–8]

The lesions of Degos disease should be viewed as a cutaneous marker indicative of intraluminal thrombosis. Several disease processes may converge to produce those clinical and histologic findings.

CLINICAL FINDINGS

(Fig. 171-1)

HISTORY

Patients seek medical advice for the appearance of small cutaneous lesions that usually are neither pruritic nor painful. In some patients, history and/or review of systems will reveal signs indicative of extracutaneous involvement: abdominal pain, diarrhea, melena, nausea, blurred vision, hemiparesis, paresthesia, or any other sign indicative of an ischemic event. History can also give a clue to previous thromboembolic or obstetrical events suggestive of the antiphospholipid antibody syndrome.

CUTANEOUS LESIONS

Cutaneous lesions start as crops of 2–10 mm, largely asymptomatic or mildly pruritic, fleshy or rose-colored macules that soon become round, smooth, often dome-shaped firm papules (Fig. 171-2). Some lesions display central umbilication and/or necrosis (Fig. 171-3). These lesions evolve over days or weeks to porcelain-white, atrophic papules with a rim of rosy erythema and/or telangiectases (Fig. 171-4). A fully developed lesion therefore closely resembles lesions of atrophie blanche. In time, the reddish border disappears, and only a varicelliform white scar remains. Usually, the lesions are separated from each other, but they may coalesce, leading to polycyclic atrophic areas or to skin ulcerations.

The lesions are localized on the trunk and limbs. Palms, soles, face, scalp, and genitalia are usually

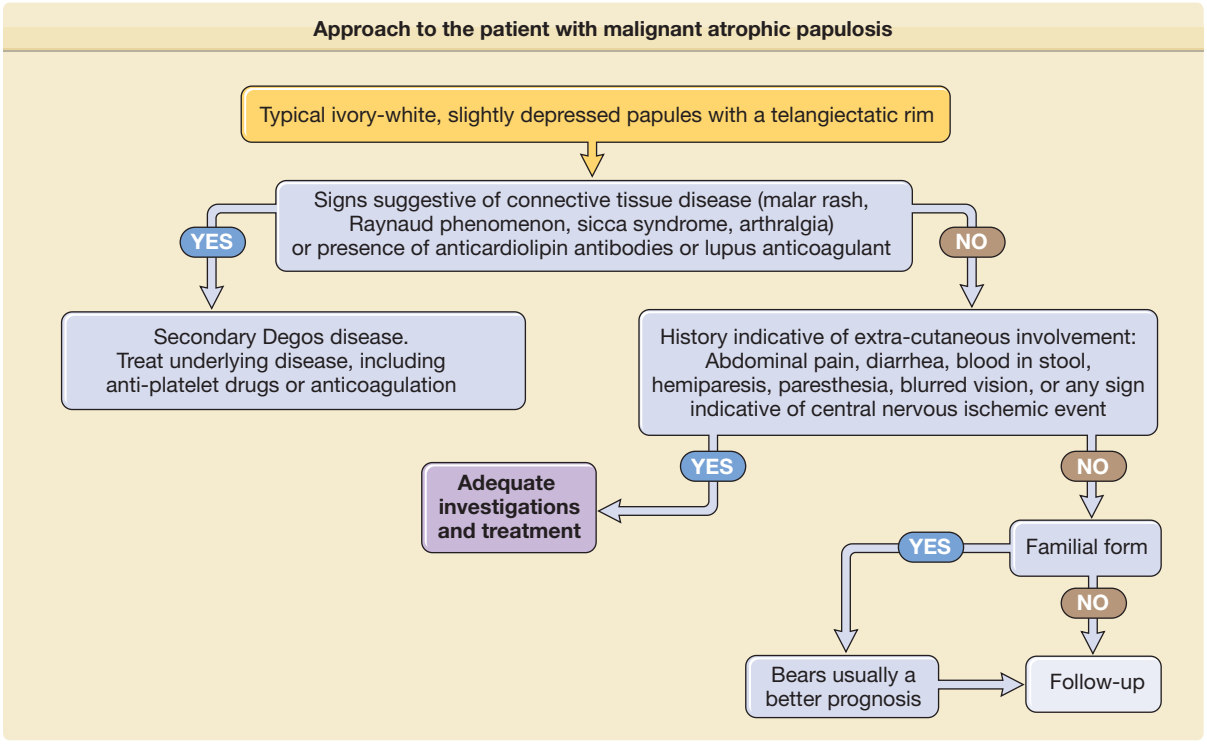

Figure 171-1 Approach to the patient with malignant atrophic papulosis.

spared, although there are exceptions. Exclusive acral localization is suggestive of connective tissue disease. A linear distribution was reported.[9] Eye involvement is possible, and the most common manifestation is an avascular patch on conjunctivae, but sclerae, episclera, retina, choroids, and optic nerves may be affected (see eFig. 171-4.1 in online edition).

Figure 171-2 Numerous typical papules of Degos disease in a young man.

CLASSIC DEGOS DISEASE. In classic Degos disease, the number of cutaneous lesions varies from a few to more than one hundred. Cutaneous findings usually precede the systemic manifestations that may involve the gastrointestinal tract, with bowel perforation and peritonitis, and/or the central nervous system, with hemorrhagic or ischemic stroke. Rarely, cutaneous lesions occur simultaneously or after gastrointestinal or central nervous system involvement. Postmortem studies have revealed small vessel thrombotic involvement of many organs, including kidney, bladder, prostate, liver, pleura, pericardium, lung, and eyes.[10] Some

Figure 171-3 Papule with central ulceration in patient with Degos disease.

Figure 171-4 Typical pathognomonic papules of Degos disease with a porcelain-white center and an erythematous raised border.

patients with classic Degos disease have antiphospholipid antibodies, and this raises the possibility of a relationship with a primary antiphospholipid syndrome.

BENIGN DEGOS DISEASE. A benign form of Degos is now widely recognized. In this form, only skin involvement is found, and most of the familial cases are benign.[4] Development during pregnancy has been reported in a patient with antiphospholipid antibodies,[11] as well as a case occurring in a patient with acquired immunodeficiency syndrome.[12] A patient developing Degos disease after interferon injections, a drug known to induce atrophie blanche-like lesions[13] and microangiopathy,[14] is known to the authors (L. Thomas, personal communication). There is no clear-cut distinction between the classic and the benign form of Degos disease, and there is no way by which one can predict which patients will or will not develop visceral involvement.

DEGOS DISEASE-LIKE LESIONS OR SECONDARY DEGOS DISEASE. Degos disease-like lesions can occur in patients with known lupus erythematosus, especially those with antiphospholipid antibodies, dermatomyositis, systemic sclerosis, granulomatosis with polyangiitis (Wegener's), Crohn's disease and during parvovirus B19 viremia, a virus with a known affinity for endothelial cells.[15,16–18]

LABORATORY TESTS

HISTOPATHOLOGY

Clinically, fully developed lesions reveal a cell-poor, wedge-shaped area of slight-to-severe dermal necrosis with dermal edema and copious mucin deposition, extending from the papillar dermis to the deep part of the reticular dermis (Fig. 171-5). At the base of the lesion, occluded vessels with occasional thrombosis, thickened vessel walls, proliferating endothelial cells, and sparse perivascular lymphocytic infiltrate can be found

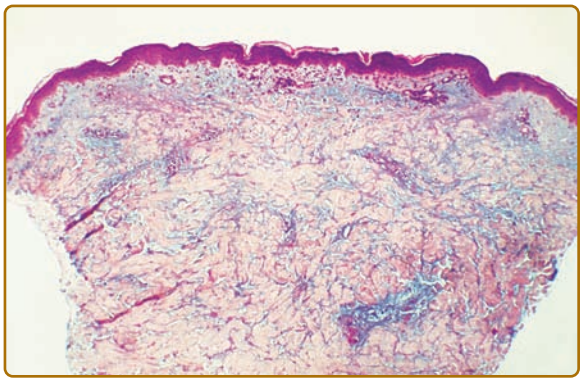

Figure 171-5 A wedge-shaped, cell poor, area of dermal necrosis, with copious mucin deposition, extending from the papillar dermis to the deep part of the reticular dermis hematoxylin-eosin-safran-Astra blue, ×40).

(Fig. 171-6). Yet, a full-blown leukocytoclastic neutrophilic vasculitis is never found in patients with malignant atrophic papulosis. This entity should therefore not be classified as vasculitis. Numerous secondary, epidermal changes can be found: hyperkeratosis, interface dermatitis, scattered necrotic keratinocytes, and atrophy. An associated sclerosing panniculitis was reported in one patient.[19] Results of direct immunofluorescence studies have been inconsistent. Electron microscopy occasionally revealed tubuloreticular aggregates within endothelial cells of uncertain significance.

Because some of those histopathologic findings, such as mucinous infiltration of the dermis, interface dermatitis, and perivascular lymphocytic dermal infiltrate, are shared by lupus erythematosus and dermatomyositis, Degos disease is considered by some authors as a possible variant of lupus erythematosus.[20]

OTHER LABORATORY TESTS AND SPECIAL TESTS

There is no diagnostic or prognostic marker of the disease. A search for antinuclear antibodies, lupus anticoagulant, and anticardiolipin antibodies should be

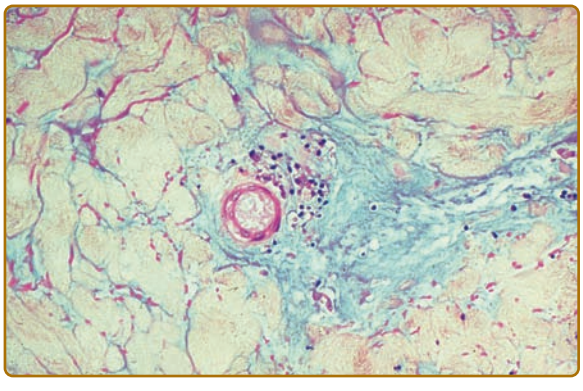

Figure 171-6 At the base of the dermal lesion, in the deep part of the reticular dermis, important mucin deposition and a slight lymphocytic infiltrate around a blood vessel (hematoxylin-eosin-safran-Astra blue, ×200).

performed in each patient. An extensive exploration of hemostasis will sometimes reveal abnormalities. When the disease starts with a sudden onset, a parvovirus B19 infection should be suspected and circulating viral DNA should be searched by PCR.[18]

Clinical evaluation can confirm secondary Degos disease if signs suggestive of connective tissue disease or antiphospholipid syndrome are present. If clinical evaluation reveals signs of intestinal or cerebral involvement (pain, diarrhea, hemiparesis, blurred vision, paresthesia), imaging studies including cerebral magnetic resonance imaging and/or endoscopic evaluation/laparoscopy are mandatory.

DIAGNOSIS

The diagnosis is usually established clinically, because of the distinctive skin lesion. A confirmatory biopsy should always be performed.

DIFFERENTIAL DIAGNOSIS

(Box 171-1)

COMPLICATIONS

Death related to an ischemic cerebral or gastrointestinal event is the major complication of Degos disease. Gastrointestinal hemorrhage, perforation, and peritonitis are the most frequent complications of the disease and are the major ominous events. Neurologic complications, including hemiparesis, aphasia, multiple cranial nerve involvement, monoplegia, sensory disturbances, and seizures, are less common. Rarely, progressive neurologic involvement can lead to death, especially in children. Exceptionally, death can result from respiratory failure or myocardial infarction.

BOX 171-1 DIFFERENTIAL DIAGNOSIS

Most Likely

- Atrophie blanche

Consider (Although Unlikely, Other Diseases with White and/or Necrotic Papules)

- Cutaneous lichen sclerosus
- Pityriasis lichenoides
- Lymphomatoid papulosis
- Syphilids, tuberculids
- Cutaneous Kikuchi disease (histiocytic necrotizing lymphadenitis)
- Clear cell papulosis
- Calcinosis cutis
- Fibroelastolytic papulosis of the neck
- White lentiginosis
- Scar, artifactual disease

Always Rule Out

- Connective tissue disease with Degos-like lesions, Crohn's disease, granulomatosis with polyangiitis (Wegener's), and parvovirus B19 infection.

PROGNOSIS AND CLINICAL COURSE

Although absence of visceral involvement 2 years after diagnosis portends a better prognosis, systemic involvement can occur up to many years after initial cutaneous lesions and thus it is impossible to predict the outcome. Lethality is above 50% if patients present with extracutaneous involvement, and most of these patients die within 2–3 years mainly because of severe intestinal involvement. Familial Degos disease bears a better prognosis.[4]

TREATMENT

Due to the rarity of Degos disease, there are no controlled clinical trials, but only anecdotal reports. Yet, in some aspects, Degos disease resembles livedoid vasculopathy, and, therefore, some treatments reported to be efficient in patients with the former entity are worth trying.

Secondary Degos disease occurring in patients with known connective tissue disease should involve, in our opinion, the introduction of antiplatelet agents in addition to the standard treatments otherwise required by those patients.

Patients with classic Degos disease should be screened for all known preventable cardiovascular risk factors. Patients should cease smoking, and their lipid levels should be screened and lowered, if necessary, using statins.

First-line treatment of patients with Degos disease should include platelet aggregation inhibitors (aspirin, clopidogrel, dipyridamole) (Box 171-2). A substantial number of patients responded to aspirin and dipyridamole.[6,7,12] A number of anecdotal treatments,

BOX 171-2 TREATMENT OF MALIGNANT ATROPHIC PAPULOSIS (DEGOS DISEASE)

First line	Aspirin (100–325 mg) and dipyridamole (3 × 400 mg)
Second line	Heparin and other anticoagulation strategies
Unresponsive or acutely ill patients	Intravenous immunoglobulins (1g/kg/day for 2 days or 0.4 g/kg/day for 5 days)
Adjunctive measures	Control of cardiovascular risk factors

including antibiotics, chloroquine, immunosuppressive agents, phenylbutazone, and fibrinolytics, have been reported with variable success. Systemic steroids have been reported to exacerbate the disease and should not be prescribed.[21] Heparin and other anticoagulation strategies such as antivitamin K (warfarin, fluindione) have variable success rates. Yet, by analogy to livedoid vasculopathy, low-molecular-weight heparin as well as the newer anticoagulants might warrant a trial in the acutely ill patient not responding to antiplatelet agents.[22] Intravenous immunoglobulins should be considered in patients not responding to other treatments or in the acutely ill.[18,23]

ACKNOWLEDGMENT

The author thanks Jean-Hilaire Saurat for his work on this chapter in previous editions.

Chapter 172 :: Vascular Malformations

:: Laurence M. Boon & Miikka Vikkula

VASCULAR MALFORMATIONS AT A GLANCE

- Worldwide prevalence: roughly 0.3%.
- Congenital, diversified but localized and well-demarcated lesions of malformed vessels of various types: capillary, venous, lymphatic, and arteriovenous.
- Histologically consist of enlarged, tortuous vessels of various types.
- Can be isolated, combined, or part of a syndrome.
- Management: multidisciplinary approach.

EPIDEMIOLOGY

Vascular malformations are believed to be due to errors of development of vessels that occur during the fourth and tenth weeks of intrauterine life. Most vascular malformations are sporadic, although several families with inherited forms have been identified. They are very heterogeneous and affect about 0.3% of the population. Vascular malformations are mostly congenital, even if they may be diagnosed only later in life.

ETIOLOGY AND PATHOGENESIS

Although several genes have been identified as the cause of inherited forms of vascular malformations, the etiology of the most common sporadic lesions is unknown.[1–3] Histologically, vascular malformations consist of enlarged, tortuous vessels with

quiescent endothelium. In contrast to hemangioma, there is neither parenchymal mass nor cellular proliferation.

CLASSIFICATION

For many years, vascular anomalies were grouped under the term *angioma*, hampering precise classification and leading to incorrect diagnosis and improper management. For example, the term *hemangioma* has been used both for vascular malformations, often of venous type (cavernous hemangioma) as well as for vascular tumors (strawberry hemangioma). This nomenclature changed in 1982 with the development of a biologic classification by Mulliken and Glowacki. It divided vascular anomalies into two major categories: (1) vascular tumors (with cellular proliferation; hemangioma being the most common) (see Chapter 126), and (2) vascular malformations (structural anomalies of blood vessels) that are subsequently subdivided, depending on the affected vessel type, into arterial, capillary, lymphatic, or venous malformations.[4,5] In 1996, this classification was adopted and further developed by the International Society for the Study of Vascular Anomalies (ISSVA) (Table 172-1).[6] Vascular malformations mostly affect only one vessel type, yet combined malformations also exist. They are named according to the affected vessel types, (e.g., capillary-venous or venolymphatic malformation). In addition to isolated forms, vascular malformations occur in syndromes such as Klippel–Trenaunay (KT) (capillary-lymphaticovenous malformation with limb hypertrophy), Maffucci syndrome (multiple enchondromas associated with multiple venous anomalies and high incidence of malignancy)[7], Cloves syndrome (congenital lipomatous overgrowth with vascular malformations, epidermal nevi, and scoliosis)[8,9], or Parkes Weber syndrome (high-flow vascular malformation of the extremity with soft tissue hypertrophy).[10]

TABLE 172-1
Classification of Vascular Tumors and Malformations

Vascular Tumors	Vascular Malformations
Hemangioma Hemangioma of infancy (HOI) Congenital Rapidly involuting congenital hemangioma (RICH) Noninvoluting congenital hemangioma (NICH)	**Capillary** Capillary malformation (CM) (Port-wine stain) Telangiectasia (hereditary benign telangiectasia, essential telangiectasia) Hereditary hemorrhagic telangiectasia (HHT) Capillary malformation-arteriovenous malformation (CM-AVM) Sturge–Weber syndrome
Hemangioendotheliomas Kaposiform hemangioendothelioma Tufted angioma	**Venous** Venous malformation (VM) Familial form: cutaneomucosal Mucocutaneous VM venous malformation cutaneomucosal (VMCM) Glomuvenous malformation (GVM) Blue rubber bleb nevus or Bean syndrome (BRBN)
Angiosarcoma	**Lymphatic** Lymphatic malformation (LM) Primary Lymphedemas **Arterial** Arteriovenous malformation (AVM) Capillary malformation-arteriovenous malformation (CM-AVM) Arteriovenous fistula (AVF) **Syndromic Malformations** Slow-flow Klippel–Trenaunay syndrome CLVM[1] (capillary-lymphaticovenous malformation with limb hypertrophy) Maffucci syndrome CLOVES syndrome Fast-flow Parkes Weber syndrome

CLINICAL FINDINGS

Vascular malformations grow proportionately with the patient. Usually they do not regress. Most frequently, they are well demarcated and localized (Fig. 172-1). In rare instances, they can be the stigmata of deep lesions. Vascular malformations are rheologically divided into *slow-flow* (capillary, lymphatic, venous, and combined) and *fast-flow* (arterial, arteriovenous, and combined). Doppler ultrasound is the best noninvasive radiologic examination that provides clues into the differentiation of the various types. Magnetic resonance imaging (MRI) details the extension and precise location of the lesion (Table 172-2).[11]

TREATMENT

Treatment of vascular malformations depends on the affected vessel type, the location of the lesion, and the symptoms. As many lesions are extensive, patients should be aware that a complete cure is often not possible. Treatment is difficult and can have severe complications. Extensive and/or complex lesions should always be managed by a multidisciplinary team.

Figure 172-1 Vascular malformations of various vessel types: **A.** capillary malformation of left lower extremity and genitalia; **B.** subcutaneous lymphatic malformation invading the cubital nerve; **C.** extensive venous malformation of right lower extremity causing pain, swelling, and coagulopathy; **D.** arteriovenous malformation of sole; and **E.** note nidus of the lesion on arteriography.

CAPILLARY MALFORMATIONS (CM)

EPIDEMIOLOGY

Capillary malformation (CM), commonly called *port-wine stain*, is a slow-flow vascular malformation with an incidence of 0.3% (Fig. 172-2).[12] Other blanchable pinkish patches, known as *stork bite, angel's kiss, salmon patch, or nevus flammeus neonatorum*, are often confused with CM. They are located on the nape of the neck (81%), the eyelids (45%), or the glabella (33%).[13] When located on the occiput, it is called *Unna nevus* (see eFig. 172-2.1 in online edition). These patches have a much higher incidence (42%) in white infants than in black infants (31%).[14] They are also present in various syndromes such as Beckwith–Wiedemann and Rubinstein–Taybi. These lesions disappear spontaneously around the ages of 1–4 years.

CAPILLARY MALFORMATIONS AT A GLANCE

- Worldwide occurrence: roughly 0.3% of the population affected.
- Congenital slow-flow malformations of the capillary bed.
- Pinkish red to purple in color. Tend to darken and thicken with time.
- In most cases, a cosmetic problem.
- Can be part of syndromes, such as Sturge–Weber or Klippel–Trenaunay.
- Pathology: capillaries that are increased in size and number with abnormal innervation.

TABLE 172-2
Diagnostic Features of Vascular Malformations

	Capillary Malformation	Venous Malformation	Lymphatic Malformation	Arteriovenous Malformation
Skin color	Pinkish-red to purple	Normal-bluish-purple GVM: red (neonates) to dark-blue-purple (adult)	Normal-yellowish-purple	Normal-red
Aspect	Flat	Flat-raised	Raised-vesicular	Flat-raised
Temperature	Normal	Normal	Normal	Warm
Palpation	Normal	Compressible GVM: nodular, painful	Firm, non compressible	Thrill, bruit
Associations	Hypertrophy pyogenic granulation	Phleboliths, deformation	–	Ulceration, deformation
Radiology	No-flow	Slow-flow	Slow-flow, cyst	Fast-flow
Histology	Dilated capillaries D2–40 negative	Thin-walled venous channels Relative lack of smooth muscle cells D2–40 negative	Cystic lymphatic channels D2–40 positive	Arterialized veins D2–40 negative
Etiology	?	VMCM: TIE2 GVM: Glomulin Sporadic VM: 50% somatic TIE2 mutations	LM: ? Primary lymphedema: SOX18, VEGFR3, FOXC2, CBR2	AVM: ? CM-AVM: *RASA1* HHT: endoglin, Activin-like receptor tyrosine kinase, SMAD4 PTHS: PTEN
Treatment	Pulsed-dye laser	Sclerotherapy, surgery	Surgery, sclerotherapy	Embolization followed by surgical resection of nidus

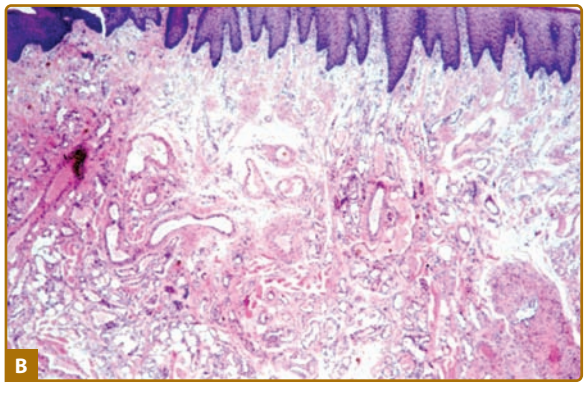

Figure 172-2 A. Extensive capillary malformation of upper extremity. **B.** Histologically, capillary malformation is characterized by dilated capillaries of normal number on the papillary and upper reticular dermis in combination with areas of increased number of normal-looking capillaries (hematoxylin and eosin staining).

CM are mainly sporadic, although there are well-documented pedigrees showing autosomal dominant inheritance.[15] When inherited, they are usually multiple and part of the CM-AVM phenotype, that associates atypical CM with arteriovenous malformation (AVM) (see Section "Arteriovenous Malformations").[16–19] No sex preponderance is noted.

ETIOLOGY AND PATHOGENESIS

Etiology of CM is currently unknown. Facial CM is thought to be due to clonal expansion of abnormal cells originating from the neural crest.[20] The identification of the affected gene (*RASA1*) in CM-AVM (see Section "Arteriovenous Malformations") might help unravel the cause of the more common sporadic CM. Histologically, CM is characterized by dilatation of normal numbers of capillaries of the papillary and upper reticular dermis combined with areas of increased number of normal-looking capillaries (see Fig. 172-2). Endothelial cells are flat. Factor VIII, fibronectin, and basement membrane protein are normal but S100 staining shows abnormal innervation.[21,22]

CLINICAL FINDINGS

CUTANEOUS LESIONS. (see Figs. 172-2 and 172-3). CM is a red homogenous congenital lesion that is often unilateral, sometimes bilateral, but usually not median. CMs involve skin and subcutis, and sometimes mucosa. Their color varies from pinkish red to deep purple with a geographic contour or a dermatomal distribution. Lesions are flat and painless, do not bleed spontaneously, and are never warm on palpation. They can extend throughout the entire body. Fifty percent of CMs are located on the face where they follow the distribution of the trigeminal nerve: ophthalmic branch V1 (front and upper eyelid), maxillary branch V2 (lower eyelid, cheek, and upper lip) (see Fig. 172-3B), or mandibular V3 (lower lip, chin, and mandibule). In combination with another vascular malformation, CM can be part of a syndrome, such as Sturge–Weber, phakomatosis pigmentovascularis (PPV), Klippel–Trenaunay (KT), Servelle–Martorell, etc. None of these syndromes is inherited. In rare instance, CM can be the cutaneous hallmark of occult spinal dysraphism, especially if located in the lumbosacral area.[23]

Sturge–Weber Syndrome. Sturge–Weber Syndrome (SWS) is a neuro-oculocutaneous syndrome consisting of a CM located on the opthalmic branch of the trigeminal nerve, a homolateral leptomeningeal capillary-venous malformation, often on the parieto-occipital area, and choroid "angioma" causing glaucoma and sometimes buphthalmos and retinal detachment (Fig. 172-4). Calcifications are frequently seen on the choroid plexus, and anomalies of the venous drainage of the encephalon can occur.[24] This malformation can cause epilepsy, leading to neural death, cerebral atrophy, and mental retardation.

Phakomatosis Pigmentovascularis. Phakomatosis pigmentovascularis (PPV) is thought to be an embryogenic anomaly affecting the vasomotor nerves and the melanocytes, both derived from neural crest. Clinically, PPV manifests as a large capillary malformation, which is metameric in distribution and mainly located on the trunk or the extremities, in association with pigmented cutaneous lesions, such as a pigmented nevus, a nevus spilus, a café au lait patch, or an atypical Mongolian spot (see Chapter 75) that is not located on the sacrum (eFig. 172-4.1 in online edition).[25] Nevus anemicus can also be seen in the vicinity as a twin spot.[26] These cutaneous lesions can be associated with systemic, visceral (e.g., larynx hypoplasia, intestinal polyposis), muscular (scoliosis), neurologic (mental retardation, epilepsy, intracranial calcification, cerebral atrophy), or ocular involvement (anomaly of the iris).

Klippel–Trenaunay Syndrome. Klippel–Trenaunay syndrome (KTS) is an eponym used for the presence of a capillary-lymphaticovenous malformation located on the extremity with hypertrophy of the affected limb (Fig. 172-5). Venous varicosities on the lateral side of the leg, first described by Servelle,

Figure 172-3 Several aspects of capillary malformations: light red lesions involving half of the body (**A**), dark red lesions on the face with mucosal involvement and soft tissue hypertrophy (**B**), and more localized on shoulder and arm (**C**).

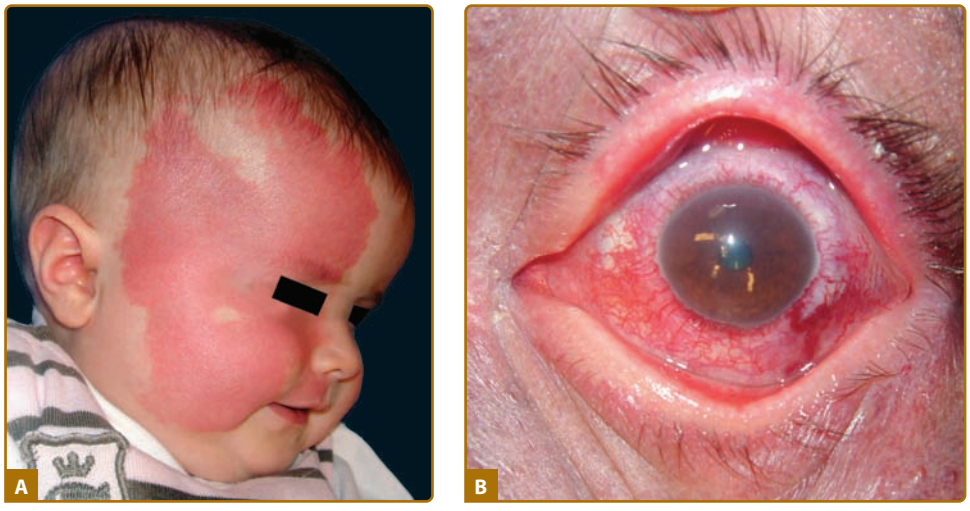

Figure 172-4 Extensive right facial capillary malformation (**A**) involving the ophthalmic and maxillary branches of the trigeminal nerve in a 6-month-old girl affected with Sturge–Weber syndrome. Choroid capillary-venous malformation (**B**) causing vision loss in a 50-year-old man with Sturge–Weber syndrome.

are very common and is specific for this syndrome in 80% of cases.[27] It is thought to be due to the persistence of embryologic veins. Valvular incompetence of deep venous system is common. Lower extremities are most commonly affected (95%), although upper limb, thorax, abdomen, and genitalia can also be involved. Lymphatic dermal vesicles cause frequent oozing. Lymphedema can be seen and tends to progress with time. Infection is common after trauma or secondary to small ulceration. VM is often seen in the underlying muscles. Hypertrophy of the limb is another sign of this disorder. It is already present at birth and occasionally evolves after puberty. Evolution toward ulceration, infection, bleeding, and thrombosis is common. Protein-loosing enteropathy can be seen with abdominal involvement. Pulmonary embolism can sometimes lead to death.

Figure 172-5 Capillary-lymphaticovenous malformation of the right lower extremity with soft tissue hypertrophy (Klippel–Trénaunay syndrome).

IMAGING STUDIES. No imaging studies are mandatory except in some rare situations. If a so-called *CM* is painful, warm, or spontaneously bleeds, Doppler ultrasound is indicated to exclude the diagnosis of a fast-flow malformation, such as an AVM, a Parkes Weber syndrome, or a proliferating hemangioma. CM located in the frontopalpebral area, especially if the inner part of the upper eyelid is involved, can be part of SWS. Therefore, a brain MRI and an ophthalmic examination have to be performed during the first months of life and repeated once a year until puberty, even if normal at younger age.[28] MRI of the spinal cord is needed in presence of a lumbosacral CM. In patients with PPV, ophthalmologic, neurologic, and orthopedic follow-up is mandatory due to the common association of CM with systemic lesion. In patients with KTS, leg length is evaluated radiologically after the age of 2 years and, if abnormal, followed once a year until the end of puberty. Doppler ultrasound evaluation of the venous status is mandatory to identify varicose veins in KTS. MRI is sometimes useful before management of the lesion.[27]

DIFFERENTIAL DIAGNOSIS

(Box 172-1)

AVF = arteriovenous fistula; AVM = arteriovenous malformation; CM = capillary malformation; CM-AVM = capillary malformation-arteriovenous malformation; CMTC = cutis marmorata telangiectatica congenita; HHT = hereditary hemorrhagic telangiectasia; M-CM = macrocephaly cutis marmorata

BOX 172-1 DIFFERENTIAL DIAGNOSIS OF CM

Differential Diagnosis of CM

Most Likely

Faint pinkish median patch
- Unna nevus
- Nevus flammeus neonatorum

Multiple, inherited
- CM of CM-AVM

Telangiectatic patch
- CMTC[a] [29]
- HHT[a] [30]
- Essential telangiectasia
- Unilateral naevoid telangiectasia

Warm on palpation
- Proliferating hemangioma
- AVM
- AVF

Ulcerated or painful
- AVM
- AVF

Rule Out

Small, multiple
- Mastocytosis
- CM of CM-AVM
- Tufted angioma [31]

Differential Diagnosis of CM (site specific)

Most Likely

Occiput
- Unna nevus

Glabella, upper eyelid, nape of neck
- Storke bite, angel's kiss, salmon patch

Consider

Extremity
- CMTC
- Klippel–Trenaunay syndrome
- Parkes Weber syndrome

Faint on trunk
- M-CM[a] [32]

Rule Out

Scalp
- Adams–Oliver syndrome [33]
- Multiple telangiectasia near canthus
- Ataxia telangiectasia [34]

[a]CMTC = Cutis Marmorata Telangiectatica Congenita; HHT = Hereditary Hemorrhagic Telangiectasia; M-CM = Macrocephaly-Capillary Malformation

COMPLICATIONS

The major concern for a patient affected with CM is cosmetic due to the visible discoloration. Hypertrophy of soft tissue can occur with time, especially when CM is located on V2 and V3 dermatomes or on the extremities. In rare instances, CM can be the stigmata of underlying anomalies such as lumbar dysraphism when located at sacrum.

PROGNOSIS AND CLINICAL COURSE

CM never regresses. It is present at birth, and slowly thickens and darkens with time. It often becomes raised and nodular.[35] Pyogenic granuloma can occur with time as well as soft tissue or bony hypertrophy.[36] (Fig. 172-6).

TREATMENT

Many therapeutical approaches have been used for CM, such as electrocoagulation, tattooing, dermabrasion, cryosurgery, and cosmetic makeup. Camouflage using Covermark is still effectively used (see eFig. 172-6.1 in online edition). Laser treatment is the gold standard for most CM. Pulsed-dye laser with its specific wavelength (585 nm) and a short pulse duration (400 ms) currently gives the best results in infants and children. There are few complications. Multiple sessions (6–12) are needed, and general anesthesia may be necessary as the procedure is painful. Laser treatment is more efficient on the cervicofacial and trunk area than on the extremities. Early treatment during childhood does not reduce the number of laser sessions.[37] The use of a dynamic cooling system to avoid heating the epidermis allows increasing of laser fluences, resulting in optimal lightening of the lesion.[38] Recurrence can occur after cessation of therapy. Laser has no impact on associated hypertrophy. Contour resection is needed mainly to treat complications such as pyogenic granuloma or lip hypertrophy.

Treatment of patients with KTS is conservative and mainly consists of elastic stockings to alleviate pain due to venous congestion. Surgical resection of varicose veins cannot be done if the deep venous system is abnormal (aplasia, incompetence). In the presence of leg discrepancy, an early-adapted shoe lift is needed to prevent scoliosis, and is followed by epiphysiodesis. If cutaneous bleeding occurs from capillary-lymphatic cutaneous vesicles,

Figure 172-6 Clinical course of capillary malformation: darkening and thickening with time: at age of 6 months (**A**), and at age of 33 years (**B**). Development of pyogenic granuloma (**C**), soft tissue (**D**), and mucosal hypertrophy (**E**).

neodymium:yttrium-aluminum-garnet laser coagulation, sclerotherapy, or skin grafting can be helpful.

PREVENTION

In patients with SWS, ophthalmic follow-up, started immediately after birth and continued until the end of puberty, is essential, as visual impairment will depend on the promptness of treatment. Prophylactic antiepileptic medication to prevent neural cell death has been advocated by some clinicians.[39,40]

VENOUS ANOMALIES

EPIDEMIOLOGY

Venous anomalies are the most common vascular malformations referred to specialized center [41]. They are mainly sporadic, although 1% are inherited (VMCM) and 5% are inherited glomuvenous malformations (GVM). No sex preponderance is reported.[42] Both VMCM and GVM have an age-dependant variation in penetrance, which reaches its maximum by 20 years of age (87% for VMCM and 92.7% for GVM).[43] Large VMCMs and GVMs are present at birth. However, 17% of affected individuals develop new small lesions over time.[42]

VM is a congenital defect on the skin or mucosa, but can involve any structure (subcutis, muscles, bones, and nerves) and any organ [central nervous system, gastrointestinal (GI) tract]. Fifty percent of VMs are located in the cervicofacial area and 37% on the extremities. VMs are mainly isolated, but can be part of complex vascular disorders of unknown etiology, such as KTS, and Maffucci and blue rubber bleb nevus (BRBN) syndromes.[44]

HISTOLOGY

VMs consist of ectatic vascular channels of venous type with flat endothelium and thin walls due to a variable number of mural smooth muscle cells that stain positive for smooth muscle cell-α-actin.[45] In contrast, GVM is characterized by distended venous channels surrounded by mural glomus cells that are aberrant

VENOUS MALFORMATIONS AT A GLANCE

- Most common referrals to specialized centers for vascular anomalies. Incidence unknown, but lower than for CM.
- Congenital slow-flow malformation of the venous bed.
- Bluish in color, localized or extensive, solitary or multifocal.
- Compressible on palpation, presence of phleboliths.
- Histologically consists of ectatic venous-like channels with anomalies in mural cells.
- Mainly sporadic but can be inherited as an autosomal dominant trait.
- Inherited venous anomalies: cutaneomucosal venous malformation (VMCM) (1%), glomuvenous malformation (GVM) (>5%).
- Syndromic venous malformation: Klippel–Trenaunay (KT), blue rubber bleb nevus (BRBN), Maffucci.

smooth muscle cells. Glomus cells are round or polygonal, instead of elongated like the normal vascular smooth muscle cells.[46] By immunohistochemistry, glomus cells stain positively for smooth muscle-α-actin and vimentin, whereas they are negative for desmin, von Willebrand factor and S100 neuronal marker.[47] By in situ hybridization, they are also negative for glomulin.[48]

PATHOGENESIS

The etiopathogenesis of at least 50% of sporadic VM are due to somatic mutations in the tyrosine kinase domain of the angiopoietin receptor TIE2, which was previously identified as the causative gene for inherited mucocutaneous VM (VMCM).[49] However, the mutations differ from the inherited ones, as the most common one (L914F) has never been identified as an inherited mutation and vice versa, the most common inherited mutation (R849W) has never been identified as a sporadic one, suggesting that sporadic mutations probably cause lethality in germline and that inherited one have weaker effects that require additional changes.[49]

VMCM is caused by amino acid substitutions in the *TIE2* gene. These gain-of-function mutations induce phosphorylation of the receptor.[50,51] GVM is genetically linked to a locus on 1p21, and caused by loss-of-function mutations in the *glomulin* gene.[43] Currently, there is no correlation between the position of a mutation in the *glomulin* gene and the characteristics of the disorder, such as the number of glomus cells in the lesion, the extent of the lesion, or the number of lesions. Moreover, for the same mutation, the expressivity is variable from patient to patient.[52] So far, a mutation in glomulin has been found in almost all GVM families tested, demonstrating locus homogeneity (Brouillard et al, unpublished).[48,52] Among the 30 different mutations found, eight are detected in several families, making efficient genetic diagnosis possible in more than 75% of patients. Several observations suggest a paradominant mode of inheritance for GVM, instead of a simple autosomal dominant transmission. A somatic double-hit mutation has been identified in one GVM resected from a patient with a known inherited glomulin mutation (Aerts et al, in preparation).[43] The combination of an inherited and a somatic mutation in the tissue suggests that a complete loss of glomulin is needed for GVM development.[43] This could explain the variation in size and location of GVMs, depending on the time of occurrence of the postzygotic second-hit mutations. The low frequency of extensive lesions (>5 cm) and the high frequency of localized lesions (<5 cm) support this model.[42]

CLINICAL FINDINGS

(Table 172-3; Fig. 172-7; and see eFig. 172-7.1 in online edition)

VMs are usually solitary, but can be multifocal, suggesting an inheritable disorder. Cutaneous VMs are congenital light-to-dark bluish lesions. Deep VM has a normal overlying skin color and is often diagnosed only at puberty or later in life with the onset of pain. Cutaneous VMs are detected early because they are usually clinically visible. Size varies from small spongy blebs to large lesions of several centimeters in diameter. VMs can easily be emptied by compression or by positioning in a non-dependent position. Skin temperature is normal. There is no thrill or bruit. Depending on size and location, VMs can cause pain, particularly in the morning on awakening, anatomic distortion, and even threaten life because of bleeding, expansion, or obstruction of vital structures. Palpation is not painful unless thrombosis occurs.[42] Local thrombosis is responsible for acute pain that lasts for 10 days and causes phleboliths, which can be identified by palpation or by radiography. VM never cause pulmonary embolism. Facial VM is usually unilateral causing asymmetry and progressive deformation and possibly dental malalignment (see Fig. 172-7 and eFig. 172-7.1 in online edition). Migraine is a common feature, if VM is located in the temporal muscle. Oropharyngeal VM can impair speech, whereas pharyngeal or laryngeal location will compromise the airway and cause snoring and even sleeping apnea. On extremities, VMs often involve muscles and joints (see eFig. 172-7.1 in online edition). They cause muscle weakness, hypotrophy, and sometimes hypertrophy, resulting in leg length discrepancy, which is less severe than in KTS. Intra-articular bleeding, if the malformation is located in the knee joint, lead to early-onset arthrosis.[53] Genital VM often occurs with limb VM and can be responsible for dyspareunia. GI VM is often diagnosed in patients with chronic anemia.

TABLE 172-3
Diagnostic Features of Venous Anomalies

	VM	VMCM	GVM	BRBN	Maffucci Syndrome
Location	50% head and neck	Extremities, mucosa	70% extremities	Especially palms and soles	Extremities
Skin color	Normal-bluish-purple	Bluish	Bluish-red-purple	Bluish-dark-blue	Normal-bluish
Aspect	Flat-raised	Raised dome-shaped	Raised, cobblestone Plaque like, hyperkeratotic	Dome shaped, nipple-like	Exophytic
	Single large	Multiple, small	Multiple	Multiple, small often + 1 large lesion	Multiple, important deformation of hands and feet
Palpation	Phleboliths	Compressible	Non compressible Painful	Firm, rubbery, Spongy	Firm
Associated	Coagulopathy	–	–	Visceral venous malformation, coagulopathy	Multiple enchondromas High risk of cancer
Radiologic	Phleboliths	Venous channels	No phlebolith	Venous channels	Venous channels Enchondromas
Tissue involved	Often deep location	Cutis and subcutis	Cutis and subcutis	Often deep component	Deep location
Histology	Thin-walled venous channels	Thin-walled venous channels	Glomus cells	Thin-walled venous channels	Spindle cells Hemangioendothelioma
Inheritance	Sporadic	Autosomal dominant	Autosomal dominant	Sporadic	Sporadic
Cause	50% somatic TIE2 mutations	Gain of function mutation in TIE2	Loss of function mutation in Glomulin	?	?

BOX 172-2 DIFFERENTIAL DIAGNOSIS OF VM

Differential Diagnosis of VM

Most Likely

Bluish subcutaneous mass, noncompressible
- Infantile hemangioma
- Lymphatic malformation

With multiple enchondromas
- Maffucci syndrome

Consider

Hyperkeratotic
- GVM, if on extremity
- HCCVM of CCM

Rule Out

Superficial, collateral normal veins
- Deep venous insufficiency, iatrogenic stenosis or congenital agenesis

Bluish non vascular lesion
- Bluish non vascular lesion such as bluish nevus

Differential Diagnosis of VM (Site Specific)

Consider

Base of the nose
- Normal prominent veins

Scalp or forehead
- Sinus pericranii
- Underlying Galen malformation

Subungual
- Solitary glomus tumor

Cheek
- Bluish nevus

Brain
- Developmental venous anomaly
- CCM

Rule Out

Neck; deep mass
- Thyroglossal duct
- Bronchogenic cyst

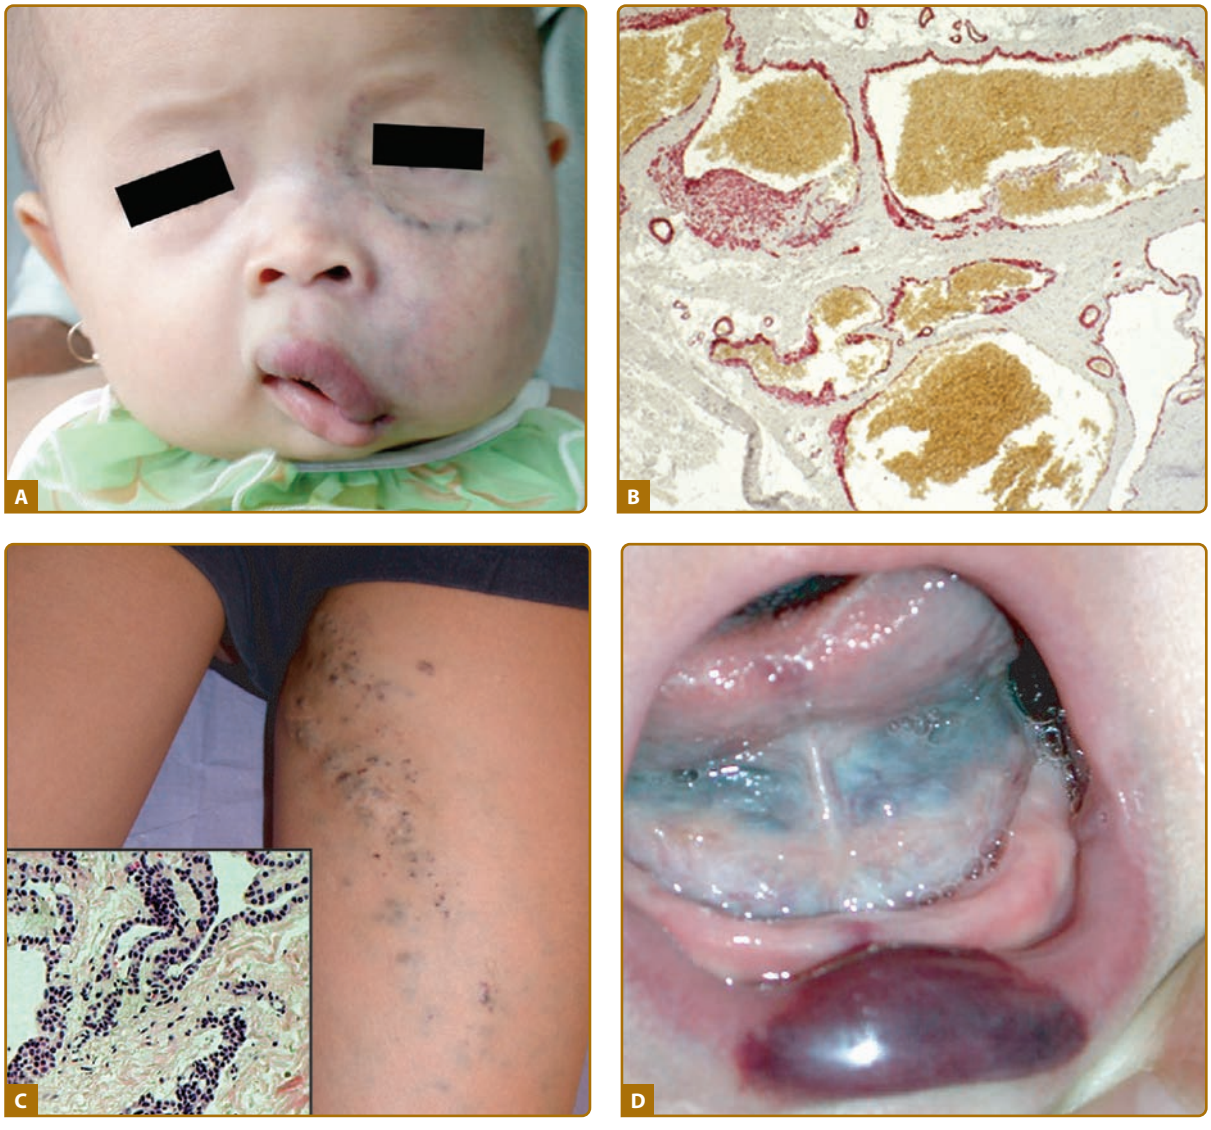

Figure 172-7 **A.** Venous anomalies: extensive hemifacial venous malformation (VM) causing soft-tissue hypertrophy and lip deformation in a 6-month-old boy. **B.** Histologically, VM consists of ectatic venous-like channels with anomalies in mural cells (hematoxylin and eosin). **C.** Superficial glomuvenous malformation of the inner thigh. Note the presence of mural glomus cells on histology (hematoxylin and eosin). **D.** Mucosal VM involving the lower lip and the floor of the mouth.

LYMPHATIC MALFORMATIONS

EPIDEMIOLOGY

Lymphatic malformation (LM) is a congenital disorder of unknown incidence. It consists of vesicles or large cysts filled with lymphatic fluid. Macrocystic LM can be diagnosed in utero as early as the first trimester of pregnancy.[83] However, most LMs are diagnosed during infancy, before the age of 2 years. Some can manifest only at puberty or during adulthood. Macrocystic LMs are often located on the neck, axilla, chest wall, or groin, whereas microcystic lesions are commonly seen in the face. LMs occur sporadically in contrast to primary lymphedema that can be inherited as an autosomal dominant trait in up to 20% of cases. Rare families with recessive inheritance have also been

LYMPHATIC MALFORMATIONS AT A GLANCE

- Worldwide occurrence is unknown.
- Congenital sporadic slow-flow malformations of the lymphatic vessels.
- Primary lymphedema can be inherited as an autosomal trait.
- LMs consist of micro- or macrocysts filled with lymphatic fluid.
- Infection is the most common complication that can lead to septicemia.
- Histologically consist of dilated lymphatic channels with flat endothelium that stains for D2-40.

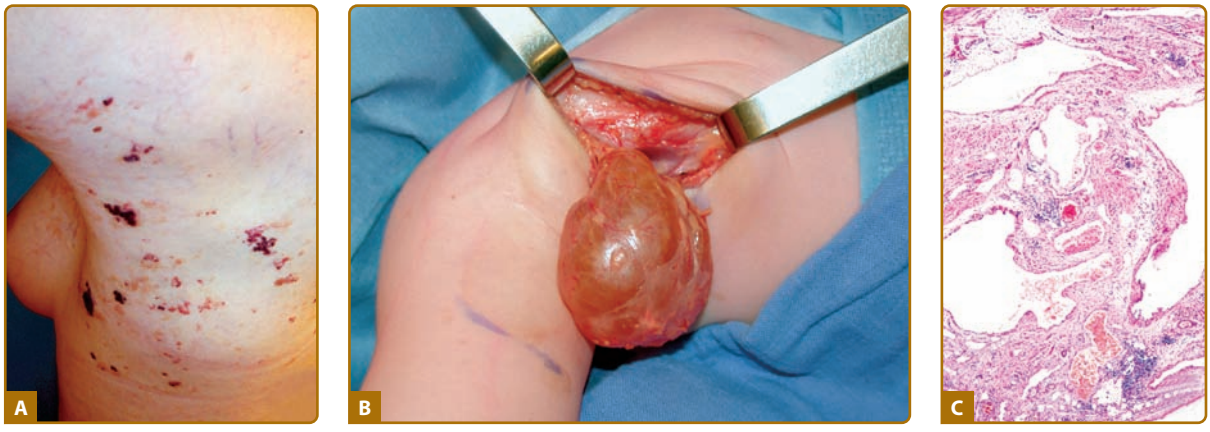

Figure 172-8 **A.** Microcystic, dermal lymphatic malformation (LM) consisting of clear and dark-red vesicles. **B.** Intraoperative view of a macrocystic LM of the axilla showing a well-delineated cyst filled with clear lymph fluid. **C.** Histologically, LM consists of dilated lymphatic channels with flat endothelium (hematoxylin and eosin).

identified.[84] Primary lymphedema is divided into congenital (present at or soon after birth) (Milroy disease, OMIM #153100) and late onset (present at puberty) (Meige disease OMIM #153200). It can be isolated or part of a syndrome, such as Turner and Noonan syndromes.[85]

ETIOLOGY AND PATHOGENESIS

LMs are errors in morphogenesis of the lymphatic vessels. The etiology is unknown. In contrast, several genes have been identified that lead to or cause lymphedema. Milroy disease is caused by a mutation that leads to loss of phosphorylation of vascular endothelial growth factor receptor 3 (VEGFR3),[86,87] whereas lymphedema distichiasis is caused by loss-of-function mutations in the FOXC2 transcription factor. Hypotrichosis-lymphedema-telangiectasia (HLT) that has an autosomal dominant or recessive pattern of inheritance, is caused by mutations in *SOX18*.[84] Hennekam syndrome is an autosomal recessive generalized lymphatic dysplasia, which is characterized by intestinal lymphangiectasia with severe and progressive lymphedema of the limbs, genitalia, and face and sever mental retardation (OMIM #235510).[88] Mutations in the Ccbe1 (collagen and calcium-binding EGF domains 1) have been identified.[89,90]

Histologically, LMs are characterized by dilated flat endothelium-lined channels of variable wall thickness. No blood cells are seen in these spaces, except after intracystic bleeding (Fig. 172-8) or in the presence of a combined lymphaticovenous malformation. Macrocystic LM shows single or multiple lymphatic cysts surrounded by thick fibrous membrane. These cysts do not communicate with each other. Endothelial vessels express specific lymphatic markers, such as podoplanin, D2-40, VEGFR-3.[91] Lymphedema is characterized by abnormalities in collecting lymphatic vessels in the affected limb (VEGFR3 and FOXC2 patients) and extensive dermal fibrosis.

CLINICAL FINDINGS

LMs are composed of microcysts (previously *lymphangioma* circumscriptum; Fig. 172-9) and/or macrocysts (larger than 1-cm diameter, previously known as cystic hygroma) that grow proportionally with the child. They are filled with clear or serosanguineous fluid (see Fig. 172-9). Macrocystic LM manifests as a soft, multilobulated, well-defined mass, whereas microcystic LMs are ill defined and often invade adjacent structures. Skin can be normal in color or, due to intracystic bleeding, have a bluish discoloration (see eFig. 172-9.1 in online edition). Dermal LMs can manifest as small millimeter-sized vesicles, clear (see Fig. 172-9 and eFig. 172-9.1 in online edition) or dark red (if intracystic bleeding) that can bleed and become purple and nodular.

Facial asymmetry, especially of the mandibule, is commonly associated with microcystic LM (see eFig. 172-9.1 in online edition). Intraorbital LM is responsible for ocular dystopia and exophthalmia as well as orbital enlargement. LM on the tongue impairs speech and produces oozing and halitosis. Airway obstruction is common when affecting the base of the tongue or the cervicofacial area.[92] Extension into the pleura can occur and cause

Figure 172-9 Lymphatic malformation. Frog-spawn-like confluent grouped "vesicles" filled with a serosanguineous fluid.

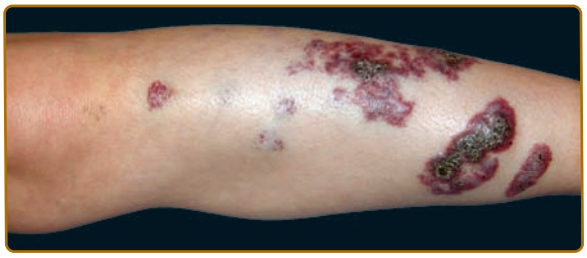

Figure 172-10 Capillary-lymphatic malformation (angiokeratoma circumscriptum) on the lower extremity, causing oozing. It is purple–red in color and slightly raised, with hyperkeratosis.

chylothorax. Abdominal lesions are associated with chylous ascites. Extensive limb LM can cause elephantiasis.

ANGIOKERATOMA CIRCUMSCRIPTUM. Angiokeratoma circumscriptum, or capillary-lymphatic malformation (CLM), is a combined, well-demarcated lesion often located on the extremity. This lesion is pink to bluish red in color, slightly raised, and usually hyperkeratotic (Fig. 172-10). Dilated capillaries and lymphatic vessels located on the superficial dermis and associated with hyperkeratosis can be seen histologically. Clinically, angiokeratoma circumscriptum (see Fig. 172-10), angiokeratoma of Mibelli

Figure 172-11 Various types of congenital primary lymphedema characterized by lymphedema of lower limb, below the knees (**A**), with papillomatosis (**B**), and with upslanting toenails (**C**), that can evolve into elephantiasis (**D**).

(circumscribed, dark-red, and hyperkeratotic plaques on the distal extremities; see eFig. 172-10.1 in online edition), and angiokeratoma of Fordyce (very common hyperkeratotic, blue–black papules on the scrotum of elderly males; see eFig. 172-10.2 in online edition) are recognized (see Table 136-2). They have to be differentiated from the angiokeratomas of Fabry disease (see Chapter136).

GORHAM–STOUT SYNDROME. Gorham–Stout syndrome ("vanishing bone disease") is an osteolytic disorder characterized by progressive demineralization and destruction of bones, which are replaced by lymphatic vessels and capillaries.[93] Depending on the location, this syndrome manifests as bone pain, muscular atrophy, fractures, pleural effusion, ascites, and cerebrospinal fluid rhinorrhea. Lethality occurs in 16% of cases.

LYMPHEDEMA. Lymphedema is characterized by swelling of the affected body part, usually the lower extremity, and caused by accumulation of lymphatic fluid into the extracellular space due to intrinsic lymphatic dysfunction (Fig. 172-11). Various phenotypes depending on the age of onset, location and associated anomalies.[90]

Congenital lymphedema. Congenital lymphedema or Milroy disease is suspected in the presence of swelling of the dorsum of the feet with familial history of lymphedema. Lymphedema is present at birth, often bilateral and affects the lower limbs, below the knees.[94] Other features can be associated with congenital lymphedema, such as hydrocele (37% of males), prominent veins (23%), upslanting toenails (14%), papillomatosis (10%), or urethral abnormalities in males (4%). Cellulitis is a common complication affecting 20% of cases.[94] Rare occurrence of pleural effusion even in utero, hydrops fetalis, and chylous ascites have been observed.[95,96] Spontaneous resorption of limited localized lymphedema has also been noted.[87,95] Moreover, in some patients ($n = 2/12$), sporadic hydrops fetalis and/or generalized subcutaneous edema was caused by a VEGFR3 mutation.[97] At birth, they had only limited edema of the lower extremities. The presence of a VEGFR3 mutation in this frequently lethal fetal condition may thus be a positive prognostic factor.

DIFFERENTIAL DIAGNOSIS

(Box 172-3)

COMPLICATIONS

LM can suddenly enlarge in response to fever, cough, or viral or bacterial infection or to intralesional bleeding (see eFig. 172-11.1 in online edition). Recurrent cellulitis is the major complication, as it can evolve into septicemia if not promptly treated. Local redness and warmth will appear and the lesion will become painful. Visceral LM can cause protein-loosing enteropathy and hypoalbuminemia.

BOX 172-3 DIFFERENTIAL DIAGNOSIS OF LM

Differential Diagnosis of LM

Most Likely

Rapid growth after birth

- Fibro- or rhabdomyosarcoma[100]

Consider

Subcutaneous mass

- Infantile hemangioma
- Venous malformation
- Teratoma[101]
- Fibrosarcoma

Differential Diagnosis of LM (Site Specific)

Rule Out

Vulvar

- Acquired lymphangiectasia due to radiotherapy
- Acquired lymphangiectasia due to Crohn disease

PROGNOSIS AND CLINICAL COURSE

LM usually grows with the child. LM often causes asymmetry with bony overgrowth. Increase in size can be seen during infection of intralesional bleeding. Episodic reports of spontaneous involution exist. As the regression is usually seen after local infection, it could be that this evolution is due to postinflammatory pseudosclerosis.

TREATMENT

Intralesional bacterial infection as well as early cellulitis should be monitored with prolonged antibiotics first given intravenously. Pain medication and anti-inflammatory drugs may be required. Immune-modifying medications, such as interferon and corticosteroids, are not effective. Neodymium:yttrium-aluminum-garnet laser or carbon dioxide laser photocoagulation has been used to treat dermal LM vesicles that cause oozing (see eFig. 172-11.2 in online edition). Macrocystic LM is treated with fluid aspiration followed by percutaneous, intralesional injection of sclerosing agents performed by an interventional radiologist. Several sclerosing agents have been used, such as sodium tetradecyl sulfate, pure ethanol, OK432 (extract from a killed strain of group A *Streptococcus pyogenes*: picibanil), doxycycline, or bleomycin. Side effects include fever, erythema, and oedema.[102,103]

Surgical resection is another alternative for LM.[104] Results depend on the anatomical site and extension of the lesion (See eFig. 172-11.3 in online edition). Recurrence is frequent since it is difficult to differentiate microcystic LM from adjacent normal tissue. This leads to either incomplete resection or unnecessary sacrifice of normal structures. One should always try to treat completely one region at a time.[105]

Lymphedema is best treated with elastic stocking, massage, and pneumatic compression devices. Family and patient education regarding the etiology and treatment is necessary, as lymphedema can be inherited.

ARTERIOVENOUS MALFORMATIONS

ARTERIOVENOUS MALFORMATIONS AT A GLANCE

- Worldwide occurrence: rare, but exact frequency unknown.
- Congenital fast-flow malformations that can be hidden until puberty.
- Histologically consist of direct communications between arteries and veins.
- Usually sporadic, but can have a genetic predisposition as in capillary malformation-arteriovenous malformation or hereditary hemorrhagic telangiectasia.
- Can be part of syndromes, such as Parkes Weber or PTEN hamartoma tumor syndrome
- Most difficult vascular malformations to treat; need a multidisciplinary approach.

Fast-flow cutaneous vascular malformations are mainly AVM and rarely arteriovenous fistula (AVF). AVF is usually traumatic. AVM is characterized by the presence of a "nidus," the epicenter of the lesion that is composed of direct communications between multiple feeding arteries and draining veins without intervening the normal capillary bed. Histologically, AVM consists of distorted arteries and veins with thickened muscle walls due to arteriovenous shunting and fibrosis (Fig. 172-12).

EPIDEMIOLOGY

The incidence of AVM is unknown. It is a rare, usually sporadic, fast-flow vascular malformation. It can affect any tissue and any organ. Seventy percent of AVMs are located on the head and neck area. AVMs are present at birth, but often manifest later in life during puberty or after trauma. They never regress. Hereditary hemorrhagic telangiectasia (HHT) is an autosomal inherited disorder with a prevalence of 1 in 10,000 individuals.

ETIOLOGY AND PATHOGENESIS

The etiology of AVM is currently unknown. An underlying predisposing genetic defect exists for these fast-flow vascular malformations when part of CM-AVM (OMIM #608354), HHT (OMIM #187300), or PTHS (OMIM #153480 and 158350). CM-AVM associates multiple, small, atypical CMs with fast-flow lesions (AVM or AVF). It is inherited as an autosomal dominant disorder with a penetrance of about 95%.[16,17,19] It is caused by loss-of-function mutations in the *RASA1* gene.[16,18] The high intrafamilial phenotypic variability could be explained by the necessity of a second hit, a somatic mutation, to occur. Prevalence of CM-AVM is unknown.

Molecules implicated in the transforming growth factor-β signaling pathway predispose to the formation of AVM/AVF, as loss-of-function mutations in endoglin and activin-like receptor tyrosine kinase cause hereditary hemorrhagic telangiectasia with fast-flow lesions in skin, mucosa and viscera (lung, brain, and liver) (OMIM # 187300).[106,107]

AVM can also be caused by loss-of-function mutation in PTEN, a tumor suppressor gene, as seen in most patients with PTHS (OMIM# 158350 & 153480).[108] This rare congenital, autosomal dominant disorder is characterized by the triad of macrocephaly, multiple lipomas and AVMs, which are often multifocal, associated with ectopic fat, and cause destruction of tissue architecture.[109,110]

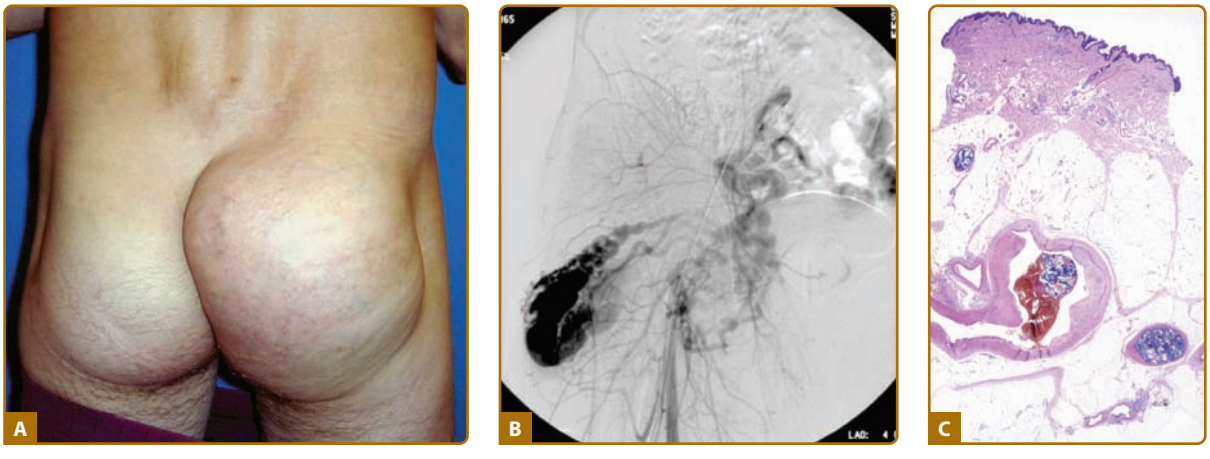

Figure 172-12 Extensive arteriovenous malformation deforming the right buttock (**A**). Arteriography showing the nidus of the malformation (**B**). Histology shows a direct connection between artery and vein, with thrombotic material secondary to the embolization procedure (**C**).

TABLE 172-4
AVM Staging: Schobinger Classification

STAGE 1	Local mass, blush or red stain Doppler ultrasound: increased vascularization
STAGE 2	+ Prominent draining veins, pulsation, thrill Doppler ultrasound: arteriovenous shunting
STAGE 3	+ Dystrophic changes
STAGE 4	+ Congestive heart failure

CLINICAL FINDINGS

During childhood, AVM is often mistaken for a CM or a hemangioma, as, at birth, AVM usually manifests as a faint, ill-defined, macular red stain. However palpation reveals its fast-flow component as it is warm. About one third of AVMs are present at birth, another one-third appear during childhood or at puberty, and the rest in adulthood. Puberty and trauma usually trigger the growth of an AVM. AVMs are staged using the Schobinger classification (Table 172-4). AVMs manifest as cutaneous, red-to-purple warm masses with a thrill, a bruit, or a pulsation of increased amplitude. They worsen with time evolving from stage I to III or even IV, never regressing spontaneously (Fig. 172-13).

CM-AVM. CM-AVM manifests as multiple atypical CM associated with fast-flow lesions in 18% to 20% of patients: AVM, AVF, Parkes Weber syndrome. The expressivity is highly variable within families, from small, asymptomatic CMs to life-threatening AVM. In contrast to sporadic CM, CMs in CM-AVM are often multiple and randomly distributed. Their size is variable: from a few millimeters to several centimeters in diameter. They are round-to-oval, pink, red or brown, and sometimes with a narrow pale halo (Fig. 172-14). The lesions are well-circumscribed and blanch on pressure with a glass. Some of them are present at birth, whereas others appear later. They grow with the child and are asymptomatic. Fast-flow lesions (AVM or AVF) are either cutaneous, subcutaneous with or without intramuscular and intraosseous involvement, intraspinal (A novel association between *RASA1* mutations and spinal arteriovenous anomalies[111], or intracerebral.[16,17,19] About 10%–15% of the CM-AVM individuals have Parkes Weber syndrome either on the lower (two-thirds) or the upper extremity (one-third). The AVMs can be asymptomatic but complications occur depending on their location and size.

HEREDITARY HEMORRHAGIC TELANGIECTASIA. Hereditary Hemorrhagic Telangiectasia (HHT) manifests as multiple cutaneous and mucosal telangiectasias that are associated with visceral, pulmonary, and cerebral fast-flow lesions. Epistaxis is a common clinical sign and can be life-threatening (ref 25).

PTEN HAMARTOMA TUMOR SYNDROME. PTEN hamartoma tumor syndrome (PTHS) regroup patients with Bannayan–Riley–Ruvalcaba syndrome (BRRS) and Cowden syndrome, as 60% and 81% of them, respectively, have a mutation in the *PTEN* gene.[110] These patients typically have macrocephaly, penile freckling, multiple developmental venous anomalies in the brain, fast-flow vascular malformations (54%) and an increased risk of malignancy. The vascular

Figure 172-14 Small atypical capillary malformations of capillary malformation-arteriovenous malformation (**A–D**). Note the pale halo (**D**).

malformations are often multifocal (57%) and musculoskeletal, and associated with ectopic fat deposition and disruption of the normal tissular architecture.

PARKES WEBER SYNDROME. Parkes Weber syndrome (OMIM # 608355) was first described by F. Parkes Weber in 1918. This condition is characterized by a large, congenital, cutaneous, vascular stain on an extremity in association with soft tissue and skeletal hypertrophy of the affected limb, and with underlying multiple arteriovenous microfistulas.[10] The affected extremity is longer and larger than the contralateral one. The signs and symptoms worsen with age. When young, these patients can develop congestive heart failure.

BONNET–DECHAUME–BLANC OR WYBURN–MASON SYNDROME. Bonnet–Dechaume–Blanc or Wyburn–Mason syndrome, is a sporadic syndromic AVM located in the centrofacial and/or hemifacial area, with oculo-orbital and cerebral involvement.[112] AVM is present at birth and worsens with time. Patients can exhibit epistaxis, exophthalmos, and hemianopia. Mental retardation can occur.

COBB SYNDROME. Cobb syndrome is another sporadic syndromic AVM that associates cutaneous and spinal cord AVMs of the same metamere.[113] It manifests in childhood with neurological complications (pain, sensory and motor disturbances and a neurogenic bladder) that depend on the location and extension of the AVM. Treatment consists of complete surgical resection of the spinal cord AVM nidus, whenever possible.

IMAGING STUDY

Ultrasonography and Color Doppler show no mass, but an aggregation of high-velocity arterial and pulsatile venous flow with low resistance. Vessels are tortuous. On extremities, noninvasive follow-up is performed by comparing the arterial outflow of the affected limb with the unaffected one. Computed tomography scan has been replaced by MRI, which better shows the extent of AVM and allows differentiation from hemangioma and VM. Flow voids, corresponding to fast-flow vessels, are pathognomonic of AVM. Arteriography

DIFFERENTIAL DIAGNOSIS

(Box 172-4)

PROGNOSIS AND CLINICAL COURSE

AVMs tend to worsen with time, causing local destruction and/or life-threatening bleeding. Puberty and trauma trigger growth. Bony hypertrophy is a common feature that causes common facial asymmetry. AVM of an extremity commonly causes peripheral ischemia due to blood flow steel phenomenon. Cardiac failure is rare (Schobinger stage IV), especially during childhood. Improper management, often due to misdiagnosis, such as ligation of feeding arteries, or partial resection of the nidus, can have dramatic consequences and expansion of the AVM (see Fig. 172-13). The CMs in CM-AVM are harmless, and usually of only cosmetic importance.

TREATMENT

This fast-flow vascular malformation is the most complex and difficult vascular anomaly to treat. Its management is multidisciplinary. AVM should be followed by periodic evaluation. In a limb AVM or multiple AVFs, elastic stockings can stabilize the lesion and protect the skin. The goal of cure of an AVM is based on obliteration (by embolization) and complete removal of the nidus or the epicenter. Early intervention for "quiescent AVM" (Schobinger Stage I) is debatable but should be considered only if complete resection is possible.[114] In contrast to AVF, superselective arterial embolization alone is only palliative and is done only in unresectable complicated AVM. The embolized particles need to reach the epicenter of the lesion to avoid refilling of the nidus through new collaterals.[115] Direct puncture of the nidus is another possibility in patients with previous arterial ligation or embolization.[116] Surgical resection is usually done only after embolization, to minimize perioperative bleeding.[117] AVM needs to be widely excised. Reconstruction often necessitates microsurgical free flap transfer.[118] At least 5-year follow-up by annual Doppler ultrasound and/or MRI is mandatory after any treatment. For patients with Parkes Weber syndrome, the treatment should be as conservative as possible (e.g., elastic stockings). Epiphysiodesis may be necessary to control leg length discrepancy. However, this procedure can sometimes aggravate the AVM.[10]

For patients with HHT, multiple treatments have been tried to reduce bleeding, for example, topical application of anti-inflammatory drugs, laser, or surgery. Due to the extensiveness of the lesions, they all give limited free symptoms-intervals. Thalidomide has recently been successfully used to reduce the frequency and duration of nosebleeds in patients with HHT.[119]

Chapter 173 :: Cutaneous Changes in Peripheral Arterial Vascular Disease

:: Veerendra Chadachan, Steven M. Dean, & Robert T. Eberhardt

OBSTRUCTIVE PERIPHERAL ARTERIAL DISEASE

OBSTRUCTIVE PERIPHERAL ARTERIAL DISEASE AT A GLANCE

- Most commonly due to atherosclerosis of the vessels supplying the lower extremity.
- Affects 15% of the US adult population over the age of 65 years.
- Stenosis or obstruction of the large arteries to the lower extremities leading to supply demand mismatch, initially with exertion but may progress to occur at rest.
- Intermittent claudication with exertional muscle pain or fatigue, critical limb ischemia with rest pain or tissue compromise, and acute limb ischemia.
- Cutaneous findings from hypoperfusion ranging from dry skin, hair loss, and malformed toenails to ulceration and gangrene.

EPIDEMIOLOGY

Although atherosclerotic obstructive peripheral arterial disease (PAD) has a prevalence of only 3% in patients of age 40–59 years, this rises to 15% in the age group older than 65 years. This translates into approximately 9 million cases in the United States in 2005, and this number is expected to increase along with the aging demographics of our population.[1,2] PAD is often unrecognized clinically and more than one-half of all patients are asymptomatic. Gender predisposition shows preponderance in males, although the incidence in females rises rapidly after menopause. Anatomically, superficial femoral artery disease predominates, with development of symptoms typically in the seventh decade. Interestingly, symptoms from aortoiliac disease usually present a decade earlier.

ETIOLOGY AND PATHOGENESIS

Atherosclerotic risk factors are similar to those identified for coronary artery disease and include diabetes mellitus, hypertension, hyperlipidemia, smoking, family history of vascular disease, and obesity. Among these, diabetes mellitus and smoking are the most significant and are associated with a fourfold and doubling of relative risk, respectively. Patients with diabetes mellitus develop the disease at an earlier age than nondiabetics and have more severe and progressive disease. The anatomic distribution of obstruction differs from nondiabetics with less aortoiliac involvement and more extensive disease of the runoff vessels below the knees; however, superficial femoral artery disease is similar in both populations. Approximately 50% of patients have hyperlipidemia. PAD is also more commonly encountered in patients with hypertension.

The pathologic findings in atherosclerosis occur in large- and medium-sized arteries, and are morphologically diverse, with focal accumulation of lipids and lipoproteins, mucopolysaccharides and collagen, smooth muscle cells and macrophages, and calcium deposits in variable quantities. Localized areas of intimal thickening secondary to smooth muscle cell proliferation and lipid-laden macrophages are seen in early stages with disruption of the internal elastic lamina. The media is often atrophic with thin strands of smooth muscle, lipid pools, collagen tissue, and calcium deposits. Enlarging plaques

encroach on the lumen despite dilation of the artery, and the plaques may ulcerate. Hemorrhages occur in the arterial wall. Thrombi may form and occlude the narrowed arterial lumen.

The etiology of atherosclerosis is complex and multifactorial, but progressive buildup of plaque narrows the vessel lumen, and complete occlusion may develop acutely secondary to thrombosis. Because disease progression is usually over an extended time period, collateral blood vessels have time to develop and are usually robust. Tissue perfusion to the affected limb is often adequate at rest, but the blood pressure distal to the occlusions is decreased secondary to high resistance and limited flow through collateral vessels. Under resting conditions, normal blood flow to extremity muscle groups averages 300–400 mL/min. Once exercise begins, blood flow increases up to tenfold owing to the increase in cardiac output and compensatory vasodilation at the tissue level. When exercise ceases, the blood flow returns to normal within minutes. In patients with PAD, resting blood flow may be similar to that of a healthy person. However, during exercise, blood flow cannot maximally increase in muscle tissue because of fixed proximal arterial stenoses. When the metabolic demands of the muscle exceed blood flow, claudication symptoms ensue. At the same time, a longer recovery period is required for blood flow to return to baseline once exercise is terminated. Dermatologic changes imply severe compromise of tissue perfusion, often secondary to tandem high-grade stenoses or occlusions present at multiple levels in the arterial tree.

CLINICAL FINDINGS

(Fig. 173-1)

HISTORY. The most classical symptom of PAD is intermittent claudication, which is usually described as pain, fatigue, or tiredness in the muscles distal to the diseased

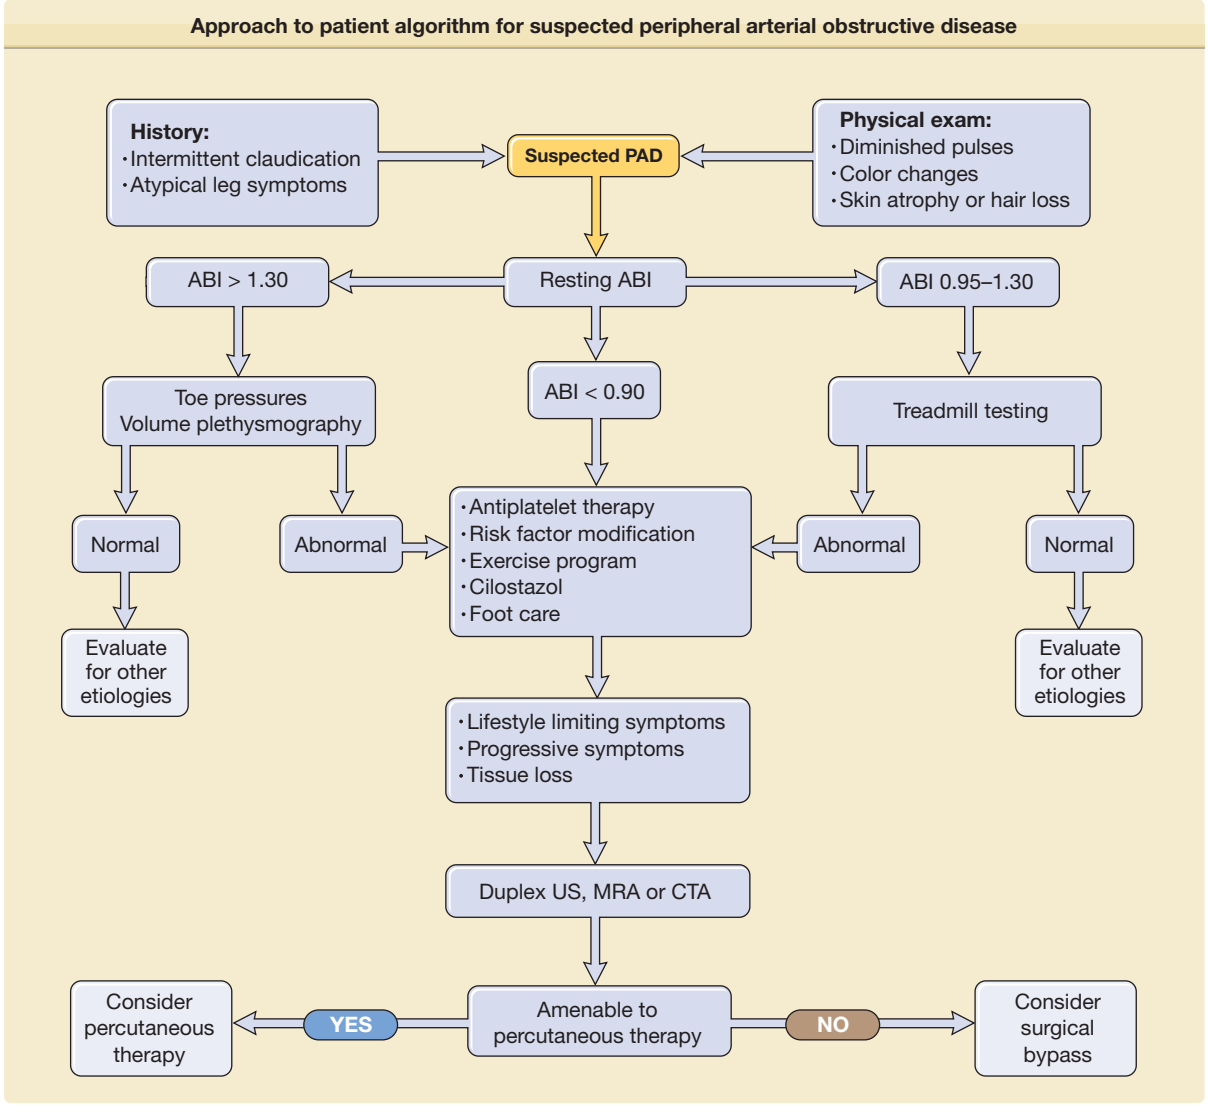

Figure 173-1 Approach to patient algorithm for suspected peripheral arterial obstructive disease. ABI = ankle–brachial index; CTA = computed tomographic angiography; MRA = magnetic resonance angiography.

BOX 173-1 ACUTE LIMB ISCHEMIA: SIX Ps

1. Pain
2. Pallor
3. Pulselessness
4. Paresthesia
5. Paralysis
6. Poikilothermia

vascular segment on walking. The location of the pain differs depending on the anatomical location of the arterial lesions. Since the disease is most common in the distal superficial femoral artery, patients most commonly present with claudication in the calf muscle area (the muscle group just distal to the arterial disease). When the disease affects the more proximal aortoiliac vessels, thigh and buttock muscle claudication predominates. The discomfort tends to be highly reproducible within the same muscle groups and is precipitated by the same level of exertion. It is crucial to determine the amount of walking distance before the onset of symptoms; this helps to quantify patients with some standard measure of walking distance before and after therapy. Resolution within several minutes of rest is an expected finding. Patients with inadequate collateral circulation may complain of cold extremities, hyperesthesia, rest pain, discolored toes, or skin breakdown. Ischemic rest pain typically affects the foot and may interfere with sleep or necessitate sleeping with the leg in a dependent position. Peripheral edema may then occur.

Acute limb ischemia secondary to vessel thrombosis or embolism presents more dramatically with (1) severe pain, usually persistent at rest, (2) pallor, (3) pulselessness, (4) paresthesias, and (5) paralysis (the five Ps). Poikilothermia (a cold extremity) may be added to this pentad of clinical findings (Box 173-1). The presence of neurologic symptoms indicates severe ischemia and need for emergent evaluation.

Since atherosclerosis is a systemic disease process, patients who present with claudication due to PAD can be expected to have atherosclerosis elsewhere. Hence, it is common for patients to present with symptoms related to disease affecting the other vascular territories.

TABLE 173-1
Cutaneous Findings in Peripheral Arterial Disease

- Pallor
- Coolness of the extremities
- Dependent rubor
- Subcutaneous atrophy
- Hair loss
- Brittle toenails
- Absence of sweating
- Ulceration
- Gangrene
- Tenderness
- Regional edema

CUTANEOUS FINDINGS. The cutaneous findings in PAD will vary depending on the severity of arterial obstruction and tissue ischemia (Table 173-1). Limbs in patients with intermittent claudication may appear normal, although associated clinical findings may include hair loss, coldness, and cyanosis, or thickened and malformed toenails. In patients with severe ischemia, the skin is apt to be atrophic, dry, and shiny. In patients with rest pain, the foot is usually bright red and cold in dependency. Ulcerations most often start at the tips of the toes or on the heel of the foot and are extremely painful except when diabetic neuropathy is also present (Fig. 173-2). Ulcers also occasionally start on the lower calves or lateral aspect of the heel. They frequently demonstrate irregular borders and a pale base. The heels may show cracks in the skin with numerous fissures. When gangrene occurs, usually one or more toes become black, dry, and mummified (Fig. 173-3). Superimposed infection is a major concern, and important associated signs include purulent discharge or decay (wet gangrene) or surrounding tissue erythema and swelling.

RELATED PHYSICAL FINDINGS. The hallmark characteristic is decreased or absent pulses distal to the stenotic arterial segment, and there may be bruits on auscultation over the diseased segment of vessel secondary to turbulent flow. It is also possible to find normal palpable pulses in a patient who presents with a history consistent with typical intermittent claudication. In such a case, the clinician can have the patient walk around

Figure 173-2 Obstructive peripheral arterial disease. An ulcer is seen on the medial aspect of the foot at the base of the great toe. **A.** Foot pallor with elevation of limb suggests severe ischemia. **B.** Foot erythema with the leg in a dependent position, termed dependent rubor, also suggests severe ischemia.

Figure 173-3 Necrotic toe in a patient with peripheral arterial obstructive disease. There is marked dependent rubor of the toes and distal aspect of the foot.

the office (or perform toe raises) until the symptoms are reproduced and then palpate for pulses. The exercise may "unmask" a stenosis causing the atherosclerotic lesion to become significant and should diminish the strength of the pulses distal to the lesion. The collateral circulation to limbs affected by PAD can be evaluated by simple bedside exam. With the patient supine, elevation of the limb at a 45° angle for 2 minutes should not produce pallor. Collateral circulation is deemed inadequate if the toes and feet become pale. The patient then assumes a sitting position with the legs dependent and the times for filling of the foot veins and flushing of the feet measured. The veins should fill within 20 seconds and the feet flush immediately in a warm environment. When these times exceed 30 seconds, the collateral circulation is deemed inadequate, and the patient must be observed frequently for the development of rest pain, ulcers, or gangrene. Venous filling times are of limited value when varicose veins coexist.

SPECIAL TESTS

A simple objective test comparing systolic blood pressure in the arms and ankles is sufficient to document the severity of arterial obstruction. The ankle systolic pressure in the supine position should be equal to or greater than the brachial artery systolic pressure. An ankle-to-arm systolic pressure ratio is calculated (ankle-brachial index, or ABI); values greater than 0.9 are generally considered normal, whereas those less than 0.4 are indicative of severe disease (see Chapter 174 for details of ABI measurements). This information is of prognostic use for determination of wound healing or the need for revascularization. One important caveat to note is that occasional patients with heavily calcified or "noncompressible" vessels, most commonly diabetics, may have falsely elevated ABIs (greater than 1.3) despite the presence of significant PAD. Under this circumstance, alternate tests, including toe pressures (as smaller vessels are rarely affected) or segmental volume plethysmography, are helpful. Duplex ultrasound scanning can be time-consuming, but further helps to define physiology and anatomic extent of disease. Magnetic resonance angiography (MRA) and computed tomographic angiography are competitive technologies used to demonstrate precise anatomic location and extent of disease in the arteries but supply limited hemodynamic information. MRA is often preferred because of lack of ionizing radiation or need for iodine-based contrast dye, but may not be tolerated by claustrophobic individuals. Conventional catheter-based arteriography is usually reserved for definitive evaluation in patients about to undergo vascular surgery or as a necessary component of percutaneous angioplasty or stenting procedures (Fig. 173-4).

BOX 173-2 DIFFERENTIAL DIAGNOSIS OF OBSTRUCTIVE PERIPHERAL ARTERIAL DISEASE

LOCAL FACTORS

- Trauma (including iatrogenic)
- Arterial dissection
- Cystic adventitial disease
- Thrombosed popliteal artery aneurysm
- Arterial entrapment syndromes
- Extrinsic compression

SYSTEMIC DISEASE

- Primary thrombotic disorder (thrombophilia)
- Embolism
- Thromboangiitis obliterans
- Fibromuscular dysplasia
- Vasculitic disorders (particularly giant cell arteritis or Takayasu arteritis)

DIFFERENTIAL DIAGNOSIS

The diagnosis of PAD can usually be made by the typical history of intermittent claudication and palpation for diminished or absent pulses in the limbs. The ABI is usually diminished, although occasional patients may have normal values at rest. When the diagnosis remains in doubt, a helpful provocative maneuver to increase blood flow is to exercise the patient. Postexercise blood flow may be limited by the arterial obstructive disease, and repeat ABI will then be diminished. The differential diagnosis of PAD includes both local factors and systemic disorders (Box 173-2). Arterial obstructive disease is just one of several potential etiologies for the development of a foot ulcer (Box 173-3). In some patients with diabetes mellitus or other disease resulting in neuropathy, ulcers may develop on the heel, toes, or anterior calf in the presence of normal pulses. These painless (neurotrophic) ulcers are due to repetitive trauma not noticed by the patient because of the peripheral neuropathy. Surrounding callus formation is a typical finding.

Thromboangiitis obliterans also causes intermittent claudication, ulcers, and gangrene. It occurs in young smokers (onset of symptoms before the age of 45 years) and is often associated with superficial thrombophlebitis and vasospasm. In contrast to PAD, it affects medium and smaller arteries and the upper extremities more commonly.

Occlusive vascular disease confined to focal anatomic locations in young patients with minimal traditional risk factors for atherosclerosis should raise suspicion for alternative etiologies. For example, popliteal artery occlusion may occur secondary to entrapment by calf muscles or cystic adventitial disease. In the former, an abnormal anatomical insertion of the medial gastrocnemius muscle head causes compression of the popliteal artery, with the tibial pulses disappearing on plantar (or dorsi) flexion of the foot and full extension of the knee. Pain is aggravated with walking but less with running because knee extension is not as severe with running. In the latter condition, adventitial cysts of unclear etiology compress the vessel lumen, most commonly in the popliteal artery (85%) or rarely, in the external iliac or femoral arteries, presenting as intermittent claudication. Surgical excision of the cysts usually alleviates symptoms although, in the event of complete vessel occlusion, an interposition graft may be necessary.

Neurogenic claudication (pseudoclaudication) is often a difficult diagnosis to distinguish and is due to compression or intermittent ischemia of the lower spinal cord or cauda equina with exercise. Etiologic factors are prolapsed intervertebral discs, congenital stenosis, or hypertrophic bony ridging of the spinal canal. In contrast to PAD, leg pain may occur in the erect position without exercise and be affected by changes in posture, neurologic signs may be present before or after exercise, and peripheral pulses are normal. The pain is frequently relieved by leaning forward against a solid surface or by sitting. Dilemmas in diagnosis and management can occur when both conditions coexist. MRI or computed tomography scan of the spine is used to confirm the diagnosis.

BOX 173-3 DIFFERENTIAL DIAGNOSIS OF FOOT ULCERS

- Obstructive peripheral arterial disease
- Microvascular disease
- Chronic venous insufficiency
- Neuropathic (particularly diabetic)
- Infection (diabetes or fungal)
- Trauma

COMPLICATIONS

The major direct complications of PAD relate to limb loss from progressive severe ischemia or superimposed infection. In patients with rest pain or tissue loss, the risk of infection is high and wound healing slow or absent. Under these circumstances, the need for revascularization is more urgent to avoid the need for amputation. Superimposed infection needs to be aggressively treated with antibiotics, wound débridement, and local foot care and, if rapidly progressive, presents a medical emergency.

PROGNOSIS AND CLINICAL COURSE

The most feared consequence of PAD is a severe limb-threatening ischemia leading to amputation. Fortunately, the peripheral vascular outcomes in patients with intermittent claudication as a consequence of

PAD tend to be relatively benign, with studies showing that 60%–90% of such patients remained stable over a period of 5–9 years.[3] In a large prospective study of 1,440 patients with intermittent claudication, only 12.2% patients were reported to require amputation during a follow-up period of 10 years. Occasional patients show spontaneous improvement in symptoms, most likely secondary to enhanced collateral blood flow, although plaque regression is possible. However, patients with diabetes mellitus tend to have progressive disease, and their amputation rate is fourfold greater than for patients without diabetes. In patients with diabetic neuropathy, trauma to the limbs must be avoided, and special shoes may be required. Ongoing smokers also have greater amputation and vascular graft occlusion rates than nonsmokers.

In contrast with the limb-related outcomes, because patients with PAD often have advanced atherosclerosis present in multiple vascular beds, the risk of associated cardiovascular morbidity and mortality is high.[1,2] The 5-year mortality in patients with intermittent claudication is 30%, with death largely attributed to cardiovascular causes. In addition, another 20% of patients will incur a nonfatal myocardial infarction or stroke. The association between PAD and cardiovascular morbidity and mortality has been shown to be independent of prior history of cardiovascular disease and independent of known cardiovascular risk factors. Studies have also shown that more severe PAD, as indicated by a lower ABI value, is associated with greater risk of cardiovascular mortality than mild PAD, as evidenced by a higher ABI value. It should be emphasized that PAD of any severity (as documented by an abnormal ABI) may be used to identify the individuals with an increased risk of cardiovascular events and mortality.[4]

TREATMENT

The goal of medical management should include measures to halt the progression of the disease in addition to alleviating the symptoms. The measures to halt the progression of disease include cessation of smoking and optimization of risk factors, such as diabetes mellitus, hypertension, and hyperlipidemia. For patients with symptoms of intermittent claudication, an exercise program is often the treatment of choice (Box 173-4).[2] Patients are instructed to exercise to the threshold of tolerable pain, briefly rest, and then exercise again for a total duration of 30–60 minutes a day in excess of their normal activity. The exercise period must be performed in one session, with walking being the preferred modality. Drawing on data from several studies, approximately 80% of patients may be expected to show significant improvements in exercise tolerance through these techniques. While the exact mechanism for improvement in walking distance with exercise remains unknown, regular exercise is thought to condition the muscles to work more efficiently (more extraction of blood) and increase collateral vessel formation. The magnitude of benefit associated with exercise programs for claudication appears to be greater than that reported for clinical trials of pharmacologic therapy. Patients should be further instructed to keep their feet warm, clean, and dry; and extremes of temperature should be avoided because ischemic tissue is more susceptible to burning and to frostbite than normal tissue. Cuts or severe bruises of the limbs or feet should be treated immediately. Conventional vasodilators appear to have no value in treatment.

BOX 173-4 TREATMENT OF OBSTRUCTIVE PERIPHERAL ARTERIAL DISEASE

	Symptom Relief	Risk Reduction
First line	Exercise regimen Cilostazol (Pletal)	Smoking cessation Statin therapy (target low-density lipoprotein <100 mg/dL) Aspirin Glycemic control Antihypertensive therapy
Second line	Pentoxifylline (Trental) Percutaneous revascularization (angioplasty, stent, atherectomy, cryotherapy) Surgical revascularization (endarterectomy or bypass)	Other lipid therapy Clopidogrel (Plavix)

Two agents have been approved for the indication of intermittent claudication in the United States. Cilostazol, a phosphodiesterase inhibitor with antiplatelet and vasodilatory properties, has been shown in several studies to have consistent benefits on treadmill walking distance and quality of life.[5] However, its benefits are balanced by high frequency of side effects, principally gastrointestinal symptoms or headaches. Furthermore, it is contraindicated in patients with congestive heart failure. Pentoxifylline affects red cell deformability and blood viscosity but has been shown to be relatively ineffective in the treatment of claudication[2]. Other agents, such as propionyl-L-carnitine an agent with metabolic effects, are under study in the United States for this indication.

Endovascular intervention with angioplasty or stenting is highly effective for aortoiliac disease and is often indicated for moderate, or lifestyle-limiting claudication. Angioplasty or stenting of the superficial femoral artery is technically feasible but limited in applicability by high restenosis rates, particularly in the setting of long occlusions, a common scenario in this location. Despite this limitation, it is a valid therapeutic option for patients with focal disease, severe claudication, or tissue loss. Endovascular management of infrapopliteal (below the knee) disease is associated with extremely high restenosis rates, and is

usually a temporizing measure to allow increased blood flow for wound healing. Surgical bypass techniques are effective but are generally high-risk procedures in a population with frequent comorbidities and are usually reserved for patients with severe intermittent claudication or rest pain, or to allow healing of ulcers and gangrene. Sympathectomy is not of value for intermittent claudication, but has been used in the past to allow small ulcers or areas of gangrene to heal. In patients with rest pain, ulcers, or gangrene who are technically unrevascularizable or very high risk for surgery, treatment options are limited. A period of rest with legs dependent may improve some patients, but amputation is a frequent outcome. Parenterally administered prostacyclin or prostaglandin E_1 despite some favorable reports of success, has not yet been thoroughly evaluated and is an expensive mode of therapy.

Dry gangrene of the digits or lower limbs should be allowed to spontaneously demarcate. Soaking or ointments are unnecessary. The edges of the gangrenous areas should be kept open if possible and observed frequently for infection. Pain medication is usually necessary for 2–3 months with digital gangrene. A conservative approach and patience will save many digits and extremities. Infected (wet) gangrenous areas must be actively débrided and appropriate antibiotics administered. Amputations may be necessary.

PREVENTION

The grim statistics regarding cardiovascular outcomes in these patients emphasize the need for aggressive secondary prevention by modifying appropriate cardiovascular risk factors when possible. Tobacco smoking is absolutely contraindicated. Continued smoking has been identified as the most consistent adverse risk factor associated with the progression of the disease. Smoking even one or two cigarettes a day can interfere with PAD treatments. Smoking is also associated with significantly higher rates of amputation compared with nonsmokers. The rate of in-hospital amputation was shown to be 23% in smokers and 10% in nonsmokers. On the other hand, quitting smoking has been shown to slow the progress of PAD and also to reduce the rates of amputation required. Hypertension and diabetes mellitus should be controlled, and hyperlipidemias should be treated with a target low-density lipoprotein <100 mg/dL (or <70 mg/dL with uncontrolled or multiple risk factors) as per recent guidelines for secondary prevention. Evidence is accumulating that aggressive lipid management will prevent progression of PAD, in addition to prevention of myocardial infarction and stroke. Similarly, antiplatelet use with aspirin is used for prevention of cardiovascular events but some controversy of effectiveness in diabetics with PAD. The use of thienopyridines such as clopidogrel (Plavix) may be of additional benefit, but may be associated with higher bleeding rates (particularly with combined therapy) and expense. Use of antiplatelet therapy is a must for those with PAD but should be individualized.

ATHEROMATOUS EMBOLISM

ATHEROMATOUS EMBOLISM AT A GLANCE

- Atheromatous embolism is the embolization of small pieces of atheromatous debris from the more proximal arteries to the smaller arteries.
- Synonyms include *cholesterol embolism, atheroembolism, blue toe syndrome,* and even *pseudovasculitis syndrome.*
- More common with advanced age and after invasive procedures.
- Manifestations include blue or discolored toes, livedo racemosa, gangrene, necrosis, ulceration, and fissure.
- Renal failure and stroke from systemic involvement.
- Diagnosis confirmed by cholesterol clefts in skin or muscle biopsies.
- Treatment focuses on prevention during invasive procedures and elimination of the embolic source. Medical therapy may include antiplatelet therapy and statin agents, while the use of anticoagulation is controversial and often avoided.

EPIDEMIOLOGY

The epidemiology of atheromatous embolism is poorly defined due to underreporting and difficulties establishing a clinical diagnosis.[6] Routine autopsy series of the adult population suggest an incidence of atheromatous embolism of between 0.15% and ~4%. The incidence increases dramatically in the presence of severe atherosclerotic disease. Atheromatous embolism has been found in more than 20% of deaths following cardiac surgery or angiography. However, it should be emphasized that the rate of clinically detected atheromatous embolism appears to be reasonably low (less than 1%). The atheromatous embolism appears to be more common in males than in females with a reported male-to-female ratio of approximately 3.4:1. It is strongly associated with older age, with the mean age reported to range from 66 to 72 years.

ETIOLOGY AND PATHOGENESIS

The pathogenesis of atheromatous embolism involves the occlusion of small arteries and arterioles (of 50–900 μm in diameter) by atheromatous debris (or

so-called *cholesterol crystals*) that are dislodged from a proximal atherosclerotic plaque, with this material inciting an inflammatory cascade characterized by leukocyte infiltration followed by monocytes. This inflammatory process leads to further occlusion with thrombus formation, endothelial cell proliferation, and intimal fibrosis, which may result in ischemia, infarction, and necrosis. The clinical picture is characterized by impaired perfusion of the skin and muscle due to small vessel occlusion, although nearly any organ of the body may be involved.

The major risk factor for the development of atheromatous embolism is atherosclerotic disease of the thoracic or abdominal aorta. The risk is higher with more extensive atheroma burden (defined by increased thickness above 4 mm) or unfavorable plaque features such as protruding mobile plaque.[7] Coexistent vascular disease including coronary artery disease, PAD, and even an abdominal aortic aneurysm are risk factors. The more traditional atherosclerotic risk factors also increase the risk of atheromatous embolism, with older age (more than 60 years) being prominent.

Atheromatous embolism often occurs after an invasive procedure.[8] Angiography, endovascular procedures, and both cardiac and vascular surgeries may create mechanical trauma to the vessel and destabilize an atherosclerotic plaque. Anticoagulation, primarily with Coumadin, and even thrombolytic therapy are potential risk factors. It has been postulated that anticoagulation may delay the healing of irregular or ulcerated plaque. Embolic events may occur spontaneously although minor stressors such as coughing or straining may be provocative factors.

CLINICAL FINDINGS

HISTORY. The clinical presentation of atheromatous embolism, although it can occur spontaneously, usually follows an invasive procedure such as an invasive angiographic or vascular surgical procedure. The clinical manifestations may be immediate, or delayed by several days to weeks after the inciting event. The precise clinical syndrome depends on the location of the source of embolism and the pattern and distribution of flow downstream. This may range from subtle clinical findings to catastrophic systemic embolic complications. Nearly any organ of the body may be involved. Involvement of the ascending aorta may result in systemic complications including transient ischemic attacks, strokes, or retinal manifestations, while involvement of the descending or abdominal aorta may lead to lower extremity ischemia, renal failure, mesenteric ischemia, or hemorrhagic pancreatitis. Since more common sites for severe atheromatous disease are in abdominal aorta and iliac arteries, the signs and symptoms more commonly result from embolism to the lower half of the body. The lower extremity involvement typically presents with manifestations of discolored or ulcerated painful toes and tender calf muscles.

In addition, constitutional symptoms including fever and weight loss may be seen due to hypermetabolism associated with the inflammatory process.

TABLE 173-2
Cutaneous Findings in Atheromatous Embolism

- Blue or purple toes
- Livedo racemosa
- Gangrenous digits
- Ulcers
- Fissures
- Nodules
- Petechiae
- Purpura
- Splinter hemorrhages

CUTANEOUS LESIONS. The dermatologic manifestations are often the presenting complaint (Table 173-2). The most common of these findings are related to tissue or digital ischemia and include cyanosis, necrosis, gangrene, ulcerations, and fissures. The finding of tender, cool, blue, or purple toes with normal pulses, found in the "blue toe syndrome," is common (Fig. 173-5A). About 50% of patients will have livedo racemosa, which typically involves the foot and leg but may extend into the trunk or buttocks. Erythematous lesions are often seen on the lateral aspect of the foot and calcaneal region. Although advanced ischemic manifestations such as ulcers or gangrene may be present (see Fig. 173-5B), the surrounding areas are normally perfused tissue. There may be other cutaneous manifestations, often hemorrhagic in nature, including petechiae, ecchymosis, purpura, and splinter hemorrhages. Raised painful inflammatory nodules may occur.

RELATED PHYSICAL FINDINGS. Examination of the vascular system often reveals normal pedal and proximal pulses, but systolic bruits may be heard on auscultation over the aorta or common femoral arteries. Tenderness of skeletal muscles, particularly in the calf, may be detected. Funduscopic examination revealing Hollenhorst plaques is a specific but insensitive finding because most atheromatous emboli arise from a source distal to the aortic arch. Fever may be present.

LABORATORY TESTS

The laboratory tests are typically nonspecific and depend upon the organ involved and the severity of disease. An elevated erythrocyte sedimentation rate, thrombocytopenia, hypocomplementemia, leukocytosis, and anemia may all been seen due to the systemic inflammatory response. With renal involvement azotemia, proteinuria, microscopic hematuria, eosinophilia, and even eosinophiluria may be seen. Transient eosinophilia has been reported in up to 80% of those with renal involvement. Involvement of the gastrointestinal tract may lead to anemia and blood in the stools. Injury to the liver, gallbladder, or pancreas may lead to abnormal liver function tests and elevated pancreatic enzymes.

Figure 173-5 **A.** Typical appearance of blue toes due to multiple atheromatous emboli to the lower limbs in a patient with extensive atheromatous disease of the aorta. **B.** Development of ulceration of the tip of the toes due to atheromatous embolism with a faint reticular pattern on the forefoot typical of livedo racemosa.

SPECIAL TESTS

Contrast angiography may reveal diffuse atherosclerotic involvement of the vessels proximal to the lesions, but is typically avoided due to the risk of precipitating further embolic events. Noninvasive imaging techniques such as computed tomographic angiography or MRA are useful to evaluate for atherosclerotic disease within the aorta or other large vessels. Although stenotic atherosclerotic disease is the most common finding, aneurysmal disease may also be present. Transthoracic echocardiography is often helpful to evaluate for a cardiac source, but the more definitive transesophageal echocardiography can also assess the thoracic aorta for plaque.

Definitive diagnosis of cholesterol embolization requires demonstration of cholesterol crystals, which are birefringent under polarized light. However, due to the solubility of cholesterol with typical solvents used in processing of tissue for histopathology, cholesterol crystals appear as empty clefts. Skin, muscle, or renal biopsies may reveal these characteristic elongated, needle-shaped clefts in small arterial vessels. There may also be inflammatory infiltrates, intimal thickening, and perivascular fibrosis as well as giant cells. The sensitivity of the biopsy depends upon the site. Muscle biopsy seems to be the most sensitive test, reportedly being positive in >95% of cases, but is technically difficult, painful, and risky to obtain. The sensitivity of skin biopsy has varied from 40% to 90%. Skin biopsies offer maximum yield when obtained directly from areas of suspected emboli, such as those with livedo racemosa, but should be cautiously obtained or avoided in areas of more overt ischemic injury.

DIFFERENTIAL DIAGNOSIS

Because of its clinical similarity to other systemic diseases, atheromatous embolism is often misdiagnosed. The diagnosis of atheromatous emboli is suggested by blue or ulcerated painful digits, livedo racemosa, petechiae, and tender calf muscles in the presence of normal pulses. However, it is difficult to establish the diagnosis, when the clinical features are subtle and nonspecific. Thus, a high index of suspicion is needed, especially in the setting of a history of preexisting atherosclerotic disease and a specific precipitating event. Definitive diagnosis can be made by skin, muscle, or even renal biopsies. Several other entities must be considered in the differential diagnosis of atheromatous embolism (Box 173-5).

Moreover, among patients who develop acute renal failure, it is important to distinguish from contrast nephropathy, which is typically reversible. Renal failure due to atheromatous emboli usually develops over

BOX 173-5 DIFFERENTIAL DIAGNOSIS IN ATHEROMATOUS EMBOLISM

- Antiphospholipid antibodies
- Atrial myxoma
- Calciphylaxis
- Chilblains (or pernio)

- Malignancies
- Multiple myeloma
- Nonbacterial thrombotic endocarditis
- Polyarteritis nodosa
- Subacute bacterial endocarditis
- Thrombocytopenia, polycythemia
- Thrombotic embolism
- Vasculitis
- Warfarin-induced skin necrosis

1–4 weeks after angiographic procedure and shows partial recovery, whereas contrast-induced renal failure typically appears soon after testing and begins to recover within 3–5 days.

COMPLICATIONS

There are numerous ischemic complications depending upon the organ involved. These include the kidneys, mesenteric circulation, and central nervous system. Renal atheroembolic disease is a consequence of showering of emboli to the renal parenchymal branch vessels. An intense inflammatory process may ensue, producing glomerular sclerosis, tubular atrophy, and interstitial fibrosis. Although there is a variable timing of onset and progression of disease, there typically is a several-week delay after the inciting event before the development of renal dysfunction. New onset of hypertension or overt renal failure may ensue. It is rare to develop gross hematuria or frank renal infarction. The development of renal failure is one of the more ominous complications with a high mortality in affected individuals.

The central nervous system is another feared site of involvement with atheromatous embolism. There is concern for ischemic manifestations such as transient ischemic attacks, stroke, and paralysis. However, other less readily appreciated manifestations may ensue, such as a confusional state or a progressive neurologic decline.

The gastrointestinal tract is perhaps the third most common organ system involved with atheromatous embolism. The manifestations may be nonspecific abdominal complaints such as abdominal pain, nausea, vomiting, or diarrhea. More severe ischemic manifestations may be seen with gastrointestinal bleeding or bowel infarction. The colon is the most common site in the gastrointestinal tract to be affected. Establishing a diagnosis may be difficult as endoscopy findings are often nonspecific, and biopsy may miss the classic findings. Splenic infarction, cholecystitis, gangrene of the gall bladder, pancreatitis, and pancreatic necrosis have also been reported.

PROGNOSIS AND CLINICAL COURSE

The prognosis of cholesterol embolism is generally poor, in part because of the severe underlying atherosclerosis. The outcome also depends upon the organ system affected with the emboli. Estimates of mortality range from 20% to 30% for 1-year mortality. The poorest outcomes have been reported in those with emboli arising from a suprarenal location.

The syndrome usually subsides, and lesions heal following successful surgical or medical treatment, although spontaneous resolution may occur. Recurrent embolism may result in limb loss in the absence of surgical or interventional management options. In the "malignant multisystem" disease, most patients die within 1 year if treatment is unsuccessful. The prognosis is extremely poor in the presence of systemic complications, particularly renal failure or stroke. The development of end-stage renal disease due to atheromatous embolism is a strong predictor of death.

TREATMENT

Early recognition is essential to minimize end-organ damage and improve the clinical outcomes.[6] Preventing further ischemic insult, supportive care, and removal of the atheromatous source are the mainstays of therapy.[9] Elimination of the source of the emboli can often be accomplished by surgical bypasses or endarterectomy although many of these patients have contraindications to major surgery. Endovascular procedures with covered stents may also be considered; however, this approach may carry significant risk with the potential to exacerbate further embolization.

Medical therapies have not been well studied, and recommendations are based on the results from small series or anecdotal reports. Antiplatelet agents, such as aspirin, dipyridamole, or clopidogrel, are most often tried and, if successful, should be continued long term. Antithrombotic therapy such as subcutaneous heparin or low-molecular-weight heparin may be beneficial with some, suggesting that these agents may reduce the secondary small vessel thrombosis. Warfarin is usually avoided due to potential for exacerbating the process, but this concern has limited basis. There is even a proposed beneficial effect of long-term anticoagulation to prevent embolic events in those with extensive mobile aortic atheroma. The use of statins may aid in plaque stabilization and has clear established benefits in prevention of cardiovascular ischemic events in those with vascular disease. Other agents such as iloprost and cilostazol have limited evidence to suggest benefit but have been tried in those with renal dysfunction and cutaneous lesions, respectively. Systemic corticosteroids are not recommended. Since most of these patients have severe underlying atherosclerosis, they should be aggressively treated for secondary prevention of cardiovascular disease with optimization of the risk factors.

PREVENTION

Because of the rarity of the disease and the difficulties in establishing the diagnosis, increased awareness of the problem is important. Primary prevention in high-risk patients, targeted to avoid the development of atherosclerotic plaque, should be performed. Once atherosclerosis develops, avoiding unnecessary invasive procedures is advised. When angiography is necessary, more cautious techniques with the use of soft-tipped guidewires and more flexible catheters help to reduce the risk. In addition, protective devices such as filters, baskets, and balloon occlusion have been used. In patients with atheromatous disease of abdominal aorta and iliac arteries, use of brachial artery approach is often considered. Surgical techniques have also been refined with less aortic manipulation and circulation arrest, which may help to minimize the chance of developing this disorder.

THROMBOANGIITIS OBLITERANS (BUERGER DISEASE)

THROMBOANGIITIS OBLITERANS AT A GLANCE

- Rare inflammatory occlusive disease affecting medium and small arteries and veins, most commonly in the extremities.
- Predominantly affects males, at age 20–40 years.
- Extremely strong association with smoking; often abates with smoking cessation.
- Clinical manifestations include ischemia, cold sensitivity, or claudication of foot, leg, or hand.
- Ischemic ulcers, peripheral cyanosis, gangrene, or superficial thrombophlebitis.

EPIDEMIOLOGY

The prevalence of this disease is greatest in the Mediterranean, Middle East, and Asia, and it is relatively less common in people of northern European descent.[10] Males are afflicted with a higher prevalence than females (with a male-to-female ratio of 3:1), although an increased incidence in females has occurred in recent years, likely reflecting the pattern of tobacco use. Patients are usually between the ages of 20 and 40 years. Over the last three decades, there has been a marked decline in the reported prevalence of thromboangiitis obliterans in the United States, possibly reflecting the impact from adoption of strict diagnostic criteria for this disease entity, although declining smoking prevalence may also play a role. In 1947, the prevalence of the disease in the United States was estimated at 104 cases per 100,000, however, more recently the prevalence has been estimated at 12–20 cases per 100,000.[11]

ETIOLOGY AND PATHOGENESIS

The etiology of thromboangiitis obliterans remains unknown. The disease occurs almost exclusively in smokers and often abates with the cessation of tobacco smoking. An increased cellular sensitivity to types I and III collagen has been reported in comparison to a group of normal individuals and patients with atherosclerotic disease. An increased prevalence of HLA-A9, HLA-A54, and HLA-B5 has been observed in these patients, suggesting a genetic component to the disease.[12] Tissue ischemia is produced by an inflammatory reaction involving medium and small arteries of the extremities and superimposed obstruction by thrombi. Despite the inflammatory process, thromboangiitis obliterans is considered serologically silent, and even during active disease inflammatory markers, such as erythrocyte sedimentation rate and C-reactive protein levels, are usually normal. In one report, serum antiendothelial cell antibody titers were found to be high, and impaired endothelial-dependent vasodilation to acetylcholine has been demonstrated to occur even in nonobstructed limbs. Veins may also be involved. Occasionally, cardiac, intestinal, and cerebral vessels are involved.

CLINICAL FINDINGS

(Fig. 173-6)

HISTORY. The most common initial complaints are claudication of the foot or lower calf, digital cyanosis or gangrene, or rest pain. Involvement of multiple limbs is typical. Patients may present with ulcers of the toes or fingers. Although the lower extremities are affected most often, more than one-third of patients have upper-extremity involvement. Ulcerations or gangrenous areas are characteristically extremely painful. Superficial thrombophlebitis, often migratory, may occur in up to 40% of patients. Cold sensitivity or even classical Raynaud phenomenon may be observed.

CUTANEOUS FINDINGS. The cutaneous findings of thromboangiitis obliterans are similar to that of PAD. Common findings include ulceration or gangrene of digits (feet worse than hands) (Fig. 173-7), peripheral cyanosis or Raynaud phenomenon, and superficial thrombophlebitis, often migratory, with indurated red nodules.

RELATED PHYSICAL FINDINGS. The hands and feet of patients with the disease are usually cold and mildly edematous. They may develop cyanotic, ulcerated, or gangrenous, and very painful digits. Typically, the distal pulses (dorsalis pedis, posterior tibial, and ulnar pulses) are often absent, while the more proximal pulses are preserved. During episodes of thrombophlebitis, small-indurated red, tender nodules will be found, which follow the course of superficial veins and are common on the thigh or calf. Typical changes of Raynaud phenomenon, with well-demarcated pallor or cyanosis of the digits, may be seen on exposure to cold; one or more extremities may be involved. Sensory abnormalities reflecting ischemic neuropathy have been observed in advanced cases. Nail fold examination with capillaroscopy may reveal multiple dilated capillary loops.

TREATMENT

There is no specific treatment (Box 173-6) other than smoking cessation. Local wound care is imperative, and adequate analgesic therapy is emphasized. In the absence of data from large randomized trials, antiplatelet agents and vasodilators may play a role and are usually initiated. Similarly, pentoxifylline or cilostazol, both agents used for improving walking

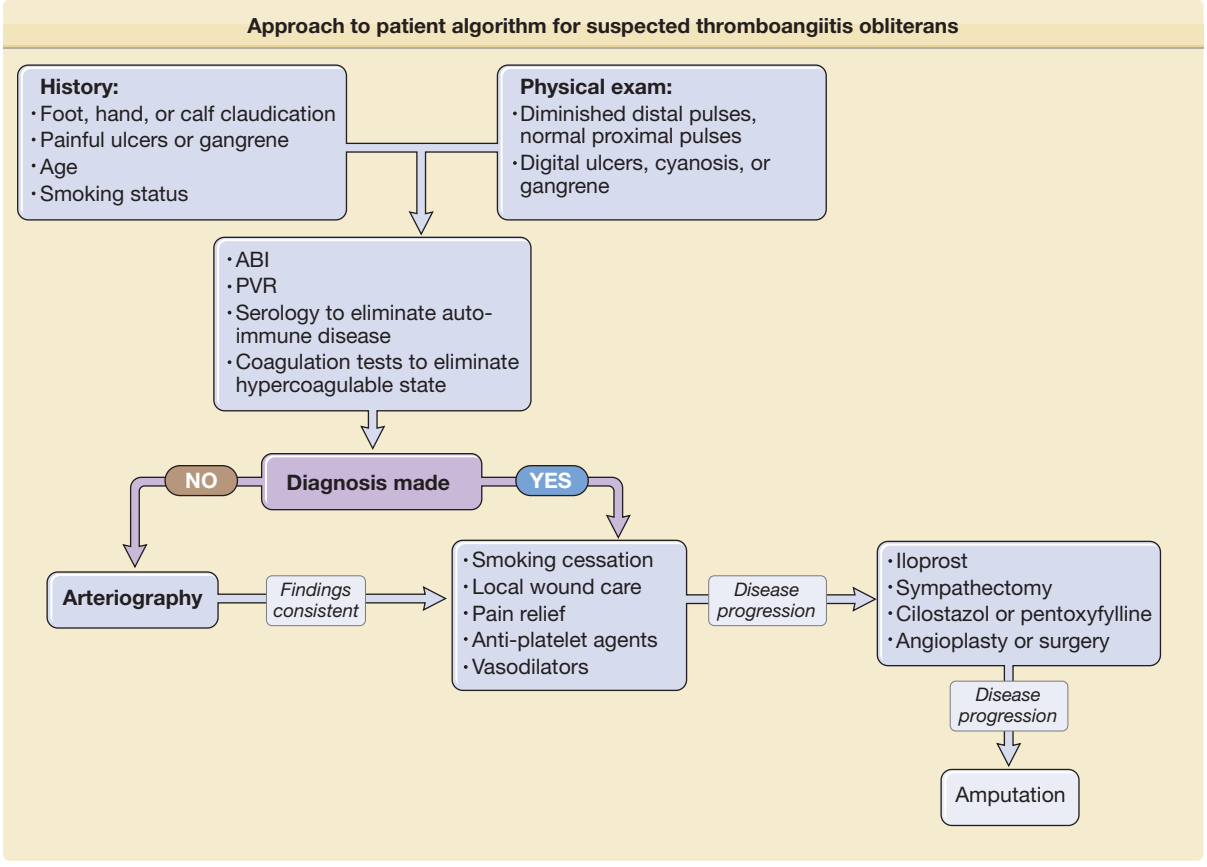

Figure 173-6 Approach to patient algorithm for suspected thromboangiitis obliterans. ABI = ankle–brachial index; PVR = pulse-volume recording.

distances in claudicants with atherosclerotic disease, may be tried. In one study, daily intravenous infusions of iloprost, a prostaglandin analog, were shown to relieve rest pain, heal ulcers, and prevent amputation more frequently than aspirin. Bypass surgery or angioplasty have been reported but are suboptimal therapeutic options because of the small size and distal location of the vessels affected. Sympathectomy may help patients with a prominent vasospastic component. Vascular endothelial growth factor gene therapy may prove of value, but has not been well studied yet. In

BOX 173-6 TREATMENT OF THROMBOANGIITIS OBLITERANS

	Improve Blood Flow	Symptom Relief
First line	Smoking cessation	Local wound care Analgesics
Second line	Antiplatelet agents Oral vasodilators Cilostazol (Pletal) Pentoxifylline (Trental)	
Third line	Iloprost Angioplasty Surgical endarterectomy or bypass	Sympathectomy Amputation

those with refractory disease with nonhealing ulcers, gangrene, or intractable pain, surgical amputation of the affected distal limbs is often unavoidable.

PREVENTION

Absolute discontinuation of tobacco use is the only strategy proven to prevent the progression of thromboangiitis obliterans. Smoking as few as one or two cigarettes daily, using chewing tobacco, or even using nicotine replacements may keep the disease active.[14] The following strategies are important in prevention of complications from the disease: use of well-fitting protective footwear to prevent foot trauma and thermal or chemical injury, avoidance of cold environments, and avoidance of drugs that lead to vasoconstriction.

LIVEDO RETICULARIS AND LIVEDO RACEMOSA

LIVEDO RETICULARIS AND LIVEDO RACEMOSA AT A GLANCE

- Livedo is an ischemic dermopathy characterized by a violaceous reticular or "net-like" mottling of the skin.
- Imperative to differentiate benign livedo reticularis from pathologic livedo racemosa.
- Livedo reticularis is a primary disorder affecting young to middle-aged females that is benign. The livid conical discoloration is symmetric, reversible, and uniform.
- Livedo racemosa is a secondary disorder that is pathologic and permanent. The livid conical discoloration is asymmetric, irreversible, and "broken."
- Antiphospholipid antibody testing should be obtained on all patients presenting with livedo racemosa.

EPIDEMIOLOGY

Livedo reticularis is typically a primary disorder that affects young to middle-aged females (20–50 years of age) who are otherwise healthy.[15] Amantadine-induced livedo reticularis is also more common in females. The epidemiologic factors of livedo racemosa are dependent on the underlying condition. It is the most frequent dermatologic manifestation in patients with antiphospholipid syndrome, present in 25% of patients with primary APS and in up to 70% of patients with SLE-associated APS.[16] The distinction between livedo racemosa and livedo reticularis is an evolving concept, which is not universally quoted, and is not referred to in most of the older literature.

ETIOLOGY AND PATHOGENESIS

In both disorders, the characteristic ring-like mottling results from (patho)physiologic changes within the cutaneous microvascular system. Anatomically, the dermis is perfused via perpendicularly oriented ascending arterioles. Individual arterioles arborize into a capillary bed at the skin surface. Ultimately, the capillary beds empty into a conical appearing, peripherally located subpapillary venous plexus.

Pathophysiologically, livedo arises from either deoxygenation or venodilatation within the venous plexus.[17] Decreased arteriolar perfusion is the predominant cause of deoxygenation within the venous plexus. Diminished arteriolar flow can result from vasospasm, hyperviscosity, and/or thrombosis. Physiologic arteriolar vasospasm produces the reversible cutaneous discoloration of livedo reticularis. The livedo reticularis can occur as a physiological reaction to cold exposure, when it is known as cutis marmorata, or the skin color changes may be unrelated to ambient temperature. Protracted arteriolar vasospasm, thrombosis, and/or hyperviscosity underlie the pathologic skin changes of livedo racemosa. Venodilatation of the venous plexus may be provoked by hypoxia or autonomic dysfunction.

A possible role for the endothelial cells (EC) has also been suggested in the subset of patients of APS with livedo racemosa. The interaction of aPL antibodies with EC could induce livedo racemosa and also lead to increased production of procoagulant substances such as tissue factor (TF), plasminogen activator inhibitor 1, and endothelin. Increased TF expression on EC induced by aPL could be responsible, in part, for hypercoagulability and might explain the thrombosis in both arterial and venous circulation that characterizes these patients.

Amantadine-induced livedo reticularis has traditionally been ascribed to catecholamine provoked arteriolar vasospasm; however, an interaction between amantadine and *N*-methyl-D-aspartic acid receptors in the skin may be responsible in some unexplained fashion.[18]

Livedoid vasculopathy is a rare ulcerative subtype of livedo racemosa due to fibrinolytic abnormalities and microcirculatory thrombosis.

CLINICAL FINDINGS

HISTORY. With the exception of a subjective feeling of coldness, the majority of patients with livedo reticularis are asymptomatic. Patients often present with concerns regarding their skin discoloration. A minority describes mild pain and numbness. The symptoms are worse during winter months. Livedo

Figure 173-8 Symmetric and relatively uniform, conical rings of primary, reversible livedo reticularis (cutis marmorata).

racemosa-associated symptoms are related to the causative secondary disorder.

CUTANEOUS LESIONS. In livedo reticularis, a symmetric, fishnet-like red or purple mottling surrounds a pallorous conical core (Fig. 173-8). This discoloration is aggravated by cold exposure and may completely dissipate with warming. The livid rings are most pronounced on the lower extremities yet the abdomen and upper extremities can be affected.

In contradistinction to the symmetric and uniform reticular pattern of livedo reticularis, the discoloration of livedo racemosa is asymmetric, irregular, and "broken" (Fig. 173-9). Although it may improve with warming, it does not resolve completely. Attendant skin manifestations of livedo racemosa may include purpura, nodules, macules, ulcerations, and/or atrophie blanche-type scarring. When associated with livedoid vasculitis, painful ulcerations about ankles and forefeet may occur.

In both livedo reticularis and racemosa, the skin is palpably cool.

RELATED PHYSICAL FINDINGS. Livedo reticularis and livedo racemosa are often associated with vasospastic digits or acrocyanosis. With exception of the characteristic skin changes, the examination in livedo reticularis is otherwise unremarkable. Patients with livedo racemosa may have concurrent abnormal physical findings related to their underlying disease (e.g., aphasia and lateralizing neurologic signs associated with Sneddon syndrome).

Figure 173-9 Permanent and "broken" rings of secondary livedo racemosa on the buttocks and thighs in a woman who had cerebrovascular thrombosis. This is an example of Sneddon syndrome.

LABORATORY AND SPECIAL TESTS

In livedo reticularis, laboratory testing is typically negative and consequently is unwarranted. An antiphospholipid antibody panel should be obtained on all patients presenting with livedo racemosa. A complete thrombophilia panel is warranted in the rare patient with livedoid vasculopathy (see Chapter 163). The need for additional laboratory analysis in a patient with livedo racemosa should be directed by the clinical assessment.

A skin biopsy is not required in livedo reticularis as the findings are nonspecific. A large punch or wedge biopsy of the deep reticular dermis and subcutaneous fat is sometimes helpful in identifying the secondary cause of livedo racemosa. Selection of the correct biopsy site (seemingly uninvolved skin in the center of the lesion) is essential for detection of relevant vascular pathology. The biopsy findings are highly variable and reflect the associated livedo racemosa etiology. For instance, cholesterol clefts suggest atheroembolic disease, calcification of the vessels and interstitium indicate calciphylaxis, noninflammatory arteriolar obstruction occurs with Sneddon syndrome, livedoid vasculopathy is associated with extensive fibrin deposition and microthrombi (see Chapter 163), whereas fibrinoid necrosis is present in polyarteritis nodosa (see Chapter 164).

DIFFERENTIAL DIAGNOSIS

The diagnosis of livedo is easily made by identifying the characteristic mottled skin discoloration. It is paramount that the clinicians distinguish between livedo reticularis and livedo racemosa. Once a diagnosis of livedo racemosa is established, the secondary cause (Table 173-3) should be sought by appropriate clinical laboratory tests. Diagnostic difficulties may occur when no other pathological signs except livedo racemosa are found. This clinical condition, known as "idiopathic livedo racemosa," may represent a very early stage of Sneddon syndrome.

TABLE 173-3
Conditions Associated with Livedo Racemosa

- Antiphospholipid antibody syndrome
- Sneddon syndrome
- Livedoid vasculopathy
- Vasculitis (especially polyarteritis nodosa)
- Collagen vascular disease
- Myeloproliferative syndromes (polycythemia vera, essential thrombocytosis)
- Paraproteinemias
- Cryoglobulinemia/cryofibrinogenemia/cold agglutinin disease
- Atheroembolic disease
- Calciphylaxis
- Hyperoxaluria
- Atrial myxoma
- Erythema ab igne
- Chronic pancreatitis
- Infections

PROGNOSIS AND CLINICAL COURSE

The prognosis for livedo reticularis is excellent as this is primarily a cosmetic condition. Livedo racemosa-associated prognosis is less favorable and parallels the associated disease. Of interest, livedo racemosa has been identified as a marker for predicting multisystem thrombosis in the antiphospholipid antibody syndrome. Additionally, up to 40% of patients manifest livedo racemosa as the initial sign of the antiphospholipid antibody syndrome.[19] In addition, increased rate of pregnancy loss has been recognized in patients with widespread livedo racemosa who were seronegative for antiphospholipid antibodies, suggesting that livedo racemosa may be an independent risk factor for pregnancy loss in the absence of APS. Livedoid vasculopathy tends to be a relapsing condition marked by recurrent painful ulcerations and subsequent atrophie blanche-type scars.

TREATMENT

Other than cold avoidance, medical treatment for primary livedo reticularis is typically unwarranted. As a last resort, vasodilator therapy may be tried in the patient that is socially inhibited by the cosmetic appearance of the disorder. The symptoms may improve spontaneously with age.

Therapy of livedo racemosa should be directed toward the underlying disorder. Patients with livedo racemosa and the antiphospholipid antibody syndrome with thrombosis require anticoagulation. Treatment of livedoid vasculopathy is often unsatisfactory but potentially beneficial medications include anticoagulants, antiplatelet agents, immunosuppressants, pentoxifylline, danazol, and tissue plasminogen activator. Alternatively, hyperbaric oxygen and psoralen and ultraviolet A light therapy have also been successfully utilized to treat livedoid vasculopathy.

ERYTHROMELALGIA (ERYTHERMALGIA)

ERYTHROMELALGIA AT A GLANCE

- Intense, burning pain with marked erythema, typically of the lower extremity.
- Typically intermittent. May be precipitated by exercise.
- Primary disorder or secondary to a myeloproliferative disorder.
- Cutaneous manifestations are often a result of attempts to alleviate the symptoms with immersion and thermal injury.
- Aspirin may be effective for secondary erythromelalgia.

EPIDEMIOLOGY

This is a rare disorder with limited epidemiologic data available.[20] In Norway, the incidence is estimated to be 0.25 for 100,000 population with a prevalence of 2 per 100,000. In the United States, extrapolation from a series of erythromelalgia patients at the Mayo Clinic suggests an incidence of 1 case per 40,000 patients; however, this could overestimate the incidence in general population. Primary erythromelalgia may occur at any age with an uncertain gender predilection, although recent studies seem to suggest a female predominance.[21] In contrast, secondary erythromelalgia has an equal sex distribution and occurs mostly after the third decade.

ETIOLOGY AND PATHOGENESIS

The etiology and pathogenesis of the erythromelalgia are unknown. Several mechanisms have been postulated for primary erythromelalgia, including arteriovenous shunting and a small fiber neuropathy. It has been speculated that precapillary sphincters may be constricted while arteriovenous shunts are open, leading to an increased total perfusion but a deficient nutritive blood flow.[22] Substances produced by local hypoxia lead to increased local blood flow, warmth, redness, and pain. In contrast, the genetics of erythromelalgia appears to be supporting a neuropathic basis. A mutation in a voltage-gated sodium channel of sensory nerves has been reported in inherited erythromelalgia.

Secondary erythromelalgia occurs in polycythemia, thrombocythemia, and autoimmune disorders and is hypothesized to be caused by platelet breakdown products based on the response to aspirin therapy.

CLINICAL FINDINGS

HISTORY. The disorder is characterized by red, hot, painful extremities with characteristic intense burning pain. It most commonly affects the lower extremities but may affect the upper extremities as well as other body parts, such as the face and ears. Involvement is usually symmetric, although it can be unilateral in secondary cases. The symptoms are typically intermittent in nature but may be constant. Their onset may be gradual or abrupt, usually precipitated by activities that increase the body temperature, such as exercise, ambient temperature, or the use of heavy blankets at night. The episodes can also be triggered by dependency of the limb, wearing socks, or tight shoes, and sometimes with the ingestion of alcohol or spicy foods. There are also reports of episodes triggered by ingestion of some drugs, such as pergolide, bromocriptine, and calcium channel blockers (nifedipine, felodipine, and nicardipine). In contrast, cold exposure (e.g., standing on a cold floor) or immersion in ice water often relieves the flares.

Patients have also been described who have both erythromelalgia and Raynaud phenomenon. During the hyperemic phase of Raynaud phenomenon, patients often complain of erythromelalgic-like symptoms. It is postulated that both syndromes have a common basis in a dysfunction of the regulation of vasomotor tone.[23]

CUTANEOUS LESIONS. Examination during attacks reveals warm, red, extremely sensitive extremities with normal pulses (Fig. 173-10). Between flares, the extremities may appear normal. The constant use of ice water leads to maceration of the skin, secondary infection, ulcers, and necrosis.

PHYSICAL FINDINGS. Physical examination is usually unremarkable in primary type of erythromelalgia, however may reveal signs of an underlying disorder in the secondary erythromelalgia. The peripheral pulses are usually normal or bounding.

Figure 173-10 Intense erythema of the feet with associated burning pain typical of erythromelalgia.

PROGNOSIS AND CLINICAL COURSE

The natural history of erythromelalgia is extremely variable.[24] Symptoms may be mild for several years or totally disabling within weeks. It has been reported that with long-term follow-up, symptoms were worse in 32%, unchanged in 27%, improved in 31%, and resolved in 10% of patients. Many patients become disabled being unable to work or carry on daily activities. As a result of the profound impact upon their life with intractable symptoms, patients have even been known to commit suicide. There is a decrease in survival compared with age- and gender-matched controls.

TREATMENT

There are limited data available to guide therapy, primarily based upon case reports or small series.[24] Behavioral modifications should include efforts to keep the limbs cool and avoid the use of ice water or prolonged soaking. Additional measures including biofeedback and even hypnosis have been tried. Pharmacologic therapy has varied but often has focused on vasoactive drugs and drugs that affect the nervous system. Most vasoactive drugs, including calcium-channel blockers and β blockers, have been minimally effective in treating this disorder. Drugs used to treat neuropathy, such as serotonin reuptake inhibitors, tricyclic antidepressants, and gabapentin, have been used and may provide some relief. Aspirin is often of great benefit but only in secondary cases. Topical therapies, such as lidocaine patch or capsaicin cream, may reduce the pain. The prostaglandin E_1 analog misoprostol has been evaluated in a double-blind, crossover trial and found to be superior to placebo. Numerous other agents, including lorazepam, cycloheptadine, methysergide, piroxicam, and pizotifen, have been tried in selected cases. Surgical or medical sympathectomies have also been tried but have been found to have mixed results.

PREVENTION

There are no established measures to prevent the development of erythromelalgia. The focus has been to prevent flares once the disorder occurs. The key to prevention is to avoid exacerbating factors and to prophylactically cool the involved extremity. The other preventive measures are to prevent the development of secondary complications often as a result of prolonged soaking in ice water. It is important to limit the duration of soaking and to use cool, not ice-cold, water.

Chapter 174 :: Cutaneous Changes in Peripheral Venous and Lymphatic Insufficiency

:: Craig N. Burkhart, Chris Adigun, & Claude S. Burton

VENOUS DISEASE AT A GLANCE

- One percent to 3% of US health care expenses are for peripheral venous diseases and their complications.
- Venous ulcers are the most common.
- Risk factors include genetics, obesity, female gender, pregnancy, occupations requiring prolonged standing, surgery, trauma, and malignancies.
- Peripheral venous disease should be considered part of a spectrum including the following:
  - Early signs: tenderness, edema, hyperpigmentation, and varicose veins.
  - Late signs: atrophie blanche, lipodermatosclerosis, and venous ulcers.
- Venous ulcers are located exclusively below the knee after venous pump failure, most often secondary to prior thrombosis.
- Treatment for all stages includes leg elevation, compression, treatment of infection, and dermatitis.
- Deep venous disease is associated with thromboembolism.

CHRONIC VENOUS DISEASE

Chronic disease of the peripheral veins includes a spectrum of diseases ranging from edema and tenderness to venous ulceration (Box 174-1).

EPIDEMIOLOGY

Chronic venous disease is extremely common. Although estimated costs and time lost from work have not been objectively assessed in over two decades, estimates state that 6–7 million people in the United States have evidence of venous stasis and that it accounts for 1% to 3% of the total health care budgets in countries with developed health care systems.[1]

Risk factors for chronic venous disease include heredity, age, female sex, obesity, pregnancy, prolonged standing, and greater height.[2]

ETIOLOGY AND PATHOGENESIS

Venous ulcer occurs after failure of the calf muscle pump (Fig. 174-1). The heart pumps blood down to the foot; the calf muscle pump (when upright), returns venous blood to the heart. Venous blood from the skin and subcutis collects in the superficial venous system including the greater and lesser saphenous veins and its tributaries, moves through the fascia in a series of "perforating" or "communicating" veins, and fills the muscle-enveloped deep venous system. With muscle contraction, the deep veins are compressed; one-way valves in the deep system allow the now high pressure flow to move against gravity, and one-way valves in the perforators close to prevent

BOX 174-1 COMMON SIGNS AND SYMPTOMS OF PERIPHERAL VENOUS DISEASE

SYMPTOMS

- Leg fullness
- Aching discomfort
- Heaviness
- Nocturnal leg cramps
- Bursting pain on standing

SIGNS

Very Early

- Tenderness to palpation

Early

- Edema
- Hyperpigmentation
- Stasis dermatitis
- Varicose veins

Late

- Venous ulcers
- Atrophie blanche
- Lipodermatosclerosis
- Acroangiodermatitis of Mali
- Postphlebitic syndrome

Figure 174-2 Extensive varicose veins on the calf and thigh.

pressure injury in the skin (see Fig. 174-1). In all patients with venous disease there is failure of these one-way valves and this can result in varicose veins (Fig. 174-2). The severity of venous disease is influenced by the number

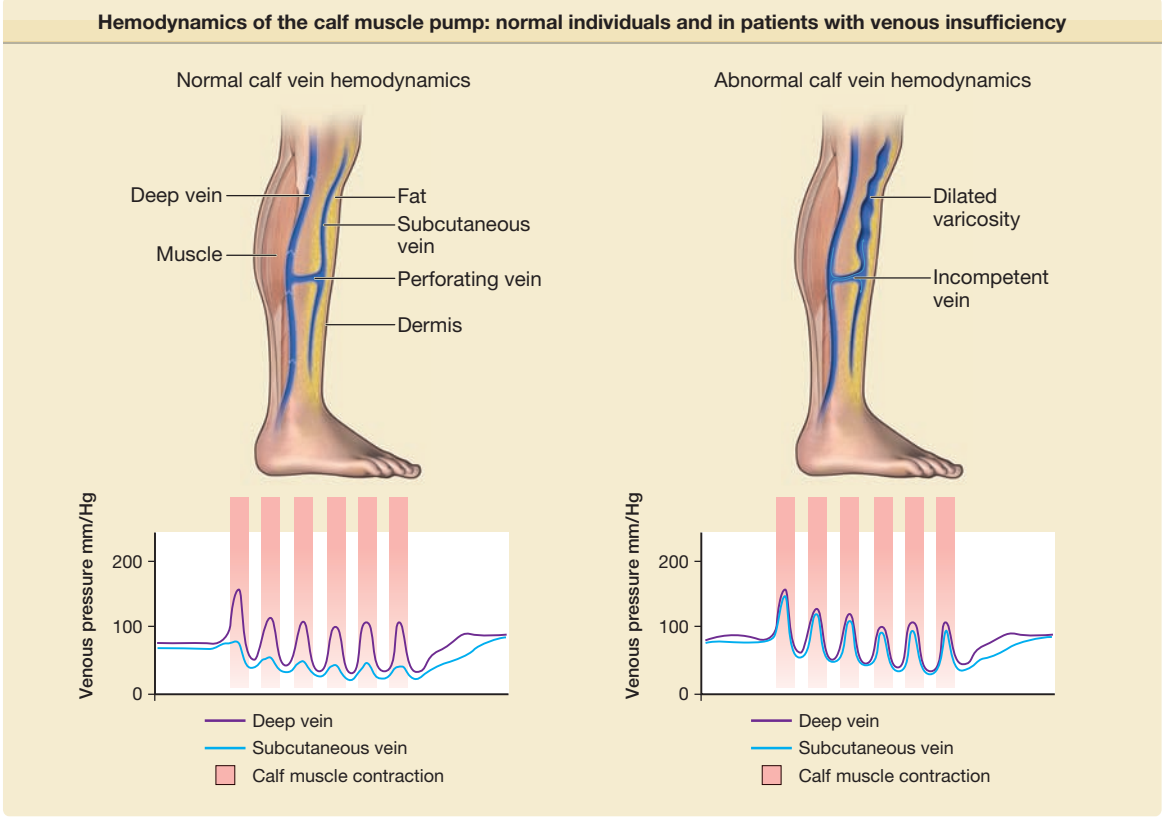

Figure 174-1 Anatomy and hemodynamics of the calf muscle pump in normal individuals and in patients with venous insufficiency. The latter is characterized by high pressure reflux from deep veins into the superficial veins and small vessels of the skin.

and distribution of incompetent valves and is worsened by any impairment of leg muscle function or ankle joint range of motion—all critical components of the calf muscle pump. Any obstruction to venous return (thrombosis, radiation fibrosis, etc.), or elevation of right atrial pressure (pulmonary hypertension, heart failure, etc.), further compromises venous return. A more detailed description of the anatomy and hemodynamics of the venous system of the lower extremities is found in Chapter 249.

The most common cause of valvular failure is thrombosis. The nidus for venous thrombosis is typically the valve cusp, and when the thrombus is lysed by plasmin, valve function is often lost as well. Calf muscle pump failure after deep venous thrombosis (DVT) is often referred to as the *postphlebitic syndrome*.[3]

Once valves fail, especially those in the perforators, high pressure blood in the deep system refluxes into the unsupported veins of the skin, there is vascular leakage of fibrinogen producing "fibrin cuffs" that may interfere with tissue nourishment, and white blood cell trapping leading to soft tissue injury, inflammation, and eventually fibrosis, as the subcutaneous fat is replaced by scar in a process described by the term *lipodermatosclerosis* (see Section "Cutaneous Lesions").

CLINICAL FINDINGS

HISTORY. An approach to the analysis of patients with ulcers is in Fig. 174-3.

Trauma frequently triggers the nonhealing venous ulcer. The events preceding ulceration happen insidiously over many years and may be ignored by the patient. A history of thrombosis may be missing because most episodes of lower extremity venous thrombosis are clinically silent. Relevant inquiry related to thrombosis risk should include a family history of similar problems (suggesting perhaps a familial thrombotic tendency), any episode of leg immobilization including knee or hip surgery and fractures, and any head injury associated with loss of consciousness.

Most patients complain of leg swelling, and many have been given diuretics, though the edema of venous disease, unlike the edema in salt-retaining states, like heart failure, cirrhosis, and nephrotic syndrome, does not respond to diuretics. An edematous leg not responsive to diuretic therapy is a strong clue to the diagnosis. Venous ulcers may or may not be painful.

CUTANEOUS LESIONS. All of the clinical syndromes described are secondary to the initial valvular syndrome and are grouped into clinical categories. Once there is venous valvular failure, a rather predictable series of changes occur in the skin. The earliest (though not universal) physical finding is soft tissue tenderness, even of normal appearing skin, discovered when checking for the presence of edema by palpation. Its association with other cutaneous signs of chronic venous disease is common.

The soft tissue injury that precedes ulceration begins in the subcutis, and visible changes may not appear for some time. Frequently one notes the appearance of petechial lesions, which have the appearance of cayenne pepper sprinkled about the gaiter area. As the hemoglobin in the petechial lesions breaks down, the iron remains in the skin as hemosiderin and may lead to impressive discoloration (Fig. 174-4).

Stasis dermatitis, characterized by erythema, scaling, pruritus, erosions, oozing, crusting, and occasional

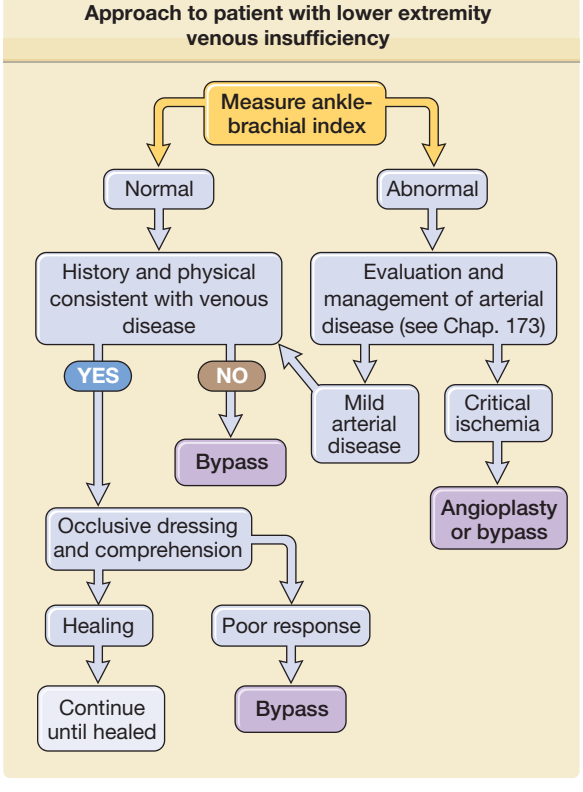

Figure 174-3 Approach to patient with lower extremity venous insufficiency.

Figure 174-4 Bilateral venous disease with dermatitis and extensive hemosiderosis.

vesicles may occur during any stage of chronic venous insufficiency (see Fig. 174-4). It typically occurs in the medial supramalleolar region where microangiopathy is most intense. Over time, lesions may lichenify. As 58% to 86% of patients with venous leg ulcers develop contact sensitization to topical therapies, it is important to evaluate for coexisting allergic contact dermatitis.

In lipodermatosclerosis (sclerosing panniculitis, hypodermatitis sclerodermiformis) pliable subcutaneous fat is gradually replaced by fibrosis, and the skin begins to feel indurated. This is a fibrosing panniculitis (see Chapter 70) characterized by a bound-down, indurated plaque that begins at the medial ankle and extends circumferentially around the entire leg.[4] As the fibrosis increases, it may constrict and strangle the lower leg further, impeding venous and lymphatic flow and leading to brawny edema above and below the fibrosis. These late changes resemble an inverted champagne bottle (Fig. 174-4).

Varicose veins, especially noticeable when the patient is standing, and smaller varicosities appear about the dorsum of the foot and ankle (see Chapter 249). Although they are usually asymptomatic, patients may complain of symptoms of aching, cramping, itching, fatigue, and swelling that are worse with prolonged standing.

Atrophie blanche refers to skin overlying areas of fibrosis that often appears porcelain white and atrophic. Fully established lesions of atrophie blanche consist of irregular, smooth, atrophic plaques with surrounding hyperpigmentation and telangiectasias (Fig. 174-5). Although mostly related to venous stasis, atrophie blanche may also be associated with an underlying disorder of coagulation (e.g., antiphospholipid syndrome, inherited coagulopathies) livedoid vasculitis (see Chapter 163) or autoimmune disease (e.g., scleroderma, lupus erythematosus).[5] Acroangiodermatitis (pseudo-Kaposi sarcoma, congenital dysplastic angiopathy, arteriovenous malformation with angiodermatitis) has purple macules, nodules, or verrucous plaques on the dorsal feet and toes of patients

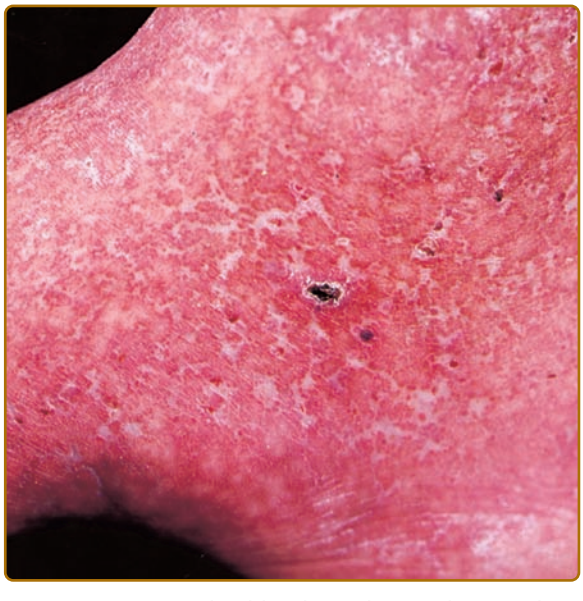

Figure 174-5 Atrophie blanche with irregular porcelain-white atrophic scars, small ulcerations, and crusting.

Figure 174-6 Venous ulceration in an area of lipodermatosclerosis, hemosiderosis, inflammation, and varicosities on the foot. Note lipodermatosclerosis constricts lower leg below the calf ("inverted champagne bottle").

with long-standing venous insufficiency and mimics Kaposi sarcoma clinically and histologically. Identical lesions have been described in arteriovenous malformations of the legs, arteriovenous shunts for hemodialysis, paralyzed limbs, and amputation stumps (http://www.accessmedicine.com/iedetect.aspx#2994638).

Occasionally, acute inflammation of the subcutaneous fat develops in patients with venous disease, and histologically one finds an acute septal panniculitis in this setting (see Chapter 70).

Though ulceration is classically located in the gaiter area (see Fig. 174-6), *venous ulcers* have been described anywhere below the knee. Venous ulcers are typically tender, shallow, irregular, red-based ulcers that are always located below the knee (Figs. 174-6 and 174-7). They are usually located on the medial ankle or along

Figure 174-7 Venous ulceration with stasis dermatitis, edema, and varicosities.

BOX 174-2 DIFFERENTIAL DIAGNOSIS OF LEG ULCERS

- Vascular diseases
  - Arterial (hypertensive atherosclerotic, vasospastic)
  - Venous (venous stasis ulcer)
  - Lymphedema
- Metabolic disorders
  - Diabetes mellitus
  - Necrobiosis lipoidica diabeticorum
  - Porphyria cutanea tarda
  - Gout
  - Pancreatitic (pancreatitis, carcinoma)
- Infections
  - Bacterial (especially *Staphylococcus aureus*, *Streptococcus*)
  - Spirochetal (syphilis)
  - Fungal (deep fungal, mycetoma)
  - Opportunistic in immunocompromised
  - Viral
- Vasculitis
  - Hypersensitivity vasculitis
  - Polyarteritis
  - Systemic lupus erythematosus
  - Rheumatoid vasculitis
  - Granulomatosis with polyangiitis (Wegener's)
  - Lymphomatoid granulomatosis
- Lymphedema
  - Congenital
  - Postinfectious
  - Postsurgical
  - Postirradiation
- Drugs
  - Halogens (bromide, iodide)
  - Ergotism
  - Drug-induced vasculitis
  - Anticoagulant necrosis (Coumadin, heparin)
  - Hydrea
- Hematologic abnormalities
  - Hypercoagulable states (protein C, protein S, antithrombin III deficiency, activated protein C resistance, prothrombin gene polymorphism)
    - Lupus anticoagulant syndrome
    - Paroxysmal nocturnal hemoglobinuria
  - Sickle cell anemia
  - Thalassemia
  - Polycythemia vera
  - Leukemia
  - Dysproteinemia (cryoglobulinemia, macroglobulinemia)
- Tumors
  - Cutaneous (basal cell cancer, squamous cell cancer, sarcoma, malignant melanoma, Merkel cell)
  - Secondary (metastatic carcinoma, lymphoma)
  - Kaposi sarcoma
- Miscellaneous
  - Pyoderma gangrenosum
  - Trauma (including factitial)
  - Burns
  - Pressure ulcers, neuropathic ulcers
  - Insect bites (brown recluse spider)
  - Ulcerative lichen planus
  - Bullous diseases (epidermolysis bullosa)
  - Sweet syndrome
  - Idiopathic

the line of the long or short saphenous veins. Clinical distinction should be made with other common ulcers of the lower extremity as discussed later in this chapter and as shown in Box 174-2.

HISTOPATHOLOGY

Histologic signs of venous hypertension include hemosiderin deposition, lobular superficial and/or deep dermal neovascularization, and fibrosis of the dermis and subcutaneous tissue in later stages. These histologic findings are found in all clinical manifestations of chronic venous disease.

LABORATORY TESTS AND IMAGING STUDIES

It is crucial to evaluate arterial blood flow. A useful bedside screening test is to calculate the ratio of the systolic blood pressure in the ankle (as measured by Doppler) to the systolic pressure in the brachial artery (also measured by Doppler). This "ankle/brachial index" is greater than or equal to one in normal individuals. Anything less than one is an indication of peripheral arterial disease. The lower the ratio, the more severe the arterial obstruction (see Fig. 174-3). An ankle/brachial index is reliable except in the presence of calcified vessels, which are noncompressible and therefore a true systolic pressure cannot be measured. Having excluded arterial disease as a cause of ulceration, a clinical diagnosis is sufficient for the initiation of empiric therapy in most cases. When the diagnosis is in doubt, skin biopsy may be useful. Functional testing of calf muscle pump function and venous valvular function using plethysmography is occasionally useful. Duplex Doppler ultrasonography can be useful to document valvular incompetence and to evaluate patients for possible sclerotherapy or surgery (see Chapter 249).

DIFFERENTIAL DIAGNOSIS

(See Box 174-2)

COMPLICATIONS

Recurrent ulceration is frequent. Any open wound provides a portal of entry for bacteria, and cellulitis, though infrequent, may develop at any time. Given that venous dermatitis may be extremely pruritic, and that these patients are easily sensitized to the topical agents they apply, contact dermatitis, especially due to topical antibiotics, is common. The skin is easily excoriated and may become infected.[6] The advent of methicillin-resistant *Staphylococcus aureus* is a threat to this population. The dermatitis of venous disease may become generalized as an id reaction (see Chapter 17) and may rarely produce an exfoliative erythroderma (see Chapter 23). Many of these individuals are predisposed to thrombi, and recurrent episodes of venous thrombosis are not uncommon.

All patients with advanced venous disease have some degree of lymphatic impairment, though lymphatic impairment may also result from inherited defects in lymphatic development or destruction of lymphatics after cellulitis lymphangitis, surgical interruption, or radiation.[7] Loss of lymphatic drainage from the lower leg may lead to verrucous changes and cutaneous hypertrophy, elephantiasis nostras (see Section "Acquired Lymphedema").

PROGNOSIS AND CLINICAL COURSE

The prognosis for healing areas of ulceration and inflammation is excellent in the absence of comorbid illness that interferes with healing. The vast majority of uncomplicated patients respond well to ambulatory outpatient therapy as outlined in the section "Treatment." Permanent changes include hemosiderosis and fibrosis that develop before the initiation of therapy. Loss of valvular function is irreversible. In the absence of continual lifelong cutaneous support in the form of inelastic wraps or elastic stockings, skin and soft tissue injury continues.

TREATMENT

Treatment of chronic venous insufficiency is outlined in Box 174-3. Treatment for all clinical manifestations of chronic venous insufficiency includes therapies that lower venous pressure and improve venous and lymphatic flow by mechanical means, dressings, drugs, and surgery.

Given the limitations of bed rest as an effective therapy, the focus is now on an ambulatory outpatient approach to the management of venous ulceration. Most experts agree on the essential role of compression in treating chronic venous insufficiency.[8] Hence, unless there are contraindications (arterial occlusive disease or abnormal ankle–arm indexes), compression therapy should remain part of any treatment regimen for chronic venous disease.

Toward the end of the nineteenth century, Paul Gerson Unna recognized that by providing a compression bandage to the distal extremity he could heal venous ulcers in an ambulatory patient population using zinc impregnated gauze wrap, the "Unna boot." Though the literature over the years continued to document the success of this approach, it proved difficult to achieve graduated compression with this wrap, and compliance was poor. Eventually, the addition of a self-adherent second layer (Coban™, for example) over a zinc wrap was introduced as the "Duke boot" and has proven to be easy to apply with reproducible graduated inelastic compression (Fig. 174-8) bandaging to

BOX 174-3 TREATMENT OF CHRONIC VENOUS INSUFFICIENCY

- Mechanical
  - Leg elevation
  - Compression stockings
  - Compression bandages
  - Intermittent pneumatic compression pumps
- Drug therapy
  - Aspirin
  - Pentoxifylline
  - Topical steroids (for stasis dermatitis)
  - Horse chestnut seed extract
- Dressings
  - Wet and dry nonadherent dressings
  - Occlusive hydrocolloid or gel dressings
  - Zinc paste-impregnated bandages (Unna boot)
- Surgery
  - Sclerotherapy
  - Long saphenous vein stripping
  - Saphenofemoral/saphenopopliteal junction disconnection
  - Calf varicosity avulsions
  - Subfascial endoscopic perforator vein ligation
  - Endovenous laser therapy
  - Radiofrequency ablation

Figure 174-8 Compression bandage using a zinc paste primary layer (Unna boot) followed by Coban™ at full stretch.

counter the outflow from perforator incompetence is the cornerstone of venous ulcer management.[9]

In 1962, George Winter reported the use of an occlusive layer enhanced healing in a pig model of acute wounds. His data suggested a roughly 100% improvement in the rate of wound healing simply by providing a moist environment. The impact on wound care has been dramatic. There are now thousands of such dressings on the market and although they differ in composition, absorption, gas exchange, and cost, all provide a moist environment (see Chapter 248). Underneath such dressings, fibrinopurulent and necrotic debris, aided by host and bacterial enzymes, dissolves painlessly (eFig. 175-8.1 in online edition). One can take advantage of these dressings to provide the best local environment for the wound, followed by a compression wrap to address the underlying hemodynamic disturbance.

The dressings should be changed weekly, or more often for heavily exudating wounds. New tissue is vulnerable to the cytotoxic effects of most topical antiseptics, and these agents are to be avoided. One should not put anything in a wound that you would not be willing to put in your eye. A gentle rinse with tap water or saline is sufficient. It is preferable to have the patient supine during dressing changes if at all possible.

Mechanical therapy is the mainstay of treatment for all clinical manifestations of chronic venous insufficiency. A Cochrane review found that "the use of elastic compression stockings to treat postthrombotic syndrome cannot be supported on the basis of the currently available data," but did find some evidence for a beneficial effect for intermittent pneumatic compression units (http://www.accessmedicine.com/iedetect.aspx#2994643). Nevertheless, daily use of elastic compression stockings has been shown to reduce swelling in some patients with postthrombotic syndrome (http://www.accessmedicine.com/iedetect.aspx#2994644); prevent worsening of established postthrombotic syndrome (http://www.accessmedicine.com/iedetect.aspx#2994635); and may reduce recurrence of healed venous (ulcershttp://www.accessmedicine.com/iedetect.aspx#2994645).

Each pharmaceutical therapy targets a specific clinical aspect of chronic venous insufficiency. Diuretics may be used in the short term for treating severe edema. Horse chestnut seed extract (often standardized to 50 mg escin twice daily) is an herbal remedy that appears to be safe and effective as a short-term treatment for leg pain and swelling.[10] Aspirin (300–325 mg/day)[11] and pentoxifylline[12] may improve healing of chronic venous ulcers. Finally, topical steroids and emollients aid resolution of stasis dermatitis.

Although all wounds harbor potential pathogens, there is no evidence that routine use of antibiotics is helpful in patients with venous ulcer. If cellulitis is suspected, empiric therapy with coverage for *S. aureus* and *Streptococci* is warranted. Topical antibiotics, especially mupirocin, are useful for folliculitis due to *S. aureus* and *Streptococci.* With the increasing incidence of community acquired methicillin-resistant *S. aureus* in this population, culture and sensitivity are suggested for suspected skin and soft tissue infections.

Venous disease is progressive and irreversible. Patients must be educated about the need for continual hemodynamic support after the wound has healed. Graduated stockings that provide a minimum of 30–40 mmHg at the ankle should be carefully fitted to all patients and worn for their lifetime. It is a mistake to place elastic stockings on edematous limbs, especially those that are tender. One should use compression bandaging until all edema, inflammation, and tenderness have resolved before fitting the patient with stockings.

In carefully selected cases, sclerotherapy or surgical techniques, especially endovenous ablation, may close incompetent perforators and correct the hemodynamic abnormalities that lead to venous ulcer (see Chapter 249).[13,14]

PREVENTION

Prevention of venous thrombosis prevents venous insufficiency. Because many thrombotic traits are genetic, it is likely those patients at extra risk for thrombosis may be identified and treated for this risk before an event, and efforts to prevent thrombosis during elective surgery and hospitalization should reduce the numbers of postphlebitic limbs. Once a patient develops venous thrombosis, elastic compression stockings are the only proven method to reduce the risk of postthrombotic syndrome.[15]

Valvular failure may develop during pregnancy. Therefore, the use of supportive stockings throughout maternity, although not proven, can be recommended. If one's occupation or lifestyle involves long periods of immobility (long-distance flights appear to be especially risky), stockings are advisable.

OTHER VENOUS DISEASES

DEEP VEIN THROMBOSIS

DVT is important for at least two reasons: (1) the thrombosed veins are the sources of pulmonary embolisms, and (2) the thrombosed leg may progress to chronic venous disease that has already been discussed.[16] Superficial thrombophlebitis has associations with internal diseases as well.

For details, see online edition of this book.

LYMPHEDEMA

Edema is an excess of fluid in the body tissues. Although most of this fluid is in the interstitial spaces, there is usually excess fluid both in the vascular bed and within cells. When this becomes chronic, inflammatory cells and their cytokines lead to an irreversible state. This chronic accumulation of protein-rich fluid may occur due to conditions that predispose to chronic edema, such as venous stasis; or it may occur due to lymphatic failure secondary to trauma, malignancy, disease, or genetic mutations that give rise to nonfunctional lymphatics. Lymphedema refers specifically to

LYMPHEDEMA AT A GLANCE

- Lymphatics are essential for the clearing of extravascular fluids and debris and as transport of immunocompetent cells during the initiation of an immune response.
- Specific markers of lymphatic endothelia exist.
- Genetic defects causing lymphedema in childhood or early adult life are often caused by defects in a vascular growth factor receptor (*VEGFR3*) and *FoxC2*, a transcription factor.
- Lymphedema acquired in adult life is often related to chronic venous disease, after mastectomy with radiation and node removal, and, in certain geographic locations, filariasis.
- Cellulitis may complicate all forms of lymphedema and should be aggressively treated.

Figure 174-9 Lymphedema of the left leg in a 47-year-old fireman. The extreme swelling began at birth and was painless. Note the lack of stasis pigmentation or ulceration. The patient functioned normally at work and wanted no treatment.

swelling of a part of the body due to impaired lymph transport capacity as a consequence of a malformation or malfunction of the lymphatics.

The typical clinical presentation of lymphedema is an edematous extremity without concurrent pain or inflammation. Acquired lymphedema leaves legs feeling heavy and the patient tired. Although the limb swells during the day, indentations from socks can be seen on the leg at nighttime, returning toward normal during the night, but the leg stays swollen, and initially concerns may be cosmetic in nature. The foot is often involved first and initially lesions pit with pressure. With time, lesions become woody or lardaceous and do not pit. The toe contours are eventually lost. The Kaposi–Stemmer sign, a feature of chronic lymphedema, appears as an inability to pinch up a fold of skin between the second and third toe on the dorsum of the foot. This condition develops due to chronic thickening of the skin overlying the digits.

Primary lymphedema is a congenitally determined intrinsic or constitutional fault in lymphatic drainage. This is most commonly due to mutations in specific genes that are critical to lymphatic development or function, but may arise as a result of a developmental abnormality due to unknown causes in utero. Depending on the cause, primary lymphedema may present at any age (Fig. 174-9).

Secondary lymphedema occurs when previously normal lymphatics suffer an external insult such as disease, infection (repeated episodes of erysipelas), trauma, or surgery, and subsequently lose their functional capability, giving rise to lymphedema. It is due most commonly worldwide to parasitic infection. In industrialized countries, secondary lymphedema occurs following trauma, infection, postsurgery, malignancy, or postradiation.[17]

In all the clinical disorders discussed, lymphedema may be transient and pitting with pressure but, with time, becomes fixed, and is accompanied by adipose tissue hypertrophy, fibrosis (Fig. 174-9), and epidermal hyperplasia (Fig. 174-10) that eventually makes pitting less evident.[18]

Figure 174-10 Verrucous skin changes in chronic lymphedema.

Patients with lymphedema are susceptible to recurrent erysipelas, physical impairment, and psychosocial stigmatization, and may be at increased risk of malignancy such as lymphangiosarcoma.

PRIMARY LYMPHEDEMA. Emberger syndrome is an autosomal dominant primary lymphedema syndrome caused by mutations in GATA2, a transcription factor involved in gene regulation during vascular development and hematopoietic differentiation.[20] Patients with this syndrome may have a low CD4/CD8 ratio, immune dysfunction (widespread cutaneous warts), sensorineural deafness, and genital lymphedema in addition to lymphedema of the lower limbs. These patients require monitoring due to their predisposition to AML (acute myeloid leukemia).

Milroy Syndrome

Etiology and Pathogenesis. Milroy syndrome is an autosomal dominant disease that characteristically has a mutation in *VEGFR3* (also called the *FLT4 gene*). This causes impaired tyrosine kinase activity of the VEGFR3 receptor, which disrupts lymphangiogenesis. Penetrance is relatively high (80%), but not complete, suggesting a role of additional genetic or environmental factors. There is a 2.3:1.0 female predominance in pedigrees; this sex ratio may be due to a more severe disease in males that leads to hydrops fetalis and fetal death.

Clinical and Radiologic Findings. Lymphedema is almost always from birth and is confined to the legs with deep creases over the toes and small deformed ("ski jump") toenails, and is typically characterized by hypoproteinemia from intestinal loss of albumen, chylous ascites, and scrotal edema.[21] Thickening of the skin overlying the digits leads to a positive Kaposi–Stemmer sign.[18]

Prenatal ultrasound can show edematous legs in the fetus. Skin biopsy from swollen feet of patients that possess the VEGFR3 mutation reveals abundant skin lymphatics that are confirmed to be nonfunctional by fluorescence microlymphangiography.[22] Interestingly, lymphangiography also demonstrates dysplastic lymphatics in both clinically affected and clinically normal extremities, emphasizing the complexity of the pathophysiology that ultimately leads to disease.

Lymphedema-Distichiasis

Etiology and Pathogenesis. Autosomal dominant nonsense and frameshift mutations in the forkhead transcription factor FoxC2 (MFH1 or mesenchyme forkhead-1), cause abnormalities in morphogenesis of the lymphatic valves in this disease.[23] Radiographic studies of patients with lymphedema-distichiasis show lymph and venous reflux of the lower limbs, illustrating the primary valve failure. Distichiasis, a double row of eyelashes, develops as a result of failure of proper differentiation of eyelid follicles into Meibomian glands.[18] Although the *FoxC2* mutation is specific for lymphedema-distichiasis,[24] further investigation has illustrated that lymphedema with ptosis may actually be one of the variable manifestations of *FoxC2* mutations, rather than a distinct disorder.[25]

Clinical and Radiologic Findings. Lymphedema typically develops during puberty, but may be delayed until early adulthood, especially in females. The lymphedema will commonly worsen in severity over time, and may be complicated by recurrent infection and eventual papillomatosis. Aberrant eyelashes are present arising along the posterior border of the eyelid margin, which frequently leads to eyelash irritation of the cornea and photophobia. Other associated findings of this syndrome include cardiac defects, cleft palate, spinal extradural cysts, and other ophthalmologic complications. Given the complexity of this disorder, and possibility of systemic involvement, treatment of this disorder frequently requires a multidisciplinary approach, including dermatologists, pediatricians, and geneticists.[18,21,26,27]

DISORDERS AFFECTING BOTH LYMPHATICS AND VEINS

SECONDARY LYMPHEDEMA

The most common cause of secondary, or acquired, lymphedema worldwide is due to lymphatic disruption and obstruction by infection with the nematode *Wuchereria bancrofti*, also known as filariasis (see Chapter 207). In the industrialized world, the most common cause is malignancy and malignancy-associated therapeutic interventions, such as surgery and radiotherapy.[17]

EPIDEMIOLOGY. Chronic edema in a community sample in London had a prevalence of 1.33 per 1,000 and was 5.4 per 1,000 for those older than the age of 65 years.[32] Twenty-five percent of chronic edema was related to malignancy; and 29% of patients had at least one episode of cellulitis over the year before the survey; 70% to 80% of patients were female.

Worldwide lymphedema due to filariasis is estimated to affect 100 million individuals[33,34] and is considered to be the second leading cause of permanent disability in the world.

For epidemiology, and clinical manifestations and treatment of filariasis see Chapter 207.

Other infectious diseases with lymphedema are much less common and include lymphogranuloma venereum, granuloma inguinale (see Chapters 203 and 204), and tuberculosis (see Chapter 184).

In regions of tropical Africa, Central America, and the Indian subcontinent where filariasis is uncommon, there is a condition of chronic lymphedema that is called podoconiosis, or nonfilarial elephantiasis. This condition causes edematous feet and legs, and is usually bilateral. Podoconiosis is not infectious in origin. It is caused by chronic inoculation of microparticles of silica through the soles of barefoot walkers.[17]

BOX 174-4 COMMON SIGNS AND SYMPTOMS OF LYMPHEDEMA

SYMPTOMS

- Edematous extremity
- Painless
- Heaviness
- Indentations from socks on standing
- Indentations improve overnight

SIGNS

Early

- Pitting edema
- Erysipelas

Late

- Nonpitting edema
- Thickened, woody skin
- Papillomatosis
- Verrucous tissue overgrowth
- "Ski-jump" upturned toe nails
- Infections (bacterial, fungal, viral warts)

CLINICAL FINDINGS. Typically, patients will present with a persistently edematous extremity without concurrent pain or inflammation (Box 174-4). The foot is often involved first, and initially lesions pit with pressure. Patients presenting later in the disease course may present with nonpitting edema. Feet may illustrate swollen toes with upturned nails. Thickening of the skin over the digits may be present, as may be the Kaposi–Stemmer sign. If the condition has been long-standing, the skin overlying the affected extremity may show generalized thickening, papillomatosis, or verrucous tissue overgrowth (Fig. 174-10). Fungal infections, erysipelas, or viral warts may also be present.

Unilateral lymphedema suggests localized obstructing factors, but bilateral lymphedema does not rule out anatomic obstruction, as the obstruction may be in the pelvis or abdomen.

Inflammation as manifested by redness, pain, and swelling is not lymphedema, but can be pyogenic infection, most commonly with *S. aureus* or *Streptococcus pyogenes*. Systemic antibiotics should be started before waiting for red lymphangitic streaking. A common complication is contact dermatitis from the use of topical antibiotics or multiple emollients and anti-inflammatory creams.

DIAGNOSIS. Chronic venous insufficiency can present with very similar features of early lymphedema. In this clinical context, both conditions will have pitting edema, and the characteristic skin changes in late-stage lymphedema have not yet developed. However, chronic venous insufficiency is typically bilateral, rather than unilateral as in lymphedema. It is imperative to exclude medical causes of lower extremity swelling, such as renal failure, hypoalbuminemia, congestive heart failure, protein-losing nephropathy, pulmonary hypertension, obesity, pregnancy, and drug-induced edema, among others. An uncommon clinical mimic to lymphedema is lipedema of the leg. This syndrome is due to bilateral adipose deposition, usually in the buttocks and lower extremities. This leads to enlargement that stops abruptly at the level of the malleoli, characteristically sparing the feet. This distinctive clinical presentation is referred to as "armchair legs."[17] This condition predominates among overweight women who spend the majority of their time with their legs in a dependent position. Chronic immobility leads to decreased lymphatic drainage and subsequent lymphedema.

SPECIAL TESTS. Diagnosis of filariasis includes assays to detect filarial antigens, and ultrasound to visualize living adult worms, even in the absence of microfilaremia.[34]

If there is doubt regarding the clinical diagnosis of lymphedema, especially when trying to differentiate from edema, there are various studies that may be employed for diagnostic confirmation. These include isotopic lymphoscintigraphy or, if necessary, radiocontrast lymphangiography.[35,36] Computed tomography (CT) and magnetic resonance imaging (MRI) are other radiographic options, though not ideal. MRI is preferred over CT because of its ability to detect water. These modalities should reveal the characteristic "honeycomb" pattern of the subcutaneous tissue present in chronic lymphedema. This pattern is not present in other types of edema. If there is suspicion for concurrent deep venous thrombosis or venous disease, a venous duplex ultrasound is often required.[17]

COMPLICATIONS. Prolonged lymphedema leads to fibrosis and epidermal hyperplasia with verrucous hyperkeratosis (Fig. 174-10). Ulceration rarely occurs, although the edema and hyperkeratotic changes may be profound. Lymphangiosarcoma, the Stewart–Treves syndrome when associated with postmastectomy lymphedema, is the common lesion in chronically lymphedematous locations (see Chapter 126).

TREATMENT. Drug therapy for lymphedema, in general, has been inadequate. Diuretics are frequently prescribed, and not only do they not alleviate the symptoms, they may actually worsen the condition. Diuretics thus should not be used as a primary treatment for lymphedema. There is some evidence to suggest the efficacy of coumarin therapy. Coumarin apparently reduces capillary filtration as well as reduces fibrotic tissue deposition.[17]

A combination of elevation, exercise, compression garments/devices, skin care aimed to prevent infection, and manual lymphatic drainage, usually via massage, are the mainstay in management of lymphedema.[17] In patients with primary and secondary lymphedema, in the absence of venous or arterial disease, manual lymphatic drainage and sequential pneumatic pumps, in addition to compression wraps and garments, may be useful.

Cellulitis or recurrent lymphangitis is a significant problem in lymphedematous sites, and there is both a rationale and results that encourage long-term antibiotic use (e.g., 2.4 million units of benzathine-penicillin G intramuscularly every 2 weeks).[37]

Microsurgery of lymphatics to bypass obstructed nodes can be considered if nonsurgical treatments are not successful. This procedure is not commonly performed in the United States because it is still considered experimental, but the literature from studies of this procedure performed in Europe is considerable. The surgery consists of the formation of multiple end-to-end lymphatic–venous anastomoses.[38] Congenital lymphatic disorders have been treated with this intervention in the early childhood years with dramatic results.[39,40]

Low-level laser therapy (LLLT), either in combination with pneumatic compression or as a solo intervention, has been studied in patients with postoperative lymphedema, primarily in postmastectomy lymphedema. Results are encouraging, and patients have had improvements in the total volume of affected limbs at follow-up analysis of up to 1 year.[41]

Excisional or suction-assisted lipectomy (liposuction) may be an option in selected patients in whom are not eligible for other treatment options, or in whom other therapeutic modalities have failed.

PREVENTION. Any patient with lymphedema, whatever the cause, should keep their feet dry, nails trimmed, and prevent and aggressively treat pyogenic infection. Lymph moves faster during limb activity and exercise (e.g., walking should be encouraged). A combination of flexibility training, aerobic training, and strengthening exercises—while wearing compression garments or devices—have shown to have significant improvement in lymphedema.[17]

LOCALIZED AREAS OF LYMPHEDEMA

Lymphedema is common in some locations, especially on the face, vulva and penis, and can lead to superficial lesions termed lymphangiectasia. These focal areas of lymphedema occur from obstruction of usually previously normal lymphatics, progressing to lymphatic valve incompetence, lymph reflux, and retrograde lymph flow to the skin. This leads to blister-like lesions full of lymphatic fluid called lymphangiectasias. These most commonly occur after trauma, treatment for malignancy, or infection. These lesions are highly symptomatic and distressing, and frequently are painful, pruritic, and exudative.[42,43] A current favored treatment modality for superficial lesions is with carbon dioxide laser ablation. Because the underlying obstructed lymph vessels are not corrected by the superficial laser, recurrences commonly occur.[43] Other options for treatment include surgical excision and superficial radiotherapy and sclerotherapy.[44]

Disease Due to Microbial Agents, Infestations, Bites, and Stings

PART 9

Bacterial Disease

Chapter 175 :: General Considerations of Bacterial Diseases

:: Noah Craft

BACTERIAL SKIN DISEASES AT A GLANCE

- Bacteria cause disease by direct invasion of tissues, by secreting toxins, and by causing immunologic consequences that result in disease.
- The innate immune system is critical in the initial defense against bacterial entry into the skin.
- The virulence and pathogenicity of bacteria is related to their ability to avoid activating the innate immune system or resisting killing within immune effector cells.
- Immunosuppression, especially neutropenia, puts the host at high risk for bacterial infections; some infections are rare except in the immunocompromised host.
- Consideration of host factors and pathogen virulence factors are critical to choose a safe and effective therapy against bacterial infections.
- There are many noninfectious conditions that can mimic the clinical presentations of bacterial infections. Consider the noninfectious differential diagnoses carefully.
- The use of up-to-date computer based resources for antibiotic resistance trends and best-practice guidelines is important when choosing empiric antimicrobial therapy.

The microbes that live on or in the human body are collectively referred to as the human microbiome. Some microbes of the human microbiome cause disease and others do not (commensals). The skin microbiome is a complex and diverse population of organisms that includes many bacteria, both commensals and pathogenic. The Human Microbiome Project includes recent work using metagenomic sequencing that describes the skin microbiome in previously inconceivable detail. The effects of multiple factors, including sebum secretion, body location, lipid content, pH, and sweat production significantly influence the growth of bacteria on the skin.[1] The effects of skin diseases such as psoriasis also dictate the composition of the skin microbiome.[2] It is clear there are many more bacteria normally living on our skin than previously imagined. Understanding the factors that contribute to healthy skin and skin disease will lead to improved treatment and prevention of

skin infections and perhaps many noninfectious skin diseases.

The relationship of bacteria and the skin may be considered in four major categories[1]: (1) primary skin infections,[2] (2) secondary infection of a primary skin disease (e.g., infected atopic dermatitis),[3] (3) the skin lesions as manifestations of primary infection in some other organ system, usually the blood, and[4] (4) reactive skin conditions resulting from bacterial infection elsewhere (e.g., erythema nodosum due to streptococcal pharyngitis). Thus, the balance of host immunity and the growth of the skin bacteria determine the disease state of the skin. Controlling a disease state, like atopic dermatitis, clearly reduces the number of skin infections that arise in the broken skin barrier. Conversely, controlling skin infections with dilute bleach baths and mupirocin ointment can lead to decreased atopic dermatitis flare as well.[3]

When considering the patient, it is important to remember that not all skin infections are suppurative but may present as reactive responses (e.g., erythema nodosum). Equally important, not all suppurative skin problems are primary skin infections (e.g., hidradenitis suppurativa). Notably, many erythematous skin lesions are not infectious at all (e.g., stasis dermatitis). The importance of the skin as a mirror of systemic infection cannot be overemphasized, especially when classic clinical findings are distorted as in immunocompromised patients. The timely recognition of the cutaneous clues of bacteremia may prevent the rapid spread of life-threatening infections due to organisms such as *Pseudomonas aeruginosa*, *Vibrio vulnificus*, *Salmonella typhi*, *Staphylococcus aureus*, and *Neisseria meningitidis*.

PATHOGENESIS OF BACTERIAL INFECTION OF THE SKIN

The development and evolution of bacterial infection involve three major factors[1]: (1) the portal of entry and skin barrier function,[2] (2) the host defenses and inflammatory response to microbial invasion, and[3] (3) the pathogenic properties of the organism.

PORTAL OF ENTRY

Normal intact pediatric and adult skin is relatively resistant to infection and most skin infections occur when there is disruption of the skin barrier. Maceration, shaving, chronic wounds, excoriation of pruritic insect bites, and disruption of the epidermal barrier by other pathogens are some of the ways bacteria can breach the skin barrier. For example, skin trauma, interdigital maceration, or tinea pedis can be predisposing factors for lower leg cellulitis in an otherwise healthy person without venous incompetence or a leg ulcer.[4]

The character of the cutaneous inflammatory response to bacteria will be influenced by how the organisms reach the involved area. Local inflammation and suppuration commonly accompany direct bacterial infection of the skin. In septicemia, the vascular wall is often the primary site of skin involvement; hemorrhage, or thrombosis with infarction is the initial manifestation leading to ulceration or eschar. Certain bacteria can produce bacteremia or distant lesions without evoking an obvious inflammatory response at the portal of entry [e.g., *Yersinia pestis*, *Streptobacillus moniliformis* (rat-bite fever)], even in a healthy host. Occasionally, a devastating *Streptococcus pyogenes* septicemia has followed closely on an innocuous pinprick or abrasion that has not induced a significant local lesion.

NATURAL RESISTANCE OF THE SKIN

The normal skin of healthy individuals is highly resistant to invasion by the wide variety of bacteria to which it is constantly exposed. It is difficult to produce localized infections such as impetigo, furunculosis, or cellulitis, if the integument is intact.[5] Pathogenic organisms such as *S. pyogenes* (group A streptococcus, GAS) and *S. aureus* produce characteristic lesions of cellulitis and furunculosis in hosts with normal defenses usually because there is a disruption of the normal skin barrier. The presence of a silk suture reduces by a factor of 10,000, in the case of *S. aureus*, the number of organisms needed to produce an abscess in the human skin.[6]

Bacteria are unable to penetrate the keratinized layers of normal skin and, when applied to the surface, rapidly decrease in number. Maceration and occlusion, which result in increased pH, higher carbon dioxide content, and higher epidermal water content, result in dramatic increases in bacterial flora.[7] Some bacteria, such as those that are Gram negative, can only be found in such sites, suggesting that normal skin conditions prevent them from colonizing the skin. The relative dryness of normal skin specifically contributes to the marked limitation of growth of bacteria, especially Gram-negative bacilli.

Lipids found on the skin surface also may have antibacterial properties.[8,9] Reduction of skin surface lipids with topical solvents prolongs the survival time of *S. aureus* on the skin. The free fatty acids, and linoleic and linolenic acids, are more inhibitory for *S. aureus* than for coagulase-negative staphylococci, a component of the normal skin flora. Sphingosine, glucosylceramides, and *cis*-6-hexadeconic acid have been demonstrated to have antimicrobial activity against *S. aureus*. Bacterial interference (the suppressive effect of one bacterial species on colonization by another) exerts a major influence on the overall composition of the skin flora.

The organisms that characteristically survive and multiply in various ecologic niches of the skin constitute the "normal cutaneous flora." As an example, the distribution of different species of coagulase-negative staphylococci varies among different anatomic areas, and their relative numbers can depend on age. In adults, *Staphylococcus epidermidis* is the principal staphylococcal species isolated from the scalp, face, chest, and axilla. In a study of the skin microbiome of healthy adults, over 98% of skin bacteria belonged to four phyla: (1) Actinobacteria (51.8%), (2) Firmicutes (24.4%), (3) Proteobacteria (16.5%), and (4) Bacteroidetes (6.3%). Although 205 genera were identified on

only 20 individuals, three were associated with more than 62% of the sequences: (1) *Corynebacteria* (22.8%; Actinobacteria), (2) *Propionibacteria* (23.0%; Actinobacteria), and (3) *Staphylococci* (16.8%; Firmicutes).[10]

ANTIMICROBIAL PEPTIDES. Human skin contains a wide range of proteins with inherent antimicrobial properties. These antimicrobial peptides (AMPs) are expressed on the skin surface as well as in eccrine sweat and saliva.[11] Activated keratinocytes produce AMPs. The AMPs produced in keratinocytes are delivered to the skin surface in the lamellar bodies, and their appearance on the skin surface is closely tied to the production of normal skin stratum corneum lipids (see Chapter 47). These small proteins have as a characteristic physical property: the presence of an amphipathic organization, with one portion being cationic and capable of binding to microbial membranes, and another being hydrophobic allowing for insertion into the bacterial lipid membrane. The insertion into the membrane results in membrane disruption and microbial death. The second principle of AMPs is that they are processed after release by enzymes on the skin surface, resulting in multiple peptides each with different activities and different targets. The third principle of AMPs is that they not only kill microbes directly, but they are also potent activators of the host immune response. There are dozens of AMPs with activity on the human skin.[12] The two major AMPs studied to date on the skin are (1) the cathelicidins (LL-37) and (2) the defensins. The marked decrease of these molecules on the inflamed skin of patients with atopic dermatitis may be related to the susceptibility of atopic patients to infections with *S. aureus*, herpes simplex virus, and vaccinia virus.[13] T-helper 2 cytokines specifically suppress the production of these AMPs, a possible explanation for why psoriatic skin has normal or elevated AMP content and is less susceptible to bacterial and viral infections.[14]

SPECIFIC FEATURES OF HOST INFLAMMATORY RESPONSE TO CUTANEOUS INFECTION. The adaptive immune system, which requires the development of targeted cells and antibodies, is highly effective in protecting humans from infection once the effector cells and antibodies have been produced. However, this takes days, and bacteria replicate and invade in hours. The discovery of the "innate" immune system explains the ability of organisms to mount an effective and targeted immune response to microbes before the adaptive immune system comes into play (see Chapter 10). The innate immune system is present in plants, invertebrates, and vertebrates. This system relies on a series of pattern recognition receptors (PRRs) that recognize pathogen-associated molecular patterns (PAMPS) that are not present on "self".[15] Binding of the PRRs to the PAMPs results in opsonization and activation of the complement system as well as induction of inflammatory signaling pathways. This process involves at least three PRRs[1]: (1) the AMPs discussed in Antimicrobial Peptides,[2] (2) Toll-like receptors (TLRs), and[3](3) the complement system. These three systems engage bacteria once they enter the skin and, by intercommunication and by signaling neutrophils and other immune cells, are vital in bringing to the site of infection the cells required to destroy the pathogen.

TLRs are a repertoire of pattern recognition receptors (see Chapter 10).[16] They occur on cell membranes and recognize certain exogenous ligands that are unique to invading microorganisms and not found in the host. They play a prominent role as primary sensors for invading pathogens. For instance, TLR2 recognizes the peptidoglycan on the surface of Gram-positive bacteria, TLR4 recognizes the lipopolysaccharide on Gram-negative bacteria, and TLR5 recognizes flagellin, unique to flagellated bacteria. These structural elements of the invading organism are essential for its pathogenicity and therefore are hard to eliminate on an evolutionary basis. The TLRs not only engage the invader, but they also orchestrate what type of immune response is generated for that specific pathogen. TLRs do this by instructing antigen-presenting cells that have engaged the organism to secrete appropriate cytokines to generate the desired immunologic milieu and eventual adaptive immune response (see Chapter 10). Alternative downstream signaling pathways can result in different immune responses from engagement of the identical TLRs.

Complement (see Chapter 37) is activated when mannin-binding lectin binds to carbohydrate patterns on bacteria and activates C2 and C4.[17] Activation of C3 liberates C3a and C3b. C3b on membranes leads to opsonization and enhanced phagocytosis. In addition, the cleavage of C5 leads to C5a, a potent activator of neutrophils and a stimulator of proinflammatory cytokines, including interleukin 1 (IL-1) and IL-8. The "membrane attack complex" is formed by completion of the complement cascade and kills invading microbes. Not surprisingly, complement components also modulate the immune system, and alter TLR stimulation of some activation pathways. Through an extensive repertoire of outcome options, the human host has the ability to develop an organism-specific response to a wide variety of infectious agents that the host has not previously encountered. In addition, the innate immune system through complement and TLR orchestrates the adaptive immune system to appropriately respond to the invading microbe. This elaborate innate immune response explains the variety of rather distinctive clinical responses to various bacterial infections that have been described. The infectious agent, the anatomic site of the infection, and the attendant inflammatory response pattern create the clinical lesion.

PATHOGENICITY OF THE MICROORGANISM

To effectively invade a host, the microbe must initially gain access. *S. aureus* uses teichoic acid and other surface proteins that promote adherence to the nasal mucosa. The bacteria are then available to contaminate any breaches in the skin, binding to fibronectin in wounds. The disease-producing capacity of bacteria is termed *virulence*. The genetic material encoding virulence factors and toxins are carried on mobile genetic elements called *pathogenicity islands*. Bacteriophages

carry genetic elements from one bacterium to the next (Panton–Valentine leukocidin for example). Panton–Valentine leukocidin is a cytotoxin directed against human immune cells. It is associated with deep-seated and more inflammatory furunculosis, and now has been correlated with methicillin resistant *S. aureus* (MRSA). Importantly, up to 37% of patients with purulent CA-MRSA infections are colonized at another anatomical location with the organism.[18] In addition, many bacterial species contain DNA elements within their own genome that specifically are designed to escape, inactivate, or suppress the host's innate immune response, especially by resisting killing by neutrophils and excreted products. These gene products that respond to the host's immune attack are usually composed of a two-protein interaction cascade involving a sensor and a response protein. This is called a *two-component gene regulatory system*. In the case of *S. aureus*, numerous specific substances target each element of the innate immune attack by the host. Staphylokinase (SAK) inactivates defensins. Aureolysin A cleaves LL-37. The *oatA* gene encodes a membrane protein that imparts lysozyme resistance. *S. aureus* is catalase positive, and the yellow pigment of *S. aureus* (carotenoids) protects it from oxidative killing by neutrophils. SAK also activates plasminogen to plasmin. Surface plasmin cleaves C3b and immunoglobulin G, removing important opsonin molecules from the bacterial surface. Chemotaxis inhibitory protein of *S. aureus* binds to C5a blocking neutrophil activation. Staphylococcal complement inhibitor binds to C3 convertase on the bacterial surface preventing it from cleaving C3 and activating the complement cascade. SAKS, chemotaxis inhibitory protein of *S. aureus*, and staphylococcal complement inhibitor are carried on the same pathogenicity islands.[19–22]

Although it is useful to distinguish between disease caused by toxins and those caused by direct invasion and virulence factors, most bacterial infections result from the combination of the invasive and toxigenic properties of the organism. Examples in which locally secreted toxins are instrumental in creating the characteristic lesions are infections with *S. aureus* (bullous impetigo), *Corynebacterium diphtheriae*, and *Bacillus anthracis* (see Chapter 177). Systemic manifestations of toxin secretion are seen in staphylococcal scalded skin syndrome and tetanus. In the case of *Clostridium perfringens*, elaboration of a variety of extracellular toxins and enzymes (α-toxin or lecithinase, proteases, collagenases) appears to play an important role in the rapidly spreading skin lesions and the systemic manifestations of clostridial myonecrosis (see Chapter 179). *S. pyogenes*, specifically GAS, also contains numerous genes that help it evade the innate immune system. These include those within the genome, such as the M protein, which prevents phagocytosis by neutrophils, and those transmitted on prophages such as exotoxin A. The production of DNase SdaD2 protects GAS from extracellular killing by neutrophils in neutrophil extracellular traps and is important in skin infections. Tissue invasion and systemic spread are enhanced by streptokinase. GAS streptokinase is active only against human plasminogen, which may be critical in restricting GAS infection to humans. The proclivity of streptococcus to share the genetic material containing these virulence factors across strains has blurred the restrictions of streptococcal types to certain disease patterns. Now, for instance, in some regions, group G streptococcus is a major cause of pharyngitis and contains the same virulence genes that gave GAS the ability to cause this condition.[23,24]

Gram-negative bacteria (*Escherichia coli*, *S. typhi*, *N. meningitidis*, *Neisseria gonorrhoeae*, *Brucella melitensis*, and others) contain endotoxin, or complex phospholipid-polysaccharide macromolecules (LPS), as an integral part of the bacterial cell envelope (see Chapter 180). Endotoxins, unlike exotoxins, are released only upon breakdown of the bacterial cell. Their toxicity appears to be linked principally to the lipid fraction, whereas their antigenic determinants reside with the polysaccharide component. Much is now known of the mechanisms by which LPS exerts its biologic effects in systemic infections due to Gram-negative bacteria or in major localized infections that may also be capable of producing the sepsis syndrome. The effects are both toxic and immunologic. The two cytokines most important in the toxic and proinflammatory effects of LPS are produced by LPS-activated macrophages: (1) tumor necrosis factor (TNF-α) and (2) IL-1. TNF-α initiates a proinflammatory cytokine cascade (see Chapter 11). TNF-α activates the coagulation system through its effects on vascular endothelium, and decreases blood pressure and tissue perfusion by reducing myocardial contractility and by relaxing smooth muscle. High circulating levels of TNF-α are demonstrable in patients with meningococcemia and other forms of severe sepsis.[25] Infusion of high concentrations of purified TNF-α alone can produce shock and death. The ability of LPS, through TNF-α production, to induce leukocyte adherence to capillary endothelium and to induce fibrin deposition has been suggested as the basis for development of the hemorrhagic necrotic skin lesions (with or without direct bacterial invasion) that sometimes occur during the course of Gram-negative bacteremias and particularly in meningococcemia. Purpura fulminans develops in 10%–20% of cases of marked meningococcal sepsis, and severe cases may develop thrombosis of large vessels with infarction of digits (see Chapters 144 and 180).

CHANGING PATTERNS OF BACTERIAL INFECTIONS OF THE SKIN

Three factors have resulted in an increase in the prevalence and virulence of bacterial infections. First, new pathogens such as *Bartonella* spp. that were not previously known to cause human disease were discovered (see Chapter 182). Second, bacteria themselves have become more difficult to treat via the acquisition of virulence factors and antibiotic resistance. Third, there is an ever increasing number of immunocompromised patients due to increasing numbers of the elderly and debilitated, the human immunodeficiency virus-infected, and the iatrogenically immunosuppressed. In addition to the usual pathogens, a variety of "non-pathogenic" members of the cutaneous microbiome are

capable of producing disease in debilitated patients and in individuals with altered humoral or cellular defenses. For example, ecthyma gangrenosum due to local or systemic destructive invasion of the skin by *Pseudomonas aeruginosa* is seen virtually always in the setting of neutropenia (see Chapter 179). In the immunocompetent host, a transient and self-healing folliculitis ("hot-tub folliculitis) is caused by the same organism. *Bartonella henselae* causes cat-scratch disease, a self-healing disorder in the immunocompetent host (see Chapter 182). In patients with advanced AIDS (CD4 <50), *B. henselae* leads to bacillary angiomatosis and systemic involvement that is fatal without treatment (see Chapters 182 and 198).

INFLUENCE OF HYPERSENSITIVITY TO BACTERIAL ANTIGENS ON INFLAMMATORY REACTION IN SKIN

The ability of bacteria to induce immunologic events on the part of the host explains certain syndromes. The flares of atopic dermatitis induced by *S. aureus* may be due to shifts in cytokine profile in the lesions induced by the bacterial infection. Similarly, streptococcal infection of the pharynx can induce an immunologic response that triggers guttate psoriasis via activation of the immune system.

NEUTROPHILIC CONDITIONS AS A CUTANEOUS RESPONSE TO SYSTEMIC INFECTION

Inflammatory changes in and about small blood vessels in the skin may occur in a variety of bacteremic infections in the absence of obvious localization of bacteria at these sites. The papular and petechial lesions of chronic meningococcemia, and at times in disseminated gonococcal infection (see Chapters 180 and 205), and the development of leukocytoclastic vasculitis following adequate treatment of endocarditis (probably induced by circulating immune complexes) are examples. The lesions of Sweet syndrome (see Chapter 32) and early erythema nodosum (see Chapter 70) can have prominent tissue neutrophilia, even though the initiating infection (e.g., streptococcal pharyngitis) is distant. The Osler nodes and petechiae of subacute bacterial endocarditis, caused by viridans streptococci, probably provide the best examples of this association of small-vessel vasculitis with bacteremia (see Chapter 181). Histologically, these lesions are more suggestive of vasculitis than of emboli. The occasional development of such lesions in profusion, localized to the lower extremities, supports the concept of cutaneous vascular inflammation rather than embolization.

CLASSIFICATION OF BACTERIAL INFECTIONS OF THE SKIN

The discovery of specific bacteria as the cause of skin infections has led, in most cases, to classification of skin diseases based on the pathogenic bacteria rather than by morphology. In many cases, however, the infectious agent will be identified by culture, and the results not known for at least 1 day. In addition, impetigo (see Chapter 176), cellulitis, and necrotizing fasciitis (see Chapter 179) are three examples where multiple pathogens are capable of causing the same clinical pattern and require treatment decision based on the most likely pathogens. Therefore, morphologic classification of skin lesions is still important and can guide initial diagnostic testing and empiric antibiotic treatment. To this end, the classification of skin findings caused by bacterial infections as[1] primary infections (pyodermas),[2] secondary infections,[3] cutaneous manifestations of systemic bacterial disease, and[4] reactive conditions resulting from distant infection, seems warranted. Primary bacterial infections are produced by the invasion of ostensibly normal skin by a single species of pathogenic bacteria. In such infections, there is usually no doubt as to the primary etiologic role of the specific agent in the pathogenesis of the lesion. Treatment aimed at the bacterial pathogen almost universally results in cure of the lesion. Impetigo, erysipelas, and furunculosis (see Chapter 176) are familiar examples of primary cutaneous infections. In contrast, secondary infections develop in areas of already damaged skin. Although the bacteria present did not produce the underlying skin disorder, their proliferation and subsequent invasion of surrounding areas may aggravate and prolong the disease. Such secondary infection may occur when the integrity of the skin has been broken, or the local immune milieu is altered by the primary skin condition, allowing infection by bacteria. In contrast to the primary infections, the secondary infections at times show a mixture of organisms on culture, and not infrequently, it is impossible to determine which, if any, play the major role. It is important to know in which conditions recovery of a bacterial pathogen is important, and in which it is less predictable of response to antibiotic treatment. In flares of atopic dermatitis (see Chapter 14), decreasing the numbers of *S. aureus* on the skin surface with antibiotics is often associated with improvement of the dermatitis. In contrast, even experts in the field disagree on the significance of culturing bacterial "pathogens" from chronic leg ulcers. In the case of secondary infections, the morphology of the primary skin disease may be minimally altered, and the presence of an exacerbating bacterial pathogen may only be suspected by poor response to treatment or an otherwise unexplained flare of the condition.

DIAGNOSTIC STRATEGIES

DIRECT EXAMINATION OF ASPIRATES AND BIOPSIES

Identification of bacteria from skin lesions may provide important information as to the cause of cutaneous infections. Although not practical in many settings, examination of a Gram-stained smear of material from a suspected skin infection can guide decisions on

early antibiotic therapy before a cultural diagnosis is made. For these reasons, bacteriologic investigation is an important part of the initial evaluation of patients with skin lesions and includes[1] appropriate sampling,[2] interpretation of Gram-stained smears, and[3] use of selective growth media for culturing.

Gram staining provides a very rapid method of examining a sample for number and type of bacteria, as well as for the character of the inflammatory exudate in sterile pustules. Obtaining an appropriate specimen for microscopic study and culture requires care to avoid contamination. Bacterial cultures from cellulitis and erysipelas are generally unrewarding. Aspirates or biopsies from the advancing edge of cellulitis yielded positive cultures in an average of 16% of patients.[26] Although not routinely performed, findings on needle aspiration, when positive, can provide an immediate useful guide to therapy. If sterile saline is injected into a lesion for diagnostic culture, solutions without bacteriostatic additives should be employed. In circumstances in which no data are available from needle aspiration, a surgical biopsy may yield information that is life saving. In the bioterrorism-associated outbreak of anthrax infections in the United States, rapid specific diagnosis of cutaneous disease was accomplished by punch biopsy of an erythematous, indurated plaque and tissue Gram stain demonstrated Gram-positive rods, confirmed as *B. anthracis* by immunohistochemical analysis (see Chapter 183).[27] Local lesions of the skin and subcutaneous tissues in immunocompromised patients should always be biopsied if aspiration fails to define a pathogen. Encouraging results have been reported in patients with suspected necrotizing fasciitis (see Chapter 179) who had biopsies done to confirm the diagnosis early in the course of this devastating infection.[28]

OTHER DIAGNOSTIC PROCEDURES

FLUORESCENT ANTIBODY. The practical use of this procedure in bacterial diseases of the skin is currently of limited applicability. Spirochetes can be demonstrated (by the direct or indirect techniques) in chancres, (see Chapter 200). *N. gonorrhoeae*, *Actinomyces israelii*, *Legionella* sp., *Francisella tularensis*, *B. anthracis*, and *Y. pestis* have been identified by this rapid direct fluorescent antibody staining method. Its greatest use is in the specific diagnosis of uncommon but serious infections.[29]

OTHER IMMUNOLOGIC METHODS. A variety of serologic tests may be helpful in the diagnosis of bacterial infections of the skin. These tests are particularly important in conditions where the cutaneous manifestations are secondary to systemic disease (e.g., "rose spots" of typhoid fever). *Bartonella* infections are routinely diagnosed in this manner.

POLYMERASE CHAIN REACTION. Polymerase chain reaction (PCR) technology can be applied to diagnosis of material obtained on skin punch biopsy of lesional tissue or aspirates from a vesiculobullous lesion just as it has been used in diagnosis of infection in body fluids (cerebrospinal fluid, pleural fluid, blood). Appropriate precautions to exclude contamination during the acquisition of the specimen must be taken. The use of this procedure is most helpful when one particular rare bacterial species is being considered, and appropriate primers are available. Such was the case in a patient with a cutaneous lesion during the bioterrorism-induced anthrax outbreak.[25,29]

ANTIBIOTIC THERAPY

(See Chapter 230)

The selection of the appropriate antibiotic should be made initially on the basis of the appearance of the skin lesion, the characteristics of any systemic illness, and a Gram-stained smear of material from a lesion, if available. Culture results and susceptibility testing of the isolated pathogen(s) are usually available within 24–48 hours. Additional epidemiologic factors (current hospitalization or residence in a nursing home, recent antibiotic use, neutropenia, and immune status) should be considered in the choice of initial antimicrobial therapy. Also, it is important to make the choice based on the latest data from the local area and from frequently updated sources in view of the rapidly changing patterns of antimicrobial resistance of various bacterial species. The use of computerized decision support, infectious disease reference systems, best-practice guidelines, or pharmacologic databases should be considered when choosing empiric therapy for bacterial infections.

DOSAGE: METHODS OF ADMINISTRATION—EXCRETION

Primary cutaneous infections of mild to moderate severity can be treated with local measures, topical drugs, oral antibiotics, or by a combination of these methods. Extensive infections of the skin, with or without systemic manifestations, should be vigorously treated with parenteral antibiotics in adequate dosages. In the immunocompromised host, parenteral treatment of cutaneous infections is virtually always recommended.

A number of factors must be considered in administering antibiotics: oral treatment may be limited by absorption and gastrointestinal disturbances; hypotension and extensive skin disease can prohibit the intramuscular route; and the proper drug selected may be suitable for administration only by a specific route. The metabolism profile of a given antibiotic should always be considered to avoid underdosing or toxic accumulation in the face of specific organ malfunction (e.g., hepatic or renal impairment).

TOXICITY

The toxicity of antibiotics should be considered on an individual basis but some problems are applicable

to all antibiotics. Hypersensitivity reactions are relatively common and can include skin rashes, fever, or more severe manifestations such as acute anaphylaxis or exfoliative erythrodermas. The penicillins and sulfonamides are particularly likely to produce these problems. Questions regarding previous drug allergy should be asked whenever any antibiotic is to be administered. All antibiotics can alter the indigenous flora, especially broad-spectrum agents such as the cephalosporins. Gastrointestinal disturbances and oral mucous membrane lesions are the major problems encountered with alteration of the flora. There are numerous other potential drug reactions (renal, hematologic, hepatic, nervous system) to antibiotics that may represent acceptable risks if the reasons for use of these drugs are compelling. It is the physician's responsibility to be aware of the usual and unusual manifestations of toxicity of any of the antibiotics used and to be alert to possible novel effects in individual patients. The use of electronic medical records with physician alerting systems will help improve these potential negative outcomes.

ANTIBIOTIC RESISTANCE

Transferable resistance to multiple antibiotics has emerged as a widespread problem. The mechanisms of acquired resistance can occur in several ways.[30] Foreign DNA containing an antibiotic resistance gene can be transferred by (a) horizontal gene transfer into a recipient by several paths; (b) cell-to-cell conjugation; (c) transformation by naked DNA plasmid or linear fragments released by dead cells; or (d) phage-mediated transduction. Antimicrobial resistance can also arise by de novo mutation. Efforts should be made to minimize the overuse of antibiotics and to use agents with the narrowest spectrum of antimicrobial coverage when appropriate.

TOPICAL ANTIBACTERIAL AGENTS

(See Chapter 218)

Topical antibacterial agents are frequently used to prevent, as well as to suppress, bacterial growth in open lesions and surgical wounds. In the case of sutured dermatologic wounds, topical antibiotics are often no better than petrolatum and have limited effect in reducing wound infections.[31] Additionally, topical neomycin and bacitracin commonly precipitate contact dermatitis and should be avoided. Contact dermatitis is especially common when these topical antibiotics are applied to venous insufficiency leg ulcers.

Among the most useful topical antibacterial agents are acetic acid (1%–5% for *Pseudomonas* nail and toe web infections, gentamicin (0.17% cream) may be useful in selected patients when mixed Gram-negative bacteria require local suppression (e.g., Erosio interdigitalis blastomycetica) and mupirocin (2% cream or ointment) with antibacterial activity against various streptococci and *S. aureus*. A number of broad-spectrum antiseptics are also available for topical use. Povidone-iodine (Betadine) is effective against most Gram-positive and Gram-negative bacteria but does not persist in the skin to provide a residual action. Chlorhexidine gluconate (4% solution) combines broad antibacterial properties with prolonged action. An alcoholic preparation is especially effective, is not appreciably absorbed into the blood, and generally is not irritating to the skin. These broad-spectrum antiseptics can be used prophylactically or to treat local wounds and superficially infected dermatoses.

ACKNOWLEDGMENT

The author thanks Timothy G. Berger, MD, for his excellent work on this chapter in the previous edition.

Chapter 176 :: Superficial Cutaneous Infections and Pyodermas

:: Noah Craft

PYODERMAS AT A GLANCE

- Bacterial skin infections (pyodermas) are primarily caused by *Staphylococcus aureus* and *Streptococcus* sp.
- Twenty percent of individuals are continuously colonized with *S. aureus*, and occasional carriage is found in 60% of healthy people. This represents a common source of many infections.
- Contributing factors: immunosuppression, atopic dermatitis, preexisting tissue injury, and inflammation.
- Local manifestations include: folliculitis, furunculosis, ecthyma, and impetigo.
- Systemic reactions include: staphylococcal toxic shock syndrome and scarlatiniform eruption.
- Not particularly localized to one anatomic area.
- Pathology: abundant neutrophilic infiltration admixed with lymphocytes.
- Treatment: topical, oral, or parenteral antibiotics; change predisposing conditions, if possible. When planning therapy, consider local and current antimicrobial resistance patterns.

Normal human skin is colonized soon after birth by a large number of bacteria that live as commensals on the epidermis and epidermal appendages (the skin microbiome). Coagulase-negative *Staphylococci* (*Staphylococcus epidermidis*) are inoculated during vaginal passage and coryneform bacteria take up residence on neonatal skin shortly after birth. Within several weeks after birth, the microbiome of neonatal skin is similar to that of adults and includes many species of bacteria and fungi (see Chapter 175).

The majority of the primary and secondary pyodermas (cutaneous bacterial infections) are caused by either *S. aureus* or group A *Streptococcus*. These bacteria cause a broad clinical spectrum of infection ranging from superficial pyodermas to invasive soft-tissue infections (STIs; see Chapter 179) depending on the organism, the anatomic location of infections, and on host factors.

STAPHYLOCOCCAL SKIN INFECTIONS

EPIDEMIOLOGY

Staphylococci are classified into two major groups: (1) the coagulase-negative *Staphylococci* and (2) coagulase-positive (*S. aureus*) *Staphylococci*. Individuals carry a minimum of 10–24 combined temporary and resident strains of *S. epidermidis*, the most common coagulase-negative strain. *S. epidermidis* is a common colonizer of the skin but is capable of causing superficial and invasive infections (particularly about implants and catheters).

S. aureus permanently colonizes the anterior nares in approximately 20% of the population. Carriage is transient or intermittent in other individuals. Approximately 60% of healthy individuals have occasional carriage of *S. aureus* at some site.[1] Other sites of colonization include the axillae, perineum, pharynx, and hands. Conditions predisposing to *S. aureus* colonization include atopic dermatitis, diabetes mellitus (insulin dependent), dialysis (hemo- and peritoneal), intravenous drug use, liver dysfunction, and human immunodeficiency virus (HIV) infection. Colonization by *S. aureus* is found at some body site in up to 37% of patients presenting with purulent community associated methicillin resistant *S. aureus* (MRSA) infections.[2]

S. aureus is an aggressive pathogen and the most common cause of primary pyodermas and STIs, as well as of secondary infections on disease-altered skin. *S. aureus* in pyodermas or STIs can invade the bloodstream, producing bacteremia, metastatic infection such as osteomyelitis, and acute infective endocarditis. Some strains of *S. aureus* also produce exotoxins, which can cause constellations of cutaneous and systemic symptoms such as staphylococcal scalded-skin syndrome (SSSS) and staphylococcal toxic shock syndrome (TSS).

Transfer of organisms to patients occurs predominantly via the hands of personnel rather than through the air. This appears to be particularly true in newborn nurseries. Any individuals with open staphylococcal infections are high-risk potential carriers and transmitters of infection. Nasal carriage of *S. aureus* appears to be a major risk factor for wound infection after cardiac surgery, resulting in higher mortality rates and longer postoperative stays.[3] The rate of *S. aureus* bacteremia is also higher in nasal carriers of *S. aureus*.[4] Good nursery technique, careful handling of patients, strict handwashing procedures, and isolation of patients with open draining staphylococcal infections are important in the reduction of transmission of *Staphylococci*. In older adults, *S. aureus* accounts for 9% of nosocomial

infections and follows only *Escherichia coli, Pseudomonas aeruginosa*, and *Enterococci* in prevalence.[5]

ETIOLOGY AND PATHOGENESIS

Colonization by *S. aureus* may be transient or represent a prolonged carrier state. *S. aureus* produces many cellular components and extracellular products that may contribute to its pathogenicity. Host factors such as immunosuppression, glucocorticoid therapy, and atopy may play a major role in the pathogenesis of staphylococcal infections. Preexisting tissue injury or inflammation (surgical wound, burn, trauma, dermatitis, retained foreign body) is of major importance in the pathogenesis of staphylococcal disease.

Some strains produce one or more exoproteins, including the staphylococcal enterotoxins (SEA, SEB, SECn, SED, SEE, SEG, SEH, and SEI), and the exfoliative toxins (ETA and ETB), TSS toxin-1 (TSST-1), and leukocidin. These toxins have unique potent effects on immune cells and other biologic effects as well, ultimately inhibiting host immune response.

TSST-1 and the staphylococcal enterotoxins are also known as *pyrogenic toxin superantigens*. These molecules act by binding directly to constitutively expressed HLA-DR molecules (major histocompatibility complex II) on antigen-presenting cells without antigen processing. Although conventional antigens require recognition by all five elements of the T-cell-receptor complex, superantigens require only the variable region of the β-chain. As a result, 5%–30% of resting T cells may be activated, whereas the "normal" antigenic response is only 0.0001%–0.01% of T cells.[6] Nonspecific T-cell activation leads to massive systemic release of cytokines, especially interleukin 2, interferon-γ, and tumor necrosis factor-β from T cells and interleukin 1 and tumor necrosis factor-α from macrophages.[7] Superantigen stimulation of T cells also results in activation and expansion of lymphocytes expressing specific T cell-receptor variable region of the β-chain. They may activate B cells, leading to high levels of immunoglobulin E (IgE) or autoantibodies.[8] Also, there is evidence that superantigens selectively induce cutaneous lymphocyte-associated antigen on T cells, thereby "homing" them to the skin.[8]

There are several other mechanisms by which *S. aureus* evades immune clearance. Approximately 60% of *S. aureus* strains secrete the chemotaxis inhibitory protein of *Staphylococci*, which inhibits neutrophil chemotaxis. Additionally, protein A, staphylokinase, capsular polysaccharide, fibrinogen binding protein, and clumping factor A all act to aid in avoidance of being opsonized and phagocytosed. Staphylokinase and aureolysin bind and cleave antimicrobial peptides, respectively, resulting in increased survival in vitro and probably in vivo.[1]

DRUG RESISTANCE. A major problem in treating staphylococcal infections has been the emergence of antibiotic-resistant strains. With ever-increasing use of penicillins, methicillin-resistant *S. aureus* (MRSA) strains have become a major epidemiologic problem since the 1980s. Resistance to methicillin indicates pan resistance to all β-lactam antibiotics. Recently, intermediate-level resistance of MRSA to vancomycin has emerged and constitutes a potential further problem in treatment. Although *S. aureus* infection prevalence has not changed much, the percentage of MRSA isolates of these infections has significantly increased in some countries. Today, MRSA can be divided into Hospital-Associated (HA) or Community-Associated (CA) MRSA. In many areas, the prevalence of CA-MRSA strains is over 50%.[9]

Attempts to eradicate MRSA have generally been unsuccessful. Treatment of anterior nares and wounds with mupirocin ointment has been shown to decrease *S. aureus* colonization but in one study did not decrease the rate of transmission to a roommate in a long-term care facility.[10] Although there are many other reports of the use of topical mupirocin to reduce colonization of MRSA and methicillin-sensitive *S. aureus*, indiscriminate use of topical mupirocin must be avoided because significant mupirocin resistance has already emerged.

IMMUNITY. The primary defense against *S. aureus* infections is the innate immunity provided by neutrophils.[11] A major component of the innate response is antimicrobial peptides. These peptides can be found in various locales and include dermicidin, LL-37, protegrin, α-defensins and β-defensins, lactoferricin, and cascocidin. However, *S. aureus* also has the ability to thwart the immune system in several ways. One of the main virulence factors of *S. aureus* is the production of adhesins that facilitate binding to host epithelial cell surfaces. The almost universal presence in adults of circulating antibodies to one or more cell-wall antigens or extracellular toxins substantiates the high prevalence of staphylococcal infections. However, these antibodies are not the primary determinants of resistance to such infections. Recent evidence demonstrates that *S. aureus* can invade and survive in many types of host cells, suggesting that a cell-mediated immune response may be required for killing intracellular organisms.

CLINICAL FINDINGS

SUPERFICIAL STAPHYLOCOCCAL PYODERMAS. Pyodermas are infections in the epidermis, just below the stratum corneum or in hair follicles. In industrialized nations, *S. aureus* is the most common cause of superficial pyodermas (Box 176-1), but group A *Streptococcus* continues to be a common cause of pyoderma in developing countries. If untreated, pyodermas can extend to the dermis, resulting in ecthyma and furuncle formation.

Impetigo. Two clinical patterns of impetigo are recognized: (1) bullous and (2) nonbullous. Bullous impetigo is caused by *S. aureus*. Currently, in industrialized nations, nonbullous impetigo is most commonly caused by *S. aureus* and less often by group A *Streptococcus*. Group A *Streptococcus* remains a common cause of nonbullous impetigo in developing nations.

BOX 176-1 INFECTIONS AND TOXIN SYNDROMES INVOLVING THE SKIN AND SOFT TISSUES CAUSED BY *STAPHYLOCOCCUS AUREUS*

SITES OF COLONIZATION (CARRIER STATE)
- Anterior nares
- Throat
- Axillae, perineum
- Hands
- Involved skin in individuals with atopic dermatitis

SITES OF COLONIZATION IN NEONATES (AND SITES OF INFECTION)
- Skin
- Umbilicus
- Circumcision site
- Conjunctivae

SUPERFICIAL PYODERMAS
- Primary pyodermas
  - Skin
    - Impetigo
    - Bullous impetigo
    - Erythema
    - Botryomycosis
  - Hair follicles
    - Superficial folliculitis (follicular or Bockhart impetigo)
    - Folliculitis (sycosis barbae)
    - Furuncle (boil)
    - Carbuncle
  - Intertriginous sites
    - Perianal dermatitis
  - Digital infections
    - Paronychia
    - Blistering distal dactylitis
  - After skin disruption
    - Trauma (physical, thermal)
    - Foreign body (intravascular catheter, prosthetic device)
- Secondary pyodermas
  - Impetiginization of dermatoses such as atopic dermatitis, herpes simplex (superinfection)
  - Pyodermas associated with systemic disease
  - Job syndrome
  - Chédiak–Higashi syndrome
  - Chronic granulomatous disease

INVASIVE INFECTIONS
- Lymphangitis, lymphadenitis
- Erysipelas
- Cellulitis
- Streptococcal gangrene
- Pyomyositis
- Bacteremia, septicemia

METASTATIC SKIN INFECTIONS ASSOCIATED WITH BACTEREMIA (OFTEN *S. aureus* ACUTE INFECTIONS ENDOCARDITIS)
- Abscesses (superficial and deep)
- Septic vasculitis (pustular purpura)

PURPURA FULMINANS
- Disseminated intravascular coagulation associated with staphylococcal bacteremia
- Meningococcemia-like syndrome

STAPHYLOCOCCAL TOXIN-ASSOCIATED SYNDROMES
- Staphylococcal scarlet fever
- Staphylococcal scalded-skin syndromes
- Staphylococcal toxic-shock syndrome

Nonbullous Impetigo. The nonbullous type of impetigo accounts for more than 70% of cases of this form of pyoderma. It occurs in children of all ages as well as in adults. Intact skin is usually resistant to colonization or impetiginization, possibly due to absence of fibronectin receptors for teichoic acid moieties on *S. aureus* and group A *Streptococcus*. Production of bacteriocins, produced by certain *S. aureus* strains (phage group 71) and highly bactericidal to group A *Streptococcus*, may be responsible for the isolation of only *S. aureus* from some lesions initially caused by *Streptococci*.

History. In a typical sequence, *S. aureus* spreads from nose to normal skin (approximately 11 days later) and then develop into skin lesions (after another 11 days). Lesions commonly arise on the skin of the face (especially around the nares) or extremities after trauma. Nasal carriers of *S. aureus* can present with a very localized type of impetigo confined to the anterior nares and the adjacent lip area (Fig. 176-1); pruritus or soreness of the area is a common complaint (Fig. 176-2). Conditions that disrupt the integrity of the epidermis, providing a portal of entry of impetiginization, include insect bites, epidermal dermatophytoses, herpes simplex, varicella, abrasions, lacerations, and thermal burns.

Differential Diagnosis. See Box 176-2 for differential diagnosis of nonbullous impetigo.

Cutaneous Lesions. The initial lesion is a transient vesicle or pustule (see Fig. 176-2) that quickly evolves into a honey-colored crusted plaque that can enlarge to greater than 2 cm in diameter (see Fig. 176-1). Surrounding erythema may be present. Constitutional symptoms are absent. Regional lymphadenopathy may be present in up to 90% of patients with prolonged, untreated infection. If untreated, the lesions may slowly enlarge and involve new sites over several weeks. In some individuals, lesions resolve spontaneously;

Figure 176-1 *Staphylococcus aureus*: impetigo. Erythema and crusting on the nose and moustache area (**A**), which can spread to involve the entire centrofacial region (**B**).

in others, the lesions extend into the dermis, forming an ulcer (see Section "Staphylococcal Ecthyma").

Bullous Impetigo. Three types of skin eruptions can be produced by phage group II *S. aureus*, particularly strains 77 and 55: (1) bullous impetigo, (2) exfoliative disease (SSSS), and (3) nonstreptococcal scarlatiniform eruption (staphylococcal scarlet fever). All three represent varying cutaneous responses to extracellular exfoliative toxins ("exfoliatin") types A and B produced by these *Staphylococci* (see Chapter 177). Exfoliative toxin A acts as a serine protease of desmoglein 1, the desmosomal cadherin that is also the target of autoantibodies in pemphigus foliaceus.[12]

In a study of bullous impetigo, 51% of patients had concurrent *S. aureus* cultured from the nose or throat, and 79% of cultures grew the same strain from both sites.

Figure 176-2 *Staphylococcus aureus*: nasal carriage with impetigo. Erythema with a small pustule on the tip of the nose and nares in individual whose nares are colonized by *S. aureus*.

Cutaneous Lesions. Bullous impetigo occurs more commonly in the newborn and in older infants, and is characterized by the rapid progression of vesicles to flaccid bullae (Fig. 176-3). Decades ago, extensive bullous impetigo (archaic term: *pemphigus neonatorum* or *Ritter disease*) occurred in epidemics within neonatal nurseries.

BOX 176-2 DIFFERENTIAL DIAGNOSIS OF NONBULLOUS IMPETIGO

Consider

- Seborrheic dermatitis
- Atopic dermatitis
- Allergic contact dermatitis
- Epidermal dermatophyte infections
- Tinea capitis
- Herpes simplex
- Varicella
- Herpes zoster
- Scabies
- Insect bite reaction
- Burns
- Erythema multiforme
- Pemphigus foliaceous
- Cellulitis
- Pediculosis capitis

Always Rule Out

- Herpes simplex
- Herpes zoster
- Scabies

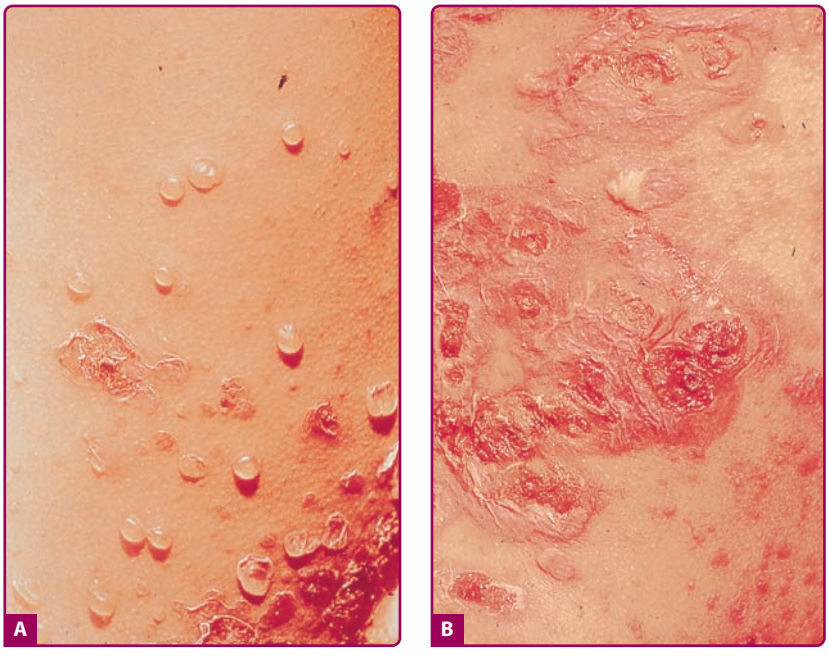

Figure 176-3 *Staphylococcus aureus*: bullous impetigo. **A**. Multiple vesicles with clear and turbid contents that rapidly coalesce to form flaccid bullae (**B**).

Bullae usually arise on areas of grossly normal skin. The Nikolsky sign (sheet-like removal of epidermis by shearing pressure) is not present. Bullae initially contain clear yellow fluid that subsequently becomes dark yellow and turbid (see Fig. 176-3A), and their margins are sharply demarcated without an erythematous halo. The bullae are superficial, and within a day or two, they rupture and collapse, at times forming thin, light-brown to golden-yellow crusts (see Fig. 176-3B). So-called *bullous varicella* represents superinfection by *S. aureus* (phage group II) of varicella lesions (bullous impetiginization).

Laboratory Tests. Gram stain of exudates from bullous impetigo reveals Gram-positive cocci in clusters. *S. aureus* belonging to phage group II can be cultured from the contents of intact bullae.

Histologically, the lesions of bullous impetigo show vesicle formation in the subcorneal or granular region, occasional acantholytic cells within the blister, spongiosis, edema of the papillary dermis, and a mixed infiltrate of lymphocytes and neutrophils around blood vessels of the superficial plexus.

Differential Diagnosis. See Box 176-3 for differential diagnosis of bullous impetigo.

Prognosis and Clinical Course. If untreated, invasive infection can complicate *S. aureus* impetigo with cellulitis, lymphangitis, and bacteremia, resulting in osteomyelitis, septic arthritis, pneumonitis, and septicemia. Exfoliatin production can lead to SSSS in infants and in adults who are immunocompromised or have impaired renal function.

Treatment. See Box 176-4. Local treatment with mupirocin ointment or cream, removal of crusts, and good hygiene is sufficient to cure most mild to moderate cases.[13] Retapamulin 1% ointment is also effective for localized impetigo and secondarily impetiginized dermatitis as well, although decreased efficacy against MRSA was noted in some trials.[14] Fusidic acid is an equally

BOX 176-3 DIFFERENTIAL DIAGNOSIS OF BULLOUS IMPETIGO

Consider

- Contact dermatitis
- Bullous insect bites
- Bullous tinea
- Bullous fixed drug reaction
- Bullous drug eruption
- SSSS
- Thermal burns
- Pemphigus vulgaris
- Bullous pemphigoid
- Erythema multiforme
- Dermatitis herpetiformis

Always Rule Out

- Herpes simplex
- Varicella
- Bullous tinea
- Bullous fixed drug reaction
- Bullous drug eruption
- SSSS

SSSS = staphylococcal scalded-skin syndrome.
Note: Any of these disorders may occur primarily and become secondarily impetiginized with *Staphylococcus aureus* or group A *Streptococcus*.

BOX 176-4 TREATMENTS FOR IMPETIGO[a]

	TOPICAL		SYSTEMIC	
First line	Mupirocin Retapamulin Fusidic acid (not available in United States)	bid bid bid	Dicloxacillin Amoxicillin plus clavulanic acid; cephalexin	250–500 mg PO qid for 5–7 days 25 mg/kg tid; 250–500 mg qid
Second line (penicillin allergy)			Azithromycin Clindamycin Erythromycin	500 mg × 1, then 250 mg daily for 4 days 15 mg/kg/day tid 250–500 mg PO qid for 5–7 days
If CA-MRSA is suspected	Mupirocin	bid	TMP-SMX Clindamycin Tetracycline Doxycycline, Minocycline	160/800 mg PO bid for 7 days 15 mg/kg/day tid 250–500 mg PO qid for 7 days 100 mg PO bid for 7 days

[a]Washing and hygiene are important in all regimens.

effective topical agent for localized impetigo and has very few adverse effects topically. However, it is currently unavailable in the United States.[15] Systemic antibiotics may be required in extensive cases. The frequency of isolation of group A *Streptococcus* makes such therapy a reasonable approach in most patients who have a significant degree of involvement. There is no role for general disinfectant treatments or bacitracin.[16]

Staphylococcal impetigo responds quite promptly to appropriate treatment. In an adult with extensive or bullous lesions, dicloxacillin (or similar penicillinase-resistant semisynthetic penicillin), 250–500 mg orally (PO) four times daily (qid), or erythromycin (in the penicillin-allergic patient), 250–500 mg PO qid, should be given. Treatment should be continued for 5–7 days (10 days if *Streptococci* are isolated). Also, a single course of oral azithromycin (in adults 500 mg on the first day, 250 mg daily on the next 4 days) has been shown to be equally as effective as dicloxacillin for skin infections in adults and children. For impetigo caused by erythromycin-resistant *S. aureus*, which is commonly isolated from impetigo lesions of children, amoxicillin plus clavulanic acid [25 mg/ kg/day given three times a day (tid)], cephalexin (40–50 mg/kg/day), cefaclor (20 mg/kg/day given tid), cefprozil (20 mg/kg once daily), or clindamycin (15 mg/kg/day tid or qid) given for 10 days are effective alternative therapies. If CA-MRSA is likely, consider the following therapies: TMP-SMX and rifampin (100%), clindamycin (95%), and tetracycline (92%). Inducible resistance to clindamycin should be excluded by performing a D-zone disk-diffusion test.

Staphylococcal Ecthyma. Ecthyma is a cutaneous pyoderma characterized by thickly crusted erosions or ulcerations. Ecthyma is usually a consequence of neglected impetigo and classically evolves in impetigo occluded by footwear and clothing. Thus, it is a lesion, typically occurring in the homeless and soldiers in combat on maneuver in a humid and hot climate. *S. aureus* and/or group A *Streptococcus* can be isolated on culture. Untreated staphylococcal or streptococcal impetigo can extend more deeply, penetrating the epidermis, producing a shallow crusted ulcer (Fig. 176-4). Ecthymatous lesions can evolve from a primary pyoderma or within a preexisting dermatosis or site of trauma. Ecthyma gangrenosum is a cutaneous ulcer caused by *P. aeruginosa* and resembles staphylococcal or streptococcal ecthyma (see Chapter 180).

Ecthyma occurs most commonly on the lower extremities of children, or neglected elderly patients, or individuals with diabetes. Poor hygiene and neglect are key elements in pathogenesis.

Figure 176-4 *Staphylococcus aureus*: ecthyma. Multiple thickly crusted ulcers on the leg of a patient with diabetes and renal failure. Ecthymatous lesions were also present on the other leg, the arms, and the hands.

The ulcer has a "punched-out" appearance when the dirty grayish-yellow crust and purulent material are debrided. The margin of the ulcer is indurated, raised, and violaceous (see Fig. 176-4), and the granulating base extends deeply into the dermis. Untreated ecthymatous lesions enlarge over weeks to months to a diameter of 2–3 cm or more.

The lesions are slow to heal, requiring several weeks of antibiotic treatment for resolution. Problems of spread by autoinoculation or by insect vectors and of poststreptococcal sequela (glomerulonephritis) are the same as with impetigo.

Management of ecthyma is usually systemic and includes the same agents used for staphylococcal impetigo (see Box 176-4).

Folliculitis. Folliculitis is a pyoderma that begins within the hair follicle, and is classified according to the depth of invasion (superficial and deep), and microbial etiology (Box 176-5).

Superficial Folliculitis. Superficial folliculitis has also been termed *follicular* or *Bockhart impetigo*. A small, fragile, dome-shaped pustule occurs at the infundibulum (ostium or opening) of a hair follicle, often on the scalps of children and in the beard area (Fig. 176-5), axillae, extremities, and buttocks of adults. Isolated staphylococcal folliculitis is common on the buttock of adults. *Periporitis staphylogenes* refers to secondary infection of miliaria of the neonate by *S. aureus*. Staphylococcal blepharitis is an *S. aureus* infection of the eyelids, presenting with scaling or crusting of the eyelid margins, often with associated conjunctivitis; the differential diagnosis includes seborrheic dermatitis and rosacea of the eyelid.

S. aureus folliculitis must be differentiated from other folliculocentric infections. Also, three noninfectious, inflammatory, follicular disorders are more common in black men: (1) pseudofolliculitis barbae, which occurs on the lower beard area (Fig. 176-6); (2) folliculitis keloidalis or acne keloidalis nuchae, on the nape of the neck; and (3) perifolliculitis capitis, on the scalp. *S. aureus* can cause secondary infection in these inflammatory disorders. Exposure to mineral oils, tar products, and cutting oils can cause an irritant folliculitis. Acne vulgaris, drug-induced acneiform

Figure 176-5 *Staphylococcus aureus*: superficial folliculitis. Multiple pustules confined to the beard area.

Figure 176-6 Pseudofolliculitis barbae. Multiple papules in the lower beard area caused by ingrowing of the curved hair shaft in a black man who shaves. If pustules are present, secondary *Staphylococcus aureus* infection must be ruled out.

BOX 176-5 CLASSIFICATION OF INFECTIOUS FOLLICULITIS

BACTERIAL FOLLICULITIS

- *Staphylococcus aureus* folliculitis
  - Periporitis staphylogenes
  - Superficial (follicular or Bockhart impetigo)
  - Deep (sycosis) [may progress to furuncle (boil) or carbuncle]
- *Pseudomonas aeruginosa* folliculitis ("hot tub" folliculitis)
- Gram-negative folliculitis (occurs at the site of acne vulgaris, usually the face, with long-term antibiotic therapy)
- Syphilitic folliculitis (secondary; acneiform)

FUNGAL FOLLICULITIS

- Dermatophytic folliculitis
  - Tinea capitis
  - Tinea barbae
  - Majocchi granuloma
- *Pityrosporum* folliculitis
- *Candida* folliculitis

VIRAL FOLLICULITIS

- Herpes simplex virus folliculitis
- Follicular molluscum contagiosum

INFESTATION

- Demodicidosis

Figure 176-7 Sycosis barbae. Deep staphylococcal folliculitis of the mustache region.

eruptions, rosacea, hidradenitis suppurativa, acne necrotica of the scalp, and eosinophilic folliculitis of HIV disease must be distinguished from infectious folliculitis as well. Also, "hot tub" folliculitis may be caused by *P. aeruginosa* (see Chapter 180).

Deep Folliculitis. Sycosis barbae is a deep folliculitis with perifollicular inflammation occurring in the bearded areas of the face and upper lip (Fig. 176-7). If untreated, the lesions may become more deeply seated and chronic. Local treatment with warm saline compresses and local antibiotics (mupirocin or topical clindamycin) may be sufficient to control infection. More extensive cases require systemic antibiotic therapy. Dermatophytic folliculitis must be differentiated from *S. aureus* folliculitis. In fungal infections, hairs are usually broken or loosened, and there are suppurative or granulomatous nodules rather than pustules. Also, in dermatophytic folliculitis plucking of hairs is usually painless (see Chapter 188).

Lupoid sycosis is a deep, chronic form of sycosis barbae associated with scarring, usually occurring as a circinate lesion. A central cicatrix surrounded by pustules and papules gives the appearance of lupus vulgaris (see Chapter 184).

Furuncles and Carbuncles. A furuncle or boil is a deep-seated inflammatory nodule that develops around a hair follicle, usually from a preceding, more superficial folliculitis and often evolving into an abscess. A carbuncle is a more extensive, deeper, communicating, and infiltrated lesion that develops when suppuration occurs in thick inelastic skin when multiple, closely set furuncles coalesce.

Furuncles. Furuncles arise in hair-bearing sites, particularly in regions subject to friction, occlusion, and perspiration, such as the neck, face, axillae, and buttocks. They may complicate preexisting lesions such as atopic dermatitis, excoriations, abrasions, scabies, or pediculosis, but occur more often in the absence of any local predisposing causes. In addition, a variety of systemic host factors is associated with furunculosis: obesity, blood dyscrasias, defects in neutrophil function (defects in chemotaxis associated with eczema and high levels of IgE, defects in intracellular killing of organisms as in chronic granulomatous disease of childhood), treatment with glucocorticoids and cytotoxic agents, and immunoglobulin deficiency states. The process is often more extensive in patients with diabetes. The majority of patients with problems of furunculosis appear to be otherwise healthy.

Cutaneous Lesions. A furuncle starts as a hard, tender, red folliculocentric nodule in hair-bearing skin that enlarges and becomes painful and fluctuant after several days (i.e., undergoes abscess formation; Fig. 176-8A). Rupture occurs with discharge of pus, and often a core of necrotic material. The pain surrounding the lesion then subsides, and the redness and edema diminish over several days to several weeks. Furuncles

Figure 176-8 **A.** Furuncle of the upper lip. The lesion is nodular, and the central necrotic plug is covered by purulent crust. Several small pustules are seen lateral to the center of the lesion. **B.** Multiple furuncles. Multiple abscesses on the buttocks of long standing in a young man with inflammatory bowel disease. The lesions healed with scarring after a prolonged course of dicloxacillin.

BOX 176-6 DIFFERENTIAL DIAGNOSIS OF FURUNCULOSIS

- Cystic acne
- Kerion (see Chapter 188)
- Hidradenitis suppurativa
- Ruptured epidermal inclusion cyst
- Furuncular myiasis
- Apical dental abscess
- Osteomyelitis

may occur as solitary lesions or as multiple lesions in sites such as the buttocks (see Fig. 176-8B).

Differential Diagnosis. See Box 176-6 for differential diagnosis of furunculosis.

Carbuncles. A carbuncle is a larger, more serious inflammatory lesion with a deeper base, characteristically occurring as an extremely painful lesion at the nape of the neck, the back, or thighs (Fig. 176-9). Fever and malaise are often present, and the patient may appear quite ill. The involved area is red and indurated, and multiple pustules soon appear on the surface, draining externally around multiple hair follicles. The lesion soon develops a yellow–gray irregular crater at the center, which may then heal slowly by granulating, although the area may remain deeply violaceous for a prolonged period. The resulting permanent scar is often dense and readily evident.

Laboratory Tests. Extensive furunculosis or a carbuncle may be associated with leukocytosis. *S. aureus* is almost always the cause with CA-MRSA being more than likely in most geographic locations. Histologic examination of a furuncle shows a dense polymorphonuclear inflammatory process in the dermis and subcutaneous fat. In carbuncles, multiple abscesses, separated by connective-tissue trabeculae, infiltrate the dermis and pass along the edges of the hair follicles, reaching the surface through openings in the undermined epidermis. The diagnosis is made on the basis of the clinical appearance. Gram stain of pus, clusters of Gram-positive cocci, or isolation of *S. aureus* on culture confirms the diagnosis.

Figure 176-9 Carbuncle. This lesion represents multiple confluent furuncles draining pus from multiple openings.

Prognosis and Clinical Course. The major problems with furunculosis and carbuncles are bacteremic spread of infection and recurrence. Lesions about the lips and nose raise the specter of spread via the facial and angular emissary veins to the cavernous sinus. Invasion of the bloodstream may occur from furuncles or carbuncles at any time, in an unpredictable fashion, resulting in metastatic infection such as osteomyelitis, acute endocarditis, or brain abscess. Manipulation of such lesions is particularly dangerous and may facilitate spread of infection via the bloodstream. Fortunately, these complications are not common. Recurrent furunculosis is a troublesome process that may continue for many years.

Treatment. Simple furunculosis may be aided by local application of moist heat. A carbuncle or a furuncle with surrounding cellulitis, or one with associated fever, should be treated with a systemic antibiotic (as for MRSA impetigo; see Box 176-4). For severe infections or infections in a dangerous area, maximal antibiotic dosage should be employed by the parenteral route. CA-MRSA should be suspected in all serious purulent infections. Vancomycin (1.0–2.0 g intravenously daily in divided doses) or other systemic parenteral agents that have anti-CA-MRSA activity are indicated for these patients. Antibiotic treatment should be continued for at least 1 week.

When the lesions are large, painful, and fluctuant, then incision and drainage are the most important actions that one should take in a timely manner. If the infection is recurrent or complicated by comorbidities, a culture can be sent. Antimicrobial therapy should be continued until all evidence of inflammation has regressed and altered appropriately as culture results become available. Draining lesions should be covered to prevent autoinoculation and diligent hand washing performed. Patients with recurrent furunculosis present a special and frequently exasperating problem (Box 176-7).

Abscess. As discussed in Section "Furuncles and Carbuncles," abscesses caused by *S. aureus* commonly occur in folliculocentric infections—that is, folliculitis, furuncles, and carbuncles. Abscesses can also occur at sites of trauma, foreign bodies, burns, or sites of insertion of intravenous catheters. The initial lesion is an erythematous nodule. If untreated, the lesion often enlarges, with the formation of a pus-filled cavity (Fig. 176-10). CA-MRSA should be suspected in all patients with abscess.

The initial and most important treatment of an abscess is incision and drainage. Antibiotic usage after incision and drainage is only recommended if the lesion is severe or associated with cellulitis, there are signs of systemic illness, there are comorbid factors or immune suppression, the patient is very young or very old, if the abscess is in a body location that is difficult to drain, there is associated septic phlebitis, or there is no response to incision and drainage alone.[9]

Botryomycosis. (See Chapter 185, Table 185-1). Botryomycosis is a rare pyogenic disease, possibly related

BOX 176-7 MANAGEMENT OF RECURRENT FURUNCULOSIS

- Careful evaluation for underlying causes.
- Systemic processes: previously discussed.
- Specific localized predisposing factors: industrial exposure to chemicals, oils; poor hygiene; obesity; hyperhidrosis; ingrown hairs; pressure from tight clothing or belts.
- Sources of staphylococcal contact: pyogenic infections in the family, contact sports such as wrestling, autoinoculation.
- Nasal carriage of *Staphylococcus aureus*: this is the site from which dissemination of the organism may occur to other body sites. The frequency of nasal carriage varies: 10%–15% in infants 1 year of age, 38% in college students, 50% in hospital physicians and military trainees.
- General skin care: the aim of these measures is to reduce the numbers of *S. aureus* on the skin. General skin care of both hands and body with water and soap is important (an antimicrobial soap solution, such as 4% chlorhexidine solution, may be used to decrease staphylococcal skin colonization). The patient should avoid trauma to the skin as well as potential skin irritants such as strong soaps and deodorants. A separate washcloth (and towel) should be used and carefully washed in hot water before use.
- Care of clothing: loose, lightweight, porous clothing should be worn as much as possible. Large numbers of *Staphylococci* are frequently present on the sheets and underclothing of patients with furunculosis and may cause reinfection of the patient and infection of other members of the family. In problem cases, it is not unreasonable to recommend that these items be carefully and separately washed in boiling water and changed daily.
- Care of dressings: dressings should be changed frequently if purulent drainage collects. They should be carefully discarded in a paper bag that can be sealed and disposed of immediately.
- General measures: despite the above measures, some patients continue to have recurrent cycles of lesions. Sometimes, the problem can be ameliorated or abolished by removing the patient from the regular routine of work. This is particularly pertinent in individuals who are under considerable emotional stress and physical fatigue. A vacation for several weeks, ideally in a cool, dry climate, may help considerably by providing rest and also the time needed for carrying out the program of careful skin care.
- Measures aimed at elimination of nasal (and skin) carriage of *S. aureus* (methicillin susceptible or methicillin resistant).
- Local use of ointment in the nasal vestibule reduces nasal carriage of *S. aureus* and secondarily reduces the "shedding" of organisms on the skin, a process that may contribute to recurrent furunculosis. Intranasal application of a 2% mupirocin calcium ointment in a white, soft, paraffin base for 5 days can eliminate *S. aureus* nasal carriage in 70% of healthy individuals for up to 3 months. In immunocompetent staphylococcal carriers with recurrent skin infections, a 5-day course of nasal mupirocin ointment every month for 1 year resulted in positive nasal cultures in only 22% of patients as compared with 83% in the placebo group. The nasal culture-negative patients also had significantly fewer skin infections during the treatment period. Staphylococcal resistance to mupirocin was observed in only 1 patient out of 17. Prophylaxis with fusidic acid ointment in the nares twice daily every fourth week for the patient and family members who are nasal carriers of the infecting strain (along with peroral antistaphylococcal antibiotic for 10–14 days for the patient) has been used with some success.
- Oral antibiotics (e.g., rifampin, 600 mg orally daily for 10 days) have been effective in eradicating *S. aureus* from most nasal carriers for periods of up to 12 weeks. Such a use of rifampin for a brief period to eradicate nasal carriage of *S. aureus* and interrupt a continuing cycle of recurrent furunculosis might be reasonable in a patient in whom other measures have failed. However, selection of rifampin-resistant strains can occur rapidly with such therapy. The addition of a second drug (dicloxacillin for methicillin-susceptible *S. aureus*; trimethoprim-sulfamethoxazole, ciprofloxacin, or minocycline for methicillin-resistant *S. aureus*) has been used to reduce the emergence of rifampin resistance and to treat recurrent furunculosis.

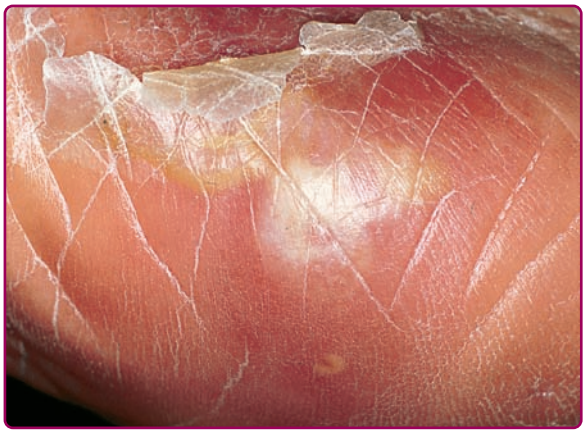

Figure 176-10 *Staphylococcus aureus* abscess. A large painful abscess on the heel of a patient with diabetes improved clinically; however, the severe pain persisted. X-ray films of the heel revealed a broken-off sewing needle. The patient had sensory neuropathy and was unaware of stepping on this foreign body.

to a balance between numbers of organisms and host defenses, presenting as a purulent chronic, subcutaneous infection. Predisposing factors include trauma, immunosuppression (HIV disease, hyper-IgE syndrome), chronic alcoholism, and diabetes mellitus. Lesions (usually solitary) can occur in skin, bone, and liver.

Cutaneous botryomycosis usually presents as a solitary lesion or a few lesions, often occurring in the genital area. The lesion has the gross appearance of a ruptured epidermal inclusion cyst (an erythematous circumscribed tender nodule), or prurigo nodularis (Fig. 176-11). In the majority of reported cases, a foreign body (fish bone, broom straw, etc.) has played a role in initiating or perpetuating the lesion. For diagnosis and treatment, see Chapter 185.

Figure 176-11 *Staphylococcus aureus* botryomycosis. A plaque on the chest had been present for several months in this human immunodeficiency virus-infected individual. The diagnosis was confirmed on lesional biopsy findings and culture.

Staphylococcal Paronychia. Individuals exposed to hand trauma or chronic moisture are predisposed to staphylococcal paronychia, as well as to other causes of paronychia (e.g., *Candida, Pseudomonas, Streptococcus,* dermatophytes). *S. aureus* is the major infectious cause of acute paronychia, usually around the fingernails, often originating from a break in the skin, such as a hangnail. Clinically, skin and soft tissue of the proximal and lateral nail fold are red, hot, and tender, and, if not treated, can progress to abscess formation (Fig. 176-12).

In contrast, chronic or recurrent paronychia caused by *Candida albicans* is an infection of the space created by separation of the proximal dorsal nail plate and the undersurface of the proximal nail fold. Candidal paronychia is most common in individuals who have their hands in water for a great deal of time (see Chapter 189).

Management of paronychia caused by *S. aureus* includes oral and topical antibiotics, and incision and drainage of abscesses.

Staphylococcal Whitlow (Felon). A whitlow is a purulent infection or abscess involving the bulbous distal end of the finger. The most common causes are *S. aureus* and herpes simplex virus. The portal of entry of *S. aureus* is a traumatic injury or possible extension of an acute paronychia. This infection is usually very painful. An obvious portal of entry is often apparent. The finger bulb is red, hot, tender, and edematous,

Figure 176-12 *Staphylococcus aureus* paronychia. An abscess is seen in the dorsum of the finger, beginning in a small break in the cuticle. In contrast, *Candida* paronychia is a space infection, occurring in the space created by the separation of the proximal dorsal nail plate and the overlying proximal nail fold.

Figure 176-13 *Staphylococcus aureus* whitlow (felon). A pyogenic granuloma arose 1 week after trauma to the bulb of the thumb. A week later, the bulb became swollen, erythematous, and very tender. Abscess formation is seen with loculation of pus. X-ray films showed early osteomyelitis complicating the whitlow.

with possible abscess formation (Fig. 176-13). In contrast, individuals with herpetic whitlows usually have a history of lesions occurring in the same site and present with grouped hemorrhagic vesicles, which may become confluent and form a single bulla (see Chapter 193). Management of a staphylococcal whitlow requires surgical drainage of loculated abscess(es) within the tissue and intravenous antibiotic therapy. X-ray examination of the involved finger is indicated to determine the presence of osteomyelitis. CA-MRSA should be suspected in all cases.

SYNDROMES CAUSED BY STAPHYLOCOCCAL EXOTOXINS. SSSS, staphylococcal scarlatiniform eruption, TSS, recalcitrant erythematous, desquamating disorders (red disorders), and recurrent toxin-mediated perineal erythema are syndromes caused by staphylococcal exotoxins and are discussed in Chapter 177.

STREPTOCOCCAL SKIN INFECTIONS

GENERAL FEATURES

EPIDEMIOLOGY. Group A *Streptococci* are usually spread by transfer of organisms from an infected person or carrier through close personal contact. The major source of such spread is from patients with infections in the upper respiratory tract. Approximately 10% of the normal population carry group A *Streptococcus* asymptomatically—a higher percentage of adults than of children in the oropharynx and less commonly in the nares and anus. Although the carriage rate of group A *Streptococcus* on normal skin is less than 1%, a variety of skin lesions and puerperal sepsis may also be the source of intrahospital spread of infection. Group A *Streptococci* introduced into the operating room in the form of a minor skin infection, or even through perianal carriage by a surgeon or anesthetist, may be responsible for an epidemic of streptococcal wound infections.

The major factor in the spread from a carrier or an infected person is the proximity to the individual disseminating the organisms. Because many patients with group A streptococcal (GAS) skin infections harbor the same organism in their pharynxes, they are, for both reasons, potential sources for spread of infection in a hospital. Particular care must be taken to prevent spread of infection by isolating such patients until antibiotic therapy has rendered them noncontagious.

The overall incidence of streptococcal disease has surged since the mid-1980s.[17] Reports of invasive GAS infections often associated with shock and multiorgan failure have increased globally. Localized epidemics continue to appear and, during such outbreaks, the carrier and infection rates in the community increase. After recovery (without antibiotic treatment) from streptococcal pharyngitis, some individuals may carry the organism for prolonged periods. The carrier state may also occur in the absence of overt antecedent infection. Fifteen percent to twenty percent of schoolchildren carry group A *Streptococci* in the throat. Some have hypothesized that the genetic predisposition to develop psoriasis may have been associated with an improved survival outcome in times of epidemic streptococcal infections.[18]

ETIOLOGY AND PATHOGENESIS. The Lancefield classification of streptococcal groups (A–T) is based on the C carbohydrate antigens of the cell wall. Although essentially all GAS strains are β-hemolytic *Streptococci*, not all *Streptococci* producing β-hemolysis belong to group A. Because serologic grouping of *Streptococci* is not generally available, a reasonably accurate presumptive test for group A *Streptococci* is necessary. Bacitracin disk ("Taxos S") sensitivity has been widely used; group A *Streptococci* are, almost without exception, susceptible to the low concentration of bacitracin contained in the disk, whereas *Streptococci* of other groups are often resistant. Subtyping of group A *Streptococci* can be performed according to their M protein antigenicity (see below). Certain M protein serotypes appear to correlate with greater virulence of the organism. The M protein inhibits phagocytosis, promotes adherence to host cells and allows bacterial growth in human blood.[19] The M protein is highly polymorphic, with more than 150 variants coded for by the *emm* gene. Other virulence factors are cell surface molecules, including the hyaluronic acid capsule, C5a peptidase, opacity factor, and streptococcal inhibitor of complement. Secreted proteins playing a role in virulence include streptolysins O and S, cysteine proteinase, pyrogenic exotoxins, streptokinase, hyaluronidase, and other enzymes. It should be noted that horizontal gene transfer in GAS strains is a

very common event. This transfer results in the rapid development of new and more virulent strains.[20]

The primary invasive streptococcal pyodermas are due almost exclusively to group A *Streptococcus*, which is usually considerably more invasive than of other *Streptococci*. Nonsuppurative postinfectious complications have been limited mostly to those produced by group A *Streptococcus*. Thus, GAS infections merit antibiotic treatment and eradication.

The hallmarks of invasive GAS infection are profuse edema, rapid spread through tissue planes, and a relatively thin exudative response. Infection may spread via the lymphatic or hematogenous routes and result in a fulminant clinical course.

The presence of *Streptococci* of groups other than A in skin lesions may represent either surface colonization or actual secondary infection in preexisting dermatoses. Group C and group G *Streptococci* have occasionally been implicated in impetiginous lesions, secondarily infected dermatitis, wound infections with lymphangitis, and even in erysipelas and cellulitis (see Chapter 178). *Streptococci* of groups B and D have been isolated from infections of skin lesions secondary to ischemia or venous stasis and have particularly involved the perineal area and operative wound sites. As with most secondary infections, those due to group B and group D *Streptococci* are frequently mixed infections with enteric bacteria or *S. aureus*. Group B *Streptococci* may cause cellulitis and otitis in neonates and, sometimes, in adults. Group L *Streptococci* (often carried by pigs, cattle, and poultry) have been responsible for impetigo, secondarily infected wounds, and paronychias in meat handlers.

The incidence of invasive complications (lymphangitis, suppurative lymphadenitis, bacteremia) of streptococcal infections of the skin has decreased in the antibiotic era. Other than these pyogenic complications, a variety of nonsuppurative complications (acute rheumatic fever, acute glomerulonephritis, erythema nodosum) may follow GAS infections. Distinct differences exist between acute rheumatic fever and acute glomerulonephritis in the site of the antecedent infection, the length of the latent period, and the streptococcal serotypes involved. Acute rheumatic fever may be a complication of GAS pharyngitis or tonsillitis, but it does not occur after streptococcal skin infections. In contrast, acute nephritis may follow infection of either the skin or the upper respiratory tract. The latent period between streptococcal pharyngitis and the onset of rheumatic fever is 2–3 weeks; whereas the latent period for pharyngitis-associated nephritis is approximately 10 days. A longer latent period of approximately 3 weeks is characteristic of acute nephritis associated with streptococcal pyoderma.

Group A *Streptococci* are classified into over 80 subtypes, based on the antigenicity of their M proteins (fibrillar structures extending out from the cell surface). Although there is no strong evidence of an association between infection with any specific group A serotypes and the subsequent development of rheumatic fever as yet, several serotypes (particularly mucoid strains of types 1, 3, and 18) have been implicated in a few outbreaks of streptococcal sore throat complicated by this sequela.[21] However, there is a clear relationship between infection with certain serotypes and the subsequent occurrence of nephritis—the so-called *nephritogenic serotypes*. Type 12 is the classic serotype responsible for pharyngitis-associated acute nephritis, but other serotypes, such as 1, 4, 25, and 49, have been implicated. The pyoderma-associated nephritogenic strains generally belong to different serotypes: types 2, 49, 42, 55, 56, 57, and 60.[22,23] Unlike the pharyngitis strains, the pyoderma serotypes produce lipoproteinase or opacity factor, illustrating a fundamental difference between the two.[17] The skin rather than the pharynx is the principal site of antecedent streptococcal infection causing nephritis, and impetigo is now the most common form of such predisposing skin infections.

The frequency of acute glomerulonephritis after infection with a known nephritogenic strain is 10%–15%; the frequency of rheumatic fever after an unrecognized or inadequately treated pharyngeal infection by any serotype of group A *Streptococcus* is 2%–3% or less. The distinction between nephritogenic and other strains of *Streptococci* that might be associated with rheumatic fever can be seen in studies from Trinidad, a hyperendemic area for pyoderma-associated nephritis. There the streptococcal serotypes causing outbreaks of nephritis differed from the serotypes associated with sporadically occurring cases of acute rheumatic fever in the same population.[21]

It has been suggested that several biologic properties are associated with broad categories of group A *Streptococci*. Most M proteins fall into one of two antigenic classes based on the presence (class I) or absence (class II) of a highly conserved antigenic domain. Almost all rheumatic fever outbreak-associated strains belong to serotypes of class I and require a precursor nasopharyngeal infection. However, because many class I serotypes are associated with impetigo as well, and because class II serotypes are responsible for both upper respiratory and skin infections, the class of M protein alone is not a determinant of tissue tropism. Current evidence indicates differences among class I organisms that may relate to their capacities to induce rheumatic fever: class I nasopharyngeal isolates appear to lack human IgG-binding activity, whereas nearly all impetigo isolates of the same class bear human IgG receptors.[24]

As in *S. aureus*, there are several GAS superantigens that have been identified. These include streptococcal pyrogenic exotoxin (or erythrogenic exotoxin) A–C, F, and G–J, streptococcal superantigen, and streptococcal mitogenic exotoxin Z. These superantigens are associated with disease.[25]

ANTIBODY RESPONSE AND IMMUNITY.

The immune response to GAS infection depends to a large measure on the site of infection. *Streptococcal infection* is usually defined as a positive throat culture with a serologic response to group A *Streptococcus* and the streptococcal carrier state by a positive throat culture and no serologic response. After streptococcal pharyngitis, specific antibodies develop to many of the extracellular enzymes of the *Streptococci*. Eighty-five percent

of patients with acute rheumatic fever and a proven preceding streptococcal infection have an elevated or increasing antistreptolysin O titer. The serologic demonstration of an antecedent streptococcal infection in this situation can be increased to virtually 100% by the simultaneous testing for several other antibodies (antihyaluronidase, anti-DNase B). Antibodies to extracellular products, with the exception of antibody to the erythrogenic toxin of scarlet fever, appear to have no effect on the manifestations of illness. Streptococcal immunity is type specific (but not group specific), long lasting, and depends on the production of bactericidal antibodies to the specific M proteins of the over 80 different serotypes of group A organisms. Although recurrent pharyngeal infections caused by the same serotype are most unusual, repeated clinical infections caused by different types are not uncommon. Early treatment of streptococcal upper respiratory tract disease with antibiotics may suppress the appearance of type-specific antibody (and immunity), as well as the development of antibody to the extracellular products of the organism.

In contrast to pharyngeal infections, the antistreptolysin O response with streptococcal skin infections or pyoderma-associated nephritis is weak. To define the latter serologically, anti-DNase B titers are much more reliable. Although pyoderma strains of *Streptococci* produce M proteins, and although type-specific antibody may develop in patients with pyoderma-associated nephritis, the frequency of production of such antibodies and their role in protection against reinfection are unclear. Although pharyngeal reinfection with the same streptococcal serotype is probably unusual, some evidence suggests that the same serotype can be associated with repeated episodes of pyoderma.

Specific diseases caused by group A (and other) *Streptococci* are listed in Box 176-8. Streptococcal pyodermas include all types of superficial streptococcal skin infections except erysipelas—that is, impetigo, ecthyma, and secondary infections of preexisting skin lesions (e.g., insect bites, abrasions, eczema). Streptococcal intertrigo such as streptococcal perianal "cellulitis" can occur primarily or secondarily in underlying conditions such as inverse psoriasis.

BOX 176-8 INFECTIONS AND TOXIN SYNDROMES CAUSED BY GROUP A *STREPTOCOCCI*

SUPERFICIAL PYODERMAS
- Nonintertriginous skin
  - Impetigo
  - Ecthyma
  - Blistering distal dactylitis
- Intertriginous skin
  - Perianal streptococcal cellulites
  - Streptococcal vulvovaginitis
  - Streptococcal intertrigo

INVASIVE INFECTIONS
- Acute lymphangitis
- Erysipelas
- Cellulitis
- Streptococcal gangrene
- Bacteremia, septicemia

TOXIN-ASSOCIATED SYNDROME
- Scarlet fever
- Streptococcal toxic-shock-like syndrome
- Streptococcal gangrene

NONSUPPURATIVE COMPLICATIONS
- Rheumatic fever
- Glomerulonephritis

OTHER ASSOCIATED CUTANEOUS REACTION PATTERNS
- Erythema nodosum
- Erythema multiforme
- Guttate-pattern psoriasis
- Vasculitis

IMPETIGO

EPIDEMIOLOGY. Impetigo caused by group A *Streptococcus* is a highly communicable infection and occurs predominantly in preschool-aged children (usually before the age of 2 years except in highly endemic areas). It is more common in warmer, more humid climates than in temperate zones. Its peak seasonal incidence is in the later summer and early fall. Nongroup A (groups B, C, and G) *Streptococci* may be responsible for rare cases of impetigo; group B *Streptococci* are associated with impetigo in the newborn. Whereas, many different serotypes of group A *Streptococci* may cause pharyngitis, a limited number of newly described types predominate in impetigo (types 49, 52, 53, 55, 56, 57, 59, and 61).

ETIOLOGY AND PATHOGENESIS. Group A *Streptococci* appear on normal skin of children approximately 10 days before the development of impetigo, and they are not recovered from the nose and throat of the same patients until 14–20 days after skin acquisition of the organism. *Streptococci* are recovered from the respiratory tract of approximately 30% of children with skin lesions, but there is no clinical evidence of streptococcal pharyngitis. Thus, the sequence of spread in a given patient is from normal skin to lesions and eventually to the respiratory tract.[26] In contrast, the sequence of spread of *S. aureus* (in cases of impetigo in which it is the only organism isolated) is from nose, to normal skin, to skin lesions (see Section "Impetigo").

When exposed to an infectious contact, preexisting lesions, such as scabies, varicella, or eczema, predispose to the appearance of infected lesions. Crowding, poor hygiene, and neglected minor skin trauma contribute to the spread of streptococcal impetigo in families. Minor outbreaks have also occurred among athletes involved in contact sports. Although the majority of cases occur in children, particularly of preschool age, young adults are also affected. The inflammatory process of impetigo is superficial, with a unilocular vesicopustule located

between the stratum corneum above and the stratum granulosum below. This is usually situated near the opening of a hair follicle. Organisms, as well as leukocytes and cell debris, fill the vesicle.

CLINICAL FINDINGS

Cutaneous Lesions. Impetigo caused by group A *Streptococcus* presents as a crusted superficial infection of the skin; an initial vesicular phase has been described but is rarely detected. Lesions are clinically indistinguishable from impetigo caused by *S. aureus*, with the exception of bullous impetigo (see Section "Nonbullous Impetigo" and Figs. 176-1 to 176-3). Pruritus and burning may occur, but the lesions are usually painless. Systemic response is minimal unless complications occur.

Laboratory Tests. A slight leukocytosis may occur. A Gram-stained smear of early vesicle fluid reveals Gram-positive cocci in chains. Culture of the weeping area or of the area beneath an unroofed crust reveals group A *Streptococci* or a mixture of *Streptococci* and *S. aureus* (particularly from older crusted lesions).

PROGNOSIS AND CLINICAL COURSE. If untreated, the process may persist and new lesions may develop over the course of several weeks; thereafter, the infection tends to resolve spontaneously unless there is some underlying cutaneous disorder such as eczema. If untreated, some lesions become chronic and deeper, such as ecthyma (see Section "Staphylococcal Ecthyma"). Complicating erysipelas, cellulitis, or bacteremia are unusual. The major serious sequela is acute poststreptococcal glomerulonephritis.

TREATMENT. Topical treatment (removal of dirt, crusts, and debris by soaking with soap and water) is a valuable adjunct. Mupirocin ointment appears to be as effective as parenteral or oral penicillin for treatment of impetigo.[27] Retapamulin 1% ointment is also effective for localized impetigo and secondarily impetiginized dermatitis as well, although decreased efficacy against MRSA was noted in some trials.[14]

In superficial pyodermas known to be caused by group A *Streptococcus*, penicillin is the drug of choice, administered either as a single injection of long-acting benzathine penicillin (300,000–600,000 units for children; 1.2 million units for adults) or orally (25,000–100,000 units/kg/day in divided doses q6h for 10 days). Although penicillin treatment clears the lesions of GAS impetigo and prevents recurrence for a short time, *Streptococci* can persist on or newly colonize unaffected skin in spite of this therapy. Erythromycin (30–50 mg/kg/day PO in divided doses q6h for children; 250–500 mg PO q6h for adults administered for 10 days) is a suitable alternative drug in patients allergic to penicillin. However, it should be noted that 20% or more of GAS strains became resistant to erythromycin in areas (Japan, Finland) where this antibiotic had been extensively used for a variety of indications.[28] There is still no evidence to suggest that treatment of GAS pyoderma can prevent subsequent nephritis in any individual. Although the latent period after impetigo is longer than that after pharyngeal infection, the mildness of the illness delays or negates the seeking of medical attention.

Practically, however, the majority of cases of nonbullous impetigo are caused by *S. aureus*, and topical or systemic antimicrobial treatment should be directed at that pathogen (see Box 176-4).

STREPTOCOCCAL ECTHYMA

See Section "Staphylococcal Ecthyma."

INTERTRIGINOUS STREPTOCOCCAL INFECTIONS

Streptococcal pyodermas occur much less commonly in occluded sites such as the perineum/perianal region, vulva/vagina, axillae (Fig. 176-14), inframammary region, groin, preputial sac, and web spaces of the feet. Perianal (group A) streptococcal "cellulitis" occurs principally in children, presenting with intense perianal erythema (Fig. 176-15), pain on defecation, blood-streaked stools associated with anal fissures, and chronicity if untreated.[29] It is often confused with psoriasis, candidiasis, seborrheic dermatitis, inflammatory bowel disease, pinworm infection, or a behavioral problem. The infection can also involve the penis and vulva. Treatment options include oral antibiotics or topical mupirocin. Guttate psoriasis has also occurred in children, associated with perianal streptococcal infection.[30]

Figure 176-14 Group A streptococcal intertrigo. A sharply marginated erythematous and oozing plaque in the axilla, which was also present in the other axilla, inframammary area, and inguinal folds, was painful in this human immunodeficiency virus-infected woman.

Figure 176-15 Group A streptococcal intertrigo—perianal streptococcal cellulitis. Well-demarcated erosive erythema in the perianal region and perineum in an 8-year-old boy who complained of soreness.

BLISTERING DISTAL DACTYLITIS. Group A *Streptococcus* is responsible for the majority of cases of blistering distal dactylitis, also called *bulla repens*, usually occurring in children and adolescents. However, group B *Streptococcus* can also cause this infection. A large, tense blister develops, filled with seropurulent fluid, over the volar skin pad of distal fingers or toes (Fig. 176-16). The blisters are often surrounded by an erythematous base. The lesion may be more proximally located on the finger or extend to involve the nail folds. Group A *Streptococcus* may be cultured from the vesicle fluid. Blistering distal dactylitis may be treated with oral penicillins or erythromycin and release of subungual pus is often required. Staphylococcal blistering distal dactylitis has been reported with an identical clinical picture.[31]

Figure 176-16 Group A streptococcal blistering dactylitis. A blister is seen on a toe adjacent to the nail fold; the patient also had group A streptococcal intertrigo of an abdominal skin fold.

ACUTE LYMPHANGITIS. Acute lymphangitis is an inflammatory process involving the subcutaneous lymphatic channels. It is most often caused by group A *Streptococci*, but occasionally may be caused by *S. aureus*; rarely, STIs with other organisms, such as *Pasteurella multocida* or herpes simplex virus may be associated with acute lymphangitis.

CLINICAL FINDINGS

History. The portal of entry is commonly a wound on an extremity, an infected blister, or a paronychia. The systemic manifestations of infection may occur either before any evidence of infection that is present at the site of inoculation or after the initial lesion has subsided. The patient may notice pain over an area of redness proximal to the original break in the skin. Systemic symptoms are often more prominent than expected from the degree of local pain and erythema.

An unusual spread of streptococcal infection of the thumb (paronychia) or of the interdigital webs between the thumb and index finger may occur occasionally. Lymphatic drainage from this area can bypass the lymph nodes at the elbow and drain into the axillary nodes, which, in turn, communicate with the subpectoral nodes and the pleural lymphatics. As a consequence, subpectoral abscesses and pleural effusion can develop. The subpectoral infection may dissect downward and appear over the lower chest and upper abdomen as an area of cellulitis. This is a very serious illness. The clinical clues to the development of this sequence of events are provided by the location of the original infection on the thumb or medial surface of the index finger and the early occurrence of axillary pain.

Cutaneous Lesions. Red linear streaks, which may be a few millimeters to several centimeters in width, extend from the local lesion toward the regional lymph nodes, which are usually enlarged and tender (Fig. 176-17).

DIFFERENTIAL DIAGNOSIS. In the upper extremities, acute lymphangitis usually can be differentiated from subacute or chronic sporotrichoid syndrome caused by organisms such as *Sporothrix schenckii*. In the lower extremities, superficial thrombophlebitis may produce somewhat similar linear areas of tender erythema. The absence of a portal of entry and of tender regional adenopathy is helpful in distinguishing this process from lymphangitis.

LABORATORY TESTS. The peripheral white blood cell count is elevated, with a marked increase in polymorphonuclear cells. The offending organism

Figure 176-17 Acute lymphangitis of forearm due to *Staphylococcus aureus*. There is a tender linear streak extending proximally from a small area of cellulitis on the volar wrist.

cannot be cultured from the skin, as the infection is restricted to the lymphatic channels. However, the primary portal of entry or a suppurative lymph node, if overt infection is present, may reveal the etiologic agent.

PROGNOSIS AND CLINICAL COURSE. The frequent development of bacteremia with metastatic infection in various organs makes this a potentially serious disease. The infection responds readily to penicillin therapy if instituted promptly.

INVASIVE STREPTOCOCCAL INFECTIONS

Erysipelas, cellulitis, and streptococcal gangrene are invasive streptococcal infections and are discussed in Chapter 178.

STREPTOCOCCAL TOXIN SYNDROMES

Scarlet fever and toxic streptococcal syndromes are streptococcal toxin syndromes and are discussed in Chapter 177.

OTHER SKIN LESIONS ACCOMPANYING OR FOLLOWING GROUP A STREPTOCOCCAL INFECTIONS

Erythema Multiforme-Like Lesions. Round erythematous macules, up to 1.5 cm in diameter, some developing bright borders and subsequently showing clearing in the center, may occur during bacteremia caused by group A *Streptococci* (or *S. aureus*) in infants and young children (see Chapter 39).

Acute Guttate Psoriasis. Rarely, erythematous, papulosquamous, guttate psoriasiform lesions may develop during or after GAS pharyngitis, perianal streptococcal infection, or other skin infections. Children appear to be most commonly affected. Clearing of the lesions may occur within weeks of antimicrobial therapy of the streptococcal infection. Although the temporal relation of the two processes is striking, a direct causal connection has not been established. There is no strong evidence to support the use of antibiotics in the treatment of guttate psoriasis.

MANAGEMENT OF GROUP A STREPTOCOCCAL SKIN INFECTIONS

GENERAL PRINCIPLES. Penicillin G is the drug of choice in the treatment of known GAS skin infections. When the etiology is not known immediately (e.g., in cellulitis) and when *S. aureus* is also a distinct consideration, a semisynthetic penicillin (nafcillin or oxacillin) should be employed initially. Penicillin treatment should be continued for at least 10 days to ensure eradication of the infection. Prophylactic penicillin therapy is indicated for close family contacts (particularly children) of patients with streptococcal pharyngitis.

ANTIMICROBIAL THERAPY. Mild instances of infections, such as impetigo, scarlet fever, or certain cases of erysipelas and cellulitis, may be treated with oral penicillin V (250–500 mg qid). When staphylococcal infection is suspected, dicloxacillin (250–500 mg PO qid) should be substituted. In adults allergic to penicillin, erythromycin (250–500 mg PO qid) is a reasonable alternative. Other alternatives include azithromycin, clarithromycin, and clindamycin (Box 176-9).

PREVENTION OF SPREAD. Patients hospitalized with GAS infections should be isolated until the

BOX 176-9 TREATMENT OF STREPTOCOCCAL PYODERMAS[a]

	TOPICAL (FOR MILD IMPETIGO)	SYSTEMIC	
First line	Mupirocin bid	Penicillin V	250–500 mg PO qid for 5–7 days
		Dicloxacillin (if *Staphylococcus aureus* is suspected)	250–500 mg qid for 5–7 days
Second line (penicillin allergy)	Retapamulin bid	Azithromycin	500 mg × 1 then 250 mg daily for 4 days
		Clindamycin	15 mg/kg/day tid
		Erythromycin	250–500 mg PO qid for 5–7 days

[a]Washing and hygiene are important in all regimens.

organisms have been eradicated by antibiotic treatment. Individuals with recurrent episodes of GAS infections can be treated with dicloxacillin or erythromycin, 250 mg twice daily (penicillin-allergic individuals), as secondary prophylaxis.

SOFT-TISSUE STREPTOCOCCAL INFECTIONS

(See Chapter 178)

CUTANEOUS INFECTIONS CAUSED BY MICROCOCCUS: PITTED KERATOLYSIS

Pitted keratolysis involves the stratum corneum of the web spaces and plantar surface. Originally named *keratoma plantare sulcatum* by Castellani in 1910, this disease has become more commonly called by its current name after Taplin and Zaias coined it in 1967. The disease was first seen in those who went barefooted during the rainy season.

ETIOLOGY AND PATHOGENESIS. The likely causative organism is *Micrococcus sedentarius*, which is a Gram-positive *Staphylococcus*-related bacterium that invades the stratum corneum softened by sweat and moisture. *Corynebacterium* sp. may also be involved. Pitted keratolysis tends to be much more severe in tropical climates than in temperate ones.

Pitted keratolysis occurs in adults and children of both sexes, but adult males with sweaty feet are most susceptible (96% of cases).[32] Sliminess of the skin, often manifest by the foot sticking to the socks, is also a common complaint (70% of cases). The feet are typically very malodorous (89%) and may be mildly pruritic (8%).

CLINICAL MANIFESTATIONS. Pitted keratolysis presents as a superficial erosion of the stratum corneum, composed of numerous small crateriform pits coalescing to form a large discrete defect with serpiginous borders on the plantar surface of the foot. The pits are usually larger than 0.7 mm in diameter, but at times are smaller than 0.5 mm. The pits have elongated configurations along the plantar furrows and are located predominantly on the pressure-bearing areas, such as the ventral aspect of the toe, ball of the foot, and the heel, but they are also seen on nonpressure-bearing areas.[32] The web spaces between the toes are also commonly involved sites, and may be the only manifestation (Fig. 176-18). The diagnosis is made clinically.

DIFFERENTIAL DIAGNOSIS. Interdigital tinea pedis can present with erosive lesions in the web spaces. Erythrasma in the web spaces is usually hyperkeratotic but can be erosive.

LABORATORY FINDINGS. Gram staining of scrapings may detect the microorganism more readily than potassium hydroxide examination. Histologically, the organisms are present in the walls and bases of the crateriform defects in the upper layer of the stratum corneum. The organisms appear as coccoid and filamentous forms with branches and septa.

Figure 176-18 Pitted keratolysis. The web spaces between the toes are sharply eroded. Interdigital tinea pedis and erythrasma may occur concurrently.

TREATMENT. Prophylactic measures are aimed at keeping the feet as dry as possible. Inert antiseptic foot powders often help. Aluminum chloride 20% solution is an effective astringent. A benzoyl peroxide wash and 5% gel are effective therapy in most cases as well. Other commonly used topical adjunctive agents include clindamycin and erythromycin solutions. Systemic use of these agents can be attempted in severe cases.[33]

INFECTIONS CAUSED BY CORYNEBACTERIUM

ERYTHRASMA. Erythrasma is a common superficial bacterial infection of the skin characterized by well-defined but irregular reddish-brown patches, occurring in the intertriginous areas, or by fissuring and white maceration in the toe clefts. It is commonly misdiagnosed as tinea cruris for many months before proper diagnosis is made.

Etiology and Epidemiology.

Corynebacterium minutissimum, the etiologic agent of erythrasma, is a short, Gram-positive rod with subterminal granules. The infection is more common in tropical than in temperate climates. In a study in a temperate climate, 20% of randomly selected subjects were found to have erythrasma by Wood's lamp examination. The generalized disease is much more common in the tropics. Erythrasma is more common in men and may occur in asymptomatic form in the genitocrural area.

Clinical Findings

History. Symptoms vary from a completely asymptomatic form, through a genitocrural form with considerable pruritus, to a generalized form with scaly lamellated plaques on the trunk, inguinal area, and web spaces of the feet. When pruritic, irritation of lesions may cause secondary changes of excoriations and lichenification.

Cutaneous Lesions. The most common site of involvement is the web spaces of the feet, where erythrasma presents as a hyperkeratotic white macerated plaque

Figure 176-19 Erythrasma. Hyperkeratosis with a yellowish hue in the web space of the foot. The three lateral web spaces of both feet were involved. The potassium hydroxide preparation was negative; the Wood's lamp examination showed a bright coral red fluorescence.

(Fig. 176-19), especially between the fourth and fifth toes. In the genitocrural, axillary, and inframammary regions, the lesions present as well-demarcated, reddish-brown, superficial, finely scaly, and finely wrinkled patches (Fig. 176-20). In these sites, the patches have a relatively uniform appearance as compared with tinea corporis or cruris, which often have central clearing.

Wood's lamp examination of erythrasma reveals a coral-red fluorescence caused by coproporphyrin III. The fluorescence may persist after eradication of the *Corynebacterium* as the pigment is within a thick stratum corneum.

Differential Diagnosis. Tinea versicolor is distinguished from erythrasma by the lesions on the trunk being most numerous at nonintertriginous sites. Tinea cruris tends to have an active scaling border with central clearing. Inverse psoriasis usually presents as sharply demarcated plaques with a shiny red color in the intergluteal cleft, inguinal folds, and axillae.

Laboratory Findings. Culture of the specific *Corynebacterium* in abundance from the lesion corroborates

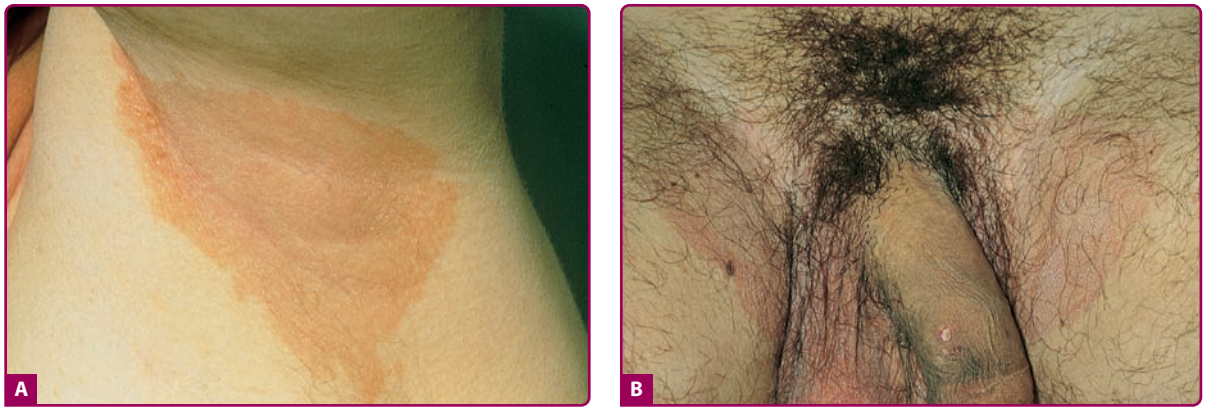

Figure 176-20 Erythrasma. Well-demarcated reddish-brown patches in the axilla (**A**) and groin (**B**). The potassium hydroxide preparations were negative; the Wood's lamp examination showed a bright coral red fluorescence.

the diagnosis. Gram-stained imprints of the horny layer of the skin show rod-like, Gram-positive organisms in large numbers.

The diagnosis is strongly suggested by the location and superficial character of the process, but must be confirmed by demonstration of the characteristic "coral-red" fluorescence with Wood's lamp illumination.

Prognosis and Clinical Course. The disease may remain asymptomatic for years or may undergo periodic exacerbations. Relapses occasionally occur even after successful antibiotic treatment.

Treatment. For localized erythrasma, especially of the web spaces of the feet, benzoyl peroxide wash and 5% gel are effective in most cases. Clindamycin or erythromycin (2% solution) or azole creams are several of the many effective topical agents. Fusidic acid has been used outside the United States. For widespread involvement, oral erythromycin is effective. A 1-g single dose of clarithromycin has been used successfully.[34] For secondary prophylaxis, an antibacterial benzoyl peroxide bar when showering is effective.

TRICHOMYCOSIS AXILLARIS AND PUBIS.

Trichomycosis axillaris, a bacterial infection of the hair shaft (not fungal as the name implies), is characterized by what appears to be nodular thickenings on the hair shaft, composed of colonies of aerobic *Corynebacterium*. The condition occurs both in the axillae and pubic areas, and not just in the axillae, as the name implies. The bacteria produce various pigments, giving the nodules a range of colors. The concretions on the hair shaft are usually a tan color but may be reddish, yellow, or black (Fig. 176-21). Lesions are most dense and may be present only in the central portion of the axillary hair. Trichomycosis is asymptomatic except for the patient's concern regarding the lesions themselves and because they are malodorous.

The diagnosis is usually made on the basis of the physical findings. The concretions can be visualized using a potassium hydroxide preparation. Pediculosis pubis infestation with multiple eggs on the hair shaft should be ruled out.

The involved hair can be removed by shaving. Benzoyl peroxide wash and gel are effective as treatment and prevention against recurrence of trichomycosis. Topical clindamycin or erythromycin solutions can be used as well.

Figure 176-21 Trichomycosis axillaris. Tan-yellow concretions on the hair shafts of the axilla.

Chapter 177 :: Gram-Positive Infections Associated with Toxin Production

:: Jeffrey B. Travers & Nico Mousdicas

GRAM-POSITIVE INFECTIONS ASSOCIATED WITH TOXIN PRODUCTION AT A GLANCE

- Caused by *Staphylococcus aureus* and/or group A *streptococcus* toxin-producing bacteria.
- Three characteristic syndromes (all with skin manifestations):
  - Predominantly cutaneous.
    - Local: bullous impetigo.
    - Generalized: staphylococcal scalded skin syndrome.
  - Cutaneous and systemic:
    - Local: recurrent toxin mediated erythema—recurrent perineal erythema.
    - Generalized: recalcitrant erythematous desquamating disorder.
    - Other abortive hybrids of predominantly systemic manifestations disorder.
- Predominantly systemic:
  - Generalized: toxic shock syndrome *Staphylococcus* (predominantly) or *Streptococcus.*
  - Scarlet fever—*Streptococcus* (predominantly) or *Staphylococcus*.

Skin infections with the Gram-positive bacteria *Staphylococcus aureus* and group A *streptococcus* (*Streptococcus pyogenes*) are an important source of morbidity and even mortality. These bacteria produce toxins that can induce characteristic syndromes, including staphylococcal scalded-skin syndrome (SSSS) and toxic shock syndrome (TSS). Moreover, the production of these toxins is thought to underlie the ability of infection with these bacteria to initiate and/or to propagate inflammatory skin diseases.

EPIDEMIOLOGY

All conditions discussed here are relatively rare but have high morbidity, and some have considerable mortality.

FACTORS IN TOXIN-MEDIATED DISEASE

Staphylococcal and streptococcal pathogenicity is due to the production of a range of immunomodulatory proteins including toxins, exoenzymes, and adhesins.[1] Among the best characterized are the toxins (Table 177-1).

Many risk factors play a role in the ability of a toxin-forming *Staphylococcus* or *Streptococcus* to produce disease. The development of disease is related to the resistance of the host to infection and to the virulence of the organism. Host resistance depends, among other factors, on intact skin and mucous membranes functioning as barriers to invasion and the host's ability to mount an immune response (e.g., neutralizing antibodies) against such toxins. Colonization by virulent *Staphylococcus* or *Streptococcus* toxin-producing organisms exposed to optimal, focal conditions for growth and toxin production (e.g., menstruation + tampon use or abscess) allows these bacteria to initiate and/or propagate infection.

Minor defects in these barriers such as those produced by superficial excoriations, toe web fungal infections or alternatively, major defects produced by surgery, trauma, burns, or foreign substances (packing, sutures, intravascular catheters, shunts) increase the risk of infection. The role of host response cannot be overstated. For example, if a patient has an underlying immunodeficiency and cannot produce adequate neutralizing antibodies; or, as in chronic granulomatous disease where neutrophils lack the oxidative burst to destroy catalase-positive bacteria (e.g., *S. aureus*), the patient is at increased risk for colonization and infection by toxin-producing bacteria. Finally, the types of immune cells that are activated play an important role in the subsequent host response, especially as it relates to toxins that act as superantigens. The ability of a superantigen to activate numerous T cells is based upon the variable region of the T-cell receptor. This could result in various types of responses depending on the specificity of the individual T cell that happened to become activated. Table 177-2 provides an overview of Gram-positive coccal toxin related diseases.

DISEASES CAUSED BY EXFOLIATIVE TOXINS: STAPHYLOCOCCAL SCALDED-SKIN SYNDROME

S. aureus-mediated production of exfoliative toxin also results in a spectrum of blistering skin disorders ranging from localized bullous impetigo (see Chapter 177)

TABLE 177-1
Toxins and Diseases Due to Staphylococcus aureus and Group A Streptococcus

Bacteria	Toxin	Toxin Type	Clinical Disease
Staphylococcus aureus	Exfoliatin type A	Epidermolytic	Bullous impetigo SSSS
	Exfoliatin type B	Epidermolytic	SSSS Bullous impetigo
	TSS toxin 1	Superantigen	TSS (menstrual > nonmenstrual), food poisoning
	Staphylococcal enterotoxins A–C	Superantigen	TSS (nonmenstrual > menstrual), food poisoning
Streptococcus pyogenes	Streptococcal pyrogenic exotoxins A, C	Superantigen	TSS (nonmenstrual), scarlet fever

SSSS = staphylococcal scalded-skin syndrome; TSS = toxic shock syndrome.

to a severe generalized form, SSSS. The syndrome is a generalized exanthematous disease consisting of cutaneous tenderness and widespread superficial blistering and denudation.

ETIOLOGY AND PATHOGENESIS

Exfoliative toxins (ETs) are made by certain strains of *S. aureus* (usually phage group 2). Exfoliatin A and B (ETA and ETB) are two serologically distinct proteins produced by *S. aureus*.[2] ETs are serine proteases that bind to the cell adhesion molecule desmoglein 1 and cleave it, resulting in a loss of cell–cell adhesion.[3] Consistent with the expression pattern of desmoglein 1, which is expressed in the upper part of the epidermis, the epidermolysis takes place usually between the stratum spinosum and granulosum. This results in a very thin-walled, flaccid blister that is easily disrupted, exhibiting a positive Nikolsky sign. The pathophysiology of ET resembles that of the autoimmune blistering disease pemphigus foliaceus, with desmoglein 1 targeted in both diseases. Presumably, staphylococcal bacteria have evolved this toxin to allow the bacteria to proliferate and spread beneath the barrier of the skin. There are two forms of ET-mediated disease: (1) localized bullous impetigo and (2) systemic SSSS. Recent studies suggest that the majority of cases of localized bullous impetigo are due to ETA, and systemic forms such as SSSS are due to ETB, possibly due to a lower titer of anti-ETB neutralizing antibodies in the general population.[4] Although some reports suggest that ET can also act as superantigens (see Section "Diseases Caused by Superantigenic Toxins") in addition to their epidermolytic activities,[5] this has been called into question.[6]

CLINICAL FEATURES

LOCALIZED FORM (BULLOUS IMPETIGO).

Infection of the upper part of the skin (epidermis) by *S. aureus* or *S. pyogenes* results in impetigo contagiosa (Figs. 177-1 and 177-2). Impetigo, which may account for up to 10% of all pediatric skin disease, consists of honey-colored crusts on an erythematous base. Approximately one-fourth of cases of impetigo are bullous, with local ET-expressing *Staphylococcus* and without hematogenous dissemination. As is the case with SSSS, bullous impetigo is usually a disease of children (see Chapter 177), although adult cases can also occur. The early lesions of bullous impetigo are cloudy vesicles or bullae surrounded by an erythematous rim (see Fig. 177-2). These blisters often rupture leaving superficial erosions. Lesions at various stages can often be seen. The lesions tend to be found around exposed parts of the body and around orifices (see Fig. 177-1). Diagnosis is usually based upon clinical appearance. In contrast to SSSS, confirmation of diagnosis can be easily obtained by aspiration of blister fluid for Gram stain and cultures will reveal *S. aureus*.

GENERALIZED FORM.

The clinical features of SSSS were first described in 1878 by the German physician Gotfried Ritter von Rittershain, who reported almost 300 cases of "dermatitis exfoliativa neonatorum" among young children.[7] Outbreaks of SSSS tend to occur in clusters as a consequence of cross infection. Typically neonatal or maternity hospital staff colonized or infected with ET-producing *Staphylococci* are the source of these outbreaks. Although more commonly seen in infants/children, SSSS can also be seen in adults. The risk factors for adults include a compromised immune response allowing for growth of the *S. aureus* and possibly impaired amounts of toxin-neutralizing antibodies or renal insufficiency, which decreases the clearance of the toxin. Affected individuals initially have a faint, orange–red macular exanthem or uniform erythema (Fig. 177-3) sparing mucosal surfaces in association with a purulent conjunctivitis, otitis media, nasopharyngeal infection, or, occasionally, pyogenic skin infection such as bullous impetigo or that which arises from an umbilical stump or boil (carbuncle). These are the staphylococcal foci from which the toxin is released. Periorificial (see Fig. 177-3A) and flexural (see Fig. 177-3B) accentuation of the exanthema is often noted.

Although the early rash is not distinctive in appearance, the concomitant cutaneous tenderness is usually present at this early stage. Tenderness can often be so severe that infants will refuse to lie down or allow

TABLE 177-2

Gram-Positive Coccal Infections Associated with Toxin Production

- Caused by *Staphylococcus aureus* and/or Group A *Streptococcus* Toxin-Producing Bacteria
- Characteristic syndromes (all with skin manifestations): can be divided into three categories depending on the predominant clinical presentation
  1. Predominantly cutaneous
     - Local: bullous impetigo
     - Generalized: staphylococcal scalded-skin syndrome
  2. Intermediate cutaneous and systemic
     - Local: recurrent toxin-mediated erythema (recurrent perineal erythema)
     - Generalized
     - Recalcitrant erythematous desquamating disorder
     - Other abortive hybrids of predominantly systemic manifestations
  3. Predominantly systemic
     - Generalized
       - Toxic shock syndrome—*Staphylococcus* (predominantly) or *Streptococcus*
       - Scarlet fever—*Streptococcus* (predominantly) or *Staphylococcus*

Predominantly Cutaneous	Intermediate Cutaneous and Systemic	Predominantly Systemic
■ Exfoliative toxins	■ Unidentified toxins	■ Superantigens
Clinical Features		
■ Erythema local or generalized ■ Tenderness ■ Nikolsky sign ■ Bullae ■ Exfoliation	■ Erythema generalized ■ Fever and hypotension ■ Desquamation ■ Mucosal involvement ■ Prolonged disease ■ Some but not all toxic shock syndrome criteria met ■ Recurrences	■ Erythema generalized with or without sandpaper characteristics ■ Toxic ■ Fever and hypotension ■ Mucosal involvement ■ Swelling of hands and feet ■ Organ failure ■ Exfoliation or desquamation
Foci of Bacterial Colonization/Infection

		  ■ All arise from skin (e.g., furuncle/carbuncle)
		  ■ Special clinical features of *Staphylococcus*, scarlet fever
		  ■ Absences of pharyngitis in a patient with generalized erythroderma with sandpaper texture

Figure 177-1 Bullous impetigo in a child. Blisters are initially filled with cloudy fluid and later rupture, resulting in erosions and crusting.

anyone to hold them. Within 1–2 days the rash progresses from an exanthematous scarlatiniform to a blistering eruption (Fig. 177-4; see Fig. 177-3C and eFig. 177-4.1 in online edition). Very superficial tissue paper-like wrinkling of the epidermis, which is characteristic, progresses to large flaccid bullae in flexural and periorificial surfaces. A positive Nikolsky sign can be elicited by stroking the skin, which results in a superficial blister (see Fig. 177-4A and B and eFig. 177-4.1 in online edition). Large sheets of the epidermal surface are typically shed, revealing a moist underlying erythematous base. At this stage, the disease looks very worrisome, resembling a generalized scalding burn. Although fevers are often present and outwardly the signs of SSSS may look serious, the infants and children do not usually appear toxic unless they have developed complications such as septicemia or pneumonia. The cutaneous process usually resolves spontaneously or faster with antibiotics and superficial desquamation, with healing completed within 5–7 days (Fig. 177-5; see eFig. 177-5.1 in online edition). Cultures obtained from an intact blister are usually sterile, consistent with the pathogenesis of a hematogenously disseminated toxin originating from a distant focus of infection.

Figure 177-2 Bullous impetigo in a child. Note blisters filled with cloudy fluid and lesions that have ruptured, leading to erosions and crusting.

Although most cases of SSSS occur in infants and children, the syndrome can also rarely be seen in adults, particularly when there is renal failure (see eFig. 177-5.2 in online edition). Histopathology shows acantholysis in the granular layer and subcorneal cleft formation in early lesions (Fig. 177-6B) and an intact viable epidermis with shedding of the stratum corneum in the desquamative stage.

INTERMEDIATE (ABORTIVE) FORMS. In addition to localized bullous impetigo and generalized SSSS, intermediate forms of staphylococcal-mediated eruptions, in which blistering can be apparent, can be encountered. One scenario is localized bullous impetigo that evolves to produce regionally limited bullae and denuded areas that may or may not actually harbor *S. aureus*. A possibly abortive form of SSSS has been described. It is known as the *scarlatiniform variant* and has features of the early erythrodermic and final desquamative stages, yet very little blister formation is present (see "Staphylococcal Scarlet Fever").[8] Again, because *S. aureus* bacterial strains can produce both exfoliative and other superantigenic toxins, and ETs could have superantigenic activity,[5] it is not surprising that overlap syndromes with features of toxic shock and scalded skin can infrequently be observed.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

All forms of SSSS are characterized by intraepidermal cleavage with splitting beneath and within the stratum granulosum. The cleavage space may contain either partially or totally unattached acantholytic cells. However, the remainder of the epidermis is usually unremarkable, and the dermis contains few inflammatory cells (see Fig. 177-6B). In localized bullous impetigo, more inflammatory cells, including neutrophils, can be often visualized (see Fig. 177-6A).

The principal diagnostic problem is distinguishing generalized SSSS from toxic epidermal necrolysis (TEN) (see Chapter 40). It should be noted that the cases that represented Lyell's first description of TEN actually included some that were probably SSSS.[9] The age distribution between SSSS (neonates, children) and TEN tends to be different, yet much overlap occurs. In contrast to TEN, SSSS never has mucosal erosions. Using a Tzanck smear that will show acantholytic cells in SSSS but not in TEN (see eFig. 177-6.1 in online edition) and the use of frozen sections that can rapidly differentiate the superficial subgranular acantholysis in SSSS versus the characteristic full-thickness epidermal necrosis and dermal–epidermal separation seen in TEN aid in the differential diagnosis.

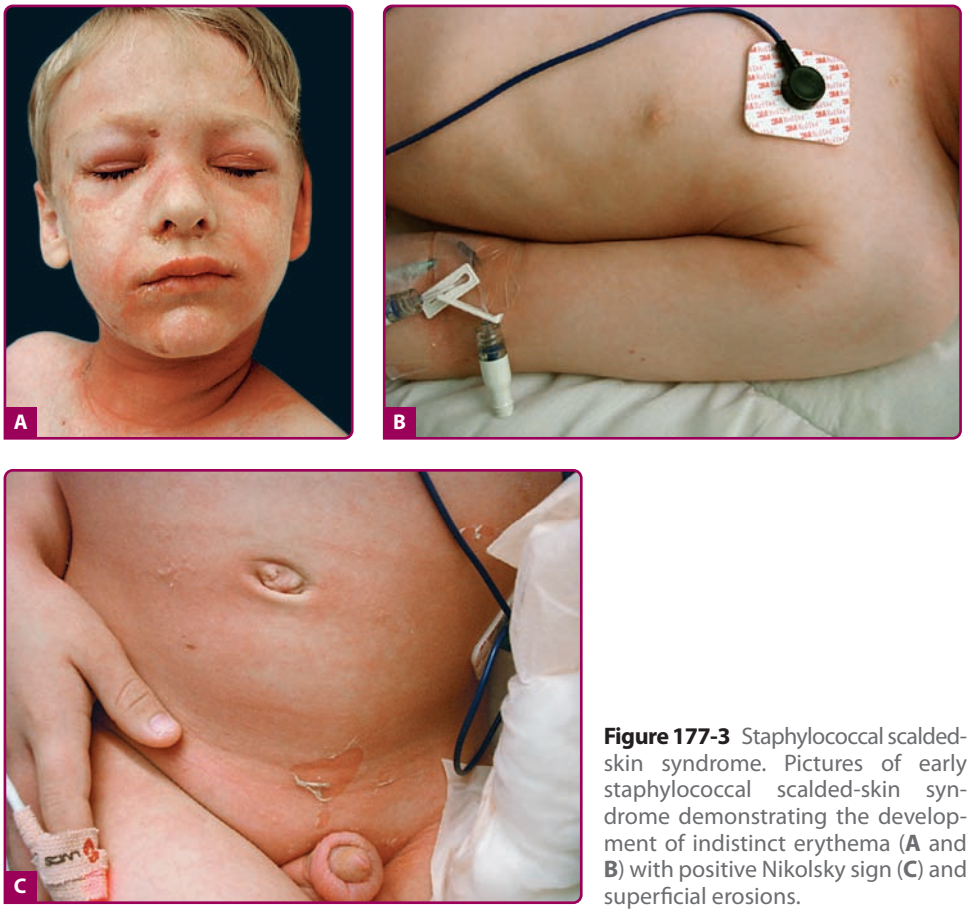

Figure 177-3 Staphylococcal scalded-skin syndrome. Pictures of early staphylococcal scalded-skin syndrome demonstrating the development of indistinct erythema (**A** and **B**) with positive Nikolsky sign (**C**) and superficial erosions.

TREATMENT AND PROGNOSIS

Therapy for bullous impetigo may include topical mupirocin ointment therapy alone and/or oral antibiotics. Prognosis for recovery is excellent. Therapy for SSSS should be directed toward eradication of *S. aureus*, which generally requires hospitalization and intravenous antistaphylococcal antibiotics. For uncomplicated cases, oral antibiotics can usually be substituted after several days. The use of suitable antibiotics, combined with supportive skin care and management of potential fluid, and electrolyte abnormalities due to the widespread disruption of barrier function, will usually be sufficient to ensure rapid recovery. Neonates benefit from incubators to maintain body temperature and humidity. The use of nonadherent dressings, including petrolatum-impregnated gauze, to the widespread areas of superficial blistering are helpful. Antibiotic mupirocin ointment applied several times per day to clearly impetiginized areas, including the original source, is often a helpful adjunct to systemic antibiotic therapy.

Major complications of SSSS are serious fluid and electrolyte disturbances. The mortality in uncomplicated pediatric SSSS is very low (2%) and is not usually associated with sepsis. Adult mortality is higher (approximately 10%) due to concomitant morbidity factors and increased likelihood of sepsis.

DISEASES CAUSED BY SUPERANTIGENIC TOXINS

ETIOLOGY AND PATHOGENESIS

Superantigens are a group of microbial and viral proteins that differ in several important respects from conventional peptide antigens (Fig. 177-7).[10,11] First, unlike conventional protein antigens, which are taken up and processed by antigen presenting cells, superantigens exert their effects as globular intact proteins. Similar to peptide antigens, they are presented by class II major histocompatibility complex (MHC) molecules; however, they do not interact with the MHC peptide β-antigen binding groove, but instead bind to conserved amino acid residues that are on the outer walls of the peptide antigen-binding groove. Thus, whereas recognition of conventional peptide antigens by the T-cell receptor is restricted by MHC alleles, recognition of superantigens is generally not MHC restricted. Second, superantigens primarily recognize and bind to the variable region of the T-cell receptor β chain (Vβ). This is in contrast to nominal peptide antigens, which require recognition by all five variable elements (i.e., Vβ, Dβ, Jβ, Vα, Jα) of the T-cell receptor. Therefore, the responding frequency of a superantigen for resting T cells is several orders of magnitude greater

Figure 177-4 Staphylococcal scalded-skin syndrome (SSSS). Pictures of later SSSS demonstrating (**A**) the same patient in **Fig. 177-3A** 24 hours later with erythema, more superficial blisters with desquamation of large sheets. **B.** Superficial erosions around the eye with underlying denuded skin. **C.** Characteristic crusting with superficial erosions noted on face of this 10-month-old child with SSSS.

Figure 177-5 Late stage of staphylococcal scalded-skin syndrome. Generalized desquamation with large sheets.

(up to 20%–30%) than a conventional peptide antigen (0.01%–0.1%) The unique ability of a superantigen to bind directly to (and signal through) MHC class II molecules, and cross-link (and thus activate) a large percentage of T cells expressing relevant T-cell receptor Vβ chains, provides an explanation for the potent immune stimulation seen with these molecules. Of note, in comparison to nominal antigens, superantigen-mediated T-cell activation tends to generate increased numbers of T cells expressing the skin homing receptor cutaneous lymphocyte antigen (CLA).[12] Given that CLA-positive T cells are the T-cell type that traffics readily to the skin, the increased numbers of CLA-positive T cells generated by these agents is thought to be responsible for the high propensity of cutaneous manifestations in these conditions. Superantigens lead to a massive release of cytokines, including tumor necrosis factor-α, interleukin 1, and interleukin 6. This cytokine "storm" is in great part responsible for a capillary leak syndrome and accounts for the majority of the clinical manifestations seen in superantigen-mediated diseases. The prototypical disease due to superantigens is TSS caused by staphylococcal or streptococcal toxins. Although specific syndromes such as TSS and

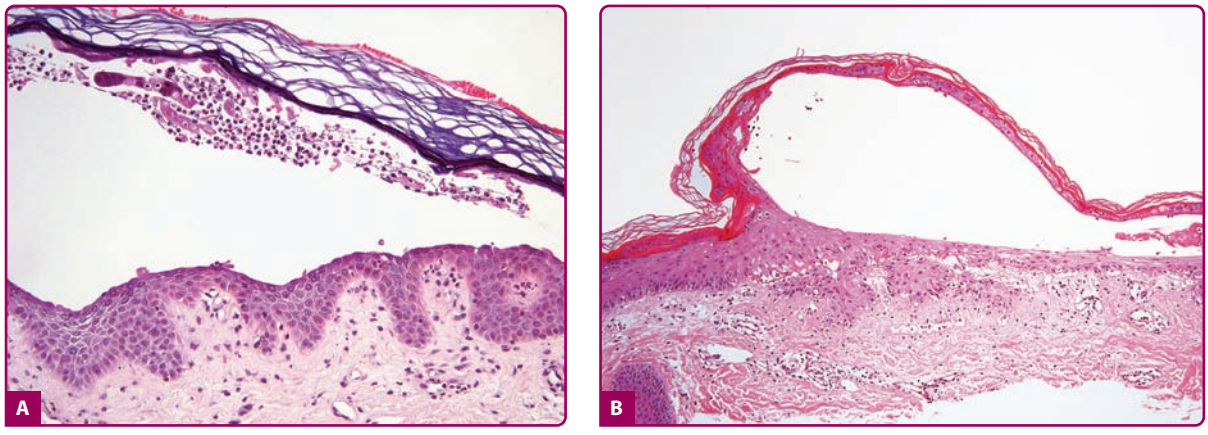

Figure 177-6 Histology of bullous impetigo (200×) (**A**) vs. staphylococcal scalded-skin syndrome (100×) (B). In both conditions, the intraepidermal cleavage induced by the epidermolytic toxin occurs within or just below the stratum granulosum. Note paucity of cells in generalized disease (staphylococcal scalded-skin syndrome) (**B**) in comparison to the large numbers of leukocytes found in the localized form (bullous impetigo) (**A**). In both, cleavage occurs in the granular layer and is due to acantholysis. Note: free-floating acantholytic cells in **A** and compacted acantholytic cells in the blister roof of **B**.

scarlet fever have characteristic findings, overlap syndromes have been described. Because the individual clinical findings are the summation of amount and type(s) of toxins and the types of cells responding to activation, it should not be surprising that heterogeneity in clinical presentations occurs.

Unlike syndromes associated with ETs that usually do not have significant systemic symptoms, those due to superantigens are characterized by systemic manifestations. Superantigen-mediated toxin syndromes can be divided into intermediate cutaneous and systemic and predominantly systemic due to the relative amounts of systemic toxicity. Disorders that have predominantly systemic manifestations are scarlet fever and the most ominous toxin-mediated disease, TSS. The intermediate cutaneous and systemic category includes syndromes such as recalcitrant erythematous desquamating disorder (REDD) and toxin-mediated erythema, which are less systemic versions of TSS and scarlet fever, respectively. All of these superantigen-mediated disorders are diagnosed based upon clinical findings and can be due to toxins produced by either *S. aureus* or group A *Streptococcus* (see Table 177-2).

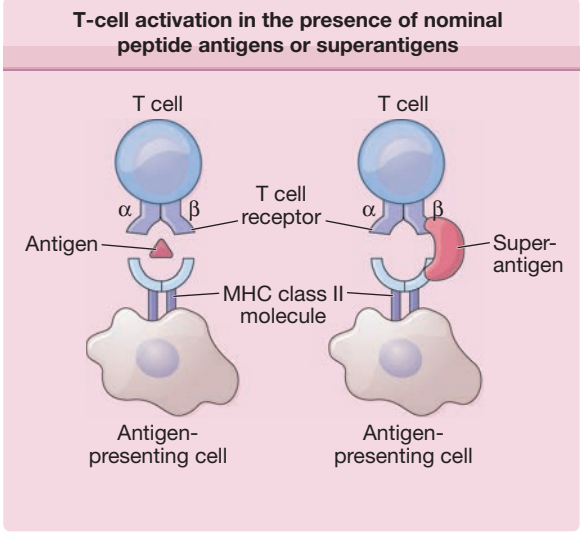

Figure 177-7 T-cell activation in the presence of nominal peptide antigens (*left*) or superantigens (*right*). The peptide antigen binds in the groove of the major histocompatibility complex (MHC) class II molecule and activates only antigen-specific T cells through the T-cell receptor. In contrast, a superantigen is a large globular protein that binds to the MHC class II molecule outside the antigen-binding groove and directly cross-links the MHC class II molecule and the Vβ chain of the T-cell receptor, leading to polyclonal T-cell activation.

TOXIC SHOCK SYNDROME

(See Table 177-2)

TSS is an inflammatory response characterized by fever, rash, hypotension, and multiorgan involvement representing the severe end of the spectrum of superantigen-mediated diseases. Although first described in 1978 in a series of children with *S. aureus* infection,[13] TSS became more broadly recognized with reports of epidemics associated with use of highly absorbent tampons in menstruating women in the early 1980s.[14] Presumably, the tampon served as a nidus for infection: the blood added protein and neutralized the normally bacteriocidal acidic vaginal pH. Since the first descriptions of the disease, TSS has been shown to be associated with many types of staphylococcal and streptococcal infections.

CLINICAL FINDINGS

Staphylococcal Toxic Shock Syndrome. The most common staphylococcal toxin associated with TSS is TSS toxin-1 (TSST-1), and it is the predominant toxin associated with menstrual-associated cases. TSST-1

appears unique among superantigens in its ability to cross-mucosal surfaces. With the removal of highly absorbent tampons from the market along with patient education, the incidence of menstruation-associated TSS decreased steadily, and at present the incidence of nonmenstrual TSS exceeds that of menstrual-associated cases. Nonmenstrual TSS is associated with postsurgical wounds, sinusitis, osteomyelitis, influenza, intravenous drug use, burn wounds, and gynecologic infection (especially in the postpartum period). Other staphylococcal toxins, including staphylococcal enterotoxins B and C (SEB and SEC), can also be found, and the latter two superantigenic toxins comprise approximately 50% of nonmenstrual TSS. The host response is an important factor in the development of TSS, as studies have shown an increased susceptibility in patients who do not have neutralizing antibodies against TSST-1.[15]

The symptoms of TSS begin with the acute onset of fever, sore throat, and myalgia. Diarrhea is common, and vomiting may also occur. The rash is most often a macular erythema but a scarlatiniform type can also sometimes be seen. The eruption usually begins on the trunk and spreads to extremities and can involve palms and soles (Fig. 177-8). If the patient is hypotensive, the eruption tends to be more prominent on the trunk than extremities. Symptoms of hypotension include orthostatic dizziness, fainting, or overt shock. Nonpurulent conjunctival hyperemia, pharyngeal inflammation, and strawberry tongue (see "Scarlet Fever") are invariably present. Signs of decreased mentation can also occur. The rash will desquamate within 1–2 weeks after it appears. The Centers for Disease Control and Prevention criteria for TSS are listed in Table 177-3. Cases of lesser severity that do not meet the full definition probably do occur frequently, especially with earlier recognition and treatment. In nonmenstruation cases, especially those associated with postoperative infections, the classic signs of a localized infection such as erythema, pain, and purulence can be absent. This is often in contrast to streptococcal TSS.

Figure 177-8 Toxic shock syndrome (TSS). Patient in intensive care unit with TSS due to *Staphylococcus aureus*. Note patient's eruption is nonspecific erythema around intertriginous areas and face. The eruption associated with staphylococcal TSS varies and could be morbilliform, scarlatiniform, or even pustular.

Streptococcal Toxic Shock Syndrome. Streptococcal TSS was described in the late 1980s as a disease similar to staphylococcal TSS, but caused by invasive group A *Streptococcus*. Recent reports have suggested streptococcal TSS is more commonly encountered than the staphylococcal form. The majority of cases of streptococcal TSS are due to streptococcal pyrogenic exotoxin A (SPEA), yet other superantigenic toxins including SPEB, SPEC, and involvement of other nongroup A *Streptococcus* have also been reported. Although not associated with tampon use, streptococcal TSS can result from nearly any type of group A streptococcal infection. The most common types of infections appear to be wounds, and streptococcal TSS has been well described as a complication of varicella and influenza A. However, in many cases the route of infection cannot be determined. In contrast to staphylococcal TSS, disease induced by group A *Streptococcus* is from skin in 80% of cases. The initial presentation is skin pain that is localized to an extremity in many cases. The localized pain often progresses over several days to localized erythema (see Chapter 179) and edema. Then cellulitis associated with necrotizing fasciitis and myositis with concomitant streptococcal invasion of the bloodstream develops. It should be noted that blood cultures are positive in more than one-half of patients with streptococcal TSS, in contrast to only one-tenth of patients with staphylococcal TSS. Thus, a patient with signs of TSS and a localized cellulitis should suggest streptococcal TSS as soft-tissue infections are not usually seen with staphylococcal TSS. Although very young, elderly, diabetic, or immunocompromised patients would be more susceptible to streptococcal TSS, the majority of cases have occurred in otherwise healthy adults.

DIFFERENTIAL DIAGNOSIS.

The differential diagnosis of staphylococcal TSS includes septic shock, staphylococcal exfoliative syndromes, Rocky Mountain spotted fever, viral hemorrhagic shock, measles, leptospirosis, and Stevens–Johnson syndrome. Although Kawasaki syndrome has many similar clinical findings, including swelling of extremities and desquamation of palms and soles during convalescence, Kawasaki syndrome differs in that the course of fever is prolonged, and there is absence of diarrhea and hypotension. Streptococcal-mediated syndromes including scarlet fever and especially streptococcal TSS can mimic staphylococcal TSS.

In a patient with fever, rash, and hypotension, a thorough search for possible sites of staphylococcal and streptococcal infection is critical. Surgical wounds should be carefully examined even if no clinical signs of infection are apparent. Vaginal examination and removal of tampon or other foreign body should be done, and vaginal irrigation with saline or povidone iodine has been recommended.

TREATMENT AND PROGNOSIS.

The treatment of TSS is supportive (and usually in the intensive care setting) and focused on eradicating the offending *S. aureus*. Large doses of a β-lactamase-resistant, antistaphylococcal antibiotics (e.g., nafcillin) have

TABLE 177-3
Centers for Disease Control and Prevention Case Definition of Staphylococcal Toxic Shock Syndrome

Major Criteria (All Four Must Be Met)	Multisystem Involvement (Three or More Must Be Met)	Normal Test Results (If Performed)

▪ Fever
  ▪ Temperature >38.9°C (102°F)
▪ Rash
  ▪ Diffuse macular erythroderma
▪ Desquamation
  ▪ 1–2 week after onset of illness, particularly on palms/soles
	▪ Gastrointestinal
	  ▪ Vomiting or diarrhea at onset of illness
	▪ Muscular
	  ▪ Severe myalgia or creatine kinase level twice upper limit of normal
	▪ Mucous membrane
	  ▪ Oropharyngeal, conjunctival, or vaginal hyperemia
		▪ Blood, throat, or cerebrospinal fluid cultures (blood cultures may be positive for *Staphylococcus aureus*)
		▪ No rise in titer in antibody tests for Rocky Mountain spotted fever, leptospirosis, or measles

▪ Hypotension
  ▪ Systolic blood pressure <95 mm Hg for adults, or less than fifth percentile by age for children <16 years of age, or orthostatic syncope
	▪ Renal
	  ▪ Blood urea nitrogen or creatinine level twice upper limit of normal, or >5 white blood cells per high-power field in urine in absence of urinary tract infection
	▪ Hepatic
	  ▪ Total bilirubin, aspartate aminotransferase, or alanine aminotransferase level at least twice upper limit of normal
	▪ Hematologic
	  ▪ Platelets <100,000/mm^3
	▪ Central nervous system
	  ▪ Disorientation or alterations in consciousness without focal neurologic signs when fever and hypotension are absent	

been used historically. Because these agents have been known to increase TSST-1 in vitro (probably as a result of cell lysis), concomitant clindamycin (which will inhibit bacterial protein toxin production) is often prescribed. Because of the increasing frequency of methicillin-resistant *Staphylococci* in the community, vancomycin is often recommended. β-lactamase-resistant penicillins are of lesser value, not only because of emerging resistance, but also they are less effective with high levels of bacteria (in contrast to clindamycin or vancomycin). Todd has recommended a combination of vancomycin and clindamycin for suspected serious staphylococcal infections pending culture and sensitivity.[16] Recently intravenous immunoglobulin (IVIG; which presumably acts in part via neutralizing antibodies against toxins) has been used and appears to have significant promise.[17] At present, IVIG is used in severe or recalcitrant cases. Contraindications to IVIG include previous hypersensitivity to it or immunoglobulin A deficiency. Systemic corticosteroids are controversial and probably have less impact than considered, as superantigen-mediated immune cell activation is associated with corticosteroid resistance.

Staphylococcal TSS is clearly a life-threatening disease but the mortality rate is only approximately 5%, most likely because the majority of cases occur in otherwise healthy young individuals. Unfortunately, recurrence can be seen in up to 20%. Women who have had TSS should avoid using tampons during menstruation as it will increase the likelihood of reinfection. Diaphragms and contraceptive sponges should also be avoided in this population.

The treatment of streptococcal TSS is similar to that for staphylococcal TSS. For cases associated with necrotizing fasciitis/myositis, rapid recognition and surgical débridement are imperative. IVIG is becoming increasingly recognized as an important part of treatment of streptococcal TSS, especially because the mortality rate in this disease can be greater than 30%.[18]

RECALCITRANT ERYTHEMATOUS DESQUAMATING DISORDER

(See Table 177-2)

A new presentation of a toxin-mediated disorder, termed *recalcitrant erythematous desquamating disorder*, was first described in 1992.[19] The clinical findings include fever and hypotension. The rash of REDD consists of diffuse macular erythema with delayed desquamation. Other findings in common with TSS include ocular and oral mucosal injection and strawberry tongue. *Staphylococci* producing TSST-1, staphylococcal enterotoxin A or B (SEA, SEB), have been isolated from various places, including nasal sinuses, soft tissues, or blood. Although the majority of patients described to date have had acquired immunodeficiency syndrome, some REDD patients without acquired

immunodeficiency syndrome have been reported. In contrast to TSS, this is a prolonged disease (measured in weeks to several months) in which only several of the TSS criteria are met. The diagnosis is often established by careful examination for occult colonization and/or infection in a susceptible individual.

SCARLET FEVER

(see Table 177-2)

Scarlet fever is a syndrome characterized by exudative pharyngitis, fever, and scarlatiniform rash. It is most commonly due to pyrogenic exotoxin-producing group A *Streptococcus*, although staphylococcal infections can produce a similar-appearing disease. The exact mechanism by which toxins produce the symptom complex is unclear. Compelling studies by Schlievert demonstrated that the scarlatiniform eruption could only be induced in mice that were previously sensitized against toxins. This suggests that a combination of conventional delayed type and superantigen-mediated processes are occurring.[20] It should be noted that streptococcal toxins, especially SPEA, have areas of significant homology with collagen, which could provide a mechanism for rare autoimmune sequelae of streptococcal scarlet fever, including renal failure and rheumatic fever.[21] Scarlet fever is no longer the major public health threat it was in the past because of antibiotic treatment, and because most streptococcal isolates causing scarlet fever express the less virulent SPEB and SPEC rather than SPEA.

CLINICAL FINDINGS

Streptococcal Scarlet Fever. Streptococcal scarlet fever is a childhood disease that occurs most commonly in winter and early spring. It is estimated that up to 10% of childhood group A streptococcal pharyngitis patients develop scarlet fever. Approximately 12 hours to 5 days after exposure, an abrupt prodrome consisting of pharyngitis, headache, vomiting, abdominal pain, and fever develops. The rash appears 1–2 days after onset of the illness, first on the neck and then extending to the trunk and extremities, although it spares the palms and soles. The exanthem texture is usually coarse, like fine-grade sandpaper, and the erythema blanches with pressure (Fig. 177-9). The skin can be mildly pruritic but usually

Figure 177-9 Scarlet fever. **A.** Exanthematous rash with a sandpaper texture in the axilla. **B.** Exanthematous rash with a sandpaper feel on the chest. **C.** Perioral pallor and strawberry tongue. **D.** Poststreptococcal desquamation.

is not painful. A few days after generalization of the exanthem, the rash becomes more intense around skin folds and lines of confluent petechiae, due to increased capillary fragility (Pastia's sign), can be seen. The generalized exanthem begins to fade 3–4 days after onset and a desquamative phase begins, usually starting on the face. Peeling from the palms and fingers and, sometimes, soles occurs approximately 1 week later and can last for up to 1 month (see Fig. 177-9D).

Oral findings of streptococcal scarlet fever include edematous, erythematous tonsils sometimes covered with a yellow, gray, or white exudate. Tender anterior cervical lymphadenopathy is common. Petechiae and punctate red macules are seen on the soft palate and uvula (Forchheimer's spots). A flushed face with circumoral pallor is also commonly noted (see Fig. 177-9C). In scarlet fever, the tongue demonstrates characteristic changes. During the first 2 days of the disease, the tongue has a white coat through which the red and edematous papillae project (white strawberry tongue). After 2 days, desquamation occurs, resulting in a red tongue with prominent papillae (red strawberry tongue) (see Fig. 177-9C).

The diagnosis of scarlet fever is made by the characteristic clinical signs and confirmed by the rapid streptococcal test or throat culture. Scarlet fever usually follows a benign course, and any undue morbidity or mortality is likely due to suppurative complications, including peritonsillar abscess, sinusitis, pneumonia, and meningitis or nonsuppurative complications associated with immune-related rheumatic fever or glomerulonephritis. The risk of acute rheumatic fever following an untreated group A streptococcal infection has been estimated to be approximately 3% in epidemics and 0.3% in endemic circumstances. Glomerulonephritis can occur in up to 10%–15% after infection with nephritogenic group A streptococcal strain. In addition to pharyngitis, group A streptococcus can cause scarlet-fever-like eruptions from skin (often surgical wounds) or uterine infections.

Scarlet fever is treated by antibiotics (penicillin or erythromycin for a 10-day course) and supportive care. Fever usually abates within 12–24 hours after initiation of antibiotic therapy. Recurrences are common.

Staphylococcal Scarlet Fever. Staphylococcal scarlet fever, also known as *scarlatiniform erythroderma or rash*, was first described almost 90 years ago and, until recently, was considered to be a milder or abortive form of SSSS. Patients usually develop a generalized erythroderma with a roughened, sandpaper-like texture very much like in streptococcal scarlet fever. However, the exanthem of staphylococcal scarlet fever tends to be more tender than corresponding streptococcal scarlet fever. Systemic signs including malaise and fever are invariably present. Within a few days of initiation of the rash, thick flakes develop, and the entire skin desquamates over the subsequent week. Unlike generalized SSSS, the scarlatiniform eruption is not associated with the formation of bullae or superficial exfoliation and can be very difficult to differentiate from other infectious erythrodermal causes such as TSS and streptococcal scarlet fever. Scarlet fever induced by *Staphylococci* differs from streptococcal-mediated disease by the lack of pharyngitis. A recent study by Wang and colleagues examined the clinical characteristics and toxin detected in 20 children with staphylococcal scarlet fever.[22] They found that all of the patients' staphylococcal infections arose from the skin; 16 of 20 cases from furuncles/carbuncles; and two each from abscesses or wound infections. All of the *S. aureus* strains expressed SEB. Of note, SEB shows significant protein sequence homology with SPEA, a known exotoxin associated with streptococcal scarlet fever. Yet other studies have implicated other staphylococcal enterotoxins.[23] One explanation for this heterogeneity of toxins associated with this disorder is that the diagnosis is made upon clinical grounds. It is indeed possible that staphylococcal scarlet fever represents an incomplete form of TSS, in which toxins spread from the skin, thus activating the skin-associated lymphoid tissue rather than mucosal-associated lymphoid tissue. Because most cases of streptococcal scarlet fever arise from a pharyngitis, the lack of a pharyngitis in a patient with characteristic rash and other clinical signs of scarlet fever should alert the clinician to look for a localized nidus of infection (e.g., furuncle) that could be cultured to establish the diagnosis.

DIFFERENTIAL DIAGNOSIS. The diagnosis of scarlet fever is made on clinical grounds with supporting positive bacterial cultures. The differential diagnosis should include other toxin-mediated disorders including SSSS. Although Kawasaki syndrome (see Chapter 167) has many similar clinical findings including mucosal involvement (e.g., strawberry tongue), swelling of extremities, and desquamation of palms and soles during convalescence, Kawasaki syndrome differs in that the course of fever is prolonged and cultures would be expected to be negative. Atypical drug hypersensitivity reactions can have some cutaneous features, but would lack the mucosal signs. There is usually a history of offending drug and peripheral eosinophilia. Scarlet fever from group A *Streptococcus* can usually be differentiated from that induced by *S. aureus* as the usual nidus of infection in streptococcal scarlet fever is from a pharyngitis while the staphylococcal variant usually has its infectious nidus in the skin.

TREATMENT AND PROGNOSIS. The treatment of scarlet fever includes antibiotics to eradicate the offending bacteria. If the localized nidus of infection is an abscess or furuncle/carbuncle, it should be drained. Acute rheumatic fever or glomerulonephritis is not associated with staphylococcal scarlet fever. For situations in which more systemic signs resemble TSS, the treatment should be that of TSS.

TOXIN-MEDIATED ERYTHEMA (RECURRENT TOXIN-MEDIATED PERINEAL ERYTHEMA)

(See Table 177-2)

In 1996, Manders and colleagues recognized a previously unreported toxin-mediated disorder, they termed

recurrent toxin-mediated perineal erythema.[24] Recurrent toxin-mediated perineal erythema is characterized by a striking diffuse macular perineal erythema that occurs within 24–48 hours after a pharyngitis with a toxin-producing group A *Streptococcus* or *S. aureus*. Clinical findings seen in scarlet fever, including a strawberry tongue, as well as erythema, edema, and later, palmoplantar desquamation, are commonly found in recurrent perineal erythema. Fever, hypotension, and other systemic signs of scarlet fever or TSS are characteristically absent although diarrhea is a common feature. Recurrences are more frequently found in this localized form. It has been proposed by Manders that that the term *toxin-mediated erythema* be used to describe the following clinical settings in which a toxin-producing *Staphylococcus* or *Streptococcus* can be found: recurrent erythroderma associated with a preceding bacterial pharyngitis, isolated episodes of toxin-mediated erythema without recurrences, and patients with episodic mild hypotension, fever, and typical mucocutaneous findings in the absence of full criteria for TSS.[25]

DISEASES INITIATED AND/OR EXACERBATED BY SUPERANTIGENS

In addition to the ability of superantigens to induce characteristic diseases including TSS, scarlet fever, and gastroenteritis, recent evidence is accumulating, which indicates that these potent immunomodulatory agents can initiate or exacerbate other skin disorders.

PSORIASIS. (See Chapter 18). Psoriasis is an autoimmune T-cell-driven keratinocyte hyperproliferative disease involving skin and rarely joints. Superantigens have been implicated in psoriasis in at least two settings: (1) the guttate (acute eruptive) form and (2) in situations where psoriasis flares in response to secondary infection.[11]

The acute guttate form of psoriasis is characterized by the rapid onset of small erythematous psoriasiform papules that can be generalized. This form can develop during or most commonly, right after a group A streptococcal infection (usually pharyngitis). More commonly found in children and young adults, guttate psoriasis has been estimated to be the initiation of psoriasis in up to 20% of patients. Studies examining a series of guttate psoriasis patients have demonstrated the association of a SPEC-expressing group A *Streptococcus* along with expansion of the appropriate T-cell receptor B Vβ pattern in the skin lesions and in perilesional skin.[26] These and other supporting studies do suggest that the superantigen-mediated systemic activation of T cells and MHC II-expressing accessory cells, resulting in the uncovering of the specific oligoclonal activation seen in chronic lesions is a plausible explanation for how infection could initiate this form of psoriasis.

In addition to the ability of systemic activation by a superantigen to initiate psoriasis, accumulating evidence has emerged that a localized infection with a superantigen-secreting microbe could be the trigger for worsening of psoriasis. For example, subjects with psoriasis have an increased cutaneous reactivity to the topical application of small (nanogram) amounts of superantigens, which is due to the increased levels of keratinocyte MHC II expression seen in subjects with activated psoriasis.[27] Thus, guttate psoriasis and flaring of existing psoriasis should prompt a careful examination and treatment for microbial infections. In women, a history of possible menstrual-associated flares of psoriasis (especially with tampon use) should prompt appropriate investigations and treatment.

AUTOECZEMATIZATION (ID) RESPONSE. (See Chapter 17). The autoeczematization (id) response is an acute, generalized skin reaction to a variety of stimuli. This stimulus may be a preexisting or new dermatitis (most often on the lower leg), or skin infection with fungi, bacteria, viruses, or parasites. The erythematous and papular pruritic rash often develops at distant sites and tends to be symmetric. No concomitant systemic toxicities are usually seen. One common clinical scenario is a patient with known stasis dermatitis who develops an allergic skin reaction to a topical agent (neomycin-containing antibiotic) used on the leg. Because of the ability of superantigens to stimulate significantly high numbers of T cells that tend to home to the skin, localized bacterial infection with a superantigen-producing *S. aureus* or group A *Streptococcus* could result in an autoeczematization response. Thus, careful examination for a microbial trigger is warranted in any patient with an autoeczematization response.

ATOPIC DERMATITIS. (See Chapter 14). Secondary infection with *S. aureus* or group A *Streptococcus* is a well-known trigger of atopic dermatitis.[28] It is estimated that *S. aureus* can be cultured from essentially all subjects with atopic dermatitis.[28] Recent studies have demonstrated that skin from subjects with active atopic dermatitis has decreased levels of antimicrobial proteins.[29] This lack of antimicrobial proteins may provide one explanation for the almost universal bacterial infection associated with flaring atopic dermatitis. Moreover, superantigen-expressing *S. aureus* have been associated with steroid-resistant AD cases.[30] The mechanisms by which bacterial infection can worsen atopic dermatitis is an active area of study, and not surprisingly, superantigens have been implicated. In addition to the "usual" mechanism of cross-linking T-cell receptor and MHC-II molecules, it has been shown that many atopic dermatitis patients have immunoglobulin E antibodies that recognize these globular proteins.[31] Thus, in addition to being a superantigen, these toxins can act as allergens in this population.

Chapter 178 :: Non-Necrotizing Infections of the Dermis and Subcutaneous Fat: Cellulitis and Erysipelas

:: Adam D. Lipworth, Arturo P. Saavedra, Arnold N. Weinberg, & Richard Allen Johnson

NON-NECROTIZING INFECTIONS OF THE DERMIS AND SUBCUTANEOUS TISSUE AT A GLANCE

- Approximately 7%–10% of hospitalizations in North America are due to skin and soft-tissue infections (SSTI), including cellulitis and erysipelas.
- The incidence of SSTI is increasing, paralleling the rise of methicillin-resistant *Staphylococcus aureus*.
- A high index of suspicion for resistant organisms shoamaintained for cases that do not improve rapidly with empiric therapy, or in areas where resistant strains have been reported.
- Newer antibiotics are currently available or undergoing testing to treat resistant infections caused by methicillin-resistant or vancomycin-resistant strains.
- Microbiologic data from various culture techniques is helpful, but swabs, aspirations, and tissue cultures generally have a low yield for uncomplicated cellulitis and erysipelas.
- Non-necrotizing soft-tissue infections are treated with antibiotics and supportive measures, with drainage of collections as needed.

EPIDEMIOLOGY

Skin and soft tissue infections (SSTI) are characterized by clinical findings that include an acute, tender, spreading, edematous, suppurative inflammation of the skin, subcutaneous fat, or muscle, often associated with systemic symptoms of malaise, fever, chills, and local pain. Cellulitis is an infection of the dermis and subcutaneous fat, while erysipelas is a more superficial variant affecting the superficial dermal lymphatics and adjacent tissues. Along with the pyodermas (see Chapter 176), cellulitis and erysipelas, are the predominant forms of non-necrotizing SSTI, which account for 7%–10% of hospitalizations in North America.[1] Over the past two decades, the incidence of SSTI has increased faster than the incidence of other acute infections, paralleling the rise of methicillin-resistant *Staphylococcus aureus* (MRSA) rates.[2]

Cellulitis and erysipelas are usually caused by *S. aureus* or β-hemolytic *Streptococci* [primarily group A *Streptococcus* (GAS)] (see Table 178-1). Factors that increase the likelihood of SSTI include exposure to pathogenic organisms, local breach of the skin barrier function (including atopic dermatitis, and less often, allergic contact dermatitis, psoriasis, trauma, intravenous drug use, surgical and cosmetic procedures, toe-web intertrigo, arthropod bites, and chronic ulcers), immunocompromise (including acquired immunodeficiency syndrome [AIDS], diabetes, end-stage renal disease/dialysis, neutropenia, cancer, and immunosuppressive medications), obesity, and circulatory compromise (see Chapter 175).

Several risk factors, relatively specific to erysipelas, include extremes of age (children and the elderly), diabetes mellitus, and nephrotic syndrome.[3] In the adult patient with erysipelas, lymphedema (including

TABLE 178-1

congenital lymphedema), venous stasis, web intertrigo, and obesity are common risk factors. Lymphedema in particular may be an important feature in erysipelas even when subclinical and only evident by lymphosyntigraphy.[4]

For all variants of cellulitis, there is less predictability in immunocompromised hosts where organisms may include a range of traditional and rare pathogens, usual commensals, yeast, fungi, and parasites. Because traditional patterns of symptoms and physical findings may be lacking or nonspecific in immunocompromised patients, determining an etiologic diagnosis is especially important.[5] In both immunocompetent and immunocompromised hosts, bullae, necrosis, or gas-forming bacterial infections signal urgency in establishing the location of infection and in defining the cause (see Chapter 179).

ETIOLOGY, MICROBIOLOGY, AND PATHOGENESIS

Pathogens isolated from cellulitis are split primarily between *S. aureus* and GAS; the best estimates place the rate of *S. aureus* cellulitis at approximately 50%, and GAS at approximately 35%.[6] However, microbiologic studies are limited by the low yield of cultures from cellulitis (see Section "Diagnostic Studies"), and anecdotal experience suggests that *S. aureus* may now be a far more common cause of cellulitis than GAS. *Haemophilus influenzae* is an important cause of cellulitis in much of the world, but the widespread use of the *Haemophilus influenza type b* vaccine has greatly decreased the incidence in the United States.

The remainder of cellulitis cases are caused primarily by groups B and G *Streptococcus*,[7,8] enteric-Gram-negative rods,[9] coagulase-negative *Staphylococcus*,[10] and *Streptococcus pneumoniae*.[11] These unusual pathogens are particularly common and problematic in association with extremes of age, prolonged hospitalization, percutaneous intravascular lines, diabetes, obesity, immunocompromised states, and glucocorticoids.[8] Liposuction and percutaneous drug use are reported risk factors that may also lead to cellulitis from less common organisms.

Erysipelas is a distinct type of superficial cutaneous cellulitis with marked dermal lymphatic vessel involvement. GAS has classically been considered the predominant cause of erysipelas, but erysipelas may also be caused by *S. aureus* and group C or G *Streptococcus*.

VIRULENCE MECHANISMS

Both *S. aureus* and GAS possess effective mechanisms of bypassing the immune system and establishing infection. GAS appears capable of inactivating cathelicidin LL-37, thereby mediating resistance to the innate immune system.[12] Although it is classically regarded as an extracellular pathogen, GAS also appears able to evade immune detection and antibiotic therapy by entering macrophages and endothelial cells.[13,14] Both GAS and *S. aureus* may produce exotoxins that result in systemic toxic reactions, including toxic shock syndrome (see Chapter 177). Panton–Valentine Leukocidin (PVL) is a β-pore forming toxin produced by many strains of *S. aureus* that damages leukocytes and predisposes to severe SSTI and other infections.[15]

ANTIMICROBIAL RESISTANCE

METHICILLIN-RESISTANT *STAPHYLOCOCCUS AUREUS* (MRSA), AND RELATED PATHOGENS. Antibiotic resistance is of increasing concern, particularly in the case of MRSA, which, in many series across disparate geographic areas in the United States and Europe, now accounts for more than

50% of cellulitis from which a pathogen could be cultured.[16–19] Healthy individuals are frequently affected, but certain populations appear to be at particular risk for MRSA skin infections, including those with immunosuppression, chronic illness (including end-stage renal disease), prisoners,[17] athletes,[20] and men who have sex with men.[21] Other risks noted in the literature include youth, recent sexual contact, presence of abscess, low body mass index, spontaneity of infection, and group home living.[16]

Methicillin resistance arises from the *mecA* gene, a component of a mobile genetic element, the staphylococcal cassette chromosome (SCC*mec*). This gene results in the production of an altered penicillin-binding protein (PBP2a), with a lower affinity for β-lactam groups, resulting in a minimum inhibitory concentration (MIC) to oxacillin of at least 4 μg.[22] This mechanism imparts resistance to all β-lactam antibiotics currently available, including penicillins, cephalosporins, monobactams, and carbapenems. Similar resistance mechanisms to β-lactams have been increasing in several important pathogenic strains of coagulase-negative *Staphylococcus* species, including *S. sciuri* and *S. haemolyticus*.[23,24]

Relative to infection with Methicillin-sensitive *S. aureus* (MSSA) and other pathogens, infection with MRSA is associated with a higher rate of adverse outcome and treatment failure,[25] as well as higher economic costs of care.[26] These unfavorable outcomes likely arise from the virulence factors closely associated with dominant MRSA strains in both community and nosocomial settings. Many MRSA strains, including the CA300 strain, which has emerged as the dominant community-acquired (CA) strain in the United States, have a very high rate of PVL expression,[27,28] and they also appear to be more effective colonizers than MSSA strains.[29]

Both hospital-acquired (HA) and CA-MRSA strains have accumulated mutations that result in resistance to other classes of antibiotics, including macrolides, tetracyclines, fluoroquinolones, and sulfonamides, though the resistance patterns to these non-β-lactam antibiotics vary widely by region. With increased use of mupirocin and chlorhexidine as adjunctive therapies for MRSA, or as part of decolonization regimens, resistance to these topical agents is also on the rise, topping 10% in some settings.[30,31] Resistance to mupirocin has been associated with increased resistance to other antibiotics,[30] and with poor outcome measures, including increased mortality in at least one study of MRSA in an intensive care unit setting.[32] In addition, resistance to the drugs often considered "salvage" medications, including vancomycin[19] and linezolid,[33] is of increasing prevalence and concern.

VANCOMYCIN-RESISTANT *ENTEROCOCCUS* (VRE). Vancomycin-resistant *Enterococcus* is most often a colonizing organism in SSTI, but it may act as a pathogen in nosocomial SSTI in immunocompromised patients.[34] Despite its relatively low virulence, VRE is of increasing concern because of its ability to transmit resistance to other bacterial species, and because of the increasing prevalence of immunocompromised patients worldwide from HIV disease/AIDS and immunosuppressive medications.[35]

SKIN SIGNS AND SYMPTOMS

CLASSICAL CELLULITIS

Cellulitis presents with erythema, pain, firm and tender induration, and less commonly, fluctuance. The erythema may rapidly intensify and spread. The margins are generally indistinct. In some cases of cellulitis, the overlying epidermis undergoes bulla formation or necrosis, resulting in extensive areas of epidermal sloughing and superficial erosion (Figs. 178-1 and 178-2). Regional lymphadenopathy may be associated with cellulitis on an extremity. In older individuals, thrombophlebitis may complicate lower leg cellulitis. Systemic symptoms, such as fever, chills, and malaise are variable, and sometimes may antedate localizing complaints and signs of SSTI. In a study of 50 patients with cellulitis, only 26% had fever higher than 38°C (100.4°F). A potential portal of entry was identified in 66% of patients.[36]

The infection may also cause deeper necrosis, resulting in dermal and subcutaneous abscess formation, fasciitis, and myonecrosis. Pain in the absence of erythema, or out of proportion to the appearance of the local area, should raise suspicion for an early

Figure 178-1 Cellulitis with swelling, erythema, and tenderness. **A.** Note the blistering and crusting on the lower extremity. **B.** The cellulitis is emanating from an upper extremity abscess.

Figure 178-2 **A.** Cellulitis after puncture trauma. The forearm is swollen, erythematous, and tender; there is abscess formation. **B.** Cellulitis arising at the site of a surgical excision: *Staphylococcus aureus*. Note discharge of pus.

deep-seated infection. Crepitus is a rare sign that signifies a gas-forming pathogen (see Chapter 179).

Cellulitis usually presents at the site of an antecedent lesion, including acute and chronic ulcers, traumatic wounds (abrasions, lacerations, animal and human bites), surgical procedure sites, dermatoses, or percutaneous catheters. Less commonly, bacteremia from systemic infections such as osteomyelitis and diverticular abscesses may cause SSTI.

ERYSIPELAS

Although erysipelas shares many clinical features with classical cellulitis (pain, tenderness, erythema, and edema), the plaque-like edema has a more sharply defined margin to normal tissue, and the erythema is classically bright red (Fig. 178-3). The surface findings are often described as *peau d'orange* (skin of an orange) in appearance. In the presence of antecedent edema or other anatomic abnormalities, the margin between normal and diseased soft tissue may be more obscure, much as in primary cellulitis.

Seventy-five to 90% of cases involve the lower extremities, while the face is affected in 2.5%–10% of cases.[37] Facial erysipelas begins unilaterally but may spread by contiguity over the nasal prominence to involve the face symmetrically (Fig. 178-4). There may not be an obvious portal of entry, and skipped areas may confuse the nature of the process. The oropharynx is a common portal of entry, and throat culture may show GAS. Inflammatory edema can extend to the eyelids, but orbital complications are rare.

Fever may precede local signs, and occasionally before distal extremity findings, patients complain of groin pain caused by swelling of femoral lymph nodes. Lymphangitis and abscess are not common, but the process may spread rapidly from the initial lesion. Infrequently, bullae or epidermal sloughing may occur in the involved area.[38]

CELLULITIS COMPLICATING SURGICAL WOUNDS

Surgical wound infections are the most common adverse events in hospitalized patients undergoing surgery and are classified as incisional (superficial) or deep.[39] Incisional wound infections involve the skin, subcutaneous tissue, and/or muscle (see Fig. 178-2B). Up to 80% of wound infections are incisional. A wound is considered to be infected if there is drainage of purulent material and evidence of inflammation. Incisional infections present with erythema, pain, tenderness,

Figure 178-3 Erysipelas. There is painful, warm erythema of the lower extremity with well-defined borders.

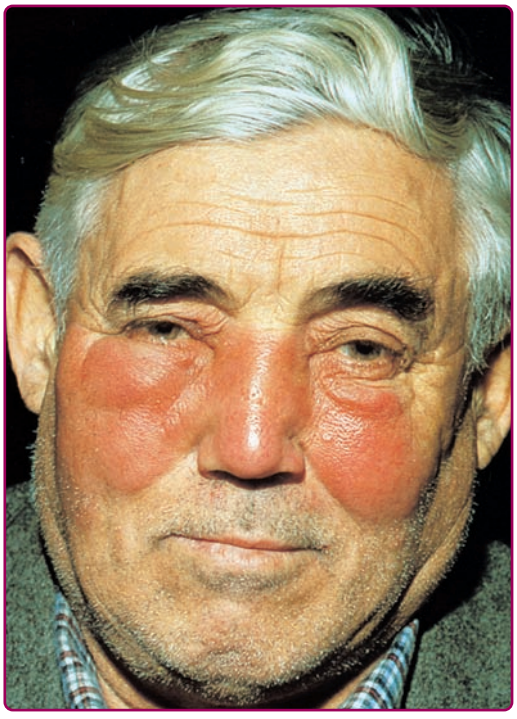

Figure 178-4 Erysipelas. Painful, edematous erythema with sharp margination on both cheeks and the nose. There is tenderness, and the patient has fever and chills.

local swelling and often, with low-grade fever. Cultures of the purulent drainage most often grow *S. aureus*. However, the microbiologic profile of cellulitis complicating surgery may reflect the structures incised during the procedure, such as an Enterobacteriaceae cellulitis after a genitourinary operation.[40]

Deep infections involve structures adjacent to the surgical wound that were entered or exposed during the procedure, such as subfascial layers, viscera, and/or spaces within the peritoneum, thorax, or joints. Deep-wound infections may be more subtle and delayed, and often present as fever of uncertain cause. Progressive bacterial synergistic gangrene and other variants of gangrenous cellulitis can arise in surgical wounds or around sutures (see Chapter 179).

The complications of superficial and deep-wound infections include poor healing, bacteremia, local and systemic effects of prolonged hospitalization, poor nutrition, residual compromised tissue integrity, and the consequences of prolonged antibiotic therapy. Additionally, wounds infected with toxin-producing *S. aureus* or GAS may result in systemic complications such as toxic shock syndrome or scarlet fever (see Chapter 177).

CELLULITIS COMPLICATING PRESSURE ULCERS

Pressure ulcers, particularly those located in the sacrum of elderly, frail, malnourished individuals, become contaminated by a variety of facultative and anaerobic microorganisms from the skin and the bowel, including *S. aureus, Enterococci*, *Pseudomonas aeruginosa,* and *Bacteroides fragilis*. In addition to pain and cellulitis, the ulcer may eventually be complicated by bacteremia, often polymicrobial, or the underlying bone can become infected. Given a high burden of colonizing organisms, the identity of the active pathogen(s) may be difficult to determine. Pressure ulcers complicated by cellulitis or sepsis should be urgently debrided.[41]

CELLULITIS COMPLICATING HUMAN AND ANIMAL BITES

Domestic dog and cat bites are common and can give rise to cellulitis caused by *Pasteurella multocida, Capnocytophaga canimorsus* (especially in asplenic individuals), and a host of other aerobes and anaerobes from the animal's mouth or the skin of the infected individual. Dog bites are often accompanied by a crush injury that devitalizes tissues. The bite of cats can inject organisms (via sharp incisors) deep into tissues, including joint spaces, tendon sheaths, or bone (see Chapters 180 and 209).

With rates of cellulitis approaching 15%, human bites have a higher incidence of infection than do animal bites because of the mix of oral bacteria (aerobes and anaerobes), as well as the crush injury imparted by the bite.[42,43] Organisms include various *Streptococci*, *S. aureus, Eikenella*, *Corynebacterium*, and the anaerobic *Peptostreptococci* and *Peptococci*. Cellulitis from bites should be monitored carefully for progression to a necrotizing infection.

PROGNOSIS AND CLINICAL COURSE

Acute cellulitis, with or without abscess formation, has a tendency to spread through the lymphatics and bloodstream and may be a serious disease, if not treated early. In patients with chronic edema, the process may spread extremely rapidly and recovery may be slow, despite drainage and sterilization of the lesions by antibiotics.

Uncomplicated erysipelas remains confined primarily to the lymphatics and subcutaneous tissues. Even in the days before antibiotic therapy, it was often a self-limited process, subsiding over 7–10 days. Occasionally, untreated erysipelas or cellulitis may be complicated by bulla formation, abscess, necrotizing fasciitis, and bacteremia with sepsis or metastatic infection in various organs. Prompt diagnosis and treatment prevents both suppurative and nonsuppurative complications. However, in young infants and elderly debilitated patients, and in individuals receiving glucocorticoids, the disease may progress with devastating rapidity to a fatal outcome.

Both classical cellulitis and erysipelas tend to recur in the same area, probably as a result of chronic lymphatic obstruction and persistent edema. Recurrent infection may specifically be seen along the lines of venectomy following saphenous vein harvest (with tinea pedis as a portal of entry). Irradiation and nodal dissection with mastectomy predisposes to recurrent

cellulitis and erysipelas over the nodal basin, or involving any part of limb distal to the procedure.

Recurrent erysipelas may produce persistent swelling of the lips (macrocheilia), cheeks (particularly the lax tissues beneath the eyes), abdomen, and lower extremities, sometimes resulting in elephantiasis nostra verrucosa (see Chapter 174). The resultant edema predisposes to further bouts of recurrent erysipelas or cellulitis, creating a cycle that can be difficult to break.[37]

Early pathogen identification, therapy, and prolonged elevation of the affected area can help to preserve better tissue resistance to reinfection. Historically, some patients with frequently recurrent GAS erysipelas have benefited from prophylactic antibiotics, usually monthly benzathine penicillin injections, but recurrences may persist in cases of noncompliance, unusual pathogens, or inappropriate antibiotic selection or dosage.[44]

DIFFERENTIAL DIAGNOSIS

Dermatologists are frequently called upon to differentiate between cellulitis and many other conditions with similar clinical presentations, including both infectious and noninfectious mimickers of cellulitis[45,46] (see Box 178-1).

DIAGNOSTIC STUDIES

STAINS AND CULTURES

The typical appearance of an SSTI, coupled with epidemiologic and clinical data, may guide antimicrobial therapy but is not completely reliable, particularly in patients who are immunocompromised. Cultures and stains from swabs, aspirates, tissue biopsies, and blood may provide valuable microbiologic data in select situations. This data can be particularly helpful with the rise of resistant bacteria and resultant uncertainty over appropriate empiric therapy.

CULTURE OF SURFACE SWABS, NEEDLE ASPIRATES, AND PUNCH BIOPSIES. Epidermal swabs are rarely helpful in cases of simple cellulitis or erysipelas, since any organism found is likely to be a colonizer or contaminant rather than a true pathogen.[47]

Needle aspirates may be of greater utility, yielding a likely pathogen at published rates of between 2% and 40% of cases.[48,49] The procedure is performed by injecting nonbacteriostatic saline into the advanced border of the infected site, followed by aspiration of tissue fluid, which is then subjected to staining and culture. Sampling the most inflamed area of the lesion, rather than the advancing edge, may increase the yield of cultures.[50] Open lesions such as postsurgical, traumatic, and pressure ulcers, may contain multiple organisms, some of which may be significant whereas others are contaminants.[51]

While the yield of needle aspirates varies widely in the literature, punch biopsies for culture can predictably identify a pathogen from a plaque of simple cellulitis in 20%–30% of the cases.[48] The Gram stain may help initially to identify the morphology of most significant staining bacteria, but cultures with sensitivities are ultimately more useful when the stains reveal bacteria with potential resistance to the commonly used antibiotics.

BLOOD CULTURES. Most studies that include only immunocompetant patients with uncomplicated, nonnecrotizing cellulitis or erysipelas demonstrate positive blood cultures in only 2%–5% of patients, suggesting that blood cultures should not necessarily be part of the routine evaluation for all simple SSTI, especially because the rate of false-positive contaminants approaches the rate of true pathogens identified.[37,48,52,53] However, the risk of bacteremia is notably higher in patients with comorbid HIV disease/AIDS and other forms of immunocompromise (approximately 25%), and in patients with an abscess, lymphedema, fever, or clinical evidence of a necrotizing or otherwise severe infection. Other factors that may signal a higher utility for blood cultures include proximal location of the infection, duration of symptoms for less than 2 days, multiple comorbid factors, and lack of pretreatment with antibiotics.[54]

HISTOPATHOLOGY

In addition to direct stains and cultures, pathologic investigation with special staining can be very useful. Histologically, erysipelas is characterized by intense edema, marked lymphatic and vascular dilatation of the superficial dermis, and a profuse infiltration of tissue spaces and lymphatic channels with *Streptococci* and neutrophils. The *Streptococci* are not found in the blood vessels, but their presence in the lymphatics produces an inflammatory reaction about these vessels. Histiocytes and granulation tissue may be seen in chronic lesions. Edema may cause dermal pallor and epidermal spongiosis.

Direct immunofluorescent techniques have been reported to identify streptococcal pathogens in 19 of 27 cases of erysipelas and in 10 of 15 cases of cellulitis, yielding a sensitivity of 70% for in situ detection of *Streptococci*.[55] Lesional skin punch biopsy is often helpful in ruling out a cellulitis-simulating noninfectious inflammatory lesion or a coexisting diagnosis such as erythema nodosum, vasculitis, or eosinophilic cellulitis.

IMAGING

Imaging modalities in the setting of SSTI are most commonly employed to rule out abscess, necrotizing fasciitis, pyomyositis, and gas forming anaerobic bacterial infections (see Chapter 179). The most common feature of cellulitis noted on MRI or ultrasound is subcutaneous tissue thickening.[56]

has changed in recent years with the increased prevalence of MRSA infections. Traditionally, simple cellulitis not requiring hospital admission has most commonly been treated with a penicillinase-resistant penicillin (e.g., dicloxacillin), or an oral cephalosporin (e.g., cephalexin) (see Box 178-2). In areas where MRSA rates are highest, clindamycin, trimethoprim-sulfamethoxazole, fluoroquinolones, and tetracyclines such as doxycycline and minocycline have recently played a more significant role in empiric therapy. However, each of these agents has deficiencies worth considering when choosing an empiric agent. The great majority

BOX 178-2 ANTIMICROBIAL TREATMENT OF NON-NECROTIZING INFECTIONS (ERYSIPELAS, CELLULITIS)

DISEASE		DRUG OF FIRST CHOICE	ALTERNATIVE DRUGS
Erysipelas	Simple, outpatient	Penicillin V[a] Intramuscular procaine penicillin Amoxicillin Vancomycin	Cefoxitin, cephalexin Dicloxacillin Amoxicillin/clavulanate Clindamycin Azithromycin
Cellulitis	Severe, hospitalized patient	Ampicillin/sulbactam Ticarcillin/clavulanate Piperacillin/tazobactam Imipenem/cilastatin, meropenem	Vancomycin Clindamycin Linezolid
	Simple, outpatient	Cephalexin Dicloxacillin	Clindamycin Azithromycin Clarithromycin
	Severe, hospitalized patient[b]	Ampicillin/sulbactam Cefazolin Piperacillin/tazobactam Ticarcillin/clavulanate Imipenem/cilastatin, meropenem	Vancomycin Linezolid Aminoglycoside + metronidazole
	Refractory, high likelihood of MRSA infection	Vancomycin Linezolid	Daptomycin Quinupristin-dalfopristin Tigecycline

MRSA: Methicillin Resistant *Staphylococcus aureus*.

[b]Consider empiric MRSA therapy in any severely ill patient.

of CA-MRSA and most HA-MRSA, remains susceptible to trimethoprim-sulfamethoxazole, but this drug is largely ineffective against GAS. *Streptococci*, MRSA, and MSSA, all have significant resistance to clindamycin, fluoroquinolones, and tetracyclines in some areas.[57,58]

Moreover, data supporting a switch to non-β-lactam empiric therapies of outpatient SSTI is lacking at this time. A cost-effectiveness analysis modeling the use of cephalexin, clindamycin, and trimethoprim-sulfamethoxazole for simple SSTI found cephalexin to be the most cost-effective choice in most clinical situations, including situations reflective of even the highest rates of MRSA documented in the literature currently.[59] A retrospective study of cellulitis in Philadelphia-area pediatric practices found that failure of empiric therapy was more likely with trimethoprim-sulfamethoxazole than with either cephalexin or clindamycin. Other factors associated with therapeutic failure across all three antibiotics included markers of infection severity, such as fever, abscess, or presentation to an emergency department; while not always statistically significant, cephalexin had the lowest failure rate in every clinical situation examined.[60] A multicenter retrospective study from Idaho found no statistically significant difference between the clinical effectiveness of β-lactam antibiotics compared with MRSA empiric coverage for outpatient cellulitis cases, but the non-β-lactams were associated with higher rates of adverse effects.[61]

The retrospective nature of these studies does not generally account for the reasons empiric MRSA coverage was selected in some cases and not others, and so these studies do not rule out the possibility that non-β-lactam drugs are more effective empiric coverage in some situations. However, at this time, despite the shift in prescribing practices to favor therapy that may cover MRSA, the data appears to favor continued use of penicillinase-resistant β-lactam antibiotics in most cases of simple SSTI not requiring hospitalization.

More severe cases of cellulitis requiring hospitalization are usually treated with parenteral antibiotics; the same controversy over whether to use a β-lactam or empiric MRSA coverage is important for hospitalized patients, but the risks of choosing an inappropriate initial therapy are potentially greater in cases of more severe infections, perhaps shifting the balance in favor of empiric MRSA-coverage, especially vancomycin, in

many situations. The most common agents chosen are intravenous semisynthetic penicillinase-resistant penicillins (e.g., nafcillin 2 g intravenously every 4 hours) and cephalosporins (e.g., cefazolin 1g intravenously every 8 hours), or vancomycin (1g intravenously twice daily) when MRSA is suspected, or when the patient has a history of an immediate type reaction (immunoglobulin E mediated) to penicillin or cephalosporin. A recent abstract presented compelling retrospective data supporting use of vancomycin over β–lactam antibiotics as empiric therapy for cellulitis in hospitalized patients.[62] Carbapenems have very broad coverage and are useful agents for severe infections when MRSA is not suspected, or when combined with anti-MRSA therapy.[63]

Linezolid (600 mg orally twice daily) is an oxazolidinone that has emerged as an effective oral alternative for infections caused by MRSA, MSSA, GAS, and VRE,[64] but linezolid resistance, while still rare, is increasing.[33] In outpatients, its use is limited largely by cost, though it may prove cost effective in many inpatient situations because it has been shown to decrease hospitalization times when compared to vancomycin.[65]

Other agents, approved by the US Food and Drug Administration (FDA) for the treatment of SSTI, include quinupristin-dalfopristin, daptomycin, and tigecycline. Use of quinupristin-dalfopristin (a streptogramin combination antibiotic) is limited by the large volumes of intravenous infusions required to achieve adequate cutaneous penetration. Daptomycin (4 mg/kg/day) is a bactericidal lipopeptide that achieves very good concentrations in the skin, and has been shown to be equivalent to vancomycin and other antibiotics in the treatment of SSTI.[66] In addition, given its novel mechanism of action, which is poorly understood but includes disruption of bacterial membrane electric potential, less chance for bacterial resistance is postulated.[67] Tigecycline, a new generation glycylcycline derived from minocycline, overcomes existing tetracycline resistance mechanisms and is broadly effective against Gram-negative and Gram-positive bacteria (including MRSA), as well as anaerobes and some atypical pathogens.[68]

Newer agents include oritavancin, dalbavancin, and telavancin, new lipoglycopeptides with long half-lives that belong to the same class as vancomycin.[69–71] More recently, two novel cephalosporins with activity against MRSA have been developed—(1) ceftaroline and (2) ceftobiprole.[72,73] Finally, a new diaminopyrimidine dihydrofolate reductase inhibitor related to trimethoprim, iclaprim, is under review by the FDA.[74]

ANTIBIOTICS FOR PREDOMINANTLY STREPTOCOCCAL INFECTIONS. It is rare in current practice that *S. aureus* can be ruled out with sufficient confidence to empirically treat with antistreptococcal drugs alone, without drugs that cover *Staphylococcus* well, but mild cases of early erysipelas known to be caused by GAS can be treated on an outpatient basis with either oral or intramuscular penicillin (See Box 178-2). Dicloxacillin or cephalexin (both 500 mg four times a day) is more commonly used because it is so difficult to rule out *S. aureus* clinically (see Box 178-2). Macrolides and clindamycin can be used in penicillin-allergic individuals, but increasing resistance of *Streptococcus pyogenes* to erythromycin has been reported.[75,76] Severe streptococcal SSTI, or SSTI complicated by comorbidities including diabetes, should be treated with high dose intravenous aqueous penicillin G (1–2 million units every 4–6 hours), but it is now rare to administer penicillin alone for cutaneous infections, without tissue culture proving monomicrobial streptococcal infection.

ADJUNCTIVE THERAPIES

Care of the local lesions of erysipelas and cellulitis includes bed rest and elevation of the involved area to reduce local edema. Cool, sterile saline dressings decrease the local pain and are particularly indicated in the presence of bullous lesions. The application of moist heat may aid in the localization of an abscess in association with cellulitis. Surgery is not generally needed for erysipelas or cellulitis unless an abscess or necrotizing infection is suspected. When present, an abscess should be drained and cultured (see Chapter 176).

PREVENTION

Education of health care providers, adherence to infection-control measures, and judicious use of antimicrobials are paramount to SSTI prevention. Decolonization strategies have thus far failed to demonstrate consistent efficacy, and development of further resistance from these protocols is a feared complication.[77] Several vaccines have been developed against *S. aureus*, which in theory circumvent staphylococcal resistance mechanisms, but so far, none has proven effective beyond phase III trials.[78] Antistaphylococcal IgG was also found to be ineffective in late testing.[79] Vaccines against the M-protein of GAS are being investigated.[80]

Chapter 179 :: Necrotizing Soft Tissue Infections: Necrotizing Fasciitis, Gangrenous Cellulitis, and Myonecrosis

:: Adam D. Lipworth, Arturo P. Saavedra, Arnold N. Weinberg & Richard Allen Johnson

NECROTIZING SKIN AND SOFT-TISSUE INFECTIONS AT A GLANCE

- Necrotizing skin and soft-tissue infections include necrotizing fasciitis, gangrenous cellulitis, and myonecrosis, and related diseases that cross soft-tissue planes.
- Necrotizing skin and soft tissue infections are locally destructive and frequently have severe systemic complications. They must be recognized rapidly and treated aggressively to minimize mortality.
- Tissue cultures have more utility in necrotizing infections than in simple cellulitis and erysipelas.
- Necrotizing soft-tissue infections require a combination of surgical treatment and antibiotics.
- Radiographic imaging may be helpful in crepitant infections but should not delay surgical therapy in cases where necrotizing infections are suspected.

EPIDEMIOLOGY

Necrotizing skin and soft tissue infections (SSTI) include gangrenous cellulitis, necrotizing fasciitis, and anaerobic myonecrosis. All of these conditions are highly destructive locally, and they frequently have severe or lethal systemic complications; they must be recognized early and treated aggressively, usually with a combination of antibiotics, surgical debridement, and supportive measures. However, the infrequency of these infections, coupled with the relatively nonspecific clinical findings early in their course, makes rapid diagnosis difficult; up to 85% of these patients do not have an accurate diagnosis at the time of admission to the hospital.[1]

Necrotizing fasciitis, especially the monomicrobial form, frequently affects young, healthy patients. However, increased age, immunocompromise including acquired immunodeficiency syndrome (AIDS), chronic illness, alcoholism, and percutaneous drug use are risk factors.[2] A chart review from New Zealand found that features common to a high proportion of necrotizing fasciitis patients included diabetes mellitus, gout, congestive heart failure, and recent surgical procedures. However, statistical analysis to assess the validity of these associations was not presented.[3] Necrotizing fasciitis arising at sites of recent tattoos[4,5] and sclerotherapy has been reported.[6] Finally, the role of nonsteroidal anti-inflammatory drugs (NSAIDS) is controversial; many studies have found an association between NSAIDS and necrotizing SSTI, but prospective studies have failed to confirm the speculation that NSAIDS may promote infection progression or delay diagnosis by obscuring early symptoms.[7]

Clostridial necrotizing SSTI, including anaerobic cellulitis and myonecrosis, arise either from deep traumatic or surgical inoculation, or from hematogenous spread from an internal infectious focus.[8] These infections are rare in healthy patients; common associations include malignancy, neutrophil dysfunction, bowel ischemia, and hemolytic-uremic syndrome.[9]

ETIOLOGY, MICROBIOLOGY, AND PATHOGENESIS

The most common pathogens mediating necrotizing SSTI are group A β-hemolytic *Streptococcus* (GAS) in

TABLE 179-1
Etiology of Necrotizing Skin and Soft-Tissue Infections

Type of Infection	Most Common Cause(s)	Uncommon Causes
Gangrenous Cellulitis		
Clostridial anaerobic cellulitis	*C. perfringens*	*C. novyi*, *C. sordellii*, *C. septicum*
Non-clostridial crepitant cellulitis	*Bacteroides* sp., Peptostreptococci	*E. coli*, other enterobacteriaceae

Necrotizing Fasciitis		
Type I Polymicrobial infection with mix of anaerobes and facultative species	Anaerobes: *Peptostreptococcus* or *Bacteroides* sp. Facultative species: non–group A streptococci, Enterobacteriaceae	Groups B, C, and G streptococcus
Type II	Group A streptococcus	
Necrotizing Fasciitis Variants that Involve Extra-Fascial Cutaneous Structures		
Synergistic Necrotizing Cellulitis: Polymicrobial with facultative and anaerobic organisms that originate in the intestine:	Facultative coliform organisms: *E. coli*, *Proteus*, *Klebsiella* Anaerobic organisms: *Bacteroides* sp., or *Peptostreptococcus*	
Progressive Bacterial Synergistic Gangrene (Meleney Gangrene)	*S. aureus* and *Peptostreptococcus* sp.	
Infectious myositis		
Pyomyositis	*S. aureus* β-hemolytic streptococcus	*S. pneumonia* *H. influenzae* Enterobactereciae Mycobacteria Fungi
Anaerobic myonecrosis (Gas gangrene)	*C. perfringens*	*C. septicum*

the case of necrotizing fasciitis type II, and anaerobes such as clostridial species in the case of gangrenous cellulitis and myonecrosis. However, other relatively common organisms that cause necrotizing SSTI include *Staphylococcus aureus*, non-group A streptococcal species, *Pseudomonas*, *Pasteurella*, *Vibrio*, and Enterobacteriaceae (such as *Escherichia coli*).[8,10] These infections are often polymicrobial, with a mix of both pathogens and contaminants (see Table 179-1).

The microorganisms associated with necrotizing cutaneous infections in the normal host are joined by a variety of other traditionally pathogenic and nonpathogenic bacteria, as well as fungi, in immunocompromised patients. In the presence of thermal burns, hematogenous *Pseudomonas aeruginosa* may infect normal skin, producing ecthyma gangrenosum (see Chapter 180), or may be attracted to burn areas, leading to extensive bacteremic pseudomonas gangrenous cellulitis. Mucormycotic gangrenous cellulitis can engraft onto thermal burns or complicate percutaneous catheter areas in immunosuppressed individuals. In the immunocompromised host, it becomes mandatory to biopsy any necrotic cellulitic lesions and to be alert to the possibility of a wide range of bacterial, viral, fungal, and even parasitic pathogens.

The pathophysiology of necrotizing fasciitis has not been fully elucidated, but the bacteria capable of producing this infection, including GAS, appear to share the ability to produce enzymes that degrade fascia and allow rapid proliferation at the level of the superficial fascia. This proliferation results in local thrombosis, progressive ischemia, liquefaction necrosis, and ultimately, more superficial gangrene.[11]

Mechanisms of clostridial virulence are better understood. Clostridial species are large spore-forming Gram-positive bacilli that produce more toxins than any other known bacteria.[12] Clostridial α-toxin, a pore-forming lecithinase that mimics the function of phospholipase C, hydrolyzes cell membranes, and increases capillary permeability and platelet aggregation, thereby mediating hemolysis and dermonecrosis. This exotoxin has been shown to be both sufficient and necessary for gas gangrene in mouse models; injection of *Bacillus subtilis* carrying a gene for the toxin produces myonecrosis, and immunizing mice against the α-toxin prevents the infection.[13] Nevertheless, other clostridial toxins do appear to play a role in human SSTI disease, including θ-toxin (containing perfringolysin O), ε-toxin, and multiple collagenases. *Clostridium perfringens* accounts for approximately 80% of clostridial SSTI; less common causes of gangrenous clostridial SSTI include *Clostridium septicum*, *Clostridium novyi*, and *Clostridium sordellii*.[12,14]

TABLE 179-2
Findings in Necrotizing Skin and Soft-Tissue Infections

Feature	Progressive Bacterial Synergistic Gangrene	Synergistic Necrotizing Cellulitis	Streptococcal Gangrene	Clostridial Myonecrosis (gas gangrene)	Necrotizing Infections in Immunosuppression
Microbiology	Streptococci, *Staphylococcus aureus*	Mixture of organisms: *Bacteroides*, peptostreptococci, or *Escherichia coli*	Group A streptococci	*Clostridium perfringens*	*Rhizopus, Mucor, Absidia, Pseudomonas aeruginosa*
Predisposing conditions	Surgery or draining sinus	Diabetes	Diabetes or abdominal surgery	Trauma	Diabetes, corticosteroid use, immunosuppression, burns

Modified with permission from Pasternack MS, Swartz MN: Cellulitis, necrotizing fasciitis, and subcutaneous tissue infections, in *Principles and Practice of Infectious Diseases*, 7th ed, edited by Mandell GL et al. Churchill Livingstone/Elsevier, Philadelphia, 2010, p 1301.

CLINICAL PRESENTATION, DIAGNOSIS, PROGNOSIS

Necrotizing infections of soft tissues may be localized to the muscle, fascia, or the overlying skin and subcutis, or they may cross these layers; the structural layers involved provide a useful framework for categorizing these infections into gangrenous cellulitis (affecting the dermis and subcutaneous tissue), necrotizing fasciitis (predominantly affecting the fascia), and pyomyositis and myonecrosis (affecting the muscle) (Table 179-2).

NECROTIZING FASCIITIS

HISTORY

Necrotizing fasciitis infections are often more extensive than the overlying skin changes would suggest. Early in the disease (stage 1), the involved area may be painful at first and then evolve with objective findings: swelling, erythema, warmth, and tenderness, resembling simple cellulitis.[11] Constitutional symptoms with high fever and toxicity are characteristic of early progression, but at least one study of necrotizing fasciitis patients found fever in only half of patients, and hypotension in only 18%.[15] It is possible that systemic manifestations are delayed or obscured by widespread use of broad-spectrum antibiotics at the first sign of a SSTI, when the disease is often thought to be a simple cellulitis.[16] Within several days, induration worsens and bullae develop (stage 2). Ultimately, the skin color becomes purple and frank cutaneous gangrene ensues (stage 3) (Fig. 179-1). At this advanced stage, the involved area is no longer tender but has become anesthetic as a result of occlusion of small blood vessels and destruction of superficial nerves in the subcutaneous tissues.[11,16–18]

Figure 179-1 Fournier's gangrene (type 1 necrotizing fasciitis of genitalia) with progressive necrosis of the pubic, perigenital, and perianal tissue.

The classification of necrotizing fasciitis can be confusing because different variants have been described in the literature using unrelated criteria, including microbiologic features, anatomic location, and etiology.

VARIANTS DEFINED BY MICROBIOLOGIC CHARACTERISTICS

TYPE I NECROTIZING FASCIITIS. Type I necrotizing fasciitis, a polymicrobial infection, is caused by a mix of facultative and anaerobic microbes, often delivered into the subcutaneous tissues after surgery, trauma, bowel perforation from neoplasm or diverticulitis, or injecting drug abuse via skin popping. It is by far the most common form of necrotizing fasciitis, accounting for nearly 90% of cases, often occurring in patients compromised by diabetes or malnutrition. Organisms include at least one anaerobic organism recovered in a mix of facultative microbes: nongroupable *Streptococci*, *Enterococci*, anaerobic *Streptococci* and *Staphylococci*, *Bacteroides*, and Enterobacteriaceae including *E. coli*, as well as various aquatic bacteria. Often, three to five species contribute to the infection, which may have a slower pace than GAS in evolving to a full-blown process with cutaneous manifestations.[19,20]

Type I necrotizing fasciitis most commonly occurs on an extremity, abdominal wall, perineum, or near operative wounds (see Fig. 179-1). It is important to recognize that when this infection presents in the thigh (dissection along the psoas muscle) or abdominal wall, it may be secondary to an intestinal source (occult diverticulitis, rectosigmoid neoplasm). Crepitus often develops, particularly in patients with diabetes mellitus if gas-forming anaerobes, such as *Bacteroides*, are causative.

TYPE II NECROTIZING FASCIITIS AND STREPTOCOCCAL GANGRENE. Type II necrotizing fasciitis is caused by a monomicrobial infection, usually GAS, which in this setting has been referred to as "flesh eating bacteria" by the lay press. If the process is not limited to the fascia, it is referred to as streptococcal gangrene. Occasionally, in the neonatal period, and very rarely in adults, group B *Streptococci* have been recovered.[21] Other streptococcal species have been reported to cause monomicrobial necrotizing fasciitis, including groups C and G *Streptococci*, as well as *Streptococcus pneumoniae*.[22] In addition, monomicrobial necrotizing fasciitis caused by methicillin-resistant *S. aureus* (MRSA) may be much more common than previously thought, with one recent study finding it to be the cause of nearly 40% of necrotizing fasciitis patients between 2001 and 2006.[23]

Patients may be immunocompromised by age or illness such as diabetes, alcoholism, or cirrhosis, but are usually healthy individuals. The location of the necrotizing lesion is most often an extremity and rarely, the face. The clinical presentation is usually indistinguishable from type I necrotizing fasciitis, but necrosis of the overlying skin can be particularly rapid and dramatic, revealing deeper structures, including tendon sheaths and muscle. Though lymphangitis is rare, metastatic abscesses can occur. Bacteremia is documented in approximately two-thirds of patients, and patients often develop a streptococcal toxic shock syndrome (see Chapter 177).[24]

VARIANTS DEFINED BY EXTRAFASCIAL STRUCTURES AFFECTED

SYNERGISTIC NECROTIZING CELLULITIS. Synergistic necrotizing cellulitis is a mixed infection of anaerobes and facultative bacteria generally classified as a type I necrotizing fasciitis because of prominent fascial involvement, but it actually may infect all soft-tissue structures, including skin and muscle. It is painful, progressive, and highly lethal, primarily affecting frail, elderly, diabetic, or obese patients, almost always with compromising cardiovascular and renal disease. The process may begin with only mild pain and low-grade fever, evolving slowly over 7–10 days. The initial skin lesion is a small reddish-brown bulla or patch on the perineum (near a perirectal or ischiorectal abscess) or lower extremity, with extreme local tenderness; the superficial appearance belies the widespread destruction of the deeper tissues. Skin sinuses (with surrounding areas of blue–gray gangrene) form, draining a foul-smelling thin pale "dishwater" exudate containing fragments of necrotic fat. Gas can be palpated in approximately one-fourth of patients. Half of the patients become bacteremic. Extensive gangrene of the superficial tissues and fat can be visualized by direct inspection through open skin areas or with skin incisions.[25–27]

Frequently isolated organisms include anaerobes (*Streptococci* and/or *Bacteroides*) and facultative bacteria, especially Enterobacteriaceae (*E. coli*, *Proteus*, and *Klebsiella* species).[25,28] Rapid and extensive surgical debridement with antibiotics guided by the Gram stain is essential; nevertheless, the mortality rate remains in the 40%–50% range.[27]

PROGRESSIVE BACTERIAL SYNERGISTIC GANGRENE (MELENEY GANGRENE). Progressive bacterial synergistic gangrene is a specific polymicrobial infection, perhaps best categorized as a form of synergistic necrotizing cellulitis, which presents with a necrotic ulcer at the site of abdominal or thoracic incisions, wire-stay sutures, or fistulous tracts. The infection typically develops insidiously, within a week or two of a procedure. It is called synergistic because by definition, two or more bacteria must coinfect to create the clinical appearance, as demonstrated by Meleney who reproduced these ulcers by injecting microaerophilic *Streptococci* and *S. aureus* into animal skin; the infection did not develop when either pathogen was injected alone.[27]

VARIANTS DEFINED BY ANATOMIC LOCATION

CERVICAL AND CRANIOFACIAL NECROTIZING FASCIITIS. These two variants of necrotizing fasciitis may be classified as either type I or type II, but

they are defined and named by their anatomic location and etiology, rather than by their microbiologic profiles. Cervical necrotizing fasciitis is usually a type I infection (polymicrobial etiology), but GAS can be the single etiologic agent in rare cases, particularly in the setting of peritonsillar abscess formation. Most commonly, cervical necrotizing fasciitis originates from dental or pharyngeal sources. Crepitus may develop as the infection spreads to the face. This is in contradistinction to craniofacial necrotizing fasciitis, which starts in the face and is most commonly caused by GAS after a traumatic episode. Cervical necrotizing fasciitis carries a much higher mortality rate than the craniofacial variant.[29–31]

FOURNIER'S GANGRENE. Fournier's gangrene is a localized gangrenous SSTI involving the genitalia. The infection tends to be limited to skin and subcutaneous tissue of the genitals, but it may spread along fascial planes to the perineum and abdominal wall. It is usually caused by a mix of facultative and anaerobic organisms, and therefore is best categorized as a form of synergistic necrotizing cellulitis or type I necrotizing fasciitis. In rare cases, GAS as the single pathogen has been implicated, and this may be related to rectal ring carriage or to oral–genital sex. The average age at onset is 50–60 years of age. Most men have underlying diseases or a history of procedures. These include diabetes mellitus, ischiorectal abscess, perineal fistula, bowel disease (rectal or colon carcinoma, diverticulitis), scrotal or penile trauma, prior hemorrhoidal or urogenital surgery, pressure ulcers of the scrotum and perineum, paraphimosis and, rarely, obscure causes, such as dissection of pancreatic secretions through the retroperitoneum and into the scrotum in acute pancreatitis.[32–34]

The onset of Fournier's gangrene can be insidious, with a discrete area of edema, erythema, and necrosis on the scrotum. Ultimately, skin necrosis begins to proceed rapidly over 1–2 days (Fig. 179-2). Pain, swelling, and crepitus in the scrotum, perineum, or suprapubic region may be marked. Foul-smelling drainage occurs, indicating a contribution from anaerobes. Purple discoloration of the scrotum, an initial "red flag," progresses to frank gangrene. The testes, glans penis, and spermatic cord are usually spared, as they have a separate blood supply. The infection may progress and invade the abdominal panniculus in obese patients, especially those with diabetes mellitus, leading to rapid and extensive destruction of tissue and requiring wide debridement and prolonged hospitalization. Fournier's gangrene carries 20% mortality even with treatment.[32–34]

Figure 179-2 Fournier gangrene. There is painful erythema with marked edema, superficial desquamation, and areas of necrosis in the inferior aspect of the scrotum.

DIAGNOSTIC STUDIES (CULTURES, HISTOPATHOLOGY, IMAGING)

The gold standard for diagnosing necrotizing fasciitis is open surgical exploration with direct visualization and palpation of the necrotic fascia, which appears grayish and does not bleed; blunt dissection reveals foul-smelling discharge and a lack of usual adherence of the superficial fascia to underlying tissues.[11] Short of open exploration, no test is specific for necrotizing infection, but several laboratory, microbiologic, histopathologic, and imaging studies have been shown to be useful in differentiating bacterial necrotizing SSTI from non-necrotizing infections or noninfectious causes of soft-tissue necrosis (see Box 179-1).

LABORATORY RISK INDICATOR FOR NECROTIZING FASCIITIS (LRINEC). In 2004, Wong et al performed a retrospective analysis to determine independent predictive factors of necrotizing fasciitis at time of presentation, and converted these factors into a scoring system they called Laboratory Risk Indicator for Necrotizing Fasciitis (LRINEC). The variables included in the score are elevated C-reactive protein, leukocytosis, anemia, hyponatremia, renal failure, and hyperglycemia; each is assigned a weight depending on the degree of abnormality. In this initial study, a score of at least six had a positive predictive value of 92%, and a score of at least eight was strongly predictive of necrotizing fasciitis. The negative predictive value for a score less than six was 96%.[35] This system may be useful for stage 1 disease, when the clinical presentation is generally identical to cellulitis, but a recent analysis of the LRINEC in a tropical tertiary care center found significantly lower sensitivity (80%) and specificity (67%) at a cutoff value of six.[36]

Another diagnostic test that has shown some promise is tissue oxygen monitoring by near-infrared spectroscopy. A cutoff oxygen saturation of less than 70% was found to be highly sensitive (100%) and specific (97%) for necrotizing fasciitis in patients without

BOX 179-1 DIFFERENTIAL DIAGNOSIS OF INFECTIOUS NECROTIZING BACTERIAL SKIN AND SOFT-TISSUE INFECTIONS

NONINFECTIOUS

- Arteriolar occlusion with cutaneous necrosis (retiform purpura with necrosis)
  - Leukocytoclastic vasculitis
  - Calciphylaxis, oxalosis
  - Warfarin necrosis
  - Disseminated intravascular coagulation
  - Hemolytic uremic syndrome
  - Thrombotic thrombocytopenic purpura
  - Hypercoagulable state
  - Emboli (cholesterol, fat, amniotic fluid, etc.)
- Panniculitides with liquefaction necrosis
  - Pancreatic panniculitis
  - α-1-antitrypsin deficiency
- Follicular occlusion syndromes
  - Acne conglobata
  - Dissecting cellulitis
  - Hidradenitis suppurativa
- Neutrophilic dermatoses
  - Pyoderma gangrenosum
  - Sweet syndrome
- Iatrogenic
  - Fixed drug eruption
  - Radiation dermatitis
- Miscellaneous causes
  - Insect bites/stings (esp. brown recluse bite)
  - Irritant contact dermatitis with necrosis
  - Sterile spontaneous diabetic myonecrosis
  - Trauma with hematoma formation
  - Metastatic Crohn's disease

INFECTIOUS

- Non-necrotizing bacterial SSTI
  - Cellulitis
  - Erysipelas
  - Abscess, furuncle
- Septic emboli/ septic vasculitis
  - Endocarditis
  - Internal organ abscess
  - Meningitis (*Neisseria meningitides*)
  - Bacteremia/Sepsis
- Herpes zoster and herpes simplex
- Deep Fungal infection
- Atypical mycobacterial infection
- Bursitis, arthritis, osteomyelitis

SSTI = skin and soft-tissue infections.

known chronic venous stasis, peripheral vascular disease, shock, or systemic hypoxia.[37]

BIOPSY FOR CULTURE AND HISTOPATHOLOGY. Tissue from a biopsy or surgical specimen is far more likely to demonstrate an organism on stain or culture in necrotizing SSTI than in simple cellulitis. One study of 198 necrotizing SSTI was able to obtain microbiologic data in 189 of the samples.[38]

Deep incisional biopsy and histopathologic examination on frozen section has been shown to decrease mortality in necrotizing fasciitis by rapidly establishing the diagnosis and thus defining the need for surgical debridement.[39] Indications for an open exploration and a biopsy include confusion, pain and tenderness, tachycardia, tachypnea, ketoacidosis/hyperglycemia, bullous or gangrenous skin changes, bronzing of the skin, spreading areas of anesthesia, thin reddish discharge with undermining of wound edges, crepitus, and an abscess with multiple tracts.

In streptococcal gangrene, the prominent angiitis and focal dermal necrosis with spread along fascial planes suggest that the disease is fundamentally gangrene of the subcutaneous tissues followed by necrosis of the overlying skin. Microscopically, fibrinoid necrosis is present in the media of many arteries and veins passing through the edematous and damaged fascia.[40] Fibrin thrombi and coagulation necrosis may be present throughout the fascia and skin. Numerous polymorphonuclear leukocytes and mononuclear cells infiltrate the lesion, and the upper layers of the dermis contain large numbers of Gram-positive cocci.

IMAGING. Several imaging modalities, including magnetic resonance imaging (MRI), computed tomography (CT), and ultrasound have all been shown to demonstrate distinctive imaging features of necrotizing fasciitis lesions, but their role in diagnosis is still controversial. All three of these modalities can show fascial thickening, as well as fluid and gas in

the adjacent tissue planes.[11] MRI is the most sensitive of these studies, and may also show a hyperintense T2-weighted signal in the muscle, and a deep dermal, dome-shaped area of increased signal.[11,41] However, the sensitivity of MRI is higher than the specificity, resulting in an excellent negative predictive value, but a relatively high false-positive rate, resulting in some unnecessary surgical explorations.[42] While these studies, especially MRI, can be helpful in ruling-out necrotizing fasciitis, or in differentiating early disease from simple cellulitis, radiographic testing should never delay open surgical examinations in cases with a high index of suspicion.

PROGNOSIS AND CLINICAL COURSE

Although subacute variants have been described, necrotizing fasciitis generally follows a hyperacute progression that results in rapid shock and multiorgan failure.[1] The mortality rate ranges in the literature from 17%–49%.[43,44] The wide range of mortality for necrotizing fasciitis and all necrotizing SSTI depends largely on the underlying health and immune status of the patients, and on the extent of diagnostic delay.

Histopathologic features can predict prognosis, with mortality increasing as the bacteria in the tissue increase and the number of neutrophils decrease.[16] Delay in diagnosis and comorbid streptococcal toxic shock syndrome are associated with particularly poor survival.[43] Other factors associated with decreased survival in individual studies include age greater than 50, tachycardia, fever, leukocytosis, renal failure, hematocrit greater than 50%,[45] APACHE II score of at least 13,[44] congestive heart failure, and a history of gout.[3]

GANGRENOUS CELLULITIS

NONCLOSTRIDIAL CREPITANT CELLULITIS

The patient with nonclostridial crepitant cellulitis may have experienced a traumatic or surgical injury that was inadequately debrided or had an underlying local infection, a poorly performed needle stick, or skin popping (injecting drug use into dermal or subcutaneous tissue).[46,47] Underlying diabetes, glucocorticoid or NSAID use, and granulopenia may be present. The clinical presentation is often insidious, with low-grade fever, mild pain, and tenderness, but with early palpable gas and edema. Anaerobic nonspore-forming isolates may include *Bacteroides* sp. or *Peptostreptococci*, often with facultative Gram-negative bacilli. In uncontrolled diabetes mellitus, the presence of gas may result from metabolism of glucose by *E. coli*, *Klebsiella*, *Aeromonas*, and other microorganisms[10] (see Chapter 180).

CLOSTRIDIAL ANAEROBIC CELLULITIS

The histotoxic clostridia are responsible for a variety of infections that involve the subcutaneous and muscular tissues, often with abrupt and dramatic changes in the overlying skin.

Clostridial anaerobic cellulitis begins as an infection of the more superficial subcutaneous zone, but it may progress to involve deeper structures including deep fascia and muscle. The human gut commensal, *C. perfringens*, with or without other bacteria, is the most common cause. The cellulitis usually arises in tissues that are already devitalized, such as dirty or inadequately debrided wound several days after injury, needle stick, or surgery. The clostridia are able to grow in the wound and extend rapidly through tissue planes with attendant formation of large quantities of gas that is both readily palpable and visible on conventional X-ray. A thin, dark-gray to brown, foul, serous discharge is often produced.[48] Gram stain of the drainage reveals short, plump, blunt-ended, "box-car" shaped Gram-positive rods with a variable number of polymorphonuclear leukocytes and, occasionally, other bacterial forms.[8]

Compared with anaerobic myonecrosis, anaerobic cellulitis is more indolent, produces less surface change and relatively little local pain, edema, or toxemia. At surgery, gas may be readily evident throughout the exudate. Anaerobic cellulitis can be distinguished from anaerobic myonecrosis by inspection of muscle to avoid needless mutilating surgery and amputations.

Other variants of anaerobic cellulitis are more commonly associated with toxemia. *C. novyi* and *C. sordellii* are specifically associated with infected wounds from intravenous drug use, childbirth, and medical abortions. Patients develop toxic shock and gangrenous cellulitis, though fever is not universally seen. The organism can usually be cultured from wounds, but blood cultures may remain negative.[49,50] The environmentally resident *C. septicum* can cause a toxic anaerobic cellulitis arising via hematogenous spread from a gastrointestinal source.

INFECTIOUS MYOSITIS

Infectious myositis is a broad term for skeletal muscle infection with any pathogen, including viruses, bacteria, fungi, and parasites. Bacteria and fungi tend to cause a local myositis, which is referred to as pyomyositis in the presence of a purulent collection. Cases of pyogenic myositis are generally divided into clostridial and nonclostridial etiologies.[51] The most common nonclostridial causes of pyomyositis and myonecrosis are *S. aureus* and β-hemolytic streptococcal species. GAS may cause myositis with severe muscle edema, necrosis, compartment syndrome, and overlying skin changes from deep ischemia.[52,53] Other potential pathogens include *S. pneumoniae*, *Haemophilus influenza*, Gram-negative bacilli, *Mycobacteria*, and fungi.[10,43,54] Bacteremia is documented in 5%–30% of pyomyositis cases.[43]

Clostridial myositis can produce a crepitant myonecrosis, often referred to as "gas gangrene." Uncommonly, nonclostridial pathogens such as *Aeromonas hydrophila*, *Peptostreptococcus*, and *Bacteroides* species can cause a similar crepitant myonecrosis.[54]

CLASSICAL ANAEROBIC (CLOSTRIDIAL) MYONECROSIS (GAS GANGRENE)

Anaerobic myonecrosis (gas gangrene) is a rapidly progressing, toxemic, potentially lethal infection involving muscle but with secondary changes in the overlying skin. Gas gangrene may also occur in the uterus, intraperitoneal viscera, brain, and eye, sometimes in the absence of bacteremia. The infection may develop as a complication of a traumatic dirty wound with extensive muscle and soft-tissue damage,[31] or after surgery on the bowel or gallbladder. *C. perfringens* is the most common pathogen in the classic presentation of anaerobic myonecrosis.

The incubation period of anaerobic myonecrosis is often short (12–24 hours) but may be delayed, rarely developing after anaerobic cellulitis. The first symptom is usually severe local pain followed by fever, tachycardia, and hypotension. Gas formation is present but not prominent in subcutaneous tissues, and may be obscured by edema of the superficial tissues. Radiography reveals extensive dissection of gas through the deep soft tissue structures.[55]

The skin often takes on a dark yellow or bronze discoloration with tense blebs or bullae containing dark brown fluid. A serosanguineous exudate can be expressed from the wound or aspirated from a bulla. Gram stain of the exudate reveals plump Gram-positive rods and rare or absent white blood cells, even with a systemic leukocytosis. This paucity of leukocytes is notable on muscle biopsy as well, perhaps a result of the θ-toxin (perfringolysin O), which appears to inhibit recruitment of neutrophils.[56] The overlying skin may develop patchy necrosis and desquamation, as a result of vascular compromise and local ischemia. At surgery, the process in the muscle is evident, with gray pallor, absence of bleeding, presence of gas, and failure of the muscle to respond to direct stimuli.[8,43,54]

Published mortality rates are generally in the 20%–30% range, but this rate increases dramatically in older patients, or in those with comorbid conditions or delayed diagnosis.[57,58]

SPONTANEOUS, NONTRAUMATIC ANAEROBIC MYONECROSIS

In the absence of an external wound, septicemic gas gangrene may occur spontaneously, usually caused by *C. septicum* and often associated with hematologic malignancies or occult colon cancer, especially in the cecal area. Spontaneous *C. septicum* gas gangrene is a fulminant disease, with a mortality approaching 100% and marked by a precipitous onset and progression, often with subcutaneous gas, myonecrosis, and high-grade septicemia. Overlying skin of an involved area becomes red–brown and the epidermis sloughs early in the illness. In addition, the organism may be aerotolerant and thus lacks susceptibility to hyperbaric oxygen. No controlled treatment trials exist for this disease.[59–61]

Spontaneous gas gangrene from *E. coli* has also been reported. All three patients had cirrhosis, and no obvious source of bacteremia was noted.[10] In addition, sterile, spontaneous diabetic myonecrosis is important to consider in the differential diagnosis, although these patients are usually not febrile and do not appear toxic. This entity is most common in women with late-stage diabetes mellitus, complicated by nephropathy and retinopathy, and it usually affects the quadriceps and thigh muscles, occasionally with slight elevation in muscle enzymes.[62]

TREATMENT

Treatment of all necrotizing SSTI involves a combination of urgent debridement, antibiotics, and often, adjunctive therapies.

ANTIBIOTICS

Antimicrobial treatment decisions for patients with crepitant or gangrenous SSTI must be based on a rapid or presumptive identification of the etiologic agent(s) (see Box 179-2). Until definitive microbiologic data is obtained, high-dose parenteral broad-spectrum antibiotics should be given to cover any pathogens on the clinical differential. An organism found on blood culture does not rule out the possibility of a polymicrobial infection, and should not necessarily prompt narrowing of the antimicrobial coverage until reliable cultures from the wound are obtained.

As a general rule, streptococcal infections should be treated with a regimen that includes penicillin G. Clindamycin should be added if toxic shock syndrome is suspected (see Chapter 177). Staphylococcal species should be treated with a penicillinase-resistant β-lactam, such as nafcillin, or with vancomycin, if MRSA is suspected. Alternative agents for empiric coverage of suspected MRSA include linezolid, daptomycin, tigecycline, and quinupristin-dalfopristin, as well as several agents still under development (see Chapter 178). Once cultures with susceptibility data are obtained, fluoroquinolones, sulfonamides, and other antibiotic classes may have a role. Clostridial infections should be treated with a combination of parenteral penicillin G and either clindamycin or metronidazole. Clindamycin-resistant *C. perfringens* SSTI has been reported.

SURGICAL DEBRIDEMENT

Treatment of all types of necrotizing SSTI requires early and complete surgical debridement of necrotic tissue, including any skin, fascia, or muscle involved. In some cases, amputation of a limb can be rapidly accomplished and may be lifesaving in selected patients. Intraoperative inspection can help determine the depth of the infection, and should also provide material for bacterial and pathologic study. Re-exploration and debridement should be performed as necessary to ensure that all necrotic tissue has been removed.

BOX 179-2 ANTIMICROBIAL TREATMENT OF NECROTIZING INFECTION OF SKIN, FASCIA, AND MUSCLE

ORGANISM	DRUG OF FIRST CHOICE	ALTERNATIVE DRUGS
Mixed infection	Ampicillin/sulbactam Imipenem/cilastatin, meropenem Ticarcillin/clavulanate Vancomycin (if suspicion for MRSA)	Cefoxitin, clindamycin, or metronidazole + an aminoglycoside
Streptococcus (A, C, G, B)	Penicillin G (+ clindamycin for toxic shock syndrome or necrotizing fasciitis)	Ceftriaxone + clindamycin Vancomycin Linezolid
Enterococcus (systemic Infection)	Penicillin G or ampicillin + aminoglycoside	Vancomycin + aminoglycoside Linezolid Quinupristin/dalfopristin Daptomycin
Staphylococcus aureus	Nafcillin (or oxacillin) Vancomycin (for methicillin-resistant strains)	Cefazolin Amoxicillin/clavulanate Clindamycin Quinupristin/dalfopristin Linezolid Daptomycin
Clostridium perfringens	Penicillin G + clindamycin	Metronidazole + carbapenem Ceftriaxone Chloramphenicol

MRSA = methicillin-resistant *Staphylococcus aureus.*

ADJUNCTIVE THERAPIES

Preoperative hyperbaric oxygen (HBO) has emerged as an important adjunctive therapy for several necrotizing SSTI, especially anaerobic infections such as clostridial cellulitis and myonecrosis.[63] It has been postulated that HBO acts synergistically with many antibiotics, and that it restores the free radical-mediated antibacterial mechanisms of leukocytes in hypoxic tissue.[64] It also appears to cease clostridial production of α-toxin and to directly suppress clostridial growth, and has been demonstrated by retrospective analysis to decrease mortality.[65]

Other adjunctive considerations in treatment of SSTI include the use of intravenous γ globulin for type II necrotizing fasciitis caused by GAS, but evidence for its benefit in the absence of toxic shock syndrome is lacking. There may be a role for granulocyte-stimulating stem cell factor,[9] calcium–channel blockers, glycoprotein IIb/IIIa inhibitors,[66] and photodynamic therapy,[67] but data for all of these adjunctive therapies is limited.

As discussed above, there is some evidence that NSAIDs should be avoided in patients suspected of incubating or expressing early bacterial infections, but this remains controversial since prospective studies have failed to confirm the link between NSAIDs and severe SSTI thus far. *C. perfringens* antitoxins are no longer available for use in humans.

Chapter 180 :: Gram-Negative Coccal and Bacillary Infections

:: Myron S. Cohen, William A. Rutala, & David J. Weber

The Gram stain is used to differentiate among different types of bacteria based on the biochemical properties of their cell walls.[1] The stain is named after Danish scientist Hans Christian Gram (1853–1938) who developed the method to differentiate between two causes of pneumonia (*Streptococcus pneumoniae* and *Klebsiella pneumoniae*).[2] The demonstration of Gram-negative cocci in sterile sites usually indicates infection due to *Neisseria meningitides* or *N. gonorrhoeae*. Gram-negative bacilli may be described as fusiform (e.g., *Fusobacterium nucleatum*, *Capnocytophaga* spp.), curved (e.g., *Vibrio* spp., *Campylobacter* spp., *Helicobacter* spp.), coccobacilli (e.g., *Haemophilus* spp., *Brucella* spp.), or rods (e.g., *Escherichia coli*, *Klebsiella* spp.).

Many of the characteristic cutaneous manifestations of infection with Gram-negative organisms are due to direct microbial invasion of the skin or subcutaneous tissues. In addition, responses of host cytokines, chemokines, receptor molecules (e.g., Toll-like receptors), and other effector cells and factors may contribute to fever, hypotension, and a variety of cutaneous manifestations.[3–7]

INFECTIONS DUE TO *NEISSERIA MENINGITIDIS* (*MENINGOCOCCUS*)

MENINGOCOCCUS INFECTIONS AND THE SKIN AT A GLANCE

- In the United States up to 2,800 cases of meningococcal disease occur annually.
- Skin lesions associated with meningococcemia result from damage to small dermal blood vessels.
- Three clinical syndromes are associated with meningococcal disease: (1) meningitis, (2) meningococcemia, and (3) chronic meningococcemia.
- Purpura and gross hemorrhage correlate with higher numbers of organisms in the bloodstream and indicate a poorer prognosis.

Three clinical syndromes associated with cutaneous involvement occur in meningococcal disease: (1) meningitis, (2) acute meningococcemia, and (3) chronic meningococcemia. Skin lesions are frequently the most dramatic manifestations of these infections. The presence of areas of purpura or gross hemorrhage is associated with higher numbers of organisms in the bloodstream and indicates a poorer prognosis than for a petechial eruption. The epidemiology, pathogenesis, and clinical presentations of these processes have been reviewed.[3,5,6,8,9]

BACTERIOLOGY AND PATHOGENESIS

Neisseria are aerobic, encapsulated, Gram-negative, bean-shaped cocci. *Neisseria meningitidis* grows well on blood-enriched media in 5%–10% CO_2. With potentially mixed bacterial exudates, these organisms should be grown on a selective medium (e.g., modified Thayer-Martin). They can be distinguished from *Neisseria gonorrhoeae* by their fermentation of both glucose and maltose rather than of glucose alone. *Meningococci* are separable on the basis of capsular antigens, of which A, B, C, Y, and W-135 are the major human pathogenic groups. Outer membrane proteins that can identify serotypes are helpful in epidemiologic studies.[5] In an epidemic of meningococcal disease, a shift of capsular group can occur (e.g., from group B to group C and vice versa), which facilitates evasion of host antibodies.[10] Persons with late terminal complement deficiencies are especially prone to systemic infections with *N. meningitides*.[11]

Skin lesions associated with meningococcemia result from damage to small dermal blood vessels. Light and electron microscopy reveal bacteria within endothelial and polymorphonuclear cells in needle aspirate or punch biopsy specimens.[12,13] Endothelial damage, thrombosis, and necrosis of the vessel walls occur. Immunoglobulins and complement are present, even in early lesions.[5,12] Edema, infarction of overlying skin, and extravasation of red blood cells are responsible for the characteristic macular, papular, pustular, petechial, hemorrhagic, and bullous lesions. Many of the cutaneous hemorrhagic lesions may be caused directly by the effects of lipopolysaccharide (LPS) endotoxin or indirectly by stimulation of lease of outer membrane vesicles (blebs) has been observed on electron microscopy of *meningococci* in the plasma of patients with very high levels of circulating endotoxin in fatal meningococcal septicemia.[14] Another contribution to the dermal inflammatory vascular injury, independent of immune complexes and cytokine activity, may be the interaction between vascular endothelium (intercellular adhesion molecule 1) and an adhesion glycoprotein (CD18) on leukocytes, the so-called *dermal (localized) Shwartzman reaction* (LSR).[15] Mouse neutrophils express a surface protein, gp 49 B1, that prevents neutrophil-dependent vascular injury in response to LPS; humans have a leukocyte analog. The LSR requires a priming dose of LPS followed by a systemic challenge 18–24 hours later. A single

intradermal injection of LPS into gp 49 B1-null mice produces an exaggerated microangiopathy in the LSR not seen in wild-type gp 49 B1 mice.[16] LSR and the generalized Shwartzman reaction (in which both doses of LPS are administered systemically) serve as models for the thrombohemorrhagic vasculopathy, purpura fulminans, of meningococcal sepsis. The profound effects on small blood vessels, caused directly by bacterial invasion or indirectly by LPS, host cytokines, or LSR, may lead to diminished blood volume, lowered cardiac output, anoxia, myocardial failure, hypotension, acidosis, and diffuse intravascular coagulation (DIC).[6] Purpura fulminans, the cutaneous manifestation of DIC (see Chapter 144), occurs in 10%–20% of children with meningococcal septic shock and is associated with functional impairment of protein C activation.[8] The latter is thought to result from (1) downregulation of thrombomodulin and endothelial protein C receptor on endothelial surfaces to which protein C binds for its activation, (2) shedding of thrombomodulin from the endothelial surface, and (3) enzymatic cleavage of the thrombin-coupled protein C activation complex.[17]

Chronic meningococcemia is an uncommon disease, which usually begins as a nonspecific febrile illness over the course of weeks to months. It then establishes a pattern of recurrent fever, joint pain, and skin lesions that are present in over 90% of patients. *Meningococci* can usually be isolated from blood during the periodic fevers and rash. As with acute invasive meningococcal infection, chronic infection has been linked to absence of terminal complement components (see below).[18,19] The chronic course of chronic meningococcemia, the lack of endotoxin-like manifestations, and the potential for eventual complications such as meningitis or endocarditis suggest that an unusual host-parasite relationship is central to this rare infection.

EPIDEMIOLOGY

Humans are the only known natural hosts of *N. meningitidis*. Nasopharyngeal carrier rates vary with age: 1% in young children, 5% in those 14–17 years of age, and 20%–40% in adults. In the United States, there are 1,400–2,800 cases of meningococcal disease annually for a case rate of 0.5–1.1 in 10^5 total population.[20] In schools and military camps, or when a carrier of a new strain develops disease in a day care or family setting, carrier rates can increase dramatically.[21,22]

Globally, group A strains have been responsible for epidemics of meningitis, especially in sub-Saharan Africa, where it accounts for about 80%–85% of all cases. In Europe and the Americas, groups B and C have predominated, and in the United States, a recent surge in the group Y disease has been reported. There is increasing evidence of serogroup W-135 being associated with outbreaks of considerable size. For example, in 2000 and 2001 several hundred pilgrims attending the Hajj in Saudi Arabia were infected with *N. meningitides* W-135.[23]

In most industrialized countries, a few clonal serogroup B electrophoretic types (e.g., ET-5 strains) have predominated during recent decades. Similarly, clonal complex ET-37 strains, usually expressing the serogroup C capsule but sometimes expressing serogroup B, W-135, or Y, are found around the world.[5] Adult family members probably introduce the organism into the household, but secondary cases are most frequently spread from ill children to other family members in the same age group, especially under crowded conditions.[24] Household spread is 500–800 times more frequent than the occurrence of secondary cases in the community, and there is an increased incidence of secondary cases in day care centers where large numbers of susceptible children congregate.[6,20] Microbiologists who are exposed to droplets or aerosols containing *N. meningitides* (e.g., by spinning CSF) are also at higher risk of meningococcal disease.[25] The absence of the spleen has been associated with fulminant meningococcal disease.[20]

Immunity to *Meningococci* increases with age, and protective bactericidal antibodies, both IgG and IgM, are found in 70%–95% of young adults. Newborns are often resistant to meningococcal disease until they are 3–6 months of age.[26] Underlying immune defects that confer a predisposition to invasive meningococcal infection include functional or anatomic asplenia, a deficiency of properdin, and a deficiency of terminal complement components.[6] Overall, 75%–85% of identified systemic bacterial infections occurring in individuals with complement deficiencies are cause by *meningococci*.[11]

The quadrivalent vaccine containing polysaccharides of groups A, C, Y, and W-135 had been the only licensed vaccine against meningococcal disease until 2005. Its inadequate protective efficacy in infants led to the development of protein polysaccharide conjugate vaccines that has high protective efficacy in children similar to the *Haemophilus influenzae* type b conjugate vaccine.[27,28] Further, the vaccine has been associated with a reduction of carriage of the vaccine types included in the vaccine. The group B capsular polysaccharide, a polysialic acid polymer similar to fetal neural tissue, does not induce protective immunity. Efforts continue to develop a vaccine using outer membrane proteins of group B organisms and clinical trials are ongoing.[29]

ACUTE MENINGOCOCCEMIA AND MENINGITIS

CLINICAL MANIFESTATIONS

History. The disease often follows a mild upper respiratory tract infection associated with headache, influenza-like complaints, nausea, and muscle soreness. These symptoms can be so short lived that fever, obtundation, and other manifestations of meningitis are the initial findings. In fulminant meningococcemia, vomiting, stupor, precipitous development of a hemorrhagic rash, and hypotension may be evident within a few hours of the onset of symptoms. Milder cases develop at a slower pace.

Cutaneous Lesions. Skin findings in acute meningococcal infections are characteristically petechial, but transient macular or papular lesions (Fig. 180-1A),

Figure 180-1 *Neisseria meningitidis* infection. Acute meningococcemia. **A.** Transient macular and papular lesions on the upper chest. **B.** Discrete pink-to-purple macules and papules, as well as purpura, on the face of a young child. These lesions represent early diffuse intravascular coagulation (DIC). **C.** Map-like gray-to-black areas of cutaneous infarction are seen in this child with DIC.

which can resemble those seen in viral exanthems, may be evident.[30] The petechiae are small and irregular with a "smudged" appearance. Although most often located on the extremities and trunk, lesions can also be found on the head (see Fig. 180-1B), palms, soles, and mucous membranes. Extensive hemorrhagic lesions with central necrosis (suggillations) and bullae can develop. Gangrenous hemorrhagic areas (indistinguishable from purpura fulminans; see Chapter 144) can appear in severe meningococcemia, often with DIC (see Fig. 180-1C). Skin lesions and bacteremia are rarely seen with meningococcal pneumonia.[31] Cellulitis has been noted occasionally, especially in children with meningococcal conjunctivitis (see Section "Primary Meningococcal Conjunctivitis").

Other Physical Findings. Patients with meningitis display signs of meningeal irritation and altered consciousness. Cranial nerve palsies, long-tract signs, seizures, and alterations in vital signs associated with changes in intracranial pressure may be present.

Obtundation and hypotension without meningeal signs, associated with the syndrome of DIC, are characteristic features of fulminant meningococcemia. Rarely, meningococcemia may result in septic foci in other areas: (1) septic arthritis, (2) purulent pericarditis with enlarging cardiac silhouette and findings of tamponade, and (3) bacterial endocarditis. More commonly, a delayed immune complex-mediated syndrome results in a sterile arthritis, pericarditis, or episcleritis.[5] The acute arthritis–dermatitis syndrome, characterized by petechiae and nontraumatic arthritis, has traditionally been identified with disseminated *N. gonorrhoeae* infection (see Chapter 205). There has been a decline of gonococcal cases and an increase in cases of this syndrome caused by *N. meningitidis*.[32]

LABORATORY FINDINGS. A polymorphonuclear leukocytosis is present in peripheral blood and cerebrospinal fluid (CSF) in meningitis. The CSF glucose value is commonly reduced. Characteristic organisms may be seen on Gram-stained smears of fluid, and *Meningococci* are usually isolated from the CSF. *N. meningitidis* may be isolated from the blood of approximately one-third of patients with meningitis and from almost 100% of patients with acute meningococcemia. Demonstration of organisms in cutaneous lesions has been variable, and the presence of Gram-negative commensal organisms on the skin requires cautious interpretation. Reports describe positive results for 50%–80% of aspirates, skin film samples, and punch biopsy specimens of petechial lesions.[12,33]

In patients already exposed to antimicrobial agents, the development of rapid, accurate, and inexpensive procedures for detection of soluble antigens in the CSF has been a major advance. The latex agglutination method and enzyme-linked immunosorbent assay methods are sensitive and very specific, but their clinical usefulness in most situations has been questioned.[34] More recently, the polymerase chain reaction (PCR)

has been used to detect *N. meningitides* in cerebrospinal fluid and/or blood.[35] Further, PCR can be used to type strains, a useful adjunct in epidemic situations. However, PCR is not widely available.

HISTOPATHOLOGY. Endothelial swelling is seen, a perivascular infiltrate of polymorphonuclear leukocytes is present, thrombi occlude capillaries and postcapillary venules, and the walls of capillaries and venules are destroyed, as in leukocytoclastic vasculitis (see Chapter 163).

DIFFERENTIAL DIAGNOSIS. Meningococcal infection warrants consideration in a patient with fever and a petechial or purpuric eruption, even in the absence of clinical meningitis (Box 180-1). Occasionally, the characteristic rash is absent, which delays consideration of meningococcal disease.

COURSE AND PROGNOSIS. If untreated, acute meningococcal disease usually ends fatally. With treatment, recovery occurs in 90% of patients with meningitis.

In severe meningococcemia, especially with the rapid emergence of cutaneous hemorrhages, hypotension, and DIC, the entire course from onset to death can be measured in hours. In patients with sepsis-associated DIC, cutaneous thrombotic hemorrhages on the distal extremities may lead to skin and digital necroses that necessitate amputation.[36] Rarely, young children with meningococcal sepsis, shock, and DIC suffer thrombotic injury that causes growth plate arrest.[37] Myocardial dysfunction often occurs in meningococcal septic shock and is associated with high circulating levels of interleukin 6.[38] These cases are often associated with massive adrenal hemorrhage (*Waterhouse–Friderichsen syndrome*). Children who die from meningococcal septic shock have relatively low cortisol levels (but not in the range expected in adrenal insufficiency).[39] The mortality rate for meningococcal septic shock approaches 100%. Gradations in the severity of meningococcal disease make it difficult to assign an accurate prognosis, although a bedside predictive model has been proposed.[6,40]

BOX 180-1 DIFFERENTIAL DIAGNOSIS OF ACUTE MENINGOCOCCEMIA

- Acute bacteremias and endocarditis: in endocarditis, mucous membrane and conjunctival lesions, as well as subungual "splinter" hemorrhages, occur. Very infrequently, numerous petechial and purpuric lesions occur in patients with acute *Staphylococcus aureus* endocarditis. Usually, a few skin lesions in a patient with acute *S. aureus* endocarditis are purulent purpura. In acute gonococcemia, the skin lesions are usually acral, nodular, hemorrhagic, and few in number (see Chapter 205). Occasional patients with *Haemophilus influenzae* or *Streptococcus pneumoniae* bacteremia develop petechial eruptions.
- Cutaneous necrotizing vasculitis (see Chapter 163): here, lesions are usually palpable. Renal involvement and hypertension may be present.
- Enteroviral infections: fever, petechial eruptions, and aseptic meningitis are frequent features.
- Rocky Mountain spotted fever: the history of exposure to ticks in an endemic area, absence of an antecedent respiratory infection, and delay in appearance of the rash are clues (see Chapter 199).
- Toxic shock syndrome (see Chapter 177).
- Purpura fulminans (see Chapters 144 and 181).
- Weil disease (leptospirosis) (see Chapter 183).

CHRONIC MENINGOCOCCEMIA

CLINICAL MANIFESTATIONS

History. The manifestations of chronic meningococcemia are vague at onset but tend to establish a pattern over a period of weeks or months.[18,41,42] Initially, there may be an acute febrile illness, but it wanes and leaves the patient with intermittent muscle aches, joint soreness, mild headache, and anorexia with weight loss. The simultaneous emergence of a localized rash with several days of fever and joint soreness is characteristic. As fever recedes, the rash fades, and the patient may be totally free of skin manifestations for days or weeks. This pattern of recurring fever and rash may last from a few weeks to 6 or 8 months. Untreated cases may eventually evolve into acute meningococcemia, meningitis, or endocarditis. Several case reports have related this syndrome to the absence of a terminal component of complement, a finding also observed in sporadic and recurrent acute meningococcal infections.

Cutaneous Lesions. Skin lesions are usually distributed about one or more painful joints or on pressure areas in contrast to the acral distribution in gonococcemia. They may vary in appearance and size (1–20 mm) from one crop of lesions to the next and include (1) pale to rose-colored macular and papular lesions (the most common type), (2) slightly indurated and tender erythema nodosum-like nodules, (3) petechiae of variable size, (4) petechiae with vesicular or pustular centers, (5) hemorrhage (minute) with an areola of paler erythema, and (6) grossly hemorrhagic areas with pale blue–gray centers.

Other Physical Findings. Aside from the rash, the physical findings of chronic meningococcemia are minimal, except for occasional joint swelling and tenderness.

HISTOPATHOLOGY. The skin lesions differ pathologically from those in acute meningococcemia in that bacteria are absent, and fluorescent antibody techniques do not detect meningococcal antigens. Also, thrombi do not occlude capillaries and venules,

endothelial cell swelling is absent, and the perivascular infiltrate consists of mixed polymorphonuclear and mononuclear cells.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS. During febrile periods, blood cultures frequently reveal *Meningococci* and provide the specific diagnosis. Recently, a novel *i-Neisseria menigitidis* specific PCR assay was used to identify *N. menigitidis* in skin biopsy specimens even though blood cultures remained negative.[43]

A number of diseases with periodic fever, skin lesions, and joint involvement resemble chronic meningococcemia:

- Subacute bacterial endocarditis: a prolonged febrile course with a pleomorphic petechial rash, joint symptoms, and no overt focus make subacute bacterial endocarditis an important consideration. A prominent heart murmur, evidence of renal impairment, and blood cultures help establish the diagnosis.
- Acute rheumatic fever: when fever is prolonged, joint findings are prominent, and macular and papular rashes appear, the diagnosis may be acute rheumatic fever (see Chapter 160).
- Henoch–Schönlein purpura: the petechial hemorrhagic rash in Henoch–Schönlein purpura is more often symmetric, usually only on the lower extremities, and does not have the periodicity of the rash of chronic meningococcemia (see Chapter 163).
- Rat-bite fever, also referred to as *Haverhill fever*, may be acute (mimicking acute meningococcemia) or chronic (resembling chronic meningococcemia). Intermittent fever, rash, and joint manifestations are hallmarks of an illness that follows a rodent bite or ingestion of contaminated milk (see Chapter 183).
- Erythema multiforme: the iris-type configuration of lesions suggests erythema multiforme (see Chapter 39).
- Gonococcemia (chronic): the cutaneous and joint manifestations of chronic gonococcemia may continue for many days or weeks (see Chapter 205), and tenosynovitis in gonococcemia can be an important clue.

COURSE AND PROGNOSIS. Some patients with chronic meningococcemia recover spontaneously without specific therapy, whereas others develop serious systemic complications, such as endocarditis or meningitis. The prognosis for treated infection is excellent.

PRIMARY MENINGOCOCCAL CONJUNCTIVITIS

N. meningitidis is responsible for up to 2% of cases of bacterial conjunctivitis. The source of infection is either direct inoculation of airborne organisms from close contact with carriers or manual contact with secretions from the patient's own nasopharynx.[44]

TREATMENT AND PROPHYLAXIS

CHEMOTHERAPY. Widespread emergence of sulfonamide-resistant strains, approximately 40 years ago, has complicated therapy for meningococcal infections. Initially, these strains belonged predominantly to serogroup B, but in recent years, they have been from serogroups A to C. More recently, increasing penicillin resistance has led to the recommendation to use a third-generation cephalosporin (ceftriaxone or cefotaxime) as primary therapy.[45] Alternatives (provided the strain is susceptible) include penicillin G, ampicillin, fluoroquinolone, or aztreonam.[45]

The usual adult dosage of ceftriaxone is 2 g every 12 hours or cefotaxime 2–3 gm every 6 hours. Penicillin G (adult dose, 4 MU every 4 hours) or ampicillin (adult dose, 2 g every 4 hours) may be used if the penicillin MIC is less than 0.1 μg/mL. The usual duration of therapy is 7 days. Similar therapy should treat chronic meningococcemia. In highly penicillin-allergic adults, administration of chloramphenicol (1 g IV every 6 hours) is preferable to risking cross-reactions with a third-generation cephalosporin. However, increasing resistance of meningococcal strains to chloramphenicol worldwide could change this recommendation.[46] All meningococcal isolates from blood, CSF, or other normally sterile body cavities should be tested for penicillin susceptibility.[6] Immune complex-associated complications (fever, sterile arthritis, vasculitis, pericarditis, episcleritis) can occur in 15% of patients 4–10 days after initiation of antimicrobial therapy for severe meningococcal disease.[47]

SUPPORTIVE THERAPY. Although it has been postulated that hypotension in acute meningococcemia may be due to adrenal failure associated with Waterhouse–Friderichsen syndrome (adrenal hemorrhage), blood cortisol levels and corticosteroid secretion rates have been found to be elevated or in the low normal range (not in the range associated with adrenal insufficiency).

The modern treatment of shock in sepsis begins with a number of well-accepted measures, including antibiotic selection, drainage procedures for abscesses, appropriate use of volume expanders, administration of β-adrenergic-stimulating drugs such as dopamine or isoproterenol, correction of severe acidosis, and, in selected patients, use of peripheral vasodilators. Therapies still considered experimental include those that neutralize host cell-mediated cytokines (e.g., interleukin 1, tumor necrosis factor) and protein C. Although numerous studies of glucocorticoid therapy have been completed, results have been variable, and on balance glucocorticoids do not appear to be indicated for septic shock.

Because of the impaired conversion of protein C to its activated form through the downregulation of thrombomodulin by inflammatory cytokines during sepsis, intravenous recombinant human activated protein C (drotrecogin alfa activated) has been evaluate for its efficacy as an adjunct in treating sepsis. However, a placebo-controlled randomized clinical trial in adults[48] with severe sepsis and a low risk of death, and a placebo-controlled randomized trial in children[49] with

severe sepsis failed to demonstrate benefit. Neither of these trials included substantial numbers of patients with meningococcal sepsis. In an earlier randomized trial of patients with severe sepsis, recombinant human activated protein C reduced the mortality rate from 30.8% in the placebo group to 24.7% in those receiving drotrecogin alfa.[50] The incidence of serious bleeding was 3.5% in the drotrecogin alfa group compared with 2.0% in the placebo group. Any patients with meningococcal infection with disseminated intravascular coagulation (DIC) should be closely monitored for increased bleeding. Severe meningococcal infections can be complicated by the syndrome of DIC. The basis for the diagnosis is usually a composite of associated hematologic abnormalities, including thrombopenia and hypofibrinogenemia, prolongation of the prothrombin time and partial thromboplastin time, and the presence of fibrin split products. If bleeding occurs, it may be necessary to administer fresh frozen plasma. Treatment for each case must be individualized, because therapy may be harmful and produce more problems than the DIC syndrome. Data on the use of heparin in treating DIC remain unconvincing, and because of potential adverse effects, this drug is no longer recommended. Investigators continue to study antibodies to various cytokines whose levels are elevated in meningococcal septicemia and immunomodulatory therapies.[51]

CHEMOPROPHYLAXIS. There is a critical need for reliable chemoprophylaxis to rapidly protect children exposed in a day care nursery, contacts in a crowded household, and institutional groups, because secondary cases can emerge, often within 24–48 hours of an index case.[21,52]

Rifampin, ceftriaxone, ciprofloxacin, and azithromycin are appropriate drugs for chemoprophylaxis in adults. The drug of choice for most children is rifampin (>1 month of age, 10 mg/kg, maximum 600 mg, orally, every 12 hours for 2 days).[53] However, rifampin resistance occurs and reports have documented the development of invasive meningococcal disease. Fortunately, ciprofloxacin and ofloxacin are effective single-dose substitutes, and ceftriaxone is available for parenteral single-dose use in children as well as adults. Azithromycin has demonstrated the ability to clear carriage in one study.

IMMUNIZATION. The meningococcal conjugate vaccine (MCV4 which contains groups A, C, Y, and W-135) is preferred for children, adolescents, and adults less than 55 years of age. MCV 4 is indicated for children 2 through 10 years of age with persistent complement component deficiency, anatomic or functional asplenia, and certain other conditions placing them at high risk. It is also indicated for all adolescents at 11 or 12 years of age (catch period, 13 through 18 years of age). MCV4 is indicated for adults less than 55 years of age who have the following risks: anatomic or functional asplenia, persistent complement component deficiencies, first year college students living in dormitories, microbiologists routinely exposed to isolates of *N. meningitides*, military recruits, and persons who travel to or live in countries in which meningococcal disease is hyperendemic or epidemic.

The polysaccharide vaccine (groups A, C, Y, and W-135 *N. meningitidis*) is safe and effective in preventing meningococcal disease in adults and is preferred for adults who are 56 years of age or older. Indications are the same for adults of 55 years of age or younger.

Elucidation of the complete genome of *N. meningitidis* has identified several conserved proteins that, in an experimental mouse model, have been protective against challenge with all pathogenic *N. meningitidis* organisms.

SPECIAL CONSIDERATIONS FOR THE HEALTHCARE WORKER. Patients, who present with cutaneous findings that are consistent with acute meningococcal infection, represent a medical emergency. Because the course of the disease is so rapid, it is imperative that appropriate diagnostic samples (i.e., blood and cerebrospinal fluid) be collected in an expedient manner and then the patient started immediately on empiric antibiotic therapy. If cerebrospinal fluid cannot be rapidly obtained, then the patient should be started on empiric therapy and the cerebrospinal fluid obtained as soon as feasible. All patients with known or suspected invasive meningococcal infection should be placed on Droplet Precautions (private room, healthcare providers wear a surgical mask when in the room). If the patient is in an open area (e.g., emergency department), a surgical mask should be placed over the patient's mouth and nose (if possible). Droplet precautions should be continued until the patient has been on appropriate therapy for at least 24 hours.

INFECTIONS DUE TO *PSEUDOMONAS AERUGINOSA*

PSEUDOMONAS AERUGINOSA INFECTIONS AND THE SKIN AT A GLANCE

- The ubiquitous Gram-negative bacillus *Pseudomonas aeruginosa* can cause serious infections, usually in individuals who have altered defenses, who are receiving intense antibiotic therapy, or who are in the hospital.
- Cutaneous manifestations of *Pseudomonas* infections are common and characteristic.
- These cutaneous manifestations may represent the overt finding in septicemia (ecthyma gangrenosum) or may be the localized focus of serious infections of the ear.
- *Pseudomonas* infection can produce trivial cutaneous lesions involving the nails, toe webs, other skin areas, and external auditory canal.

BACTERIOLOGY AND PATHOGENESIS

Pseudomonas aeruginosa is a nonfermentative, obligately aerobic, Gram-negative bacillus. Some strains produce a blue pigment (pyocyanin), a water-soluble yellow–green substance (fluorescein), or black pyomelanin. With Wood's lamp, the presence of organisms in lesions of skin or nails can be detected if the infecting strain produces fluorescein. The pigments impart a characteristic greenish color to the surrounding growth media or the tissue substrate involved in clinical disease (e.g., "green nail" syndrome, Fig. 180-2). In addition, an odor of grapes, characteristic of trimethylamine, often accompanies the growth of these microorganisms.

Organisms gain entry at sites of maceration, dermatophytic foci, trauma, or foreign bodies (e.g., indwelling venous catheters), or via aspiration into the respiratory tract. Infections in otherwise healthy individuals are unusual; when they occur, the involved regions are often areas with increased moisture (e.g., toe webs, the external auditory canal). Infection may begin in the base of the nail in persons who frequently have their hands or feet in water. This can progress to paronychia, followed by development of a green–blue discoloration of the nail due to local pigment production. The ability of this organism to infect healthy, but moistened, skin is evidenced by the occurrence of disseminated papules and pustules on areas of skin of people immersed in hot tubs ("hot tub folliculitis," Fig. 180-3), wading pools, and swimming pools.[52] These ubiquitous organisms can sometimes be aggressive secondary invaders in open wounds, in decubitus and other skin ulcerations, or in association with thermal burns. Rarely, a superficial pyoderma due solely to *Pseudomonas* is engrafted on a generalized or localized dermatitis, such as tinea pedis or eczema, producing irregular pustular areas with macerated borders.[64] Serious invasive infections occur in debilitated patients; malnourished infants; individuals whose normal bacterial flora has been suppressed by antibiotics; patients with neoplastic diseases, granulocytopenias, or impaired circulating or cellular immunity, including that associated with acquired immunodeficiency syndrome (AIDS)[65]; and individuals requiring mechanical respiratory assistance. These organisms frequently colonize body surfaces and survive exposure to antibiotics. *P. aeruginosa* can spread widely via the bloodstream, producing a disseminated infective vasculitis in which organisms can appear in the adventitia and media of vessels without luminal clots. Occasionally, features of the generalized Shwartzman reaction are found, but less frequently than in infections due to *N. meningitidis* or *Enterobacteriaceae*.

Figure 180-2 *Pseudomonas aeruginosa* infection. "Green nails." This 36-year-old bartender noted a greenish yellow discoloration of 8 of 10 fingernails during the preceding year. Several of the fingers show chronic candidal paronychia as well.

Figure 180-3 *Pseudomonas aeruginosa* infection. "Hot tub folliculitis." This 22-year-old woman noted the appearance of erythematous, pruritic papules and pustules on the trunk, buttocks, and upper thighs several days after bathing in a hot tub. The eruption resolved without antibiotic therapy.

EPIDEMIOLOGY

Because *P. aeruginosa* is widely distributed in nature, it is not surprising that it may contaminate plants, vegetables, hot tubs, and swimming and wading pools. Moist regions of skinfolds and the external auditory canal are the most common sites of colonization (3%–5% of cases). *P. aeruginosa* is found in small numbers in the feces of 10%–20% of the population.

Any activity that leads to excessive local moisture—laundry work, dishwashing, or hiking for long periods in wet terrain—will enhance the growth of these organisms. Moist or weeping cutaneous lesions

(e.g., thermal burns) encourage the growth of *Pseudomonas* as well as of other Gram-negative bacteria. Increased environmental humidity is frequently associated with overgrowth of these organisms. Synthetic sponges easily become contaminated with Gram-negative bacteria and have served as vehicles of transmission.

Systemic infection with *P. aeruginosa* depends primarily on altered susceptibility of the host rather than on spread from individual to individual or on increased pathogenicity. However, exceptions may be seen in newborn nurseries, respiratory care units, and occasionally urology wards, where dissemination from a primary source may occur. Neutropenic or immunocompromised hospitalized patients are more likely to become colonized and develop invasive disease. *P. aeruginosa* is the sixth most common pathogen in healthcare-associated infections (ranks seventh for central line-associated bloodstream infections, fourth for catheter-associated urinary tract infections, second for ventilator-associated pneumonia, and fifth for surgical site infections).[66]

LOCAL AND SECONDARILY INFECTED LESIONS

Pseudomonas produces a number of characteristic lesions. In addition, colonization by these organisms complicates other skin diseases and open wounds.[51]

CLINICAL MANIFESTATIONS

History. Painful paronychial lesions, with or without characteristic green discoloration of the nails, occur most often in women with a history of continual immersion of the hands in water with soaps and detergents. People with toe web infection characteristically work in an atmosphere of high humidity, often have wet feet, and experience soreness and scaling of web tissues. There are numerous reports of the appearance of skin rashes in healthy individuals within 1–5 days after the use of public bathing facilities such as therapeutic or recreational whirlpools, hot tubs, or swimming pools (see Fig. 180-3).[67] *P. aeruginosa* organisms have been isolated in large numbers from pool water. The rash usually clears without therapy within 1 week but is often accompanied by malaise, low-grade fever, external otitis, and mastitis. *P. aeruginosa* folliculitis has also occurred after shower or bath exposure or exposure to contaminated bath articles.[68] Hot-foot syndrome caused by *P. aeruginosa* contamination of a wet surface exemplifies the organism's opportunism in infecting the ventral surfaces of feet abraded by a roughened floor.[69,70]

Cutaneous Lesions. In addition to a tender paronychial lesion, patients with green nail syndrome may have a nail that is partly or entirely green. The color may be in horizontal bands, representing intermittent activity of the infection at the nail base (see Fig. 180-2). Individuals with toe web *Pseudomonas* infections have thick, macerated, scaling, foul smelling discolored areas between the toes. Hot-foot syndrome is characterized by tender, painful, red plantar nodules that develop within 1–2 days of exposure to an abrasive wet surface, such as a wading pool.[70]

In acute diffuse external otitis, the lesion has a swollen, macerated appearance in the local area without involving the eardrum. Often referred to as *swimmer's ear*, the condition produces intense swelling and discoloration with excruciating pain on movement of the pinna. The most common pathogen causing swimmer's ear is *P. aeruginosa*, although other organisms can cause the syndrome including *Proteus vulgaris*, *E. coli*, *Staphylococcus aureus*, *Streptococci*, *Enterobacter aerogenes*, *K. pneumoniae* and *Citrobacter* spp.[71] If the skin is traumatized, local infection can spread to the pinna, producing perichondritis and chondritis with intense tender swelling. Cartilaginous necrosis may result unless immediate drainage with through-and-through incisions and appropriate antibiotic therapy are instituted.[72] The most severe form of *Pseudomonas* infection, malignant external otitis, has a high mortality rate if therapy is delayed or inadequate.[73,74] It usually occurs in elderly people with diabetes but may also be seen in healthy elderly people after surgery or minor trauma, such as water irrigation of the external canal, and in patients with AIDS.[75] The onset and early progression are insidious, with swelling, erythema, moderate discharge, and pain without fever or constitutional symptoms. As the surface breaks down, *Pseudomonas* invades the soft tissues at the junction of cartilage and bone; the process then advances to involve cartilage, mastoid, and temporal bone. Inflammation at the stylomastoid and jugular foramina can lead to seventh nerve palsy followed by palsy of the ninth to eleventh nerves. Diagnosis is made clinically if granulation tissue can be seen erupting at the cartilage-bone interface in the posterior inferior canal wall. The pinna is often swollen, and pain is intense.[74]

In patients who develop folliculitis, the rash can be localized if only a limb has been immersed, or generalized, or in intertriginous areas. The rash begins as erythematous papules, evolves to papulopustules (see Fig. 180-3), and eventually heals with fine desquamation and occasional pigmented macules. Pruritus and pain may accompany the lesions along with localized areas of mastitis and external otitis. Serotype 0–11 of *P. aeruginosa* is most commonly involved.

A small outbreak of *P. aeruginosa* 0–11 folliculitis occurred in granulocytopenic patients in a cancer treatment center, but the lesions in these patients, in contrast to those in healthy individuals with swimming pool folliculitis, rapidly became widespread and progressed to bullae, which became necrotic (ecthyma gangrenosum like) unless systemic antibiotic treatment was begun immediately.[76] Thus, ecthyma gangrenosum (see Section "Septicemia and Cutaneous Involvement") can result from progression of initial folliculitis in an immunocompromised patient as well as from *P. aeruginosa* bacteremia.

Although gangrene of the genitalia and perineum (Fournier gangrene) is almost always caused by a polymicrobial (facultative species and anaerobes) or group A streptococcal infection, exceptional cases have been attributed to *P. aeruginosa*.[77] Necrotizing

fasciitis generally has similar causes, but in rare cases monomicrobial *P. aeruginosa* necrotizing fasciitis has occurred, usually involving the vulva or abdominal wall, in children with acute lymphoblastic leukemia.[78] Such patients are febrile; the infected area is painful, erythematous, and edematous, with subsequent skin necrosis; and bacteremia is present. Necrotizing fasciitis due to *P. aeruginosa* has also occurred in an immunocompetent infant.[79]

In secondarily infected skin areas, irregular, superficial pustular lesions may be superimposed on underlying skin disease; the margins of these regions are usually sharply defined and may exhibit the characteristic grape-like odor and pigmented exudate.[80] *P. aeruginosa* infection of a chronic ulcer occasionally progresses to *Pseudomonas* cellulitis.[81]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS.

Nail and skin lesions, resulting from *Pseudomonas* infection, are recognized by the characteristic pigment. The organisms can be identified as thin Gram-negative rods, or a mixed infection (e.g., with *Candida*) may be observed. Fluorescence, demonstrated with a Wood's lamp, can support the diagnosis. Occasionally, *Aspergillus* infection of the nails produces a greenish color, and there is usually no associated paronychia. A subungual hematoma may superficially resemble *Pseudomonas* nail infection.

COURSE AND PROGNOSIS.

Patients with minor *Pseudomonas* infections (e.g., onychia and paronychia, toe web inflammation, whirlpool-associated skin rash, and external otitis) usually improve rapidly with topical therapy and drying of the affected area. Malignant external otitis requires the systemic administration of antibiotics directed against *Pseudomonas*, including a fluoroquinolone with or without an antipseudomonal β-lactam antibiotic (e.g., ceftazidime, cefepime, imipenem or meropenem). High dosages and prolonged therapy are combined with surgical debridement to limit spread to bone and nervous system.[82]

SEPTICEMIA AND CUTANEOUS INVOLVEMENT

CLINICAL MANIFESTATIONS

History. In individuals with suspected *Pseudomonas* septicemia, history taking is most frequently centered around the underlying problem and antecedent therapy. A premature infant may have required resuscitation and treatment of a nonspecific pneumonitis before developing high fever, obtundation, and macular or hemorrhagic vesicular skin lesions. Infants may present initially with omphalitis or severe diarrhea, followed by septicemia and skin lesions. Urinary tract infections complicating exstrophy of the bladder may predispose the infant to bacteremia. In adults, there is usually a background of antibiotic therapy, immunoglobulin deficiency, diabetes mellitus, treatment with glucocorticoid hormones or antitumor agents, or the use of percutaneous catheters. Frequently, the patient is granulopenic, has already had a significant febrile illness, and may still be receiving antibiotics when one of the characteristic cutaneous manifestations develops. The local lesions are rarely painful. Occasionally, hemorrhagic manifestations may develop secondary to platelet reduction or DIC.

Pseudomonal involvement of the gastrointestinal tract, particularly in the tropics, may produce the picture of an acute enteric infection, with headache, high fever, diarrhea, and rose spots (Shanghai fever) resembling typhoid fever. The same enteric syndrome with ecthyma gangrenosum has occurred in previously healthy infants.[82]

Cutaneous Lesions. Skin lesions, the most characteristic physical findings in *Pseudomonas* septicemia, consist of four types[83]:

1. *Vesicles and bullae*. Singly or in clusters, these lesions spread in random fashion over the skin. They become hemorrhagic as they evolve. Occasionally, in infants they may be surrounded by large erythematous halos and be mistaken for erythema multiforme.
2. *Ecthyma gangrenosum*. This lesion starts with an erythematous or purpuric macule and develops rapidly into a hemorrhagic bulla that ruptures; becomes a gunmetal gray, infarcted lesion with surrounding erythema (Fig. 180-4); and evolves into a necrotic black or gray–black eschar and surrounding erythema (Fig. 180-5). Frequently, the lesion is in the anogenital or axillary region. Noma neonatorum, a gangrenous process of the nose, eyelids, oral cavity, or anal area and genitalia, occurs in premature newborns and other infants.[84] It is similar in appearance to noma, which occurs in young debilitated infants. Whereas the infecting agent in noma is *Fusobacterium*, noma neonatorum is caused *by P. aeruginosa*.

Figure 180-4 *Pseudomonas aeruginosa* infection. Ecthyma gangrenosum. Gunmetal gray, painless, infarcted lesions with surrounding erythema.

Figure 180-5 *Pseudomonas aeruginosa* infection. Ecthyma gangrenosum. This 32-year-old man with human immunodeficiency virus infection noted the onset of a very tender plaque on the right buttock associated with fever and malaise. **A.** Five-day-old lesion with a central infarcted, necrotic area surrounded by erythema. **B.** At 5 weeks, the lesions had improved after ciprofloxacin treatment, which was discontinued because of an adverse drug reaction. Without antibiotic treatment, the necrotic area enlarged and was associated with bacteremia. Eventually, the lesion reepithelialized, but the patient died of pseudomonal pneumonia.

3. *Gangrenous cellulitis*. Sometimes presenting as a sharply demarcated, superficial, painless, necrotic lesion, gangrenous cellulitis may resemble a decubitus ulcer. However, it is located in a nonpressure area and may complicate a prior area of injury, such as a thermal burn. Also, it may begin abruptly, producing local pain, swelling, and erythema, and involving deep subcutaneous tissue and fascia. Local injury or bacteremia may introduce the infection.
4. *Macular or papular nodular lesions*. These lesions are small, oval, and painless, located predominantly over the trunk. They resemble the rose spots of typhoid fever.

Another cutaneous manifestation of *Pseudomonas* septicemia, usually occurring after days or weeks, is suppurative panniculitis. The lesions are red, warm, and sometimes fluctuant, but often situated deeply enough to feel solid. Surgical incision reveals suppuration, and *P. aeruginosa* can be isolated.[83,85] A variation of this manifestation consists of numerous red, nonfluctuant, hot, nontender, subcutaneous nodules that may be accompanied by other characteristic lesions, such as hemorrhagic bullae and ecthyma gangrenosum. Such lesions may be treated successfully by combination antipseudomonal antibiotic therapy.

Other lesions that may appear in systemic *Pseudomonas* infection include petechiae, ecchymoses, dermal Shwartzman-like reactions, and purpura fulminans.

Other Physical Findings. Patients with *Pseudomonas* septicemia frequently exhibit physical findings associated with their underlying diseases: malnutrition, mucous membrane ulcerations, glossitis secondary to antibiotic therapy and granulocytopenia, urinary tract infections, proctitis, adenopathy, hepatosplenomegaly, and hemorrhagic bronchopneumonia.

LABORATORY FINDINGS.

Hematologic examination may reveal leukocytosis or leukopenia, based on the underlying illness. Platelet levels may be diminished, and levels of fibrinogen and other clotting factors may be reduced in association with DIC, liver disease, or profound malnutrition.

Characteristically, in *Pseudomonas* septicemia aspirated material from bullae, areas of cellulitis, and papular or nodular lesions reveals numerous organisms but few leukocytes, even in patients with leukocytosis. Cultures of these lesions and of blood show *Pseudomonas*.

PATHOLOGY.

The distinctive finding in *Pseudomonas* lesions is a necrotizing vasculitis in which a myriad of bacteria invade the walls of small arteries and veins.[79] Extravasation occurs around the vessels, edema and bland necrosis in the perivascular and adventitial regions are extensive, and blood flow supplied by the affected vessel is decreased. Organisms tend to spread along the exterior surfaces of vessels and invade the skin. Similarly, bacterial invasion of the blood vessel walls in lungs, liver, and other organs produces nodular necrotic lesions.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS.

Ecthyma gangrenosum skin lesions in an acutely ill patient suggest the diagnosis of *Pseudomonas* septicemia. The finding of abundant Gram-negative rods with rare granulocytes in vesicle fluid or in association with gangrenous or hemorrhagic cellulitis constitutes further presumptive evidence.

The differential diagnosis of *Pseudomonas* septicemia includes other infections that can produce ecthyma gangrenosum and other skin lesions through direct involvement of blood vessels (e.g., those caused by *N. meningitidis*, *Aeromonas hydrophila*, *Escherichia coli*, *Klebsiella pneumoniae*, *Citrobacter freundii*, *Morganella* sp., *Vibrio vulnificans*, *Burkholderia cepacia*, *Stenotrophomonas*

maltophilia, *Moraxella* sp., and fungi of the *Aspergillus*, *Fusarium*, and *Rhizopus* groups).[86] *Chromobacter violaceum*, a saprophyte present in water and soil in tropical and subtropical (e.g., Southeastern United States) environments, is a rare cause of ecthyma gangrenosum in the setting of chronic granulomatous disease of childhood, a condition predisposing to infections with this microorganism.[87] Pyoderma gangrenosum and gangrenous herpes simplex may mimic ecthyma gangrenosum.[88]

COURSE AND PROGNOSIS.

Pseudomonas septicemia is frequently the terminal event in a patient with malignant disease or altered defense mechanisms. Therapy may be effective and recovery complete in some instances when septicemia occurs in patients with more favorable underlying problems, such as urinary tract infections, or in patients with venous catheters.

TREATMENT AND PROPHYLAXIS

Local Infections. Superficial skin and toe web infections and onychia usually respond to application of acetic acid, silver nitrate, or gentian violet compresses two to three times daily between long periods of drying. Paronychia is best treated by surgical drainage, nail trimming, and application of 4% thymol in chloroform. Acetic acid, polymyxin (0.1%) in acetic acid, or glucocorticoids with neomycin are effective for otitis externa. When acetic acid is used topically on chronic ulcers, a 2%–5% solution is often effective.[71] In addition, topical silver nitrate (0.5%) or silver sulfadiazine may eradicate these organisms in burn patients (see Chapter 95).

Systemic Infections. *Pseudomonas* septicemia requires early systemic bactericidal antimicrobial therapy. Effective agents include the aminoglycosides (gentamicin, tobramycin, amikacin). One of these drugs is combined with ceftazidime or cefepime, an antipseudomonal penicillin (e.g., piperacillin-tazobactam), or a carbapenem (imipenem or meropenem or doripenem) and given IV to patients who are acutely ill. In the presence of hypotension or any renal impairment, the dosage of aminoglycoside must be reduced; aminoglycoside serum levels should guide therapy.

In addition to the parenteral administration of antibiotics, surgical drainage is appropriate for nodular and fluctuant lesions. Acute *P. aeruginosa* gangrenous cellulitis/fasciitis requires debridement (often extensive), sometimes with a surgical "second look" 1 or 2 days later. *P. aeruginosa* infections are especially serious in neutropenic patients. A number of different vaccines and monoclonal antibodies have been developed in the past decade for active and passive immunization against *P. aeruginosa* but all remain experimental at the present time.[89]

SKIN INFECTIONS DUE TO OTHER *PSEUDOMONAS* SPECIES

Pseudomonas putrefaciens, now renamed *Shewanella putrefaciens*, is a rare cause of cellulitis, particularly chronic infected ulcers of the lower extremities.[90] The natural habitat of the organism is water and soil, and it is a rare cause of cellulitis and bacteremia after contamination of a laceration.[91]

INFECTIONS DUE TO *HAEMOPHILUS INFLUENZAE*

HAEMOPHILUS INFECTIONS OF THE SKIN AT A GLANCE

- *Haemophilus influenzae* cellulitis involves the face, neck, or upper extremities.
- Most cases occur in young children (6–24 months of age), but the infection can occur in adults.
- Because of immunization with *H. influenzae* conjugate vaccines, invasive *H. influenzae* disease has nearly disappeared in industrialized countries, but it persists as a major problem in developing countries.

BACTERIOLOGY AND PATHOGENESIS

Haemophilus influenzae is a small, pleomorphic Gram-negative coccobacillus with fastidious growth requirements, including the presence of heme and nicotinamide nucleoside. There are rough and encapsulated forms, the latter of which are divided into six types (a through f) based on capsular polysaccharide antigens.

Most invasive infections with *H. influenzae*, including meningitis, epiglottitis, and cellulitis, are caused by encapsulated type b strains (Hib). Rough strains do not cause cellulitis, but are involved in acute otitis media, exacerbations of chronic bronchitis, and pneumonia.[92] A hyperacute disease, Brazilian purpuric fever, characterized by fever, purpura, and shock, is caused by nontypeable *H. influenzae* biogroup aegyptius strains producing an extracellular hemagglutinin that may be a virulence factor.[93] Fever often reaches 39.4°C–40.6°C (103°F–105°F) by the end of the first week. During the second week, rose spots may appear on the trunk, and diffuse abdominal cramping becomes prominent, sometimes accompanied by diarrhea.

Most Hib skin infections are preceded by an upper respiratory tract infection or acute otitis media. The characteristic localization of the cellulitis to the upper part of the body argues for the sequence of upper respiratory tract infection, fallout onto or invasion of the skin locally, and then bacteremia. This sequence is evident in adult as well as in pediatric cases. A primary bacteremic mechanism with secondary localization in the skin would be favored by a more random and widespread distribution of lesions than is seen. Localization of a subclinical bacteremia could follow

trauma and has been suggested as a possible predisposing event.

EPIDEMIOLOGY

Humans are the only known natural host for *H. influenzae*. These potentially pathogenic bacteria are carried in the oropharynx and nasopharynx, especially in children up to age 5 years, as part of the normal indigenous flora. However, early immunization using conjugate Hib vaccines has markedly decreased nasopharyngeal carrier rates, increased herd immunity, and caused a dramatic decline in invasive clinical disease.[94] Cellulitis, meningitis, pneumonia, and epiglottitis due to *H. influenzae* type b have all but disappeared in vaccinated populations.[95] There is growing evidence for strain replacement with increased cases of invasive infection due to nontypeable strains of *H. influenzae* as well as serotypes a and f.[96,97]

CLINICAL MANIFESTATIONS

HISTORY. Typically, a nonimmunized young infant or child develops an area of swelling and discoloration on the face or arm after several days of coryza and abruptly rising temperature. Rarely, a similar process occurs in adults as a complication of upper respiratory tract infection.[98]

CUTANEOUS LESIONS. The typical lesion is a single, circumscribed, indurated area usually located on the face, neck, upper chest, or upper extremity. Although described in infants as characteristically blue–red to purple–red and surrounded by a zone of edema, the early lesion may be an area of pale edema or erythema (Fig. 180-6). The margins are indistinct, in contrast to the sharply defined borders of erysipelas. Regional adenopathy is rarely present. Occasionally, in children with Hib buccal cellulitis, erythematous buccal mucosal lesions appear on the side of the affected cheek, which suggests direct bacterial spread from the oropharynx into buccal soft tissues.[99]

When *H. influenzae* cellulitis occurs in adults, the infection follows a striking sequence: marked pharyngitis at first, high fever, then rapidly progressive anterior neck swelling, tenderness, erythema, and dysphagia.[98]

OTHER PHYSICAL FINDINGS. Associated otitis media, sinusitis, or epiglottitis as well as pneumonia may occur; occasionally, metastatic infections such as septic arthritis or meningitis develop.

Figure 180-6 Cellulitis caused by *Haemophilus influenzae*. Erythema and edema of the face in a child. (Used with permission from Richard A. Johnson, MD.)

LABORATORY FINDINGS

The white blood cell count is elevated, usually in the 20,000/mm^3 range. Results of blood cultures are positive in approximately 50% of cases. Aspiration and culture of specimens taken from the margin of the cellulitis have yielded positive results in about half of patients.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

H. influenzae cellulitis should be suspected when a child aged 3–24 months develops an acute facial (buccal) cellulitis with high fever. Immediate confirmation of the diagnosis may be possible from inspection of Gram-stained smears of an aspirate of the lesion. Although upper body cellulitis caused by other microorganisms is more common in adults, Hib should also be considered in patients with respiratory infections, especially adults or young children not fully immunized.

Streptococcal (group A, C, or G) or pneumococcal cellulitis may produce discoloration of the skin similar to that in Hib infection. Erysipelas, which occurs rarely in infants, is usually homogeneously erythematous, and the margins of the plaque-like swelling are distinct, whereas the lesion borders in *H. influenzae* cellulitis are indefinite. The presence of pustules or boils is helpful in identifying *S. aureus* as the etiologic agent.

COURSE AND PROGNOSIS

Most patients do well with antibiotic therapy, even though the disease is often associated with bacteremia. The abrupt onset of high fever and easily observed cellulitis indicates the urgency of the situation. Constant vigil must be maintained for suppurative complications in the upper airways, meninges, lungs, bones, joints, and other organs.

TREATMENT AND PROPHYLAXIS

Third-generation cephalosporins (ceftriaxone or cefotaxime) are currently the drugs of choice in the treatment

of Hib disease because of their activity against both ampicillin-susceptible and β-lactamase-producing strains of *H. influenzae* and because of their efficacy in treating any complicating meningeal spread of infection. Infections caused by β-lactamase-negative isolates can be treated with ampicillin given IV in four to six divided doses daily. Many Hib strains now show plasmid-mediated ampicillin resistance.[100] For this reason, therapy should begin with a third-generation cephalosporin.

The use of Hib conjugate vaccine (capsular polysaccharide covalently linked to a protein moiety) has dramatically decreased the incidence of invasive Hib disease in the developed world. These vaccines stimulate the production of protective antibodies when given to infants before 6 months of age.[101]

CUTANEOUS MANIFESTATIONS OF *SALMONELLA* INFECTIONS (ENTERIC FEVER)

SALMONELLA INFECTIONS AND THE SKIN AT A GLANCE

- *Salmonella* organisms are widespread in nature.
- Carried by cold- and warm-blooded animals, they contaminate foods derived from animals and are global in distribution.
- *Salmonella* infections manifest as gastroenteritis, enteric fever, or septicemia.
- Rose spots are the classic skin lesions of systemic *Salmonella* infection.
- These lesions occur in 10%–60% of natural (untreated) typhoid fever cases but less frequently in cases of enteric fever caused by other *Salmonella* sp.

BACTERIOLOGY AND PATHOGENESIS

Isolation of salmonellae from stool is made difficult by the fact that, when present, they represent only a small part of the fecal flora. Extragastrointestinal isolates are easier to identify, because they are usually pure cultures of a given *Salmonella* sp. The use of selective media (e.g., MacConkey agar, *Salmonella–Shigella* agar) that inhibit the growth of Gram-positive organisms, as well as many Gram-negative species, facilitates isolation of the organisms from stool. Salmonellae are Gram-negative bacilli that do not ferment lactose. In stool bacteriologic testing, initial selection of nonlactose-fermenting colonies is followed by biochemical and serologic (agglutination) procedures for identification. There are over 2,400 serovars determined by surface and flagellar antigens. Modern molecular biology has established a revised nomenclature, with *Salmonella enterica* the single species, and all others serovars (serotypes) of this single species (e.g., *S. enterica* serotype Typhimurium). Because habits are difficult to change, organisms are usually still referred to as familiar species [e.g., *Salmonella typhi*, *Salmonella paratyphi* (A, B or C), *Salmonella enteritidis*] rather than as serotypes of *S. enterica*.

EPIDEMIOLOGY

People acquire *S. typhi* and other *Salmonella* species causing enteric fever by ingestion of contaminated water or food, often during travel in developing countries. A history of recent travel and of suspicious food or water encounters should be sought in a patient with appropriate clinical manifestations.

Humans are the only hosts for *S. typhi* and *S. paratyphi*. The chronic carrier state that may follow clinical typhoid fever is almost always asymptomatic, except for manifestations of gallbladder disease, if cholelithiasis and active cholecystitis are present. Other serotypes of *Salmonella* can occasionally produce an enteric fever syndrome similar to, but usually milder than, that of typhoid fever. Unlike *S. typhi*, these other *Salmonella* serotypes are ubiquitous in nature (occurring in animals, reptiles, and poultry).

CLINICAL MANIFESTATIONS

HISTORY. Symptoms begin several days to several weeks after the ingestion of contaminated water or food. Headache, fever, generalized aching, abdominal discomfort, cough, and constipation are common. Delirium or mental torpor is not unusual, especially with high fever. Heart rate may be slower than expected for the magnitude of the fever. Symptoms increase in intensity and fever rises in a stepwise fashion. During the second week abdominal pain and rash often occurs. Finally, the third week of typhoid fever is characterized by hepatosplenomegaly and intestinal bleeding. Intestinal perforation and/or peritonitis may occur.

CUTANEOUS LESIONS. After 7–10 days of high fever, the rose spots characteristic of *S. typhi* infection may appear. These lesions are 2–3 mm, slightly raised, nontender, pink maculopapules that blanch on pressure. Appearing in crops of approximately 10–20 lesions, they are often located between the nipple area and the umbilicus on the anterior trunk, rarely on the back or extremities. Without therapy, the spots usually become brownish as they fade and disappear in 3–4 days. New lesions emerge over the ensuing 2–3 weeks in untreated patients. Their presence in 63% of a group of 62 patients should encourage careful observation for this subtle rash.[102] Early institution of antimicrobial therapy may be responsible for the decreasing incidence of rose spots. The rash is less frequently reported in people of color, but this may be

because of the difficulty in detecting the small lesions on dark skin. Rose spots occur infrequently in enteric fevers caused by other *Salmonella* sp.

Other skin changes have been noted during the acute phase of enteric fever. Erythema typhosus, an erythematous confluent rash, may occur during the first week. Erythema nodosum and urticarial lesions have been observed. In several reports from the Indian subcontinent, subcutaneous and cutaneous abscesses and skin ulcers have been described.[103,104] It is distinctly uncommon to observe herpes labialis in enteric fever.

OTHER PHYSICAL FINDINGS. During the time cutaneous lesions are appearing, the patient may be disoriented and have signs of pneumonia. The abdomen is often distended, tympanitic, and diffusely tender, with some localization to the right lower quadrant. The spleen is often enlarged but may be difficult to palpate because of abdominal distension and guarding.

LABORATORY FINDINGS

Leukopenia is often present, but values range from 3,000 to 20,000/mm^3. The percentage of mononuclear cells may be increased, and atypical lymphocytes can appear in small numbers, which suggests a viral illness. Thrombocytopenia and, rarely, hemolysis may occur. During the initial week of illness, blood culture results are usually positive for *Salmonella*. During the second week, or when diarrhea begins, stool culture results become positive for *Salmonella*, and the white blood cell count may increase. Isolation of *S. enterica* serotype Typhi from the blood is the gold standard for diagnosis of typhoid fever.

HISTOPATHOLOGY

Histologic examination of a rose spot reveals gross dilatation of capillaries. There is considerable edema and abundant pericapillary infiltration with macrophages. Organisms may be present within these cells.[92]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of *Salmonella* enteric fever may be difficult in a sporadic case, especially if the characteristic rash and gastrointestinal symptoms have not yet appeared and there is no history of travel in an endemic area. Headache, cough, and high fever are not very specific findings. However, when these symptoms are associated with delirium, relative bradycardia, and leukopenia with increased numbers of circulating mononuclear cells, the diagnosis of enteric fever should be considered. The diagnosis is usually made by performing blood cultures, which yield positive results for *Salmonella* in approximately 80% of untreated cases during the first 10 days. Results of Widal's tests are usually negative during the early phase of the illness. Likewise, enteric fever due to *S. enterica* serotypes other than serotype Typhimurium can usually be diagnosed through blood cultures. Culture of other material (e.g., bone marrow, rose spots) may be important, especially in patients who have had prior antibiotic therapy. PCR testing of blood may have a role in the latter.

Differential diagnosis includes a wide range of diseases. Prominent cough and severe headache in the early phases may suggest a viral or atypical pneumonia. Typhus and Rocky Mountain spotted fever can usually be excluded by geographic and epidemiologic considerations, serologic studies, the characteristic petechial component of the rash, and its distribution on the distal parts of the extremities. Miliary tuberculosis may begin as an acute febrile illness with similar symptoms, leukopenia, and splenomegaly. The diagnosis may be delayed until a secondary complication such as meningitis occurs. Infectious mononucleosis is suggested by headache, fever, lymphadenopathy, splenomegaly, and a blood profile with leukopenia and some atypical mononuclear cells.

Malaria and toxoplasmosis are two parasitic illnesses that deserve consideration. Epidemiologic information plus intermittency of symptoms usually suggest the former. In generalized toxoplasmosis, manifestations may be very similar to those of early enteric fever: prominent cough, high fever, lymphadenopathy, and a truncal rash. The rash tends to be more florid than in enteric fever and has a petechial component. Diagnosis usually requires identification of *Toxoplasma gondii* in biopsy material or a rising antibody titer.

COURSE AND PROGNOSIS

The response of patients with enteric fever to antibiotic therapy is usually gradual, with 3–6 days needed for the temperature to return to normal. With prolonged treatment, the incidence of relapse has declined. The major complications in the preantibiotic era were bowel perforation and hemorrhage. Although rare, these complications still occur and are responsible for 75% of mortality. Deaths have been reduced from 10% to 1% to 2% with antibiotic therapy, although mortality is higher in immunocompromised patients. After recovery from typhoid fever, 1%–4% of patients continue to harbor organisms in the gallbladder and to excrete them in the stools, becoming a potential source for spread.

TREATMENT AND PREVENTION

The emergence of multidrug-resistant *Salmonella*, including *S. typhi*, in many areas of the world has essentially eliminated the use of chloramphenicol, ampicillin, and trimethoprim-sulfamethoxazole as first-line antimicrobials.[105] The fluoroquinolones (ciprofloxacin, ofloxacin) are active against drug-susceptible and multidrug-resistant *S. typhi* or other salmonellae causing enteric fever but are not approved for use in persons under 18 years of age. Blood cultures become sterile promptly on treatment with ciprofloxacin, and this drug has become the treatment of choice for typhoid fever. Ciprofloxacin is administered in 500–750-mg

doses given orally (or 400 mg given IV) every 12 hours in adults for 7–14 days. Other active drugs include ceftriaxone, cefotaxime, and azithromycin.

SKIN INFECTIONS DUE TO NONTYPHOIDAL *SALMONELLA* SEROTYPES

Skin infections due to nontyphoidal abscesses. Very uncommonly, *Salmonella* necrotizing fasciitis has been reported, usually in the setting of immunosuppression.[106]

INFECTIONS WITH OTHER GRAM-NEGATIVE BACILLI THAT HAVE CUTANEOUS MANIFESTATIONS

OTHER GRAM-NEGATIVE BACILLARY INFECTIONS AND THE SKIN AT A GLANCE

- An acute cellulitis, with or without production of gas, may be caused by *Escherichia coli*, *Proteus* sp., *Klebsiella* sp., *Enterobacter* sp., *Serratia marcescens*, and other organisms.
- These infections occur often, but not exclusively in the very elderly; in individuals with diabetes; in patients after trauma surgery, bowel or perineal inflammation; and in immunocompromised individuals.
- The infectious process may be limited to the superficial soft tissues or found primarily in the deep fascia.
- Drug addicts develop such infections after "skin popping," which lead to cellulitis and necrotizing fasciitis.
- Rhinoscleroma is a granulomatous infection caused by *Klebsiella pneumoniae* subspecies *rhinoscleromatis*. It has a slowly progressive course and may involve the upper airway and tracheobronchial tree.

ENTERIC GRAM-NEGATIVE BACILLI

EPIDEMIOLOGY

Cellulitis usually follows contamination of adjacent tissues by bowel contents or a breakdown of skin. Predisposing conditions include (1) bowel perforation, (2) colon surgery, (3) chronic edema, (4) vascular insufficiency, (5) injection of addictive drugs,[114] (6) decubitus ulcers, (7) presence of percutaneous lines, and (8) superficial perineal dermatitis. Poorly controlled diabetes, altered host defenses, and poor nutrition often further predispose to such infections in these patients. Crepitant (gas-containing) cellulitis results from infection with gas-forming strains of bacteria (*E. coli*, *Klebsiella*, *A. hydrophila*), especially in patients with diabetes, or in the presence of *Bacteroides* sp. or anaerobic *Streptococci*.[115,116]

CLINICAL MANIFESTATIONS

HISTORY. Diabetes mellitus, malnutrition, or a chronic condition (e.g., paraplegia with decubitus ulcers) is usually present at the time of infection. The onset may be insidious or abrupt. Pain, often severe, frequently precedes local skin changes, especially if the infection is at the level of the deep fascia. High fever, shaking chills, increasing pain, and falling blood pressure may follow. Rectal or perineal pain can indicate a local process that may be especially devastating in a patient deficient in granulocytes.

CUTANEOUS LESIONS. In the early stages, the skin is rarely discolored beyond a pink hue, and vesicles or bullae are almost never present. At this juncture, unless pain is present, the process may easily be overlooked. As the cellulitis progresses, edema and redness increase; tenderness, crepitus, and hemorrhagic bullae may develop; and areas of cutaneous gangrene may appear. The cellulitis may remain localized to the skin and superficial subcutaneous tissues, but progression to the deep fascia with necrosis of fat and increasing pain and toxicity suggests a diagnosis of necrotizing fasciitis[117] (see Chapter 179). Although most cases of Gram-negative bacillary necrotizing fasciitis are polymicrobial in etiology, a striking monomicrobial form caused by *Klebsiella* sp. occasionally occurs, almost always in individuals with diabetes mellitus.[118] *Klebsiella* necrotizing fasciitis results from direct inoculation or commonly from hematogenous spread from another site.

SUPERFICIAL NASAL LESIONS. *K. pneumoniae* subspecies *rhinoscleromatis* is the etiologic agent of a hypertrophic, granulomatous infection of the external nares known as *rhinoscleroma*. It often produces changes in the overlying nasal skin (Fig. 180-7) and the contiguous surfaces of the respiratory, sinus, and posterior pharyngeal regions. Most cases seen in the United States have been in patients who have emigrated from specific areas of Eastern and Central Europe, Africa, the Near East, and parts of Central and South America.[119] Dissemination of the organism is by prolonged close contact. Infected individuals can shed organisms for years. The disease has been reported in patients with AIDS.[120] As in leprosy, the disease rarely becomes clinically apparent until early adulthood. Patients complain of fetid, purulent nasal discharge, epistaxis and obstructive symptoms, cutaneous nasal masses, and eventual scarring of nasal passages. Diagnosis depends on biopsy-based identification of characteristic vacuolated Mikulicz

Figure 180-7 *Klebsiella pneumoniae* subspecies *rhinoscleromatis* infection. Rhinoscleroma. The nasal passages and nose are infected, which results in obstructed respiration.

cells and isolation of the organism on routine cultures. If untreated, rhinoscleroma has a slowly progressive course over many years and may extend to involve any portion of the upper airway and tracheobronchial tree.[121]

K. pneumoniae subspecies *rhinoscleromatis* is susceptible to ciprofloxacin, 250–500 mg administered twice daily for 1–3 months. Alternatively, the combination of rifampin plus trimethoprim-sulfamethoxazole for 6 months may be used.

OTHER PHYSICAL FINDINGS. The clinical course is often dominated by systemic manifestations of the underlying illness or decreased mental alertness, hypotension, and dehydration. Abdominal distension and other manifestations of localized or generalized peritonitis may be present. Extreme tenderness of the rectum, with or without a mass, can indicate the local source of a perineal process.

LABORATORY FINDINGS

The leukocyte count is usually elevated but may be markedly diminished in the presence of Gram-negative septicemia. Elevated blood glucose values and findings of ketoacidosis are not unusual. In crepitant cellulitis, radiographs or magnetic resonance imaging of the soft tissue may show the depth and extent of the gas-forming process.[122]

PATHOLOGY

Edema, gangrene of overlying skin, fat necrosis, and exudate containing polymorphonuclear leukocytes are usually present. Gas may be evident in the subcutaneous tissues. Blood vessels are often involved in a necrotic, obliterative, inflammatory reaction. Underlying muscle is usually not involved unless there is septicemia associated with major vascular thrombosis or there is myonecrosis due to an organism such as *A. hydrophila*.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

A bacteriologic diagnosis can be made by analysis of specimens from needle aspiration of the cellulitis or an overlying bleb. Several Gram-positive as well as Gram-negative organisms may be present. When gas is present, anaerobic cocci and *Clostridia* must also be considered. A foul, fetid odor may accompany the presence of anaerobes in the exudate. Radiologic and surgical evaluation can be helpful in determining a descriptive diagnosis such as crepitant cellulitis or necrotizing fasciitis.

COURSE AND PROGNOSIS

The process may be indolent and may respond quickly to effective antibiotic therapy. In obese diabetic patients with perineal lesions, the progression of necrotizing fasciitis may be astonishingly rapid, even with vigorous antibiotic and surgical therapy. When the process is located centrally, in the perineal–gluteal area, the mortality rate is often as high as 50%. Infection of an extremity is frequently treated by antibiotics, drainage, and debridement, or by amputation, with more favorable results. The course is often prolonged and complex.

TREATMENT

Immediate antibiotic therapy and surgical drainage, guided by Gram-stained smears of the exudate and determinations of the extent of the process, are essential. Incision and drainage of focal collections associated with cellulitis are indicated. In necrotizing fasciitis, debridement of involved skin and subcutaneous tissues should be extended until normal fascia is reached. The adjunctive use of hyperbaric oxygen therapy for necrotizing fasciitis is controversial but may have some rationale in selected cases with a polymicrobial etiology in which anaerobes play an important role.[123] Judgment and experience are vital in surgical decisions.

Patients with necrotizing fasciitis or gangrenous cellulitis should receive initial combination antimicrobial therapy (modified by specific findings of Gram-stained smears and culture): ampicillin, gentamicin and clindamycin; ampicillin, gentamicin, and metronidazole; ampicillin–sulbactam plus gentamicin; or meropenem or imipenem or doripenem plus gentamicin. Fluoroquinolones can substitute for aminoglycosides in patients with renal impairment. If *P. aeruginosa*, *Klebsiella*, or *Serratia* is suspected in certain hospital-acquired infections, tobramycin or amikacin may be preferred to gentamicin, and a broad-spectrum penicillin (e.g., piperacillin-tazobactam) or cephalosporin (ceftazidime or cefepime) added in place of ampicillin if *Pseudomonas* is a major pathogen. If methicillin-susceptible *S. aureus* is suspected, nafcillin is included; if resistant *Enterococci* or methicillin-resistant *Staphylococci* are suspected, then vancomycin is included.

Chapter 181 :: The Skin in Infective Endocarditis, Sepsis, Septic Shock, and Disseminated Intravascular Coagulation

:: Laura Korb Ferris & Joseph C. English

INFECTIVE ENDOCARDITIS, SEPSIS, SEPTIC SHOCK, DIC, AND THE SKIN AT A GLANCE

- Infective endocarditis: staphylococcal or streptococcal bacteria most common cause in intravenous drug use setting.
- Sepsis: Gram-positive bacteria most common cause; tenth leading cause of death in the United States.
- Disseminated intravascular coagulation: most commonly from sepsis; results from systemic activation of the coagulation cascade.
- Cutaneous manifestations of these entities include: splinter hemorrhages, Janeway lesions, Osler nodules, erythroderma, cellulitis, purpura, hemorrhage, purpura fulminans, and skin necrosis.

INFECTIVE ENDOCARDITIS

EPIDEMIOLOGY

In the United States, the incidence of native-valve endocarditis is 1.7–6.2 cases per 100,000 person-years. The highest rate of infective endocarditis (IE) is seen in intravenous drug users, with an incidence estimated at 150–2,000 per 100,000 person-years. The risk of prosthetic valve IE decreases with time following valve implantation and the cumulative risk is about 2%–3% after 60 months.[1]

ETIOLOGY AND PATHOGENESIS

IE can be subdivided by native valve versus prosthetic valve. The causative organisms in most cases of IE are *Staphylococci* or *Streptococci*, implicating skin as the initial site of infection in many cases. Native valve endocarditis occurs most commonly in the setting of valvular disease or in people who use intravenous

drugs. Rheumatic valve disease has been replaced by aortic stenosis and mitral regurgitation, as the most common settings in which native valve endocarditis is encountered. At sites of endothelial injury, a sterile thrombus can occur which is particularly susceptible to seeding of bacteria from transient episodes of bacteremia. This can result in the development of valvular vegetations that can cause local tissue destruction and embolic events.

Intravenous drug users are particularly susceptible to IE even though most have no preexisting structural heart disease. More than half of the cases of IE in injection drug users are right sided, involving the tricuspid valve. The most common causative organism is *Staphylococcus aureus*.

Prosthetic valve endocarditis can be classified as early (in the first 2 months following valve replacement) or late (2 months or later). The newly placed prosthetic valve is particularly susceptible to bacterial colonization because the process of endothelialization does not occur until 2–6 months following surgery. Early prosthetic valve endocarditis is most commonly caused by *Staphylococcus epidermidis* followed by *S. aureus*. Late prosthetic valve endocarditis can be due to a variety of organisms including the so-called HACEK organisms (*Haemophilus parainfluenzae*, *Haemophilus aphrophilus*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kinsella kinasae*).

Most cases of nosocomial endocarditis are secondary to indwelling catheters or to surgical procedures, and are caused by *Streptococci*. However, nosocomial endocarditis in dialysis patients is most commonly due to *S. aureus*. Other less common causes of IE include fungi, *Pseudomonas*, *Coxiella burnetii*, *Bartonella quintana*, and *Proprionobacteria acnes*.

CLINICAL FINDINGS

HISTORY. Patients with IE generally present with noncardiac complaints of fever, malaise, and anorexia. The presence of a murmur that is new or has changed in character is often present. Unexplained fever in a patient with a prosthetic heart valve should prompt an evaluation for endocarditis. The Duke criteria,[2] (Box 181-1 are helpful in making the diagnosis of IE.

CUTANEOUS LESIONS. Cutaneous signs of IE are nonspecific but may help the clinician in making the appropriate diagnosis. Cutaneous findings are caused either by embolic events, thrombosis, or focal vasculitis.

Splinter hemorrhages (Fig. 181-1) are 1–2 mm red–brown longitudinal streaks under the nail plate. They are seen in about 15% of patients with IE and are considered to be of greater diagnostic value if proximally located. Splinter hemorrhages associated with IE are the result of small capillary vasculitis, or from microemboli. In the absence of other signs or symptoms of IE, the mere presence of splinter hemorrhage is not specific enough evidence to warrant a workup. Crops of petechiae are commonly seen in the buccal membrane, soft palate, and extremities.

BOX 181-1 MODIFIED DUKE CRITERIA FOR IE[a2]

Major Criteria

1. Microbiological
   a. Two separate blood cultures positive for typical microorganism
   OR
   b. Persistently positive blood culture for typical microorganism
   OR
   c. Single positive blood culture for *Coxiella burnetii* or a phase I IgG antibody titer to *Coxiella burnetii* greater than 1:800
2. Evidence of endocardial involvement
   a. New valvular regurgitation
   OR
   b. Positive echocardiogram showing oscillating echogenic intracardiac mass at the sire of endocardial injury, a periannular abscess, or new dehiscence of a prosthetic valve

Minor Criteria

1. Predisposition to infective endocarditis
2. Fever
3. Vascular phenomena such as Osler nodes or Roth spots
4. Immunologic factors such as a positive rheumatoid factor or glomerulonephritis
5. Serologic evidence of active infection not meeting microbiological major criteria

[a]Clinically definite case is defined as fulfilling 2 major, 1 major plus 3 minor, or 5 minor criteria.
Clinically suspicious case is defined as fulfilling 1 major and 1 minor, or 3 minor criteria.

Figure 181-1 Globular proximal splinter hemorrhage and several distal linear splinter hemorrhages in a patient with IE. (Photo used with permission from William James, MD and James Fitzpatrick, MD).

Janeway lesions are painless, irregular, nonblanchable, erythematous maculopapules that appear on the palms and soles and last days to weeks (eFig. 181-1.1 in online edition). Histologically, thrombi are found in small vessels in the absence of vasculitis. Neutrophilic microabscesses can be seen in the dermis with occasional Gram-positive organisms. Osler's nodes present as painful red papulonodules with a pale center on the fingertips lasting days to weeks (eFig. 181-1.2 in online edition). Osler's nodes are painful, perhaps due to involvement of the glomus bodies located in the fingertips. Histologically, neutrophilic microabscesses are present in the dermis, and arteriolar microemboli may contain Gram-positive cocci.

Septic emboli of valvular vegetation fragments can cause ischemia of distal extremities. Toes are most commonly involved, followed by fingers, and this condition presents as reticulated purpura similar to that seen in cholesterol emboli syndrome (see Chapter 174). While this condition generally resolves without sequelae, tissue necrosis or gangrene can result.

RELATED PHYSICAL FINDINGS. The most common noncutaneous finding in IE is fever. Signs and symptoms related to the bacterial infection and septic emboli may include splenomegaly, microscopic hematuria, pneumonitis, cerebral vascular accident, meningoencephalitis, brain abscess, retinal hemorrhages (Roth spots), acute abdomen, myocardial infarction, pericarditis and congestive heart failure, arthralgias and arthritis, or chronic wasting disease.

LABORATORY TESTS

A positive blood culture is the most helpful laboratory test in making the diagnosis of IE. Other tests that may be abnormal in this setting include a positive rheumatoid factor, elevated erythrocyte sedimentation rate, C reactive protein, leukocytosis, or a urinalysis showing hematuria. Subacute bacterial endocarditis can be associated with the presence of antineutrophilic cytoplasmic antibodies (ANCAs).

SPECIAL TESTS

Echocardiography allows the visualization of the valves and can provide information as to the level of myocardial involvement. Transthoracic echocardiography (TTE) is less invasive and less expensive than transesophageal echocardiography (TEE). However, the sensitivity and specificity of TTE are 60%–70% and 98%, respectively, whereas the sensitivity of TEE is 75%–95% without a compromise in specificity.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of splinter hemorrhages is reviewed in Box 181-2. Janeway lesions and Osler nodes can be similar in appearance to septic emboli and neutrophilic eccrine hidradenitis. Cases of culture-negative, ANCA-positive subacute bacterial endocarditis, particularly in the presence of cutaneous manifestations such as purpura, may mimic ANCA-associated vasculitis.

BOX 181-2 DIFFERENTIAL DIAGNOSIS OF SPLINTER HEMORRHAGE[3]

- Trauma
- Atopic dermatitis
- Psoriasis
- Thyrotoxicosis
- Internal malignancy
- Drug induced
- Vascular endothelial growth factor receptor (VEGFR) inhibitors[4]
- Tetracyclines
- Scurvy
- Trichinosis
- Idiopathic

COMPLICATIONS

Cardiac complications of IE include congestive heart failure, extension of disease to the myocardium and pericarditis. Embolic complications include stroke, mycotic intracranial aneurisms and splenic abscess.[1]

PROGNOSIS AND CLINICAL COURSE

The overall mortality for IE has dropped by about 50% over the past 40 years and is currently about 28%.[2] Prognosis depends on age, the nature of the responsible microorganism, the presence of emboli, and the extent of cardiac damage. Early diagnosis and treatment improve outcome.

TREATMENT

Appropriate antibiotic therapy should be initiated in suspected cases of IE after blood cultures have been drawn. Long-term (4–6 weeks) parenteral antibiotics, usually with a penicillin derivative, are used to treat streptococcal or staphylococcal IE. Antibiotic treatment has been shown to reduce the risk of subsequent embolism. Treatment of infective endocarditis caused by other organisms is reviewed elsewhere.[5] Indications for surgical treatment include persistent bacteremia, despite 7 days of parenteral antibiotic therapy, prosthetic valve endocarditis, the presence of large vegetations, severe valvular dysfunction, and infection with *Pseudomonas*, *C. burnetii*, or fungus.[6]

PREVENTION

Currently, prophylactic antibiotics for skin surgery are not indicated for procedures performed on noninfected, surgically scrubbed skin regardless of cardiac history.

Guidelines issued by the American Heart Association in May 2007 shifted from recommending antibiotic prophylaxis for patients at increased risk for IE, to recommending IE prophylaxis for patient who have a high risk of an adverse outcome associated with IE who are to have a procedure that involves a contaminated or infected wound, or surgery on oral or nasal mucosa.[7] For dermatologists, this would include patients with a prosthetic heart valve, a personal history of IE, valvulopathy in a cardiac transplant patient, or an unrepaired cyanotic heart defect.

SEPSIS AND SEPTIC SHOCK

EPIDEMIOLOGY

Sepsis, most commonly from Gram-positive bacteria, is the 10th leading cause of death in the United States. A review of approximately 750 million hospitalizations over 22 years in the United States showed that sepsis accounts for 1.3% of all hospital admissions. The incidence of sepsis has been steadily increasing since 1971 although the mortality rate has been dropping.[8]

ETIOLOGY AND PATHOGENESIS

The prevailing presumption has been that sepsis is a result of uncontrolled activation of the inflammatory response to pathogens. This increased inflammation leads to uncontrolled coagulation, which in turn causes the release of more inflammatory mediators. Sepsis is often characterized by an initial burst of immunologic activation, including a surge in TNF-α production. This is thought to be mediated by binding of specific pathogen-associated molecules to toll-like receptors found on cells of the immune system. Toll-like receptors activate signaling through transcription factors such as nuclear factor-κB (NF-κB) that activate the expression of a cascade of inflammatory cytokines. However, this is followed by a relative decrease in immunity with impaired delayed type hypersensitivity, a loss of critical cells of the immune response including B cells, $CD4^+$ helper T cells, and dendritic cells, and the inability to clear infection.[9]

Sepsis is often complicated by impaired organ function. Autopsy studies revealed that even in the setting of profound organ dysfunction, cell death is minimal and not sufficient to account for the clinical picture. Thus, sepsis appears to activate a state of cellular hibernation in which cells reduce their activities to only those required for cell survival. This would explain why organ function is often regained in those patients who recover from sepsis.

CLINICAL FINDINGS

HISTORY. The septic patient is usually febrile, or in some cases hypothermic, with tachycardia and tachypnea. Patients with severe sepsis can also have dysfunction of major organ systems and those in septic shock develop hypotension that is refractory to the administration of fluid.

CUTANEOUS LESIONS. The causative organism in sepsis is not always identifiable by routine culture. In some cases, the cutaneous exam can provide clues to the identity of the responsible pathogen, providing a valuable clinical tool in the management of the septic patient.

Erythroderma in the septic patient suggests staphylococcal or streptococcal toxic shock syndrome (TSS). Patients with TSS are usually young and otherwise healthy. Patients with staphylococcal TSS are much more likely to be erythrodermic but much less likely to have positive blood culture than are patients with streptococcal TSS. Streptococcal TSS is commonly associated with a soft tissue infection.

The finding of pustules on the skin of a septic patient, particularly in the neonate or immunocompromised individual, may be suggestive of fungal infection, particularly with *Candida* species. Congenital candidiasis, most often seen in infants born to mothers with vaginal candidiasis, is generally a skin-limited disease. However, in the septic infant with pustules, candidemia should be considered.

The vasculitis and coagulopathy that can occur in the septic patient may cause purpura, sometimes prominent in the nail fold small capillaries (Fig. 181-2). Purpura is particularly prominent in those patients with thrombocytopenia. Such infections are seen most commonly in oncology patients undergoing bone marrow transplantation. In the immunocompromised host, opportunistic fungal infection, such as with *Aspergillus* sp., *Fusarium* sp., and *Candida* sp., often presents as erythematous papules, petechiae, or pustules that progress to purpuric lesions (Fig. 181-3).

Pustules due to disseminated gonococcemia are acrally located, typically tender and a characteristic gun-metal gray color, hemorrhagic or black, and are most commonly seen in the otherwise healthy adolescent or young adult (eFig. 181-3.1 in online edition).

Figure 181-2 Proximal nail fold purpura from leukocytoclastic vasculitis due to *Clostridium difficile* sepsis.

Figure 181-3 Petechiae from *Fusarium* sepsis in an immunosupprressed patient.

Gram stain of the pustule will reveal intracellular Gram-negative diplococci. In its most extreme form, meningococcemia can cause purpura fulminans (see below). Pustules may also be secondary to a local inoculation site, as in the case of staphylococcal sepsis.

Cellulitis is characterized by intense local inflammation in the presence of relatively few infectious organisms and blood cultures are rarely positive (see Chapter 179). Most commonly occurring on the legs, the affected extremity is typically erythematous, hyperemic, and edematous. The most common causes of cellulitis are *S. aureus* and Group A *Streptococcus*. Rarely, anaerobic organisms including clostridial species and other anaerobic bacteria species such as *Bacteroides*, *Peptostreptococcus*, or *Peptococcus* are the causative organism. In immunosuppressed patients, *Cryptococcus neoformans* can also cause cellulitis, particularly in the setting of AIDS. Patients with liver compromise can develop cellulitis from *Vibrio vulnificus*, a Gram-negative bacterium that lives in warm marine environments and becomes concentrated in filter-feeding shellfish. Infection occurs either via consumption of contaminated organisms such as raw oysters, or through contact with infected waster. Mortality rates exceed 40% in those with *V. vulnificus* sepsis.[10]

A more aggressive local soft tissue infection, necrotizing fasciitis, can be associated with positive blood cultures later in the course of the disease due to hematogenous seeding by the organisms. Clinically, necrotizing fasciitis is rapidly progressive, initially painful, and accompanied by fever and leukocytosis (see Chapter 179). Blood cultures are frequently positive. After several days, the involved area may become anesthetic secondary to destruction of cutaneous nerves.[11]

Ecthyma gangrenosum (see Chapter 180) begins as an erythematous papule that expands and eventually becomes a necrotic bulla. Lesions are most commonly seen between the umbilicus and the knees. Classic ecthyma gangrenosum represents cutaneous seeding of bacteria, usually *Pseudomonas aeruginosa*, from a hematogenous source, and is seen almost exclusively in neutropenic patients, often in association with an underlying malignancy. Nonclassical cases have been reported with *Aeromonas hydrophila*, *Escherichia coli*, *Citrobacter freundii*, and *Corynebacterium diptheriae*, fungal infection including *Candida*, *Aspergillus*, *Fusarium*, and mucormycosis-causing species, and even herpes simplex virus.[12]

RELATED PHYSICAL FINDINGS. Sepsis is defined as infection plus systemic inflammation and is characterized by hyper- or hypothermia, tachycardia and tachypnea. Sepsis is further subdivided into severe sepsis, which is defined as infection with systemic inflammation and organ dysfunction. The organ systems commonly affected in sepsis include the renal, hepatic, central nervous, pulmonary, gastrointestinal, and cardiovascular systems. Septic shock occurs when patients with severe sepsis also have hypotension (SBP <90) refractory to fluid administration.

LABORATORY TESTS

The septic patient will generally have a white blood cell count greater than 12×10^9/L or less than 4×10^9/L, or a bandemia of greater than 10%. Elevated CRP and procalcitonin levels are common. Organ dysfunction can manifest as low cardiac output, elevated creatinine, thrombocytopenia, and elevated INR or PTT, or hyperbilirubinemia.[13] Blood cultures can be helpful in guiding treatment of the septic patients, however, only 30%–50% of septic patients will have positive blood cultures.[14]

SPECIAL TESTS

Special tests including imaging studies and culture of suspected involved tissue can sometimes be helpful in identifying the source of infection in the septic patient.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of skin findings in the septic patient is reviewed in Box 181-3.

COMPLICATIONS

Complications of sepsis include death, loss of limbs due to hypoperfusion and permanent organ dysfunction.

PROGNOSIS AND CLINICAL COURSE

There are over 750,000 cases of sepsis each year in the United States and mortality rate from severe sepsis and septic shock is 30%–60%.[15]

BOX 181-3 DIFFERENTIAL DIAGNOSIS OF SKIN FINDINGS IN THE SEPTIC PATIENT

- Erythroderma
- Staphylococcal or streptococcal scalded skin syndrome
- Drug reaction
- Cutaneous T cell lymphoma
- Psoriasis
- Papules
- Drug reaction
- Contact Dermatitis
- Pustules
- Candidemia
- Disseminated gonococcemia
- Folliculitis
- Miliaria
- Steroid acne
- Acute generalized exanthematous pustulosis
- Purpura
- Invasive fungal infection, especially in thrombocytopenic patient
- Disseminated intravascular coagulation
- Vasculitis (infectious, neoplastic, drug induced, or autoimmune)
- Trauma induced
- Heparin or coumadin necrosis
- Thrombotic thrombocytopenic purpura
- Cryoglobulinemia
- Cellulitis
- Infectious cellulitis
- Necrotizing fasciitis
- Stasis dermatitis
- Ecthyma gangrenosum
- Pseudomonal ecthyma gangrenosum
- Nonpseudomonal bacterial or fungal ecthyma gangrenosum
- Herpes simplex infection in immunosupressed patient
- Necrotizing vasculitis
- Cryoglobulinemia

TREATMENT

Treatment of sepsis is usually done in an intensive care unit and involves the use of antimicrobial drugs, chosen empirically or on the basis of the culture of a particular microorganism started as soon as possible, but no longer than one hour after the diagnosis of severe sepsis or septic shock is mad. Choice of antibiotic therapy should be reevaluated on a daily basis to minimize toxicity and maximize efficacy. The administration of activated drotrecogin-α has been shown to reduce mortality in cases of sever sepsis. Patient outcomes in sepsis haven been shown to improve with the use of standardized treatment protocols. Supportive care is important to preserve organ function.

PREVENTION

The prevention of sepsis in a hospital setting is achieved by the implementation of basic infection control measures including routine hand washing and the minimization and regular replacement of indwelling catheters. In patients who are immunocompromised, particularly in the setting of organ transplantation or AIDS, the use of prophylactic antibiotics can help to reduce the incidence of sepsis.

DISSEMINATED INTRAVASCULAR COAGULATION

EPIDEMIOLOGY

The incidence of disseminated intravascular coagulation (DIC) is not known. Approximately 15% of septic patients may develop DIC.

ETIOLOGY AND PATHOGENESIS

DIC represents systemic activation of the coagulation cascade. This leads to fibrin deposition in the vasculature, which can cause organ ischemia and death. In addition, the consumption of platelets and coagulation factors can lead to bleeding. DIC occurs most commonly secondary to an underlying disorder as listed in Box 181-4.

In DIC, coagulation activation is tissue factor dependent (i.e., extrinsic or factor VIIa pathway). Inflammatory cytokines, such as TNF-α, promote damage to endothelial cells and activation of mononuclear cells. These cells then produce tissue factor that binds to factor VIIa and activates downstream coagulation cascades. Thrombin generation is amplified by defective

BOX 181-4 SETTINGS IN WHICH DIC CAN OCCUR

- Sepsis
- Trauma
- Malignancy
- Obstetrical complication (amniotic fluid embolism, placental abruption)
- Vascular abnormalities
- Hepatic failure
- Immunologic reaction to drugs or toxins
- Transfusion reactions
- Transplant reaction
- Protein C or S deficiency

anticoagulant mechanisms and results in increased fibrin deposition. The fibrin that is generated fails to be degraded by the fibrinolytic system. In the healthy state, antithrombin regulates thrombin activity. In DIC, antithrombin levels are low due to continuous consumption, degradation by neutrophil elastase and impaired synthesis due to liver failure in some settings. Fibrinolysis is inhibited by plasminogen activator inhibitor type I (PAI-1). Studies show that individuals with high plasma levels of PAI-1 are at higher risk of mortality in DIC. This correlates with a mutation in PAI-1 that is associated with higher PAI-1 plasma concentrations. Thus, some individuals may be genetically predisposed to fatal outcomes from DIC due to a point mutation in PAI-1.[16]

The infection, most commonly associated with DIC, is meningococcal sepsis. However, DIC has been reported following viral and other bacterial infections. Many recent reports suggest an emergence of sepsis due to *Staphylococcus*, particularly those isolates containing exotoxins including, staphylococcal enterotoxin serotypes B and C (SEB and SEC), toxic shock syndrome toxin-1 (TSST-1), and Panton–Valentine leukocidin (PVL), a leukocyte toxin believed to be important in the pathophysiology of skin and soft-tissue infections and necrotizing pneumonia, as a factor in initiating DIC.[17]

DIC can also be associated with obstetric complications including preeclampsia, abruption, and amniotic fluid embolism. In these cases, the placenta appears to play a central role in the hemostatic pathway.

CLINICAL FINDINGS

HISTORY. DIC is always secondary to an underlying condition or disorder, and thus the patient will generally first present with the antecedent condition. Often, patients with DIC will develop simultaneous bleeding, thrombosis, and multiorgan failure. Platelet count is not useful in predicting a patient's risk of thrombosis as clots can form even in the setting of thrombocytopenia. The onset of DIC in the neonatal period is suggestive of protein C or S deficiency.

CUTANEOUS LESIONS. The most characteristic cutaneous finding in DIC is noninflammatory purpura with extensive microvascular occlusion referred to as purpura fulminans (Fig. 181-4). Patients will have diffuse bleeding, hemorrhagic necrosis of tissue, and skin necrosis (eFig 181-4.1 in online edition). Patients with purpura fulminans may present with ischemic digits or extremities that, if left untreated, can progress to gangrene.

RELATED PHYSICAL FINDINGS. In its most extreme form, patients with DIC will develop the Waterhouse–Friderichsen syndrome, most commonly seen in meningococcal sepsis (see Chapter 180). This is a syndrome of multiorgan failure characterized by a petechiae or purpura, coagulopathy, cardiovascular collapse, and bilateral adrenal hemorrhage.

Figure 181-4 Purpura fulminans from *Escherichia coli* sepsis.

LABORATORY TESTS

DIC is characterized by laboratory evidence of massive activation of the coagulation cascade and the destruction of platelets. Platelet counts are generally less than 100,000. Platelet counts tend to be lowest in acute sepsis-associated DIC and increased in chronic DIC associated with malignancy. Because of the high conversion of fibrinogen to fibrin, soluble fibrin monomers and the D-dimer assay are usually elevated. The prothrombin time is usually prolonged to at least 1.2 times the upper limit of normal as well. Several scoring systems exist that assign numerical values to particular laboratory findings and allow the calculation of a single numerical score that is helpful in predicting the presence of and mortality from DIC as reviewed elsewhere.[18]

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of DIC includes other conditions causing small and midsize vessel thrombotic occlusions leading to organ failure and microangiopathic hemolysis. This includes thrombocytopenic thrombotic purpura, the hemolytic uremic syndrome, and the HELLP (hemolysis, elevated liver enzymes, low platelets) syndrome seen in obstetric patients.

COMPLICATIONS

Complications of DIC include tissue necrosis and infection, often requiring amputation of limbs or digits, multiorgan failure (particularly the Waterhouse–Friderichsen syndrome), and death.

PROGNOSIS/CLINICAL COURSE

The mortality risk is doubled in patients with DIC who are septic or have experienced trauma.

TREATMENT

Because DIC is always secondary to another condition, the most important factor in the management of DIC is treatment of the underlying cause. However, replacement of components consumed during DIC and inhibition of the coagulation cascade has an important role as well. Despite the conventional wisdom that replacement of platelets and coagulation factors in the patient with DIC adds "fuel to the fire", more recent clinical trials have not shown this to be the case. These studies have demonstrated a survival benefit to treating patients with DIC with low-dose heparin or activated protein C.[18] Asymptomatic DIC is treated with low molecular weight heparin, synthetic protease inhibitor (SPI), or antithrombin. The marked bleeding type of DIC is treated with SPI; fresh-frozen plasma and platelets are added in cases of severe bleeding. Finally, in organ failure type DIC, antithrombin is used in addition to supportive care.

There is very little published experience regarding the treatment of the cutaneous necrosis seen in DIC. Skin necrosis secondary to DIC is similar to that seen in full thickness cutaneous burns. Excision of necrotic tissue and coverage with autografts, and/or amputation of extremities are possible treatment options.[19]

PREVENTION

Most interventions in DIC are aimed at minimizing organ damage and bleeding. Prevention of DIC itself can be achieved by the prompt diagnosis and treatment of its causes, particularly sepsis.

Chapter 182 :: Bartonellosis

:: Timothy G. Berger & Francisco G. Bravo

BARTONELLOSIS AT A GLANCE

- Cat-scratch disease, trench fever/bacteremia, bacillary angiomatosis, and Carrion disease are all caused by different species of the Bartonella family.
- *Bartonella* sp. are able to live inside erythrocytes, explaining the presence of bacteremia in many of the clinical conditions.
- *Bartonella bacilliformis* are the primary host for humans. Immunocompetent patients develop a systemic disease and an eruptive phase.
- Cat-scratch disease is mainly a zoonosis. Infected humans will mostly develop a lumphocutaneous syndrome.
- Bacillary angiomatosis, which is analogous to the eruptive phase of Carrion disease, mostly occurs in immunosuppressed hosts, especially acquired immunodeficiency syndrome patients.
- Diagnosis often made by histologic examination or serology due to the difficulty in culturing these bacteria.

Bartonella are Gram-negative bacilli, with the remarkable capacity for intraerythrocyte persistence and the production of bacteremia. Until the 1980s, *Bartonella* were felt to only cause a rather exotic illness, Carrion disease. Since the description of a peculiar vascular proliferation in patients infected with Human Immunodeficiency Virus (HIV) infection, the number of identified *Bartonella* sp. has been rapidly expanding.

The genus includes three important species that are human pathogens: (1) *Bartonella henselae*, the cause of most cases of cat-scratch disease (CSD) as well as some cases of bacillary angiomatosis (BA), hepatic and splenic peliosis (cystic blood-filled spaces in hepatic lobules or the splenic parenchyma), and endocarditis; (2) *Bartonella quintana*, the cause of trench fever, urban trench fever, BA, and endocarditis; and (3) *Bartonella bacilliformis*, the cause of Carrion disease and its eruptive phase known as verruga peruana (VP). Other potential human pathogens are *Bartonella elizabethae* and *Bartonella vinsonii*, which cause endocarditis, *Bartonella grahamii*, a cause of neuroretinitis, and *Bartonella washoesis*, which causes myocarditis (Table 182-1).[1] Infections caused by most *Bartonella* are associated with arthropod vectors that may simultaneously carry several species. Adaptation to specific vectors and reservoirs seems to be a common strategy of *Bartonellae* for transmission and host diversity. At least one mammal host is known for every one of the *Bartonella* species identified to date.[2] Human beings are the exclusive hosts for *B. bacilliformis* and *B. quintana*, whereas in the case of *B. henselae*, the cat is the host of choice with man being a more accidental host. Asymptomatic bacteremia rates in primary vertebrate (reservoir) hosts may exceed 50%. This suggests high prevalence of infection and prolonged and persistent bacteremia as characteristics of *Bartonella* infection. The extent of disease caused by *B. henselae* will depend on the integrity of the immune system: if the person affected is immune competent, the clinical presentation can be a lymphocutaneous syndrome. If the person affected is immune deficient, the disease will be systemic and very similar to that seen in Carrion disease. [3]

The genus *Bartonella* contains organisms previously in the genuses *Rochalimaea* and *Grahamella*. *Bartonella* organisms are small aerobic, fastidious, pleomorphic, Gram-negative bacteria; they are difficult to culture from clinical samples. Initial clinical isolates grow slowly and visible colonies may not be detected for weeks, but subsequent passages grow much more rapidly. The organisms are short rods, ranging from 0.3 to 0.5 µm wide by 1.0–1.7 µm long. The organisms are best visualized in tissue using modified silver stains (Warthin–Starry). Polymerase chain reaction (PCR) and immunohistochemistry can also detect infection.[4,5]

The family of Bartonella keeps expanding. A new species, *Bartonella rochalimae*[6] has recently been described as causing a febrile illness with splenomegaly in a tourist visiting Peru.

CAT-SCRATCH DISEASE

CAT-SCRATCH DISEASE AT A GLANCE

- Vast majority of cases caused by *Bartonella henselae.*
- Transmitted by the scratch or bite of a cat.
- Most common cause of localized, chronic lymphadenopathy in children.
- Diagnosis established serologically.

EPIDEMIOLOGY

Approximately 29.2 million households (31%) in the United States own a cat, averaging close to two cats per household, for a total household cat population

TABLE 182-1
***Bartonella* Species and the Diseases They Cause**

IC = immunocompetent; ICD = immunocompromised.
[a]The cat flea transmits *Bartonella henselae* from cat to cat, but not cat to human.

of 57 million. This large population of domestic cats explains the more than 22,000 cases of CSD reported annually. Although cats behave as adapted hosts, they also can develop a systemic bacteremic illness. CSD affects persons of all ages, although 60%–90% of classic cases are reported in children and young adults. CSD is seen worldwide and does not appear to have a racial prevalence. Veterinarians may be a particular group at risk.[7] Most patients with CSD recall a history of cat contact, but this is not absolute (90.3%–99.1%). The incidence of CSD is slightly higher in males and it occurs seasonally, mostly between July and October.[8–10]

CSD is associated with exposure to a cat, usually a kitten. The method of spread from cat to human is usually a scratch or bite. In California, 39.5% of cats are bacteremic for *B. henselae* with a single sampling, indicating a very high infection rate. Infection in cats is a worldwide phenomenon, as shown by seroprevalence studies in cats in Sao Paulo, Brazil revealing 46% reactivity to *Bartonella* spp.[7] Bacteremic cats were more likely to be stray cats, young (less than 1 year old), and flea infested. Seroprevalence for *B. henselae* is as high in pet cats as in shelter and feral cats.[11] The seroprevalence of *B. henselae* among pet cats in North America is 27% overall but highly variable, with a higher seroprevalence in warm rainy regions. When the geographic seroprevalence of *B. henselae* is compared with predicted estimates of cat flea populations on the basis of temperature and humidity, there is considerable overlap, supporting the role of the cat flea (*Ctenocephalides felis*) as the arthropod vector among cats. *B. henselae* can be transmitted from cat to cat via the cat flea, cat fleas contain *Bartonella* organisms after feeding on infected cats, cat flea feces contains viable *Bartonella*, and cats can be experimentally infected by the intradermal injection of infected cat flea feces.[12] The cat flea has not been demonstrated to spread *Bartonella* infection from cats to humans. Rather, the disease transmission to human is a consequence of traumatic or subclinical inoculation. Cats' claws and teeth may be contaminated by infected flea feces during scratching and grooming allowing for transmission to humans by scratches.

ETIOLOGY AND PATHOGENESIS

B. henselae causes the vast majority (more than 95%) of cases of CSD. Two main genogroups have been identified in human and cats: (1) Houston-1 and (2) Marseille (also known as genotype II). These two geno groups are further subdivided into 4 variants: (1) Marseille, (2) CAL-1, (3) Houston-1, and (4) ZF-1.[13] The disease caused by all variants is clinically identical.

CLINICAL FINDINGS

CUTANEOUS LESIONS. The clinical spectrum of CSD has expanded since serologic diagnosis has become possible. Less than 10% of patients have a fever higher that 39°C, and one third are afebrile.[13] Typical CSD exhibits two components: (1) the primary inoculation papule and (2) adenopathy proximal to the inoculation site. The papule appears at the site of inoculation within 3–10 days of exposure and progresses through an edematous or vesicular and crusted stage. The primary inoculation papule lasts 1–3 weeks. The lymphadenopathy, seen in at least 90% of patients with typical CSD, develops on average 2 weeks after inoculation (range, 3–50 days; Fig. 182-1). The inoculation papule is still present in 60%–90% when the adenopathy develops, making it a valuable diagnostic finding.[14] The most commonly affected lymph nodes are axillary, epitrochlear, cervical, submandibular, and groin,[13] with 98% of patients having involvement of only one anatomic region. The nodes are generally firm, tender and between 1 and 5 cm in diameter (Fig. 182-2). The lymphadenopathy usually remits spontaneously after

Figure 182-1 Bartonellosis: cat-scratch disease with axillary adenopathy. Acute, very tender, axillary lymphadenopathy in a child; cat scratches were present on the dorsum of the ipsilateral hand. (Used with permission from Howard Heller, MD.)

Figure 182-2 Bacillary angiomatosis. Multiple, grouped, dusky-red, and violaceous papules and nodules that resemble pyogenic granulomas.

several months, although in 20% of cases, the adenopathy lasts longer than 6 months. Recurrences are uncommon.

Suppuration of clinical significance occurs in less than 10% of cases, but when affected nodes are followed with ultrasonography, suppuration is found to be the natural course of resorption of affected nodes in nearly all cases.[14] Surgical drainage is seldom necessary.

RELATED PHYSICAL FINDINGS. With improved diagnosis, atypical cases of CSD have increased from fewer than 5% of cases to more than 30% of cases in some series.[15] The exact prevalence of these atypical presentations is not known, as they are often reported as single cases, and the total number of CSD cases from which they come is unknown. In one pediatric series, a picture of "atypical mononucleosis" with pharyngitis and bilateral cervical adenopathy and thrombocytosis was a common presentation of *B. henselae* infection.[16] One recent study identified *B. henselae* as the third leading cause of FUO in children, after Epstein–Barr virus infection and osteomyelitis. Exposure to cats is not uniformly reported by patients with fever and *Bartonella* infection.[13] Endocarditis, hepatic and splenic granulomatosis, and massive lymph node enlargement resembling lymphoma are less common presentations.[15] Involvement of the terminal ileum may rarely mimic inflammatory bowel disease and intra-abdominal lymphadenopathy may very rarely obstruct the portal vein.[17,18]

Ocular complications of *B. henselae* infection have been frequently reported. The Parinaud oculoglandular syndrome consists of fever, regional lymphadenopathy, and follicular conjunctivitis, and is the most common presentation of ocular *B. henselae* infection. Other manifestations include neuroretinitis, focal retinochoroiditis, arterial and venous occlusion, iridocyclitis, and macular hole.[19,20] The most common neurologic complication of CSD is acute encephalopathy, presenting with seizures in 66% and status epilepticus in 10% of patients.[21–23]

In one study, up to 20% of immunocompetent patients with serologically confirmed CSD had PCR positivity for *B. henselae* in peripheral blood, suggesting bacteremia may be common.[24] Not surprisingly, hematogenous dissemination of *B. henselae* complicating CSD in immunocompetent persons has been reported to affect bone (osteomyelitis), liver and spleen, lungs (pneumonia, pleural effusion, pulmonary nodules), and the optic nerve.[25–27] These lesions may be markedly symptomatic, or, in one case of pulmonary involvement, completely asymptomatic.[25] *B. henselae* not infrequently causes endocarditis in persons with known valvular heart disease, usually affecting the aortic valve, and 90% of patients require valvular surgery as a consequence of severe damage.[28]

Reactive conditions of the skin and joints may be seen in patients with CSD. Two percent of CSD patients develop erythema nodosum.[29] Three percent of patients with CSD suffer a rheumatoid-factor-negative arthropathy of the larger joints of the extremities.[30] These patients are older than 20 years of age and two-thirds are female. Twenty percent have lesions of erythema nodosum. In 80%, the arthropathy resolved in 6 weeks, but in 20%, there is a more chronic course averaging 2.5 years.

LABORATORY TESTS

Routine laboratory findings are nonspecific and usually not helpful, except to exclude other diseases. Patients with CSD may have a slightly elevated white blood cell count and elevated erythrocyte sedimentation rate during the acute phase. Blood cultures are rarely positive when using current testing techniques. PCR of affected lymph nodes may be positive in 30% of cases. Between 80% and 90% of cases of CSD have positive serology for *B. henselae* at the time of presentation, and many of the seronegative cases are positive 2–8 weeks later. Serologic testing has replaced the CSD skin test as the confirmatory test of choice in cases of CSD. The 2 major serologic diagnostic methods used are indirect fluorescence assay (IFA) and enzyme immune-assay (EIA). Titer levels seems to correlate with the type of disease: titers of IgG >1:50 suggest a diagnosis of acute infection, such as CSD, whereas IgG titers >1:800 suggests a diagnosis of endocarditis.[31]

HISTOPATHOLOGY

Histopathologic examination of CSD lymph node lesions is not specific. Lymph nodes undergo three stages in the formation of a granuloma: (1) enlargement with hypertrophy of the germinal centers and thickening of the cortex; (2) formation of granuloma with invasion of lymphocytes and epithelioid cells; and (3) necrosis and infiltration with neutrophils—all of which may be simultaneously present within a single lymph node. Abscess formation may occur. Organisms can be detected in lymph nodes and primary skin lesions, often in clumps or filaments, usually in or adjacent to areas of necrosis.

In primary skin lesions, microscopic examination reveals necrosis of the epidermis and upper dermis, and dermal inflammation ranging from neutrophil and macrophage infiltration to granuloma formation. Conjunctival lesions have similar histological findings. In a few cases, conjunctival lesions produce proliferating blood vessels and a homogenous eosinophilic to basophilic granular appearance in the background—features similar to those of BA.

DIFFERENTIAL DIAGNOSIS

(Box 182-1)

TREATMENT

Virtually all cases of CSD remit spontaneously without therapeutic intervention. In a retrospective study of 202 patients with CSD who were treated with antibiotics, commonly prescribed antibiotics, including

BOX 182-1 DIFFERENTIAL DIAGNOSIS[32]

macrolides, tetracycline derivatives, and cephalosporins, were ineffective.[28] However, antibiotic susceptibility studies have shown that *B. henselae* is highly sensitive to macrolides, tetracycline derivatives, and second- and third-generation cephalosporins, and is variably sensitive to quinolones. The failure of antibiotics in classic CSD in the immunocompetent host may relate to the small infectious burden and the frequent initiation of therapy, once the disease is already improving spontaneously (in its lymphatic phase). In a prospective randomized trial, azithromycin for 5 days was demonstrated to reduce the lymph node volume during the first 30 days of observation. Half of azithromycin-treated patients reached 20% of baseline lymph node volume by 1 month, as opposed to 7% of untreated patients. However, there was no difference in any other symptoms or findings, or in the long-term outcome, and some treated patients had increase in lymph node size after treatment.[14] For complicated CSD of the eye or central nervous system, doxycycline 100 mg twice daily plus rifampin 300 mg twice daily is recommended. In children less than 8 years of age, erythromycin may be substituted for doxycycline.

TRENCH FEVER, URBAN TRENCH FEVER, AND BACTEREMIA/ ENDOCARDITIS

TRENCH FEVER, URBAN TRENCH FEVER, AND BACTEREMIA/ ENDOCARDITIS AT A GLANCE

- Infection transmitted by the body louse.
- Etiology: *Bartonella Quintana*.
- Systemic symptoms: headache, fever, and shin and back pain.
- Endocarditis.

EPIDEMIOLOGY

B. quintana is the etiologic agent of trench fever, a disease that affected more than 1 million troops of the German and Allied armies during World War I.[33] In the last three decades, *B. quintana* has been identified as a cause of bacteremia and endocarditis in the United States and France (urban trench fever).[28,33] Virtually all of the patients are human immunodeficiency virus-negative, homeless, alcoholic men. Moreover, in cities where urban trench fever has been described, from 15% to 50% of the indigent alcoholic inner city male population has serologic evidence of infection with *B. quintana*.[34]

ETIOLOGY AND PATHOGENESIS

Trench fever is caused by *B. quintana*. As opposed to most other *Bartonella* species, humans are the only known reservoir for this organism. The disease is transmitted from human to human by the human body louse (*Pediculus humanus corporis*). Close body contact and unsanitary conditions are associated with outbreaks. The incubation period ranges from 5 to 20 days. The organism can be isolated from patients with the disease and can be transmitted from person to person by direct inoculation or through lice. Recovered patients may be bacteremic for weeks.[33] *Bartonella* are the only bacterial pathogens that are able to invade and live inside the human erythrocyte. This may be the reservoir of bacteria in persistently infected persons.[1]

CLINICAL FINDINGS

Classic trench fever is characterized by a fever lasting approximately 1 week, followed by recurrent fevers every 4–8 days, most commonly every 5 days (quintana fever). Clinically, patients complain of severe headaches and neck, back, and shin pain (shin bone fever). There are no specific cutaneous manifestations. Although significant morbidity is associated with the disease, fatalities are rare.

LABORATORY TESTS

The diagnosis is usually made by blood culture, which is >90 percent positive if done specifically to isolate *Bartonella*, and before any antibiotic therapy. After even a single dose of antibiotics, blood cultures are usually negative. All patients are serologically negative at presentation but become positive after several weeks, making this a useful delayed confirmatory test, but of no value in the acute setting.

TREATMENT

For uncomplicated bacteremia, 4 weeks of doxycycline 100 mg bid plus gentamicin 3 mg/kg/day intravenously for 2 weeks is recommended.[1] For documented *Bartonella* endocarditis, doxycycline 100 mg bid for

6 weeks plus gentamicin 3 mg/kg/day for 2 weeks is recommended.[1]

BARTONELLA INFECTION IN THE IMMUNOSUPPRESSED (BACILLARY ANGIOMATOSIS; PELIOSIS OF THE LIVER AND SPLEEN)

BACILLARY ANGIOMATOSIS AT A GLANCE

- Etiology: *Bartonella henselae or B. Quintana*.
- Acquired from infected cats or body lice respectively.
- Most commonly in patients with acquired immunodeficiency syndrome but also in other forms of immunosuppression.
- Pyogenic granuloma-like and subcutaneous nodules.
- Hyperpigmented plaques in African-Americans.
- May be associated with hepatic and systemic lesions.
- Treatment: erythromycin or doxycycline.

EPIDEMIOLOGY

BA is most commonly seen in patients with acquired immunodeficiency syndrome (AIDS) and a CD4 count less than 50 cells/mm, with an incidence of 1.2 cases per 1,000 at-risk patients.[35] Patients with other forms of immunosuppression, including patients with leukemia and recipients of organ transplants, have been reported.[36] Uncommonly, human immunodeficiency virus-negative and nonimmunosuppressed persons develop BA.[37] Although, in the cases of BA in immunocompetent persons, the lesions were proliferative vascular papules, they were limited in number, the affected persons had limited or no systemic involvement and a benign course. There is no predisposition in terms of race, sex, or age.

ETIOLOGY AND PATHOGENESIS

Both *B. henselae* (the CSD bacillus) and *B. quintana* (the agent of trench fever) have been identified as causative agents of BA. At one end of the clinical spectrum, classic CSD is seen in young, immunocompetent hosts as a limited infection. At the other end, BA is seen in patients who are severely immunocompromised as a systemic disease. Thus, it is the immune-competence of the host and the bacterial load that dictates the clinical manifestations of the disease. The presence of intracellular bacilli in endothelial cells leads to intracellular hypoxia. Hypoxia induces Hypoxia-Inducible Factor-1 (HIF-1) that in turn induces vascular endothelial cell growth factor, leading to vascular proliferation.[38] BA caused by *B. henselae* is acquired from infected cats and is a manifestation of CSD in the immunecompromised host. Peliosis hepatitis is exclusively associated with *B. henselae* infection.[39] In contrast, patients with BA caused by *B. quintana* develop subcutaneous masses and lytic bone lesions.

CLINICAL MANIFESTATIONS

CUTANEOUS LESIONS. The incubation period for BA is unknown. In AIDS patients, the clinical constellation includes fever, cutaneous or subcutaneous vascular lesions, lymphadenopathy, and/or abdominal symptoms. The most common cutaneous morphologies of BA are (1) pyogenic granuloma-like lesions, (2) subcutaneous nodules, and (3) hyperpigmented indurated plaques. The same patient may have several morphologies. Lesions resembling pyogenic granuloma can range in size from 1 mm to many centimeters and are dusky red in color with a collarette of scale and peripheral satellite lesions (Fig. 182-2). The lesions are firm, bleed easily, and are often tender. They occur on skin and mucosa. Subcutaneous nodules can range from distinct nodules to diffuse swellings with or without induration and are also often tender. Hyperpigmented plaques are most commonly seen in African-Americans with BA and are oval in shape; they are several centimeters in diameter with indistinct borders. Large, fungating masses rarely occur. Patients with BA may have few to thousands of lesions with the number of lesions gradually increasing over time. Additional immunosuppression with chemotherapeutic agents may be followed by a shower of miliary skin lesions.

RELATED PHYSICAL FINDINGS. In addition to cutaneous lesions, other organ systems may be affected. Hepatic and splenic vascular lesions can occur concomitantly with or independent of cutaneous lesions and can be a cause of significant blood loss and anemia. *Bartonella* infection, especially that caused by *B. quintana,* can affect bone and soft tissues. Lesions of the central nervous system have been reported and can result in neurologic and psychiatric disorders. Bacteremia, chronic fevers, and pulmonary and gastrointestinal lesions have also been reported. Radiologic studies usually identify areas of systemic involvement. Ocular vascular proliferative lesions can produce loss of vision.[40]

There are several reports of patients with other cutaneous diseases concomitant with BA, as well as the simultaneous existence of BA and another infection within the same lesion. Several patients have been reported with both BA and Kaposi sarcoma. Cytomegalovirus, Epstein–Barr virus, *Cryptococcus neoformans,*

- Merkel cell carcinoma

and *Mycobacterium avium-intracellulare* have been found within lesions of BA.

DIFFERENTIAL DIAGNOSIS

(Box 182-2)

LABORATORY FINDINGS

Patients with AIDS and BA are anemic and may have elevated liver function tests (characteristically, lactic acid dehydrogenase and alkaline phosphatase are more elevated than hepatocellular enzymes). Blood cultures are positive for *Bartonella* sp. in approximately one-half of BA patients. *B. henselae* or *B. quintana* can be cultured from skin lesions. The organisms grow slowly and may not be detected without prolonged culture (more than 1 month). PCR of affected tissue is virtually always positive if lesions are histologically characteristic. The vast majority of cases are diagnosed histologically, with identification of the causative bacteria by Warthin–Starry staining.

HISTOPATHOLOGY

Lesions of BA have the general features of a lobular capillary hemangioma (pyogenic granuloma) (Fig. 182-3A), but in contrast to a pyogenic granuloma, the endothelial cells are often larger and polygonal; they may have marked atypia. There is a prominent inflammatory infiltrate, with significant numbers of neutrophils as well as leukocytoclastic debris (see Fig. 182-3B). Polymorphous-clear leukocytes (PMNs) are scattered throughout the lesion, as opposed to classic pyogenic granuloma lesions in which the PMNs are at or near the surface, even if the pyogenic granuloma is eroded and impetiginized. There is usually a finely granular pink to purple material

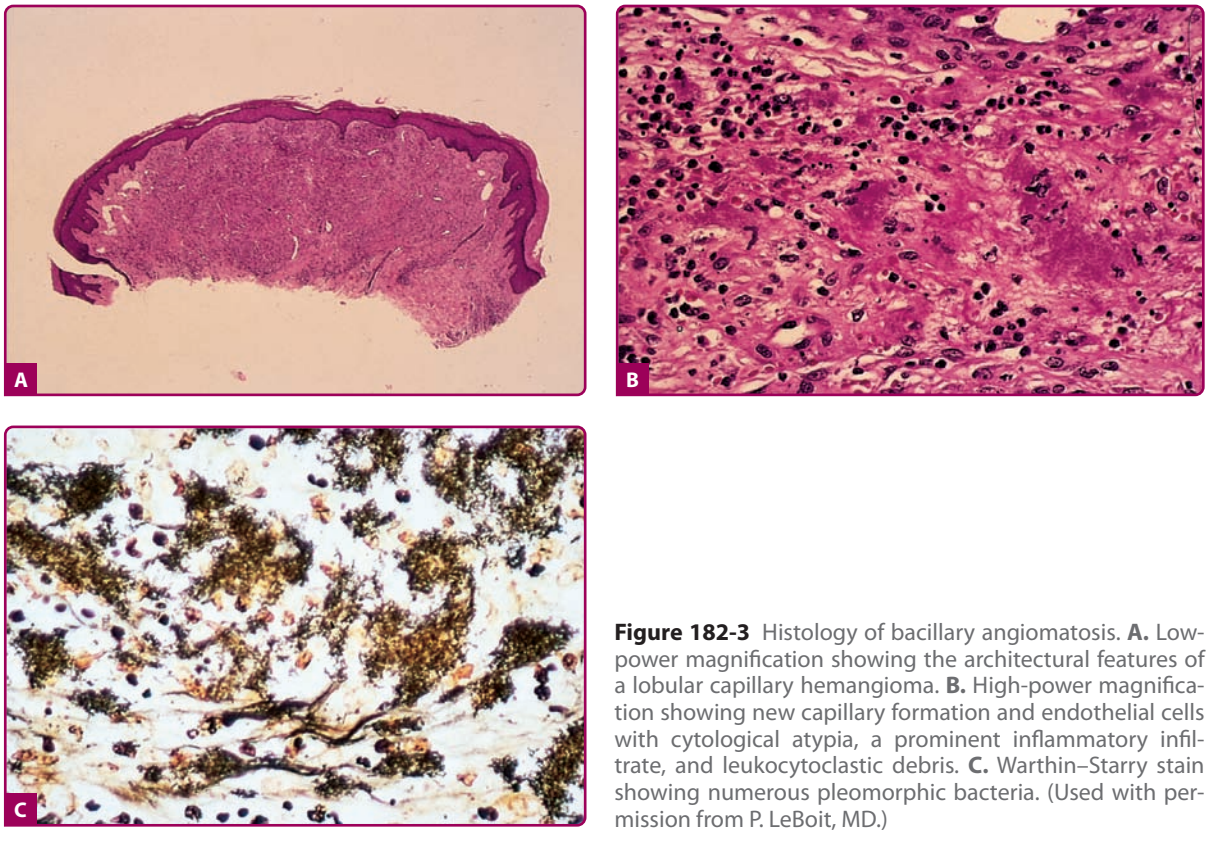

Figure 182-3 Histology of bacillary angiomatosis. **A.** Low-power magnification showing the architectural features of a lobular capillary hemangioma. **B.** High-power magnification showing new capillary formation and endothelial cells with cytological atypia, a prominent inflammatory infiltrate, and leukocytoclastic debris. **C.** Warthin–Starry stain showing numerous pleomorphic bacteria. Figure 182-4 Bartonellosis (verruga peruana). Multiple small papules on the extremities. The lesions may ulcerate.

in areas of PMN infiltration adjacent to blood vessels. This represents large clumps of bacteria, best visualized with a modified Warthin–Starry stain (see Fig. 182-4C). Standard tissue Gram stain and the Warthin–Starry stain used for syphilis do not stain the organisms. If the diagnosis cannot be confirmed with special stains, electron microscopy may be used. The histological findings are identical to those seen in VP, except for the number of bacilli that can be seen on special stains (bacilli are sparse in VP). The lack of spindle cells, atypically shaped vascular channels, and hyaline globules distinguish BA from Kaposi sarcoma. Lesions of BA in tissues other than liver show similar histological features.

CLINICAL COURSE

In the immunocompromised host, the natural history of untreated BA is gradually progressive disease, with increasing numbers of skin lesions and involvement of many visceral organs. If untreated, severely immunocompromised patients may die of their infection.

TREATMENT

Erythromycin, 500 mg four times a day, or doxycycline, 100 mg twice a day for 3 months, is the treatment of choice for BA. Other antibiotics thought to be effective are minocycline, tetracycline, chloramphenicol, azithromycin, and roxithromycin. For peliosis hepatitis, 4 months of treatment is recommended. Some patients require life-long suppressive therapy. Relapses have been reported, especially with shorter treatment courses[39] A Jarisch–Herxheimer reaction, not uncommonly, occurs after initiation of therapy. Most patients respond rapidly to antibiotic therapy. The disappearance of the vascular lesions may relate to the effects of the macrolides and tetracyclines on protein synthesis, stopping the production of vascular growth factors. Patients not treated for a sufficient period are likely to relapse, despite the fact that their skin lesions vanish after a few weeks of treatment. The additional treatment is required to sterilize visceral or hematologic reservoirs of bacteria.

CARRION DISEASE, INCLUDING OROYA FEVER AND VERRUGA PERUANA

CARRION DISEASE AT A GLANCE

- Etiology: *Bartonella bacilliformis*.
- Arthropod vector: Sandfly—Lutzomyia.
- Geographically restricted to South American Andes and lower highland jungles.
- Biphasic disease: acute hematic phase (Oroya fever) and eruptive phase (verruga peruana).

EPIDEMIOLOGY

Carrion disease was the first and for many years the only *Bartonella* infection known. The disease has two well-defined phases: (1) a systemic febrile illness, described historically as Oroya Fever (OF), and (2) an eruptive phase, most relevant to dermatologist, known as verruga peruana. The disease is restricted to the South American Andes, from 2°5′ latitude north to 13° south of the equator, including southern Colombia, parts of Ecuador, and Peru. Most cases have been reported in regions of altitude ranging from 500 to 3,200 meters above sea level. Recent epidemics have been reported in previously nonendemic areas of Peru, suggesting that the endemic area is expanding to lower highland jungle areas near the Amazon basin.[41] Sea surface temperature warming is associated with higher minimum daily temperatures, and an increase in the arthropod vectors. El Niño-related climate changes resulted in up to a fourfold increase in *B. bacilliformis* infection in some geographic regions.[42] Humans are the only known reservoir for *B. bacilliformis*, and asymptomatic bacteremia occurs in 0.5% of persons in endemic regions. In one endemic area, the annual incidence of infection was 12.7% in the overall population, 38% in children, and 1% in those 60 years of age or older. Cases cluster in households.[41]

ETIOLOGY AND PATHOGENESIS

The disease is named after Daniel A. Carrión, who, as a Peruvian medical student in 1885, inoculated himself with a lesion of VP and died after developing the systemic illness known as Oroya fever, demonstrating that

both diseases are in fact caused by the same agent. The causative organism is *B. bacilliformis*. The arthropod vector is most commonly a sandfly, particularly *Lutzomyia verrucarum*, the same vector that transmits *Leishmania peruviana*, an agent of cutaneous leishmaniasis.

CLINICAL MANIFESTATIONS

Carrion disease had been considered a biphasic disease with an acute form (acute hematic bartonellosis or Oroya fever) and a chronic form with skin lesions called verruga peruana. With the ability to culture the causative organism and do serologic testing, the disease spectrum has expanded. In a prospective study in an endemic area, 1% of patients presented with acute hematic disease, 37% with VP and symptoms of acute hematic disease, 32% with VP without systemic symptoms, and 20% have an asymptomatic infection with seroconversion only. Only a minority of patients will manifest both phases of the disease.

After an incubation period between 10 and 210 days (average, 60 days), the acute stage (acute hematic bartonellosis) develops. Patients have severe fevers, headache, abdominal pain, malaise, adenopathy, and a profound paleness. Other signs of hemolysis may also be present. Patients may develop signs of neurologic involvement, including coma. During the acute state, the patients are extremely susceptible to superinfection, either bacterial (classically *Salmonella*) or parasitic (classically *Toxoplasma*). After acute hematic bartonellosis, the patients may experience recurring episodes of fever and transitory bone, joint, and muscle pain.

Patients often present with the eruptive lesions of VP having had no preceding acute phase. VP are highly vascular lesions, identical to pyogenic granuloma or BA (see Fig. 182-4). Three patterns of cutaneous lesions have been described: (1) miliary, (2) nodular, and (3) mular. In the miliary form, lesions are about 3 mm in diameter. Mular lesions are larger, fewer in number, and either sessile or pedunculated, with superficial erosion. Nodular lesions are deep dermal or subcutaneous papules and nodules may not have overlying erythema. Mucosal lesions may occur.

LABORATORY FINDINGS

During the acute hemolytic phase, a profound anemia may be present. Red blood cell counts can fall below $106/mm^3$ (two-thirds of patients have a hematocrit below 20). Oroya fever is one of the few bacterial diseases in which the agent can actually be seen on peripheral blood smears. On Giemsa stained smears, the organisms are seen as blue-colored extraerythrocytic and intraerythrocytic bacilli or coccobacilli. Although B bacilliformes may parasitize up to 100% of the red blood cells, sensitivity of this method for diagnostic purposes can be as low as 36% in unskilled hands.[43] The microorganism can be isolated from peripheral blood during the acute phase and less commonly during the eruptive phase. The isolation of *B. bacilliformis* from patients with lesions of VP underlies the role of such patients as reservoir for the microorganism in endemic areas. Serological tests, such as enzyme-linked immunosorbent assay (ELISA), immunoglobin IgM or IgG indirect inmunofluorescence, hemagglutination test, inmunoblotting of specific 17 or 18 kDa antigen, Western blotting, and polymerase chain reaction are available in reference laboratories, but are not part of routine practice in the remote endemic areas.

HISTOPATHOLOGY

Lesions of VP are histologically identical to those of BA, showing the distinct angioproliferative pattern with areas of neutrophilic collection within the stroma. The pattern of proliferation varies with the type of lesion. In miliary lesions, it is in the papillary and superficial reticular dermis, and in nodular and mular lesions, it is in the deeper dermis. Old verrugas tend to lose the inflammatory component, retaining the vascular frame. At that point, the lesion may look very similar to a pyogenic granuloma. In contrast to BA, the purple bodies of bacteria are hardly seen in VP lesions. However, the organisms can be seen in the tissue with modified silver stain techniques.

DIFFERENTIAL DIAGNOSIS

(Box 182-3)

TREATMENT

If untreated, Oroya fever is a fatal disease in 40%–90% of cases. Because of the frequent concomitant infection with *Salmonella*, the treatment of choice for Oroya fever is chloramphenicol (50–75 mg/kg/day, maximum 3 g/day) for 14 days plus a β-lactam antibiotic. Ciprofloxacin, 500 mg bid for 10 days, also appears effective. Rifampin, 600 mg daily in adults and 10 mg/kg/day in children for 14–21 days, is the treatment of choice for VP, although the macrolides and tetracyclines are also effective. Oral azithromycin, 500 mg daily for 7 days or ciprofloxacin, 500 mg bid for 7–10 days, are considered valid alternatives.[1,43] VP may also regress spontaneously.

BOX 182-3 DIFFERENTIAL DIAGNOSIS OF VERRUGA PERUANA

Chapter 183 :: Miscellaneous Bacterial Infections with Cutaneous Manifestations

:: Scott A. Norton

This chapter focuses on a group of unrelated bacterial diseases that are rarely encountered in a conventional urban or suburban setting but are acquired after a distinctive environmental exposure, such as saltwater immersion, animal bites, handling of an infected animal carcass, or travel to specific areas around the world. Several of these diseases present primarily as cutaneous disorders with rare systemic involvement (e.g., erysipeloid); others present primarily as systemic disorders with rare cutaneous involvement (e.g., brucellosis). Several of the pathogens can be aerosolized and disseminated for respiratory transmission, naturally or with human intervention. The ease of dissemination and the potential virulence of several organisms make them suitable for intentional spread as biologic weapons. The intentional spread of these diseases is discussed in greater detail in Chapter 213.

In this chapter, these infections are grouped by their most common, natural means of transmission to humans: atraumatic exposure to animals, animal bites, and contact with contaminated water (Fig. 183-1).

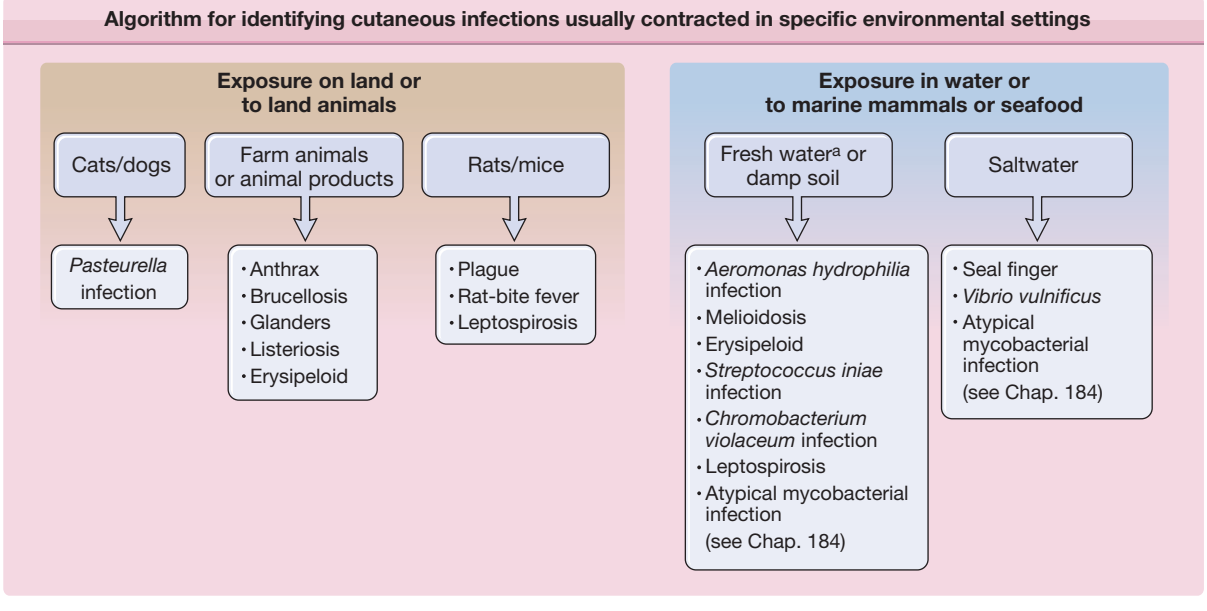

Figure 183-1 Algorithm for identifying cutaneous infections usually contracted in specific environmental settings. [a]Brackish water may harbor the same organisms.

ANTHRAX

ANTHRAX AT A GLANCE

- A large Gram-positive rod, *Bacillus anthracis*, changes into dormant spores under environmentally harsh conditions. Spores are infectious particles that revert to active bacillary form in host tissues.
- Natural pathogen of livestock, especially sheep, goats, and cattle. Most human diseases are occupationally related to exposure to live animals or animal products.
- Cutaneous anthrax is the most common form and is associated with the lowest morbidity. Inhalational and gastrointestinal anthrax are more virulent and frequently lethal.
- Cutaneous lesions arise from percutaneous spore inoculation, usually unnoticed. They present as painless edematous papules or plaques that develop jet-black central eschars.
- The organism is a Centers for Disease Control and Prevention Category A bioweapon in aerosolizable micropowder form. There is no human-to-human transmission.

ETIOLOGY AND EPIDEMIOLOGY

Anthrax is a zoonotic infectious disease caused by *Bacillus anthracis*, a large aerobic, spore-forming Gram-positive rod.[1] Anthrax occurs naturally in ruminant mammals, such as sheep, cattle, and goats. Human disease is seen most often in agrarian, livestock-dependent regions. Consequently, human anthrax usually follows agricultural or industrial exposure, either through direct handling of infected animals or contaminated soil or through the processing of hides, wool, hair, or meat.[2] Anthrax has potential as a class A bioweapon (Table 183-1; see also Chapter 213).

The clinical presentation of human anthrax depends on the route of inoculation. In 95% of human cases, the disease is acquired through percutaneous inoculation of anthrax spores. Human anthrax can also be acquired as inhalational and gastrointestinal disease. Recent cases in the United States of both forms have been associated with recreational use of drums made of unprocessed animal hides imported from West Africa.[3,4] Each of anthrax's form has distinctive clinical, epidemiologic, and prognostic features.[5]

Outbreaks still occur in endemic areas.[6–11] During the late twentieth century, thousands of people in the African nations of Zambia and Zimbabwe developed anthrax.[12] More than 90% of cases were cutaneous and the remainder represented an equal mix of inhalational and gastrointestinal disease. Dying animals typically release vegetative bacilli into the environment, which then convert into the dormant, yet infectious, spores. There are ongoing outbreaks of animal anthrax among free-ranging wood bison (Athabaskan buffalo) in Northern Canada,[13] several species of antelope in Zambia,[14] hippopotami in Uganda, and domesticated grazing animals in North Dakota.[15]

CLINICAL FINDINGS

HISTORY. After an incubation period of 1–7 days, patients may experience low-grade fever and malaise and develop a painless papule at the exposed site. As the lesion enlarges, the surrounding skin becomes increasingly edematous. Pain, if present, is usually due to edema-associated pressure or secondary infection.

CUTANEOUS LESIONS. Cutaneous anthrax develops when spores enter minor breaks in the skin, especially on exposed parts of the hands, legs, and face (Fig. 183-2). In the hospitable environment of human skin, spores revert to their rod forms and produce their toxins. A dermal papule, often resembling an arthropod bite reaction, develops over several days, and then progresses through vesicular, pustular, and escharotic phases. Lesions are surrounded by varying degrees of edema. Depending on the manner of inoculation, one to several lesions may appear, and there may be regional lymphadenitis, malaise, and fever. Individual lesions may appear pustular, leading to the name "malignant pustule," but they do not suppurate. In anthrax, true pustules are rare; a primary pustular lesion is unlikely to be cutaneous anthrax.

The lesion enlarges into a glistening pseudobulla that becomes hemorrhagic with central necrosis and may be umbilicated (see Fig. 183-2). The necrotic ulcer is usually painless, which is an important feature in differentiating it from a brown recluse spider bite. There may be small satellite papules and vesicles that may extend along lymphatics in a sporotrichoid manner. An area of brawny, nonpitting edema ("malignant edema") often surrounds the main lesion. Lesional progression is due to toxins and is unaffected by antibiotic therapy. Fatigue, fever, chills, and tender regional adenopathy may cause an ulceroglandular syndrome. The eschar dries and separates in 1–2 weeks.[16–20]

RELATED PHYSICAL FINDINGS. Cutaneous anthrax may cause fever, tachycardia, and hypotension.

HISTOPATHOLOGY

The prominent features are hemorrhagic edema, dilated lymphatics, and epidermal necrosis. Bacilli

TABLE 183-1
Overview of Bacterial Infections

Infection	Expected Demographic Distribution	Typical Presentation (Skin)[a]	Typical Exposure	Bioweapon Potential[b]	Treatment
Anthrax	Worldwide, especially developing agrarian areas	Painless edematous plaque with central black ulcer or eschar	Goats, sheep, cattle, or products made from them	A	PCN, doxycycline, ciprofloxacin
Tularemia	North America, Europe	Ulceroglandular: painful papule that ulcerates and forms eschar	Tick bites, rabbits, rodents	A	Aminoglycoside, fluoroquinolone, doxycycline.
Plague	Worldwide, especially United States Southwest, India	Buboes (tender regional lymphadenopathy) followed by purpura and gangrene	Flea bites, spread from infected rodents	A	Aminoglycoside, doxycycline, cotrimoxazole
Brucellosis	Worldwide, especially developing agrarian areas	Variable; skin manifestations present in <5% of patients	Cattle, sheep, goats, or untreated milk	B	Doxycycline plus aminoglycoside or rifampin
Glanders	Rare and focal in Asia, Middle East	Nodule with cellulitis that ulcerates; later, deep abscesses and sinuses	Donkeys, mules, horses	B	Sulfadiazine, gentamycine, doxycycline
Pasteurella infection	Worldwide	Rapid onset of cellulitis at bite site followed by necrosis	Dog or cat bite	NR	Amoxicillin plus CA
Rat-bite fever (streptobacillary)	Worldwide, especially Asia	Morbilliform eruption with fever followed by arthritis	Rats or their excreta	NR	Amoxicillin plus CA
Seal finger	Cool coastal regions worldwide	Extremely painful nodule on finger	Seals or sea lions	NR	TCN, ceftriaxone
Listeriosis	Worldwide	In neonates, generalized petechiae, papules, and pustules	In neonates, infected mother with transfer in utero or shortly after birth	NR	Ampicillin or PCN IV
Vibrio vulnificus infection	Worldwide	Necrotizing fasciitis, hemorrhagic bullae often beginning as a wound infection	Warm saltwater or brackish water or undercooked seafood	NR	Doxy and ceftazidime IV, debridement of lesions
Aeromonas hydrophila infection	Worldwide	Cellulitis evolving to abscess formation, often beginning as a wound infection	Fresh or brackish water, contaminated fish	NR	Third-generation cephalosporins, fluoroquinolones; debridement
Melioidosis	Wet tropical areas, especially Southeast Asia and northern Australia	Indolent abscesses; suppurative parotitis (in children)	Wet soil (classically rice paddies), flooded regions	B	Ceftazidime plus a carbipenem IV, then prolonged oral amoxicillin CA or TMP-SMX
Erysipeloid	Worldwide	Tender violaceous plaque on hand at site of injury	Contaminated fish, shellfish, poultry, meat, and animal products	NR	PCN, ampicillin, ceftriaxone, fluoroquinolone
Streptococcus iniae infection	Worldwide, especially freshwater fish farms	Rapid onset of hand cellulitis following a puncture wound	Contaminated farm-raised fish	NR	PCN, cephalosporin
Leptospirosis	Worldwide, especially the tropics	Papules, petechiae, jaundice	Contaminated freshwater, moist soil, or animal urine	NR	Doxy, PCN
Diphtheria	Worldwide where immunization is not practiced	Pustule or superinfected abrasion, evolving to an ulcer with gray membrane at base	Asymptomatic human carriers	NR	PCN IV or erythromycin plus antitoxin

[a]For many entities, multiple presentations are possible depending on the route of inoculation (percutaneous entry, oral ingestion, or inhalation). See text.
[b]If aerosolized, per criteria of the Centers for Disease Control and Prevention.
A = highest (systemic disease, often fatal); B = substantial (severe systemic disease, sometimes fatal); CA = clavulanic acid; doxy = doxycycline; genta = gentamicin; IV = intravenously; NR = not rated; PCN = penicillin; TCN = tetracycline; TMP-SMX = trimethoprim-sulfamethoxazole.

Figure 183-2 Anthrax. The classic cutaneous lesion of a primary infection in anthrax is a painless papule that evolves into a hemorrhagic bulla with surrounding brawny nonpitting edema. Note the typical localization on the hand. The name *anthrax* comes from the Greek word ανθραξ *(anthrax)*, meaning coal, which refers to the coal-black hue of the lesions of cutaneous anthrax.

may be found in the eschar. Anthrax is toxin-mediated and induces scant inflammatory infiltrate. Immunohistochemical stains are quite useful.[21]

TREATMENT

Naturally occurring anthrax is treated with penicillin or doxycycline. Weaponized anthrax, on the other hand, may be resistant to these antibiotics, and, therefore, a fluoroquinolone is recommended for the initial treatment of confirmed or suspected bioterrorism-associated anthrax, even in pregnant women and children. Once drug sensitivities have been established, the patient may be switched to another antibiotic as clinically indicated. Antibiotics will kill activated *B. anthracis* bacilli but will not alter tissue damage already caused by toxins.[22,23] To neutralize the anthrax toxins, the Centers for Disease Control and Prevention (CDC) now possesses human antianthrax immunoglobulin and monoclonal antibodies directed against the toxins are in development.

Although cutaneous anthrax is usually an uncomplicated and readily treatable infection, public health concerns warrant hospitalization. Standard universal precautions are appropriate but specific measures against secondary respiratory transmission are unnecessary because anthrax is not transmitted from person-to-person.

Parenteral crystalline penicillin G (2 million units every 6 hours) was the treatment of choice prior to the 2001 bioterrorism outbreak. In one study, smears and cultures from vesicles or from the necrotic tissue beneath the eschar became negative within 6 hours of initiation of penicillin therapy. Treatment of primary cutaneous anthrax is continued with parenteral therapy until the local edema disappears or the lesion dries up over 1–2 weeks. When the edema resolves, the patient may complete the 60-day treatment with oral therapy.

Other than to obtain material for culture or histopathology, incision and debridement of the cutaneous lesion is unnecessary. First of all, the lesions contain no purulent material needing evacuation and, second, without effective antibiotics, these procedures increase the risk of bacteremic spread of the disease.

PROGNOSIS AND CLINICAL COURSE

Untreated cutaneous anthrax, particularly if nonedematous, is a largely self-resolving disease. In contrast, some lesions, especially ones with massive edema, pose the risk of bacteremia with subsequent septicemia. Thus, the mortality rate of untreated cutaneous anthrax is roughly 5%–20%. With prompt and appropriate antibiotics, there is rapid defervescence and clinical improvement. Massive facial edema associated with cutaneous lesions of the head or neck may lead to respiratory compromise, requiring intubation or tracheostomy and systemic corticosteroids. Palpebral lesions may scar the eyelids and edema-associated seventh-nerve palsy may occur.[24] Hospitalization in an intensive care unit is recommended for any patient with inhalational or gastrointestinal anthrax.

PREVENTION

In nonendemic areas, any case of anthrax requires immediate reporting to public health authorities and a prompt public health response because of the threat of intentional criminal or terroristic release. Although anthrax is a dangerous disease, it is not transmitted from person-to-person. Instead, the spore is the infectious propagule. Therefore patients with anthrax—of whatever clinical presentation—do not require isolation.

An anthrax vaccine has been in use since 1954 for people with occupational exposure to natural anthrax (e.g., veterinarians, wildlife biologists). The CDC recently released new guidelines on its use in the post-9/11 era for routine occupational use and for pre- and postoutbreak exposure use.[25]

Although cutaneous anthrax is usually an uncomplicated and readily treatable infection, public health concerns warrant hospitalization. Standard universal precautions are appropriate but specific measures against secondary respiratory transmission are unnecessary because anthrax is not transmitted from person-to-person.

TULAREMIA (*FRANCISELLA TULARENSIS* INFECTIONS)

TULAREMIA AT A GLANCE

- Caused by *Francisella tularensis*, a Gram-negative coccobacillus found in rabbits, rodents, other mammals, and their immediate environments in temperate and cold regions of North America.
- Has diverse clinical presentations related to route of transmission. Ulceroglandular disease after tick bites is most common.
- Bacteria are easily aerosolized and highly infectious in small inocula; therefore, tularemia poses risks of laboratory accidents or use as a bioweapon.

ETIOLOGY AND EPIDEMIOLOGY

Tularemia is a zoonotic infectious disease caused by *Francisella tularensis*, a pleomorphic Gram-negative coccobacillus found in many species of mammals, most important, lagomorphs (rabbits and hares) and rodents, and in their immediate environments. The bacteria are highly infectious, can be transmitted in many ways, and cause at least eight different patterns of disease.

Tularemia occurs solely in temperate and cold regions of the Northern Hemisphere. The most common form in the United States is ulceroglandular disease in which organisms are inoculated directly into the skin by minor trauma or by bites of infected arthropods that maintain the enzootic cycle. Before 1950, most US infections occurred in hunters who handled infected rabbits and hares. Two incidence peaks each year corresponded with summer and winter hunting seasons. Currently, 100–150 US cases occur each year, mostly in Arkansas, Missouri, and Oklahoma, with transmission of the organism largely via tick bites. The most common tick vectors are *Dermacentor variabilis*, *Amblyomma americanum*, and, in Europe, *Ixodes* sp.[26–30]

Of several subspecies, the most virulent (*F. tularensi* subspecies *tularensis*) lives only in the North America. A more benign one (*F. tularensis* subspecies *holarctica*) is the only subspecies in Eurasia. Although these bacteria do not produce spores, they can survive environmentally—and maintain infectivity—for months.[28,29]

Tularemia is transmitted in other ways, too. Other arthropod vectors include the deerfly (*Chrysops discalis*) in the Western United States, and mosquitoes in Scandinavia and the Baltic region.[31] An outbreak of pulmonary tularemia on Martha's Vineyard, Massachusetts, was associated with springtime mowing of tall grass.[32] The precise environmental source was not clear, perhaps aerosolization of animal excreta in the grass. Domestic cats may spread the organism via direct contact, bite, or aerosol. In parts of Europe, aquatic rodents (muskrats and beavers), household rodents, and drinking water contaminated by these animals are the major sources of infection. Rarely, direct inoculation into conjunctivae or ingestion of poorly cooked, contaminated meat causes infection. There is no human-to-human transmission. A second species, *Francisella philomiragia*, can infect patients with inherited defects in phagocytosis such as chronic granulomatous disease (OMIM #306400).

CLINICAL FINDINGS

HISTORY. Duration of incubation varies with size of inoculum, ranging from 2–10 days. All forms of tularemia present as a sudden flu-like illness characterized by fever, headache, malaise, and myalgias.

CUTANEOUS LESIONS. In ulceroglandular tularemia, a painful red papule appears at the inoculation site (Fig. 183-3). It enlarges rapidly and evolves into a necrotic chancriform ulcer often covered by a black eschar. Regional lymph nodes are large and tender.[32] Bacteremia may cause sepsis and virulent pneumonia. In two recent Scandinavian outbreaks with the less virulent *holarctica* type of tularemia, due primarily to mosquito-borne ulceroglandular disease, approximately one-third of nearly 300 patients developed nonspecific secondary cutaneous manifestations, such as erythema nodosum, erythema multiforme, or an asymptomatic id-like papular eruption on the extremities.[31,33]

RELATED PHYSICAL FINDINGS. In oculoglandular tularemia, organisms are introduced directly

Figure 183-3 Tularemia. A chancre-like ulcer with raised margins on the dorsum of the fourth digit with accompanying axillary lymphadenopathy. The rash on the chest is unrelated and is pityriasis versicolor.

into the conjunctivae, for example, after handling an infected tick or rabbit. This causes purulent conjunctivitis with pain, edema, and local adenopathy. In a recent outbreak in Bulgaria, more than 90% of cases were oropharyngeal, reflecting transmission via contaminated well water. Swallowing the organism may cause ulcerative pharyngotonsillitis with cervical adenopathy or may cause "typhoidal" tularemia.[34] Pulmonary tularemia may be primary (i.e., due to inhalation of organisms) but is more often because of bacteremic spread from another focus.

LABORATORY FINDINGS

Laboratories should be notified of suspected tularemia so that cultures can be set under biohazard conditions to avoid aerosolization. *F. tularensis* grows best on cysteine-supplemented blood agar, producing nonmotile, nonsporulating, pleomorphic, Gram-negative coccobacilli. Some reference laboratories also use animal inoculation techniques.

HISTOPATHOLOGY

The pathogen survives intracellularly in phagocytes, and small granulomas develop in lymph nodes, liver, and spleen. Some lesions may caseate and progress to frank abscess formation. Hepatic granulomas may resemble tuberculosis or brucellosis.

DIFFERENTIAL DIAGNOSIS

The primary lesion of tick-transmitted tularemia resembles a furuncle, paronychia, common ecthyma, the initial lesion of anthrax, *Pasteurella multocida* infection, or sporotrichosis. Prominent regional adenopathy may suggest cat-scratch disease, plague, or melioidosis. Fever after a tick bite might suggest Rocky Mountain spotted fever, but that usually has an exanthem rather than a chancriform lesion. Other tick-borne febrile diseases include other rickettsioses, ehrlichiosis, babesiosis, and viral tick fevers. *F. tularensis* is difficult to grow so the diagnosis is usually made by serologic tests showing a rise in titers. Although the subspecies of *F. tularensis* are clinically and epidemiologically distinct, they are serologically indistinguishable.[28]

TREATMENT

A presumptive diagnosis of tularemia on clinical and epidemiologic grounds is sufficient to initiate treatment while awaiting serologic confirmation (see Table 183-1). Treatment consists of an aminoglycoside antibiotic, such as gentamicin, or a fluoroquinolone; these should be given for at least 10 days. A tetracycline antibiotic, such as doxycycline, given for at least 15 days is an acceptable alternative. Patients improve within 24–48 hours, but treatment should continue for at least 7–10 afebrile days to reduce the risk of relapse.

COURSE, PROGNOSIS, AND COMPLICATIONS

Untreated pulmonary and typhoidal tularemia have mortality rates of about 30%. Without antibiotics, ulceroglandular disease lasts many weeks and has a mortality rate of 5%. Brief courses of antibiotics may permit relapse but, with proper treatment, uncomplicated recovery is expected.

PREVENTION

Hunters and animal handlers should wear impervious gloves when handling game, especially rabbits. Game meat should be cooked thoroughly, even if stored frozen for long periods. A live-attenuated (but rarely used) vaccine was developed in Russia; the US government is currently funding vaccine research. The disease is reportable in the United States and any cluster of pulmonary tularemia cases should raise concerns of bioterrorism.[29,35]

PLAGUE

PLAGUE AT A GLANCE

- Focal enzootic sites worldwide, including the Southwestern United States. Human disease is caused by bites from infected fleas or direct contact with rodent reservoirs.
- The bubonic form is the most common, producing large tender lymph nodes (buboes) proximal to the site of fleabite. All forms can lead to sepsis, distal gangrene (origin of the term *black death*), and death.
- Pneumonic plague because of respiratory spread of aerosolized *Yersinia pestis* has a high mortality and is a possible weapon of bioterrorism.

ETIOLOGY AND EPIDEMIOLOGY

Plague is a severe, acute, febrile zoonosis caused by the aerobic Gram-negative bacillus *Yersinia pestis*. Plague exists in an enzootic cycle, infecting humans through contact with rodent reservoirs or flea vectors. Human plague has three clinical forms: (1) bubonic; (2) bubonic septicemic, a more virulent form due to secondary bacteremia and sepsis; and (3) pneumonic (fulminant disease due to respiratory spread). Distal purpura and gangrene associated with septicemic plague likely gave rise to the term *black death*. The plague bacillus likely evolved from the fecal–oral pathogen, *Y pseudotuberculosis*, by acquiring several virulence plasmids.[36]

Endemic or sylvatic plague occurs in wild rodents in the Western United States, parts of South America,

much of sub-Saharan Africa, and across Southern Asia. In most places, plague is sporadic but Madagascar currently has epidemic plague.[37,38] There are several thousand cases of plague worldwide each year and the disease prevalence is increasing across Africa; Madagascar alone account for nearly half the number of human cases each year.[36,39]

In this country, human disease is almost always transmitted by fleas. Direct handling of infected rodents, rabbits, or their carcasses can also transmit plague. Some cases are transmitted by direct contact with pet dogs or cats that become ill after contact with infected wild animals. Between 1990 and 2005, 107 plague cases, more than 80% bubonic, were reported in the United States, averaging seven per year, mostly in summertime. In Western States, winter cases are often linked with handling of animal carcasses while hunting. In recent years, epizootics have occurred among prairie dogs, and sporadic human cases were seen on several Indian reservations, associated with ground squirrels. Rarely, bacteremic bubonic disease may evolve into pneumonic plague and further initiate respiratory spread to others.[40,41]

The flea associated with epidemic plague in the Old World is *Xenopsylla cheopis*, but fleas in other genera (e.g., *Anomiopsyllus*, *Aetheca*, *Pulex*) are also vectors in the United States.

Because *Y. pestis* can be aerosolized, is devastatingly lethal, and can spread from person-to-person, it is considered a Category A biologic weapon (see Table 183-1). *Y. pestis* produces an intracellular toxin and virulence factors (see Chapter 213).

CLINICAL FINDINGS

HISTORY. Bubonic plague incubates for roughly 2–6 days, followed by the sudden onset of high fever, prostration, malaise, myalgias, backache, and tachycardia. Primary pneumonic plague has a shorter incubation time.

CUTANEOUS LESIONS. In bubonic plague, the initial skin lesion is related to the fleabite and may appear as papular urticaria. However, the hallmark of bubonic plague is prominent, exquisitely tender regional lymphadenopathy with extensive subcutaneous edema. Inguinal buboes are most common in adults; cervical and axillary buboes are more common in children.[36]

Any form of plague can lead to overwhelming endotoxic septicemia accompanied by disseminated intravascular coagulopathy (DIC) (see Chapter 144 and 181). Subsequent purpura and gangrene are most severe on distal extremities.[42]

RELATED PHYSICAL FINDINGS. Primary septicemic plague lacks buboes and presents with typical Gram-negative sepsis. Many patients also have severe abdominal pain, nausea, vomiting, and bloody diarrhea. Pneumonic plague has an abrupt onset with high fever, tachycardia, tachypnea, chest pain, and dyspnea. Within 24 hours of onset, the patient is critically ill and producing bloody sputum laden with *Y. pestis*. Meningitis may complicate all forms of plague.

DIFFERENTIAL DIAGNOSIS

Most patients with bubonic plague present with the rapid onset of a toxic febrile illness, painful buboes, and evidence of an arthropod bite without surrounding cellulitis. Bubonic plague should be distinguished from tularemia, lymphogranuloma venereum, cat-scratch disease, chancroid, Kikuchi's disease, and suppurative lymphadenitis due to staphylococcal or streptococcal infections. Pneumonic plague must be differentiated from other acute bacterial pneumonias. Epidemiologic considerations and the tempo of the illness are major points in the differential diagnosis. The diagnosis is made by examining Gram-stained (or specific fluorescent antibody stained) smears of infected material or by culturing organism from blood, sputum, or aspirated buboes. Serologic methods help retrospectively by demonstrating a fourfold or greater rise in titers. A convalescent passive hemagglutination titer of >1:16 suggests the diagnosis.

TREATMENT

Because the original drug of choice, streptomycin, is not widely available, another aminoglycoside antibiotic, gentamicin, is the preferred treatment (although the US Food and Drug Administration has not approved it for this indication) (see Table 183-1). Doxycycline is also effective and maybe the treatment of choice when oral therapy is required or to use as postexposure prophylaxis. Cotrimoxazole is useful when combination therapy is desired.[43] Patients with pneumonic plague must be placed in respiratory isolation to prevent further transmission. The course of treatment, irrespective of medication, is 10 days. Ordinarily, buboes should not be drained until they are well-localized and antibiotic therapy has been started.[46]

PROGNOSIS AND CLINICAL COURSE

Pneumonic and septicemic plague, if untreated, are nearly always fatal. Untreated bubonic plague has a mortality rate of roughly 50% but early antibiotic therapy has reduced this to 5%–10%. Because primary septicemic plague lacks telltale buboes, the clinical suspicion of plague is often delayed, hence antibiotics are started late and mortality is high.

PREVENTION

Most cases in the United States are acquired peridomestically so it is important in endemic areas to control rodents around homes. Children should be taught to avoid rodent nests, burrows, and dead animals. Pets should be given regular flea treatments, examined properly when ill, and trained not to hunt small mammals or eat sick or dead mammals. Rabbit hunters should wear gloves when handling carcasses. With pneumonic cases, respiratory isolation is mandatory and close contacts should receive antibiotic prophylaxis

with doxycycline or cotrimoxazole. Plague vaccine is no longer available. Because the disease is a zoonosis, it is considered ineradicable, so prevention through rodent control is the most important way to prevent plague.[36,39]

BRUCELLOSIS

BRUCELLOSIS AT A GLANCE

- Zoonosis transmitted by contact with infected animals or consumption of contaminated dairy products.
- May be transmitted via aerosolized bacteria, hence the concern regarding the use of *Brucella* in bioterrorism.
- Usually presents with undulant fever and can involve all organ systems, especially the joints, reproductive organs, liver, and central nervous system. Endocarditis can be fatal.
- Cutaneous lesions are seen in fewer than 5% of patients, usually children. Variable morphologies include vasculitis, erythema nodosum, panniculitis, abscesses, and polymorphous papules, pustules, and papulosquamous lesions. Children with acute brucellosis may have a violaceous papulonodular eruption primarily on the trunk and lower extremities.

GLANDERS

GLANDERS AT A GLANCE

- Rare zoonosis caused by the Gram-negative bacillus *Burkholderia mallei* (formerly *Pseudomonas mallei*), found focally in Asia and the Middle East.
- Animal glanders occurs in horses, mules, and donkeys. Humans are infected through direct occupational exposure to animal reservoirs.
- Most human cases are acquired by direct inoculation into skin or contact of open skin with an infected animal or its secretions. Inhalational transmission is rare.
- A cutaneous ulcer develops after a 1–5-day incubation period, followed by several presentations: ulceroglandular syndrome, localized abscesses (acute or chronic), or bacteremic dissemination (often fatal).

PASTEURELLA MULTOCIDA INFECTIONS

PASTEURELLA MULTOCIDA INFECTIONS AT A GLANCE

- Normal flora in oropharynx of many domestic animals. Most human infections are due to dog or cat bites.
- Local pain and swelling appear rapidly, usually less than 2 days after exposure.
- Gram-negative organism; nevertheless, infection is treated with penicillin or presumptively with amoxicillin/clavulanic acid.

ETIOLOGY AND EPIDEMIOLOGY

P. multocida is a small, ovoid, Gram-negative rod that can cause local skin infection with regional adenitis after a superficial animal bite, scratch, or lick,[65] or septic arthritis and osteomyelitis after a deeper animal bite. Respiratory infections unassociated with trauma occur in rare cases, and bacteremia may accompany meningitis or osteomyelitis.

P. multocida commonly colonizes the oropharynx and nasopharynx of healthy cats, dogs, rats, mice, pigs and other livestock, and poultry. Nearly all patients with *P. multocida* infection have had animal exposure, most commonly a dog or cat bite. Cat teeth are often longer and sharper than those of dogs and therefore may penetrate more deeply to cause septic arthritis or osteomyelitis. Compromising conditions such as cirrhosis, malignancy, and chronic obstructive pulmonary disease coexist in most severe cases.[66–71]

Neonatal pasteurellosis can be acquired by exposure to animals, usually pet dogs and cats in the household, even without known or recognized traumatic contact, possibly via respiratory droplets from the animal, or via vertical transmission from an asymptomatic mother.[72]

CLINICAL FINDINGS

HISTORY. Local pain and swelling occur within a few days of an animal bite or contact exposure. Fever is uncommon.

CUTANEOUS LESIONS. Redness, swelling, ulceration, and seropurulent drainage develop at the bite site. Cellulitis may progress rapidly and extensively, producing lymphangitis. Local necrosis may follow, and necrotizing fasciitis with septic shock has been reported.[66,73]

RELATED PHYSICAL FINDINGS. Regional adenopathy may be present. Deep bites may introduce organisms into a joint or beneath periosteum and cause septic arthritis or osteomyelitis.

LABORATORY FINDINGS

Mild leukocytosis is present. After several weeks, a radiograph of underlying bone may show osteomyelitis. The organism is Gram-negative, and Wright–Giemsa stain reveals a bipolar appearance. Histopathologically, an acute pyogenic response is seen.[67]

DIFFERENTIAL DIAGNOSIS

The diagnosis is suspected when a painful infection develops rapidly (<2 days) at the site of an animal bite. Approximately 75% of infected cat bites are caused by *P. multocida*. Local ulceration and proximal lymphadenitis mimic ulceroglandular tularemia, but *P. multocida* characteristically produces a necrotizing cellulitis and not chancriform syndrome. The diagnosis is confirmed by isolation of the organism, although treatment is often initiated according to an animal bite protocol or based on the history of a rapidly appearing painful cellulitis after a dog or cat bite.[73,74]

TREATMENT

Because most animal bite wounds show polymicrobial contamination, an amoxicillin/clavulanic acid preparation should be started after a dog or cat bite. Although *P. multocida* is a Gram-negative organism, most strains are susceptible to penicillin, which is the drug of choice if only *Pasteurella* is cultured. If one suspects that the bite reached periosteum, parenteral penicillin should be given until the local lesion is well healed. *P. multocida* is also susceptible to doxycycline, later-generation cephalosporins, and trimethoprim-sulfamethoxazole (see Table 183-1).

PROGNOSIS AND CLINICAL COURSE

Infection usually responds promptly to antibiotic therapy. Osteomyelitis, abscesses, and remnant foreign bodies should be treated surgically as well as medically. *P. multocida* infections may be more severe or lead to sepsis in immunocompromised or acquired immunodeficiency syndrome (AIDS) patients.

PREVENTION

A great many animal bites are unprovoked by family pets onto a child's hand, therefore judicious selection of pets and instruction to children are useful, but not guaranteed, ways to reduce domestic animal bites.[75]

RAT-BITE FEVER

RAT-BITE FEVER AT A GLANCE

- Rat-bite fever refers to two clinically similar zoonoses caused by *Streptobacillus moniliformis* and *Spirillum minus*.
- Infection is usually acquired through rat bite or ingestion of rat-contaminated food or drink.
- The disease is characterized by the classic triad of fever, polyarthralgias, and rash.

SEAL FINGER

SEAL FINGER AT A GLANCE

- Occupational zoonosis after contact with seals or sea lions. Occurs worldwide in marine environments.
- Usually presents as an exquisitely painful nodule on the distal phalanx of the finger that may progress to tenosynovitis or joint destruction.
- The pathogen is likely to be a marine *Mycoplasma* found in the seal's normal oropharyngeal flora. The infection responds quickly to tetracyclines.

LISTERIOSIS (*LISTERIA MONOCYTOGENES* INFECTIONS)

LISTERIOSIS AT A GLANCE

- Caused by anaerobic Gram-positive bacillus transmitted in fecal–oral manner through consumption of contaminated dairy products.
- Human listeriosis is most common in pregnant women, neonates, and patients with acquired immunodeficiency syndrome, and in food-borne outbreaks. May cause miscarriages, stillbirths, and virulent neonatal infections.
- Generalized petechiae, papules, or pustules may be seen in neonatal listeriosis, especially in meconium-stained newborns.

ETIOLOGY AND EPIDEMIOLOGY

L. monocytogenes is an anaerobic Gram-positive bacillus found widely in soil, water, vegetation, and the gut flora of humans and other animals. Exposure to this organism occurs through fecal–oral contamination, but the disease has an opportunistic nature, appearing in very young, very old, pregnant, or immunocompromised individuals. *L. monocytogenes* is found in the feces of many domestic and wild animals and birds, and is therefore widespread in the environment.[90] Typically, livestock become infected by eating manure-contaminated silage; this can cause abortions, septicemia, and a peculiar form of encephalitis called *circling disease*.[91]

Human listeriosis is uncommon but occurs in three typical settings: (1) sporadic disease in pregnant women and neonates; (2) sporadic disease in AIDS patients; and (3) food-borne outbreaks.[92] Humans usually become infected by eating contaminated, unpasteurized, or improperly pasteurized dairy products. In adults, the disease can present as septicemia, meningitis, vaginal infection, pneumonitis, or oculoglandular syndrome and can cause miscarriages and stillbirths.[62] Infantile listeriosis presents acutely with septicemia, meningitis and meningoencephalitis, and septic granulomatosis.

Approximately 5% of humans are fecal carriers of *Listeria*. Higher rates of carriage have been observed in family contacts of patients with listeriosis. Several outbreaks have implicated unpasteurized soft cheeses imported from Mexico or vegetables from farms that fertilize crops with manure.[93]

The highest incidence of human listeriosis is seen among infants in the perinatal period, which suggests that the transmission occurs in utero or at birth. One-fourth of adult cases occur in pregnant women. Many other adult cases occur in patients with altered cellular immunity, such as those with Hodgkin disease, leukemia, or AIDS or those who have undergone organ transplantation. Hepatic disorders such as cirrhosis and iron overload also predispose to infection. Recent reports suggest that biological therapies that interfere with tumor necrosis factor activity, such as treating psoriatic arthritis with infliximab, may increase the risk for listeriosis.[94]

CLINICAL FINDINGS

HISTORY. Early-onset neonatal listeriosis develops in infants infected in utero by untreated bacteremic mothers shortly before labor begins. Findings are evident at birth or become apparent within the first few days. These neonates are acutely ill and have generalized pustular, papular, or petechial skin lesions. Late-onset neonatal listeriosis occurs several weeks after a healthy birth, is presuably acquired postpartum, and usually presents as meningitis.[93,95,96]

Listeriosis from food-borne organisms usually causes outbreaks of acute gastroenteritis in families or communities. Patients have fever, vomiting, and nonbloody diarrhea, but this form lacks skin lesions.

CUTANEOUS LESIONS. In septic infants, cutaneous lesions appear as generalized petechiae, papules, or pustules. Veterinarians or farmers who handle infected bovine fetuses may develop an acute febrile illness with headache, malaise, and regional adenopathy. Tender red papules develop on exposed surfaces and may evolve into pustules over 2–3 days. These contain the characteristic Gram-positive rods.

RELATED PHYSICAL FINDINGS. Neonates with early onset listeriosis are often meconium-stained at birth, lethargic, and have an enlarged liver and spleen. Central nervous system listeriosis has a spectrum of neurologic manifestations, ranging from typical acute bacterial meningitis, abscesses, encephalitis, and infarcts.[96]

LABORATORY FINDINGS

L. monocytogenes is a small pleomorphic bacillus that often appears coccoid in infected tissues and body fluids. Pustules, meconium, cerebrospinal fluid (CSF), or blood cultures reveal the characteristic Gram-positive rods. The organism is β-hemolytic when cultured on sheep blood agar and exhibits a characteristic tumbling motility when grown in broth. In adults with meningitis, the CSF contains neutrophils, but about one-third of meningitic infants have a mononuclear response.

HISTOPATHOLOGY

Skin lesions show focal necrosis, neutrophilic infiltrates, and monocytes around blood vessels. In septic patients, viscera may show abscesses and granulomas.

DIFFERENTIAL DIAGNOSIS

Neonatal listeriosis should be suspected in a meconium-stained newborn with intrauterine growth retardation who develops a papular skin eruption or subsequently failure to thrive. The differential diagnosis includes other in utero neonatal infections such as toxoplasmosis, cytomegalovirus infection, rubella, disseminated herpes simplex infection, and disseminated bacterial infections, such as those caused by group B *Streptococci*, *Escherichia coli*, *Salmonella*, and *Pseudomonas*.

TREATMENT

Neonates with listeriosis should be treated with intravenous ampicillin (or penicillin) (see Table 183-1). Penicillin-allergic patients may be treated with cotrimoxazole or erythromycin. Cephalosporins are generally ineffective.[90]

PROGNOSIS, CLINICAL COURSE, AND COMPLICATIONS

In neonatal septicemia or meningitis, mortality is around 50%, even with treatment. In adults, prompt treatment is usually effective, unless there is a severe underlying debility. Pregnant woman, even if treated, are at risk for miscarriage.

PREVENTION

Prepartum strategies to reduce neonatal group B streptococcal infections may also reduce risk of neonatal listeriosis.[96]

Farmers should not feed contaminated silage to livestock nor use untreated manure to fertilize crops. Still, it is almost impossible to guarantee *Listeria*-free foods. Therefore, people at greatest risk should avoid foods typically linked to listeriosis, such as raw (unpasteurized) dairy products, unwashed vegetables, and poorly cooked meats. Veterinarians and farmers should use gloves and protective garments when handling aborted fetuses or placentae.[95]

VIBRIO VULNIFICUS INFECTIONS

VIBRIO VULNIFICUS INFECTIONS AT A GLANCE

- Noncholera *Vibrio* organisms are found in warm saltwater worldwide. Exposures occur via percutaneous injury, often minor (e.g., while ocean fishing) or via ingestion of filter-feeding shellfish, which concentrate organisms.
- Severe illness presents with necrotizing fasciitis, hemorrhagic bullae, and hypotensive shock. Cirrhosis and other liver diseases predispose to a virulent, often fatal, course.

ETIOLOGY AND EPIDEMIOLOGY

Vibrio are facultatively anaerobic, pleomorphic, Gram-negative rods found in marine waters, estuaries, brackish lakes, and their sediments wherever the water temperature is above 20°C (68°F). The most well-known vibriosis is cholera, caused by antigenic strains of *Vibrio cholerae*. Although cholera organisms do not infect the skin, many other *Vibrio* do. The most important of these, *V. vulnificus* can cause fulminant cellulitis, myositis, necrotizing fasciitis, and death.[97]

People become infected with *V. vulnificus* through oral or percutaneous exposure. After eating contaminated raw or undercooked seafood, people who have chronic liver disease or diabetes mellitus, or who are otherwise immunocompromised, are at risk for primary septicemia. Percutaneous infections are acquired by handling raw seafood, by entering saltwater with an open wound, or by experiencing skin trauma while in or around saltwater. Immunocompromised individuals are again at increased risk for secondary septicemia.[98,99]

V. vulnificus lives in warm seawater, where it colonizes the skin of fish and is concentrated in filter-feeding shellfish, such as oysters. Infections are particularly common along the Gulf of Mexico and, because of global warming, are now found in increasingly higher latitudes, such as on the Baltic Sea.[100–102]

Most cases of wound infection are sporadic and depend more on host susceptibilities than environmental conditions. However, after Hurricane Katrina struck the Gulf Coast in 2005, thousands of people were exposed to brackish floodwaters. There were 18 known cases of *Vibrio* wound infections—14 due to *V. vulnificus*, 3 due to *V. parahaemolyticus*, and 1 unspeciated case.[103]

CLINICAL FINDINGS

HISTORY. There is nearly always a history of contact with saltwater, injury while ocean fishing, or consumption or handling of shellfish. After oral exposure, primary septicemia often begins with watery diarrhea, fever, chills, nausea, vomiting, and abdominal pain. People with wound infections usually recall an open skin lesion present before the saltwater exposure or a percutaneous injury during the exposure. *Vibrio* cellulitis is painful and has a rapid onset within 12–24 hours of exposure. Secondary bacteremia with sepsis may occur several days later.[104]

CUTANEOUS LESIONS. Infected wounds may present as pustules, lymphangitis, or cellulitis. These infections may be mild or may develop into rapidly progressive, painful cellulitis with extensive skin necrosis, myositis, and necrotizing fasciitis (Fig. 183-4).

Figure 183-4 *Vibrio vulnificus* cellulitis with hemorrhagic plaque and bullae on the legs of an older diabetic patient with cirrhosis.

Secondary bacteremia may cause metastatic cutaneous lesions.[98,105] In septic patients, large hemorrhagic bullae commonly arise on the extremities or trunk and usually progress to necrotic ulcers and necrotizing fasciitis (see Table 183-1; see also Chapter 179).

RELATED PHYSICAL FINDINGS. *V. vulnificus* septicemia causes high fever, tachycardia, and hypotension. One-third of patients develop Gram-negative septic shock.

LABORATORY FINDINGS

In primary septicemia, leukopenia is more common than leukocytosis. Thrombocytopenia is typical and may be part of disseminated intravascular coagulation. Usually, there is laboratory evidence for the person's predisposing condition (e.g., diabetes). All *Vibrio* species can be grown in regular blood culture media and cause hemolysis on sheep blood agar, but only *V. vulnificus* ferments lactose on MacConkey's agar. Histopathology shows noninflammatory bulla, epidermal necrosis, hemorrhage, and bacteria in dermal vessels. Radiographic studies show accumulations of nonspecific soft tissue edema.

DIFFERENTIAL DIAGNOSIS

A cirrhotic or diabetic patient with fever, shock, and hemorrhagic bulla within several days of saltwater exposure or eating raw oysters should alert the physician to possible *Vibrio* septicemia, especially along the American Gulf Coast.

Similar presentations include disseminated intravascular coagulation, clostridial myonecrosis, meningococcemia, purpura fulminans, any form of necrotizing fasciitis, and other aggressive soft tissue infections. Wound infections sustained in fresh water suggest infection with *Aeromonas* rather than *Vibrio*. Clostridial myonecrosis may present with necrotizing fasciitis and shock, but is further suggested by local wound crepitus and the finding of Gram-positive rods.

TREATMENT

Primary or secondary septicemia due to *V. vulnificus* (or other *Vibrio* sp.) requires prompt management of hypotensive shock, parenteral administration of antibiotics, and vigorous debridement of necrotic lesions. Amputation of the affected limb may be necessary. The antibiotics of choice are a combination of doxycycline and ceftazidime (see Table 183-1). Alternatives to doxycycline include chloramphenicol, ciprofloxacin, and minocycline. Alternatives to ceftazidime include cefotaxime. Application of compresses with modified Dakin's solution (0.025% sodium hypochlorite) may help arrest the progression of the cutaneous lesions.[106]

PROGNOSIS, CLINICAL COURSE, AND COMPLICATIONS

The mortality rate for *V. vulnificus* primary septicemia is approximately 50%, about three times higher than the mortality for wound infections caused by the same organism.

PREVENTION

People with cirrhosis, diabetes, AIDS, and other immunocompromising illnesses should not eat raw shellfish and, if they have open skin wounds, should not enter seawater, estuaries, or brackish lakes. If an at-risk individual exposes open skin to saltwater, the site should be cleansed promptly with soap and clean water. Similarly, these individuals should not handle raw fish and shellfish. Vigilant attention to onset of illness is then required. Some authorities consider of a course of prophylactic oral doxycycline for an immunocompromised person with a high-risk exposure.

OTHER CUTANEOUS *VIBRIO* INFECTIONS

The most common other *Vibrio* to cause wound infections are *Vibrio parahaemolyticus* and nontoxigenic *Vibrio cholerae* (i.e., antigenic strains other than 01 and 139). Usually, these *Vibrio* cause an infection after oral exposure, producing an acute but self-limited noninflammatory gastroenteritis. Wound infections may occur after open skin is exposed to saltwater. The disease course is usually less severe than that of *V. vulnificus* although in an immunocompromised host, it may cause hemorrhagic bulla, shock, and necrotizing fasciitis.

AEROMONAS HYDROPHILA INFECTIONS

AEROMONAS HYDROPHILA INFECTIONS AT A GLANCE

- Caused by a facultatively anaerobic Gram-negative bacillus found in fresh and brackish water worldwide.
- Usually presents as cellulitis after exposure to fresh or brackish water but may cause necrotizing fasciitis or myonecrosis.
- Sepsis risk in cirrhotic and immunocompromised patients.

MELIOIDOSIS

MELIOIDOSIS AT A GLANCE

- Caused by *Burkholderia pseudomallei* (formerly *Pseudomonas pseudomallei*), a Gram-negative aerobic bacillus that lives as a saprophyte in freshwater and damp soil.
- Occurs in humans and animals, primarily in wet tropical areas such as Southeast Asia and coastal northern Australia. People who develop melioidosis elsewhere usually had prior exposure in endemic areas.
- Rice farmers, particularly if compromised by diabetes mellitus or chronic renal disease, are most susceptible.
- The disease is acquired after exposure to contaminated soil or water, either directly via the skin or through inhalation of particulate soil or dust.
- Clinical presentation ranges from focal indolent cutaneous and subcutaneous abscesses to fulminant pneumonia with septicemia.
- On the Centers for Disease Control and Prevention's Category B list of possible bioweapon agents.

ERYSIPELOID

ERYSIPELOID AT A GLANCE

- An occupational zoonosis is caused by *Erysipelothrix rhusiopathiae* and associated with percutaneous trauma while handling raw fish or poultry.
- Classic dermatologic presentation is localized nonsuppurative purple–red plaques on the dorsal hands. Rare chronic and bacteremic forms exist.

ETIOLOGY AND EPIDEMIOLOGY

Erysipeloid, an acute infection of traumatized skin caused by *Erysipelothrix rhusiopathiae* (formerly *Erysipelothrix insidiosa*), occurs most frequently in fishermen, butchers, kitchen workers, and others who handle raw fish, poultry (especially turkey), and meat products.[136,137,141–143] The disease is especially common in pigs, where it is known as swine erysipelas. In humans, erysipeloid occurs primarily during the summer months and can be considered an occupational dermatosis.

E. rhusiopathiae is a thin, Gram-positive, microaerophilic, nonmotile bacillus that is hardy enough to survive putrefaction of tissue and exposure to saltwater or freshwater. The organism is found in rats, birds, the slime on saltwater fish, and crabs and other shellfish, and is associated with poultry, meats, hides, and bones.

In humans, organisms usually enter broken skin on the hands and takes one of the four clinical forms: (1) a local nonsuppurative cutaneous infection (erysipeloid of Rosenbach); (2) a diffuse chronic cutaneous form consisting of multiple plaques with sharply defined angular borders; (3) subacute bacterial endocarditis, particularly of the aortic valve; or (4) a bacteremic form without endocarditis, usually found only in immunocompromised patients. The disease does not seem to confer lasting immunity.[144]

CLINICAL FINDINGS

HISTORY. The patient is usually employed in the fishing or animal product industry. After inoculation, there is an incubation period of 2–7 days. Initially, burning pain occurs at the injured site, then a violaceous dermal plaque develops. Lymphangitis and regional adenopathy occasionally occur, as well as low-grade fever and malaise. Bacteremia and endocarditis are rare but serious sequelae. Untreated, erysipeloid usually heals on its own within 3 weeks.

CUTANEOUS LESIONS. The distinctive erysipeloid lesion is usually on a finger or the back of the hand; is violaceous, warm, and tender; and has well-defined, raised margins with an angular or polygonal border (Fig. 183-5). It often involves the web spaces

Figure 183-5 Erysipeloid. Characteristically, the violaceous, sharply marginated lesion is composed of macules and plaques and is located on the hand.

but spares the terminal phalanges and does not progress beyond the wrist. The borders usually expand, whereas the central region clears without desquamation or ulceration. Rarely, multiple lesions distant from the original site of injury arise, presumably through bacteremic spread. Postinflammatory hyperpigmentation may persist after the lesion resolves.

RELATED PHYSICAL FINDINGS. Arthritis may be associated with the local lesion, and, in rare cases, distant joints are involved. Sepsis produces typical peripheral stigmata, including signs of endocarditis.[142]

LABORATORY FINDINGS

Gram stains rarely show *E. rhusiopathiae* although culturing tissue from the advancing edge may reveal the organism. Growth occurs best on serum-fortified media between 30°C and 37°C under hypercapnic conditions. Agar-gel diffusion precipitation or fluorescent antibody techniques are helpful in establishing the diagnosis.[136,137]

HISTOPATHOLOGY

The findings are nonspecific but may include marked superficial dermal edema, vascular dilation, and mixed lymphocytic and neutrophilic perivascular infiltrates.

DIFFERENTIAL DIAGNOSIS

The character of the local lesion in a person handling fresh meat or fish products suggests the diagnosis. As its name suggests, erysipeloid resembles other forms of bacterial cellulitis or erysipelas. It may resemble a severe, acute irritant contact dermatitis. In erysipelas, the central area is most affected region compared with central clearing in erysipeloid. "Seal finger" may be mistaken for erysipeloid.

TREATMENT

The treatment of choice for erysipeloid is high-dose penicillin or ampicillin for 7–10 days. Patients who cannot take penicillins may be treated with a third-generation cephalosporin (such as ceftriaxone), imipenem, or ciprofloxacin (see Table 183-1). This recommendation is based primarily on in vitro studies, not clinical experience. If arthritis, septicemia, or endocarditis is present, the penicillin dosage should be increased and the drug should be administered intravenously for several weeks.[142]

PROGNOSIS, CLINICAL COURSE, AND COMPLICATIONS

Untreated lesions usually last for 2–3 weeks but may have waxing and waning cycles over several months. Improvement is often dramatic and recurrence is rare if penicillin is administered. The prognosis in systemic infections depends on early and appropriate treatment. The bacteremic form occasionally leads to endocarditis with its attendant morbidity and mortality.

PREVENTION

Erysipeloid can be prevented by wearing gloves when handling live animals or animal products and by washing skin wounds promptly with soap and water.

STREPTOCOCCUS INIAE INFECTIONS

STREPTOCOCCUS INIAE INFECTIONS AT A GLANCE

- Caused by a recently recognized streptococcal species that colonizes or infects freshwater fish, such as tilapia, grown in intense aquaculture.
- Most human clinical cases present as cellulitis of the hand after an accidental puncture wound during preparation of live fish for cooking.
- Bacteremia commonly occurs.

PREVENTION

Aquaculture farms are becoming increasingly aware of *S. iniae* infections in their produce and have an economic incentive to maintain healthy fish. Nevertheless, cooks who prepare live-bought, aquaculture-raised fish will continue to be exposed to this pathogen.

LEPTOSPIROSIS

LEPTOSPIROSIS AT A GLANCE

- Waterborne zoonosis with worldwide distribution caused by serovars of *Leptospira interrogans*, which are excreted in urine of reservoir animals, especially rodents. Outbreaks during rainy seasons or after flooding in areas with poor sanitation.
- Most human cases are mild or subclinical. In severe cases there may be fever, hepatic and renal failure, jaundice, hemorrhage, and death.
- Cutaneous findings include jaundice, conjunctival suffusion, petechiae, and nonspecific papules.

ETIOLOGY AND EPIDEMIOLOGY

Leptospirosis is a waterborne zoonosis caused by *Leptospira interrogans*. The disease is found worldwide, except in the Polar Regions, wherever animal urine can contaminate bodies of freshwater. Rodents are the most important reservoirs, although over 160 species of mammals are known to harbor *Leptospira*, including wild, farm, pet, and laboratory animals. Infected humans can also serve as transient reservoirs, particularly in urban slums in the wet tropics. Reservoir animals excrete leptospires in their urine, which contaminate the environment. Humans generally acquire the disease through broken skin after direct contact with an infected animal or exposure to contaminated water or soil. People are infected less commonly through mucous membranes, ingestion of contaminated water, or inhalation of fomites.[154, 155]

L. interrogans thrives in warm fresh water, so leptospirosis has its highest incidence in tropical areas, particularly those with inadequate sanitation and where people go barefoot. Leptospirosis is an important cause of undifferentiated fever in the developing world, along with dengue, malaria, and typhoid. Serological surveys in some endemic regions suggest that >80% of people had prior infection.[156] The disease is most prevalent among children who play or swim in contaminated water and among adults with occupational exposures (e.g., sugarcane workers or rice farmers) to infected animals or to contaminated soil and water. Travelers to hyperendemic areas, particularly ecotourists or adventure travelers who are exposed to contaminated water, are at increased risk. Many outbreaks of leptospirosis have been reported after heavy rains and floods as they cause sewers to overflow.[157,158] Hawaii has the highest incidence in the United States.[157,159,160]

CLINICAL FINDINGS

HISTORY. Patients usually have had recent occupational or recreational contact with contaminated water or mud. Most human infections are asymptomatic, self-limited, and detectable only on serologic surveys. Ill patients have one of two clinical forms of the disease: (1) a mild anicteric form that resolves without complications, or (2) a severe, icteric form (Weil disease). Both forms typically have two phases: the acute bacteremic phase, followed by the delayed immune or convalescent phase. Incubation usually takes 5–14 days and then the leptospiremic phase begins suddenly with headache, fever, chills, nausea, vomiting, abdominal pain, and myalgias (particularly of the calves and thighs). This initial nonspecific phase continues for about a week, then defervescence occurs.[159]

After several relatively asymptomatic days, the second phase of illness begins with low-grade fever. In severe cases rash, meningitis, uveitis, and hepatic and renal failure may develop.

CUTANEOUS LESIONS. In the first week of illness, the conjunctivae become suffused (red but not exudative). Skin lesions occur in fewer than 50% of cases. These consist of nonspecific macules, papules, urticaria, and petechiae, mostly on the trunk. Desquamation and infarcts have been observed on the hands or feet of some infected children. Weil disease has prominent hepatic (jaundice) and renal (hematuria, azotemia) components. Hemorrhages occur in a variety of organs, including the skin, and petechiae are common on the palate. A variant called *pretibial fever* or *Fort Bragg fever*, caused by *L. interrogans* serovariant *autumnalis*, has a distinctive rash that appears on the fourth or fifth day of illness, consisting of slightly raised, 1- to 5-cm, tender, erythematous papules on the shins. The rash subsides within 4–7 days.[155]

RELATED PHYSICAL FINDINGS. Most patients present with a fever of unknown origin without localizing signs. Other physical findings depend on the severity of the presentation, ranging nuchal rigidity in aseptic meningitis; or jaundice, hepatomegaly, and interstitial nephritis in Weil's disease. Some patients have generalized hemorrhages with epistaxis, hematuria, and gastrointestinal bleeding, and pretibial fever with splenomegaly.

LABORATORY FINDINGS

Laboratory tests help establish the diagnosis and the disease's severity. Direct isolation of leptospires is possible from the blood or CSF during the acute phase or from urine during the convalescent phase. A recently developed serum dipstick assay rapidly detects anti-leptospire immunoglobulin M or IgM antibodies. Thrombocytopenia is common but the white blood cell count is widely variable, reaching levels up to 40,000/mm^3 in Weil's disease. A CSF pleocytosis, with up to several hundred mononuclear cells, may be present. Liver function abnormalities and jaundice are common. Azotemia and hematuria occur in patients with renal involvement.[159,161]

TREATMENT

Public health authorities in endemic areas recommend starting antibiotic therapy early, perhaps presumptively, to reduce the risk of severe disease while laboratory confirmation is awaited. Doxycycline is effective and can be taken prophylactically for short-term exposure in a hyperendemic area. Penicillin has also been recommended, although controlled studies are lacking, and it may precipitate a Jarisch–Herxheimer reaction (see Table 183-1).

PROGNOSIS, CLINICAL COURSE, AND COMPLICATIONS

Perhaps 90% of patients have either asymptomatic or mild anicteric disease. Both forms resolve spontaneously without complications. In Weil's disease,

close attention must be given to fluid and renal status. Untreated Weil's disease has a mortality rate of 5%–40%, usually due to renal failure, less often due to cardiopulmonary failure or pulmonary hemorrhage. Late sequelae among survivors of untreated illness include neuropsychiatric diseases.[162]

PREVENTION

Water sanitation and rodent control measures will reduce the incidence of leptospirosis in a community. There is no vaccine against leptospirosis. Individuals who expect frequent contact with contaminated water or soils (e.g., military personnel or adventure travelers) should consider protective clothing and other ways to limit exposures or they may decrease the risk of disease by taking prophylactic doxycycline 200 mg, once weekly during these periods.[158,162]

DIPHTHERIA

DIPHTHERIA AT A GLANCE

- Classic diphtheria produces adherent gray membranous pharyngeal lesions, which may cause lethal airway obstruction. Exotoxin may cause latent peripheral neuritis or lethal cardiomyopathy.
- Cutaneous diphtheria usually affects the legs and begins as tender pustules that break down to punched-out ulcers covered by gray membranes. It is primarily found in the tropics or in travelers returning from these areas.
- Diphtheria can be prevented with toxoid immunization. It is treatable with antibiotics and antitoxin.

Chapter 184 :: Tuberculosis and Infections with Atypical *Mycobacteria*

:: Aisha Sethi

Tuberculosis is still an important worldwide disease. There were an estimated 9.27 million incident cases globally of TB in 2007.[1] This is an increase from 9.24 million cases in 2006, to 8.3 million cases in 2000 and 6.6 million cases in 1990. Most of the estimated number of cases in 2007 were in Asia (55%) and Africa (31%), with small proportions in the Eastern Mediterranean region (6%), the European region (5%) and the Americas (3%). The five countries that ranked first to fifth in terms of total numbers of cases in 2007 were India, China, Indonesia, Nigeria, and South Africa. Of the 9.27 million incident cases in 2007, an estimated 1.37 million (14%) were HIV positive; 79% of these HIV-positive cases were in the African region.

In 2008, a total of 12,898 incident tuberculosis (TB) cases were reported in the United States; the TB rate declined 3.8% from 2007 to 4.2 cases per 100,000 population, the lowest rate recorded since national reporting began in 1953. In 2008, the TB rate in foreign-born persons in the United States was 10 times higher than in US-born persons. TB rates among Hispanics and blacks were nearly eight times higher than among non-Hispanic whites, and rates among Asians were nearly 23 times higher than among non-Hispanic whites. To ensure that TB rates decline further in the United States, especially among foreign-born persons and minority populations, TB prevention and control capacity should be increased. Additional capacity should be used to (1) improve case management and contact investigations; (2) intensify outreach, testing, and treatment of high-risk and hard-to-reach populations; (3) enhance treatment and diagnostic tools; (4) increase scientific research to better understand TB transmission; and (5) continue collaboration with other nations to reduce TB globally.[2]

HIV-positive people are about 20 times more likely than HIV-negative people to develop TB in countries with a generalized HIV epidemic, and between 26 and 37 times more likely to develop TB in countries where HIV prevalence is lower.

The so-called atypical *Mycobacteria* (*Mycobacteria* other than *Mycobacteria tuberculosis*, or MOTT) cause skin disease more frequently than does *M. tuberculosis*. They exist in various reservoirs in the environment. Among these organisms are obligate and facultative pathogens as well as nonpathogens. In contrast to the obligate pathogens, the latter do not cause disease by person-to-person spread.

MYCOBACTERIA AND THE ACQUIRED IMMUNODEFICIENCY SYNDROME PANDEMIC

The pandemic of acquired immunodeficiency syndrome (AIDS), with its profound and progressive suppression of cellular immune functions, has led to a resurgence of tuberculosis and the appearance

or recognition of new mycobacterial pathogens. The *Mycobacterium avium*-intracellulare (MAI) complex is the most common cause of disseminated bacterial infections in patients with AIDS in the United States, but is much less frequently so in Europe. In AIDS patients, *Mycobacterium kansasii* is more common than *M. tuberculosis*. The incidence of tuberculosis in patients with AIDS is almost 500 times than that in the general population. Cutaneous disease in AIDS patients is frequently caused by MOTT.

TUBERCULOSIS OF THE SKIN

TUBERCULOSIS AT A GLANCE

- Infection with *Mycobacterium tuberculosis* or other very closely related strains, as well as the inflammatory reaction of the host define, the disease (tuberculosis, or TB).
- One-third of the world's population is infected with TB.
- TB is the main cause of death of patients infected with human immunodeficiency virus.
- TB usually affects the lung, but virtually all other organ systems may be involved.
- TB of the skin is a relatively rare manifestation with a wide spectrum of clinical findings depending on the source of infection and the immune status of the host.
- Diagnosis is based on clinical manifestations, histopathologic analysis, demonstration of the relevant *Mycobacteria* in tissue or in culture and host reaction to *M. tuberculosis* antigen.
- Treatment is with standard multidrug regimens; cases of multidrug-resistant (MDR) TB or extensively multidrug-resistant (XDR) TB require special attention.
- Course and prognosis depend on the immune status of the host. Treatment is curative except for patients with a severely compromised immune system.

EPIDEMIOLOGY

Tuberculosis of the skin has a worldwide distribution. Once more prevalent in regions with a cold and humid climate, it now occurs mostly in the tropics. Cutaneous TB incidence parallels that of pulmonary TB and developing countries still account for the majority of cases in the world. The emergence of resistant strains and the AIDS epidemic have led to an increase in all forms of TB (Table 184-1).

Figure 184-1 Scrofuloderma in an Ethiopian patient. (Used with permission from Dr. Kassahun Bilcha.)

The two most frequent forms of skin tuberculosis are lupus vulgaris (LV) and scrofuloderma (Fig. 184-1). In the tropics, LV is rare, whereas scrofuloderma and verrucous lesions predominate. LV is more than twice as common in women than in men, whereas tuberculosis verrucosa cutis is more often found in men. Generalized miliary tuberculosis is seen in infants (and adults with severe immunosuppression or AIDS), as is primary inoculation tuberculosis. Scrofuloderma usually occurs in adolescents and the elderly, whereas LV may affect all age groups.

THE *MYCOBACTERIUM*. *Mycobacteria* multiply intracellularly, and are initially found in large numbers in the tissue.

M. tuberculosis, *M. bovis*, and, under certain conditions, the attenuated BCG organism cause all forms of skin tuberculosis.

In LV, the bacteria often have virulence as low as that of the BCG. Large number of bacteria can be found in the lesions of a primary chancre or of acute miliary tuberculosis; in the other forms, their number in the lesions is so small that it may be difficult to find them.

M. tuberculosis may become dormant in the host tissue.

New diagnostic tools are emerging,[4,5] as described below.

THE HOST. The human species is quite susceptible to infection by *M. tuberculosis*, with big differences among populations and individuals. Populations that have been in long-standing contact with tuberculosis are, in general, less susceptible than those who have come into contact with *Mycobacteria* more recently, presumably reflecting widespread immunity from subclinical infection. Age, state of health, environmental factors, and particularly the immune system are of importance. In Africans, tuberculosis frequently takes an unfavorable course, and tuberculin sensitivity may be more pronounced than in whites.

TUBERCULIN REACTION (KOCH PHENOMENON). An extract of *M. tuberculosis* (tuberculin) was shown to produce a different skin reaction in sensitized individuals than in naive individuals, and this

TABLE 184-1
Classification of Cutaneous Tuberculosis

	Host Immune Status	Clinical Disease
Exogenous infection	Naive Immune	 Primary inoculation tuberculosis Tuberculosis verrucosa cutis
Endogenous spread	High Low	Lupus vulgaris Scrofuloderma Acute miliary tuberculosis Orificial tuberculosis Metastatic tuberculous abscess (tuberculous gumma)
Tuberculosis due to Bacille Calmette-Guérin	Naive	Normal primary complex-like reaction Perforating regional adenitis Postvaccination lupus vulgaris
Tuberculids	Not clear	Tuberculids: Lichen scrofulosorum Papulonecrotic tuberculid Facultative tuberculids: Nodular vasculitis Erythema nodosum

difference became the basis of a widely used diagnostic test. This reaction is a delayed-type hypersensitivity reaction, induced by *Mycobacteria* during primary infection. This "old tuberculin" has now been replaced by purified protein derivative (PPD). More recently, purified species-specific antigens have been developed.[6]

Local intradermal injection (the method most widely used) leads to the local tuberculin reaction, which usually reaches its maximum intensity after 48 hours. It consists of a sharply circumscribed area of erythema and induration, and in highly hypersensitive recipients or after large doses, a pallid central necrosis may appear.

In an attempt to quantify the tuberculin reaction, an assay known as the QuantiFERON®-TB Gold test was developed to measure specific antigen-driven interferon-γ synthesis by whole blood cells and was approved by the FDA in 2005.

Tuberculin sensitivity usually develops 2–10 weeks after infection and persists throughout life. The state of sensitivity of an individual infected with *M. tuberculosis* is of considerable significance in the pathogenesis of tuberculosis skin lesions.

In patients with clinical tuberculosis, an increase in skin sensitivity usually indicates a favorable prognosis, and in tuberculous skin disease accompanied by high levels of skin sensitivity, the number of bacteria within the lesions is small. Tuberculin sensitivity (skin reactivity) is not necessary for immunity, however, and sensitivity and immunity do not always parallel each other.

ROUTE OF INFECTION. Cutaneous inoculation leads to a tuberculous chancre or to tuberculosis verrucosa cutis (Fig. 184-2), depending on the immunologic state of the host.

Spread of *Mycobacteria* may occur by continuous extension of a tuberculous process in the skin (scrofuloderma) by way of the lymphatics (LV), or by hematogenous dissemination (acute miliary tuberculosis of the skin or LV).

HISTOPATHOLOGY

The hallmark of tuberculosis and infections with some of the slow-growing atypical *Mycobacteria* is the tubercle: an accumulation of epithelioid histocytes with Langhans-type giant cells among them and a varying amount of caseation necrosis in the center, surrounded by a rim of lymphocytes and monocytes. Although this tuberculoid granuloma is highly characteristic of several forms of tuberculosis, it may be mimicked by deep fungal infections, syphilis, and leprosy, as well as other diseases. As in leprosy, the histopathologic features of skin tuberculosis may be reflective of the host's immune status.

Figure 184-2 Tuberculosis Verrucosa cutis on the foot of an Ethiopian patient. (Used with permission from Dr. Kassahun Bilcha.)

POLYMERASE CHAIN REACTION PROCEDURE

The polymerase chain reaction (PCR) procedure has been used increasingly to ascertain the presence of mycobacterial DNA in skin specimens.[7] Although the detection of specific DNA in tissues has yielded valuable information and will conceivably gain importance in the future, interpretation of the results of these tests in individual patients is still problematic.[8] In one study, samples from 16 of 20 patients with sarcoidosis contained mycobacterial DNA, both tuberculous and nontuberculous.[9] In another study of patients with confirmed or highly probable cutaneous tuberculosis or with erythema induratum, believed to indicate a host response to the infection, PCR testing showed 100% sensitivity and specificity in multibacillary disease. In paucibacillary disease, PCR testing showed 55% sensitivity and specificity, and only 80% of PCR-positive patients responded to antituberculosis therapy.[7]

QUANTIFERON®-TB GOLD (QFT-G) TEST

In 2005, the FDA approved QFT-G as an in vitro diagnostic aid. In this test, blood samples are mixed with antigens and controls. For QFT-G, the antigens include mixtures of synthetic peptides representing two *M. tuberculosis* proteins: (1) ESAT-6 and (2) CFP-10. After incubation of the blood with antigens for 16–24 hours, the amount of interferon-γ (IFN-γ) is measured.

If the patient is infected with *M. tuberculosis*, their white blood cells will release IFN-γ in response to contact with the TB antigens. The QFT-G results are based on the amount of IFN-γ that is released in response to the antigens.

Although more sensitive than the tuberculin skin test, the QFT-G may be negative in patients with early active tuberculosis and indeterminate results are more common in immunocompromised individuals and young children. Another similar assay, the T-SPOT®.*TB* test, measures the number of IFN-γ-producing T cells and is currently available in Europe. QFT-G testing is indicated for diagnosing infection with *M. tuberculosis*, including both TB disease and latent TB infection. Whenever *M. tuberculosis* infection or disease is being diagnosed by any method, the optimal approach includes coordination with the local or regional public health TB control programs.

SKIN DISEASES CAUSED BY *MYCOBACTERIUM TUBERCULOSIS/BOVIS* INFECTION

Infection with *M. tuberculosis* used to be thought to result in characteristic clinical features.[10] However, with increasing number of cases in immunocompromised individuals and improved diagnostic tools, many uncharacteristic manifestations have been discovered.

PRIMARY INOCULATION TUBERCULOSIS (TUBERCULOUS CHANCRE, TUBERCULOUS PRIMARY COMPLEX)

EPIDEMIOLOGY. Tuberculous chancre and affected regional lymph nodes constitute the tuberculous primary complex in the skin. The condition is believed rare, but its incidence may be underestimated. In some regions with a high prevalence of tuberculosis and poor living conditions, primary inoculation tuberculosis of the skin is not unusual. Children are most often affected.

ETIOLOGY AND PATHOGENESIS. Tubercle bacilli are introduced into the tissue at the site of minor wounds. Oral lesions may be caused by bovine bacilli in nonpasteurized milk and occur after mucosal trauma or tooth extraction. Primary inoculation tuberculosis is initially multibacillary, but becomes paucibacillary as immunity develops.

CLINICAL FINDINGS. The chancre initially appears 2–4 weeks after inoculation and presents as a small papule, crust, or erosion with little tendency to heal. Sites of predilection are the face, including the conjunctivae and oral cavity, as well as the hands and lower extremities. A painless ulcer develops, which may be quite insignificant or may enlarge to a diameter of more than 5 cm (Fig. 184-3). It is shallow with a granular or hemorrhagic base studded with miliary abscesses or covered by necrotic tissue. The ragged edges are undermined and of a reddish-blue hue. As the lesions grow older, they become more indurated, with thick adherent crusts.

Figure 184-3 Primary inoculation tuberculosis. Note tuberculous chancre on the thigh and regional lymphadenopathy. A positive tuberculin reaction is noted on the arm.

Wounds inoculated with tubercle bacilli may heal temporarily but break down later, giving rise to granulating ulcers. Mucosal infections result in painless ulcers or fungating granulomas. Inoculation tuberculosis of the finger may present as a painless paronychia. Inoculation of puncture wounds may result in subcutaneous abscesses.

Slowly progressive, regional lymphadenopathy develops 3–8 weeks after the infection (Fig. 184-3) and may rarely be the only clinical finding. After weeks or months, cold abscesses may develop that perforate to the surface of the skin and form sinuses. The lymph nodes draining the primary glands may also be involved. Body temperature may be slightly elevated. The disease may take a more acute course, and in half of the patients, fever, pain, and swelling simulate a pyogenic infection. Early, there is an acute nonspecific inflammatory reaction in both skin and lymph nodes, and *Mycobacteria* are easily detected by Fite stain. After 3–6 weeks, the infiltrate and the regional lymph nodes acquire a tuberculoid appearance and caseation may occur.

DIAGNOSIS. Any ulcer with little or no tendency to heal and unilateral regional lymphadenopathy in a child should arouse suspicion. Acid-fast organisms are found in the primary ulcer and draining nodes in the initial stages of the disease. The diagnosis is confirmed by bacterial culture. The PPD reaction is negative initially and later converts to positive (Fig. 184-3).

DIFFERENTIAL DIAGNOSIS. The differential diagnosis encompasses all disease with a primary complex (Box 184-1).

COURSE. If untreated, the condition may last up to 12 months. Rarely, LV develops at the site of a healed tuberculous chancre. The regional lymph nodes usually calcify.

The primary tuberculous complex usually produces immunity, but reactivation of the disease may occur. Hematogenous spread may give rise to tuberculosis of other organs, particularly of the bones and joints. It may also lead to acute miliary disease with a fatal outcome. Erythema nodosum occurs in approximately 10% of cases.

BOX 184-1 DIFFERENTIAL DIAGNOSIS OF PRIMARY INOCULATION TUBERCULOSIS

- Sporotrichosis

Consider
- Tularemia
- Bartonellosis

Always Rule Out
- Other mycobacterioses

TUBERCULOSIS VERRUCOSA CUTIS (WARTY TUBERCULOSIS, PROSECTOR'S WART, LUPUS VERRUCOSUS)

ETIOLOGY AND PATHOGENESIS. Tuberculosis verrucosa cutis is a paucibacillary disorder caused by exogenous reinfection (inoculation) in previously sensitized individuals with high immunity.

Inoculation occurs at sites of minor wounds or, rarely, from the patient's own sputum. Members of professional groups handling infectious material are at risk. Children may become infected playing on contaminated ground.

CLINICAL FINDINGS. Lesions usually occur on the hands or, in children, on the lower extremities as a small asymptomatic papule or papulopustule with a purple inflammatory halo. They become hyperkeratotic and are often mistaken for a common wart. Slow growth and peripheral expansion lead to the development of a verrucous plaque with an irregular border (Fig. 184-4). Fissures discharging pus extend into the underlying brownish-red to purplish infiltrated base. The lesion usually is solitary, but multiple lesions may occur. Regional lymph nodes are rarely affected.

Lesions progress slowly and, if untreated, persist for many years. Spontaneous involution eventually occurs, leaving an atrophic scar.

HISTOPATHOLOGY. The most prominent histopathologic features are pseudoepitheliomatous hyperplasia with marked hyperkeratosis, a dense inflammatory infiltrate, and abscesses in the superficial dermis or within the pseudoepitheliomatous rete pegs. Epithelioid cells and giant cells are found in the upper and middle dermis. Typical tubercles are uncommon, and the infiltrate may be nonspecific.

Figure 184-4 Tuberculosis verrucosa cutis on the back of the hand.

BOX 184-2 DIFFERENTIAL DIAGNOSIS OF TUBERCULOSIS VERRUCOSA CUTIS

Most Likely
- Warts or keratoses
- Hyperkeratotic lupus vulgaris
- Blastomycosis
- Hypertrophic lichen planus

Consider
- Chromomycosis
- Bromoderma
- Tertiary syphilis

Always Rule Out
- Lesions due to other *Mycobacteria*

DIFFERENTIAL DIAGNOSIS. (Box 184-2)

LUPUS VULGARIS (TUBERCULOSIS LUPOSA)

EPIDEMIOLOGY. LV is an extremely chronic, progressive form of cutaneous tuberculosis occurring in individuals with moderate immunity and a high degree of tuberculin sensitivity. Once common, LV has declined steadily in incidence. It has always been less common in the United States than in Europe. Females appear to be affected two to three times as often as males; all age groups are affected equally.

ETIOLOGY AND PATHOGENESIS. LV is a postprimary, paucibacillary form of tuberculosis caused by hematogenous, lymphatic, or contiguous spread from elsewhere in the body. Spontaneous involution may occur, and new lesions may arise within old scars. Complete healing rarely occurs without therapy.

CLINICAL FINDINGS. Lesions are usually solitary, but two or more sites may be involved simultaneously. In patients with active pulmonary tuberculosis, multiple foci may develop. In approximately 90% of patients, the head and neck are involved. LV usually starts on the nose, cheek, earlobe, or scalp and slowly extends onto adjacent regions. Other areas are rarely involved.

The initial lesion is a brownish-red, soft or friable macule or papule with a smooth or hyperkeratotic surface. On diascopy, the infiltrate exhibits a typical apple jelly color. Progression is characterized by elevation, a deeper brownish color (Fig. 184-5), and formation of a plaque (see Fig. 184-5). Involution in one area with expansion in another often results in a gyrate outline border. Ulceration may occur. Hypertrophic forms appear as a soft nodule (see eFig. 184-3.1 in online edition) or plaque with a hyperkeratotic surface (eFig. 184-3.2 in online edition). The mucosae may be primarily involved or become affected by the extension of skin lesions. Infection is manifest as small, soft, gray or pink papules, ulcers, or friable granulating masses.

After a transient impairment of immunity, particularly after measles (thus the term lupus postexanthematicus), multiple disseminated lesions may arise simultaneously in different regions of the body as a consequence of hematogenous spread from a latent tuberculous focus. During and after the eruption, a previously positive tuberculin reaction may become negative but will usually revert to positive as the general condition of the patient improves.

HISTOPATHOLOGY. The most prominent histopathologic feature is the formation of typical tubercles. Secondary changes may be superimposed: epidermal

Figure 184-5 **A.** Slightly raised, brownish plaque of lupus vulgaris. **B.** Large plaque of lupus vulgaris of 10 years' duration involving the cheek, jaw, and ear.

thinning and atrophy or acanthosis with excessive hyperkeratosis or pseudoepitheliomatous hyperplasia. Acid-fast bacilli are usually not found. Nonspecific inflammatory reactions may partially conceal the tuberculous structures. Old lesions are composed chiefly of epithelioid cells and may be impossible to distinguish from sarcoidal infiltrates (see eFig. 184-4.1 in online edition).

DIAGNOSIS. Typical LV plaques may be recognized by the softness of the lesions, brownish-red color, and slow evolution. The apple jelly nodules revealed by diascopy are highly characteristic; finding them may be decisive, especially in ulcerated, crusted, or hyperkeratotic lesions. The result of the tuberculin test is strongly positive except during the early phases of postexanthematic lupus. Bacterial culture results may be negative, in which case the clinical diagnosis can usually be supported by positive PCR results for *M. tuberculosis.*

DIFFERENTIAL DIAGNOSIS. (Box 184-3)

COMPLICATIONS. Involvement of the nasal or auricular cartilage may result in extensive destruction and disfigurement (Fig. 184-6). Atrophic scarring, with or without prior ulceration, is characteristic, as is recurrence within a scar. Fibrosis may be pronounced and mutilating.

Dry rhinitis is often the only symptom of early nasal LV, but lesions may also destroy the cartilage of the nasal septum. Scarring of the soft palate and laryngeal stenosis also occur.

COURSE. LV is a very long-term disorder and without therapy progresses over many years to functional impairment and disfiguration (see Fig. 184-6). Long-standing LV may lead to the development of carcinoma (see Fig. 184-6). Squamous cell carcinomas outnumber basal cell carcinomas by far, and the risk of metastases is high. In 40% of patients, there is associated tuberculous lymphadenitis, and 10%–20% have active pulmonary tuberculosis or tuberculosis of the bones and joints.[11] Pulmonary tuberculosis is 4–10 times more frequent in patients with LV than in the general population.

BOX 184-3 DIFFERENTIAL DIAGNOSIS OF LUPUS VULGARIS

Most Likely
- Sarcoidosis
- Discoid lupus erythematosus

Consider
- Lymphocytoma
- Tertiary syphilis
- Leprosy
- Lupoid leishmaniasis

Always Rule Out
- Blastomycosis or other deep mycotic infections

Figure 184-6 Lupus vulgaris of long duration that has led to the destruction of the nose. Ulcerating squamous cell carcinoma has developed on the upper lip.

SCROFULODERMA (TUBERCULOSIS COLLIQUATIVA CUTIS)

EPIDEMIOLOGY. Prevalence is higher among children, adolescents, and the aged.

ETIOLOGY AND PATHOGENESIS. Scrofuloderma is subcutaneous tuberculosis leading to cold abscess formation and a secondary breakdown of the overlying skin. It may be either multibacillary or paucibacillary.

Scrofuloderma represents contiguous involvement of the skin overlying another site of infection (e.g., tuberculous lymphadenitis, tuberculosis of bones and joints, or tuberculous epididymitis).

CLINICAL FINDINGS. Scrofuloderma most often occurs in the parotidal, submandibular, and supraclavicular regions and may be bilateral. It first presents as a firm, subcutaneous nodule, usually well defined, freely movable, and asymptomatic. As the lesion enlarges, it softens. After months, liquefaction with perforation occurs, causing ulcers and sinuses (Fig. 184-7). The ulcers are linear or serpiginous with undermined, inverted, bluish edges and soft, granulating floors. Sinusoidal tracts undermine the skin. Clefts alternate with soft nodules. Scar tracts develop and bridge ulcerative areas or even stretches of normal skin. Tuberculin sensitivity is usually pronounced.

HISTOPATHOLOGY. Massive necrosis and abscess formation in the center of the lesion are nonspecific.

Figure 184-7 Scrofuloderma in the clavicular region. Note abscess formation, ulceration, and extrusion of purulent and caseous material.

However, the periphery of the abscesses or the margins of the sinuses contain tuberculoid granulomas.

DIAGNOSIS. If there is an underlying tuberculous lymphadenitis or bone and joint disease, the diagnosis usually presents no difficulty. Positive results on culture confirm the diagnosis.

DIFFERENTIAL DIAGNOSIS. (Box 184-4)

COURSE. Spontaneous healing does occur, but the course is very protracted, and it may be years before lesions have been completely replaced by scar tissue. Presence of the typical cribriform scars permits a correct diagnosis, even after the process has become quiescent. LV may develop at or near the site of scrofuloderma.

BOX 184-4 DIFFERENTIAL DIAGNOSIS OF SCROFULODERMA

Most Likely
- Sporotrichosis
- Hidradenitis suppurativa

Consider
- *Mycobacterium scrofulaceum* infection
- Syphilitic gummas
- Actinomycosis
- Severe forms of acne conglobata

Always Rule Out
- *Mycobacterium avium*-intracellulare lymphadenitis

ORIFICIAL TUBERCULOSIS (TUBERCULOSIS ULCEROSA CUTIS ET MUCOSAE, ACUTE TUBERCULOUS ULCER)

ETIOLOGY AND PATHOGENESIS. Orificial tuberculosis is a rare form of tuberculosis of the mucous membranes and orifices that is caused by autoinoculation of *Mycobacteria* from progressive tuberculosis of internal organs.

The underlying disease is far advanced pulmonary, intestinal, or, rarely, genitourinary tuberculosis. *Mycobacteria* shed from these foci in large numbers are inoculated into the mucous membranes.

CLINICAL FINDINGS. A small yellowish or reddish nodule appears on the mucosa and breaks down to form a soft ulcer with a typical punched-out appearance, undermined edges, and circular or irregular border (Fig. 184-8). The ulcer floor often exhibits multiple yellowish tubercles and bleeds easily. The surrounding mucosa is edematous and inflamed. Lesions may be single or multiple and are extremely painful, resulting in dysphagia.

The tongue is most frequently affected, particularly the tip and the lateral margins, but the soft and hard palates are also common sites. In advanced cases, the lips are involved, and the oral condition often represents an extension of ulcerative tuberculosis of the pharynx and larynx. In patients with intestinal tuberculosis, lesions develop around the anus, and in females with active genitourinary disease, the vulva is involved.

HISTOPATHOLOGY. There is a massive nonspecific inflammatory infiltrate and necrosis, but tubercles with caseation may be found deep in the dermis. *Mycobacteria* are easily demonstrated.

Figure 184-8 Orificial tuberculosis in advanced cavitary pulmonary tuberculosis.

BOX 184-5 DIFFERENTIAL DIAGNOSIS OF ORIFICIAL TUBERCULOSIS

Most Likely
- Aphthous ulcers

Consider
- Syphilitic lesions (not painful)

Always Rule Out
- Squamous cell carcinoma

DIFFERENTIAL DIAGNOSIS. (Box 184-5)

COURSE. Orificial tuberculosis is a symptom of advanced internal disease and usually portends a fatal outcome.

SEQUELAE OF BACILLE CALMETTE–GUÉRIN INOCULATION

Vaccination with attenuated bovine BCG appears to protect infants and young children from the more serious forms of tuberculosis, but its ability to prevent disease in adults remains uncertain. In the United States, guidelines for BCG immunization have been developed.[12,13]

In the normal course of BCG vaccination, an infiltrated papule develops after approximately 2 weeks, attains a size of approximately 10 mm after 6–12 weeks, ulcerates, and then slowly heals, leaving a scar. Vaccination may provoke an accelerated reaction in a previously infected person. The regional lymph nodes may enlarge, but usually heal without breaking down. Tuberculin sensitivity appears 5–6 weeks after vaccination.

The true incidence of complications caused by the BCG organism is difficult to ascertain, but it is extremely low in comparison to the great number of vaccinations performed in Europe in the past 50 years.[14] Problems include the following:

- LV at or near the vaccination site (latency of months to years)
- Koch phenomenon in individuals sensitive to tuberculin [see Section "Tuberculin Reaction (Koch Phenomenon)"]
- Regional adenitis, sometimes severe and with systemic symptoms, more often in children
- After deep injection, local abscesses, excessive ulceration
- Scrofuloderma with suppuration for 6–12 months
- Generalized tuberculid-like reactions (rare)
- Generalized adenitis, osteitis, organ tuberculosis (e.g., in the joints) occasionally

THE TUBERCULIDS

Lichen scrofulosorum, erythema induratum, papulonecrotic tuberculids, lupus miliaris disseminatus faciei, and other eruptions with rather exotic designations were originally included in the tuberculids (Table 184-2).

TABLE 184-2
Tuberculids

Terminology: Relationship to Tuberculosis	Entities
Tuberculids: conditions in which *Mycobacterium tuberculosis/bovis* appears to play a significant role	Lichen scrofulosorum Papulonecrotic tuberculid
Facultative tuberculids: conditions in which *M. tuberculosis/bovis* may be one of several pathogenic factors	Nodular vasculitis/erythema induratum of Bazin Erythema nodosum
Nontuberculids: conditions formerly designated as tuberculids; there is no relationship to tuberculosis	Lupus miliaris disseminatus faciei Rosacea-like tuberculid Lichenoid tuberculid

With the sharp decline in incidence and the effective treatment of tuberculosis in developed countries, the tuberculids also became rare. However, this does not apply to areas in which tuberculosis is still common, and with the recent resurgence of tuberculosis associated with AIDS in some Western countries, some tuberculids are also being observed again.

The pathogenic relationship of the tuberculids to tuberculosis is still poorly understood. Although there is no doubt that such a relationship exists for some tuberculids, in other cases it appears highly unlikely.

PCR testing revealed *M. tuberculosis* DNA in skin lesions of erythema induratum/nodular vasculitis and papulonecrotic tuberculid in one series of patients, but in another, results were uniformly negative.[18,19] Thus, *M. tuberculosis* infection may be responsible directly or indirectly for some cases of these diseases but not all, and the usefulness of lesional PCR testing may vary among clinical settings. Consistent with this statement, antituberculosis drugs are beneficial in some cases but not all; spontaneous involution may occur, and some patients appear to respond well to other therapies. It should be noted that, although not considered a tuberculid, sarcoidosis has been postulated to result from an immunologic reaction to mycobacterial antigens.[20]

The following discussion includes only those conditions for which a preponderance of the evidence supports a tuberculous etiology (see Table 184-2).

LICHEN SCROFULOSORUM

EPIDEMIOLOGY AND PATHOGENESIS. Lichen scrofulosorum is an uncommon lichenoid eruption ascribed to hematogenous spread of *Mycobacteria* in an individual strongly sensitive to *M. tuberculosis*. Usually associated with chronic tuberculosis of the lymph nodes, bones, or pleura, it has also been observed after BCG vaccination and in association with *M. avium-intracellulare* infections.[21]

BOX 184-6 DIFFERENTIAL DIAGNOSIS OF LICHEN SCROFULODERMA

Most Likely
- Lichen planus
- Lichen nitidus

Consider
- Lichenoid secondary syphilis
- Micropapular forms of sarcoidosis

CLINICAL FINDINGS. Lesions are usually confined to the trunk and occur most often in children and adolescents with active tuberculosis. The lesions are asymptomatic, firm, follicular or perifollicular flat-topped yellowish or pink papules, sometimes with fine scale. Lichenoid grouping is pronounced, and lesions may coalesce to form rough, discoid plaques. Lesions persist for months, but spontaneous involution eventually occurs. Antituberculosis therapy results in complete resolution within weeks.

HISTOPATHOLOGY. Superficial tuberculoid granulomas develop around hair follicles or independent of the adnexa. *Mycobacteria* are not seen in the sections and cannot be cultured from biopsy material.

DIFFERENTIAL DIAGNOSIS. (Box 184-6)

PAPULONECROTIC TUBERCULID

EPIDEMIOLOGY. Papulonecrotic tuberculid is a symmetric eruption of necrotizing papules, appearing in crops and healing with scar formation that occurs preferentially in children or young adults. It is rarely reported but may not be uncommon in populations with a high prevalence of tuberculosis.

ETIOLOGY AND PATHOGENESIS. As a rule, bacteria cannot be demonstrated in lesions. In most cases, the tuberculin test shows a positive reaction, and associated pulmonary or extrapulmonary tuberculosis is common. LV has been reported to evolve with papulonecrotic tuberculid. Lesions are reported to respond promptly to antituberculosis therapy whether or not a tuberculous focus is identified.

In studies of skin lesions in patients with papulonecrotic tuberculid, *M. tuberculosis* DNA was detected in approximately 50% of the skin biopsies (11 out of 22 samples).[22,23,24] *M. kansasii* infection was documented in one patient.[25]

Some cases of papulonecrotic tuberculid have been associated with discoid lupus erythematosus, arthritis, or erythema nodosum. Although papulonecrotic tuberculid is classified as an id reaction and therefore, by definition, is not due to direct involvement of the skin by the organism, some of the lesions have been positive on culture. It seems most likely that papulonecrotic tuberculid is a reaction to particulate tuberculous antigen and, in some cases, to living organisms as well.[26]

Figure 184-9 Papulonecrotic tuberculid on the forearm.

CLINICAL FINDINGS. Sites of predilection are the extensor aspects of the extremities, buttocks, and lower trunk (Fig. 184-9), but the eruption may become widespread. Distribution is symmetric, and consists of disseminated crops of livid or dusky red papules with a central depression and an adherent crust over a crater-like ulcer. There is spontaneous involution, which leaves pitted scars.

HISTOPATHOLOGY. Characteristically, a wedge-shaped necrotic area in the upper dermis extends into the epidermis. The inflammatory infiltrate surrounding this necrotic area may be nonspecific, but is usually tuberculoid. Involvement of the blood vessels is a cardinal feature and consists of an obliterative and sometimes granulomatous vasculitis leading to thrombosis and complete occlusion of the vascular channels.

TREATMENT OF CUTANEOUS TUBERCULOSIS

In general, the management of cutaneous tuberculosis is similar to that of tuberculosis of other organs.[27–30] Chemotherapy is usually the treatment of choice (Table 184-3A and eTable 184-3B in online edition), but ancillary measures may be required. Vaccines against *M. tuberculosis* have been attempted,[27] but are still not available.

Although they are not yet established as a therapeutic option, cytokines such as interleukin 2, interferon-γ,

TABLE 184-3A
Therapy Guidelines for *Mycobacterium tuberculosis* Infections

Initial Phase			Continuation Phase			Range of Total Doses (Minimal Duration)	Rating (Evidence)[a,b]	
Regimen	Drugs	Interval and Doses[c] (Minimal Duration)	Regimen	Drugs	Interval and Doses[c,d] (Minimal Duration)		HIV⁻	HIV⁺
1	INH RIF PZA EMB	7 days per week for 56 doses (8 weeks) or 5 days per week for 40 doses (8 weeks)[e]	1a 1b 1c[f]	INH/RIF INH/RIF INH/RPT	7 days per week for 126 doses (18 weeks) or 5 days per week for 90 doses (18 weeks)[e] Twice weekly for 36 doses (18 weeks) Once weekly for 18 doses (18 weeks)	184–130 (26 weeks) 92–76 (26 weeks) 74–58 (26 weeks)	A (I) A (I) B (I)	A (II) A (II)[c] E (I)
2	INH RIF PZA EMB	7 days per week for 14 doses (2 weeks), then twice weekly for 12 doses (6 weeks), or 5 days per week for 10 doses (2 weeks)[e], then twice weekly for 12 doses (6 weeks)	2a 2b[f]	INH/RIF INH/RPT	Twice weekly for 36 doses (18 weeks) Once weekly for 18 doses (18 weeks)	62–58 (26 weeks) 44–40 (26 weeks)	A (II) B (I)	B (II)[c] E (I)

4	INH RIF EMB	7 days per week for 56 doses (8 weeks) or 5 days per week for 40 doses (8 weeks)[e]	4a 4b	INH/RIF INH/RIF	7 days per week for 217 doses (31 weeks) or 5 days per week for 155 doses (31 weeks)[e] Twice weekly for 62 doses (31 weeks)	273–195 (39 weeks) 118–102 (39 weeks)	C (I) C (I)	C (II) C (II)

[a]Definitions of evidence ratings: A = preferred; B = acceptable alternative; C = offer when A and B cannot be given; E = should never be given.
[b]Definitions of evidence ratings: I = randomized clinical trial; II = data from clinical trials that were not randomized or were conducted in other populations; III = expert opinion.
[c]DOT, Directly Observed Therapy. Among patients with extrapulmonary tuberculosis, regimen 1 is recommended as initial therapy unless the organisms are known or strongly suspected of being resistant to the first-line drugs. If PZA cannot be used in the initial phase (i.e., regimen 4), the continuation phase must be increased to 7 months. Doses of medications (maximum dose) when given daily: INH, isoniazid 5 mg/kg (300 mg); RIF, rifampin 10 mg/kg (600 mg); PZA, pyrazinamide 25 mg/kg (2000 mg); EMB, ethambutol 18 mg/kg (1600 mg); RPT, rifapentine, which is given once weekly at 10 mg/kg.
When DOT is used, drugs may be given 5 days/week and the necessary number of doses adjusted accordingly. Although there are no studies that compare five with seven daily doses, extensive experience indicates this would be an effective practice.
[d]Patients with cavitation on initial chest radiograph and positive cultures at completion of 2 months of therapy should receive an 8-month (31-week; either 217 doses [daily] or 62 doses [twice weekly]) continuation phase.
[e]Five-day-a-week administration is always given by DOT. Rating for 5 day/week regimens is AIII.
Not recommended for HIV-infected patients with CD4+ cell counts <100 cells/ml.
[f]Options 1c and 2b should be used only in HIV-negative patients who have negative sputum smears at the time of completion of 2 months of therapy and who do not have cavitation on initial chest radiograph. For patients started on this regimen and found to have a positive culture from the 2-month specimen, treatment should be extended an extra 3 months.
From American Thoracic Society, CDC, and Infectious Disease Society of America: Treatment of tuberculosis. *MMWR Recomm Rep* 2003; **52**:1-77

interleukin 12, and granulocyte-macrophage colony-stimulating factor may help to control intracellular pathogens and thereby shorten the duration of therapy and overcome drug resistance.[31] The immunomodulatory drug thalidomide (see Chapter 235) may prove to be useful in controlling problems related to the inflammatory response that may follow treatment of multibacillary infection and could become a useful adjunctive drug, as it is in the treatment of leprosy.

SPECIAL CONSIDERATIONS IN TREATING TUBERCULOSIS OF THE SKIN

In contrast to systemic infection, for which triple-drug therapy is recommended, tuberculosis verrucosa cutis and localized forms of LV without evidence of associated internal tuberculosis may be treated with isoniazid alone for up to 12 months. Because viable *Mycobacteria* have been found in clinically healed lesions, treatment should be continued for at least 2 months after complete involution of the lesions. Surgical intervention is quite helpful in scrofuloderma, because it reduces morbidity and shortens the required length of chemotherapy. Small lesions of LV or tuberculosis verrucosa cutis are also best excised, but tuberculostatics should be given concomitantly. Plastic surgery is important as a corrective measure in cases of long-standing LV with mutilation.

Extensively drug resistant (XDR) TB is defined as resistance to at least rifampicin and isoniazid from among the first line anti-TB drugs (which is the definition of MDR TB) in addition to resistance to any fluoroquinolone, and to at least one of the three injectable second-line anti-TB drugs used in TB treatment [(1) capreomycin, (2) kanamycin, and (3) amikacin]. The CDC and WHO have outlined that XDR TB poses a grave global public health threat and has a higher risk of death as it renders patients virtually untreatable with currently available drugs.[32]

DISEASES CAUSED BY *MYCOBACTERIA* OTHER THAN *M. TUBERCULOSIS*

MOTT were identified as human pathogens in 1938 (*Mycobacterium fortuitum*), in 1948 (*Mycobacterium ulcerans*), and in 1954 (*Mycobacterium marinum*). However, overshadowed by the infectious disease burden due to *M. leprae* and *M. tuberculosis*, the pathogenic potential of slow-growing MOTT species has been recognized only in recent decades. Because MOTT infections usually closely mimic infections with *M. tuberculosis*, and the bacteria have strict and often unusual requirements for culture, they are still probably underdiagnosed.

IDENTIFICATION OF *MYCOBACTERIA* OTHER THAN *M. TUBERCULOSIS*

As with other infectious diseases, the diagnosis of mycobacterial infection depends on the identification of the microorganism isolated from the host. Specimens for culture should be sent to a special laboratory familiar with the special growth requirements of these organisms.

Antigens for intradermal skin testing (PPDs) for many of the clinically relevant mycobacterial species have been prepared in analogy to PPD from *M. tuberculosis*, but their accessibility is very limited and they are therefore little used.

Histopathologic analysis is supportive but cannot distinguish among mycobacterial species, because all share similar histopathologic features.[33]

Treatment is summarized in Table 184-4. Importantly, some MOTT organisms are resistant to standard tuberculosis therapy. PCR testing for mycobacterial DNA is not yet reliable enough to play a role in the diagnosis of disease but can sometimes be useful in distinguishing among species.

DISEASES CAUSED BY *MYCOBACTERIA* OTHER THAN *M. TUBERCULOSIS* AT A GLANCE

- A heterogeneous group of diseases caused by a variety of obligate or facultatively pathogenic *Mycobacteria* other than those of the *Mycobacterium tuberculosis* complex.
- Involvement depends on the type of *Mycobacterium*, the route of infection, and the immune status of the host.
- Various organs may be involved.
- *Mycobacteria* other than *M. tuberculosis* (MOTT) are more often the cause of skin disease than *M. tuberculosis*.
- Diagnosis relies on histopathologic analysis and the results of culture.
- Incidence is unknown, but endemic areas exist for certain types of MOTT.
- Treatment is unlike that of tuberculosis, and no strict international guidelines have been developed. Effective antibiotics are known for each mycobacterial species but should be checked by sensitivity testing.

ETIOLOGY AND PATHOGENESIS. MOTT are widely distributed in nature and are usually commensals or saprophytes, rather than pathogens. Atypical *Mycobacteria* are usually acquired from environmental sources such as water or soil, and their role in disease reflects their natural distribution and, possibly, local lifestyles. These organisms are thought to cause mycobacterial skin disease more often than does *M. tuberculosis*. Cases tend to be sporadic, but certain types of exposures may lead to small community outbreaks.[3,34] Any organ or organ system may be affected (Table 184-5), but MOTT seem much less likely to disseminate than *M. tuberculosis*, and infections usually run a more benign

and limited course. As a rule, MOTT are much less responsive to antituberculosis drugs but may be sensitive to other chemotherapeutic agents.

Only two organisms, *M. ulcerans* and *M. marinum*, produce a characteristic clinical picture. An immunosuppressed state of the host or damage to a particular organ (e.g., in *M. kansasii* infection of the lung) facilitates these infections.

New mycobacterial pathogens are described from time to time, which suggests that their full pathogenic potential is not yet appreciated. Recently, an outbreak of skin disease caused by a nontuberculous *Mycobacteria* in Pacific Islanders from Satowan was reported in the literature.[35] These patients presented with long-standing verrucous and keloidal plaques (locally known as "spam" disease) (Fig. 184-10). Histopathological and PCR data demonstrated a nontuberculous mycobacterial infection as the cause.

SKIN INFECTIONS WITH *MYCOBACTERIA* OTHER THAN *M. TUBERCULOSIS*

MYCOBACTERIUM ULCERANS (BURULI ULCER DISEASE).

The natural habitat of *M. ulcerans* is still not known, and it has never been found outside the human body, but *M. ulcerans* infection occurs in wet, marshy, or swampy areas and seems to have to do with contaminated water. *M. ulcerans* is the third most frequent mycobacterial pathogen, after *M. tuberculosis* and *M. leprae*.

Clinical Findings. The disease is found most often in children and young adults, and affects females more often than males. A subcutaneous nodule gradually enlarges and eventually ulcerates. A blister may develop before ulceration. The ulcer is deeply undermined, and necrotic fat is exposed (Fig. 184-11). The preceding nodule as well as the ulcer is painless, and the patient continues to feel well. The painless nature of the ulcer has been attributed to nerve damage and tissue destruction caused by the toxin mycolactone. The lesions may occur anywhere on the body but tend to be limited to the extremities in adults. They may be large, involving a whole limb. The ulceration may persist for months and years, and healing and progression of the ulceration may occur in the same patient. This process may lead to appreciable and sometimes disabling scarring and lymphedema. Neither lymphadenopathy nor any constitutional signs appear at any time unless the disease process is complicated by bacterial superinfection.

Differential Diagnosis. (Box 184-8)

MYCOBACTERIUM MARINUM (*MYCOBACTERIUM BALNEI*, FISHTANK/SWIMMING POOL GRANULOMA).

M. marinum occurs in freshwater and saltwater, including swimming pools and fish tanks.

Clinical Findings. Risk factors for *M. marinum* infection are a history of trauma and water- or fish/seafood-related hobbies and occupations. The disease begins as a violaceous papule at the site of a trauma 2–3 weeks after inoculation. Patients may have a nodule or a psoriasiform or verrucous plaque at the site of inoculation, usually the hands, feet, elbows, or knees (Fig. 184-12). The lesions may ulcerate. Usually, the

lesions are solitary, but occasionally lymphocutaneous spread occurs. They may heal spontaneously within 1–2 years, with residual scarring. Occasionally, the lesions are suppurative, rather than granulomatous, and may be multiple in both normal or immunosuppressed hosts.

Differential Diagnosis. (Box 184-9)

MYCOBACTERIUM KANSASII .

M. kansasii is the atypical *Mycobacterium* most closely related to *M. tuberculosis*. It is usually acquired from the environment. Endemic areas include Texas, Louisiana, the Chicago area, California, and Japan. Skin disease caused by *M. kansasii* usually occurs in adults, and is more common in individuals with underlying immunosuppression caused by Hodgkin disease, treatment for organ transplantation, or AIDS. Inoculation is usually attributable to minor trauma such as a puncture wound.

Clinical Findings.

M. kansasii infection may present in several forms. Most frequently, there are papules in a sporotrichoid distribution. Sometimes, subcutaneous nodules extend to deeper structures and may result in a carpal tunnel syndrome or joint disease. An ulcerated plaque may also develop as a metastatic lesion. Disseminated disease caused by *M. kansasii* infection occurs in immunosuppressed patients, and such patients have cellulitis and abscesses rather than granulomatous lesions. The most commonly affected organ is the lung, usually in patients with other pulmonary

conditions (silicosis, emphysema). Infection may also cause cervical lymphadenopathy. As with *M. tuberculosis*, *M. kansasii* present in nasopharyngeal secretions can lead to periorificial cutaneous infection. These infections usually progress slowly, although a chronic stable lesion or even spontaneous regression may occur. Drug therapy should be initiated as soon as the diagnosis is made.

Differential Diagnosis. (Box 184-10)

MYCOBACTERIUM SCROFULACEUM. *Mycobacterium scrofulaceum* is widely distributed in the environment.

Clinical Findings. The usual manifestation of *M. scrofulaceum* infection is cervical lymphadenitis, frequently unilateral, in children, mainly between the ages of 1 and 3 years. Submandibular and submaxillary nodes are typically involved, rather than the tonsillar and anterior cervical nodes, as is characteristic for *M. tuberculosis* infection. There are no constitutional symptoms. Involved lymph nodes enlarge slowly over several weeks, and eventually ulcerate and develop fistulae. There is rarely an evidence of lung or other organ involvement. In most cases, the disease is benign and self-limited.

Differential Diagnosis. The differential diagnosis includes other forms of bacterial lymphadenitis; viral infections, including mumps and mononucleosis; and malignancy, including solid tumors, lymphoma, and leukemia.

MYCOBACTERIUM AVIUM-INTRACELLULARE. *M. avium*-intracellulare encompasses organisms with a wide variety of microbiologic and pathogenic properties. Well over 20 subtypes can be separated by immunologic techniques, although this is not necessary for clinical purposes.

These organisms are usually grouped together with *M. scrofulaceum* in the so-called *M. avium*-intracellulare-scrofulaceum complex, but are separated here for clinical reasons. Whereas *M. scrofulaceum* produces only a benign, self-limited lymphadenopathy with no organ involvement, *M. avium*-intracellulare infection usually causes lung disease or, less frequently, osteomyelitis. It may also produce a cervical lymphadenitis with sinus formation that is clinically indistinguishable from tuberculous scrofuloderma.

Clinical Findings. Primary skin disease caused by *M. avium*-intracellulare has been reported in rare instances, presenting as single or multiple painless, scaly yellowish plaques, sometimes resembling LV, or as subcutaneous nodules with a tendency to ulceration and a slowly progressive, chronic course. Sometimes, skin involvement occurs secondary to disseminated infection with *M. avium*-intracellulare. Skin lesions have included generalized cutaneous ulcerations, granulomas, infiltrated erythematous lesions on the extremities, pustules, and soft-tissue swelling. *M. avium*-intracellulare infections are an important cause of morbidity in patients with AIDS (see Chapter 198).

MYCOBACTERIUM SZULGAI, MYCOBACTERIUM HAEMOPHILUM, MYCOBACTERIUM GENAVENSE. *Mycobacterium szulgai*, *Mycobacterium haemophilum*, and *M. genavense* are rarely found to cause human disease in cases of otherwise unexplained cervical lymphadenitis, cellulitis, draining nodules and plaques, bursitis, pneumonia, and subcutaneous granulomatous eruptions.

MYCOBACTERIUM FORTUITUM, MYCOBACTERIUM CHELONAE, MYCOBACTERIUM ABSCESSUS. *M. fortuitum, Mycobacterium chelonae, and Mycobacterium abscessus*—three species of fast-growing, facultative pathogenic *Mycobacteria*—were previously grouped in the *M. fortuitum* complex but are now recognized as distinct species. These organisms seem to be widely distributed and can commonly be found in soil and water. Contamination of various materials, including surgical supplies, occurs but does not always result in clinical disease.

Clinical Findings. *M. fortuitum, M. chelonae, and M. abscessus* cause similar clinical diseases. Infection usually follows a puncture wound or a surgical procedure. The disease manifests itself as a painful red infiltrate at the site of inoculation; there are no signs of dissemination and no constitutional symptoms. Cold postinjection abscesses, especially in the tropics, may also be caused by fast-growing *Mycobacteria*. Recent cases in the United States have followed after pedicures and water immersion in salons.

The lesion is a dark red nodule, often with abscess formation and clear fluid drainage. Healthy children and adults may become infected, but disseminated disease usually occurs in hemodialysis patients or other immunologically compromised individuals. The disease course consists of multiple recurrent episodes of abscesses on the extremities or a generalized macular and papular eruption. Internal organs may be involved.

Histopathology. There is simultaneous occurrence of polymorphonuclear leukocyte microabscesses and granuloma formation with foreign body-type giant cells, the so-called dimorphic inflammatory response. There is usually necrosis but no caseation. Acid-fast bacilli may occasionally be found within microabscesses.

Diagnosis. Organisms of the *M. fortuitum* complex may be identified by special laboratories to permit a rational treatment.

ACKNOWLEDGMENT

The author thanks Bernard Naafs, MD, for his work on this chapter in the previous editions of this book.

Chapter 185 :: Actinomycosis, Nocardiosis, and Actinomycetoma

:: Francisco G. Bravo, Roberto Arenas & Daniel Asz Sigall

Actinomyces and *Nocardia* are a group of filamentous bacteria belonging to the same class, Actinobacteria, and same order, Actinomycetales. They cause human disease with prominent skin involvement. Microorganisms under this category were wrongly classified as fungi for a long time, because of their tendency to produce branching filaments, mimicking radiating hyphae (from the Greek *actino*, meaning sun). Their taxonomy is still evolving, resulting in continuous reclassification of different species in old and new families. Anaerobic endogenous *Actinomyces*, part of our normal respiratory, intestinal, and genitourinary flora, will cause localized suppurative disease with fistula formation that is analogous to the lumpy jaw of cattle. Aerobic environmental *Nocardia* sp. cause diseases ranging from cellulitis to paronychia to abscesses, with the most striking presentation being a lymphocutaneous, sporotrichoid syndrome. In addition, other aerobic environmental species of *Nocardia* and *Actinomyces* will cause one of the two known forms of mycetoma, the actinomycetoma.

The sulfur granule or grain, a clumping of filamentous bacteria seen in infected living tissue, is considered characteristic of the infection by these microorganisms, but is not always present and is also not specific (Table 185-1). Practicing dermatologists should be aware of the various morphologic variants of these diseases, so that measures may be taken to ensure the appropriate culturing techniques required for isolation.

ACTINOMYCOSIS

ACTINOMYCOSIS AT A GLANCE

- Worldwide distribution, relatively uncommon.
- *Actinomyces* are part of normal upper respiratory, intestinal, and genitourinary flora.
- *Actinomyces israelii* is the most common causative agent, usually mixed with Gram-positive cocci and anaerobes.
- Classical presentation is a chronic, localized infiltrative process with abscess fistula formation and draining sinuses.
- Most common location is cervicofacial (related to dental pathology), followed by abdominal, pelvic, and chest wall involvement.
- Pathologic findings include a chronic inflammatory infiltrate with granulation tissue or granuloma formation.
- Grains (sulfur granules) are characteristic but neither invariably present nor pathognomonic.

EPIDEMIOLOGY

Described by Israel in 1878, the disease has a worldwide distribution. It is more commonly seen in males, ages 20–60, with females affected at a younger age. In the preantibiotic era, the incidence in the Netherlands and Germany was 1:100,000 inhabitants/year; in the 1970s, the reported incidence in Cleveland, Ohio, was 1:300,000 inhabitants/year, and in 1984, in Cologne, Germany, it was estimated to be 1:40,000 inhabitants/year.[1] Recently, an increased incidence of genitourinary actinomycosis has been described in females, related to the use of intrauterine devices (IUDs). Nowadays, there is a tendency of subtle cases with more limited involvement, many of them restricted to the oral cavity. Diagnosis in such circumstances requires a high index of suspicion.

ETIOLOGY AND PATHOGENESIS

The term *actinomycosis* implies disease produced by endogenous, anaerobic, or microaerophile, Gram-positive, nonspore-forming bacteria, belonging to the families Actinomycetaceae and Propionibacteriaceae, of the order Actinomycetales; and Bifidobacteriaceae, of the order Bifidobacteriales.[1] Their normal habitat is human or animal mucosal surfaces, with considerable host specificity, from the mouth to the upper respiratory, gastrointestinal, and female genital tract. Species known to cause disease in humans include *A. israelii*, *Actinomyces naeslundii*, *Actinomyces gerencseriae*, *Actinomyces viscosus*, *Actinomyces odontolyticus*, and *Actinomyces meyeri*, as well as *Propionibacterium propionicum* and *Bifidobacterium dentium*. The disease in most cases is mixed with other microorganisms sharing the same habitat, so it should be considered a synergistic infection, with the *Actinomyces* playing the role of guiding organism, defining the course, the symptoms, and the ultimate prognosis. Accompanying organisms may vary in number, from one to nine different species, and may include coagulase negative staphylococci, *Staphylococcus aureus*, α- and β-hemolytic streptococci, microaerophile and anaerobic streptococci, *Fusarium* and *Bacteroides* spp., and even *Propionibacterium* sp. other than *P. propionicum*.[1] This concomitant flora may be in part responsible for the disease course. If pyogenic bacteria are involved, such as *S. aureus* or β-hemolytic streptococci, the lesion will be acutely inflammatory and painful. If, on the contrary, anaerobes predominate, the course will be subacute and insidious. A distinctive more chronic course is seen when *A. israelii* or *A. gerencseriae* is accompanied by *Actinobacillus actinomycetemcomitans*. In recent years, with better culturing techniques, more than one *Actinomyces* have been isolated from one single lesion in several patients, stressing the possibility that single bacterial isolation, common in the past, was a technical artifact.

The infection has its portal of entry at a break on a mucous membrane. Most cervical and facial cases originate from periapical abscesses or after dental procedures. *Actinomyces* bacteremia seems to occur quite commonly after dental procedures.[2] Thoracic cases represent involvement of the chest wall by continuity

either from pleural or lung disease acquired by obstruction or aspiration. The same mechanism of spreading applies to disease of the abdominal wall, secondary to gut or genital pathology, following appendicitis, diverticulitis, surgery, or trauma. Perineal disease occurs as a consequence of involvement of the internal organs of the pelvis, often secondary to use of an intravaginal device or IUD. The only exception to the endogenous origin of the infection is hand involvement that follows fist or bite trauma.[3]

In tissue, the bacteria cluster in filamentous aggregates, the so-called *sulfur granules* (grains; see Table 185-1). They are commonly surrounded by acute and chronic inflammation, usually neutrophils, granulation tissue, and fibrosis. Granuloma formation is unusual. The fistula formation may give way to drainage of granules, their presence at once should not be considered specific for this disease.

CLINICAL FINDINGS

Actinomycosis should always be suspected when dealing with one of three features: (1) a mass-like inflammatory infiltrate of the skin and subcutaneous tissue, (2) sinus formation with drainage, and (3) a relapsing or refractory clinical course after short-term therapy with antibiotics. Actinomycotic granules may be seen macroscopically. Although most patients are immunocompetent, a recent series underlies the importance of *Actinomyces* as an emerging pathogen in patients with chronic granulomatous disease.[4]

Cervical actinomycosis is the most frequent form of disease,[5] accounting for approximately 55% of cases. Commonly, there is a history of poor dental hygiene, dental or periodontal disease, dental procedure, surgery, or penetrating trauma through the oral mucosa. Most of the infections start as a periapical abscess. The most common location is on the jaw angle and high cervical area (60%), followed by the cheek (16%), the chin (13%), and less commonly, the temporomandibular joint and the retromandibular area. The lesion starts as a solid mass in any of those locations, and initially may be confused with a neoplastic process (Fig. 185-1). It may progress to form recurring abscesses and later will spread to adjacent structures, not respecting anatomic planes. Propagation to lymph nodes is uncommon but eventually may involve the orbit, cranium, spine, and even vascular structures. The lesion is sometimes reported as painless, but pain may be present, as well as fever and leukocytosis. With extension to the skin surface, sinus tracts appear (Fig. 185-2). The overlying skin may have a purplish red hue. Trismus may develop. Bone involvement, mostly of the jaw, is present in 10% of cases. More limited disease may produce a mass or an ulcer, affecting any structure in the mouth or the nasopharyngeal region. Extension to the ear may present as chronic otitis media or mastoiditis. In addition to orbital involvement, there are reported cases of lacrimal canaliculitis and endophthalmitis.

Thoracic actinomycosis comprises 15% of cases. The common source of infection is the aspiration of microorganism from the oropharynx, although other routes

Figure 185-1 Cervicofacial actinomycosis. A solid mass on the mandibular angle that can be confused with a neoplastic process.

are possible, such as propagation of cervicofacial disease to the mediastinum. The disease may involve the lung, pleura, mediastinum, and chest wall. The course is indolent, with chest pain, fever, weight loss, cough, and less frequently, hemoptysis, mimicking tuberculosis. Radiologically, the disease will present as a mass or pneumonia, with pleural involvement by continuity. Relevant to dermatologists, up to 26% of cases will have chest wall involvement[5] with the developing of a cutaneous abscess and sinus formation (Fig. 185-3). Parenchymal, pleural, and chest wall disease occurring

Figure 185-2 Typical cervicofacial actinomycosis: a lump with sinus formation. (Used with permission from Wilson Delgado, DDS; and Lepoldo Meneses, DDS; Universidad Peruana Cayetano Heredia, Lima.)

Figure 185-3 Thoracic actinomycosis from a patient who died from disseminated disease.

together will make actinomycosis a most likely diagnosis. Mediastinal actinomycosis may show either as anterior chest wall disease (rarely sternal involvement), or paraspinal abscess. Involvement of breast tissue and breast implants has also been described.

Abdominal actinomycosis represents about 20% of all cases. It is as a consequence of spreading from the gastrointestinal tract or from the female genital tract. Appendicitis and diverticulitis are common precipitating events. Any organ in the peritoneal cavity may be affected; by continuity, the disease may spread to the abdominal wall. An inflammatory mass may appear in the skin surface of the abdominal region or the perineum, with later development of sinuses. In the perianal area, multiple abscesses and fistula formation may occur. From there on, spreading to buttocks, thigh, scrotum, or groin may follow.

Primary pelvic disease most commonly originates from ascending infection from the female genital tract and less commonly from abdominal disease. The role of IUD as a risk factor has been well-established and infection is usually associated with prolonged use, 8 years on average.

Punch or fist actinomycosis represents a particularly uncommon but interesting clinical presentation. It usually follows blunt trauma of a closed fist against an adversary's mouth; similar findings may originate from a human bite. It usually involves the proximal phalanges and metacarpal bones. First a soft tissue infection, it will eventually spread to the bony structures. Grains are commonly seen in this particular form.

Actinomycosis of the central nervous system (CNS) may present as brain abscess, meningitis, meningoencephalitis, subdural empyema, actinomycoma, and spinal abscess. It is usually secondary to hematogenous spread.

LABORATORY FINDINGS

Laboratory tests considered useful include direct examination of draining material, culture, and biopsy. Direct examination will show the presence of filamentous *Actinomyces* on Gram stain. The isolation of *Actinomyces* in culture should be considered diagnostic, if coming from a sterile site. However, positive culture rates are as low as 35% in some series. The processing should be done in anaerobic conditions, and when all techniques available today are used, the percentage of isolates that cannot to be identified is as low as 2.8%.[1] Needle aspiration has been recently reported as an additional diagnostic procedure.[6]

The best material to culture is tissue, pus, or microscopic granules, and avoidance of any antibiotic treatment is recommended. Appropriate culture media include thioglycolate with 0.5 sterile rabbit serum at 35°C (95°F) for 14 days. Colonies may appear within 5–7 days, but up to 2 weeks may be required. *A. israelii* classically will produce a "molar tooth" colony on agar and will look clumpy on broth. *A. odontolyticus* colonies are red or rusty in color. *Actinomyces* are indole negative. The microbiologic identification of different species occurs only in a minority of cases. Tests for urease, catalase, gelatin hydrolysis, and fermentation of cellobiose, trehalose, and arabinose may also be performed, as well as gas liquid chromatography, indirect immunofluorescence testing, and sequencing or restriction analysis of amplified 16S ribosomal DNA.

The presence of granules, either microscopically or macroscopically, is very relevant, especially if obtained from tissues not connected to mucosal surfaces. Grains are usually yellow (hence the name *sulfur granules*), but can be white, pinkish gray, gray, or brown. In tissue samples, special stains, such as Brown–Brenn, Gram, Giemsa, or Gomori stains, are required to demonstrate filamentous structures. The number of grains is usually scanty: only one single granule was identified from 25% of specimens in a study of 181 cases.[5] The microscopic examination of the granules may reveal the Splendore–Hoeppli phenomena, a rim of eosinophilic material surrounding the granules in tissue sections. The lack of staining with Fite-modified acid-fast stain separates *Actinomyces* from *Nocardia* sp. Eumycetoma granules stain positive with periodic acid-Schiff and Gomori stains, whereas granules from Botryomycosis should show clumps of bacteria. Direct immunofluorescent staining is available for some species, including *A. israelii* (see Table 185-1).

DIFFERENTIAL DIAGNOSIS

Depending on the site affected, the differential diagnosis will include infections such as tuberculosis, noninfectious inflammatory processes such as hidradenitis or inflammatory bowel disease, and neoplasia (Box 185-1).

BOX 185-1 DIFFERENTIAL DIAGNOSIS OF ACTINOMYCOSIS (SITE SPECIFIC)

Most Likely

- Face: tuberculosis, odontogenic abscesses, parotid tumors
- Chest: tuberculosis, neoplasm, pyogenic infections
- Abdomen and pelvis: tuberculosis, inflammatory bowel disease, hidradenitis suppurativa, neoplasm

Consider

- Face: lupus panniculitis, granuloma inguinale
- Pelvis: granuloma inguinale

PROGNOSIS AND THERAPY

There is general agreement that the treatment of actinomycosis requires high-dose antibiotics to be given for a long period. The treatment of choice is penicillin G, 18–24 million units intravenously for 2–6 weeks, followed by oral penicillin or amoxicillin, to be given for 6–12 months. Cervicofacial disease or any more limited disease can receive a shorter course of therapy. A good rule to follow is to treat until there is full resolution of clinical disease. Alternative treatment for those allergic to penicillin includes tetracycline, doxycycline, erythromycin, and clindamycin. Imipenem has been used successfully as short-term therapy. Chloramphenicol is the alternative to penicillin in cases of CNS involvement. Risk factors for death or relapse include duration of disease longer than 2 months, lack of antibiotic therapy or surgical therapy, and needle aspiration rather than open drainage or excision.

With early diagnosis and more limited disease, as compared to the bulky disease of the past, treatment can be shorter: 30 days for cervicofacial disease and 3 months for pelvic or thoracic disease.[7] Periapical actinomycosis can be successfully treated with curettage and 10 days of antibiotic therapy.

Surgery is indicated for bulky disease involving the chest, abdomen, pelvis, and CNS. It should be directed to resection of necrotic tissue, excision of sinus tracts, draining of empyemas and abscesses, and curettage of bone, always accompanied by antibiotic therapy.

Antibiotics effective against synergistic microbes that accompany the *Actinomyces* can reasonably be included in the initial therapy.

PREVENTION

Good oral hygiene and prevention of periodontal disease may decrease colonization by *Actinomyces*. Physicians managing patients using an IUD should be aware of the risk of developing the disease.

NOCARDIOSIS

NOCARDIOSIS AT A GLANCE

- Aerobic Gram-positive filamentous bacteria.
- Worldwide distribution, environmentally acquired infection, due to primary traumatic inoculation.
- Pulmonary infections mostly in immunocompromised patients and skin infections mostly in immunocompetent patients.
- Skin disease mostly caused by *Nocardia brasiliensis*; less commonly *Nocardia asteroides*, *Nocardia otitidiscaviarum*, and *Nocardia farcinica*.
- Cutaneous nocardiosis can take the form of either cellulitis or more characteristic lymphocutaneous nodules in a sporotrichoid pattern; skin lesions also occur in disseminated disease.
- Diagnosis is based on Gram stain of clinical specimen showing thin, Gram-positive branching bacteria, weakly positive with acid-fast staining; microbiologic isolation of *Nocardia* sp. is diagnostic, but requires keeping cultures under observation 5–7 days.
- Treatment: sulfonamides.

EPIDEMIOLOGY

The *Nocardia* sp. are aerobic, Gram-positive, filamentous, higher bacteria found worldwide in soil and decaying organic plant matter. They can be found in house dust, beach sand, garden soil, and swimming pools. They are able to cause disease in many organs, including the skin. Approximately 1,000 cases of nocardiosis occur annually in the United States.[8] Cutaneous disease comprises 5%–22% of all cases.[8] A higher incidence of primary cutaneous nocardiosis in Europe may be explained on the basis of more frequent isolation of *Nocardia brasiliensis* in the environment. Patients have also been reported in India and Argentina.[9] Disease occurs more commonly in males.

Immunocompromised patients account for 50% of cases, mostly pulmonary, systemic, and CNS infections. They are commonly seen in transplant patients, patients with acquired immunodeficiency syndrome (AIDS)[8] or malignancy, or those receiving steroids. Primary cutaneous disease is most commonly seen in immunocompetent patients and has been reported

rarely in children in United States, mostly in the south and southwestern part of the country.[10]

ETIOLOGY AND PATHOGENESIS

The *Nocardia* sp. of medical importance includes *Nocardia asteroides*, most commonly associated with lung and systemic disease, and *N. brasiliensis*, most commonly associated with skin infection. Other species include *Nocardia farcinica*, *Nocardia otitidiscaviarum*, *Nocardia nova*, *Nocardia pseudobrasiliensis*, *Nocardia transvalensis*, and *Nocardia abscessus*. It is only recently that many of these species have been completely separated, especially those of the *N. asteroides* group, including *N. farcinica* and *N. nova*. It is interesting to note that *Nocardia* sp. belong to a subgroup of bacteria called the *aerobic nocardioform actinomycetes* that also include *Mycobacterium*, *Corynebacterium*, *Rhodococcus*, and *Gordona*. All these microorganisms have mycolic acid as constituent of their cell wall, which explains the varying acid fastness on appropriate staining. The proposed etiologic agent for Whipple disease, *Tropheryma whippelii*, also belongs to this group.

The usual inflammatory response in infected tissue is neutrophilic, with branching, beading filamentous bacteria within abscesses. Sulfur granules are uncommon in primary cutaneous nocardiosis; they have been described in disseminated disease. They are more commonly seen when the clinical picture is that of mycetoma (see Section "Actinomycetoma").

Certain virulent strains of *Nocardia* are resistant to neutrophil-mediated killing.[11] They can inhibit phagosome–lysosome fusion in vitro, giving rise to L-forms able to survive inside macrophages. The existence of cell wall deficient L-forms may explain the occasional late relapse. The presence of superoxide dismutase in growth media is characteristic of the more virulent strains. Complex cell wall glycolipids also contribute to virulence.[11]

The initial neutrophilic reaction is followed by a more cell-related immune response that is responsible for clearing the infection from the lung tissue and prevents dissemination. If this fails, a chronic neutrophilic response results in a more indolent course. Reduced cellular immunity predisposes transplant and AIDS patients to infection, with transplant patients accounting for up to 13% of cases in the United States.[9] Some species are considered more difficult to treat: *N. farcinica* has a high degree of resistance to various antibiotics, especially third-generation cephalosporins and aminoglycosides. Another recently described species, *N. pseudobrasiliensis*, has a higher rate of dissemination.

CLINICAL FINDINGS

Cutaneous involvement by *Nocardia* can manifest either as cellulitis or more characteristically, as lymphocutaneous nodules in a sporotrichoid pattern. Disseminated disease can also present in the skin as a consequence of hematogenous spread. In most series, skin disease is second only to pulmonary involvement in frequency. Mycetoma due to *Nocardia* is discussed in Section "Clinical Findings" under "Actinomycetoma."

Predisposing factors for primary cutaneous nocardiosis include soil or sand exposure while gardening or farming; or superficial injury from domestic shrubbery, outdoor falls, or accidents. The frequent history of thorn injury or gardening may suggest incorrectly a diagnosis of sporotrichosis. Cat scratches or insect bites may be also the portal of entry, especially in children.[7]

The most common cause of primary cutaneous nocardiosis is *N. brasiliensis*, but *N. asteroides*, *N. otitidiscaviarum*, *N. nova*, and *N. farcinica* have also been implicated. Most patients are immunocompetent, but *Nocardia* cutaneous infection may also occur in the context of immunosuppression. A recent series of nocardial infection in AIDS patients showed skin lesions in 11% of cases, most commonly cutaneous abscesses and suppurative adenitis.[8] Nocardiosis has recently described in patients receiving antitumor necrosis factor (TNF) biologic therapy for Crohn's disease.[12]

The disease has been also described in ulcerobullous, linear/keloid, and nodulopustular forms (Fig. 185-4A) that may evolve into the more typical sporotrichoid pattern (see Fig. 185-4B). Patients

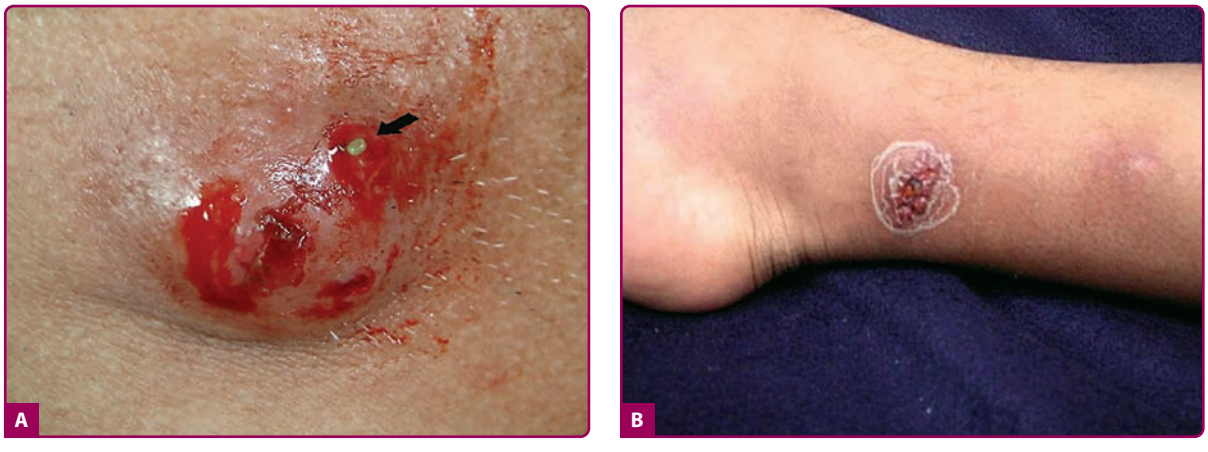

Figure 185-4 **A.** Early lesions of lymphocutaneous nocardiosis. **B.** Lymphocutaneous nocardiosis: typical sporotrichoid pattern. (Used with permission from Marcia Karam, Daniel Asz, and Roberto Arenas, Hospital Manuel Gea González, Mexico City.)

may also present acutely with eccrine hidradenitis, or chronically with hyperkeratotic plaques. Cutaneous nocardiosis may begin suddenly, reactivate after months to years, or follow a chronic course for up to 10 years. A case of simultaneous infection in a husband and wife has been described. Very rarely, pure cutaneous disease may lead to systemic illness. The cellulitic form most commonly affects the lower extremities, as compared to sporotrichoid form, in which the upper extremities are most commonly involved. Children frequently present with cellulitis, abscesses, and lymphadenitis affecting lower extremities and trunk; 20% of cases will have lesions at multiple sites.[10]

Lymphocutaneous forms may account for 24% of all *Nocardia* cutaneous infections (see Fig. 185-4B).[13] The first case proven to be because of *N. brasiliensis* was described by Alarcon[14]; the patient developed acute nodular suppurative lymphadenitis after injuring the finger with a rose thorn. Although the upper extremity is the most common location, disease of lower extremity and cervicofacial region have also been reported. A common history is appearance of a solitary papule or nodule on the upper limbs, 2–4 weeks after cutaneous inoculation. Then, proximal nodules develop along lymphatic drainage. The primary lesion is initially warm and tender, then becomes fluctuant and later ulcerates. Macroscopic grains may be seen, but draining sinuses are rare. Systemic symptoms are mild. Regional lymphadenitis is common but lymphangitis is unusual.

Sternal wound infections usually develop 1 month after thoracic surgery. The symptoms include erythema, clear-to-purulent drainage, wound dehiscence, and/or fever. Diabetes mellitus seems to be the only identifiable risk factor. At least in one outbreak, the hands of an anesthesiologist were culture positive for *N. farcinica*. In another case of sternal osteomyelitis and mediastinal abscess, the patient's occupation (carrying wooden crates loaded with vegetables) may have been the relevant risk factor for infection.

Pulmonary disease is the most common form of clinical infection, but, compared to primary cutaneous diseases, is often due to different species (*N. asteroides* predominates). The disease may take the form of an acute pneumonia or a chronic process with bronchopneumonia, abscesses, and development of cavities. Ten percent of pulmonary infections disseminate to the skin.

Bacteremia due to *Nocardia* is seen in debilitated patients with concomitant malignancy, and *N. asteroides* is the agent most commonly isolated. Cutaneous or subcutaneous nodules and abscesses occur in many patients, and the skin may be the portal of entry in some cases. Catheter-associated nocardemia is well-documented.

LABORATORY FINDINGS

Laboratory tests considered useful include direct examination of clinical specimens, culture, and biopsy. The importance of direct microscopic examination for the presence of granules cannot be overemphasized. Organisms are detected as Gram-positive, branched filamentous "hyphae," and branching at right angles is diagnostic. Acid-fast stains, including Fite Faraco and the modified Kinyoun technique, show the filamentous bacteria. For isolation, cultures should be kept for up to 2–3 weeks. The microorganisms grow satisfactorily on most of the nonselective media used for isolation of bacteria, mycobacterium, and fungi. Because slow growth of *Nocardia* colonies over 2 days to 2 weeks on routine culture media allows bacterial overgrowth, isolation of this organism from soil and nonsterile sites may be difficult. *Nocardia* do not survive the digestive procedures used routinely in mycobacterial culture. Thayer–Martin and buffered charcoal–yeast extract agar may be used and pretreatment of specimens with a low pH potassium chloride-hydrochloric acid solution for 4 minutes is required.

After initial isolation, subcultures should be incubated at 25°C (77°F), 35°C (95°F), and 45°C (113°F). *N. asteroides* grows best at 35°C (95°F). Aerial hyphae, giving a chalky appearance, may be seen macroscopically in cultures; however, in the early stages of growth, they are only seen with the microscope. *N. asteroides* complex colonies vary from salmon pink to orange, whereas *N. brasiliensis* are usually orange, and *N. otitidiscaviarum* are usually pale. Identification of genus can be achieved by microscopic and colonial morphology, growth requirements, metabolism of glucose, arylsulfatase production, growth in lysozyme, and phenotypic molecular characteristics. Genotyping methods, including polymerase chain reaction, DNA hybridization, and sequencing of 16 ribosomal RNA, are useful, if available.

Histologic patterns described on histology include monocytic infiltrates, fibrinopurulent exudates, granuloma formation, chronic nodular dermatitis, microabscess formation, and coccobacillary organisms; the presence of granules has been described in disseminated cases.[9]

DIFFERENTIAL DIAGNOSIS

In cases of cellulitis, the differential diagnosis is extensive, including both infectious and noninfectious etiologies. However, in the lymphocutaneous form, the differential diagnosis can be approached more systematically. The sporotrichoid pattern should be differentiated from the more acute ulceroglandular syndrome, as is seen in tularemia and cat-scratch disease (Box 185-2).

PROGNOSIS AND CLINICAL COURSE

Primary cutaneous nocardiosis is usually subacute or chronic but has a good prognosis when treated appropriately. However, the disease has the potential to disseminate; sternal wound infections may be complicated with osteomyelitis.[9] Systemic disease, especially sepsis, has a high mortality rate, 44%–85%, if the patient is nocardemic.[11]

TREATMENT

The treatment of *Nocardia* infection is appropriate antimicrobial therapy and surgical drainage and debridement.

BOX 185-2 DIFFERENTIAL DIAGNOSIS OF LYMPHOCUTANEOUS NOCARDIOSIS

Most Likely

- Sporotrichosis
- *Mycobacterium marinum* infection
- Leishmaniasis
- Pyoderma due to *Staphylococcus aureus*

Consider

- Cryptococcosis
- Tuberculosis
- *Mycobacterium kansasii, Mycobacterium chelonae,* and *Mycobacterium fortuitum*
- Cysticercosis

Rule Out

- Epithelioid sarcoma
- Metastatic disease

Factors to consider include site and severity of infection, the immune status of the host, potential for interactions and the species of *Nocardia* involved. The current standard for sensitivity testing is by the broth microdilution method.

Sulfonamides, alone or in combination with trimethoprim (TMP), are the cornerstone of therapy for *Nocardia* infections, but are ineffective against *N. otitidiscaviarum*.[11] For primary cutaneous nocardiosis of mild to moderate intensity, sulfonamide (either sulfadiazine or sulfisoxazole) alone has been considered adequate therapy,[11] but other authors consider TMP–sulfamethoxazole (SMX) the treatment of choice, despite lack of controlled trials. This is based on synergistic activity of these drugs in vitro against *Nocardia*. The commercially available preparation has a fixed ratio of 1:5, and the dose recommended at the present time is 5–10 mg/kg TMP and 25–50 mg/kg SMX in two to four divided doses. For primary cutaneous nocardiosis, 5 mg/kg of TMP should be sufficient. Clinical improvement should be seen within 3–10 days, and 1–4 months of treatment should be curative for sporotrichoid nodules and cutaneous ulcers. Prolonged therapy is required for immunosuppressed patients. Minocycline 100–200 mg twice a day is considered the alternative treatment in cases of sulfonamide hypersensitivity or poor tolerance.

In more severe cases or disease involving other organs, a combination of sulfonamide with a second agent is recommended. The second-line drugs most recommended are amikacin, imipenem, and ceftriaxone. Alternative second-line drugs include amoxicillin clavulanate and linezolid. Immunosuppression is a good indication for a two-drug regimen, including amikacin; 88% cure rate has been reported when this drug is used.[9] Sternal infections due to *N. asteroides* have responded to oral ofloxacin therapy.[8] *N. farcinica* has a high degree of resistance to various antibiotics, especially third-generation cephalosporin and imipenem, and combined therapy is highly recommended. Extended treatment for extracutaneous nocardiosis, with parenteral therapy followed by an oral regimen is necessary. Surgery is indicated in cases of abscesses (drainage) or extensive necrosis (debridement). Spontaneous resolution or good clinical response despite inappropriate therapy has been seen in children with *Nocardia* cellulitis or lymphadenitis.[10]

PREVENTION

The low incidence of *Nocardia* infections in immunodeficient states does not justify prophylactic use of antibiotics. AIDS patients receiving TMP–SMX for *Pneumocystis* are already protected against *Nocardia*.

ACTINOMYCETOMA

(See also Chapter 185)

ACTINOMYCETOMA AT A GLANCE

- Actinomycetoma is caused by bacteria, as opposed to eumycetoma, which is caused by fungi.
- More commonly seen in the tropics.
- Several microorganisms cause the disease. Some species are specific for some geographic areas. In the Americas, *Nocardia brasiliensis* predominates.
- More common in men and in lower extremities.
- Visceral involvement has bad prognosis.
- Characterized by inflammation, tumefaction, and discharging sinus tracts.
- Macroscopic or microscopic grains are usually white. Gram staining shows filamentous bacteria.

EPIDEMIOLOGY

Mycetomas are chronic infections of the skin, underlying tissues, sometimes bones, and rarely viscera, caused by both bacteria (actinomycetomas) and fungi (eumycetomas).[10] Only actinomycetoma is discussed further in this chapter (for eumycetomas, see Chapter 185). The disease has a worldwide distribution but it is more frequent in the tropics, especially in India, Sudan, Somalia, Mexico, and Venezuela. *Actinomadura pelletieri* and *Actinomadura madurae* are common agents in Senegal.[15] Occasional cases are seen in the United States, particularly in the south. Actinomycetoma

affect mainly men, but frequency before 15 years of age is similar in both sexes.[16]

ETIOLOGY AND PATHOGENESIS

Microorganisms reported to cause actinomycetomas include *N. brasiliensis*, *A madurae*, *A. pelletieri*, *Streptomyces somaliensis*, and less commonly, *N. asteroides*, *N. otitidiscaviarum*, *Nocardiopsis dassonvillei*, and *N. transvalensis*.[17] *N. pseudobrasiliensis*, *Nocardia veterana, Nocardia mexicana and Sesamia sudanensis* sp. have also been reported. The new taxon *N. pseudobrasiliensis* has been associated with invasive or disseminated infections.[18] The infection most commonly affects people living in rural areas in developing countries.

Recent studies using DNA hybridization and ribosomal RNA sequencing have confirmed marked heterogeneity among the genera of aerobic actinomycetes.

In North America (Mexico), South America, and Australia, *N. brasiliensis* is the leading cause of actinomycetomas; in Africa, Saudi Arabia, and India, *S. somaliensis* and *A. madurae* predominate; this species is also identified as the etiologic agent in 10%–15% of cases in Mexico and Venezuela.[19]

Cell-mediated immunity may influence mycetoma pathogenesis; $CD8^+$ lymphocytes and macrophages are the main cells implicated. *N. brasiliensis* as an intracellular bacterium modulates macrophage cytokine production, which aids survival of the pathogen.[20] In patients with actinomycetoma the levels of IgG1, IgG2, IgG3, IgG4, and IgM have demonstrated to be higher than in a control group. These findings suggest that the increase or deficiency of a determined immunoglobulin class, as well as the relationship between different subclasses, play a role in the pathogenesis of actinomycetoma.

Figure 185-5 Actinomycetoma of the lower leg. Multiple, indolent, coalescing nodules.

Figure 185-6 Mycetoma of the foot produced by *Nocardia* sp.: typical location, with multiple draining sites.

CLINICAL FINDINGS

Actinomycetoma is a chronic, localized, slowly progressive, painless disease of the skin and subcutaneous tissue. The pathologic process usually begins with a minor injury. Walking barefooted or wearing sandals may be considered a risk factor for these infections in rural communities. The lower limbs are involved in 64% of the cases (Fig. 185-5), the foot being the most common site (Fig. 185-6 and 185-7). The lower leg, knee, and thigh, as well as the hand, forearm (Figs. 185-8 and 185-9), face, neck, and abdominal wall, may also be affected. In Mexico, the upper back (Figs. 185-10 and 185-11) is involved in 17%–25% of cases in relation to occupational activity such as firewood collection. Actinomycetoma caused by *Nocardia* sp. is a very inflammatory process characterized by tumefaction, destructive granuloma with a nodular appearance, deformity, and discharging sinus tracts with communicating channels that exude pus. Ulceration, crusting, and scarring are also observed.[14] Mycetoma due to *A. madurae*, *A. pelletieri*, and *S. somaliensis* are less inflammatory with smaller sinus tracts; *A. madurae* is mainly seen in women with plantar involvement.[19] With all these agents, the granules may be seen with the naked eye (see Table 185-1), usually in a cream color; the exception will be *A. pelletieri*, in which the granules are red.

Figure 185-7 Mycetoma of the foot by *Actinomyces* sp.: this is a less inflammatory form that what is seen in *Nocardia* cases.

Figure 185-8 Mycetoma of the hand and wrist caused by *Nocardia brasiliensis*. Note gross deformity. (Used with permission from Roberto Arenas, MD, Hospital Manuel Gea González, Mexico City.)

The course is chronic and progressive, with potential involvement of bones, lung, and abdominal viscera. In women, mycetomas increase in size during pregnancy and spontaneously improve after delivery. Advanced cases may cause functional disability. Atypical clinical forms include the cryptic mycetoma (without sinus tracts), the so-called *mini-mycetoma* (single or multiple small lesions observed mainly in children and adolescents), and the occasional inguinal "metastatic" lesions from a primary mycetoma of the foot.[14]

LABORATORY FINDINGS

Skin biopsy plays an important role in the diagnosis of actinomycetoma. Typically, in hematoxylin and eosin stained tissue sections, there is a suppurative reaction characterized by the presence of polymorphonuclear cells, fibrosis, neovascularization, and rarely, a granulomatous reaction with a tuberculoid granuloma.[14] *Nocardia* infection is characterized by granules 30–200 m in diameter, partially basophilic to amphophilic, with an amorphous, eosinophilic, radially arranged material on the periphery (the so-called *Splendore–Hoeppli phenomenon*). Granules of *A. madurae* are soft and bigger (1–3 mm diameter), purple with a cartographic shape and an eosinophilic fringe (Fig. 185-12). *A. pelletieri* granules are firm and red with a diameter of 200–500 m. Granules of *S. somaliensis* are rounded, hard, pale, and 1.5–10.0 mm in diameter.[14] These organisms stain in tissue with Gomori methenamine silver, periodic acid-Schiff, and the Brown–Brenn modification of the Gram stain.

Figure 185-9 Radiograph from patient in **Fig. 185-6** shows associated marked destruction of bones and underlying soft tissues. (Used with permission from Roberto Arenas, MD, Hospital Manuel Gea González, Mexico City.)

Figure 185-10 Mycetoma of the shoulder caused by *Nocardia brasiliensis*. (Used with permission from Maria Cecilia Albornoz, MD, Instituto de Biomedicina, Caracas.)

Clinical specimens should be sent for direct examination (Gram stain) and culture. On direct examination, *Nocardia* granules are microscopic with a yellowish color. Granules produced by other agents are macroscopic: those of *A. madurae* are white, yellow, or cream, whereas grains from *A. pelletieri* are red and those of *S. somaliensis* are cream to brown color. Fine needle aspiration cytology has been reported as a good diagnostic tool. The cell block technique of mycetoma aspirates can be use for cytodiagnosis, showing findings similar to histopathologic sections.[21]

The microorganisms can be cultured on Sabouraud's dextrose agar or Lowenstein–Jensen at room temperature; *Nocardia* strains are white–yellow hard colonies. Microscopically, its very thin filaments are Gram-stain positive and acid-fast with the Kinyoun's stain. *A. madurae* produce slowly growing beige or pink colonies; *A. pelletieri* colonies are red. *S. somaliensis* produce beige or tanned colonies. All *Actinomyces* and *Streptomyces* sp. are acid-fast negative.[14]

Biochemistry can be used for identification. *N. brasiliensis* hydrolyzes casein and tyrosine, but not xanthine;

Figure 185-11 **A.** Huge scapulothoracic mycetoma caused by *Nocardia brasiliensis*. Note multiple fistulae. **B.** Close-up. Note doughnut-shaped masses and purulent drainage. (**B,** Used with permission from Maria Cecilia Albornoz, MD, Instituto de Biomedicina, Caracas.)

N. otitidiscaviarum is negative to casein and tyrosine and positive to xanthine testing; *N. asteroides* is negative to all these tests.

An enzyme-linked immunosorbent assay has been described for the diagnosis of mycetoma due to *N. brasiliensis*; it has been proposed as a method to predict the response to therapy. This test detects antibodies against two immunodominant antigens (24 and 26 kDa). An additional advantage of this particular assay might be its demonstrated cross-reactivity with *N. asteroids*.[22]

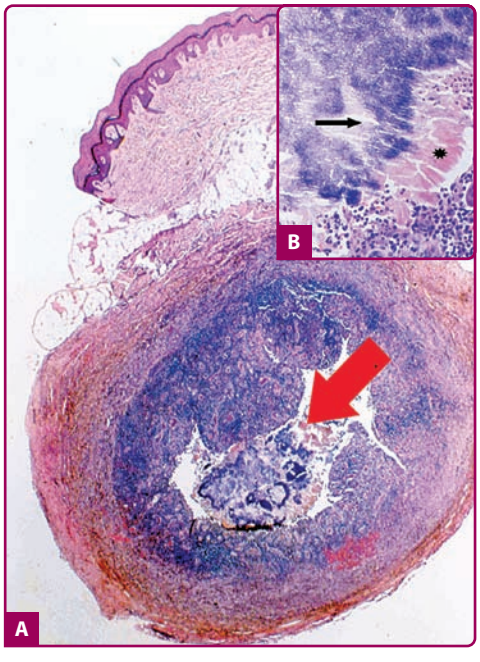

Figure 185-12 **A.** Skin biopsy of an *Actinomadura* mycetoma shows the granule (*red arrow*) inside the inflammatory reaction (hematoxylin and eosin, 20×). **B.** The contrast between the blue fibrillary material (*black arrow*), representing bacteria, and the eosinophilic proteinaceous material of the Splendore–Hoeppli phenomenon (*star*) (hematoxylin and eosin, 100×).

The most common radiographic abnormalities are soft tissue swelling, periosteal reaction and sclerosis and bone cavities.[23] Ultrasonography is also a useful modality. The utility of helical computed tomography (HCT) especially in trunk mycetomas provides evidence about the grade of invasion such as visceral, muscular, and vascular systems, and calculation of the affected area.[24]

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes other infections causing fistulae; such as eumycotic mycetoma, actinomycosis, botryomycosis, scrofuloderma, and atypical mycobacterial infections (Box 185-3). Botryomycosis is a condition that can mimic actinomycetoma and eumycetoma, both clinically and histologically. The disease can be caused by several organisms, most commonly *S. aureus*, *Escherichia coli*, *Pseudomonas aeruginosa*, *Proteus vulgaris*, *Actinobacillus* sp., *Streptococcus* sp., Gram-negative coccobacilli, *Propionibacterium* acne, and other anaerobic bacteria. The cutaneous form accounts for 75% of the cases; visceral involvement, mainly the lung, is rare. The disease is characterized by localized areas of infiltration, with mass effect and draining sinuses. Extension to the underlying structures, including bone, is not uncommon. Most commonly affected areas are exposed surfaces, such as hands, head, and feet. Patients usually have a predisposing

BOX 185-3 DIFFERENTIAL DIAGNOSIS OF ACTINOMYCETOMA

- Eumycotic mycetoma
- Actinomycosis
- Botryomycosis
- Scrofuloderma
- Atypical mycobacterial infections

factor such as local trauma, a foreign body, diabetes, or HIV infection. Botryomycosis is also characterized by the presence of granules, which can be seen macroscopically and microscopically. As in mycetoma, the center of the granule will show agglomeration of the causal agent, most commonly, Gram-positive cocci. Splendore–Hoeppli phenomenon may also be seen around the granules.

TREATMENT

Therapy for patients with actinomycetoma should be individualized. Economic considerations may influence the choice of therapy, particularly in developing countries.

Molecular identification of the causal agents and development of genetic markers for disease can improve management. Cure may be defined by a lack of clinical activity, absence of grains and negative cultures. The cure rates vary between 60% and 90%. Treatment periods are very long, especially with bone and visceral involvement, for which prognosis is poor.[25]

Combined antibiotic therapy prevents the development of drug resistance and eradicates any residual infection. The treatment of choice in actinomycetoma caused by *N. brasiliensis* is diaminodiphenylsulfone (Dapsone) 100–200 mg/day (3–5 mg/kg) plus TMP–SMX 160/800 mg twice a day for several months in initial cases; treatment should continue for up to 2 years.[14] Dapsone can also be combined with streptomycin, 1 g/day; clofazimine, 100 mg/day; rifampin, 300 mg twice/day; tetracycline, 1 g/day; or isoniazid, 300–600 mg/day; alternative drugs include kanamycin and phosphomycin. Some resistant cases have been treated with amoxicillin, 500 mg, plus clavulanic acid, 125 mg/day for 5 months.

Amikacin alone or combined with imipenem are powerful antibiotics used as alternative treatments for severe or multiresistant mycetomas, especially those with bone and visceral involvement. In adults, amikacin is administered 15 mg/kg/day (500 mg intramuscularly twice a day) for 3 weeks; ototoxicity and nephrotoxicity may develop.[26] Carbapenems as imipenem and meropenem have a broad microbicidal activity refractory to hydrolysis by β-lactamases. They have demonstrated good in vitro and in vivo activity against *Nocardia* asteroides complex, good in vitro sensitivity against *A. madurae*, and apparent low in vitro activity against *N. brasiliensis*. Imipenem has been proposed as a suitable option for severe *N. brasiliensis* infection refractory to other drug therapies.[27] Patients treated with intravenous imipenem must be hospitalized; the drug can be given as monotherapy at 500 mg three times daily, or in combination with intravenous amikacina in a dose of 500 mg twice daily (15 mg/kg) in cycles of 21 days, especially in patients with pulmonary or peritoneal involvement.[25]

Ramam et al[28] used a two-step regimen consisting of an intensive phase of therapy with intravenous penicillin (1,000,000 IU every 6 hours), intravenous gentamicin (80 mg twice a day), and oral TMP–SMX (80–400 mg twice a day) for 5–7 weeks. Linezolid, a new oxazolidinone, has shown in vitro antimicrobial activity against *N. brasiliensis*; it also has demonstrated efficacy in patients with nocardiosis. Its main disadvantage of this alternative is the cost. It is available as intravenous and oral preparations.

The use of clindamycin, ciprofloxacin, and moxifloxacin has been suggested in *Nocardia* infections.[29]

Patient follow-up is always important, and improvement can be monitored by clinical assessment as well as by laboratory tests: hemoglobin level, white cell count, C-reactive protein, erythrocyte sedimentation rate, enzyme-linked immunosorbent assay (when available), biopsy, and culture.

Amputation is not indicated in actinomycetoma because the very low risk of lymphangitic or hematogenous dissemination. Functional impairment is common with osseous, pulmonary, or abdominal visceral involvement. The disease may be fatal.

Chapter 186 :: Leprosy

:: Delphine J. Lee, Thomas H. Rea, & Robert L. Modlin

LEPROSY AT A GLANCE

- Definition: a chronic granulomatous infection and caused by *M. leprae*.
- Involvement: affecting primarily skin and nerves.
- Diagnosis: acid-fast bacilli in tissue or classic peripheral nerve abnormality.
- Incidence: approximately 250,000–500,000 new cases yearly, worldwide.
- Long-term morbidity: despite curative antibacterial treatment, one-quarter to one-third of patients will have a debilitating and permanent neurological deficit.
- A clinical challenge: diverse manifestations result from a granulomatous spectrum, and are further increased by superimposed, reactional states.
- An immunologic opportunity: an exemplary model for the understanding of cell-mediated immunity in humans.

ETIOLOGY AND PATHOGENESIS

Risk factors are birth or residence in a known endemic area, a family member with leprosy, reflecting common genetic susceptibility, environmental exposure, or both, and, as with many other infections, poverty. Therapeutic use of anti-tumor necrosis factor (TNF) antibodies and the immune reconstitution inflammatory syndrome (IRIS) of highly active antiretroviral therapy (HAART) have been associated with the onset of leprosy.[15,16]

Mycobacterium leprae, the cause of leprosy, is a non-cultivable, Gram-positive, obligate intracellular, acid-fast bacillus. Sequencing of the bacillary genome[17] revealed gene deletion and decay leaving *M. leprae* with few respiratory enzymes, providing an explanation for the failure to cultivate the organism in cell-free media, as well as for its obligatory intracellular environment. In tissues or smears, *M. leprae* is quantified by the biopsy index (BI), a logarithmic scale as to the numbers of bacilli per oil immersion field (OIF): a BI of 6 is 1,000 or more bacilli/OIF; a BI of 5 is 100–1,000/OIF; a BI of 4 is 10–100/OIF; a BI of 3 is 1–10/OIF; a BI of 2 is 1 bacillus/1–10 OIFs; a BI of 1 is 1 bacillus/10–100 OIFs; and a BI of 0 is no bacilli in 100 OIFs. Because a BI of 6 indicates 10^9 bacilli per gram of granuloma, tissue with a BI of 0, may have as many as 10^3 organisms per gram.

The bacillary cell wall consists of a peptidoglycan backbone linked to arabinogalactan and mycolic acids. Immunogenic proteins are associated with the cell wall, and also are present in the cytoplasm. The cell-wall-associated lipoproteins, ligands for pattern recognition receptors (PRRs) such as TLR2 and NOD2 of the innate immune system, probably initiate the host's first response *M. leprae*. This response may be important in determining the eventual clinical outcome.[18] A lipoglycan target of both antibody and cellular immune responses, lipoarabinomannan, courses through the outer membrane and inserts into the cell membrane. Phenolic glycolipid I is a major, species specific and immunogenic constituent of the highly nonpolar outer layer of the bacillus. Entry into nerves is mediated by the binding of the species-specific trisaccharide in phenolic glycolipid I to laminin-2 in the basal lamina of Schwann cell–axon units,[19] providing a rationale for why *M. leprae* is the only bacterium known to invade peripheral nerves.

A twin study has provided compelling evidence that both genetic and environmental factors are important in determining disease susceptibility and expression.[20] A region on chromosome 10p13, including the PARK2 and PACRG, loci for susceptibility to Parkinson's disease, has been found to also contain a risk factor for the development of leprosy.[21] This includes both tuberculoid and lepromatous forms, and has been identified in a number of genetically diverse populations, but not all. Major histocompatibility complex class II antigens appear to influence the clinical presentation, but not disease susceptibility,[22] while PRRs such as the TLRs and NOD2 may influence both.[23–27] The great majority of people exposed to *M. leprae* are presumed to make a curative immunologic response, while the clinical presentation of the granulomatous spectrum of leprosy provides an immunologic spectrum of host defense, thus providing an exemplary model for examining cell-mediated immunity (CMI) in humans.

CLINICAL FINDINGS

HISTORY

For physicians practicing in nonendemic areas, learning that the patient has risk factors for leprosy, i.e., birth or residence in an endemic area, or a blood relative with leprosy may lead to a correct diagnosis of leprosy.

Historic data or symptoms that should elicit further suspicion of leprosy include complaints referable to peripheral neuropathy, persistent nasal stuffiness, ocular symptoms, and, in young men, loss of sexual drive or infertility.

CUTANEOUS LESIONS

THE GRANULOMATOUS SPECTRUM. Ridley and his associates provided the most detailed description of the granulomatous spectrum of leprosy,[28,29] integrating both clinical and histologic changes. Ridley's construct is a six-member spectrum, ranging from high to low resistance, TT (polar tuberculoid), BT (borderline tuberculoid), BB (borderline), BL (borderline lepromatous), LLs (subpolar lepromatous), and, finally, LLp (polar lepromatous):

$$\text{TT} \leftarrow \text{BT} \leftrightarrows \text{BB} \leftrightarrows \text{BL} \leftrightarrows \text{LLs LLp}$$

Conceptually, TT and LLp are clinically stable, but, between the poles, the host response may change, as indicated by the arrows, upgrading (or reversing) to a state of higher resistance, often with devastating inflammation, or downgrading to a posture of lower resistance, usually silent but occasionally inflammatory. BT patients may upgrade to TT, thus, becoming stable, but LLs patients do not downgrade to LLp nor do LLp patients upgrade. ("LL" includes both LLs and LLp patients.) The host's granulomatous response is the result of the degree of CMI directed against *M. leprae*. The classification is determined primarily by clinical and histologic changes, bacillary numbers being a secondary consideration. Patients along the clinical spectrum of leprosy are presumed to be manifestations of evolving immune responses, which, based on environmental and genetic factors, will eventually gravitate toward one of the two poles.

In comparison of pre-Ridley and Ridley terminology, "tuberculoid" corresponds to TT and BT, "borderline" or "dimorphic" to BB and BL, and "lepromatous" to LLs and LLp. In virtually all TT patients, and in most BT cases, acid-fast bacilli (AFB) cannot be found, whereas in BB, BL, LLs, and LLp, bacilli are demonstrable with ease. Ridley's construct is useful in classifying patients, especially for immunity.

PERIPHERAL NERVE CHANGES. Five types of peripheral nerve abnormalities are common in leprosy. (1) Nerve enlargement (usually perceived as asymmetry), particularly in those close to the skin, generally thought to be due to the fact that those locations are coolest in temperature, such as the great auricular, ulnar, radial cutaneous, superficial peroneal, sural, and posterior tibial. (2) Sensory impairment in skin lesions. (3) Nerve trunk palsies either with signs and symptoms of inflammation or without such overt manifestations, that is, silent neuropathy,[30] usually with both sensory and motor loss (weakness and/or atrophy) and, if long standing, also with contracture. (4) Stocking-glove pattern of sensory impairment (S-GPSI), with a slow loss of type C fibers, involving heat and cold discrimination before loss of pain or light touch, beginning in acral areas and, over time, extending centrally but initially sparing the palms. (5) Anhidrosis on palms or soles suggests sympathetic nerve involvement.

Figure 186-1 A solitary, anesthetic, and annular lesion of polar tuberculoid leprosy (TT), which had been present for 3 months. Its sharp margins, erythema, and scale are more evident than its elevation. The central red dots are the sequelae or "footprints" of testing for pinprick perception when it is absent. (If present, the patient withdraws, preventing overly purpuric consequences.) The central portion of the lesion was slightly hypopigmented as compared to the surrounding normal skin.

Polar Tuberculoid Leprosy. In TT leprosy immunity is strong as manifested by spontaneous cure and the absence of downgrading to a posture of less host resistance. The primary skin lesion of TT is a sharply marginated plaque, often annular secondary to peripheral propagation and central clearing. Typically, the lesion is firmly indurated, elevated, erythematous, scaly, dry, hairless, and hypopigmented (Fig. 186-1), but clinically, considerable variation is encountered (eFig. 186-1.1 in online edition).

A nearby sensory nerve may or may not be enlarged (eFig. 186-1.1 in online edition), but the lesion itself is characteristically anesthetic and anhidrotic. Skin lesions are often solitary, particularly in those patients who are TT de novo, as contrasted to those who upgrade to TT from BT, where multiple lesions, usually no more than three, may be found. In both groups, immunity is sufficient to affect cure, thus, placing an upper limit of 10 cm on lesion size, but antibiotic therapy is recommended.

TT Histology. In de novo TT lesions, small, well-developed epithelioid tubercles are surrounded by large lymphocytic mantles, but are uncommonly seen. In TT upgrading from BT, abundant Langhans-type giant cells and a brisk exocytosis into the epidermis are usually found in addition to the lymphocytic mantle (Fig. 186-2). Rarely caseation necrosis is seen, and, if present, warrants the classification of TT (eFig. 186-2.1 in online edition). AFB are not found.

Borderline Tuberculoid Leprosy. In BT disease (Fig. 186-3 and eFigs. 186-3.1 and 186-3.2 in online edition), immunologic resistance is strong enough to restrain the infection, in that the disease is limited and bacillary growth retarded, but the host response is

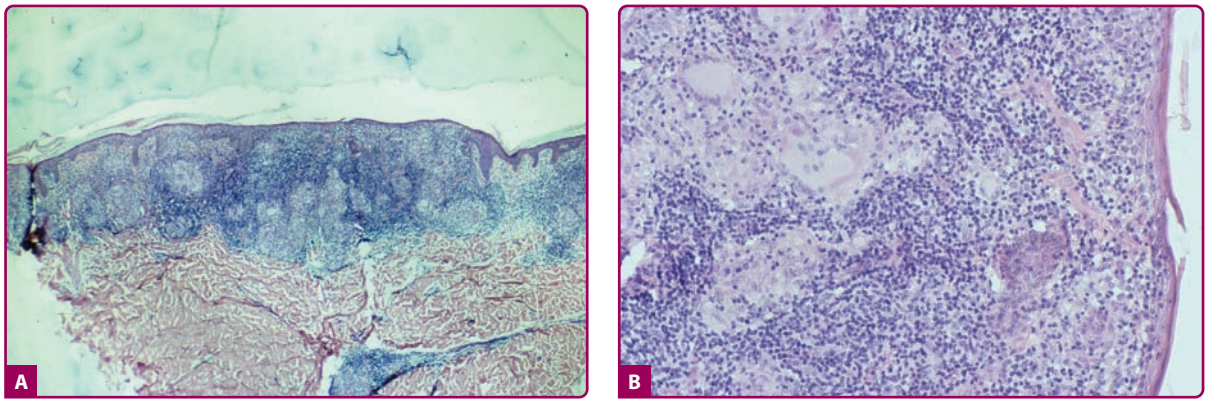

Figure 186-2 Two views of the histology of a TT lesion. **A.** The lower power view looks a lot like that of lupus vulgaris, which is the origin of the term "tuberculoid" leprosy. (H&E, 10· objective.) **B.** The high-power view of the same lesion shows abundant Langhan's giant cells, epithelioid tubercles, a dense lymphocytic infiltrate and a brisk exocytosis into the epidermis. (H&E, 20· objective.)

insufficient to self-cure. These patients are somewhat unstable—resistance may increase, upgrading to TT, or decrease, downgrading to BL.

The primary skin lesions of BT are plaques and papules (Box 186-1). As in TT, an annular configuration is common and both borders are sharply marginated but annular lesions or plaques may have sharply marginated satellite papules (Fig. 186-3). Hypopigmentation may be conspicuous in darkly pigmented patients (eFig. 186-3.1 in online edition). In contrast to TT, typically, there is little or no scaling, less erythema, less induration, and less elevation, but lesions may become much larger, that is, well over 10 cm in diameter, a single lesion sometimes involving an entire extremity over time (eFig. 186-3.1 in online edition). Multiple, asymmetric lesions are the rule, but solitary lesions are not rare. Impairment of sensation in skin lesions is the rule and nerve trunk involvement, enlargement or palsies, usually in no more than two and asymmetric, are common. Nerve abscesses, when they occur, are most often seen in males with BT disease (eFig. 186-3.2 in online edition).

Figure 186-3 One of several lesions of borderline tuberculoid leprosy (BT), which had an incompletely annular configuration with satellite papules. Compared to the TT lesion in **Fig. 186-1**, there is less erythema, no evident scales, but the sharp margination, and the "footprints" of absent pinprick perception are well developed. The lesional histology is shown in **eFig. 186-8.2** in online edition.

BT Histology. In BT tissues, well-organized epithelioid tubercles are present but the lymphocytic mantles are less well developed than in TT disease (eFigs. 186-3.3 and 186-3.4 in online edition). Also, Langhans-type giant cells are inconstant. Epidermal exocytosis, if present at all, is focal. AFB are only rarely seen in BT. The presence of AFB or plasma cells in what otherwise appears to be BT warrants consideration of a reversal reaction.

Borderline Leprosy. BB is the immunologic midpoint or midzone of the granulomatous spectrum, being its most unstable area, with patients quickly up- or downgrading to a more stable granulomatous posture with or without a clinical reaction. Characteristic skin changes are said to be annular lesions with sharply marginated interior and exterior margins, large plaques with islands of clinically normal skin within the plaque, giving a "Swiss cheese" appearance, or the classic dimorphic lesion. Because of instability, the BB posture is short lived and such patients are rarely seen. For example, we have yet to see a nonreactional patient meeting both clinical and histologic criteria.

BB Histology. In BB, the epithelioid differentiation remains, but lymphocytes are sparse, giant cells are absent, and bacilli are easily found.

Borderline Lepromatous Leprosy. In BL disease, resistance is too low to significantly restrain bacillary proliferation, but still sufficient to induce tissue destructive inflammation, especially in nerves. Thus, BL patients have the worst of both worlds. The

BOX 186-1 DIFFERENTIAL DIAGNOSIS

PRIMARY LESIONS

- **Macules and patches.** The hypopigmentation of pityriasis alba and indeterminate leprosy mimic each other. If the patient was born in, or had resided in, an endemic area, then the distinction between the two may be made by neurological or histological examination. Hypopigmented BL plaques can be so faintly indurated as to mimic patches. Telangiectasias may be eruptive or present as mats on the face and upper trunk.
- **Papular to nodular lesions.** In the dermis, leprosy may mimic, or be mimicked by dermatofibromas, histiocytomas, lymphomas, sarcoidosis, and other granulomas. Eruptive and recurrent inflammatory subcutaneous nodules may be ENL, erythema nodosum, erythema induratum, and vasculitis. Palpable, but not visible, subcutaneous nodules in Latapi's lepromatosis may mimic lipomas.
- **Plaques.** Erythematous plaques may mimic mycosis fungoides. Plaques without pigmentary change may be wheal like in appearance, causing confusion with urticaria. Hypopigmented plaques may mimic papulosquamous eruptions. Islands of normal skin within a plaque may suggest psoriasis.
- **Polymorphous vesiculobullous eruption/Dermoepidermal separation.** They may occur in ENL. Up to 30% of LL patients may have an antibody directed to desmoglein 1, giving rise to bullous lesions. Also, IgM is deposited not uncommonly at the epidermal basement membrane in LL. These antibodies are not necessarily pathogenic but may confuse diagnosis.
- **Annular lesions.** Leprosy may mimic, or be mimicked by, annular erythemas, sarcoidosis, syphilis, or tinea.

SECONDARY LESIONS

- **Infarcts.** Lucio's phenomenon lesions and necrotic ENL mimic septic infarcts.
- **Ulcers.** Ulcers occur in Lucio's phenomenon and ENL secondary to vascular occlusion. In patients with nerve destruction, neurotrophic ulcers occur on the plantar surface, patients with Leg ulcers secondary to venous insufficiency are seen in Latapi's lepromatosis.

CLINICAL CONSTELLATIONS

- **Systemic lupus erythematosus-like changes.** Fusiform fingers, swan neck deformity, false positive syphilis tests, antiphospholipid antibodies, lupus anticoagulant, hyperglobulinemia, and anemia.
- **Vasculitis.** A true vasculitis may occur in ENL, Lucio's reaction, and Latapi's lepromatosis. Clinically, leprosy lesions of a nodular character may be misdiagnosed as "vasculitis."

BL category is highly variable in its clinical expression (eFigs. 186-3.5 in online edition and Fig. 186-4). Although seen in only a third of BL patients, the classic dimorphic lesion is the most characteristic, having an annular configuration with a poorly marginated outer border (lepromatous like) but a sharply marginated inner one (tuberculoid like), hence, having both morphologies thus "dimorphic leprosy." Variation may be considerable in one patient and even greater across the entire BL population. Poorly or sharply marginated plaques with "punched out" or "Swiss cheese" sharply marginated areas of normal skin in the interior of the plaque are also characteristic, and can be thought of as a variant of the classic dimorphic lesion (eFig. 186-3.5 in online edition). Annular lesions with sharply marginated exterior and interior borders are not uncommon. Lepromatous-like, poorly defined papules and nodules may be numerous, but are usually accompanied by sharply marginated lesions somewhere.

Lesions range in number from solitary to numerous and widespread. Generally, the annular and plaque lesions are asymmetrically distributed, but the lepromatous-like nodules, if numerous, are symmetric (Fig. 186-4). Skin lesions are often hypesthetic or anesthetic, but not necessarily so. Nerve trunk palsies have their highest prevalence in BL disease, but are variable in number, ranging from none to serious neurologic deficits, both motor and sensory, in all four extremities. Involvement of both median and ulnar nerves, not infrequently bilateral, is characteristic. When disease is extensive, BL patients may also develop S-GPSI.

Figure 186-4 Multiple lesions in a patient with borderline lepromatous leprosy (BL). The annular lesions vary in size and are asymmetrically distributed. In contrast, the poorly defined papular and nodular lesions are roughly symmetric. Impaired sensation was present in most lesions.

Untreated BL patients have slow relentless progression of skin and nerve changes. With or without treatment, this course may be altered by a reactional state (see section below), upgrading or reversal reactions being more common than erythema nodosum leprosum (ENL). Also, BL patients may silently downgrade to an LLs granulomatous posture.

Borderline Lepromatous Histology. One classic BL dermal response is a relatively dense lymphocytic infiltrate restricted to the space occupied by the macrophages (eFig. 186-4.1 in online edition). The macrophages are often foamy, but undifferentiated macrophages may be common. The epidermis is undisturbed. In nerves, the other classic BL response is lamination of the perineurium with infiltration by inflammatory cells (eFig. 186-4.2 in online edition). In BL, as contrasted to LLs, the inflammatory infiltrate is so dense as to obscure the lamination. An alternative BL pattern is that of a chronic lymphohistiocytic infiltrate (eFigs. 186-4.3 and 186-4.4A in online edition). Plasma cells may be present. Bacilli are easily found, and globi are not unusual.

Lepromatous Leprosy. In lepromatous leprosy (LL) the diminished CMI toward *M. leprae* permits unrestricted bacillary replication and widely disseminated, multiorgan disease. Diffuse dermal infiltration is always present subclinically and, may be overtly manifested by enlargement of ear lobes, widening of the nasal root, fusiform swelling of the fingers, and the skin being thrown into folds. Poorly defined nodules are the most common lesions, usually up to 2 cm in diameter, and are symmetrically distributed. A conjunction of skin folding and nodule formation produces the "leonine faces."

Dermatofibroma-like or histiocytoma-like lesions, usually multiple, are sharply marginated erythematous papules or nodules, sometimes confluent into plaques (Fig. 186-5A and 186-5B). These were first identified in relapsing patients as "histoid" leprosy, but are not unusual as presenting lesions. Less common presenting skin lesions include digitate, barely indurated patches of erythema (Fig. 186-6), which in light-skinned patients are sometimes followed by a mild hyperpigmentation, a veil of melanin concealing the erythema; in dark-skinned patients multiple hypopigmented macules may be seen. Also, rarely, a dense dermal infiltrate may mimic a nevoid lesion (see eFig. 186-6.1 in online edition).

A clinical clue of LLs is a sharply marginated region in a lesion, perhaps the residual of a BL lesion in a patient who has downgraded to LLs, or the presence of dermatofibroma-like lesions. The distinction between LLs and LLp is usually made histopathologically.

Hair loss is most common in the eyebrows (eFig. 186-6.2 in online edition), where it may progress medially to laterally or be patchy. Hair loss may also occur on the eyelashes and extremities, and may be partially reversible if treated early. Scalp involvement is rare. Loss of eccrine sweating from sympathetic nerve involvement is common, as manifested by dry palms or soles. Any given skin lesion may or may not be hypoesthetic but generally, in each patient, some are. Nerve trunk palsies occur, but are less common than in BL. The stocking glove pattern of sensory impairment

Figure 186-5 **A.** Multiple dermatofibroma-like papules, with some confluence to form plaques. **B.** Multiple dermatofibroma-like and histiocytoma-like lesions in a patient who had sought no help for these, until taken to the hospital from an automobile accident. The senior pathologist who reviewed the case suggested a Fite stain. The skin between such nodules is diffusely infiltrated.

Figure 186-6 These multiple, barely palpable, erythematous, and asymptomatic lesions had been erupting over the previous 2 months in an LLs patient. With treatment, as the lesions remitted they became mildly hyperpigmented. Here, the accentuation of the normal skin markings is in contrast to their effacement, as shown in **Fig. 186-4.**

is common and may be so severe as to lead to debilitating trophic changes of the hands or feet.

Untreated LL disease is relentlessly progressive, but this course may be altered by reactional states. LLs and LLp subjects frequently develop erythema nodosum leprosum (ENL). LLp patients do not develop reversal reactions (see below), whereas LLs patients may.

LL Histology. LLs and LLp have many histologic features in common. (1) Nodular lesions, consisting mainly of foamy or undifferentiated macrophages, have replaced much of the dermis, with loss of appendages. The epidermis is attenuated by the nodule, but a thin layer of dermis (grenz zone) separates the two and a Fite stain shows numerous bacilli. (2) Clinically normal skin will show a variably dense infiltrate of foamy or undifferentiated macrophages, often scant in a perivascular and periappendageal distribution, but the epidermis is undisturbed (eFig. 186-6.3 in online edition). (3) Both LLs and LLp may show small but dense aggregates of lymphocytes, which may be B-cells. (4) The appearance of the macrophages varies with the age of the lesion, ranging from undifferentiated to foamy cells (eFigs. 186-6.4 and 186-6.5 in online edition). (5) Endothelial AFB are not uncommon in LLs and LLp. (6) Plasma cells and mast cells, the latter often easily identified by the AFB counter stain, are sometimes increased. (7) In older lesions, foreign-body giant cells may be common, probably arising in response to the death of macrophages containing many dead AFB (eFig. 186-6.6 in online edition).

In LLs, lymphocytes are sparsely distributed generally, and the perineurium is laminated, but sparsely infiltrated by inflammatory cells making the laminations conspicuous (see eFig. 186-6.7 in online edition). In LLp, lymphocytes are fewer than in LLs, and the perineurium is undisturbed (see eFig. 186-6.8 in online edition). In our experience, the dermatofibroma-like lesions have all been in LLs patients, may resemble dermatofibromas histologically as well as clinically (eFig. 186-6.9 in online edition).

Indeterminate Leprosy. Indeterminate leprosy is a term with nearly as many meanings as it has users. We prefer the definition of Khanolkar,[31] designating an early lesion appearing before the host makes a definitive immunologic commitment to a curative or overt granulomatous response. Clinically, the indeterminate lesion is a hypopigmented macule or patch, with or without an associated sensory deficit in or near the defect, and AFB, if found, are present in very small numbers. Such lesions are rare. The term is sometimes used, inappropriately in our opinion, to describe lesions rich in bacilli but having neither typical tuberculoid nor lepromatous histological patterns. Such patients are usually BL or occasionally LL.

Indeterminate Leprosy Histology. The indeterminate lesions usually show a patchy infiltrate in both the papillary and reticular dermis, consisting of lymphocytes and a few macrophages. Bacilli are rare or are not found. If bacilli are present in good numbers then BL or LL disease is much more likely than "indeterminate leprosy."

RELATED PHYSICAL FINDINGS

Insensitivity of the cornea is common in all forms of leprosy. In BL and LL diseases, numerous changes in the cornea and anterior chamber are possible. Iritis is a common serious change, occurring de novo or in association with reactions. Also, beading of the corneal nerves is common, and may be a helpful diagnostic sign.

In all LL patients and in BL with extensive disease, wide dissemination of the infection is the rule. In the upper respiratory tract involvement is from the tip of the nose through the vocal cords, manifesting as rhinitis, septal perforation, nasal collapse and hoarseness. As judged by elevated FSH and LH levels, testicular involvement with loss of testosterone production is common in LL men, less so in BL men, and is clinically manifested by complaints of impotence and infertility, and, on examination, by atrophy. Involvement of liver, spleen, peripheral lymph nodes, and bone marrow is common, but clinically evident organ injury is unusual. With effective chemotherapy, chronic disability from ocular or upper respiratory tract involvement is less common than previously, but has not disappeared. Ophthalmologists and otolaryngologists are still vital to evaluate and treat acute changes, and to prevent chronic changes in patients with leprosy.

PREGNANCY AND POSTPARTUM. Pregnancy is said to be a precipitating factor for leprosy in 10%–25% of women patients, presumably because of altered immunity. When pregnant, LL and BL patients are predisposed to develop ENL, but in the postpartum period, they are predisposed to develop reversal reactions, putatively due to reduced immunity in the former and restored immunity in the latter.[32] Untreated lactating BL and LL patients have viable bacilli in their milk, but no increased risk of disease transmission has been identified in infants ingesting such bacilli.[33] Dapsone in mother's milk may produce hemolysis in the baby.

ACQUIRED IMMUNODEFICIENCY SYNDROME OR AIDS. In contrast to the high incidence of tuberculosis and *M. avium*-intracellulare infections in AIDS or HIV patients, leprosy has not been regarded as an opportunistic infection in these individuals, perhaps as a consequence of *M. leprae* being an obligatory intracellular parasite. For example, in one study AIDS or HIV did not appear to influence disease expression (tuberculoid versus lepromatous) or the frequency of reactional states, but was a risk factor for recurrent DTH reactions.[34] However, recent reports of leprosy presenting as DTH reactions in the setting of highly active antiretroviral therapy (HAART) (eFig. 186-6.10 in online edition) suggest that the current views may need revision.[35]

RELAPSING LEPROSY. "Multibacillary" patients who are noncompliant or who develop drug resistance are prone to relapse. Such individuals present in several ways, including (1) a reprise of their initial presentation, (2) florid dermatofibroma-like lesions (histoid lesions), (3) a reactional state, and (4) a clinical state of higher resistance than their initial presentation, for example, an initially LLs individual having BL or even BT disease. LLp patients do not develop reversal reactions.

REACTIONAL STATES

The reactional states of leprosy are distinctive, tissue destructive, inflammatory processes that are putatively immunologically driven. They greatly increase the morbidity of the disease and, because of the experience required for optimal patient care, justify leprology as a clinical subspecialty. When present, a reactional state is superimposed upon the underlying granuloma, but the reactional state usually dominates the clinical picture. Too often, the reactional states are dismissed as complications of treatment, but they may occur before treatment is initiated or after it has been completed. They distress the patient who correctly complains, "I did every thing the doctor advised, but I got worse."

REVERSAL REACTION (JOPLING'S TYPE I REACTION). Reversal reactions are particularly common in BL patients, but are not rare in LLs, BB, or BT.[36] Reversal reactions are supported by substantial evidence to be a delayed-type hypersensitivity (DTH) response and are also known as DTH reactions. Though theoretically patients may upgrade to a more-resistant granulomatous posture, remain unchanged, or downgrade to a less-resistant posture. Downgrading is rarely if at all ever observed, and type I reactions are associated with reversal (upgrading). Therefore, reversal reaction is often synonymous with "upgrading" resulting in improved CMI or DTH "reactions." LLp patients do not develop DTH reactions.

Clinically, DTH reactions are characterized by the abrupt conversion of previously torpid plaques to tumid lesions, and new tumid lesions arising in clinically normal skin with or without an abrupt onset of neuritis. A purplish dusky erythematous color is characteristic (eFigs. 186-6.10 and Figs. 186-7A and 186-7B in online edition). Morphologic variants include annular, concentric and eczematous changes (eFigs. 186-7.1–186-7.3 in online edition). Lesions are rarely solitary, as can happen in BT upgrading to TT, often multiple, and occasionally myriad, as in BL or LLs upgrading to BT (eFig. 186-6.10 in online edition). Iritis and lymphedema (eFig. 186-7.4 in online edition) (elephantiasis graecorum) may be concomitant changes. Neuritis also ranges from mild to severe, and is potentially disastrous, particularly if involving multiple nerves. For example, in LL commonly, and in BL occasionally, a withering away of the type C pain fibers results in diminished pain perception and in severe cases may result in loss of the protective pain sensation. This may be referred to as a "stocking glove pattern of sensory impairment." Motor loss with nerve involvement in addition to loss of sensation may occur in distal arms and legs.

Patients often present with DTH reactions, and DTH reactions occurring soon after presentation and the

Figure 186-7 **A.** Some of the initial presenting lesions in a patient with a DTH reaction, who had BL leprosy. The tumidity, purplish hue and sharp margination strongly suggest a reversal reaction. The lesions were neither painful nor tender. The differences between these lesions and those shown in **eFig. 186-2.3** in online edition emphasize that the DTH reaction, not the underlying BL disease, dominates the clinical picture. **B.** The patient also had, in the left foot, an irreversible foot drop of recent onset. The redness in the skin of the left foot and leg reflects the associated loss of sympathetic nerves.

initiation of treatment may well have been DTH reactions from the beginning.[37] Presumably, the increased prominence of signs and symptoms motivate patients to seek medical attention. Most common in the first year of treatment, DTH reactions may occur 7 years or longer after starting therapy, and well after treatment has stopped. The diagnosis of a DTH reaction is primarily clinical, but histologic confirmation, if available, should be sought.

REVERSAL REACTION HISTOLOGY. Biopsies of reversal reaction tissues, when compared with prereactional biopsies in the same patient, occasionally do not differ. However, the most common change is edema (eFig. 186-7.5 in online edition). Other common changes are enhanced epithelioid differentiation of macrophages, increased lymphocytes, Langhans-type and foreign-body giant cells often mixed together, epidermal thickening, and, occasionally, enhanced bacteriolysis (eFigs. 186-7.5–186-7.6 in online edition). Nerve histology may change rapidly in a reversal reaction, in which nerves may be destroyed by a granulomatous infiltrate (eFig. 186-7.7 in online edition). Edema and well-developed epithelioid tubercles associated with AFB, plasma cells, or a mixture of Langhans and foreign-body giant cells should arouse suspicion of a reversal reaction.

ERYTHEMA NODOSUM LEPROSUM (JOPLING'S TYPE II REACTION). ENL occurs most often in LL, in up to 75% of cases, but is not rare in BL patients. ENL is not erythema nodosum occurring in leprosy; it is a leprosy-specific response, which has some clinical and histologic features in common with erythema nodosum. It may occur before, during, or after chemotherapy. Excluding untreated patients who present because of ENL, the median time of onset of ENL is close to 1 year after onset of treatment. Clinically, this reaction is characterized by crops of painful and tender, bright pink, dermal and subcutaneous nodules in clinically normal skin, in association with fever, anorexia, and malaise. Arthralgias and arthritis are more common in ENL than are neuritis, adenitis, orchitis/epididymitis, or iritis, but each may rarely be the initial presentation. Involvement of both upper and lower extremities is the rule and facial lesions occur in half the patients. Lesions may be targetoid, vesicular, pustular, ulcerative, or necrotic (Fig. 186-8 and eFigs. 186-8.1–186-8.5 in online edition). A neutrophilic leukocytosis is often present, occasionally leukemoid in degree. Severe episodes can be associated with an abrupt fall in hemoglobin level, up to 5 g/dL, easily mistaken for dapsone-induced hemolysis. The improvement in response to thalidomide is dramatic in more than 90% of patients, perhaps qualifying as a diagnostic criterion. When leprosy presents as ENL, there may be few or no stigmata of the underlying disease. ENL may be precipitated by pregnancy or pyogenic infections.

Although episodes of ENL may be sporadic, in the more severely involved patients, episodes can be frequent to virtually unremitting. In the latter, brawny induration of the anterior thighs and preaxial portion of the arms is characteristic, perhaps a reversible fibrosis. The course of ENL is often prolonged, the median duration of anti-inflammatory treatment being approximately 5 years. If the diagnosis of ENL is considered, it is usually not difficult, as the clinical and histologic features and the response to thalidomide therapy are highly characteristic.

Figure 186-8 Papular ENL lesions occurring on the face and arms of an LL patient. Some papules are becoming confluent, forming a plaque. In contrast to nodular ENL lesions, in the papular ENL lesion the dermis is more extensively involved than the subcutis.

ENL HISTOLOGY. A "bottom-heavy" pattern is a low-power feature of most ENL lesion, showing a gradient of inflammatory cells, scant in the papillae and heavy in the deep dermis or subcutis (eFig. 186-8.6 in online edition). An uncommon alternative histology is a pan-dermal infiltrate with marked edema of the papillary dermis (eFig. 186-8.7 in online edition). In ENL lesions, neutrophils are the "signature" cells, but may not be found if older lesions are sampled. The extent of the neutrophil infiltrate is highly variable, being so dense as to form a small abscess (eFig. 186-8.8 in online edition), or very scarce. Other common features are an increase in lymphocytes, epidermal thickening, lobular panniculitis, and fibrosis. An uncommon but not rare finding is vasculitis (eFig. 186-8.9 in online edition) that appears focal in distribution.

LUCIO'S PHENOMENON. This is an often dramatic onset of hemorrhagic infarcts on the skin, most prevalent in Mexico and the Caribbean region and restricted to patients with Latapi's lepromatosis (Lucio's leprosy).

When fully developed, Latipi's lepromatosis features diffuse infiltration of the skin, as well as a purplish suffusion of the hands and feet, telangiectatic mats or eruptive telangiectasias, nasal septum perforation, total alopecia of eye brows and eye lashes, and often a stocking glove pattern of sensory impairment. Firm subcutaneous nodules are palpable but not visible. Ocular sparing is the rule.

Lucio's phenomenon usually occurs after Latapi's lepromatosis is well developed and, with few exceptions, before treatment is initiated. Hemorrhagic infarcts, arising in crops, have serrated margins characteristic of septic infarcts and are painful but not tender (eFigs. 186-8.10 and 186-8.11 in online edition). Lesions usually crust and may heal with scarring.

Some lesions are bullous. Ulceration is common, especially below the knees. Lesions vary in size and extent, ranging from a few small lesions on the ankles to many large ulcerations that are life threatening. With dapsone alone, lesions may worsen, but in our experience, with one exception, new lesions ceased within 1 week of beginning rifampin.

LABORATORY TESTS

Polymerase chain reaction (PCR) testing for diagnosis of leprosy is not used in clinical practice, as in AFB-negative BT tissue a positive signal occurs less that half the time. Most laboratory abnormalities occur in LL or extensive BL disease. Hyperglobulinemia is the most common, giving an elevated sedimentation rate. A biologic false-positive serologic test for syphilis, anemia of chronic disease, and mild lymphopenia are also common. Clinically insignificant antiphospholipid antibodies are present in 50% of LL patients, and may give rise to a lupus anticoagulant or agglutination of sheep erythrocytes (Rubino factor).[53] If sought, the stained smear of the buffy coat shows bacilli up to 10^5/mL. Elevated serum lysozyme and angiotensin-converting enzyme values reflect the extensive accumulation and activation of macrophages synthesizing these proteases. Proteinuria, not uncommon, is associated with a focal glomerulonephritis, seen mostly in patients with ENL. Low testosterone levels, accompanied by high serum follicle-stimulating hormone (FSH) and luteinizing hormone (LH) values indicating testicular disease, occur in a majority of men with LL, but in a minority of men with BL.

DIAGNOSIS

A firm diagnosis of leprosy requires demonstration of a consistent peripheral nerve abnormality or the demonstration of AFB in tissues.

In nonendemic areas the diagnosis is missed only because the possibility of leprosy is not considered. There is no test to exclude leprosy.

Because *M. leprae* does not grow in cell-free media, demonstration of mycobacteria by their acid-fast property is used most commonly in diagnosis. AFB in tissue sections are best shown by carbolfuchsin staining, using modifications of the Ziehl–Neelsen method, collectively called Fite–Farraco stains. *M. leprae,* like *Nocardia* species, is only weakly acid-fast. In smears, either the Ziehl–Neelson method or auramine–rhodamine staining with fluorescent microscopy is satisfactory. Because of characteristic clinical and histologic changes, positive specification of *M. leprae* is rarely required. The presence of *M. leprae* in nerves or the presence of epithelioid cell granulomas within nerves are diagnostic, while characteristic histologic changes may suggest or corroborate the diagnosis of leprosy.

BOX 186-2 ANTIBACTERIAL TREATMENT OF LEPROSY RECOMMENDATIONS

RECOMMENDING ORGANIZATION	DISEASE TYPE	RIFAMPIN	DAPSONE	CLOFAZIMINE	DURATION	FOLLOW UP
World Health Organization	PB (1–5 lesions)	600 mg/ month	100 mg/day	—	6 months	No mandated follow up. To return prn
	MB (>5 lesions)	600 mg/ month	100 mg/day	50 mg/day 300 mg/month	1 year	No mandated follow up To return prn
U.S. Public Health Service	PB (1–5 lesions)	600 mg/day	100 mg/day	—	1 year	At 6 months intervals for 5 years
	MB (>5 lesions)	600 mg/day	100 mg/day	50 mg/day	2 years	At 6 months intervals for 10 years

OTHER MICROBICIDAL AGENTS	DOSE
Clarithromycin	500 mg/day
Minocycline (substitute for dapsone or clofazimine)	100 mg/day
Ofllaxacin	400 mg/day

BOX 186-3 MEDICAL MANAGEMENT OF REACTION STATES

	THALIDOMIDE	PREDNISONE OR PREDNISOLONE	DURATION	OTHER AGENTS OF UNPROVEN VALUE
Reversal reactions (type 1 reactions)	Of no value	0.5–1.0 mg/kg Rifampin may increase their catabolism Taper slowly Alternate-day treatment may be well tolerated	Usually needed for 6 months—2 years. May be longer or shorter	Nonsteroidal anti-inflammatory agents
Erythema nodosum leprosum (type II reactions)	The most efficacious drug if available and not contraindicated Initially 1 dose of 100–200 mg qd hs Maintainable dose range 50 mg every other day to 500 mg daily	If thalidomide not available, 0.5–1.0 mg/kg/day.	Median duration of treatment is approximately 5 years. Can persist for 10 years	Pentoxifylline clofazimine
Lucio phenomenon (usually ceases with use of a microbicidal agent)	Of no value	May be helpful	—	Plasmapheresis reported as helpful in unremitting patients

COMPLICATIONS

The common complications of leprosy arise from peripheral nerve injury, venous insufficiency, or scarring. Approximately one-quarter to one-third of newly diagnosed patients with leprosy have, or will eventually have, some chronic disability secondary to irreversible nerve injury, usually of the hands or feet, or from eye involvement. Exposure keratitis may result from a variety of factors including a dry eye, corneal insensitivity, and lagophthalmos. This keratitis and the anterior chamber lesions (including involvement of iris, sclera or corneal nerves) may result in blindness. Venous insufficiency, secondary to endothelial involvement of deep vein valves, leads to stasis dermatitis and leg ulcers. Destruction of joints (Charcot joints) may occur due to loss of the protective pain sensation. Sympathetic nerve involvement results in decreased hidrosis, leading to dry palms and soles. This in combination with repetitive cycles of skin injury from diminished protective pain results in hyperkeratosis, fissuring and bacterial superinfection. Collapse of the nose in LL is from the contracture of the scar tissue, which has replaced the bone and cartilage. Uncommon complications of Lucio's phenomenon include septicemia from extensive ulceration and contracture secondary to scar formation.

Nerve injury leading to loss of muscle innervation may lead to weakness. Repetitive cycles of injury and bacterial superinfection, permitted by loss of protective pain sensation, are the sources of severe tissue destruction in leprosy. Contracture, secondary to muscle weakness or scar formation, may produce further deformity. Management and prevention of the problems arising from nerve injury may require the skills of orthopedic surgeons, ophthalmologists, podiatrists, plastic surgeons, physical therapists, orthotists, and/or occupational therapists.

PROGNOSIS AND CLINICAL COURSE

The only leprosy patients who will cure themselves without therapy are those with TT, or BT patients who upgrade to TT. Otherwise the disease will be progressive, with morbidity due to nerve injury and/or superimposed reactional states. Treatment arrests much of disease activity but the stocking-glove pattern of sensory impairment may progress. Peripheral neuritis of resent onset may improve with corticosteroid treatment. Like the postpolio syndrome, late arising sensory impairment is sometime seen and is difficult to understand and to manage.

Chapter 187 :: Lyme Borreliosis

:: Meera Mahalingam, Jag Bhawan, Daniel B. Eisen, & Linden Hu

LYME DISEASE AT A GLANCE

- Lyme disease is caused by *Borrelia burgdorferi*, a spirochete.
- Clinical course can be prolonged and may involve multiple organ systems.
- Cutaneous hallmarks are erythema migrans and acrodermatitis chronica atrophicans.
- Diagnosis is typically made on clinical grounds, identification of the organism from tissue sections and/or serologic testing.
- Early treatment with antibiotics (doxycycline, amoxicillin, or cefuroxime) is highly successful.

Lyme borreliosis, or Lyme disease, is the most commonly reported arthropod-borne illness in both the United States and Europe.[1] It was first recognized in the 1970s after epidemiologic investigations of a clustering of cases of oligoarthritis among children in eastern Connecticut established a probable microbial etiology for the disease.[2] In 1981, Burgdorfer isolated a new spirochetal bacterium, *Borrelia burgdorferi*, from the midgut of the *Ixodes dammini* tick (now *Ixodes scapularis*).[3] Recovery of the organism subsequently from cutaneous lesions, cerebrospinal fluid (CSF), and blood specimens of patients with Lyme disease in both the United States[4,5] and Europe[6–8] definitively linked the disease with *B. burgdorferi*.

EPIDEMIOLOGY

The existence of *B. burgdorferi* in the Northeastern United States likely predates the presence of European settlers by several thousand years.[9] The incidence and range of the organism has steadily grown since its recognition in the 1970s. Deer and birds are thought to be the primary drivers in dispersal of infected ticks into new areas. In the United States, the Centers for Disease Control and Prevention (CDC) initiated surveillance for Lyme disease in 1982, and the Council of State and Territorial Epidemiologists made Lyme disease a nationally notifiable disease in 1991. Since 1992, 248,074 cases have been reported to the CDC.[10] In 2006, the number of new cases in the United States was 19,931(national median incidence 0.5 cases per 100,000 people). This represents a 101% increase in annual incidence since 1992. There is believed to be significant underreporting of Lyme disease, and the real number of new cases each year in the United States is actually thought to approach 150,000. For the 15-year period for which the CDC has data, approximately 93% of reported cases occurred in ten states located in the Northeastern, mid-Atlantic, and North Central regions: Connecticut, Delaware, Maine, Maryland, Massachusetts, Minnesota, New Hampshire, New Jersey, New York, Pennsylvania, Rhode Island, and Wisconsin. Nearly all states have reported cases of Lyme disease at some point during the past 15 years, though average incidence varies markedly from 0.0 for Colorado, Montana, and Hawaii to 73.6 per 100,000 people for Connecticut. Disease in many of the states with low incidence represents travelers infected during travel to more endemic regions.

Lyme disease is also widely distributed in Europe, with an estimated 120,000 new cases each year.[11] The

highest reported frequencies occur in forested areas of central and Northern Europe (Germany, Austria, Slovenia, and Sweden).[12,13] The infection is also found in Eastern Russia, China, Korea, and Japan.[14]

ETIOLOGY

ORGANISM

Borrelia burgdorferi sensu lato, the agent of Lyme borreliosis, belongs to the eubacterial phylum of Spirochaetales, which are vigorously motile, corkscrew-shaped bacteria. The borrelial genome is made up of a linear chromosome and more than 20 circular and linear plasmids, the largest number known for any bacterium.[15] Some of the plasmids can be considered minichromosomes, as they are required for survival of the organism. Among the interesting characteristics of the organism are the large number of lipoproteins (more than 150). *B. burgdorferi*'s genome encodes no toxins or other identified virulence factor. *Borrelia* also lack biosynthetic machinery to produce many essential nutrients (e.g., amino acids and fatty acids) suggesting that *B. burgdorferi* is highly dependent on its host for obtaining crucial nutrients.[15]

Eleven *Borrelia* spp. have been described worldwide within the *B. burgdorferi sensu lato* family. Only three—(1) *B. burgdorferi sensu stricto*, (2) *Borrelia afzelii*, and (3) *Borrelia garinii*—have been confirmed to be pathogenic in humans and to cause Lyme borreliosis, although other species are under investigation for their relationship to human diseases (including *Borrelia bissettii*[16,17] and *Borrelia lonestari*[18]).

In the United States, the etiologic agent of Lyme disease is exclusively *B. burgdorferi sensu stricto*. *B. afzelii* and *B. garinii* cause the majority of Lyme disease in Europe, although *B. burgdorferi sensu stricto* is also present.[19] In Asia, only *B. afzelii* and *B. garinii* have been confirmed to exist.

ENZOOTIC LIFE CYCLE OF THE AGENT OF DISEASE

B. burgdorferi is maintained in nature through a cycle involving small rodents, birds, and ticks of the *Ixodes* species.[20,21] Although not important reservoirs for *B. burgdorferi*, deer are an important feeding source for adult ticks and reductions in deer populations can lead to significant decreases in the tick population.[22]

Ixodes ticks have a 2-year, three-stage (larval, nymphal, and adult) life cycle. Larval ticks acquire *B. burgdorferi* organisms by taking a blood meal from an infected animal and maintain the infection during the subsequent molting to the nymphal and adult stages. *B. burgdorferi* remain dormant in the tick's midgut between feedings.[23] Each tick life stage takes one blood meal: larval ticks feed in late summer, nymphal ticks feed the subsequent spring and early summer, and adult ticks feed in the fall and early winter. The major reservoirs for *B. burgdorferi* are small rodents and birds that are fed on by larval and nymphal ticks. Adult ticks feed on larger mammals (e.g., deer) that are not important reservoirs for *B. burgdorferi*. Humans are incidental hosts not important in maintaining *B. burgdorferi* in the wild. Most cases of human illness occur in the late spring and summer months when the ticks are most active and human outdoor activity is greatest.

Of clinical relevance, certain *Ixodes* ticks are vectors of other tick-borne illnesses in addition to Lyme disease: *I. scapularis* ticks in the United States and *Ixodes ricinus* ticks in Europe may transmit *Babesia microti* (a red blood cell parasite) or *Anaplasma phagocytophilum* (formerly referred to as the agent of human granulocytic ehrlichiosis).[24,25] *I. ricinus* in Europe and *Ixodes persulcatus* in Asia are also vectors of tick-borne encephalitis virus.[26]

PATHOGENESIS

Once in the host's skin, *B. burgdorferi* begins to spread from the initial inoculation site rapidly into the bloodstream where it disseminates to multiple sites. Time from inoculation to dissemination varies from as little as 3 days to weeks.[5]

B. burgdorferi has developed strategies to adapt to and survive in markedly different microenvironments.[27] The organism expresses a variety of proteins during its life cycle, facilitating binding to different host proteins, migration within host tissues, transmission, and evasion of the host immune response.[28,29] A well-documented example of host adaptation is the variable expression of outer-surface proteins (Osp) A and C. OspA, primarily expressed while the spirochete is dormant in the tick's midgut,[30] is thought to serve as an anchor by binding the tick midgut protein, TROSPA.[31] When the tick engorges on a host, *B. burgdorferi* downregulates OspA, releases from the midgut, and begins to multiply and travel to the salivary glands. This process takes between 24 and 48 hours, which explains why removal of the tick before 24 hours of attachment prevents transmission of disease.[32]

As the organism downregulates OspA, it upregulates OspC, which facilitates migration from the tick's gut to its salivary glands. OspC binds to a tick salivary protein, Salp15, which protects the organism from clearance by host immune defenses.[33] Immunosuppressive characteristics of tick saliva also aid in the establishment of early infection. For example, tick saliva contains proteins that bind host chemokines.[34] These proteins, termed evasins, help suppress recruitment of inflammatory cells into the area where the tick is feeding allowing the tick to better feed and incidentally providing protection to organisms such as *B. burgdorferi* that are transmitted during feeding.

B. burgdorferi also bind host factor H to protect itself from complement-mediated killing.[35,36] Specificity of strains of *B. burgdorferi* for factor H from different animal species may, in part, explain differences in host range between the species. *B. burgdorferi* have been shown to upregulate host proteases such as matrix metalloproteinases in the skin and joints which may play a role in pathogenesis by digesting extracellular matrix proteins and allowing dissemination, but this requires further clarification.[37]

IMMUNOLOGY

Both innate and acquired host immune defenses have important roles in the control of *B. burgdorferi* infection; however, neither can typically eradicate the disease.[38,39] Phagocytosis, both complement mediated and noncomplement mediated, is the first line of host defense against *B. burgdorferi*.[40,41] Natural antibodies (polyclonal IgM antibodies) may also function as a first line of defense against *B. burgdorferi*, killing spirochetes in the tick midgut during the blood meal and limiting pathogen burden before the development of a specific adaptive immune response.

Once inside the host, *B. burgdorferi* is a strong inducer of inflammation. Its outer surface lipoproteins are potent inflammatory stimuli.[42–44] Recognition of borrelial lipoproteins occurs through binding to Toll-like receptor 1 and 2 heterodimers, which initiates a cascade of intracellular signaling events culminating in the production of proinflammatory cytokines, chemokines, and other molecules important in host defense. Studies using Toll-like receptor-deficient mice have shown that other signaling pathways are also activated by *B. burgdorferi* and result in release of inflammatory mediators. Among the other innate immune receptors recognizing *B. burgdorferi* and mediating inflammation are integrin receptors.[45,46]

Development of a specific humoral immune response generally occurs over weeks to months.[47,48] The IgM response usually peaks between 3 and 6 weeks after disease onset and may remain elevated for months to years; the immunoglobulin G (IgG) response usually follows the IgM response by several weeks so that approximately 90% of patients have detectable IgG levels 4–6 weeks into the infection. The development of the humoral antibody response typically heralds a significant decrease in the number of organisms and decrease in the level of inflammation. Of note, the acquired humoral response is not typically protective against reinfection, in part due to significant sequence variability in protective antigenic epitopes between *B. burgdorferi* strains and the lack of expression of less variable protective antigens (e.g., OspA) in the mammalian host.[49]

CLINICAL MANIFESTATIONS

The clinical course of Lyme disease is typically described in stages that parallel that of another spirochetal disease, syphilis: early localized, early disseminated, and late disseminated. Localized disease closely follows the bite of an infected tick and is characterized by the erythema migrans (EM) rash with or without constitutional symptoms. Early disseminated Lyme disease presents days to months after onset of infection as a number of distinct clinical entities affecting the skin, joints, nervous system, and heart. Late-disseminated Lyme disease typically presents in only a subgroup of untreated patients months to years later, and manifests as chronic symptoms localized most often to the skin, joints, and nervous system. A minority of patients go on to develop prolonged posttreatment syndromes. These include a syndrome of antibiotic-resistant arthritis thought possibly to be autoimmune in nature, and, separately, a constellation of symptoms with similarities to fibromyalgia and chronic fatigue syndrome. The relationship of these latter symptoms to infection with *B. burgdorferi* is still debatable.

The disease caused by each species of *B. burgdorferi* is largely the same but certain clinical manifestations are more closely associated with infection due to a particular species.[19,50] For instance, *B. burgdorferi sensu stricto* is the most arthritogenic of the three *Borrelia* species.[51] For this reason, Lyme arthritis is the most frequent presentation of late Lyme disease in North American patients. Similarly, because *B. afzelii* is the species that has most often been associated with late skin manifestations; some dermatologic conditions [e.g., acrodermatitis chronica atrophicans (ACA) and borrelial lymphocytoma] are nearly exclusively found in Europe. Finally, *B. garinii*, the most neurotropic of the three species, causes a wide range of neurologic abnormalities.

EARLY CUTANEOUS MANIFESTATIONS OF LYME DISEASE

ERYTHEMA MIGRANS

Clinical Features. In early case reports, EM lesions were reported in 50%–80% of patients with Lyme disease. More recent studies have shown lower rates of EM, likely due to improved patient education. Definite history of tick bite at the site of the lesion is obtained in only a small proportion of patients.[52] The lesion itself is believed to be the result of the direct presence of the spirochete, corroborated by reports showing aspiration and cultivation of the organism from the lesion (see Fig. 187-1). EM lesions develop within 3–30 days of the tick bite (median, 7 days).[53]

EM may be seen anywhere on the body but is most common on the lower extremities, inguinal and axillary regions of adults (Fig. 187-2), and on the face in children ("slapped cheek" appearance) reflecting sites of predilection of the tick.[2] Although no definite sex predilection has been noted in the United States, women are reported to be more commonly affected in European studies.[8]

The skin lesion has a characteristic and pathognomonic appearance (see Fig. 187-2) of an expanding erythema encircling the bite site, with the transition between the central zone and periphery being less well demarcated than between that of the periphery and adjacent skin.[52] The border is usually continuous and not patchy. Cases in which the erythema appears stationary or even linear are reported.[5] Typically described as round, the lesion in reality is more oval with the "long line of the oval parallel to the lines of least skin tension" (Langer lines) (see Fig. 187-2).[54] As migration of the lesion proceeds, distortion of this configuration occurs.[55] The center fades after a few weeks leaving only the annular border erythematous (see eFigs. 187-2.1 and 187-2.2 in online edition).

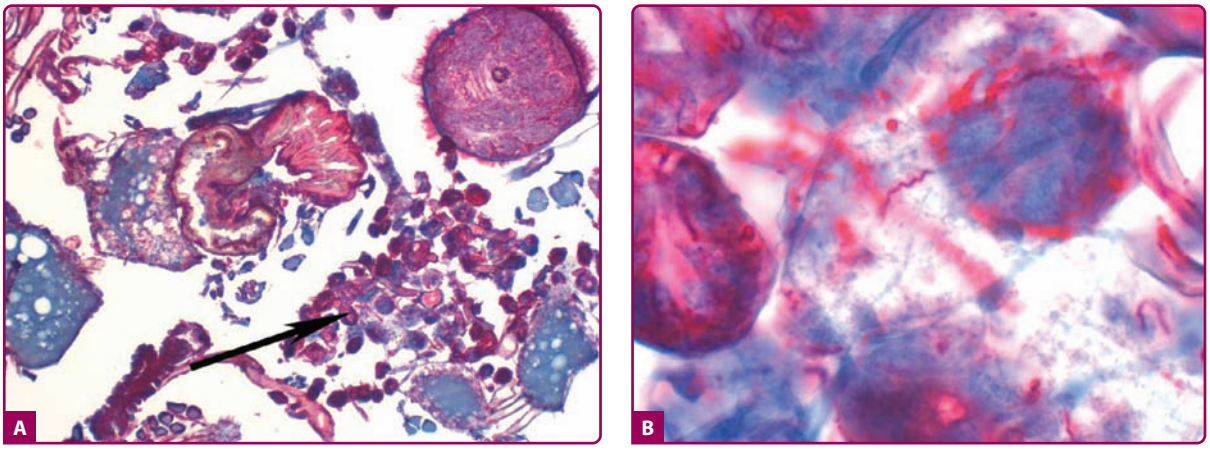

Figure 187-1 Tick with *Borrelia* (**A**) 10× and (**B**) 100×. (Used with permission from Dr. K Eisendle, Innsbruck Medical University.)

In very large lesions, only a portion of the erythematous border can be seen (see eFig. 187-2.3 in online edition).

Uncommon presentations include the entire lesion being homogenously erythematous ("solidly erythematous") (10%), forms with marked central necrosis, minimal size EM (size of the ring less than 5 cm at initial presentation) (2%), and the vesicular variant (5%).[56–58]

The lesion in itself is usually asymptomatic, but 50% of patients report mild tingling or itching.[59] Systemic manifestations, reported in approximately 50% of patients, may appear before, during, or after the classic lesion.[52,55]

EM has an excellent prognosis, attributable in part to the activation of proinflammatory cytokines such as interferon-γ.[60] EM usually heals spontaneously, but may persist for as long as 6–12 months; median duration in the United States is approximately 4 weeks and in Europe is approximately 10 weeks.[8,19,59]

Multiple EM-like lesions occur in between 1% and 17% of patients.[52] The reported prevalence of multiple lesions is believed to be higher in the United States (25%–48%) than in Europe (8% or less).[61] The spatial relationship of multiple lesions to the initial lesion indicates that they may be the consequence of hematogenous dissemination. Secondary EM lesions number from 2 to more than 80, usually occur away from the original lesion, and are usually smaller and less migratory (occur in "crops" of similar size, color, and shape) in comparison to classic EM.[52] Lesions are usually asymptomatic and if untreated spontaneously resolve over weeks to months. Like the primary lesion, secondary EM expands over days to weeks resulting in both solid and annular erythema. Primary EM may still be present but more often a primary lesion is not found. Constitutional symptoms are usually more severe than those associated with classic EM.[56]

Figure 187-2 Lyme borreliosis. Erythema migrans in the groin with expanding margin at the site of the tick bite of a week's duration. (Reprinted with permission from *Dermatopathology Interactive Atlas*, edited by J Bhawan, P Sau, HR Byers, 2001; http://www.dermpathatlas.com.)

Histopathologic Features. Histopathologic findings vary with the biopsy site[55] and age of the lesion. Biopsies of early lesions show papillary dermal edema and a mixed infiltrate of lymphocytes, neutrophils, a few plasma cells, and a few eosinophils (Fig. 187-3). Biopsies of older lesions display a variably dense perivascular and interstitial infiltrate of lymphocytes and plasma cells (Fig. 187-4). Helpful, albeit nonspecific, clues include the presence of plasma cells and mast cells in the infiltrate.[62] The presence of plasma cells and eosinophils in the same specimen is reported to be much less common than the presence of either alone.[55]

Immunohistochemical studies indicate the infiltrate to be composed of $CD4^+$ T lymphocytes with the exception of those seen in association with HIV infection in which the infiltrate is mainly $CD8^+$ T lymphocytes, reflective of the CD4 lymphopenia of HIV infection.[63]

Histopathologic features of multiple lesions of EM are identical to primary EM.

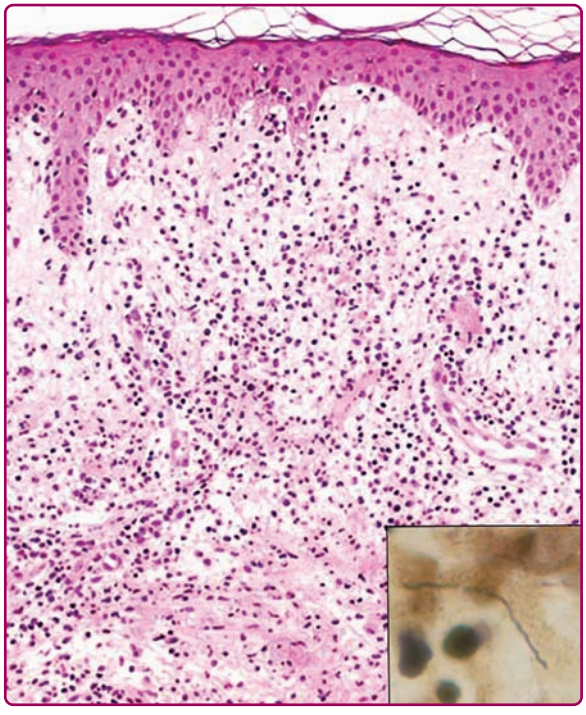

Figure 187-3 Histopathology of erythema migrans. Papillary dermal edema, mixed infiltrate of lymphocytes, neutrophils, few plasma cells, and few eosinophils (hematoxylin and eosin stain). *Inset* shows a spirochete in same biopsy stained with Warthin–Starry stain (oil immersion). (Reprinted with permission from *Dermatopathology Interactive Atlas*, edited by J Bhawan, P Sau, HR Byers, 2001.)

Diagnosis and Differential Diagnosis. The diagnosis of EM is typically made on clinical appearance in patients in an endemic area. From biopsy specimens, spirochetes, detected using special stains, are best located in the papillary dermis and may be short or elongate at this stage of the disease (see Fig. 187-3 inset).[55] Direct detection of the spirochete from biopsy specimens using newer modified immunohistochemical methods such as focus floating microscopy have a better yield in detection of organisms from EM cases. Both sensitivity and specificity are higher than for culture or polymerase chain reaction (PCR)-based techniques.[64,65]

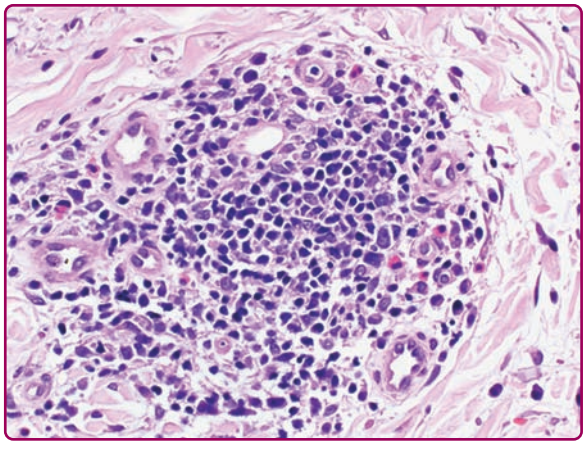

Figure 187-4 Histopathology of erythema migrans. Dense nodular perivascular lymphoid cell infiltrate with many plasma cells and few eosinophils in a biopsy from a later stage of erythema migrans. (Hematoxylin and eosin stain, ×40.)

Atypical lesions exist and broaden the clinical differential diagnosis to include cellulitis, tinea, other contact dermatitis, or a fixed drug reaction (Table 187-1). The differential diagnosis of vesicular EM includes poison ivy, contact dermatitis, cellulitis, herpes simplex, and impetigo.

LATE CUTANEOUS MANIFESTATIONS OF LYME DISEASE

ACRODERMATITIS CHRONICA ATROPHICANS

Clinical Features. Observed mainly in elderly patients in Europe, ACA has an insidious onset and appears to have predilection for females.[66] Rare cases of ACA have been reported in children.[67] The time interval from the spirochete inoculation to the onset of symptoms of ACA is extremely difficult to evaluate. Most patients do not recall the specific tick bite that initiated the disease.[8,68] That the spirochete can survive for decades is favored by reports indicating recovery of the spirochete from biopsies of skin from ACA patients even after 20 years.[8]

An inflammatory phase characterizes the early clinical stages of this biphasic disease.[69] The inflammatory phase presents as a bluish-red discoloration on the extensor aspect of fingers, hands, joints, and lower extremities (see eFigs. 187-4.1 and 187-4.2 in online edition).

Joints commonly involved include the elbows and knees. Infiltrated purple bands of varying widths may be observed adjacent to involved joint(s). Associated findings include a cushion-like ("doughy") swelling of the dorsum of the hands and feet (see eFig. 187-4.2 in online edition).[69]

The extremities are most commonly involved, although extensive lesions on the trunk have also been documented. Lesions typically extend from the distal to the proximal portion of the extremity involved. The erythema and swelling initially vary in intensity ("waxes and wanes"), and swelling of the posterior aspect of the lower extremities is believed by some to be particularly indicative of Lyme disease.[59]

Cutaneous atrophy (Fig. 187-5), characteristic of the later clinical stage, is not an obligatory sequel to the inflammatory phase of ACA.[69] Rarely, coexistence of both kinds of lesions at different sites in the same patient has been documented. The atrophic phase is characterized by lesions with a "cigarette paper-like" appearance and a prominence of superficial veins (see Fig. 187-5).

Extracutaneous Features. Central and peripheral nervous system involvement has also been documented in approximately 45% of patients with ACA.

TABLE 187-1
Cutaneous Manifestations of Lyme Disease

	Onset	Diagnosis/Differential Diagnosis
Common Manifestations		
Erythema migrans	Days to weeks (early)	Arthropod bite, erythema multiforme granuloma annulare, urticaria, erysipelas, brown recluse spider bite, fixed drug eruption
Acrodermatitis chronica atrophicans	Months to years (late)	Venous insufficiency, lichen sclerosus, scleroderma, physiologic age-related atrophy, corticosteroid-induced atrophy
Uncommon Manifestations		
Cutaneous scleroborrelioses	Months to years (late)	
Morphea		Primary morphea
Lichen sclerosus		Primary lichen sclerosus
Periarticular fibrous nodules		Rheumatoid nodule, gouty tophi
Progressive facial hemiatrophy		Primary progressive facial hemiatrophy/Parry–Romberg syndrome
Eosinophilic fasciitis		Primary eosinophilic fasciitis/Shulman syndrome
Cutaneous atrophoborrelioses	Months to years (late)	
Anetoderma		Primary anetoderma
Cutaneous lymphoborrelioses	Months to years (late)	
B-cell dominant (including B-cell lymphoma)		Arthropod bite reaction, response to vaccination, granulomas, neoplasm
T-cell dominant		Pityriasis lichenoides, polymorphous light eruption
Other cutaneous lesions	Weeks to months to years (early or late)	
Panniculitis		Erythema nodosum
Granuloma annulare		Insect bite reaction
Erythema multiforme		Drug eruption
Syphilis-like papulosquamous eruption		Secondary syphilis

Figure 187-5 Acrodermatitis chronica atrophicans. Typical end-stage cutaneous atrophy with prominence of superficial veins.

Thirty percent to 45% of patients suffer from a polyneuropathy, often most pronounced in the limb with cutaneous involvement.[61] Chronic joint and bone involvement, attributed to persistence of spirochetes in cutaneous lesions, is most often seen in patients with long-standing ACA or an untreated lesion of EM/ACA and is typically restricted to the extremity involved. The characteristic symptom, exhibited in approximately one-third of patients in one study, was a swollen or painful foot and heel.[61] Other symptoms include subluxation of small joints, bursitis, arthritis, and cortical thickening of bone. Solitary or multiple fibrotic lesions near joints, particularly in the olecranon area, may develop in some patients.[69]

Histologic Features. All three species of *B. burgdorferi* that infect humans have been found in ACA lesions.[70] Histopathologic features of biopsied lesions vary with the clinical phase of ACA. In inflammatory lesions, three layers are typically described: an atrophic epidermis, a zone of uninvolved papillary dermis, and a layer of inflammatory cells composed of lymphocytes and plasma cells.[71] The presence of plasma cells in the infiltrate is documented mainly from studies from Europe, as American reports indicate that few or no plasma cells are found.[68,69] The infiltrate may be

deep with extension into the subcutis.[59] Occasionally, interface dermatitis has been reported. Unusual findings include the presence of vacuoles, either singly or in groups, at different levels of the dermis.[72] Although some believe these represent mature adipocytes, others believe them to be an expression of lymphedema, given that they are mainly observed from biopsies of markedly edematous sites. In favor of the latter hypothesis is the absence of such vacuoles from the same site posttreatment.

Phenotypic studies indicate the lymphocytes in the infiltrate are mainly of the CD4 phenotype, favoring the concept that ACA is a T cell-mediated immune response.[73] Further in support of this theory is the expression of adhesion molecules, such as intracellular adhesion molecule-1, on endothelial cells, lymphocytes, and basal keratinocytes in the inflammatory infiltrate.[74] Chronicity of the lesions may be partially explained by downregulation of major histocompatibility complex class II molecules on Langerhans cells.[75]

Diagnosis and Differential Diagnosis. Detection of the spirochete using special stains, novel immunohistochemical techniques such as focus floating microscopy or PCR-based techniques substantiates the infective etiology, further supported by positive serologic findings.[65] Serology is of great utility in the diagnosis of ACA. Antibodies to *B. burgdorferi* can be detected in almost all of patients with ACA even years after treatment.

Lesions of ACA are notoriously overlooked or misinterpreted. In those with a relevant clinical history, the onset appears to be related to an untreated lesion of EM and/or neurologic manifestations. In one study, a history of EM months to years earlier on the same side was found in approximately 18% of patients.[75] Differential diagnoses are listed in Table 187-1.

CUTANEOUS SCLEROBORRELIOSES

Clinical Features. Sclerotic skin lesions clinically indistinguishable from primary lichen sclerosus (LS) or morphea (see eFig. 187-5.1 in online edition) develop not only in association with other dermatoborrelioses [approximately 10% of patients with ACA and borrelial lymphocytoma (see Section "Uncommon Cutaneous Manifestations of Lyme Disease")] but also in the absence of other cutaneous manifestations of Lyme disease.[56,76,77]

Periarticular ("ulnar") fibrous nodules (Fig. 187-6), described in association ACA, may also occur in the absence of dermatoborrelioses.[78] They usually present as hard nodules on the elbows, knees, and on the lateral aspect of the digits near joints and have been reported to be provoked by trauma, surgery, and electromagnetic radiation.[79]

Uncommon sclerotic disorders associated with Lyme disease include progressive facial hemiatrophy (Parry–Romberg syndrome) and eosinophilic fasciitis (Shulman syndrome) (see Chapter 157).[80] In support of an infectious etiology is the clinical similarity of the cutaneous lesions, positive history of tick bite, and, in rare cases, antiborrelial serologic evidence and positive culture and PCR from lesions.[81,82] Eosinophilic fasciitis associated with borrelial infection has been termed *borrelial fasciitis*, reflective of the infectious nature of these lesions.[80] Patients with borrelial fasciitis lack the peripheral blood eosinophilia typical of patients with Shulman disease.

Figure 187-6 Lyme borreliosis. Fibrotic nodules and multiple large, firm subcutaneous nodules on both elbows.

Histologic Features. A unifying feature of LS- and morphea-like scleroborrelioses is the abundance of plasma cells in the inflammatory infiltrate.[69] Unusual histologic findings include a scleromyxedema-like picture with increased dermal mucin and fibroblast proliferation.[78]

Histopathologic examination of a periarticular fibrous nodule reveals relatively well-circumscribed nodules of broad hyalinized bundles of collagen with macrophages and plasma cells.[79,83] Adjacent capillaries may be occluded by similar deposits.

Progressive facial hemiatrophy and eosinophilic fasciitis show variable dermal sclerosis, loss of appendages, and a perivascular infiltrate composed predominantly of lymphocytes and plasma cells with scattered histiocytes.[69] In borrelial fasciitis, eosinophilic infiltration of the fascial planes is not as impressive as in the idiopathic disorder, Shulman disease.[80]

Diagnosis and Differential Diagnosis. (See Table 187-1). In the absence of other dermatoborrelioses, definitive diagnoses can only be made by positive evidence of infection in the form of identification of the spirochete using special stains in tissue sections positive cultures, or positive serology.[84] (Identification of the organism in periarticular nodules has been reported despite the lengthy delay following the tick bite). Conflicting evidence regarding serologic findings in patients with scleroderma or LS-like lesions exists.[77] Although some reports indicate a

high frequency of elevated titers of anti-*Borrelia* antibodies, others suggest that such serologic evidence is minimal.

CUTANEOUS ATROPHOBORRELIOSES

Clinical Features. Atrophic lesions indistinguishable from primary anetoderma (see Chapter 67) may also occur in the absence of other dermatoborrelioses.[69,84] When associated with ACA, these lesions are usually seen at the periphery of an extensive lesion.[85]

Histologic Features. Biopsy specimens from atrophic or anetoderma-like skin lesions show abnormal elastic tissue fibers in association with a perivascular infiltrate of lymphocytes with occasional histiocytes, neutrophils, or eosinophils.[69] Spirochetes may be found with difficulty in histologic sections.

Diagnosis and Differential Diagnosis. (See Table 187-1). Definitive diagnosis is made by identification of the spirochete in tissue sections, positive cultures, or positive serology in combination with a compatible clinical presentation.[84]

UNCOMMON CUTANEOUS MANIFESTATIONS OF LYME DISEASE

CUTANEOUS LYMPHOBORRELIOSES (B- AND T-CELL LYMPHOID HYPERPLASIAS)

Clinical Features. Lymphocytic infiltrates associated with *Borrelia* are the least common of the cutaneous hallmarks of Lyme disease (1%) and may present either as single borrelial lymphocytoma (lymphadenosis benigna cutis, LABC) or as multiple lesions.[59] The coexistence of lymphocytoma with other dermatoborrelioses led to the suggestion of a unifying causative organism, favored by the development of EM-like lesions following passive inoculation of an infiltrate from a lesion of LABC.[8,86] Lymphocytoma has been reported solely in Europe. However, all three species of *B. burgdorferi sensu lato* have been associated with lymphocytoma, so it is unclear whether the lack of US cases is related to strain differences.[70]

More common in children than in adults, lymphocytoma clinically presents as a nodulopapular lesion on the ear lobe (Fig. 187-7) or scrotum (see eFig. 187-7.1 in online edition) in children and the nipple-areolar area in adults.[56] The precise reason for this predilection is not known but is believed to be tissue temperature related.[59] It can occur in other locations. (see eFig. 187-7.2 in online edition).

As with the other dermatoborrelioses, most patients are not aware of a preceding tick bite. The incubation period varies anywhere from a few weeks to 10 months. The duration of an untreated solitary lesion can vary from months to years (average, 5 years). Spontaneous resolution may occur, but typically lesions resolve more rapidly with antibiotic therapy.[61] Lesions of multiple lymphocytomas can be entirely subcutaneous, may last for decades, and typically have

Figure 187-7 Borrelial lymphocytoma of ear lobe, 3 months' duration.

no specific site predilection or associations with other dermatoborrelioses.

Discoid lesions that start as small papules and expand peripherally with central clearing and that wax and wane have also been described in association with borrelial infection.[87] The name given for these lesions is *benign lymphocytic infiltrates* of the skin (Jessner–Kanof) (see Chapter 146). More common in men, they tend to be located on the face, neck, and upper trunk. Annular lesions clinically resembling EM have also been described.

Several reports suggest an association of low-grade cutaneous B-cell lymphoma with *B. burgdorferi* infection.[88,89] Clinical presentation of *Borrelia*-associated B-cell lymphoproliferative disease is varied and consists of multiple ill defined, slowly progressive plaques and nodules presenting on the trunk, extremities, or both, of usually older patients. The highest frequency of infection with *Borrelia* has been found in marginal zone lymphoma (20%–52%), followed by follicular center lymphoma (15%–26%) and diffuse large B-cell lymphoma (15%–16%; see Chapters 145 and 146).[88,90] That antigenic drive by *Borrelia* may be a pathogenic factor in more than one subtype is supported by the association of *B. burgdorferi* in patients who subsequently present with multiple subtypes of cutaneous B-cell lymphoma. Demonstration of the organism in the skin before development of overt cutaneous B-cell lymphoma serves to confirm the temporal progression of *B. burgdorferi*-associated B-cell lymphoproliferative disease. Clinical regression of marginal zone lymphoma ("pseudolymphoma") after eradication of *B. burgdorferi* argues in favor of a benign process.[89,91,92]

Histologic Features. Histopathologic findings of benign B- and T-cell dominant hyperplasias are essentially similar to benign lymphoid hyperplasias (Fig. 187-8) secondary to an arthropod bite, vaccination, or other causes (see Chapter 146). Definitive classification of *Borrelia*-associated B-cell lymphoma is confounded by the immunohistochemical profile. Expression of CD5 and CD10 (common acute lymphoblastic leukemia antigen), antigens typically associated with centrocytic lymphoma, are absent in *Borrelia*-associated B-cell lymphoma.[88]

Diagnosis and Differential Diagnosis. (See Table 187-1). Positive history of tick bite and presence

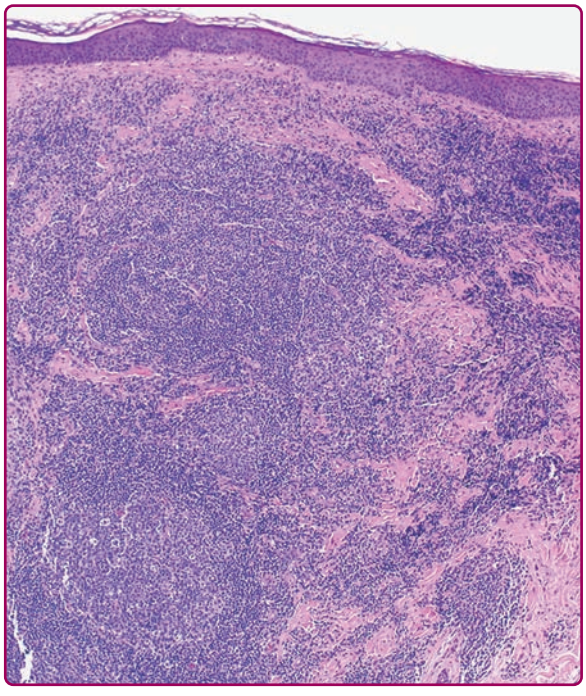

Figure 187-8 Cutaneous borrelial lymphocytoma with definitive history of tick bite. Nodular and diffuse dense lymphohistiocytic infiltrate with prominent germinal center (hematoxylin and eosin stain).

of other dermatoborrelioses are helpful, given that the histologic findings of cutaneous lymphoborrelioses are not diagnostic. Direct evidence of an infective etiology has been provided from studies demonstrating the presence of fragmented spiral forms suggestive of *B. burgdorferi* in lesions of benign lymphocytic infiltrates[87] and has been confirmed by immunofluorescence using species-specific monoclonal antibodies. Spirochetes may be cultured directly from biopsy specimens or *B. burgdorferi* DNA may be detected by PCR. High titers of antiborrelial antibodies have been reported in more than 50% of patients with LABC solitaria.[86] The common denominator in patients with *Borrelia*-associated lymphoma appears to be a high titer of antibodies, typical of the chronic stage of the infection, against *B. burgdorferi*.[88]

OTHER CUTANEOUS LESIONS. Other cutaneous lesions reported in patients with documented Lyme disease include panniculitis, vasculitis, granuloma annulare, erythema multiforme, and a syphilis-like papulosquamous eruption (see Table 187-1), but *B. burgdorferi* has not been directly recovered from any of these lesions, arguing against routine molecular analysis of these disorders for the presence of *Borrelia*.[65]

NONCUTANEOUS MANIFESTATIONS OF LYME DISEASE

NERVOUS SYSTEM MANIFESTATIONS. *B. burgdorferi* can cause early disseminated neurologic disease in 10%–15% of patients in the United States who have not received antibiotics.[93] Meningitis, cranial neuropathy, and radiculopathy are the most common neurologic manifestations and can manifest as soon as 1 week after EM.[94] Facial palsy is the most characteristic neuropathy of early Lyme disease in the United States, occurring in 40%–50% of patients with borrelial neurologic involvement, usually within 4 weeks after onset of EM. Bilateral facial palsy should immediately raise suspicion for Lyme disease, as it is uncommon in most other causes of facial palsy. Involvement of other cranial nerves has been reported, but is relatively rare.[94] The triad of lymphocytic meningitis, cranial palsy (often facial), and radiculoneuritis, known as *Bannwarth syndrome*, is pathognomonic for Lyme disease. It is frequently reported in Europe but is rare in the United States.[95,96] Acute or subacute myelitis leading to spastic paraparesis and CSF pleocytosis, mononeuritis, and a Guillain–Barré-like syndrome may also occur in early disseminated disease.[94,97] Late neurologic manifestations include encephalomyelitis, encephalopathy, and chronic polyneuropathies.[97,98]

CARDIAC MANIFESTATIONS. Cardiac involvement occurs in 4%–10% of untreated patients in the United States and in 0.3%–4.0% of European patients. It usually occurs within several weeks after the onset of infection, although it can occur as early as 1 week and as late as 7 months into the infection.[99,100] Within the heart, *B. burgdorferi* has a predilection for the atrioventricular node, resulting in atrioventricular block. Acute myopericarditis and left ventricular dysfunction can also occur, but are usually self-limited and mild, only sometimes resulting in transient cardiomegaly or pericardial effusion.[101] *B. burgdorferi* has been isolated from endomyocardial biopsy samples from several European patients with chronic dilated cardiomyopathy, a complication observed less frequently in the United States.[102,103]

MUSCULOSKELETAL MANIFESTATIONS. Early musculoskeletal manifestations of *B. burgdorferi* infection are typically nonspecific. Inflammatory arthritis is the most frequent clinical sign of late-disseminated Lyme disease in the United States, occurring in 50%–70% of patients with untreated or incompletely treated infection. It usually presents 1 or more months after the onset of Lyme disease as asymmetric mono- or oligoarthritis of large joints, most often of the knee.[93] Migratory arthritis is also relatively common.[5,51] Bouts of arthritis are generally frequent and short at first, becoming longer and less frequent with time, each lasting from several days to 1 year.

OTHER MANIFESTATIONS OF LYME DISEASE. Ophthalmic complications in the form of conjunctivitis, keratitis, iridocyclitis, retinal vasculitis, choroiditis, and optic neuropathy are rare manifestations of Lyme disease. They are believed to be the direct result of tissue inflammation by *B. burgdorferi* and are usually associated with other signs and symptoms of disease.[104,105] The eye may also be affected by extraocular manifestations of Lyme disease, such as cranial nerve pareses and orbital myositis. Findings

in other organ systems (gastrointestinal, lymphatic, respiratory, urinary, and genital) have been reported, but the associations with borrelial infection are loose.

PERINATAL LYME DISEASE. Studies in both human and animal models indicate that *B. burgdorferi* can cross the placenta during the initial spirochetemia, but evidence of a fetal immune response or an adverse neonatal outcome are not definitively established.[106]

LYME DISEASE IN CHILDREN. Other than differences in localization of EM lesions (more typically in the head and neck), pediatric Lyme disease is similar to that of adults. Of note, however, is that in children optic nerve involvement may lead to blindness.[107]

PROGNOSIS AND CLINICAL COURSE

Virtually all manifestations of Lyme disease resolve over time, even in the absence of antibiotic therapy. Antibiotic therapy can hasten resolution of some (EM, arthritis), but not all (facial palsy, radiculitis) manifestations, and early antibiotic therapy can clearly prevent late manifestations.

Dual infection with *B. burgdorferi* and either of *Babesia microti* or *A. phagocytophilum* occurs at different frequencies depending on the geographic location, and may alter the clinical presentation of Lyme disease in some patients. Some studies suggest more severe disease in patients who are coinfected, but this remains uncertain.[108–110]

COMPLICATIONS

A small number of patients have symptoms that persist for years despite appropriate antibiotic therapy. Up to 10% of patients with Lyme arthritis treated with appropriate antibiotics may have continued arthritis that persists for years.[111,112] Arthritis in these patients does typically respond to immunosuppressive agents (methotrexate, antitumor necrosis factor therapies), which has led to suggestions that these patients may have an infection-induced autoimmune syndrome. Molecular mimicry of borrelial antigens with host proteins has been proposed as one possible mechanism, but this remains unproven.[113]

There have been many reports of patients who develop a fibromyalgia-like syndrome including profound fatigue, depression, myalgias, polyarthralgias without arthritis, and paresthesias, as well as neurocognitive difficulties involving memory, concentration (particularly auditory), and impaired verbal fluency after infection with *B. burgdorferi*.[43,114,115] This syndrome is often referred to as *chronic Lyme disease*. The linkage of these symptoms with *B. burgdorferi* infection remains controversial and several large epidemiologic studies have shown that patients who have contracted Lyme disease are no more likely to suffer from these symptoms than persons in the general population.[116,117]

DIAGNOSIS OF LYME DISEASE

Physical findings, a history of potential exposure, known tick bites, or symptoms consistent with the typical multisystem presentation of Lyme disease can all be helpful in making a diagnosis. In the presence of classic EM or of Bannwarth syndrome, the diagnosis of Lyme disease can be made on clinical grounds alone. Diagnostic conundrums arise in presentations that involve other compatible skin, cardiac, neurologic, or musculoskeletal symptoms in the absence of a history of EM or tick exposure.

LABORATORY TESTS

DIRECT DETECTION OF *B. BURGDORFERI*. The organism is notoriously difficult to detect even with the use of special stains that include silver impregnation techniques such as Warthin–Starry, modified Dieterle or Bosma–Steiner.[118] More recently, focus floating microscopy (FFM), a novel modified immunohistochemical detection method has been shown to be reliable in detecting the organism from formalin-fixed paraffin-embedded tissue with a sensitivity surpassing that of PCR-based methods (96.0% vs. 45.2%) and a comparable specificity nearly equaling its sensitivity (99.4% vs. 100%).[65] The technique takes into consideration the scant presence of these spirochetes in tissue sections and their tiny size (0.2 µm thick) (Fig. 187-9). Added advantages of FFM include the fact that it is a fairly rapid, robust and relatively inexpensive method.

The gold standard for diagnosis of Lyme disease is culture of *B. burgdorferi*. However, the need for specialized media and the slow growth of the organism make it impractical in most clinical settings. *B. burgdorferi* can readily be cultured from biopsies of EM and ACA[64] as well as from CSF samples in patients with meningitis.[119,120] Recent studies have also demonstrated that the organism can be recovered from the blood in up to 50% of untreated adult patients with EM.[121] However, cultures are generally insensitive in patients with

Figure 187-9 Immunohistochemical staining for *Borrelia* using focus floating microscopy. (Used with permission from Dr. K Eisendle, Innsbruck Medical University.)

extracutaneous manifestations of Lyme borreliosis, particularly in later stage disease.

PCR-based assays, although utilized in detecting *B. burgdorferi* DNA in skin biopsy and synovial fluid specimens from patients with EM and Lyme arthritis, respectively, have varied sensitivities (30%–90%) based on the *Borrelia* strains, substrate (fresh frozen tissue or formalin-fixed paraffin-embedded tissue) and primers (specific for human pathogenic strains) used.[122] However, PCR testing for *B. burgdorferi* DNA has not been approved by the U.S. Food and Drug Administration (FDA), and its routine use is not recommended.[7]

SEROLOGIC DIAGNOSIS OF LYME DISEASE.

Immunologic diagnosis is the main laboratory modality used to support a clinical diagnosis of Lyme disease. In the United States, the FDA has approved more than 70 different immunoassays for Lyme disease[123]—mainly enzyme-linked immunoabsorbent (ELISA) and western immunoblot assays. ELISA tests use whole-cell lysates of *B. burgdorferi sensu lato* or, less commonly, purified *B. burgdorferi* antigens to capture either anti-*B. burgdorferi* IgG and/or IgM antibodies present in a given sample. Although relatively sensitive, ELISA tests are associated with a high rate of false-positive results.[124,125] Patients with autoimmune diseases (lupus, rheumatoid arthritis), Epstein–Barr virus, bacterial endocarditis, and other tick-borne diseases appear to be at an increased risk for false-positive IgM serologic testing; syphilis; patients with systemic lupus erythematosus, ehrlichiosis, and babesiosis or infections with H. pylori for false-positive IgG serologic testing.[125–127] A newer ELISA test that uses only a small peptide of the constant region of *B. burgdorferi* VlsE protein appears to have greater specificity than traditional whole cell ELISA testing. This test, also known as the *C6 peptide test*, measures only IgG antibody, but IgG antibody to the C6 peptide develops early in the course of disease and sensitivity of the assay in patients with early disease has been equivalent to that seen with IgM whole cell ELISA tests.[128,129] Western immunoblot assays are more specific because they enable detection of antibodies to individual components of *B. burgdorferi*. Currently, there are no widely accepted standard tests or criteria for serodiagnosis of Lyme disease in either Europe or Asia, in part because of the presence of multiple strains of *B. burgdorferi* that have only partial antigen cross-reactivity in a research setting.

Other Available Tests for the Diagnosis of Lyme Disease

Current Recommendations for Use of Serologic Testing for Lyme Disease. Because of its limitations, particularly high false-positive results within the general population, serologic testing should be initiated based on the pretest probability of disease and serve only to support a clinical diagnosis.[7] It is most helpful in patients with an intermediate pretest probability of Lyme disease—namely those who reside in endemic areas and who present with signs and symptoms consistent with, but not diagnostic of, Lyme disease (e.g., facial palsy, arthritis, or atrioventricular nodal conduction abnormalities in the absence of an EM lesion). Patients who reside in areas of high endemicity and have clear EM lesions should be diagnosed on clinical grounds alone without laboratory testing. Testing should be avoided in patients with low suspicion for disease (patients not living in endemic areas, or with nonspecific systemic symptoms, or after a tick bite) as the rates of false-positive tests greatly outnumber true positive tests in this setting. An algorithm for workup of patients presenting with an eruption suspicious for EM is shown in Fig. 187-10.

Once the decision is made to obtain serologic testing, current recommendations are for two-stage testing, starting with a highly sensitive ELISA test first. If the ELISA is negative, the likelihood of Lyme disease is low, and further testing is not generally recommended. However, if the test is positive or indeterminate, a western immunoblot assay with high specificity should be used to confirm the results. The specificity of this two-step approach is thought to be 99%–100% in late-stage Lyme disease.[130] If testing is negative early in the course of disease, the tests can be repeated in 3–4 weeks. However, antibiotic therapy, if given very early, may abort antibody development. It is important to note that in patients with untreated disease for longer than 1 month, IgM testing should not be performed. A positive IgM western blot with a negative IgG western blot in this setting is considered a negative result due to the high false positivity rate of IgM testing. Misuse or misinterpretation of the IgM tests one major factor in overdiagnosis of Lyme disease. Seronegativity in patients suspected of having late Lyme disease practically excludes the diagnosis.[7] Finally, because IgG and IgM antibody titers may persist for years despite antibiotic therapy,[131,132] persistent seropositivity is not in itself an indication of treatment failure, nor is it proof of recent infection or reinfection. Currently, there is no test that allows confirmation of successful clearance of the organism after treatment.

Some recent studies have suggested that the use of two-step testing for Lyme disease may result in underdiagnosis of Lyme disease. The performance of traditional ELISA tests against nonisogenic genotypes of *B. burgdorferi* is poor and early in the course of the disease results in lower sensitivity in patients infected with these strains.[133] The C6 antibody test appears to function better across genotypes of *B. burgdorferi* and with the European strains *B. garinii* and *B. afzelii*. Newer strategies incorporating C6 as a single step test or utilizing a C6 band in the second step western blot IgG test[134] have shown promising results but require further confirmation before they can be recommended.

TREATMENT RECOMMENDATIONS

Treatment is indicated for all stages of Lyme disease, even though most manifestations resolve over time without therapy. Patients may not be asymptomatic at the time of completion of the antibiotic course but this is not an indication for extending length of therapy; symptoms generally continue to improve steadily over

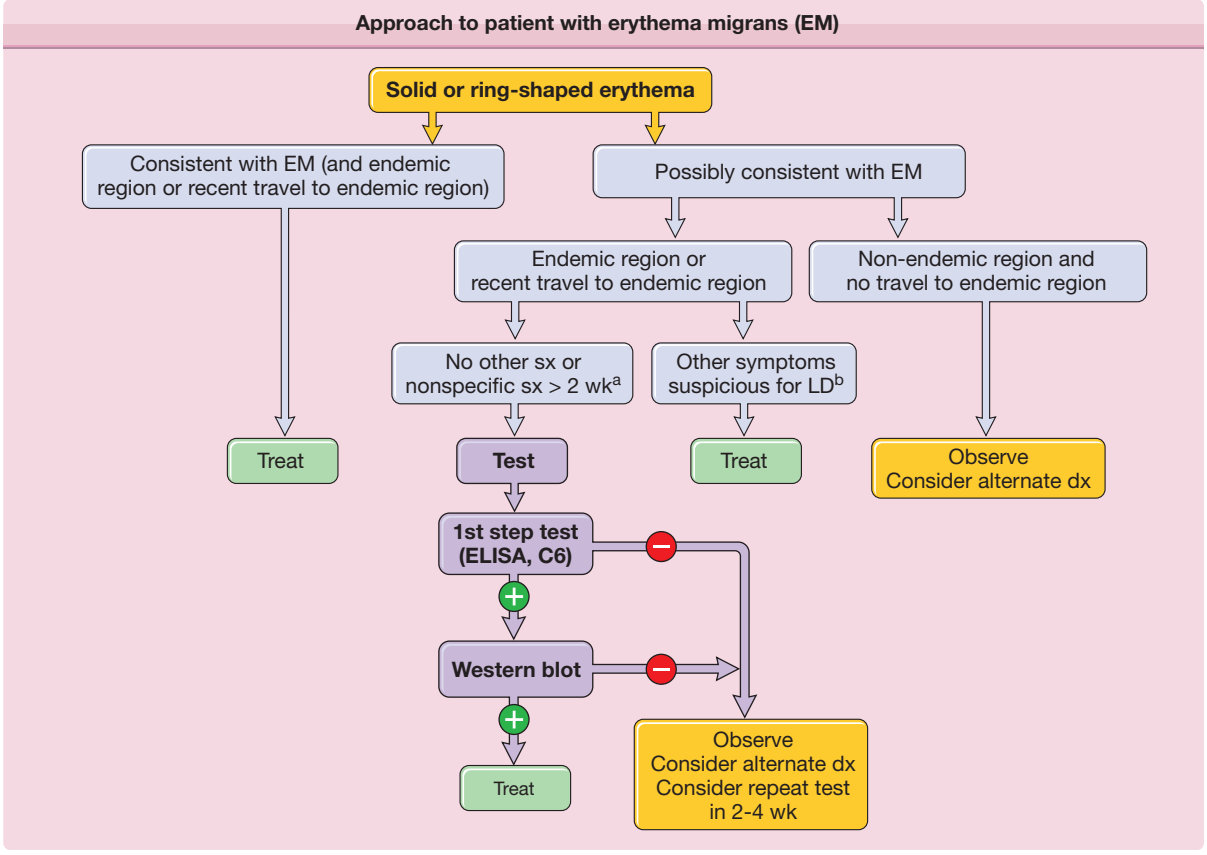

Figure 187-10 Approach to patient with erythema migrans (EM). [a]Fever, chills, fatigue. [b]Bell palsy, radiculoneuritis, meningitis, arthritis. dx = diagnosis; ELISA = enzyme-linked immunosorbent assay; LD = Lyme disease; sx = symptoms; dx = diagnosis.

time. Of note, Jarisch–Herxheimer reactions (fevers, chills, and worsening arthralgias and myalgias) are sometimes reported after the initial dose of antibiotics; the reaction is thought to be caused by host reaction to the dying organisms.

The Infectious Disease Society of America has published guidelines for the treatment of all manifestations of Lyme disease,[135] although many of the recommendations are based on expert opinion and not on rigorously controlled clinical trials. Treatment patterns differ among countries, but no data suggest differences in either the efficacy of specific antibiotics or in the optimal duration of therapy between patients in North America and Europe.

Treatment of all of the cutaneous manifestations of Lyme disease should initially be with oral antibiotics (Table 187-2). Doxycycline is generally considered as first-line therapy, because it has excellent penetration into the central nervous system and is also effective against *A. phagocytophilum*, the agent of human granulocytic ehrlichiosis. Amoxicillin should be used in children and pregnant women. Cefuroxime is a more expensive first-line agent. These three agents have been found to be equally effective.[26,135–137] Macrolides are second-line agents and some evidence suggests that they are less effective than the first-line agents.[135] Duration of therapy is generally recommended to be 14–21 days; a recent study showed similar outcomes in patients with EM treated with either a 10- or a 20-day course of oral doxycycline.[138]

Intravenous antibiotics (ceftriaxone, cefotaxime, or penicillin G) may be recommended for patients with cutaneous manifestations that are accompanied by neurologic disease (meningitis, encephalopathy) or high degree heart block. Intravenous antibiotics are also sometimes used for patients with refractory ACA or arthritis.

Treatment of patients with nonspecific fibromyalgia-like disease after infection with *B. burgdorferi* is controversial. There are no controlled trials supporting the use of long-term antibiotic therapy.[139]

PREVENTION

Prompt removal of the tick is the most effective measure in preventing disease, as the tick must usually be attached for 24–48 hours for transmission to occur. For adult or nymphal *I. scapularis* ticks that have attached for longer than 36 hours within an endemic area, a single 200-mg dose of doxycycline within 72 hours of tick removal is 87% effective in preventing early cutaneous manifestations.[135,140]

TABLE 187-2
Treatment of Lyme Disease

Presentation[a]			Treatment (Alternate)	Treatment Length (Days)	Comments
Early Lyme disease	Skin	Erythema migrans	A (B)	14 (14–21)	Can consider treating for 10 days if using doxycycline
		Lymphocytoma	A (B)	14 (14–21)	
	Cardiac	First and second degree AV block	A (B)	14 (14–21)	Consider IV antibiotics, temporary pacemaker if symptomatic
		Third degree AV block	C (D)	14 (14–21)	Consider temporary pacemaker
	Neurological	Cranial nerve palsy	A (B, C)	14 (14–21)	Consider lumbar puncture to exclude central nervous system involvement
		Meningitis	C (D)	14 (14–28)	
		Radiculopathy	C[b] (D)	14 (14–28)	Response to treatment usually is slow and may be incomplete; do not repeat antibiotics unless objective relapse
Late Lyme disease	Skin	Acrodermatitis	A (B)	21 (14–28)	If persistent or recurrent joint swelling, repeat 28-day course of oral antibiotics or 14–28-day course of IV ceftriaxone. If arthritis persists despite two courses of antibiotics: nonsteroidal antiinflammatory drugs, disease-modifying antirheumatic drugs, arthroscopic synovectomy
	Rheumatological	Arthritis	A (B, C/D)	28	
	Neuro	Encephalopathy	C (D)	28 (14–60)	Use 14–28 days initially. If no improvement, may consider a second course of similar duration
		Radiculopathy	C (D)	14 (14–28)	

Treatment (doses need to be adjusted in children):
A: First-line oral: Doxycycline[c] (100 mg PO bid), or Amoxicillin[d] (500 mg PO tid), or Cefuroxime (500 mg PO bid)
B: Alternative oral[e]: Azithromycin (500 mg PO qd), or Erythromycin (500 mg PO qid), or Clarithromycin (500 mg PO bid)
C: First-line parenteral: Ceftriaxone (2 g IV qd)
D: Alternative parenteral: Penicillin G (18–24 M units/day divided into doses given q4h),[f] or Cefotaxime (2 g IV q8h), or Doxycyline (200–400 mg/day IV in two divided doses)

[a]If several manifestations of Lyme disease are present, the route (PO or IV) and length of therapy should be as for the manifestation with the longest and most aggressive (e.g., IV >PO) recommendation.
[b]According to some small studies, oral doxycycline has been found to be effective.
[c]Also effective against *Anaplasma phagocytophilum*, the agent of human granulocytic ehrlichiosis. Relatively contraindicated during pregnancy or lactation and for children younger than 8 years.
[d]Preferred choice in children and pregnant women.
[e]Reserved for patients who are intolerant of first-line agents.
[f]Assuming normal renal function.

In 2002, the only FDA-approved Lyme disease vaccine for humans, a recombinant form of OspA, was withdrawn by the manufacturer despite an 80% efficacy in preventing Lyme disease in North America.[141,142] Withdrawal of the vaccine was related to concerns linking the emergence of autoimmune arthritis with host immune responses to OspA.[143] Recently, trials of an OspA vaccine lacking the epitope thought to be linked to autoimmune arthritis have begun in Europe.[144]

Available preventive measures in Lyme disease endemic areas include use of repellents, such as DEET or picaridin, or permethrin treatment of clothing; routine checks for ticks; and landscaping practices to create an inhospitable environment for ticks (removing brush and leaf litter, creating buffer zones of wood chips or gravel between forest and lawn, and application of pesticides to yards). Novel approaches under investigation include biologic agents (fungi) to kill the ticks, the use of devices to target acaricides to rodents and deer without harming them, the development of vaccines to eradicate disease in the wild reservoirs and vaccinations to prevent tick feeding. The control of infection on a larger scale by the eradication of deer or widespread use of acaricides have had limited public acceptance.[1,145]

Fungal Diseases

Chapter 188 :: Superficial Fungal Infection

:: Stefan M. Schieke & Amit Garg

SUPERFICIAL FUNGAL INFECTIONS AT A GLANCE

- Dermatophyte species are contained in three genera: *Epidermophyton*, *Microsporum*, and *Trichophyton*. They are divided further according to three natural habitats (humans, animals, and soil).
- Dermatophytes infect keratinized tissue including skin, hair, and nails.
- Microscopic examination, culture, Wood's light evaluation and histopathology may all be useful in confirming a dermatophytosis.
- *Trichophyton* is the most common species isolated in the US.
- Several topical preparations (imidazoles and allylamine) and oral agents (griseofulvin, itraconazole, fluconazole, and terbinafine) serve as effective antifungal therapeutic options for dermatophytoses.
- Tinea nigra is a superficial dermatophyte infection that may mimic acral lentiginous melanoma.
- Piedra, which consists of white and black forms, is an asymptomatic superficial fungal infection of the hair shaft.

MYCOSES

Mycoses are divided among three forms: (1) *superficial*, involving stratum corneum, hair, nails, (2) *subcutaneous*, involving dermis and/or subcutaneous tissue, and (3) *deep/systemic*, representing hematogenous spread of organisms including opportunistic pathogens in immunocompromised hosts. The focus of this chapter is the superficial mycoses and their patterns of integumentary infections (Table 188-1). A glossary of terms used in this chapter is contained in Table 188-2.

TABLE 188-1
Patterns of Integumentary Infections by Superficial Mycoses

Genera	Skin	Hair	Nails
Trichophyton	×	×	×
Microsporum	×	×	
Epidermophyton	×		×
Tinea Nigra	×		
Black Piedra		×	
White Piedra		×	

TABLE 188-2
A Glossary of Terms

Anthropophilic—preferring humans over other animals as natural habitat

Arthroconidia—asexual spore produced by segmentation of hyphae

Dematiaceous—melanin in the cell walls of its conidia, hyphae, or both results in a darkly colored fungus

Ectothrix—dermatophyte growth pattern with spores forming a sheath on the outside of the hair shaft

Endothrix—dermatophyte growth pattern with spore formation within the hair shaft

Favus—dermatophyte growth pattern with hyphae and air spaces within the hair shaft

Geophilic—preferring the soil over humans and animals as natural habitat

Hyphae—long, filamentous fungus cells forming a branching network called mycelium

Macroconidia—asexual large multinucleate spores produced by vegetative reproduction

Microconidia—asexual small spores produced by vegetative reproduction

Zoophilic—preferring animals over humans as natural habitat

DERMATOPHYTES

The universe of fungi comprises more than 1.5 million species worldwide. Dermatophytes (term derived from the Greek words for "skin plant") are contained in the family of arthrodermataceae and are represented by approximately 40 species divided among the three genera: *Epidermophyton*, *Microsporum*, and *Trichophyton*. In the United States, *Trichophyton* species, and namely *T. rubrum* and *T. interdigitale*, represent the most common species isolated. Dermatophytes are classified further according to their natural habitats—humans, animals, or soil. Their ability to attach to and invade keratinized tissue of animals and humans and to utilize degradation products as nutritional sources form the molecular basis for superficial fungal infections of skin, hair, and nails, termed *dermatophytoses*.[1]

TAXONOMY AND EPIDEMIOLOGY

Recent modifications to the taxonomical system of dermatophytes affecting clinical practice require mention. While previous taxonomy was based largely on phenotypical characteristics of dermatophytes, recent inclusion of genotypical analyses necessitated regrouping of some taxa since many of these genotypical differences were not reflected phenotypically, and *vice versa*.[2] Current taxonomy includes a synthesis of new data based on sequencing of variable genomic regions such as the internal transcribed spacer (ITS) regions of fungal ribosomal DNA as well as classic phenotypical characterizations. The difficulty in devising such a taxonomical system for dermatophytes relates to reduced genetic diversity due to recent speciation and population of the same ecological niches. Phenotypically, this is reflected by similar clinical manifestations being caused by multiple taxonomically different dermatophyte species. It should be noted, however, that the current framework is still a work in progress, and the taxonomy will likely undergo further refinements in the future. Table 188-3 lists the most commonly encountered dermatophyte pathogens including the new taxonomy according to their natural habitats and reservoirs. The current medical literature on dermatophytes and infections, however, does not stringently follow the new taxonomy.

TABLE 188-3
Habitats and Hosts of Common Dermatophytes

Habitat	Dermatophyte	Host
Anthropophilic	*Trichophyton rubrum*	Humans
	Trichophyton tonsurans	
	Trichophyton interdigitale (syn: Trichophyton mentagrophytes var. interdigitale)	
	Trichophyton schoenleinii	
	T. rubrum (syn: Trichophyton megninii, Trichophyton gourvilii)	
	Trichophyton soudanense	
	Trichophyton violaceum (syn: Trichophyton yaoundei)	
	Trichophyton concentricum	
	Microsporum audouinii	
	Microsporum ferrugineum	
	Epidermophyton floccosum	
Zoophilic	*T. mentagrophytes (syn: T. mentagrophytes var. quinckeanum)*	Rodents
	T. interdigitale (syn: T. mentagrophytes var. mentagrophytes, T. mentagrophytes var. granulosum)	Rodents
	Trichophyton erinacei	Hedgehogs
	Trichophyton simii	Primates
	Trichophyton verrucosum	Cattle
	Microsporum canis (syn: Microsporum distortum, Microsporum equinum)	Cats, dogs, horses
	Microsporum amazonicum	Rodents
	Microsporum gallinae	Poultry
	Microsporum nanum	Pigs
	Microsporum persicolor	Rodents
Geophilic	*Microsporum gypseum*	Soil
	Microsporum cookie	
	Microsporum persicolor	
	Trichophyton vanbreuseghemii	
	Trichophyton eboreum	
	Trichophyton terrestre	

In order to avoid confusion over the dynamic status of the taxonomy as well as to remain reflective of the current nomenclature in the literature, this chapter will use both nomenclatures, resulting in some apparent contradictions. The authors hope that a more unified nomenclature is accepted for future editions of this chapter.

The additional classification of superficial fungi according to natural habitat is clinically relevant, since anthropophilic, zoophilic, and geophilic dermatophytoses provide important information about the source of infection and demonstrate varied clinical features.

ANTHROPOPHILIC. species are typically restricted to human hosts and are transmitted via direct contact. Infected skin or hair retained in clothing, combs, caps, socks, and towels, for example, also serve as source reservoirs. Unlike the sporadic geophilic and zoophilic infections, anthropophilic infections are often epidemic in nature. These dermatophytes have adapted to humans as hosts and as such elicit a mild to noninflammatory host response.

ZOOPHILIC. species are transmitted to humans from animals. Cats, dogs, rabbits, guinea pigs, birds, horses, cattle and other animals are common sources of infection. Transmission may occur through direct contact with the animal itself, or indirectly via infected animal hair. Exposed areas such as the scalp, beard, face, and arms are favored sites of infection. *Microsporum canis* is often transmitted to humans from cats and dogs, while guinea pigs and rabbits are a frequent source of human infection with zoophilic strains of *T. interdigitale.* While host adaptation by zoophilic dermatophytes may lead to relatively silent infections, these dermatophytes tend to produce acute and intense inflammatory responses in humans.[1]

GEOPHILIC. fungi cause sporadic human infection upon direct contact with the soil. *Microsporum gypseum* is the most common geophilic dermatophyte cultured from humans. There is a potential for epidemic spread due to the higher virulence of geophilic strains as well as an ability to form long-lived spores that may reside in blankets or grooming tools. As with zoophilic infections, geophilic dermatophytes typically result in intense inflammatory responses.[3]

Clinical presentations of dermatophytoses depend not only on the source, but also on host factors. Immunocompromised individuals are more susceptible to refractory dermatophyte infections or to deep mycoses.[4,5] Interestingly, only the severity of dermatophytosis appears to be increased with HIV infection, and not the prevalence.[6] Other host factors such as age, sex, and race appear to be additional epidemiologic factors for infection, although their relationship to dermatophyte susceptibility remains unclear. As an example, dermatophyte infections are five times more prevalent in males than females.

Superficial fungal infections are a worldwide problem that affects more than 20%–25% of the population.[7] Some species demonstrate ubiquitous distribution whereas others are geographically limited. Accordingly, predominant species reflect considerable geographic differences, as in the case of tinea capitis. In the United States, *Trichophyton tonsurans* has replaced *Microsporum audouinii* as the most common cause of tinea capitis in the second half of the 20th century, and *M. canis* has now become the second most common cause.[8] In Europe, *M. canis* remains the most common cause of tinea capitis despite a significantly increased incidence of *T. tonsurans*.[9] The etiologic profile is quite different in Africa where *M. audouinii*, *Trichophyton soudanense*, and *Trichophyton violaceum* are the most prevalent pathogens.[10] However, human travel and migration results in dynamic patterns of infection. As an example, *T. soudanense* and *T. violaceum*, typically restricted to Africa, were isolated in US cases of tinea capitis in 2007.[11] Finally, local customs may also influence rates and patterns of dermatophytoses. The use of macerating occlusive footwear, for example, in industrialized nations has made tinea pedis and onychomycosis much more common in these regions.[6]

PATHOGENESIS

Dermatophytes exhibit a broad armamentarium of enzymes (keratinolytic proteases, lipases etc.) that act as virulence factors to allow adherence and invasion of skin, hair, and nails, and also to utilize keratin as a source of nutrients for survival. The initial steps in dermatophyte infections are adherence to keratin followed by invasion and growth of mycelial elements. As a consequence of keratin degradation and subsequent release of proinflammatory mediators, the host develops an inflammatory response of varying degree. The classic "ringworm," or annular morphology of tinea corporis results from an inflammatory host response against a spreading dermatophyte followed by a reduction or clearance of fungal elements from within the plaque, and in many cases by spontaneous resolution of the infection.

ADHERENCE. Dermatophytes overcome several lines of host defense before hyphae begin to thrive in keratinized tissues. The first step is successful adherence of arthroconidia, asexual spores formed by fragmentation of hyphae, to the surface of keratinized tissues.[12] Early nonspecific lines of host defense include fungistatic fatty acids in sebum as well competing bacterial colonization.[13,14] Several recent studies have focused on the molecular steps involved in arthroconidial adherence to keratinized surfaces. Dermatophytes have been shown make selective use of their proteolytic armamentarium during adherence and invasion.[15,16] The basis for this highly concerted attack may be explained partially by specific upregulation of multiple genes induced by contact with keratin, as has been shown by differential gene expression analysis in *T. rubrum.*[17] Following several hours of successful adherence, the spores begin to germinate in preparation for the next step in the infective chain of events, invasion.

INVASION. Trauma and maceration facilitate penetration of dermatophytes through the skin. Invasion of germinating fungal elements is further accomplished

through secretion of specific proteases, lipases and ceramidases, the digestive products of which also serve as fungal nutrients.[18] Interestingly mannans, which are components of the fungal cell wall, show inhibitory effects on keratinocyte proliferation and cell-mediated immunity.[19,20]

HOST RESPONSE. Dermatophytes encounter a range of host responses from several lines of nonspecific mechanisms including fungistatic fatty acids, increased epidermal proliferation, and secretion of inflammatory mediators to cell mediated-immunity. In the line of defense mechanisms, keratinocytes represent the first frontier of living cells to encounter invading fungal elements. The key position of keratinocytes is reflected by their complex response to invasion including proliferation to increase shedding as well as secretion of antimicrobial peptides including human β defensin-2[21] as well as proinflammatory cytokines (IFN-α, TNFα, IL-1β, 8, 16, and 17) that further activate the immune system. Once deeper layers of epidermis are involved, new nonspecific defenses such as competition for iron by unsaturated transferrin emerge. The degree of host inflammatory reaction depends on the host's immune status as well as the natural habitat of the dermatophyte species involved. Interestingly, anthropophilic dermatophytes induce secretion of a limited cytokine profile from keratinocytes in vitro compared to zoophilic species.[22,23] This difference may reflect the augmented inflammatory response generally observed with zoophilic species.

The next level of defense is cell-mediated immunity resulting in a specific delayed type hypersensitivity response against invading fungi. The inflammatory response associated with this hypersensitivity is associated with clinical resolution, while defective cell-mediated immunity may result in chronic or recurrent dermatophytoses. The Th2 response does not appear to be protective, since patients with elevated fungal antigen antibody titers are observed to have widespread dermatophyte infections.[24] A possible role for the Th17 response to dermatophyte infections is suggested by the recent discovery of binding of hyphal elements to Dectin-2, a C-type lectin pattern recognition receptor on dendritic cells, critical for inducing Th17 responses.[25,26] However, the relative importance of the Th17 immune response to dermatophytosis remains to be elucidated.

GENETICS

Despite epidemiological observations suggesting a genetic predisposition to fungal infections, molecular insight confirming this hypothesis has been lacking. Recently, however, two families with increased susceptibility to fungal infections and mutations in the C-type lectin fungal pattern recognition pathway have been described. In addition, mutations in CARD9, an adaptor molecule downstream of Dectin-1 and Dectin-2, which result in failure of Th17 activation, were associated with susceptibility to chronic mucocutaneous candidiasis along with chronic dermatophyte infections.[27]

DIAGNOSTIC PROCEDURES

(Table 188-4)

The clinical diagnosis of a dermatophyte infection can be confirmed by microscopic detection of fungal elements, by identification of the species through culture, or by histologic evidence of the presence of hyphae in the stratum corneum. In addition, fluorescence patterns under Wood's light examination may support a clinical suspicion.

MICROSCOPIC EXAMINATION

Although microscopic evaluation of potassium hydroxide (KOH)-treated samples of scale does not allow for speciation or characterization of the susceptibility profile, it is used (or underused) as a quick and inexpensive bedside tool to provide evidence of dermatophytosis. In dermatophytosis involving the skin, hair or nails, septate and branching hyphae without constriction (Fig. 188-1) may be visualized under microscopic examination with 10%–20% KOH preparation. All superficial dermatophytes appear identical when visualized in this manner. Because KOH examination may yield false-negative results in up to 15% of cases,[28] patients suspected of having dermatophytosis on clinical impression should be treated. Culture confirmation should be considered whenever systemic treatment is warranted, such as in the case of tinea capitis.

Scale from skin should be collected by scraping the involved area with a dull edge outward from the advancing margins. Full thickness nail clippings should involve the dystrophic portion, as proximal from the distal edge as possible without causing injury. Hairs should be plucked (not cut), placed on a glass slide and prepared with 10%–20% KOH and covered with a coverslip. Slightly warming the slide with a low intensity flame allows better penetration of the KOH solution into keratin. Low-power microscopy will reveal three possible patterns of infection (Fig. 188-2): (1) Ectothrix—small or large arthroconidia forming a sheath around the hair shaft, (2) Endothrix—arthroconidia within the

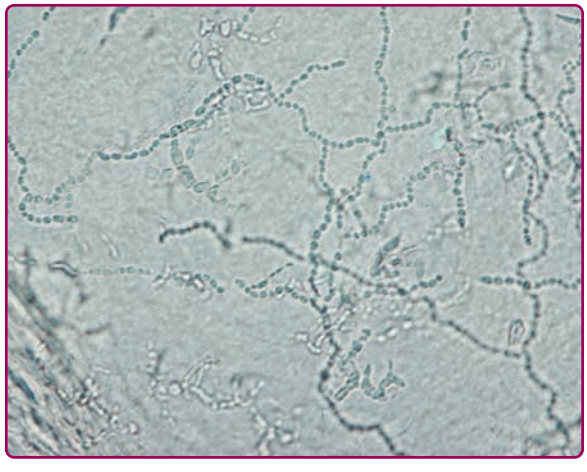

Figure 188-1 Microscopic examination of skin scrapings (scales) revealing septate, branching hyphae.

TABLE 188-4
Common Laboratory Dermatophyte Identification Methods

Laboratory Test	Method	Function	Findings
Potassium hydroxide preparation	Scales from the advancing border, subungual debris, or affected hair removed and placed on a glass slide. KOH 10% dropped on specimen and covered with a cover slip. The undersurface of the glass slide may be gently heated with a low-lit flame.	KOH solution and gentle heating softens keratin and highlights the dermatophyte.	Long narrow septated and branching hyphae
Culture	Sabouraud medium (4% peptone, 1% glucose, agar, water)	Facilitates growth of dermatophytes	Microscopic morphology of microconidia and macroconidia, along with culture features including surface topography and pigmentation. The reader is referred to http://www.mycology.adelaide.edu.au/ for a comprehensive characterization of fungal colonies. Common colonies are characterized in Table 188-5.
	Modified Sabouraud medium (addition of chloramphenicol, cycloheximide, and gentamicin)	Facilitates growth of dermatophytes and inhibits growth of non-*Candida albicans*, *Cryptococcus*, *Prototheca* species, *P. werneckii*, *Scytalidium* species, *Ochroconis gallopava*	
Dermatophyte test medium	Scales from the advancing border, subungual debris or affected hair embedded in the medium.	Medium contains the pH indicator phenol red. Dermatophytes utilize proteins resulting in excess ammonium ion and an alkaline environment.	Incubation at room temperature for 5–14 days results in change in color of medium from yellow to bright red in the presence of a dermatophyte.
Histolopathology special stains: periodic acid-Schiff and Grocott's methenamine silver	Tissue may be obtained by skin or nail biopsy techniques	Stains fungal cell wall to detect fungal elements in tissue sections	Pink (PAS) or black (GMS) fungal elements noted in the stratum corneum

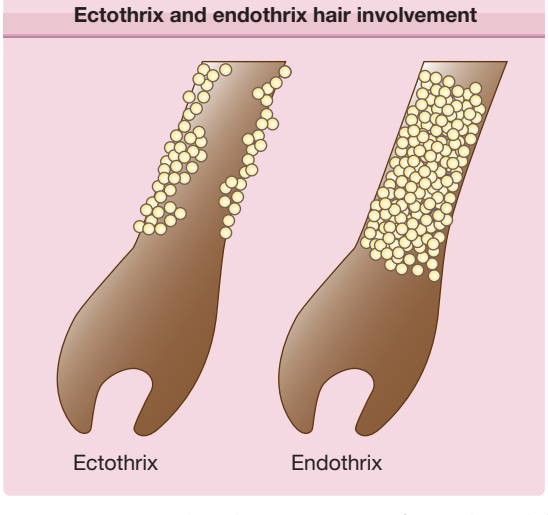

Figure 188-2 Graphic demonstration of ectothrix (*left*) and endothrix hair involvement.

hair shaft, or (3) Favus—hyphae and air spaces within the hair shaft.

CULTURE

Speciation of superficial fungi is based on macroscopic, microscopic and metabolic characteristics of the organism. While some dermatophytes are readily identified on the basis of their primary isolation cultures, most require further differentiation through subcultures on specific media (identification culture) or through specific biochemical tests.

Sabouraud's dextrose agar (SDA) is the most commonly used isolation medium for dermatophytes and it serves as the medium on which most morphologic descriptions are based. Elimination of contaminant molds, yeast and bacteria is achieved by the addition of cycloheximide and chloramphenicol (+/−gentamicin) to the medium making it highly selective for the

isolation of dermatophytes. The development of colonies can take 5–7 days in the case of *Epidermophyton floccosum* and up to 4 weeks for *Trichophyton verrucosum*. Cultures are incubated at room temperature (20°C–25°C) for at least 4 weeks before being finalized as no growth. Dermatophyte test medium (DTM) is an alternative isolation medium that contains the pH indicator phenol red. The medium turns red when dermatophyte proteolytic activity increases the pH to 8 or above, and it remains amber with the growth of most saprophytes. Nondermatophyte acidic byproducts turn the medium yellow. While DTM serves as a good alternative for isolation of dermatophytes, it may not allow for their direct identification due to altered growth and thus morphology of dermatophytes in DTM. Table 188-5 describes general microscopic features of microconidia and macroconidia of the three genera of dermatophytes, while Table 188-6 describes

TABLE 188-5
Microscopic Features of Dermatophyte Microconidia and Macroconidia

Genera	Microconidia	Macroconidia
Trichophyton	Smooth walled. Used for identification.	Absent or nondiagnostic.
Microsporum	Absent or nondiagnostic.	Rough walled. Used for identification.
Epidermophyton	Absent.	Smooth walled. Used for identification.

TABLE 188-6
Colony and Microscopic Morphology Features of the Most Common Dermatophytes

Organism	Colony Morphology		Microscopic Appearance
Epidermophyton floccosum 	Flat feathery colonies with a central fold and yellow to dull gray–green pigment. Yellow to brown reverse pigment.		Numerous thin and thick-walled, club-shaped macroconidia.
Microsporum audouinii 	Flat and white to gray with widely spaced radial grooves. Tan to salmon reverse pigment. Salmon-pink pigment on PDA. No growth on polished rice.		Terminal chlamydoconidia and pectinate (comb-like) hyphae.
Microsporum canis 	Flat, white to light yellow, coarsely hairy, with closely spaced radial grooves. Yellow to orange reverse pigment. Yellow on PDA. Growth on polished rice.		Numerous thick walled and echinulate spindle shaped macroconidia with terminal knobs and greater than 6 cells.
Microsporum gypseum 	Flat and granular with tan to buff pigment, no reverse pigment.		Numerous thin-walled pickle shaped macroconidia without knobs and fewer than 6 cells.

TABLE 188-6
Colony and Microscopic Morphology Features of the Most Common Dermatophytes (Continued)

Organism	Colony Morphology		Microscopic Appearance
Ticrosporum interdigitale 	White to creamy with a cottony, mounded surface. None to light brown reverse pigment. No pigment on PDA. Urease positive, which helps to distinguish it from *T. rubrum*.		Grape-like clusters of round microconidia, rare cigar-shaped macroconidia, occasional spiral hyphae. Hair perforation positive, which helps to distinguish it from *T. rubrum*.
Ticrosporum rubrum 	Mounded white center with maroon periphery. Maroon reverse pigment. Cherry red on PDA. Urease negative.		Few tear-shaped microconidia, rare pencil-shaped macroconidia. Hair perforation negative.
Ticrosporum schoenleinii 	Heaped or folded and whitish. Colorless to yellow-tan reverse pigment.		Knobby antler-like hyphae (favic chandeliers), numerous chlamydoconidia.
Ticrosporum tonsurans 	Suede-like center with feathery periphery, white to yellow or maroon color. Reverse pigment usually dark maroon, sometimes none to yellow. Partial thiamine requirement.		Numerous multiform microconidia and rare cigar-shaped macroconidia.
Ticrosporum verrucosum 	Small and heaped, although sometimes flat, white to yellow–gray. Reverse pigment none to yellow. Requires thiamine and usually inositol for growth.		Chains of chlamydoconidia on SDA. Long and thin "rat-tail" macroconidia with thiamine.
Ticrosporum violaceum 	Waxy and heaped, deep purplish-red. Purple reverse pigment. Partial thiamine requirement.		Irregular hyphae with intercalary chlamydoconidia. No micro- or macroconidia on SDA, rare micro- and macroconidia with thiamine.

PDA = potato dextrose agar; SDA = Sabouraud's dextrose agar.

colony and microscopic features of the most common dermatophyte species.

Identification of isolated fungi is facilitated by subculture on specific media such as potato dextrose agar (PDA) or Borelli's lactrimel agar (BLA) that stimulate sporulation, production of pigment and development of typical morphology. Finally, dermatophytes may be differentiated further by their ability to grow on autoclaved polished rice, perforate short strands of hair in vitro or hydrolyze urea (urease test), or require nutritional supplementation for growth (Table 188-7).

HISTOPATHOLOGY

Skin biopsy is not often employed in the workup of typical dermatophytoses. Localized cutaneous eruptions suspected to represent dermatophytosis with equivocal KOH examination are often treated despite the lack of confirmation. Biopsy may confirm the diagnosis when a systemic agent is being considered for treatment of a recalcitrant or more widespread eruption. Biopsy may be used to aid in the diagnosis of Majocchi's granuloma in which KOH examination of scale on the surface may more often be negative. Biopsy is also sometimes useful in confirming the presence of hyphae involving hair shafts on the scalp in tinea capitis, although culture is necessary to allow speciation of the pathogen. When present, hyphae may be appreciated in the stratum corneum on hematoxylin and eosin staining. However special stains, most commonly periodic acid-Schiff (PAS) and methenamine silver stains, highlight hyphae that may otherwise be subtle in appearance on routine staining. Whereas culture is the most specific test for onychomycosis, PAS examination of nail clippings is the most sensitive[29] and it obviates the need to wait weeks for a result.

WOOD'S LIGHT FLUORESCENCE

Examination of involved hair bearing areas, such as the scalp or beard, with a Wood's lamp (365 nm) may reveal pteridine fluorescence of hair infected with particular fungal pathogens. Hairs that fluoresce should be selected for further examination, including culture. While ectothrix organisms *M. canis* and *M. audouinii* will fluoresce on Wood's light examination, the endothrix organism *T. tonsurans* will not fluoresce. *T. tonsurans*, which is now the most common cause of tinea capitis in the United States, thus limits the use of Wood's light examination. Table 188-8 lists common patterns of dermatophyte hair involvement and fluorescence.

DERMATOPHYTOSES

TINEA CAPITIS

Tinea capitis describes dermatophyte infection of hair and scalp, typically caused by *Trichophyton* and *Microsporum* species, with exception of *Trichophyton concentricum*.

EPIDEMIOLOGY. Tinea capitis is most commonly observed in children between 3 and 14 years of age. The fungistatic effect of fatty acids in sebum may help to explain the sharp decrease in incidence after puberty.[30] Overall prevalence of the carrier state is around 4% in the United States with a peak prevalence of approximately 13% in girls of Sub-Saharan African American descent.[31] In general, tinea capitis is more common among children of African descent for unknown reasons. Transmission is increased with decreased personal hygiene, overcrowding and low socioeconomic status. The anthropophilic dermatophyte *T. tonsurans* is the most prevalent species found in the United States, while *M. canis* remains the

most common cause of tinea capitis in Europe.[32] Organisms responsible for tinea capitis have been cultured from fomites such as combs, caps, pillowcases, toys and theater seats. Even after shedding, hairs may harbor infectious organisms for more than 1 year.[33] The high prevalence of asymptomatic carriers thwarts eradication of the disease.

PATHOGENESIS. Infection of hair by dermatophytes follows 3 main patterns—ectothrix, endothrix and favus. Dermatophytes establish infection in the perifollicular stratum corneum and spread around and into the hair shaft of mid- to late-anagen hairs before descending into the follicle to penetrate the cortex. With hair growth, the infected part of the hair rises above the surface of the scalp where it may break because of its increased fragility.

In *ectothrix* infections (see Fig. 188-2), only the arthroconidia on the surface of the hair shaft may be visualized, although hyphae are also present within the hair shaft. The cuticle is destroyed. On Wood's lamp examination, a yellow–green fluorescence may be detected, depending on the causative organism. In *endothrix* infections (see Fig. 188-2), arthroconidia and hyphae remain within the hair shaft and leave the cortex and cuticle intact. This pattern of tinea capitis is associated with the appearance of "black dots" which represent broken hairs at the surface of the scalp. *Endothrix* organisms do not show fluorescence on Woods lamp exam. *Favus* is characterized by longitudinally arranged hyphae and air spaces within the hair shaft. Arthroconidia are not usually noted in infected hairs.

CLINICAL FINDINGS. (Table 188-9). The clinical appearance of tinea capitis depends on the causative species as well as other factors such as the host immune response. In general, dermatophyte infection of the scalp results in hair loss, scaling and varying degrees of an inflammatory response.

TABLE 188-9
Pathogens Associated with Clinical Types of Tinea Capitis

Inflammatory	*Microsporum audouinii* *Microsporum canis* *Microsporum gypseum* *Microsporum nanum* *Trichophyton interdigitale* *Trichophyton schoenleinii* *Trichophyton tonsurans* *Trichophyton verrucosum*
Noninflammatory	*M. audouinii* *M. canis* *Microsporum ferrugineum* *T. tonsurans*
Black dot	*T. tonsurans* *T. violaceum*
Favus	*T. schoenleinii* *Trichophyton violaceum* *Trichophyton mentagrophytes*

Note: A single dermatophyte may have more than one presentation.

Figure 188-3 Tinea capitis "gray patch" type. A large, round hyperkeratotic plaque of alopecia due to breaking off of hair shafts close to the surface, giving the appearance of a mowed wheat field on the scalp of a child. Remaining hair shafts and scales exhibit a green fluorescence when examined with a Wood's lamp. *Microsporum canis* was isolated on culture.

Noninflammatory Type. Also called the seborrheic form of tinea capitis since scale is the predominant feature,[34] noninflammatory tinea capitis is seen most commonly with anthropophilic organisms such as *M. audouinii* or *Microsporum ferrugineum.* Arthroconidia may form a sheath around affected hairs turning them gray and causing them to break off just above the level of the scalp. Alopecia may be imperceptible or in more inflammatory cases there may be circumscribed erythematous scaly patches of nonscarring alopecia with breakage of hairs ("gray patch" type; Fig. 188-3). Patches often occur on the occiput.[33] When involving an ectothrix pattern, infected hairs may exhibit green fluorescence under Wood's light (see Table 188-8).

"Black Dot" Tinea Capitis. (Fig. 188-4). The "black dot" form of tinea capitis is typically caused by the anthropophilic endothrix organisms *T. tonsurans* and *T. violaceum*. Hairs broken off at the level of the scalp leave behind grouped black dots within patches of polygonal shaped alopecia with finger-like margins. Normal hairs also remain within patches of broken hairs. Diffuse scaling is also often present. While "black dot" tinea capitis tends to be minimally inflammatory, some patients may develop follicular pustules, furuncle-like nodules, or in rare cases kerion—a boggy, inflammatory mass studded with broken hairs and follicular orifices oozing with pus.[35]

Inflammatory Type. Zoophilic or geophilic pathogens, such as *M. canis*, *M. gypseum*, and *T. verrucosum*, are more like to cause an inflammatory type of tinea capitis. Inflammation, which is the result of a hypersensitivity reaction to the infection, in this setting ranges

Figure 188-4 "Black dot" tinea capitis caused by *Trichophyton tonsurans*.

from follicular pustules to furunculosis (Fig. 188-5) or kerion (Fig. 188-6). Intense inflammation may also result in scarring alopecia. The scalp is usually pruritic or tender. Inflammatory tinea capitis is often associated with posterior cervical lymphadenopathy, which serves as a clinical pearl in differentiating tinea capitis from other inflammatory disorders involving the scalp.

DIFFERENTIAL DIAGNOSIS. (Box 188-1)

LABORATORY TESTS. (See Tables 188-4, 188-6)

HISTOPATHOLOGY. (See Table 188-4). In tinea capitis, PAS and methenamine silver stains readily reveal hyphae around and within hair shafts. The dermis demonstrates a perifollicular mixed cell infiltrate with lymphocytes, histiocytes, plasma cells, and eosinophils. Follicular disruption leads to an adjacent foreign-body giant cell reaction. Markedly inflammatory lesions such as a kerion demonstrate an acute infiltrate of polymorphonuclear leukocytes within the dermis and follicle.[36] Organisms may not be visualized in kerion since the intense host response destroys many of the fungal organisms. However, fungal antigens may be detectable with immunofluorescent techniques.[37]

Figure 188-5 Inflammatory tinea capitis caused by *Microsporum canis*. Along with alopecia, there are inflammatory papules, pustules and nodules. This patient also had posterior cervical lymphadenopathy.

Figure 188-6 Kerion of the scalp.

TINEA FAVOSA

Tinea favosa or favus (Latin, "honeycomb") is a chronic dermatophyte infection of the scalp rarely involving glabrous skin, and/or nails characterized by thick yellow crusts (scutula) within the hair follicles which leads to scarring alopecia.

EPIDEMIOLOGY. Favus is usually acquired before adolescence, although it may extend into adulthood.[38] Associated with malnutrition and poor hygiene, favus has become geographically limited over the past century, and it is now seen almost exclusively in Africa, the Middle East and parts of South America. Even in these regions, its incidence has declined dramatically, and studies from South Africa, Lybia, and Arabia suggest disappearance of favus over the last few decades.[39–41]

ETIOLOGY. *Trichophyton schoenleinii* is the most common cause of human favus, although *T. violaceum* and *M. gypseum* are also rare isolates.[42] Although favus occurs in animals including domesticated birds (*Microsporum gallinae*) and mice (*Trichophyton mentagrophytes* formerly *T. mentagrophytes var. quinckeanum*), there exist only a few reports of humans infected by the pathogens responsible for animal favus.[43]

CLINICAL FINDINGS. Early favus (first 3 weeks of infection) is characterized by patchy perifollicular

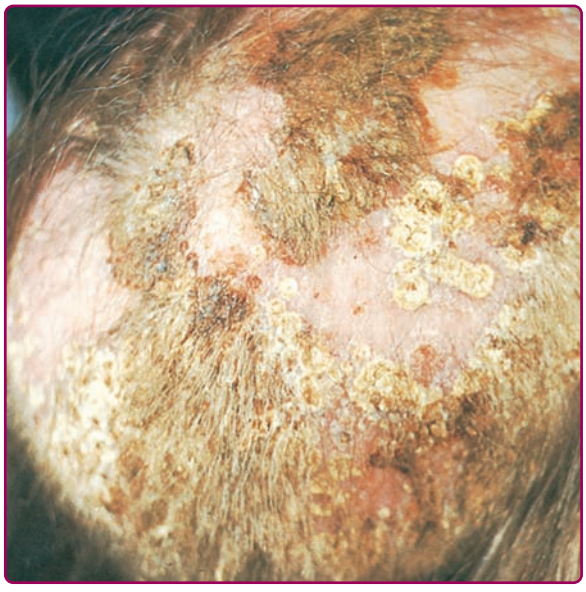

Figure 188-7 Favus caused by *Trichophyton schoenleinii*. Note the numerous yellow scutula.

erythema with slight scaling and matting of the hair. Progressive hyphal invasion distends the follicle, first producing a yellow–red follicular papule and then a yellow concave crust (scutulum) around a single dry hair (Fig. 188-7) that is less brittle than hair of endothrix infections. The scutulum may reach 1 cm in diameter, engulfing surrounding hairs and coalescing with other scutula to form large adherent mats with an unpleasant cheese-like or musky odor. Over several years, the plaques advance peripherally leaving behind central, atrophic areas of alopecia.[42]

DIFFERENTIAL DIAGNOSIS. (Box 188-1)

LABORATORY TESTS. (See Tables 188-4, 188-6).

T. schoenleinii exhibits subtle, blue–gray fluorescence along the entire hair with Wood's lamp examination. Microscopy with KOH preparation reveals hyphae arranged lengthwise around and within the hair shaft, rare arthroconidia, and vacant air spaces.[42]

BOX 188-1 DIFFERENTIAL DIAGNOSIS OF TINEA CAPITIS

Most Likely

- Seborrheic dermatitis, contact dermatitis, pustular or plaque psoriasis, atopic dermatitis, bacterial pyodermas, folliculitis decalvans, lichen planopilaris, and dissecting cellulitis of the scalp

Consider

- Alopecia areata, trichotillomania, pseudopelade

Rule Out

- Subacute cutaneous lupus erythematosus, syphilis

HISTOPATHOLOGY. (See Table 188-4)

TINEA BARBAE

EPIDEMIOLOGY.

Tinea barbae, as its name would imply, occurs predominantly in males. The incidence of tinea barbae has decreased as improved sanitation has reduced transmission by contaminated barbers' razors. Direct exposure to cattle, horses, or dogs is now the more common mode of acquisition, and this accounts for a shift in prevalence toward farmers or ranchers in rural settings.

ETIOLOGY.

Tinea barbae is most commonly caused by the zoophilic strains of *T. interdigitale* (former *T. mentagrophytes var. mentagrophytes)*, *T. verrucosum*, and less commonly *M. canis*. Among the anthropophilic organisms, *T. schoenleinii*, *T. violaceum* and certain strains of *T. rubrum* (former *T. megninii*), cause tinea barbae in endemic areas.[42]

CLINICAL FINDINGS.

Tinea barbae affects the face unilaterally and involves the beard area more often than the moustache or upper lip. Two forms exist.

Superficial Type. Caused by anthropophiles such as *T. violaceum*, this form of tinea barbae is less inflammatory and resembles tinea corporis or bacterial folliculitis. The active border shows perifollicular papules and pustules accompanied by mild erythema (Fig. 188-8A). Alopecia, if present, is reversible.

Inflammatory Type. Usually caused by *T. interdigitale* (zoophilic strains) or *T. verrucosum*, inflammatory tinea barbae is the most common clinical presentation. It presents analogously to kerion formation in tinea capitis with boggy-crusted plaques and a seropurulent discharge (Fig. 188-8B). Hairs are lusterless, brittle, and easily epilated to demonstrate a purulent mass around the root. Perifollicular pustules may coalesce and eventuate in abscess-like collections of pus, sinus tracts, and scarring alopecia.

DIFFERENTIAL DIAGNOSIS. (Box 188-2)

LABORATORY TESTS. (See Tables 188-4, 188-6)

HISTOPATHOLOGY. (See Table 188-4)

BOX 188-2 DIFFERENTIAL DIAGNOSIS OF TINEA BARBAE

Most Likely

- Bacterial folliculitis (sycosis vulgaris), pseudofolliculitis barbae, acne vulgaris, rosacea, contact dermatitis, perioral dermatitis, candidal folliculitis

Rule Out

- Herpes simplex, halogenoderma

Figure 188-8 Tinea barbae. **A.** Superficial type. Scattered follicular papules, pustules and small nodules that may be easily mistaken for *Staphylococcus aureus* folliculitis. **B.** Kerion type. Sharply demarcated red edematous nodule studded with multiple yellowish weeping pustules. Note hairs have been lost from this nodule.

TINEA CORPORIS

Tinea corporis refers to any dermatophytosis of glabrous skin except palms, soles, and the groin.

EPIDEMIOLOGY. Tinea corporis may be transmitted directly from infected humans or animals, via fomites, or it may occur via autoinoculation from reservoirs of dermatophyte colonization on the feet.[44] Children are more likely to contract zoophilic pathogens, especially *M. canis,* from dogs or cats. Occlusive clothing and a humid climate are associated with more frequent and severe eruptions.[45] Wearing of occlusive clothing, frequent skin-to-skin contact, and minor traumas such as the mat burns competitive wrestling create an environment in which dermatophytes flourish. "Tinea corporis gladiatorum" is caused most commonly by *T. tonsurans*, and it occurs most frequently on the head, neck, and arms.[46]

ETIOLOGY. Although any dermatophyte may cause tinea corporis, it is caused most commonly by *T. rubrum*. *T. rubrum* is also the most likely candidate in cases with concomitant follicular involvement.[35] *Epidermophyton floccosum*, *T. interdigitale* (anthropophilic and zoophilic strains), *M. canis*, and *T. tonsurans* are also common pathogens.[1] Tinea imbricata, caused by *T. concentricum*, is limited geographically to areas of the Far East, South Pacific, and South and Central America.

CLINICAL FINDINGS. The classic presentation is that of an annular ("ring-worm"-like; Fig. 188-9A) or serpiginous plaque with scale across the entire active erythematous border. The border, which may be vesicular, advances centrifugally. The center of the plaque is usually scaly but it may exhibit complete clearing. Whereas concentric vesicular rings suggest tinea incognito, often caused by *T. rubrum*, the erythematous concentric rings of tinea imbricata demonstrate little to no vesiculation. *T. rubrum* infections may also present as large, confluent polycyclic (Fig. 188-9B) or psoriasiform (Fig. 188-9C) plaques, especially in immunosuppressed individuals.

Majocchi's granuloma is a superficial and subcutaneous dermatophytic infection involving deeper portions of the hair follicles that presents as scaly follicular papules and nodules that coalesce in an annular arrangement (Fig. 188-10). It is caused most commonly by *T. rubrum, T. interdigitale,* and *M. canis*. Majocchi's granuloma is observed on the legs in women who become inoculated after shaving or who apply topical corticosteroids to the involved area, which facilitates infection. It is also observed increasingly among immunocompromised patients.[47]

DIFFERENTIAL DIAGNOSIS. (Box 188-3)

LABORATORY TESTS. (See Tables 188-4, 188-6)

HISTOPATHOLOGY. (See Table 188-4)

BOX 188-3 DIFFERENTIAL DIAGNOSIS OF TINEA CORPORIS

Most Likely

- Erythema annulare centrifugum, nummular eczema, psoriasis, tinea versicolor, subacute cutaneous lupus erythematosus, cutaneous candidiasis

Consider

- Contact dermatitis, atopic dermatitis, pityriasis rosea, seborrheic dermatitis

Rule Out

- Mycosis fungoides, parapsoriasis, secondary syphilis

Figure 188-9 Tinea corporis. **A.** Annular. Tinea corporis demonstrating the classic annular or "ring worm" like configuration and advancing raised erythematous and scaly border. Note that because the dorsum of the foot is predominantly involved, this eruption is considered tinea corporis and not pedis. **B.** Polycyclic. Tinea corporis demonstrating multiple polycyclic red erythematous plaques with a raised scaly border. **C.** Psoriasiform. Tinea corporis resembling psoriasis.

TINEA CRURIS

Tinea cruris is a dermatophytosis of the groin, genitalia, pubic area, and perineal and perianal skin. The designation is a misnomer, because in Latin "cruris" means of the leg. It is the second-most common type of dermatophytosis worldwide.

Figure 188-10 Majocchi's granuloma. Follicular papules and nodules with scale coalescing to form an annular shaped plaque on the leg of a woman applying topical corticosteroids to the area.

EPIDEMIOLOGY. Much like tinea corporis, tinea cruris spreads via direct contact or fomites, and it is exacerbated by occlusion and humid climates. Autoinfection from distant reservoirs of *T. rubrum* or *T. interdigitale* on the feet, for example, is common.[44] Tinea cruris is three times more common in men, and adults are affected more commonly than children.

ETIOLOGY. Most tinea cruris is caused by *T. rubrum* and *E. floccosum*, the latter being most often responsible for epidemics.[42] *T. interdigitale* and *T. verrucosum* are implicated less commonly.

CLINICAL FINDINGS. Tinea cruris presents classically as a well-marginated annular plaque with a scaly raised border which extends from the inguinal fold on to the inner thigh, often bilaterally. Erythematous scaly patches with papules and vesicles involving the inner thighs is also a common but perhaps less obvious presentation. Pruritus is common, as is pain when plaques are macerated or secondarily infected. Plaques in tinea cruris due to *E. floccosum* are more likely to demonstrate central clearing, and are more often limited to the genitocrural crease and the medial upper thigh. In contrast, plaques in tinea cruris due to *T. rubrum* coalesce with extension to the pubic, perianal, buttock, and lower abdominal areas (Fig. 188-11). Genitalia including the scrotum are infrequently affected.[42]

Figure 188-11 Tinea cruris. Annular eythematous plaques with a raised scaling border expanding from the inguinal on the inner thighs and pubic region.

DIFFERENTIAL DIAGNOSIS. (Box 188-4)

LABORATORY TESTS. (See Tables 188-4, 188-6)

HISTOPATHOLOGY. (See Table 188-4)

TINEA PEDIS AND TINEA MANUUM

Tinea pedis denotes dermatophytosis of the feet, whereas tinea manuum involves the palmar and interdigital areas of the hands. Infection of the dorsal aspects of feet and hands is considered to be tinea corporis.

EPIDEMIOLOGY. Occurring worldwide, tinea pedis and tinea manuum are the most common dermatophytoses. High prevalence, estimated to be around 10%, is attributed primarily to modern occlusive footwear, although increased worldwide travel has also been implicated.[42] Incidence of tinea pedis is higher among those using communal baths, showers or pools. With the ubiquitous presence of dermatophytes in the environment, however, it may be that host factors such as an individual's immune response to dermatophytes, in addition to exposure, play a determining role in the acquisition of tinea pedis. The authors, however, are not aware of any studies formally addressing this question.

Tinea manuum is acquired through direct contact with an infected person or animal, the soil, or via autoinoculation. Most commonly only one hand (*singular*: tinea manus) is involved, concomitant with infection of feet and toenails for which the term "*two feet–one hand*" syndrome has been coined. This classic presentation of tinea manus represents a secondary infection of the hand acquired from excoriating and picking infected feet and toenails.[48] Tinea manuum should be suspected in individuals who have fine dry scaling of the palm or palms, often accentuated in the creases.

BOX 188-4 DIFFERENTIAL DIAGNOSIS OF TINEA CRURIS

Most Likely

- Erythrasma, cutaneous candidiasis, intertrigo, contact dermatitis, psoriasis, seborrheic dermatitis, lichen simplex chronicus, folliculitis

Consider

- Familial benign pemphigus, Darier-White disease, histiocytosis

ETIOLOGY. Tinea pedis and tinea manuum are caused predominantly by *T. rubrum* (most common), *T. interdigitale*, and *E. floccosum*.

CLINICAL FINDINGS. Tinea pedis may present as any of four forms, or combinations thereof.

Interdigital Type. The most common presentation of tinea pedis begins as scaling, erythema and maceration of the interdigital and subdigital skin of the feet, and in particular between the lateral third and fourth and fourth and fifth toes (Fig. 188-12A).

Figure 188-12 Tinea pedis. **A.** Interdigital type. The inderdigital space is macerated with opaque white scales and has erosions. **B.** Moccasin type. Patchy erythema and scaling in a moccasin distribution on the foot. The arciform pattern of scales is characteristic. **C.** Bullous type. Ruptured bullae, erosions and erythema on the plantar aspect of the great toe. Hyphae were detected on KOH 10% preparation obtained from epithelial cell on the roof of the inner aspect of the bulla.

Under appropriate conditions, the infection will spread to the adjacent sole or instep, but it rarely involves the dorsum. Occlusion and bacterial coinfection (*Pseudomonas*, *Proteus*, and *Staphylococcus aureus*) soon produce the interdigital erosions with pruritus and malodor that are characteristic of the dermatophytosis complex, or "athlete's foot."

Chronic Hyperkeratotic (Moccasin) Type. In chronic hyperkeratotic type tinea pedis, there is patchy or diffuse scaling on the soles and the lateral and medial aspects of the feet, in a distribution similar to a moccasin on a foot (Fig. 188-12B). The degree of erythema is variable, and there may also exist few minute vesicles that heal with collarets of scale less than 2 mm in diameter. The most common pathogen is *T. rubrum* followed by *E. floccosum* and anthropophilic strains of *T. interdigitale*.

Vesiculobullous Type. Vesiculobullous type of tinea pedis, typically caused by zoophilic strains of *T. interdigitale* (former *T. mentagrophytes var. mentagrophytes*), features tense vesicles larger than 3 mm in diameter, vesiculopustules, or bullae on the soles and periplantar areas (Fig. 188-12C). This type of tinea pedis is uncommon in childhood but has been caused by *T. rubrum*.[49]

Acute Ulcerative Type. Tinea pedis with zoophilic *T. interdigitale* along with rampant bacterial superinfection with Gram-negative organisms produces vesicles, pustules and purulent ulcers on the plantar surface. Cellulitis, lymphangitis, lymphadenopathy and fever are frequently associated.

Vesiculobullous and acute ulcerative types commonly produce a vesicular Id reaction, either on the lateral foot or toes, or on the lateral aspects of the fingers.

Tinea manus, dermatophyte infection of the hand, usually has a noninflammatory presentation with diffuse dry scaling and accentuation in the creases (Fig. 188-13). However, vesicles, pustules and exfoliation may be present, especially when zoophilic dermatophytes involved. Tinea manus commonly occurs in association with moccasin type tinea pedis and onychomycosis, which should also be treated to minimize relapse.[50]

Figure 188-13 Tinea pedis and manus. "Two feet–one hand" presentation of *Trichophyton rubrum*. Scaling in the involved (*right*) hand is accentuated in the creases.

BOX 188-5 DIFFERENTIAL DIAGNOSIS OF TINEA PEDIS

Most Likely

- Interdigital: erosio interdigitalis blastomycetica, erythrasma, bacterial coinfection
- Hyperkeratotic: dyshidrosis, psoriasis, contact dermatitis, atopic dermatitis, hereditary or acquired keratodermas
- Vesiculobullous: dyshidrosis, contact dermatitis, pustular psoriasis, bacterid, palmoplantar pustulosis, bacterial pyodermas, scabies

Consider

- Pityriasis rubra pilaris

Rule Out

- Reactive arthritis

DIFFERENTIAL DIAGNOSIS. (Box 188-5)

LABORATORY TESTS. (See Tables 188-4, 188-6).

KOH examination of blister roofs (vesicules or bullae) yields the highest rate of positive findings.

HISTOPATHOLOGY. (See Table 188-4).

In tinea pedis, fungal organisms are highlighted in the stratum corneum by PAS or methenamine silver stains and are sometimes accompanied by foci of neutrophils.

There may also be a sparse, chronic, superficial perivascular infiltrate in the dermis. The vesiculobullous type demonstrates subcorneal or spongiotic intraepithelial vesiculation.

DERMATOPHYTID (ID) REACTION

These inflammatory reactions, named apparently after the instinctual component of the psyche as defined by Freud, occur in 4%–5% of patients with dermatophytosis at sites distant from the primary inflammatory fungal infections such as tinea pedis or kerion.[51] Although the precise mechanism is unknown, the Id reaction is associated with a DTH response to the *Trichophyton* test and may involve a local DTH response to systemically absorbed fungal antigen.[52] Id reactions appear polymorphic, ranging in morphology from follicular or nonfollicular papules and vesicles of the hands and feet to reactive erythemas including erythema nodosum, erythema annulare centrifugum, or urticaria.[53–56] Unlike the primary eruption, the Id eruption is KOH examination and culture negative. Criteria for establishing the presence of an Id eruption are the following: (1) dermatophytosis on another part of body, (2) absence of fungal elements from the id eruption, and (3) resolution of the id eruption with clearing of the primary dermatophyte infection.

ONYCHOMYCOSIS

Onychomycosis describes fungal infection of the nail caused by dermatophytes, nondermatophyte molds, or yeasts. Tinea unguium refers strictly to dermatophyte infection of the nail. Clinically, different three types of onychomycosis are distinguished: (1) distolateral subungual onychomycosis (DLSO), (2) proximal subungual onychomycosis (PSO), (3) white superficial onychomycosis (WSO).

EPIDEMIOLOGY.

Onychomycosis is the most prevalent nail disease and accounts for approximately 50% of all causes of onychodystrophy. It affects up to 14% of the population with both an increasing prevalence among older individuals.[57] and an overall increasing incidence.[58] Onychomycosis is also increasing in incidence among children and adolescents and accounts for up to 20% of dermatophyte infections diagnosed in children.[59] Risk factors for nail infection include nail trauma, immunosuppression such as HIV infection, diabetes mellitus, and peripheral vascular insufficiency.[60] The increasing prevalence of this disease may be secondary to wearing of tight shoes, increasing numbers of individuals on immunosuppressive drugs, and an increased use of communal locker rooms. The dermatophytosis commonly begins as tinea pedis before extending to the nail bed, where eradication is more difficult. This site serves as a reservoir for local recurrence or for infections spreading to other areas. Up to 40% of patients with toenail onychomycosis show concomitant skin infections, most commonly tinea pedis (30%).[61]

ETIOLOGY.

In the majority of cases, onychomycosis is caused by dermatophytes, and *T. rubrum* and *T. interdigitale* are responsible for approximately 90% of all cases. *T. tonsurans* and *E. floccosum* are also well documented causative agents.[62] Yeast and nondermatophyte molds such as *Acremonium*, *Aspergillus*, *Fusarium*, *Scopulariopsis brevicaulis*, and *Scytalidium* are the source of approximately 10% of toenail onychomycosis. Interestingly, *Candida* species are responsible for up to 30% of fingernails cases, whereas nondermatophyte molds were not detected in diseased fingernails.[63]

CLINICAL FINDINGS

Distolateral subungual type. DLSO is the most common form of onychomycosis and may be caused by any of the organisms listed above. It begins with invasion of the stratum corneum of the hyponychium and distal nail bed, forming a whitish to brownish–yellow opacification at the distal edge of the nail (Fig. 188-14A). The infection then spreads proximally up the nail bed to the ventral nail plate. Hyperproliferation or altered differentiation of the nail bed in response to the infection results in subungual hyperkeratosis, while progressive invasion of the nail plate results in an increasingly dystrophic nail.

Proximal Subungual Type. (Fig. 188-14B). PSO results from infection of the proximal nail fold primarily with *T. rubrum* and *T. megninii* and is apparent as a white to beige opacity on the proximal nail plate. This opacity gradually enlarges to affect the entire nail and eventuates in subungual hyperkeratosis, leukonychia, proximal onycholysis, and/or destruction of the entire nail. Patients with PSO should be screened for HIV, as PSO has been considered a marker for this disease.[6,64]

White Superficial Type. (Fig. 188-14C). WSO results from direct invasion of the dorsal nail plate resulting in white to dull yellow sharply bordered patches anywhere on the surface of the toenail. It is usually caused by *T. interdigitale*, although nondermatophyte molds such as *Aspergillus*, *Scopulariopsis*, and *Fusarium* are also known pathogens. *Candida* species may invade the hyponychial epithelium to eventually affect the entire thickness of the nail plate.[65]

DIFFERENTIAL DIAGNOSIS. (Box 188-6)

LABORATORY TESTS. (See Tables 188-4, 188-6).

Although onychomycosis is responsible for 50% of dystrophic nails, laboratory diagnostic confirmation prior to treatment with potentially toxic oral, antifungal treatments is judicious. KOH examination of subungual debris, culture of the nail plate and accompanying debris on SDA (with and without antimicrobials),

Figure 188-14 Tinea unguium. **A.** Distal subungual type. Discoloration, thickening and subungual debris of the distal aspect of the toenails. **B.** Proximal subungual type. Discoloration and thickening of the proximal nail in a patient with acquired immunodeficiency syndrome; Kaposi sarcoma is also seen on the fourth toe. **C.** White superficial type. Irregular opaque white patches on various parts of the nail plates.

BOX 188-6 DIFFERENTIAL DIAGNOSIS OF ONYCHOMYCOSIS

Most Likely

- Psoriasis, lichen planus, trauma, onychogryphosis

Consider

- Pachyonychia congenita, acquired and congenital leukonychias, Darier-White disease, Yellow Nail syndrome

Rule Out

- Melanoma

and PAS staining of a nail clipping are most useful. However, KOH examination is often negative even when clinical suspicion is high, and nails with hyphae reported on KOH examination often yield negative cultures. The simplest measure to minimize false-negatives caused by sampling error is to maximize sample size and repeat collections. The following guidelines are suggested to discern pathogens from contaminants: (i) if a dermatophyte is isolated on culture, it is considered a pathogen; (ii) a nondermatophyte mold or yeast cultured is significant only if hyphae, spores, or yeast cells are seen on microscopic examination, and (iii) there is repeated heavy growth of a nondermatophyte mold without concurrent isolation of a dermatophyte.[66] Whereas culture is the most specific test for onychomycosis, PAS examination of nail clippings is the most sensitive[29] and it obviates the need to wait weeks for a result.

HISTOPATHOLOGY. (See Table 188-4). Hyphae are seen between the nail laminae parallel to the surface and have a predilection for the ventral nail and stratum corneum of the nail bed.[67] The epidermis may show spongiosis and focal parakeratosis, and there is a minimal dermal inflammatory response. In WSO, the organisms are present superficially on the dorsal nail and display unique "perforating organs" and "eroding fronds." In candidal onychomycosis there is invasion of pseudohyphae throughout the entire nail plate, adjacent cuticle, granular layer, and stratum spinosum of the nail bed, as well as the hyponychial stratum corneum.[65]

TREATMENT OF DERMATOPHYTES

(Table 188-10)

Multiple systemic and topical antifungal agents are available to treat dermatophytoses of skin, hair and nails.

TINEA CAPITIS AND FAVUS

Infections involving hair-bearing skin usually necessitate oral antifungal treatment since dermatophytes penetrating the follicle are usually out of reach for topically applied agents. Griseofulvin along with the allylamine (terbinafine) and oral triazoles (itraconazole and fluconazole) are considered safe and effective in the treatment of tinea capitis.

GRISEOFULVIN. Griseofulvin along with terbinafine in patients older than 4 years are systemic treatments for tinea capitis approved by the US Food and Drug Administration. The previously recommended pediatric dosage was 10–20 mg/kg/day in divided doses for 6–8 weeks taken with a fatty meal to facilitate absorption.[33] However, high failure rates with this regimen resulted in the current dosage recommendation of griseofulvin 20–25 mg/kg/day of the microsize form, and 15 mg/kg/day in divided doses of the ultramicrosize form for 8 weeks.[68] Although the current recommendation is not based on outcomes of controlled trials, the collective clinical experience suggests its high therapeutic efficacy. Disadvantages of griseofulvin include poor compliance related to length of treatment and its bitter taste in liquid form. Common side effects include photosensitivity, headache, and gastrointestinal upset.[69] Griseofulvin also is a potent inducer of cytochrome P450 enzymes.

TERBINAFINE. Doses of 3–6 mg/kg/day of terbinafine can cure *Trichophyton* tinea capitis in 2–4 weeks; however, 4–8 weeks of treatment may be required for eradication of *Microsporum*.[68] Two randomized trials confirmed the increased efficacy of terbinafine (5–8 mg/kg/day) in the treatment of *T. tonsurans* infection with significantly higher cure rates compared to lower dose griseofulvin (10–20 mg/kg/day). However, even at this lower dose range, griseofulvin showed significantly higher cure rates for *M. canis* infections.[70] Further, it is not clear that terbinafine (5–8 mg/kg/day) has a therapeutic advantage in curing tinea capitis over the higher dose regimen of griseofulvin (20–25 mg/kg/day). Terbinafine may cause gastrointestinal upset. As with itraconazole, there are reports of liver failure in patients using terbinafine. Terbinafine has an inhibitory effect on the CYP 2D6 subset of the cytochrome P450 system. While fewer medications are metabolized through this CYP 2D6 subset as than through the CYP 3A4 subset inhibited by itraconazole and ketoconazole, notable interactions still exist with β-blockers and tricyclic antidepressants.

ITRACONAZOLE. At doses of 5 mg/kg/day for 2–4 weeks, itraconazole effectively eradicates tinea capitis caused by either *Microsporum* or *Trichophyton*.[68] Pulse therapy at 5 mg/kg/day for 1 week out of each month for one to three cycles is also effective. Possible adverse effects of itraconazole include gastrointestinal upset, diarrhea with the liquid formulation, and peripheral edema, especially when used in conjunction with calcium channel blockers. Itraconazole is better absorbed in the presence of food, which results in secretion of gastric acid and lower gastric pH. On the contrary, antacids such as H_2 blockers may decrease the absorption of itraconazole by increasing the gastric pH. Like with fluconazole, hepatotoxicity with itraconazole occurs at lower rates than with ketoconazole.[35]

TABLE 188-10
Treatment of Dermatophytes

Disease	Topical Treatment	Systemic Treatment
Tinea capitis	Only as adjuvant Selenium sulfide 1% or 2.5% Zinc pyrithione 1% or 2% Povidone iodine 2.5% Ketoconazole 2%	Adults: Griseofulvin, 20–25 mg/kg/day · 6–8 weeks Terbinafine, 250 mg/day · 2–8 weeks Itraconazole, 5 mg/kg/day · 2–4 weeks Fluconazole, 6 mg/kg/day · 3 weeks Children: Terbinafine, 3–6 mg/kg/day · 2–8 weeks all others are the same
Tinea barbae	Only as adjuvant Topical antifungals	Griseofulvin, 1 g/day · 6 weeks Terbinafine, 250 mg/day · 2–4 weeks Itraconazole, 200 mg/day · 2–4 weeks Fluconazole, 200 mg/day · 4–6 weeks
Tinea corporis/cruris	Allylamines Imidazoles Tolnaftate Butenafine Ciclopirox	Adults: Terbinafine, 250 mg/day · 2–4 weeks Itraconazole, 100 mg/day · 1 week Fluconazole, 150–300 mg/week · 4–6 weeks Griseofulvin, 500 mg/day · 2–4 weeks Children: Terbinafine, 3–6 mg/kg/day · 2 weeks Itraconazole, 5 mg/kg/day · 1 week Griseofulvin, 10–20 mg/kg/day · 2–4 weeks
Tinea pedis/manuum	Allylamine Imidazoles Ciclopirox Benzylamine Tolnaftate Undecenoic acid	Adults: Terbinafine, 250 mg/day · 2 weeks Itraconazole, 200 mg twice daily · 1 week Fluconazole, 150 mg/week · 3–4 weeks Children: Terbinafine, 3–6 mg/kg/day · 2 weeks Itraconazole, 5 mg/kg/day · 2 weeks
Onychomycosis	Ciclopirox Amorolfine	Adults: Terbinafine, 250 mg/day · 6–12 weeks Itraconazole, 200 mg/day · 2–3 months Fluconazole, 150–300 mg/week · 3–12 months Children: Terbinafine, 3–6 mg/kg/day · 6–12 weeks Itraconazole, 5 mg/kg/day · 2–3 months Fluconazole, 6 mg/kg/week · 3–6 months

Itraconazole has also rarely been linked to congestive heart failure. Itraconazole is an inhibitor of the CYP 3A4 subset of cytochrome P450 system.

FLUCONAZOLE. Available as both tablets and a pleasant-tasting liquid, fluconazole at doses of 6 mg/kg/day for 20 days is effective in curing tinea capitis.[68] Alternatively, fluconazole can be administered as a pulse, once weekly, regimen with 6 mg/kg/day for 8–12 weeks.[71] Absorption of fluconazole is not affected by gastric pH, and gastrointestinal side effects are less common. Hepatitis has been reported but it occurs less frequently than with ketoconazole.[35] Fluconazole is a potent inhibitor of cytochrome P450 enzymes, in particular CYP 2C9 and 2C19. Since most medications metabolized by the cytochrome P450 system are through the CYP 3A4 subset, fluconazole has less potential to interact with medications than other systemic imidazoles.

ADJUVANT THERAPY. Selenium sulfide (1% and 2.5%), zinc pyrithione (1% and 2%), povidone iodine (2.5%), and ketoconazole (2%) are shampoo preparations that help eradicate dermatophytes from the scalp of children. Adjunctive use of these shampoos is recommended 2–4 times weekly for 2–4 weeks.[72] The use of ketoconazole 2% shampoo or selenium sulfide 2.5% three times weekly by all household members also reduces transmission by decreasing the shedding of spores.[69]

Oral glucocorticoids may reduce the incidence of scarring associated with markedly inflammatory varieties of tinea capitis. Although there is no consistent evidence for improved cure rates with use of oral glucocorticoids, they appear to relieve pain and swelling associated with infections. The usual regimen prednisone is 1–2 mg/kg each morning during the first week of therapy.

TINEA BARBAE

Like tinea capitis, an oral antifungal is usually necessary in the treatment of tinea barbae. Ultramicronized griseofulvin 500 mg twice daily for 6 weeks, terbinafine 250 mg daily for 2–4 weeks, itraconazole 200 mg daily for 2–4 weeks, and fluconazole 200 mg daily for 4–6 weeks are regimens that have been used effectively. Systemic glucocorticoids used for the first week of therapy are helpful in cases with severe inflammation.

TINEA CORPORIS AND TINEA CRURIS

For isolated plaques on the glabrous skin, topical allylamines, imidazoles, tolnaftate, butenafine, or ciclopirox are effective. Most are applied twice daily for 2–4 weeks. Oral antifungal agents are reserved for widespread or more inflammatory eruptions. Comparative studies in adults show that terbinafine 250 mg daily for 2–4 weeks, itraconazole 200 mg daily for 1 week, and fluconazole 150–300 mg weekly for 4–6 weeks are preferable over griseofulvin 500 mg daily until cure is reached.[73] Safe and effective regimens for children include terbinafine 3–6 mg/kg/day for 2 weeks, itraconazole 5 mg/kg/day for 1 week, and ultramicrosize griseofulvin 10–20 mg/ kg/day for up to 2–4 weeks.

TINEA PEDIS AND TINEA MANUUM

Mild interdigital tinea pedis without bacterial involvement is treated topically with allylamine, imidazole, ciclopirox, benzylamine, tolnaftate, or undecenoic acid based creams.[74] Terbinafine cream applied twice daily for 1 week is effective in 66% of cases.[75] The dosing schedule of oral terbinafine is 250 mg daily for 2 weeks. Itraconazole in adults is given 400 mg daily for 1 week, 200 mg daily for 2–4 weeks, or 100 mg daily for 4 weeks with similar efficacies of all regimens,[76] whereas itraconazole in children is administered at 5 mg/kg/day for 2 weeks. Fluconazole 150 mg weekly for 3–4 weeks is also effective.[71] Topical or systemic corticosteroids may be helpful for symptomatic relief during the initial period of antifungal treatment of vesiculobullous tinea pedis. Maceration, denudation, pruritus, and malodor obligate a search for bacterial coinfection by Gram stain and culture, the results of which most often demonstrate the presence of Gram-negative organisms including *Pseudomonas and Proteus*. Patients suspected of having Gram-negative coinfections should be treated with a topical or systemic antibacterial agent based on the culture and sensitivity report. Associated onychomycosis is common; if present, more durable treatment of the onychomycosis is necessary to prevent recurrence of tinea pedis. Newer oral antifungal agents have replaced griseofulvin as the treatments of choice for severe or refractory tinea pedis when this infection is also accompanied by onychomycosis.

ONYCHOMYCOSIS

The management of onychomycosis depends on several factors including the severity of nail involvement, associated tinea pedis, along with efficacy and potential adverse effects of any treatment regimen. While it seems reasonable not to treat minimal nail involvement, concurrent tinea pedis should always be treated, particularly in the setting of diabetes mellitus, to prevent cellulitis.

TOPICAL THERAPY. In those patients with distal nail involvement and/or contraindication for systemic treatment, topical therapy should be considered. Ciclopirox 8% lacquer applied daily for 48 weeks achieved mycologic cure in 29%–36% of cases and clear nails (clinical cure) in 7% of mild to moderate cases of onychomycosis caused by dermatophytes.[77] Despite its much lower efficacy compared with oral antifungal agents, use of topical ciclopirox avoids risk of drug interactions. Amorolfine 5% applied twice weekly is another agent specifically prepared for use as a nail lacquer. It is the first member of a new class of antifungal drugs, the morpholine derivatives, which show activity against yeasts, dermatophytes and molds that cause onychomycosis. Amorolfine may have higher mycologic cure rates (38%–54% after 6 months of treatment) compared to ciclopirox lacquer; however, prospective controlled trials validating a significant difference are needed.[78]

SYSTEMIC THERAPY. An oral antifungal is required for onychomycosis involving the matrix area, or when a shorter treatment regimen or higher chance for clearance or cure is desired. Selection of the antifungal agent should be based primarily on the causative organism, the potential adverse effects, and the risk of drug interactions in any particular patient.

Terbinafine is fungistatic and fungicidal against dermatophytes, *Aspergillus*, and less so against *Scopulariopsis*. Terbinafine is not recommended for candida onychomycosis since it demonstrates variable efficacy against *Candida* species. A course of terbinafine 250 mg daily for 6 weeks is effective for most fingernail infections, while a minimum 12-week course[12–16] is required for toenail infections. Most adverse effects are gastrointestinal such as diarrhea, nausea, taste disturbance, and elevation of liver enzymes. Evidence suggests that a 3-month continuous regimen of terbinafine is the most effective oral treatment for onychomycosis of the toenails available today.[79] Clinical cure rates among different studies are approximately 50%, although the success rate is lower in patients over 65 years.[80] Itraconazole is fungistatic against dermatophytes,

nondermatophyte molds and yeasts. Safe and effective schedules include pulse dosing with itraconazole 400 mg daily for 1 week per month or a continuous dose of 200 mg daily, both of which require 2 months or 2 pulses of treatment for fingernails and at least 3 months or 3 pulses for toenails.[73] Itraconazole is dosed by weight in children at 5 mg/kg/day.[81] Elevated liver enzymes occur in 0.3%–5% of patients during therapy and return to normal within 12 weeks of discontinuation. Although itraconazole has a broader spectrum of activity than terbinafine, studies have shown a significantly lower rate of cure (about 25% vs. 50%) and higher relapse rate (about 50% vs. 20%) with itraconazole compared with terbinafine.[82,83] Fluconazole is fungistatic against dermatophytes, some nondermatophyte molds, and Candida. The usual regimen for fluconazole is 150–300 mg once weekly for 3–12 months.[73] Griseofulvin is no longer considered standard treatment for onychomycosis because of its prolonged treatment course, potential for adverse effects and drug interactions, and its relatively low cure rates.

Combination therapy regimens may have a higher clearance rate than either oral or topical treatments alone. Oral terbinafine combined with amorolfine nail lacquer was shown to result in clinical cure and negative mycology in 59% of patients compared to 45% of patients treated with oral terbinafine alone.[84] However, another study failed to show any additional benefit of combining oral terbinafine with ciclopirox 8% solution.[85]

In vitro fungicidal activity demonstrated by thymol, camphor, menthol, and oil of *Eucalyptus citriodora*[86,87] offers the potential for additional therapeutic strategies to treat onychomycosis. Thymol 4% prepared in ethanol may be used as drops applied to the nail plate and hyponychium. The application to nails of commercially available topical preparations with thymol, such as Vicks VapoRub™, has anecdotally led to success. Final options for refractory cases include surgical avulsion or chemical removal of the nail with 40% urea compounds in combination with topical or oral antifungals.

TINEA NIGRA

Tinea nigra is a superficial dermatomycosis caused by dematiaceous, darkly pigmented, *Hortaea werneckii* (formerly named *Phaeoannellomyces werneckii* and *Exophiala werneckii*).[88]

EPIDEMIOLOGY. Tinea nigra occurs in tropical or subtropical areas, including Central and South America, Africa, and Asia. Its incidence is low in the United States and Europe. While the majority of the approximately 150 North American cases reported since 1950 were associated with tropical travel,[42] endemic foci exist in the coastal southeastern United States and in Texas. Person-to-person transmission is rare.[89] Tinea nigra has a female/male predilection of 3:1.

ETIOLOGY. Tinea nigra is almost always caused by *H. werneckii*, although other dematiaceous fungi such as *Stenella araguata* may produce the same clinical picture. Dematiaceous fungi are commonly found in soil, sewage, and decaying vegetation.[89] Tinea nigra arises after trauma to the skin, subsequent inoculation and a typical incubation period of 2–7 weeks.

Figure 188-15 Tinea nigra palmaris. An irregular, brownish-black patch on the palm caused by *Phaeoannellomyces werneckii*. (Used with permission from Stuart Salasche, MD.)

CLINICAL FINDINGS. Tinea nigra is found on otherwise healthy people and presents typically as an asymptomatic, mottled brown to greenish-black macule or patch with minimal to no scale on the palms or soles (Fig. 188-15). The macule is often darkest at the advancing border. Because of its coloration and location on palms and soles, tinea nigra is frequently misdiagnosed as acral lentiginous melanoma.

DIFFERENTIAL DIAGNOSIS. (Box 188-7)

LABORATORY TESTS. KOH examination of scrapings from the macule reveals brown to olive-colored, thick branching hyphae, along with oval to spindle-shaped yeast cells that occur singly or in pairs with

a central transverse septum. Cultures performed on SDA with cycloheximide and chloramphenicol grow within 1 week. The colony is initially yeast-like with a brown to shiny black color and appears as typical two-celled yeast forms under microscopic examination. With time, mycelial growth predominates creating a fuzzy grayish-black colony.

TREATMENT. Tinea nigra responds readily to topical therapy with a keratolytic (Whitfield's ointment, 2% salicylic acid), tincture of iodine, or topical antifungal.[90,91] Treatment should be continued for 2–4 weeks after clinical resolution in order to prevent relapse. Although oral ketoconazole, itraconazole and terbinafine are also effective, systemic therapies are rarely indicated.[88]

PIEDRA

Piedra is an asymptomatic superficial fungal infection of the hair shaft also known as trichomycosis nodularis. Black piedra is caused by *Piedraia hortae*, whereas white piedra is caused by pathogenic species of the *Trichosporon* genus, namely *Trichosporon asahii*, *Trichosporon ovoides*, *Trichosporon inkin*, *Trichosporon mucoides*, *Trichosporon asteroides*, and *Trichosporon cutaneum*.[88]

EPIDEMIOLOGY. Black piedra is seen commonly in humans and primates of tropical areas of South America, the Pacific Islands, and the Far East, and less commonly in Africa and Asia. *P. hortae* is present in the soil and in stagnant water and crops. Scalp hair is most commonly affected. In fact, infection is encouraged for religious and esthetic reasons by some indigenous cultures.[92]

White piedra is most common in temperate and semitropical climates of South America and Asia, the Middle East, India, Africa, and Japan. It occurs infrequently in the United States and Europe. White piedra affects facial, axillary, and genital hair more commonly than scalp hair. *T. ovoides* is found more commonly on scalp hair, *T. inkin* on pubic hair and *T. asahii* on other body surfaces. Person-to-person transmission is rare, and infection has not been associated with travel to endemic areas.[93]

CLINICAL FINDINGS. Black piedra is characterized by firmly attached, hard or gritty, brown–black colored concretions on the hair shaft that vary in size from the microscopic range to a few millimeters in size. Concretions are most commonly noted on frontal portions of the scalp. Black piedra weakens the hair shaft and results in hair breakage.

White piedra consists of softer and less adherent whitish to beige colored concretions that are discrete or may coalesce into sleeve-like structures along the hair shaft. These concretions affect the outer layers of the hair shaft and may be easily detached. Broken hairs, although sometimes present, are less common than in black piedra.[88]

Microscopy readily differentiates piedra from nits, hair casts, developmental hair shaft defects, and trichomycosis axillaris. In addition, the nodules of trichomycosis axillaris are usually smaller and may fluoresce under a Wood's lamp.

BOX 188-8 DIFFERENTIAL DIAGNOSIS OF PIEDRA

Most Likely

- Pediculosis, trichomycosis axillaris, tinea capitis

Consider

- Monilethrix

DIFFERENTIAL DIAGNOSIS. (Box 188-8)

LABORATORY TESTS. Nodules of black piedra examined by KOH preparation display a periphery of aligned hyphae and a well-organized center of thick-walled cells packed closely together, sometimes termed pseudoparenchyma. These nodules are mostly outside of the hair shaft. *P. hortae* grows well, albeit slowly, on most laboratory media and is uninhibited by cycloheximide.

The nodules of white piedra have a less organized and more intrapilar appearance than do nodules of black piedra. Hyphae are arranged perpendicularly to the hair shaft. *T. asahii* thrives on SDA and it is inhibited by cycloheximide.

TREATMENT. Shaving the infected hair is curative and represents the best treatment for both black and white piedra, although this approach should be supplemented with a topical azole preparation. Because of high relapse rates as well as evidence for intrafollicular organisms in white piedra, some advocate the use of systemic antifungal agent such itraconazole.[93]

Chapter 189 :: Yeast Infections: Candidiasis, Tinea (Pityriasis) Versicolor, and *Malassezia* (*Pityrosporum*) Folliculitis

:: Roopal V. Kundu & Amit Garg

CANDIDIASIS

YEAST INFECTIONS AT A GLANCE

- *Candidiasis* refers to a diverse group of acute and chronic integumentary or disseminated yeast infections, most commonly caused by *Candida albicans*.
- *Candida* species are the most common cause of fungal infection in immunocompromised persons.
- *Malassezia* yeast, although normal flora in most healthy individuals, cause a wide spectrum of superficial cutaneous disease, including tinea versicolor and *Malassezia* folliculitis.
- Common predisposing factors associated with *Candida* and *Malassezia* infection include a warm, humid environment; hyperhidrosis; occlusion of skin and hair follicles; oral contraceptive, antibiotic and systemic corticosteroid use; diabetes mellitus; and immunosuppression.
- Potassium hydroxide preparation of skin scrapings demonstrates the characteristic fungal elements that identify *Candida* and *Malassezia*.
- Multiple topical and systemic agents are effective in treating infection with *Candida* and *Malassezia*; however, recurrences are common.

The genus *Candida* is comprised of a heterogeneous group of over 200 yeast species.[1] *Candida* species are ubiquitous yeast-like fungi that form true hyphae, pseudohyphae, and budding yeasts. *Candidiasis* (or *candidosis*) refers to a diverse profile of yeast infections caused by members of the genus *Candida*, and predominantly by *Candida albicans*. *Candida* species are among the most common fungal pathogens to affect humans. While the skin, nails, mucous membranes, and gastrointestinal tract are typical sites of infection, *Candida* may involve any part of the body. Although considered opportunistic human pathogens, *Candida* species may also exist as commensal organisms of skin and mucosal membranes of the gastrointestinal, genitourinary, and respiratory tracts.

EPIDEMIOLOGY

FREQUENCY. *Candida* are usually limited to human and animal hosts, however they have also been recovered from the hospital environment: countertops, air-conditioning vents, floors, respirators, and on medical personnel. Oropharyngeal colonization with *Candida* is observed in up to 50% of healthy individuals [2] and may also be detected in 40%–65% of normal stool samples. In addition, *C. albicans* exists as a commensal organism in the vaginal mucosa of 20%–25% of asymptomatic, healthy women[3] and up to 30% of healthy pregnant women.[4] Vulvovaginal candidiasis (VC) is the second most common cause of vaginitis in women.

Candida species are the most common cause of fungal infection in immunocompromised persons. More than 90% of persons infected with HIV not receiving highly active antiretroviral therapy (HAART) develop oropharyngeal candidiasis and 10% of these patients develop esophageal candidiasis.[5–6] *Candida* species are now the fourth most commonly isolated pathogens from blood cultures in patients with systemic infections.[7]

MORTALITY/MORBIDITY

Most candidal infections are mucocutaneous. While in few cases there may be pronounced effect on morbidity, these infections do not lead to death. However, immunocompromised patients including hospitalized patients, may develop candidemia and disseminated candidiasis which have a 30%–40% mortality rate. In fact, systemic candidiasis causes more case fatalities than any other systemic mycosis.

SEX. Neither sex is predisposed to candidal colonization.

AGE. Neonates and adults >65 years of age are most susceptible to candidal colonization and mucocutaneous candidiasis.

ETIOLOGY AND PATHOGENESIS

Responsible for 50%–60% of all candidal infections, *C. albicans* is the most common candidal pathogen identified.[8] *C. albicans* has its own virulence factors including adhesion molecules that permit attachment

of the organism to other structures, proteinase secretions [aspartyl proteinases (SAP1-9)] that facilitate damage to cell envelopes, as well as the ability to convert to the hyphal form which is thought to be important for the virulence of *C. albicans*.[9]

The relative prevalence of *C. albicans* in clinical isolates is declining, and other species such as *Candida glabrata*, *Candida parapsilosis*,[1,10] *Candida tropicalis*, *Candida krusei*,[1,11] and *Candida dubliniensis*[12] are increasingly being encountered as pathogens.[13] *C. glabrata* and *C. albicans* account for approximately 70%–80% of *Candida* species recovered from patients with candidemia or invasive candidiasis. Other species of *Candida* have gained importance because of their frequent intrinsic resistance to systemic antifungal therapy. Certain patient populations are more susceptible to specific *Candida* species: the presence of *C. parapsilosis* should be considered in hospitalized patients and those with vascular catheters or prosthetic devices, while *Candida tropicalis* has been observed to cause candidemia in patients with leukemia and in those who have undergone bone marrow transplantation.

CLINICAL MANIFESTATIONS

The mucocutaneous manifestations of candidiasis are represented by several distinct clinical syndromes.

MUCOCUTANEOUS CANDIDIASIS

ORAL CANDIDIASIS

Acute pseudomembranous candidiasis or thrush is the most common form of oral candidiasis. Predisposing factors include diabetes mellitus, systemic steroid and antibiotic use, pernicious anemia, malignancy, radiation to head and neck, and cell-mediated immunodeficiency[2,15–16] (Table 189-1). Thrush appears as discrete white patches that may become confluent on the buccal mucosa, tongue, palate, and gingivae (Fig. 189-1A). This friable pseudomembrane resembles cottage cheese or milk curds and consists of desquamated epithelial cells, fungal elements, inflammatory cells, fibrin, and food debris (Figs. 189-1A–189-1C). Scraping the patches exposes a brightly erythematous surface underneath. Microscopic examination of this material reveals masses of tangled pseudohyphae and blastospores (Fig. 189-2). In severe cases, the mucosal surface may ulcerate.

Acute atrophic candidiasis (erythematous candidiasis), which occurs after sloughing of the thrush pseudomembrane,[15] is observed most often in the setting of broad-spectrum antibiotic or systemic glucocorticoid therapy and human immunodeficiency virus infection.[2] The most common location is on the dorsal surface of the tongue, where depapillated atrophic patches with minimal pseudomembrane formation are noted. There are both asymptomatic and symptomatic variants, the latter characterized by burning or pain.[17]

Chronic atrophic candidiasis (denture stomatitis) (Fig. 189-1B) is a common form of oral candidiasis seen in 24%–60% of denture wearers,[18] and more commonly occurs in women. Chronic erythema and edema of the palatal mucosal surface in contact with the dentures is present. Presumably, the chronic low-grade trauma and occlusion caused by dentures predispose to candidal colonization and subsequent infection.[19]

TABLE 189-1
Factors Predisposing to *Candida* Infections

MECHANICAL FACTORS
- Dentures
- Local occlusion (dressings or garments), moisture, and/or maceration
- Obesity
- Trauma

NUTRITIONAL FACTORS
- Avitaminosis (vitamin A and C)
- Generalized malnutrition
- Iron deficiency (chronic mucocutaneous candidiasis)
- Parenteral hyperalimentation

PHYSIOLOGIC ALTERATIONS
- Extremes of age
- Menses
- Pregnancy

SYSTEMIC ILLNESSES
- Acrodermatitis enteropathica
- Down syndrome
- Endocrine disease
- Cushing disease
  - Diabetes mellitus
  - Hypoadrenalism
  - Hypoparathyroidism
  - Hypothyroidism
- Acute and chronic renal failure (hemodialysis)
- Bone marrow transplantation
- Malignancy (especially hematologic, thymoma)
- Solid organ transplantation (liver, kidney)
- Immunodeficiency
  - Acquired immunodeficiency syndrome
  - Severe combined immunodeficiency syndrome
  - Myeloperoxidase deficiency
  - Chédiak–Higashi syndrome
  - Hyperimmunoglobulinemia E syndrome
  - Chronic granulomatous disease
  - DiGeorge syndrome
  - Nezelof syndrome
  - Hypocomplementemia
  - Granulocytopenia

IATROGENIC
- Indwelling catheters and intravenous lines
- Prolonged hospitalizations
- X-ray irradiation
- Medications
  - Corticosteroids
  - Other immunosuppressive agents
  - Antibiotics (especially broad spectrum, metronidazole)
  - Oral contraceptives (especially estrogen dominant)
  - Colchicine
  - Phenylbutazone
  - Chemotherapy

Figure 189-1 **A.** Pseudomembranous candidiasis or thrush. Note the characteristic white patches on the palate. **B.** Atrophic candidiasis under dentures. Edema and erythema at the site of contact with dentures. **C**. *Candida* perlèche with erythema and fissuring at the corners of the mouth. **D.** Hyperplastic candidiasis of the tongue.

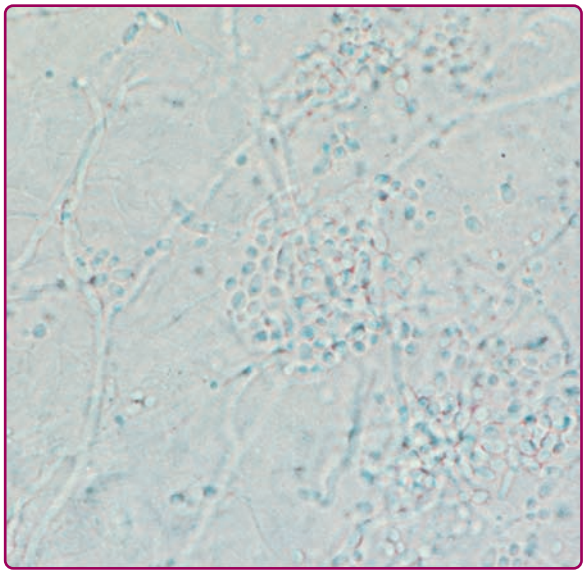

Figure 189-2 *Candida* in potassium hydroxide preparation. Pseudomycelia in clusters of grape-like yeast cells.

Candidal cheilosis (angular cheilitis or *perlèche)* is characterized by erythema, fissuring, maceration, and soreness at the angles of the mouth (Fig. 189-1C). This condition is commonly encountered in habitual lip lickers and in elderly patients with sagging skin at the oral commissures. Loss of dentition, poorly fitting dentures, malocclusion, and riboflavin deficiency also predispose one to cheilosis. Cheilosis is often associated with chronic atrophic candidiasis in denture wearers.[15]

The differential diagnosis for oral candidiasis is summarized in Box 189-1.

VAGINAL AND VULVOVAGINAL CANDIDIASIS

VC is the second most common cause of vaginitis, and approximately three-fourths of all women will experience an episode of VC in their lifetime. *C. albicans* causes 80%–90% of VC and is followed by *C. glabrata* in frequency.[20] Risk factors for VC include systemic antibiotic or steroid use, diabetes mellitus, presence

- Pemphigus vulgaris

of an intrauterine device, wearing of tight-fitting and synthetic clothing, and immunosuppression.[21,22] These factors disrupt vaginal flora of lactobacilli that serve to inhibit overgrowth of *Candida*.[20]

Recurrent VC, defined as four or more episodes per year, occurs in up to 10% of women.[20] Changes in hormone levels during pregnancy and the luteal phase of the menstrual cycle may induce relapses. Use of genital cleansing solutions or douche may elicit a hypersensitivity response and increase susceptibility to *Candida*. Frequent sexual intercourse, resulting in vaginal abrasions and involving semen allergy, may also predispose women to recurrent VC.[23] When none of the above mentioned factors is involved in VC, one should consider use of antibiotics, immunosuppression, or diabetes mellitus as potential contributors.[24]

Patients with VC present with a vaginal discharge associated with vulvar pruritus, burning, and occasional dysuria or dyspareunia. Examination shows thick curd-like whitish plaques on the vaginal wall with underlying erythema and surrounding edema that may extend to the labia and perineum. The cervix is normal upon speculum examination.[25]

BALANITIS AND BALANOPOSTHITIS

Candida spp. cause 30%–35% of infectious balanitis. Factors predisposing to candidal balanitis include diabetes mellitus, an uncircumcised state, and candidal vaginal infection in sexual partners. Occasionally, patients with balanitis complain of transient erythema and burning occurring shortly after intercourse. The eruption involving the penis is pruritic. Physical findings include white patches on the glans or prepuce. Small papules or fragile vesiculopustules on the glans or along the coronal sulcus (Fig. 189-3) break to leave erythematous erosions with a collarette of whitish scale. Infection may spread to the scrotum, gluteal folds, buttocks, and thighs. In diabetic or immunosuppressed patients, a severe edematous, ulcerative balanitis may occur.

Figure 189-3 Candidal balanoposthitis. Multiple discrete pustules on the glans penis and inner aspect of the foreskin.

CUTANEOUS CANDIDIASIS

INTERTRIGO

C. albicans has a predilection for colonizing skin folds, intertriginous zones in which the local environment is moist and warm. Usual locations for candidal intertrigo include the genitocrural, gluteal, interdigital, inframammary (Fig. 189-4) areas, and beneath the pannus and axillary areas. Predisposing conditions include obesity, diabetes mellitus, wearing of occlusive clothing and occupational factors.[26] The pruritic eruption appears as macerated red erythematous patches and thin plaques with satellite vesiculopustules. These pustules enlarge and rupture, leaving an erythematous base with a collarette of easily detachable scale that contributes to further maceration and fissuring. Cutaneous candidal infection is diagnosed by the typical appearance of the eruption and confirmed by KOH examination and, when necessary, culture. See Box 189-2 for the differential diagnosis of intertriginous candidiasis.

Several clinical variants of *Candida* intertrigo deserve special mention. Candidal diaper dermatitis results from yeast colonization of the gastrointestinal tract and chronic occlusion with wet diapers. The eruption with pronounced red erythema first appears in the perianal region and spreads to the perineum and inguinal creases (Fig. 189-4C).[27] *Erosio interdigitalis blastomycetica* refers to interdigital candidal or polymicrobial infection of the hands or feet, usually affects the third or fourth interdigital space, where moisture trapping is thought to underlie the condition (Fig. 189-4D). *Candida* miliaria affects the back in bedridden patients. The eruption begins as isolated vesiculopustules containing

Figure 189-4 Candidal intertrigo. **A.** Erythematous, eroded, pustular papules coalescing to plaques involving the scrotum and inguinal area with satellite lesions. Collarette-like scales where pustules have eroded. **B.** Confluent and discrete erythematous, eroded areas with pustular and erosive satellite lesions. **C.** Red, partially eroded plaques on the vulva surrounded by a delicate collarette in an infant. Outside the main lesions are a few pustular satellite lesions. **D.** Erosio interdigitalis blastomycetica. Erythematous eroded areas between the fingers.

BOX 189-2 DIFFERENTIAL DIAGNOSIS OF INTERTRIGINOUS CANDIDIASIS

Most Likely
- Intertrigo, irritant contact dermatitis
- Dermatophytosis (e.g., tinea cruris)
- Psoriasis
- Erythrasma
- Seborrheic dermatitis

Consider
- Familial benign pemphigus
- Flexural Darier disease
- Leiner disease

Rule Out
- Glucagonoma
- Extramammary Paget disease
- Secondary syphilis
- Zinc deficiency

yeast, which spread over occluded regions on the back. *Candida* also colonizes and infects skin around wounds covered with occlusive dressings (Fig. 189-5). Broad-spectrum topical antibiotics contribute to these *Candida* wound infections.[28]

GENERALIZED CUTANEOUS CANDIDIASIS

This is an unusual form of cutaneous candidiasis that manifests as a diffuse eruption beginning as individual vesicles and spreading into confluent areas involving the trunk, thorax, and extremities. The associated generalized pruritus is increased in severity in the genitocrural folds, anal region, axillae, and hands and feet (Fig 189-6).

CANDIDA FOLLICULITIS

Superficial infection involving the infundibulum of hair follicles occurs also in the predisposed patient,

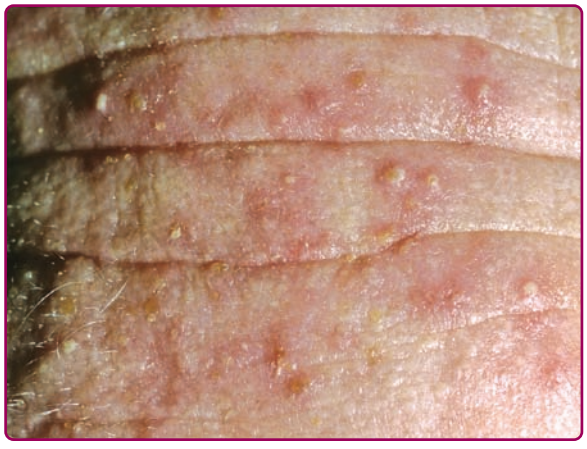

Figure 189-5 *Candida* miliaria on the forehead of a diabetic patient that arose after use of a semiocclusive dressing for headache.

Figure 189-6 Cutaneous candidiasis. Erythematous, unroofed vesicles and vesiculopustules coalescing into plaques involving the lower back and buttocks. Collarette-like scales where vesicles have eroded.

most commonly in the setting of diabetes mellitus or immunocompromised states. KOH examination of the contents of follicular pustules distinguishes this condition from bacterial folliculitis.

CANDIDAL PARONYCHIA AND ONYCHOMYCOSIS

Candidal infection of the nails and paronychial folds occurs most often in those with diabetes mellitus or who habitually immerse their hands in water (i.e., housekeepers, bakers, fishermen, and bartenders). In paronychia, there is initial redness, swelling and tenderness of the proximal and lateral nailfolds with retraction of the cuticle toward the proximal nail fold (Fig. 189-7). Pain and erythema may extend along the entire nail plate and nail bed.[29,30] Candidal paronychia should be differentiated from acute bacterial paronychia or paronychia associated with hypoparathyroidism, celiac disease, acrodermatitis enteropathica (Chapter 130), reactive arthritis syndrome (Chapter 20), acrokeratosis paraneoplastica, and retinoid therapy. Candidal onychomycosis is associated with secondary nail thickening, ridging, whitish discoloration, and occasional nail loss.

CHRONIC MUCOCUTANEOUS CANDIDIASIS

Chronic mucocutaneous candidiasis (CMC) is characterized by chronic, treatment-resistant, superficial candidal infections of the skin, hair, nails, and mucous membranes. There is virtually no propensity for disseminated visceral candidiasis.

Figure 189-7 Chronic onychia and paronychia caused by *Candida albicans*. **A.** Note the warm but not hot, slightly tender, edematous nail fold with some onycholysis. This is very often misdiagnosed as staphylococcal paronychia. **B.** This is a chronic inflammatory condition with pustulation of the nail fold that also can involve the nail plate.

CMC is frequently associated with endocrinopathies including hypoparathyroidism, hypoadrenalism, and hypothyroidism, as well as conditions associated with specific abnormalities in cell-mediated immunity, such combined immune deficiency syndrome, DiGeorge syndrome, or patients with severely impaired T-cell function (i.e., AIDS). CMC first appearing in adulthood is often associated with thymoma.[31] There are several more or less distinct clinical syndromes of CMC (Table 189-2)[32–34] in which

TABLE 189-2
Classification of Chronic Mucocutaneous Candidiasis

Clinical Syndrome	Inheritance	Age at Onset	Distribution of Lesions	Endocrinologic Abnormality	Associated Findings	Notes
Chronic oral candidiasis	Sporadic	Any	Mucosa of tongue, lips, buccal cavity; perlèche; no skin or nail involvement	None	Esophagitis	Denture stomatitis is a variant
Chronic candidiasis with endocrinopathy (APECED)	Autosomal recessive	Childhood	Mucous membranes, skin, and/or nails	Frequent (hypoadrenalism, hypothyroidism, hypoparathyroidism, or polyendocrinopathy)	Alopecia totalis, thyroiditis, vitiligo, chronic hepatitis, pernicious anemia, gonadal failure, malabsorption, diabetes mellitus	Endocrinopathy may be delayed in onset
Chronic candidiasis without endocrinopathy	Autosomal recessive	Childhood	Mucous membranes, perlèche, and nail involvement; less common skin involvement	None	Blepharitis, esophagitis, laryngitis	–
	Autosomal dominant	Childhood		None	Dermatophytosis, loss of teeth, recurrent viral infections	–
Chronic localized mucocutaneous candidiasis	Sporadic	Childhood	Mucous membranes, skin, and/or nails	Occasionally	Pulmonary infections, esophagitis	Hyperkeratotic lesions (*Candida*), granuloma
Chronic diffuse candidiasis	Autosomal recessive	Childhood	Widespread on mucous membranes, skin and nail involvement	None	–	Erythematous, serpiginous skin lesions
		Adolescence	Widespread on mucous membranes, skin and nail involvement	None	History of frequent course of antibiotics	–
Chronic candidiasis with thymoma	Sporadic	Adulthood (after third decade)	Mucous membranes, nails, and skin	None	Thymoma, myasthenia gravis, aplastic anemia, neutropenia, hypogammaglobulinemia	Chronic mucocutaneous candidiasis often precedes diagnosis of thymoma

Figure 189-8 Mucocutaneous candidiasis. Well-demarcated serpiginous lesions with massive scaling. Lesions look like psoriasis.

Figure 189-9 Invasive candidiasis with candidemia. Multiple erythematous papules on the hand of a febrile patient with granulocytopenia associated with treatment of acute myelogenous leukemia. The usual source of the infection is the gastrointestinal tract. *Candida tropicalis* was isolated on blood culture. Candidal forms were seen in lesional skin biopsy specimens.

candidal infections cause oral thrush, diaper dermatitis, angular cheilitis (perlèche), lip fissures, nail and paronychial involvement, vulvovaginitis, and cutaneous involvement. The cutaneous eruption may appear with an erythematous, serpiginous border, or areas of brownish desquamation on a background of mild erythema (Fig. 189-8). Nail involvement is characterized by markedly thickened and dystrophic nail plates in which the entire thickness is invaded by *Candida*. The paronychial folds are red and edematous, there may be pus, and the fingertips are often bulbous (Fig. 189-7B).

DISSEMINATED CANDIDIASIS

The incidence of disseminated candidiasis is steadily rising as the prevalence of immunosuppressed patients with longer life spans has also increased. The responsible organisms, *C. albicans, C. tropicalis, C. glabrata,* and *C. parapsilosis,*[35] gain hematogenous access from the oropharynx or gastrointestinal tract when mucosal barrier function is compromised (e.g., by mucositis secondary to chemotherapy), or when intravenous catheters become contaminated. Multiple organ systems including gastrointestinal and respiratory may become involved.[36] Recognition of a candidal eruption in the context of disseminated infection may be important to early diagnosis, as ante-mortem blood cultures are negative in a high percentage of patients with autopsy-proven systemic candidiasis.[36] Approximately 10% of patients with disseminated candidiasis develop metastatic 0.5–1.0-cm nontender erythematous papules with a hemorrhagic or pustular center (Fig. 189-9) over the trunk and extremities associated with fever and myalgias.[37] Some papules may be necrotic in appearance. The differential diagnosis for disseminated candidiasis is provided in Box 189-3.

LABORATORY FINDINGS

Direct microscopic examination of specimens for the presence of yeast or isolation of yeast in culture confirms infection. In superficial candidal infections, the diagnosis can be confirmed by microscopic examination skin scrapings or smears obtained from skin, nails, or mucosal surfaces that reveal hyphae, pseudohyphae, or budding yeast cells (Fig. 189-2). Potassium hydroxide smear, or Gram or methylene blue

BOX 189-3 DIFFERENTIAL DIAGNOSIS OF DISSEMINATED CANDIDIASIS

Most Likely

- Bacterial sepsis (e.g., gonococcal, meningococcal, staphylococcal)

Consider

- Pityrosporum folliculitis
- Miliaria
- Deep fungal infections (e.g., cryptococcosis, Torulopsis, or sporotrichosis)

Always Rule Out

- Disseminated fungal infections (e.g., aspergillosis)
- Disseminated Varicella Zoster or Herpes infections

stain is useful for direct demonstration of fungal cells. Cultures from affected nails may help identify the etiologic agent responsible for onychomycosis (dermatophyte vs. yeast). *C. albicans* readily produce whitish mucoid colonies within 2–5 days on Sabouraud's agar with added antibiotics.

In systemic candidiasis associated with an eruption, the diagnosis may be confirmed from histopathologic examination and tissue culture of lesional skin. Blood cultures are positive in only 50%–60% of cases of disseminated infection.[35] Serologic studies using immunodiffusion, counterimmunoelectrophoresis, and latex agglutination methods are fraught with false-negative and false-positive reactions which limit their utility in confirming diagnosis. Newer techniques to detect circulating candidal antigens (e.g., mannan or enolase) or metabolic products (e.g., arabinitol) show improved sensitivities and specificities in serial testing.[38] Specifically, the serum (1,3)β-D-glucan detection assay (Glucatell, Fungitell) is a nonculture assay that measures level of β-glucan, a component of the fungal cell wall. In a large multicenter study, the assay yielded high sensitivity (75%–100%), specificity (88%–100%) and positive predictive value with highly reproducible results.[39]

MICROSCOPIC STUDIES

Since *Candida* sp. may infect virtually any organ system, specimens for laboratory examination will vary from body fluids to tissue samples. Direct microscopic examination of scrapings from mucosa, skin or nails for the presence of yeast provides bedside evidence to support the clinical diagnosis. Body fluids such as urine and cerebrospinal fluid should be centrifuged and the sediment examined directly to increase the probability of detecting yeast. Specimens must be treated with a clearing agent such as 10% KOH and ink before the material is examined. *Candida* appears as oval budding cells, elongated filamentous cells connected end-to-end (pseudohyphae), or septate hyphae (Fig. 189-2).

PATHOLOGY

Superficial candidiasis is characterized by subcorneal pustules on histopathological examination. Organisms are seldom seen within the pustules but rather are highlighted in the stratum corneum with periodic acid-Schiff (PAS) staining. Examination of a candidal granuloma shows marked papillomatosis and hyperkeratosis and a dense dermal infiltrate consisting of lymphocytes, granulocytes, plasma cells, and multinucleated giant cells. In systemic candidiasis with skin involvement, foci of yeast are observed in the dermis and within dermal vessels. Organisms are identified using PAS, methenamine silver, or methylene blue stains.

TREATMENT

Treatments used to manage *Candida* infections may vary based on species of *Candida* responsible for infection, sensitivity to specific antifungal drugs, anatomic location of infection, underlying disease, and immune status of the patient.

Guidelines in the management of candidiasis were updated in 2009 by the Infectious Disease Society of America.[40] These guidelines include recommendations on the appropriate use of echinocandins, caspofungin, micafungin, and anidulafungin, along with voriconazole and posaconazole, as well as lipid formulations of amphotericin B. Fluconazole is still considered a first-line agent in nonneutropenic patients with candidemia or suspected to have invasive candidiasis. Therapeutic options in the management of invasive candidiasis and candidemia include triazoles as well as newer agents such as echinocandins.[41,42] A brief discussion on the treatment of candidal infections is included herein. For a detailed review on current therapeutic strategies, please refer to Chapter 232.

ORAL CANDIDIASIS. Uncomplicated oral candidiasis may be treated with nystatin suspension 400,000–600,000 units four times per day, or clotrimazole troches 10 mg dissolved in the mouth five times per day. For recurrent cases, oral azoles (see Chapter 232) are proven to be more effective.

CANDIDAL VULVOVAGINITIS AND BALANITIS. Two therapeutic approaches exist when considering treatment for candidal vaginitis. Topical imidazole preparations available over the counter, such as butoconazole, miconazole, and clotrimazole, as well as those available by prescription, including tioconazole, econazole, and terconazole are easy to use and effective over 3–7 days of treatment.[24] These agents are also safe to use during pregnancy.[43] Oral fluconazole, itraconazole, and ketoconazole offer efficacy similar to that of topical therapy (see Chapter 219). Prophylactic regimens to prevent recurrences include weekly clotrimazole 500-mg tablet used intravaginally or fluconazole 150 mg/week orally.[24] The recommended treatment for candidal balanitis is topical clotrimazole cream or a single oral 150-mg dose of fluconazole.

CUTANEOUS. Candidal intertrigo has been treated successfully with topical antifungals (e.g., clotrimazole, econazole, ciclopirox, miconazole, ketoconazole, and nystatin). Powder preparations also keep dry otherwise moist environments that facilitate candidal infections. Systemic antifungal therapy is recommended for extensive cutaneous infections, follicular involvement, or infections in immunocompromised patients.

CANDIDAL PARONYCHIA. Chronic paronychia due to *Candida* is often resistant to therapy. The most important aspects of therapy include minimizing contributing factors such as water exposures, as well as drainage of any abscess. Topical imidazole in solution form should be considered initially.[26] Four percent thymol in ethyl alcohol (compounded by the pharmacy, as it is not commercially available) is drying to candida, and thus may be a suitable alternative. Oral azoles may also be used in otherwise refractory cases.[29]

CANDIDAL ONYCHOMYCOSIS. Oral itraconazole or fluconazole (triazoles) appear to be most efficacious for candidal onychomycosis. Two treatment regimens are available: the daily dose or pulsed-dose regimen. Itraconazole, which is approved for use for onychomycosis in the United States, may be administered at 200 mg daily for 6 weeks for fingernails and for 12 weeks for toenails. It may also be administered in pulse therapy, 200 mg twice daily for 1 week per month, for a total of two pulses for fingernails and three pulses for toenails.[44]

DISSEMINATED CANDIDIASIS. Amphotericin B, available in newer lipid-based formulations, as well as caspofungin are effective in treating disseminated candidiasis (see Chapter 232).[45]

CHRONIC MUCOCUTANEOUS CANDIDIASIS. Oral azoles are first line agents in the treatment of CMC. Regimens include fluconazole 100–400 mg/d or itraconazole 200–600 mg/d used until there is clinical improvement. Initial therapy for acute infection should always be followed by maintenance therapy with the same azole for life.

PITYROSPORUM INFECTIONS OF THE SKIN: TINEA VERSICOLOR AND *PITYROSPORUM* FOLLICULITIS

The genus *Malassezia*, formerly known as *Pityrosporum*, currently includes twelve species of lipophilic basidiomycetous yeast: *Malassezia furfur*, *Malassezia pachydermatis*, *Malassezia sympodialis*, *Malassezia globosa*, *Malassezia restricta*, *Malassezia slooffiae*, *Malassezia obtusa*, *Malassezia dermatitis*, *Malassezia nana*,[46] *Malassezia yamatoensis*,[47] *Malassezia japonica*,[48] and *Malassezia equi*.[49,50] In 1996, a new taxonomic classification [51] based specifically on morphologic, physiologic and ultrastructural features detected by molecular techniques allowed for the addition of several new species to the *Malassezia* genus.

The species of *Malassezia* may be differentiated by their nutritional requirements, morphology, and molecular biology.[49,51] All *Malassezia* species require lipids for growth, because with the exception of *M. pachydermatis* which has the ability to produce phospholipase, they do not synthesize C14–C16 saturated fatty acids.[52] Although previously recognized as a zoophilic organism, *M. pachydermatis* has been identified only recently as a human pathogen. In one study, the organism caused a series of infections in a neonatal care nursery, where *M. pachydermatis* was presumably spread to patients from health care workers whose pet dogs were colonized with the fungus.[53] It was later shown that the vast majority of dog owners tested positive for *M. pachydermatis* on their hands.[54] Other members of the genus, including *M. sympodialis* and *M. slooffiae*, are part of the normal skin flora.[55] A few studies also linked *M. sympodialis* with neonatal cephalic pustulosis, also known as neonatal acne.[56,57]

Cutaneous infections with *Malassezia* take two main primary forms: (1) pityriasis versicolor and (2) *pityrosporum* folliculitis. However, *Malassezia* may also play some role in the course of other common skin diseases such as seborrheic dermatitis, atopic dermatitis, and psoriasis.[49,58]

TINEA (PITYRIASIS) VERSICOLOR

EPIDEMIOLOGY. The prevalence of tinea versicolor in the United States is estimated to be 2%–8% of the population. The infection occurs more frequently in regions with higher temperatures and relative humidity. Tinea versicolor has a worldwide prevalence of up to 50% in the hot and humid environments and as low as 1.1% in colder climates.

Incidence of tinea versicolor is the same in all races, but the eruption is often more apparent in darker-skinned individuals due to resulting alteration in skin pigmentation. No sex predominance is apparent. Tinea versicolor is most common among adolescents and young adults, in whom lipid-producing sebaceous glands are more active.

Etiology and Pathogenesis. *M. furfur* can be cultured from both affected and normal skin and is considered part of the normal flora, particularly in sebum-rich areas of the body.[59] Experimental inoculation of *Malassezia* under occlusion has resulted in infection.[59] The resulting increase in humidity, temperature and CO_2 tension appear to be important factors contributing to infection.[60] While removal of occlusion promotes healing of the eruption, the organism may still be cultured from clinically uninvolved areas.[60] Furthermore, this colonization of follicular structures facilitates a high recurrence rate.

M. furfur is a dimorphic, lipophilic organism that grows in vitro only with the addition of C12–C14 fatty acids such as olive oil and lanolin. Under appropriate conditions, it converts from the saprophytic yeast to the predominantly parasitic mycelial form, which causes clinical disease. Factors predisposing to mycelial transition include a warm, humid environment, hyperhidrosis, oral contraceptive, and systemic corticosteroid use, Cushing's disease, immunosuppression, and a malnourished state.[59,61]

The yeast may filter natural sunlight and interfere with normal tanning.[62] Mayser et al discussed a specific compound synthesized by *Malassezia* called *pityriacitrin* that absorbs ultraviolet light.[63] Other metabolites of *M. furfur* are listed on Box 189-4. Specifically, via lipases *Malassezia* metabolizes various fatty acids such as arachidonic or vaccenic acids and subsequently releases azelaic acid as one of the metabolites. Azelaic acid inhibits the action of the tyrosinase in the melanin production pathway, which results in persistent hypopigmentation of affected skin for months, and sometimes years.[64] This hypopigmentation may be accentuated further in summer months if surrounding unaffected skin becomes tan.

While *M. furfur* had long been identified as the fungus causing tinea versicolor, *M. globosa* is now thought

BOX 189-4 *MALASSEZIA* FURFUR METABOLITES

Azelaic acid: a dicarboxylic acid that inhibits tyrosinase
Malassezin: an aryl hydrocarbon receptor agonist that induces apoptosis in melanocytes
Pityriacitrin: a yellow compound that absorbs UV light
Pityrialactone: an indole alkaloid (tryptophan derivative) that fluoresces under 366 nm UV light
Pityriarubins: red indole alkaloids that inhibit the neutrophil respiratory burst in vitro in a dose dependent manner and inhibit 5-lipoxygenase activity

to be the predominant species involved in its pathogenesis.[65]

CLINICAL FINDINGS

The typical presentation of tinea versicolor is scaly oval to round macules scattered over characteristic areas of the body, including the upper trunk, neck, and upper arms (Fig. 189-10). The macules often coalesce forming irregular shaped patches of pigmentary alteration. The color of patches varies from almost white to pink to reddish brown or fawn colored (Fig. 189-10C). The scale is characteristically described as dust-like or furfuraceous (Fig. 189-10D). Extensive scaling can be produced by lightly scraping a #15 scalpel blade over the involved skin.[66] Patches may have a wrinkled surface appearance (Fig. 189-11) and this feature serves as a useful clinical pearl for the diagnosis. The presenting concern often relates to the cosmetic appearance of the eruption rather than any symptoms, since pruritus is usually mild or absent. The diagnosis made on clinical grounds is supported by Wood's light (365 nm) examination which may show yellow–orange fluorescence thought to be due to the presence of pteridine and is confirmed by microscopic KOH examination of the scale. Tinea versicolor tends to recur in warmer months of the year.

An inverse form of tinea versicolor is encountered predominantly in flexural areas.[67] These sharply demarcated confluent pink erythematous patches may be confused with inverse psoriasis, seborrheic dermatitis, erythrasma, candidiasis, and dermatophytic infections. The differential diagnosis of tinea versicolor is presented in Box 189-5.

LABORATORY TESTS

Potassium hydroxide (KOH) preparation of skin scrapings demonstrates the characteristic fungal spores and short cigar-butt hyphae ("spaghetti and meatballs"). Visualization of fungal elements may be enhanced by the addition of methylene blue stain to the KOH preparation. Culture is rarely necessary and requires a lipid-containing medium (i.e., olive oil) to demonstrate growth.

BOX 189-5 DIFFERENTIAL DIAGNOSIS OF TINEA VERSICOLOR

Most Likely
- Pityriasis alba
- Pityriasis rosea
- Seborrheic dermatitis
- Dermatophyte infections

Consider
- Erythrasma
- Vitiligo
- Psoriasis
- Pityriasis rubra pilaris
- Confluent and Reticulated Papillomatosis of Gougerot and Carteaud

Always Rule Out
- Secondary syphilis
- Hypopigmented mycosis fungoides

PATHOLOGY

While the yeast may be identified with hematoxylin and eosin staining alone, visualization is enhanced through PAS stain. Microscopic examination reveals clusters of oval budding yeast cells 3.5 × 4.5 µm long with short, septate, and occasionally branching hyphae (Fig. 189-12) inhabiting the stratum corneum.

DIAGNOSIS. The clinical appearance of tinea versicolor is usually characteristic, and KOH examination is confirmatory. A Wood's lamp examination may show orange–yellowish fluorescence of involved skin, suspected to be a due to pteridine. In some cases, however, the eruption may appear darker, rather than more fluorescent, than unaffected skin under the Wood's light.

Treatment

Tinea Versicolor. Several topical agents are useful in treating tinea versicolor, and these include selenium sulfide, zinc pyrithione, sodium sulfacetamide,[68] ciclopiroxolamine,[69] as well as azole[70] and allylamine antifungal preparations.

A widely used and inexpensive protocol involves using selenium sulfide lotion 2.5%, which is applied liberally to affected areas for 7–10 minutes prior to rinsing. While daily use may be considered for extensive cases, application 3–4 times per week is adequate, and this frequency may be tapered further to once or twice monthly and used as a maintenance regimen to prevent recurrences. Alternatively, ketoconazole shampoo 2% is lathered on to affected areas and left for 5 minutes prior to rinsing; this treatment is repeated for three consecutive days.[71] Terbinafine solution 1% applied twice daily to affected areas for 7 days has yielded cure rates of more than 80%.[72]

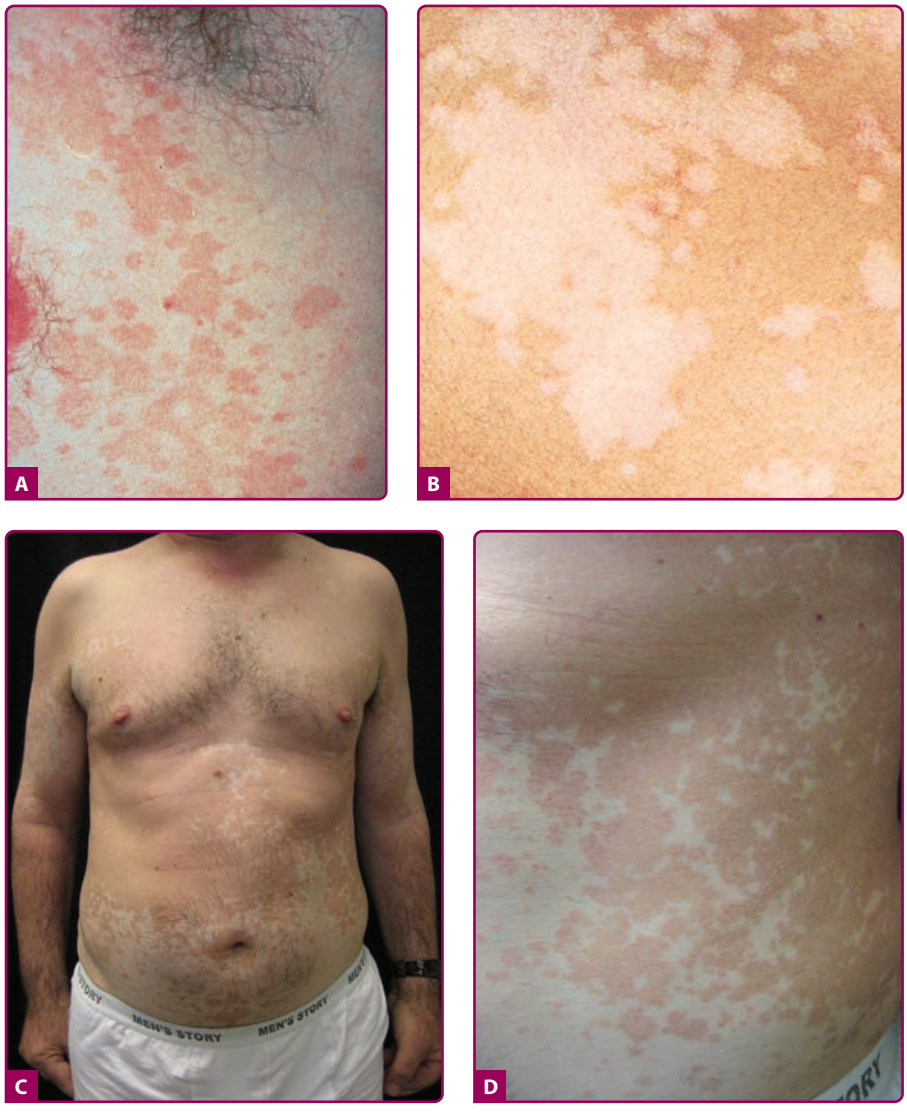

Figure 189-10 Pityriasis (tinea) versicolor. **A.** These lesions are darker because of hyperemia secondary to inflammatory response and increased melanin. **B.** There are sharply marginated, uniformly hypopigmented macules with fine, sometimes barely perceptible scales, which are easily scraped off with a glass slide. When the lesions are very large, as on the left, they can be confused with vitiligo. **C.** Salmon-colored finely scaled macules coalescing into large patches. **D.** Fine, dust-like scale seen on closeup.

Figure 189-11 Pityriasis (tinea) versicolor. Macules and patches may have a wrinkled surface appearance.

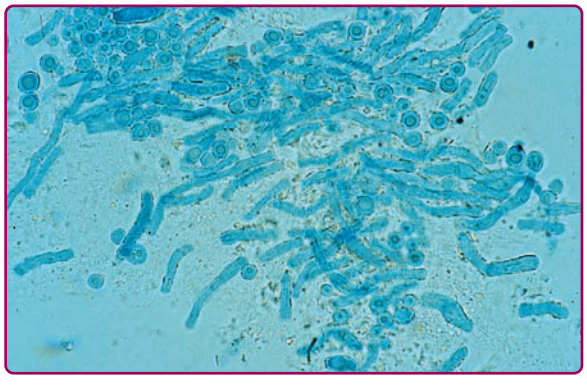

Figure 189-12 "Spaghetti and meatballs" appearance of *Malassezia* in a KOH preparation.

Although topical therapy is ideal for localized or mild infections, systemic treatment may be necessary for patients with extensive disease, frequent recurrences, or for whom topical agents have failed.[73] Ketoconazole, fluconazole, and itraconazole are the preferred oral agents, and various dosing regimens are effective.[74] Oral ketoconazole 200 mg daily for 7 or 10 days, or oral itraconazole 200–400 mg daily for 3–7 days is almost universally effective.[75–76] Oral ketoconazole administered as a single 400 mg dose is an easy to use regimen with comparable results.[75] Similarly, a single dose of oral itraconazole 400 mg has been shown to be more than 75% effective, and in one study, just as effective as itraconazole given for 1 week.[77] Fluconazole is also effective when administered as a single oral dose of 400 mg.[78] Oral terbinafine, an allylamine, is not recommended in the treatment of *Malassezia* related disorders, since the drug is not delivered efficiently to the skin's surface. The potential for drug toxicity and interactions via the influence of azoles on cytochrome p450 isoenzyme activity should be addressed when considering the use of oral azole agents to treat tinea versicolor.[79]

Prevention. Recurrence is common and regular maintenance application of any of the topical agents helps to reduce high rates of recurrence. While the condition does not leave any permanent scar or pigmentary changes, skin tone may take several months to return to normal. Prevention of recurrences is helpful in limiting long-lasting dyschromia. A regimen of one tablet a month of ketoconazole, fluconazole, and itraconazole has been used successfully to prevent recurrences.[80]

PITYROSPORUM (*MALASSEZIA*) FOLLICULITIS

EPIDEMIOLOGY. *Malassezia* organisms are observed as skin flora in 75%–98% of healthy people. Colonization by *M. furfur* begins soon after birth and peaks during adolescence and young adulthood, concomitant with an increase in sebaceous gland activity. No known racial or gender differences exist. Those living in warm and humid climates have higher incidences of *Malassezia* folliculitis.[81]

Etiology and Pathogenesis. *Malassezia* yeasts are classified as superficial mycoses that by definition do not invade past the cornified epithelium. However, in *Pityrosporum* folliculitis, follicular ostia, and central and deep segments of the hair follicle are involved by *Malassezia*, most commonly *M furfur*.[82]

Clinical Features. The chronic pruritic eruption of *Malassezia (Pityrosporum)* folliculitis appears as numerous monomorphic 2–4 mm follicular papules and papulopustules with perifollicular erythema on the upper trunk, neck, and upper arms of young and middle-aged adults (Fig. 189-13A). Some may have concomitant seborrheic dermatitis or tinea versicolor, and there have also been cases of associated recalcitrant acne vulgaris.[83] KOH examination or culture may be required to distinguish this infection from the more common bacterial folliculitis. On occasion, histologic evaluation via skin biopsy may be necessary for diagnosis. Routine staining with hematoxylin and eosin may identify organisms, although *Malassezia* may be more easily visualized through PAS stain (Fig. 189-13B). Systemic diseases and pharmacologic agents that hasten growth of yeast, possibly through alterations in host immunity, facilitate infections of hair follicles. Some of these risk factors include pregnancy, diabetes mellitus, Hodgkin disease,[84] cancer treated with epidermal growth factor receptor inhibitors,[85] HIV infection, and therapy with oral antibiotics, corticosteroids and/or immunosuppressants. Other contributing factors include high heat and humidity and occlusion of the skin and hair follicles with cosmetics, lotions, sunscreens, emollients, olive oil, or clothing.[86] As in the case of pityriasis versicolor, recurrence of *Malassezia* folliculitis is common. See Box 189-6 for the differential diagnosis of *Malassezia* folliculitis.

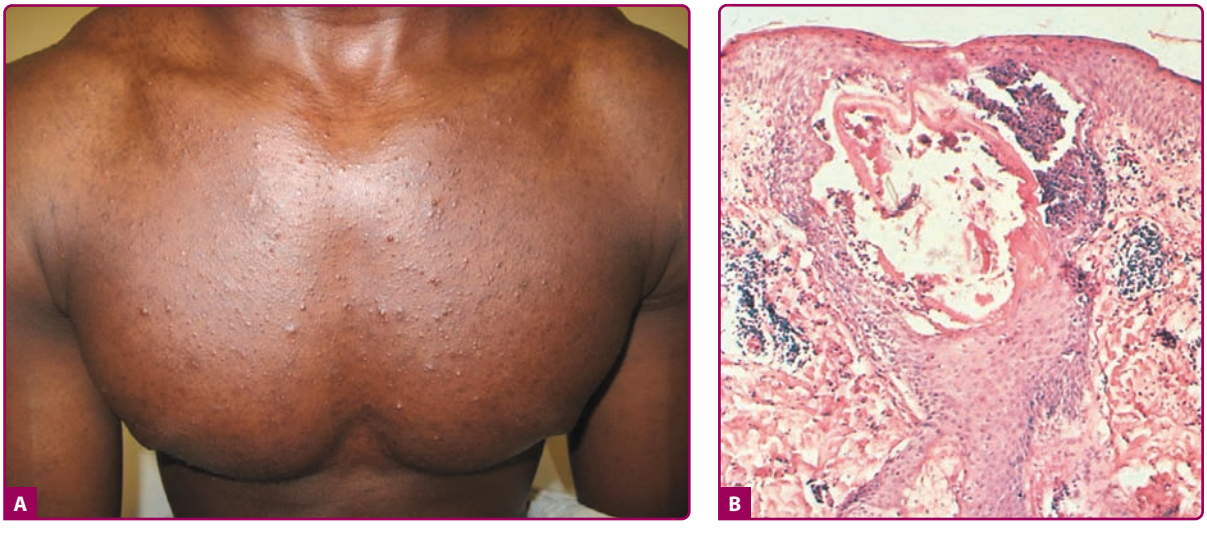

Figure 189-13 **A.** *Pityrosporum* folliculitis on the anterior chest. **B.** Histopathology. Note the organisms in the follicular ostia on staining with hematoxylin and eosin.

BOX 189-6 DIFFERENTIAL DIAGNOSIS OF *PITYROSPORUM* FOLLICULITIS

Most Likely
- Acne vulgaris
- Bacterial folliculitis

Consider
- Candidal folliculitis
- Eosinophilic folliculitis
- Steroid folliculitis

Always Rule Out
- Disseminated candidiasis
- Pustular drug eruption

Laboratory Findings. To identify the *Malassezia* yeast forms, scale from involved skin should be scraped with a #15 scalpel blade onto a glass slide and treated with 10% KOH. Alternatively, cellophane tape used to pick up scales from the skin may be mounted on a glass slide with methylene blue that selectively stains the organisms.[87] The microscopic appearance of the yeast is classically described as "spaghetti and meatballs" (Fig. 189-12), with fungal spores and short cigar-butt pseudohyphae.

Pathology. *Malassezia* organisms are noted in dilated follicular units, which may show keratin plugging and cellular debris (Fig. 189-10B). Staining with PAS or methenamine silver will reveal the oval single-budding yeast. When follicular walls rupture, there is a resulting mixed inflammatory infiltrate of lymphocytes, histiocytes, and neutrophils surrounding follicles. Microscopic examination of pustules usually shows budding yeast forms and spores, not hyphae.

Diagnosis. Diagnosis of *Malassezia* folliculitis is made on clinical grounds, and confirmed by KOH examination of scrapings. Skin biopsy is rarely necessary to make the diagnosis.

Treatment and Prognosis

***Malassezia* Folliculitis.** Both topical and oral antifungal agents are effective agents in the treatment of *Malassezia* folliculitis and are commonly combined to hasten resolution and maintain clearance. Topical regimens include daily use of ketoconazole shampoo 2%, selenium sulfide lotion 2.5%, and ciclopirox olamine cream 0.77%. There are limited data on the use of systemic agents in treating *Malassezia* folliculitis. Commonly used regimens include oral ketoconazole 200 mg daily for 4 weeks, fluconazole 150 mg weekly for 2–4 weeks, and itraconazole 200 mg daily for 2 weeks.[49,87] Oral terbinafine is not recommended in the treatment of *Malassezia* related disorders, since the drug is not delivered efficiently to the skin's surface.

PREVENTION

Recurrence is common. Because relapses almost always occur after treatment is complete, topical agents are continued indefinitely at reduced frequency as a preventative measure. Topical protocols used in the prevention of *Malassezia* folliculitis include selenium sulfide 2.5% lotion once weekly, ketoconazole 2% cream once weekly, and ketoconazole 2% shampoo 2–3 times weekly. Maintenance therapies with systemic agents include oral itraconazole 400 mg once monthly and oral fluconazole 200 mg once monthly.

Chapter 190 :: Deep Fungal Infections

:: Roderick J. Hay

Deep fungal infections comprise two distinct groups of conditions, the subcutaneous and systemic mycoses. Neither are common, and the subcutaneous mycoses, with some exceptions, are largely confined to the tropics and subtropics. In recent years, the systemic mycoses have become important opportunistic infectious complications in immunocompromised patients, including those with acquired immunodeficiency syndrome (AIDS) and patients receiving treatment for malignancies. They also include a group of primary respiratory infections, such as histoplasmosis and coccidioidomycosis, which may affect otherwise healthy individuals and those with underlying illness. The fungi that cause these respiratory infections are usually dimorphic or exist in a different morphologic phase (e.g., yeast or mold) at different stages of their life cycle.

Patients with subcutaneous fungal infections often present to a physician with signs of skin involvement. By contrast, patients with systemic mycoses only occasionally have skin lesions, either following direct involvement of the skin as a portal of entry or after dissemination from a deep focus of infection. There are a number of excellent texts about fungi and the diseases they cause.[1–4]

Treatment of these conditions remains difficult in many cases, although there is now a wide range of antifungal drugs with different modes of action.

SUBCUTANEOUS MYCOSES

SUBCUTANEOUS MYCOSES AT A GLANCE

- Are usually sporadic.
- Are contracted in the tropics and subtropics.
- May cause chronic disability.
- Are best diagnosed by histopathology, except for sporotrichosis.
- Often require months of successful antifungal treatment.

The subcutaneous mycoses, or mycoses of implantation, are infections caused by fungi that have been introduced directly into the dermis or subcutaneous tissue through a penetrating injury, such as a thorn prick. Although many are tropical infections, others, such as sporotrichosis, are also prevalent in temperate climates; any of these infections may present as an imported disease in a patient who has originated from an endemic area, sometimes after a lapse of many years. The most common subcutaneous mycoses are sporotrichosis, mycetoma, and chromoblastomycosis. Rarer infections include lobomycosis and subcutaneous zygomycosis.

SPOROTRICHOSIS

Sporotrichosis is a subcutaneous or systemic fungal infection caused by the dimorphic fungus *Sporothrix schenckii*.[5,6] The fungus occurs in the natural environment, presumably in mold (cells growing in a chain) form, but develops as a yeast (cells growing as single cells) in infections. The most frequent site of this infection is the dermis or subcutis. There is also a systemic form of sporotrichosis whose clinical features range from pulmonary infection to arthritis or meningitis. One important characteristic of the diagnosis of cutaneous lesions is the scarcity of organisms in tissue, making confirmation of the diagnosis by microscopy potentially difficult.[6] Sometimes in tissue, fungal cells are surrounded by an eosinophilic refractile fringe, the asteroid body, that is a characteristic of the organism, although a similar phenomenon may occur with other infectious organisms (e.g., Schistosome eggs).

EPIDEMIOLOGY. Infections occur in both temperate and tropical countries. They are seen in North, South, and Central America, including the Southern United States and Mexico, as well as in Africa, Egypt, Japan, and Australia.[6] The countries where the highest rates of infection occur are Mexico, Brazil, and South Africa. However, sometimes hyperendemic areas are found where large numbers of cases occur.[7] In the United States, infections are most common in the Midwestern river valleys. Infections are now rare in much of Europe. In nature, the fungus grows on decaying vegetable matter such as plant debris, leaves, and wood. Although it is usually a cause of sporadic infection, *S. schenckii* also may affect groups of workers exposed to the organism, such as those using straw as a packing material, gardeners, forestry workers, and those whose recreational activities bring them into contact with plant debris. A recent outbreak of sporotrichosis in Brazil has accentuated the role of exposure to other courses of infection, in this case domestic or feral cats. The organism is thought to be introduced into the skin through a local injury.

CLINICAL FINDINGS. The two clinical varieties of sporotrichosis are the subcutaneous and systemic forms of disease.[5,8,9] Subcutaneous sporotrichosis is by far the more common and includes two main forms: (1) lymphangitic and (2) fixed infections. The lymphangitic form is the more common and usually develops on exposed skin sites such as hands or feet. The first

Figure 190-1 Sporotrichosis. An ulcerated nodule is seen on the thumb, with proximal lymphangitic spread represented by subcutaneous nodules. (Used with permission from Takeji Nishikawa, MD.)

sign of infection is the appearance of a dermal nodule that breaks down into a small ulcer. Draining lymphatics become inflamed and swollen, and a chain of soft secondary nodules develops along the course of the lymphatic (Fig. 190-1); these also may break down and ulcerate. In the fixed variety, which accounts for about 15% of cases, the infection remains localized to one site, such as the face, and a granuloma develops that subsequently may ulcerate. Satellite nodules or ulcers may form around the rim of the primary lesion. Other clinical variants of subcutaneous sporotrichosis may mimic mycetoma, lupus vulgaris, and chronic venous ulceration. In some cases, deep extension of the infection may affect joints or tendon sheaths. Patients with AIDS who develop sporotrichosis often have multiple cutaneous lesions[9] without prominent lymphatic involvement, but deep infections, such as arthritis, are also reported.

In the much rarer systemic form of sporotrichosis, lesions can develop almost anywhere, although chronic lung nodules, with cavitation, arthritis, and meningitis have been described most frequently. These may coexist with cutaneous lesions of sporotrichosis.

DIFFERENTIAL DIAGNOSIS. Conditions commonly confused with sporotrichosis are mycobacterial (see Chapter 184) and primary cutaneous *Nocardia* infections (see Chapter 185) and leishmaniasis (see Chapter 206). The nontuberculous mycobacterial infection due to *Mycobacterium marinum* (fish-tank granuloma), in particular, closely resembles lymphangitic sporotrichosis.

LABORATORY TESTS. The best sources of diagnostic material are smears, exudates, and biopsies. *S. schenckii* is seen very rarely in direct microscopic examination because yeasts are usually present only in small numbers; the organism can be isolated readily on Sabouraud's agar. In primary culture, the fungus grows as a mold, with compact, white colonies that darken with age. Microscopically, the hyphae produce small oval or triangular conidia either on specialized hyphae or elsewhere on the mycelium. Ideally, the organism should be converted to yeast phase on enriched media such as brain-heart infusion agar at 37°C (98.6°F) to complete the identification.

Pathologically, sporotrichosis causes a mixed granulomatous reaction with neutrophil microabscesses. The fungus, if present, is usually in the form of small (3–5 μm) cigar-shaped or oval yeasts that may, on occasion, be surrounded by a thick, radiating eosinophilic fringe forming the distinctive asteroid body. Organisms are usually sparsely distributed in lesions, and it may be necessary to scan several sections to identify a single yeast. An intradermal sporotrichin skin test is available in some countries and may have a role to play in allowing the physician to identify the most appropriate laboratory investigations to instigate.

TREATMENT. Although spontaneous remissions may occur, most patients are treated with antifungal chemotherapy.[10] Treatments include itraconazole, 200 mg daily, and terbinafine, 250 mg daily, which are better tolerated, and intravenous amphotericin B for deep infection; at present there has been little experience with voriconazole or posaconazole. In all cases, treatment is continued for at least 1 week after clinical resolution. A cheaper alternative is potassium iodide (saturated solution), 4–6 mL tid, which is effective in the cutaneous types of sporotrichosis and should be continued for 3–4 weeks after clinical cure. The daily dose is built up slowly from 1 mL tid over 2–3 weeks to avoid side effects such as hypersalivation and nausea. This is an inexpensive form of therapy, but it is unpalatable.

MYCETOMA (MADUROMYCOSIS, MADURA FOOT)

Mycetoma is a chronic localized infection caused by different species of fungi or actinomycetes. It is characterized by the formation of aggregates of the causative organisms, known as *grains* that are found within abscesses. These either drain via sinuses onto the skin surface or involve adjacent bone, causing a form of osteomyelitis. Grains are discharged onto the skin surface via these sinuses. The disease advances by direct spread, and distant metastatic sites of infection are very rare. Mycetomas caused by species of fungi are known as *eumycetomas*, and those caused by aerobic actinomycetes or filamentous bacteria are known as *actinomycetomas* (see Chapter 185). The organisms are usually soil or plant saprophytes[11] that are only incidental human pathogens.

EPIDEMIOLOGY. Mycetomas are mainly, but not exclusively, found in the dry tropics where there is low annual rainfall.[11,12] They are sporadic infections that are seldom common, even in endemic areas.[13] Occasionally, nonimported cases are reported from temperate climates, although in these cases, the most common organism is *Scedosporium apiospermum*. Actinomycetomas due to *Nocardia* sp. are most common in Central America and Mexico. In other

parts of the world, the most common organism is a fungus, *Madurella mycetomatis*. The actinomycete *Streptomyces somaliensis* is isolated most often from patients originating from Sudan and the Middle East. The causative organisms of mycetoma have been isolated or detected by molecular methods from either soil or plant material, including Acacia thorns, in endemic areas.

The organisms are implanted subcutaneously, usually after a penetrating injury. It is unusual to find any underlying predisposition in patients with mycetoma, and the persistence of the organism after the initial inoculation appears to be related to its ability to evade host defenses through a variety of adaptations such as cell wall thickening and melanin deposition.[14]

CLINICAL FINDINGS. The clinical features of both fungal and actinomycete mycetomas are very similar.[12] They are most common on the foot, lower leg, or hand, although head or back involvement also may occur. Infection of the chest wall is most characteristic of *Nocardia* infections (see Chapter 185). The earliest stage of infection is a firm, painless nodule that spreads slowly with the development of papules and draining sinus tracts over the surface (Fig. 190-2). Local tissue swelling, chronic sinus formation, and later bone involvement distort and deform the original site of infection (Figs. 190-3 and 190-4). Lesions are seldom painful except in the late stages and where sinus tracts are about to emerge onto the skin surface. Dissemination from the initial site is exceptionally rare, although local lymphadenopathy may occur.

X-ray changes include periosteal erosion and proliferation, as well as the development of lytic lesions in the bone. Bone scans or magnetic resonance imaging may identify bone lesions at an earlier stage.

Figure 190-2 Mycetoma. Brawny edema and crusted papules on the plantar surface.

Figure 190-3 Eumycetoma caused by *Scedosporium* leading to significant distortion of the forefoot.

DIFFERENTIAL DIAGNOSIS. Chronic bacterial or tuberculous osteomyelitis may resemble mycetoma. Actinomycosis (see Chapter 185) is also similar but usually develops close to certain sites, such as the mouth or the cecum, where the causative organisms are sometimes commensal.

LABORATORY TESTS. Finding the mycetoma grains is the key to establishing the diagnosis, and these are generally discharged from the openings of sinus tracts. However, they may also be obtained by removing the surface crust from a pustule or sinus tract with a sterile needle and gently squeezing the edges. Grains are 250–1,000-µm white, black, or red particles that can be picked out with the naked eye (Table 190-1). Direct microscopy of grains is important because it will show whether the grain is composed of the small actinomycete or broader fungal filaments. In general, it is not possible to distinguish the fine actinomycete filaments in potassium hydroxide (KOH) mounts or, for that matter, in hematoxylin and eosin-stained material. In addition, black grains are always caused by fungi; red grains, by actinomycetes (see Table 190-1).

Final identification requires isolation of the causal agent in culture. In view of the number of possible species, a series of different culture media and conditions of incubation should be used. Morphologic and physiologic characteristics are used to distinguish between the genera and species. There are now a few examples where the organism has been identified using specific primers through use of the polymerase chain reaction. Serology is diagnostically helpful only in some cases (e.g., in *S. somaliensis)*, and even then, more as a guide to therapeutic response. In a few centers, molecular tools are used to identify organisms.

Figure 190-4 Mycetoma. Chronic fibrotic involvement of the foot with lymphatic spread to the popliteal fossa.

TABLE 190-1
Macroscopic and Histopathologic Features of Mycetoma Grains[a]

Organisms	Hematoxylin and Eosin Section Appearances
Eumycetoma	
Dark grains	
Madurella mycetomatis	Cement present, vesicles sometimes prominent
M. grisea	Cement absent, compact outer layer
Leptosphaeria senegalensis	Cement in outer zone, dark periphery with vesicular center
Exophiala jeanselmei	Cement absent, often hollow
Pyrenochaeta romeroi	Cement lacking, compact outer layer
Pale grains	
Fusarium sp., *Acremonium*, *Scedosporium apiospermum*, *Aspergillus nidulans*, *Neotestudina rosati*	Compact, pigment lacking, interwoven fungal filaments (*Scedosporium apiospermum* may have prominent vesicles)
Actinomycetoma	
Pale (white to yellow) grains	
Actinomadura madura	Basophilic-stained fringe in layers
Nocardia brasiliensis	Small, pale blue, eosinophilic fringe
Yellow to brown grains	
Streptomyces somaliensis	Grains fractured, basophilic, or pink
Red to pink grains	
A. pelletieri	Small, basophilic layers

[a]Helpful rules of thumb:
Black or dark grains are always produced by fungi.
Red grains are always produced actinomycetes.
But pale (white) grains may be produced by either fungi or actinomycetes.

Histologically, there is a chronic inflammatory reaction with neutrophil abscesses and scattered giant cells and fibrosis.[11] Grains are found in the center of the inflammation. Their size and shape may help in the identification, although with nonpigmented (pale or white grain) eumycetomas, this is seldom sufficient (Fig. 190-5).

TREATMENT. Of the fungal causes of mycetoma, some cases of *M. mycetomatis* infection respond to ketoconazole, 200 mg, itraconazole 200 mg or voriconazole 200–400 mg daily over several months. For the others, a trial of therapy with griseofulvin, or terbinafine, is worth attempting. However, responses to chemotherapy are unpredictable, although antifungals may slow the course of infection. Surgery, usually amputation, is the definitive procedure and may have to be used in advanced cases. However, the value of major surgery in a disfiguring but nonlife-threatening infection has to be weighed against the availability of appropriate prosthetic limbs.

Actinomycetomas (see Chapter 185) generally respond to antibiotics such as a combination of dapsone with streptomycin or sulfamethoxazole-trimethoprim plus rifampin or streptomycin. Amikacin or imipenem also may be used in recalcitrant *Nocardia* infections. The responses in all but a few cases are good.[15]

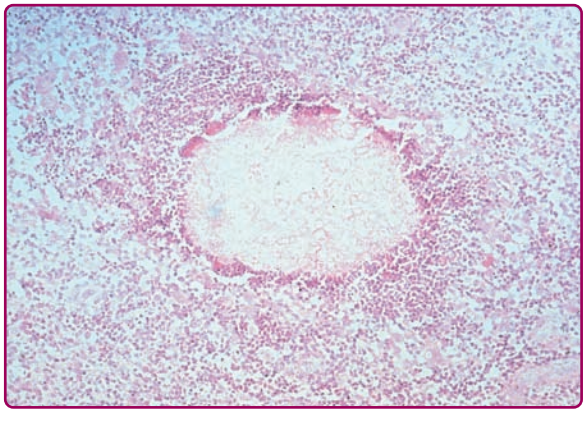

Figure 190-5 Pale eumycetoma grain (hematoxylin and eosin stain).

CHROMOBLASTOMYCOSIS (CHROMOMYCOSIS)

Chromoblastomycosis is a chronic fungal infection of the skin and subcutaneous tissues caused by pigmented (dematiaceous) fungi that are implanted into the dermis from the environment. In the ensuing inflammation, they form thick-walled single cells or cell clusters (sclerotic or muriform bodies), and these may elicit a marked form of pseudoepitheliomatous hyperplasia often accompanied by transepidermal elimination of organisms. The infection can be caused by a number of different pigmented fungi, the most common being *Phialophora verrucosa*, *Fonsecaea pedrosoi*, *Fonsecaea compactum*, *Wangiella dermatitidis*, and *Cladophialophora carrionii*.[16]

EPIDEMIOLOGY. The fungi that cause chromoblastomycosis can be isolated in the environment from wood, plant debris, or soil.[17] The vast majority

Figure 190-6 Chromoblastomycosis. A solitary, large, verrucous plaque surrounded by a halo of erythema is seen on the calf. (Used with permission from Ted Rosen, MD, and Howard Rubin, MD.)

of infections are caused by *F. pedrosoi* and *C. carrionii*. As with other subcutaneous mycoses, infection follows implantation through a tissue injury. The infection is found as a sporadic condition in Central and South America, although rarely in North America. It occurs in the Caribbean region, Africa (particularly Madagascar), Australia, and Japan. It also may occur as an imported infection outside the usual endemic areas. The disease is most frequent in male rural workers.

CLINICAL FINDINGS. The initial site of the infection is usually on the feet, legs, arms, or upper trunk. The clinical features vary.[17] The initial lesion is often a warty papule that expands slowly over months or years (Figs. 190-6 and 190-7). Alternatively, lesions may be plaque-like with an atrophic center. The more common verrucous form spreads slowly and locally. Individual lesions may be very thick and often develop secondary bacterial infection. Satellite lesions around the initial site of infection are local extensions of the infection and usually are produced by scratching. Complications of chromoblastomycosis include local lymphedema, leading to elephantiasis and squamous carcinomas in some chronic lesions.

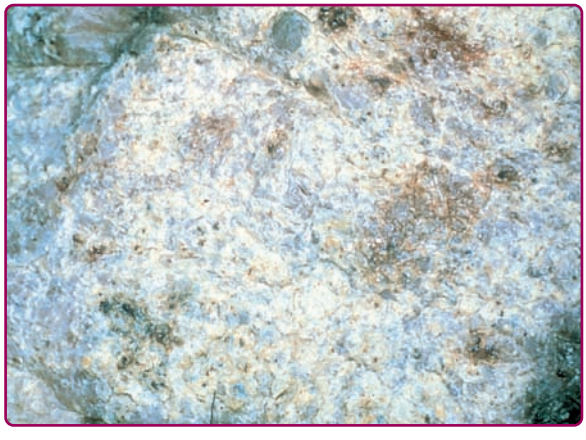

Figure 190-7 Closeup view of chromoblastomycosis. Note hyperkeratosis with pigmentation.

DIFFERENTIAL DIAGNOSIS. The disease must be differentiated from podoconiosis or chronic tropical lymphedema with hyperplasia (mossy foot) which is due to a reaction to soil microparticles. Other chronic verrucous lesions, such as tuberculosis and blastomycosis, are often more extensive. The identification of organisms in the lesions of chromoblastomycosis is essential.

LABORATORY TESTS. The typical sclerotic or muriform fungal cells can be seen in skin scrapings taken from the surface of lesions, particularly areas where there is a small dark spot on the skin surface, using KOH mounts. The lesions also should be biopsied because the pathologic changes and presence of muriform cells are typical. The histology shows a mixed granulomatous response, with small neutrophil abscesses and often exuberant epidermal hyperplasia.[18] The organisms, which are often seen either in giant cells or in neutrophil abscesses, appear singly or in small groups of brown pigmented cells, often with a single or double septum and thick cell wall.

In culture, these fungi are very similar in gross macroscopic appearance, producing black colonies with a downy surface. Their cultural identification depends on demonstrating the presence of different but specific types of sporulation, and either single or multiple sporulation mechanisms may be seen in each organism. Accurate differentiation between the different fungi may be difficult. At this stage, the choice of treatment does not depend critically on correct identification of the organisms, although there may be differences in the speed of response to azole drugs (see Section "Treatment").

TREATMENT. The main treatments for chromoblastomycosis are itraconazole, 200 mg daily;[19] terbinafine, 250 mg daily;[20] and, in extensive cases, intravenous amphotericin B (up to 1 mg/kg daily). Lesions can be spread by surgery, which should be used only as an adjunctive therapy after drug treatment. The local application of heat may be helpful in some instances. The responses of these fungi to different antifungal agents do not appear to differ significantly, although there is some evidence that *C. carrionii* responds more rapidly to terbinafine and itraconazole. In any event, treatment is continued until there is clinical resolution of lesions, which usually takes several months. Extensive lesions often respond poorly to conventional treatment and combinations of antifungal drugs have been used, for example, amphotericin B and flucytosine or itraconazole and terbinafine.

PHAEOHYPHOMYCOSIS (PHAEOMYCOTIC CYST, CYSTIC CHROMOMYCOSIS)

Phaeohyphomycosis is a rare infection characterized by the formation of subcutaneous inflammatory cysts or plaques. It is caused by dematiaceous fungi, the most common of which are *Exophiala jeanselmei* and *W. dermatitidis*, but some 103 species have been described as causal agents.[21] However, unlike in chromoblastomycosis, these organisms form short, irregular, pigmented hyphae in tissue. The infection may occur in any climatic area, although it is more common in the tropics. It also may appear in immunosuppressed patients, particularly those receiving long-term glucocorticoid therapy. The lesions present as cysts and may be mistaken for other similar structures such as synovial or Baker's cysts. The diagnosis is usually made after surgical excision. Histologically, the cyst wall consists of palisades of macrophages and other inflammatory cells surrounded by a fibrous capsule, and the fungal hyphae are found in the macrophage zone. Although the fungi in tissue lesions are usually pigmented, this is not always the case; cystic lesions caused by nonpigmented fungi being called hyalohyphomycotic cysts. The treatment is surgical excision, although relapse can occur, particularly in immunocompromised patients.

LOBOMYCOSIS (KELOIDAL BLASTOMYCOSIS, LOBO DISEASE)

Lobomycosis is an uncommon infection seen in Central and South America, often in remote rural areas. The source of the organism is unknown, although similar lesions have been found on freshwater dolphins. Lobomycosis is characterized by the appearance of keloid-like skin lesions on exposed sites.[22] Although it cannot be cultured in vitro, it is caused by a fungus, *Lacazia loboi*, that forms chains of rounded cells in tissue, each joined by a small tubule. Lesions may occur anywhere on the body but usually are found on exposed parts such as the legs, arms, and face. They can spread from site to site by autoinoculation. Antifungal drugs are not effective, and surgical removal is the main treatment.

SUBCUTANEOUS MUCORMYCOSIS [BASIDIOBOLOMYCOSIS, SUBCUTANEOUS PHYCOMYCOSIS AND CONIDIOBOLOMYCOSIS, (RHINO)-ENTOMOPHTHOROMYCOSIS]

Subcutaneous mucormycosis is a rare tropical subcutaneous mycosis characterized by the development and spread of a chronic, firm swelling involving subcutaneous tissue. There are two main varieties caused by different organisms.[23] The first, most often caused by *Basidiobolus ranarum* (*B. haptosporus*), is more common in children. It occurs in a wide variety of countries and environments from South America to Africa and Indonesia. The organism can be found in plant debris and in the intestinal tracts of reptiles and amphibians. Lesions usually develop around limb girdle sites and present with a firm, slowly spreading, woody cellulitis. The second form, caused by *Conidiobolus coronatus*, is seen in adults. The organism can be isolated from soil, plant debris, and some insects. The early infection starts in the region of the inferior turbinates of the nose. Spread involves the central part of the face, and once again, the swelling is hard and painless. It may cause very severe deformity of the nose, lips, and cheeks. These infections are distinct to those caused by related fungi.

Histopathologically, a chronic granulomatous response with large numbers of eosinophils can be seen. The fungi are present as large, strap-like hyphae without cross walls or septa. They are also often surrounded by refractile eosinophilic material (Splendore–Hoeppli phenomenon). The organisms can be cultured readily on Sabouraud's agar. Ketoconazole (400 mg daily) and itraconazole (100–200 mg daily) also may be useful in this condition, although experience to date is limited to a few cases. Lesions also respond to oral treatment with potassium iodide, given in similar doses to those used in sporotrichosis (see Section "Treatment" under "Sporotrichosis").

RHINOSPORIDIOSIS

Rhinosporidiosis is a chronic infection caused by the organism *Rhinosporidium seeberi*, which causes the development of polyps affecting the mucous membranes. The organism has never been cultured, and it is now thought to be an aquatic protist and a member of the Mesomycetozoea. Rhinosporidiosis is seen most often in Southern India and Sri Lanka. Cases also have been described in South America, the Caribbean, and South Africa. Exposure to water (lakes, pools) has been associated with the infection. The main site affected is the nasal mucosa, but the conjunctival mucosa also may be affected.[24] The infection causes the development of polyps that are studded with white flecks; these are small cysts or sporangia containing small spores. These are best seen in histopathologic sections, where the large sporangia or spore sacs in different phases of development are readily seen. The only treatment is surgical excision.

SYSTEMIC MYCOSES

The systemic mycoses are fungal infections whose initial portal of entry into the body is usually a deep site such as the lung, gastrointestinal tract, or paranasal sinuses. They have the capacity to spread via the bloodstream to produce a generalized infection. In practice, there are two main varieties of systemic mycosis: (1) the opportunistic mycoses and (2) the endemic respiratory mycoses.

The chief opportunistic systemic mycoses seen in humans are systemic or deep candidiasis, aspergillosis, and systemic zygomycosis. These affect patients

ENDEMIC AND OPPORTUNISTIC SYSTEMIC MYCOSES AT A GLANCE

- Where the patient has lived or visited is important for diagnosis.
- History of underlying disease states and their treatment is critical.
- Erythema nodosum may be caused by some endemic mycoses (e.g., coccidioidomycosis).
- Skin biopsy is important in making the diagnosis.
- Positive fungal culture must be interpreted with caution, as the organism identified may simply be colonizing the site.
- Warn the laboratory if you are sending material from a suspected endemic mycosis case for culture, as these are dangerous pathogens and require containment facilities.
- Treatment usually requires prolonged therapy with intravenous drugs such as amphotericin B, voriconazole, or caspofungin.

with severe underlying disease states, such as AIDS, or with neutropenia associated with malignancy, solid-organ transplants, or extensive surgery. With the use of combination antiretroviral therapy, the incidence of systemic mycoses in patients infected with human immunodeficiency virus (HIV) has dropped considerably. In the neutropenic patient in particular, other fungi also may cause infection occasionally. Different underlying conditions predispose to different mycoses, and a scheme for this is shown in Table 190-2. Generally, skin involvement is not common with most of these opportunistic infections, which can occur in any climate and environment. The clinical manifestations of the opportunistic mycoses are also variable because they depend on the site of entry of organism and the underlying disease.

The endemic respiratory mycoses are histoplasmosis (classic and African types), blastomycosis, coccidioidomycosis, paracoccidioidomycosis, and infections due to *Penicillium marneffei*. The clinical manifestations of these infections are affected by the underlying state of the patient, and many develop in the presence of particular immunodeficiency states, notably AIDS. However, they follow similar clinical patterns in all infections. These infections also may affect otherwise healthy individuals. They have well-defined endemic areas determined by factors that favor the survival of the causative organisms in the environment, such as climate. The usual route of infection is via the lung (Fig. 190-8).

TABLE 190-2
Underlying Predisposition and Opportunistic Systemic Mycoses

Predisposition	Infection
Neutropenia (whatever cause) functional neutrophil defects	Aspergillosis, oropharyngeal, and/or systemic candidiasis, mucormycosis, infections due to rare organisms
CD4 lymphopenia (e.g., acquired immunodeficiency syndrome)	Oropharyngeal candidiasis, cryptococcosis, and endemic respiratory mycoses such as histoplasmosis, nocardiosis
Diabetes mellitus	Mucormycosis
Heart valve surgery	Various but mainly *Candida albicans* and non-*albicans Candida* sp.
Abdominal surgery	Candidiasis

In practice, because of the tendency for both groups of infections to develop in predisposed patients, the distinction between opportunistic and endemic mycoses is blurred. This is particularly the case with cryptococcosis, which shares clinical and pathologic features of the two main types of respiratory systemic mycoses but is mainly seen now in untreated AIDS patients.

HISTOPLASMOSIS

Fungi of the dimorphic genus *Histoplasma* cause a number of different infections in animals and humans. These range from equine farcy, or equine histoplasmosis, a disseminated infection of horses caused by *Histoplasma farciminosum* to two human infections known as (1) classic or small-form histoplasmosis and (2) African histoplasmosis. These are caused, respectively, by two variants of *Histoplasma capsulatum*: (1) *H. capsulatum* var. *capsulatum* and (2) *H. capsulatum* var. *duboisii*. They can be distinguished because their respective yeast phases differ in size, the *capsulatum* variety producing cells from 2 to 5 µm in diameter and the *duboisii* form producing cells of 10–15 µm in diameter. The other important differences are in their epidemiology and clinical manifestations. They also show minor antigenic differences that are apparent in serodiagnosis but their mycelial phases are identical. The two types of human infections will be referred to as histoplasmosis and African histoplasmosis because this nomenclature is used most widely.

SMALL-FORM OR CLASSIC HISTOPLASMOSIS OR HISTOPLASMOSIS CAPSULATI.

Histoplasmosis results from infection with the dimorphic fungus *H. capsulatum* var. *capsulatum*. A sexual state of this fungus, *Ajellomyces capsulatus*, also has been described. The infection starts as a pulmonary infection that, in most individuals, is asymptomatic

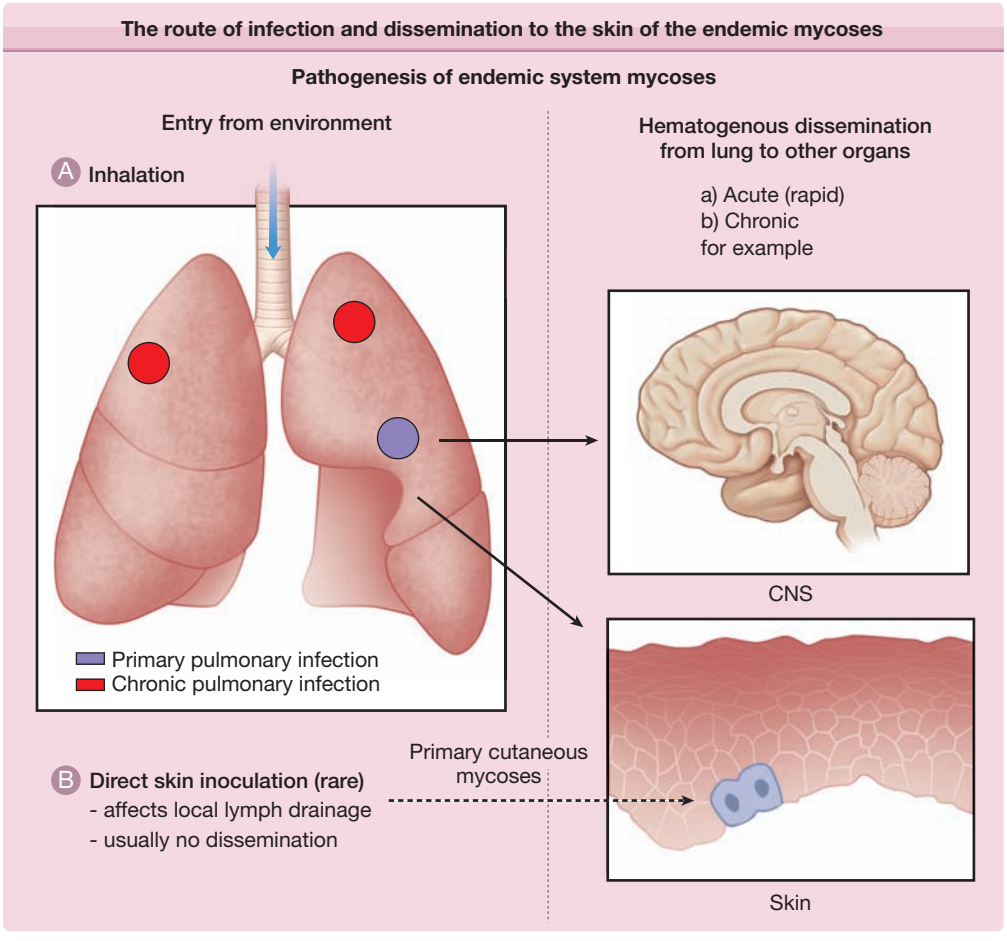

Figure 190-8 The route of infection and dissemination to the skin of the endemic (respiratory) mycoses. CNS = central nervous system.

and heals spontaneously, the only evidence of exposure being the development of a positive intradermal skin test reaction to a fungal antigenic extract, histoplasmin.[25] However, in addition, there is a symptomatic disease that includes respiratory infections and acute or chronic pulmonary histoplasmosis, as well as a disseminated infection that may spread to affect the skin or mucous membranes. Direct inoculation into the skin may occur as a result of a laboratory accident.

Epidemiology. Histoplasmosis occurs in many countries from the Americas to Africa, India, and the Far East. In the United States, it is endemic in the Mississippi and Ohio River valleys, where often more than 80% of the population may have acquired the infection asymptomatically. Exposure rates are usually lower in all other endemic areas, although high rates are also found in Northern South America and some Caribbean islands. Histoplasmosis is not found in Europe. *H. capsulatum* is an environmental organism that can be isolated from soil, particularly when it is contaminated with bird or bat excreta. The disease is acquired by inhalation of spores, and epidemics of respiratory infection may occur in persons exposed to a spore-laden environment when exploring caves or cleaning sites heavily contaminated with bird droppings, such as bird roosts or barns. Although any person can acquire histoplasmosis through inhalation, it causes a distinctive disseminated infection in patients with disease affecting cellular immune capacity, such as AIDS or lymphoma.[26,27]

Clinical Findings. The spectrum of histoplasmosis includes asymptomatic as well as benign symptomatic infections and a progressive disseminated variety with bloodstream spread to multiple organs.[25] Skin lesions may develop as a result of immune-complex formation in the primary infection (erythema multiforme) or from direct spread after dissemination from the lungs; rarely, infections may develop at a point of inoculation into the skin.

Asymptomatic forms of histoplasmosis are, by definition, without signs or symptoms, but those exposed usually have a positive histoplasmin skin test. The percentage of skin test reactors in the community indicates the chances of exposure, and, in endemic areas, this may range from 5% to 90%. Occasionally, asymptomatic pulmonary nodules removed at surgical exploration or autopsy are found to contain *Histoplasma*.

Acute Pulmonary Histoplasmosis. In acute pulmonary histoplasmosis, patients are often exposed to large quantities of spores such as may be encountered in a cave or after cleaning a bird-infested area. Patients present with cough, chest pain, and fever, often with accompanying joint pains and rash—toxic erythema, erythema multiforme, or erythema nodosum. These skin rashes are not common, occurring in fewer than 15% of patients, but they may be precipitated by treatment of the acute infection. On chest X-ray, there is often diffuse mottling, which may calcify with time.

Chronic Pulmonary Histoplasmosis. Chronic pulmonary histoplasmosis usually occurs in adults and presents with pulmonary consolidation and cavitation, closely resembling tuberculosis. Skin involvement is not seen.

Acute Progressive Disseminated Histoplasmosis. In patients with acute disseminated histoplasmosis, there is widespread dissemination to other organs such as the liver and spleen, lymphoreticular system, and bone marrow. Patients present with progressive weight loss and fever. This form is the type that is most likely to occur in untreated AIDS patients, who often develop skin lesions as a manifestation of disseminated infection (Fig. 190-9).[28] There are papules, small nodules, or small molluscum-like lesions that subsequently may develop into shallow ulcers. These skin lesions are more common in HIV positive patients than in others with disseminated histoplasmosis. Diffuse micronodular pulmonary infiltrates also may develop. Patients have progressive and severe weight loss, fever, anemia, and hepatosplenomegaly.

The distinction between acute and chronic dissemination in histoplasmosis is somewhat artificial because these merely represent extremes of behavior, with progression occurring over a few months, on the one hand, and over several years, on the other. Intermediate forms occur, and other organs such as the meninges and heart may be affected.

Figure 190-9 Histoplasmosis, disseminated. Multiple erythematous keratotic papules and small plaques resembling guttate pattern psoriasis are seen on the chest and arm of a man with advanced human immunodeficiency virus disease. (Used with permission from J. D. Fallon, MD.)

Chronic Progressive Disseminated Histoplasmosis. Chronic disseminated histoplasmosis may appear months or years after a patient has left an endemic area. The most common clinical presenting features are oral or pharyngeal ulceration, hepatosplenomegaly or adrenal insufficiency (Addison disease) due to adrenal infiltration. The mouth ulcers are often large, irregular, and persistent and may affect the tongue as well as the buccal mucosa. The patients otherwise may appear well, but it is important to investigate for evidence of infection elsewhere (e.g., by abdominal computed tomography scan). Adrenal infection in particular should be excluded.

Primary Cutaneous Histoplasmosis. Primary cutaneous histoplasmosis is rare and follows inoculation of the organism into the skin, for instance, after accidental laboratory- or postmortem room-acquired infection. The primary lesion is a nodule or indurated ulcer, and there is often local lymphadenopathy.

Differential Diagnosis.

The organism is the same size as a number of others causing deep mycoses such as *P. marneffei* and small forms of *Blastomyces* and *Cryptococcus* (see Section "Laboratory Tests"). It is also similar in size to *Leishmania* sp., and in the tropics, kala-azar is an important part of the differential diagnosis. These observations emphasize the importance of carrying out appropriate laboratory tests to confirm the diagnosis.

Laboratory Tests.

The diagnosis of histoplasmosis is established by identifying the small intracellular yeast-like cells of *Histoplasma* in sputum, peripheral blood, bone marrow, or biopsy specimens. *Histoplasma* must be separated from *P. marneffei* because the two organisms are of a similar size, although the latter shows characteristic septa formation. The identity of the organism should be confirmed by culture; it grows as a mold at room temperature. The white, cottony colonies develop at room temperature on Sabouraud's glucose agar to produce two types of spores, the larger (8–15 µm), rounded, tuberculate macroconidia being typical; the smaller microconidia are infectious. Confirmation of the identity should be obtained by demonstrating ribosomal RNA using a DNA probe. Mycelial-phase cultures of *H. capsulatum* are very infectious, and laboratories receiving specimens should be warned about the suspected diagnosis.

The intradermal histoplasmin skin test is an epidemiologic tool that is of no help in diagnosis. In patients with disseminated histoplasmosis, it is often negative. By contrast, serology is often useful in diagnosis. A rising complement-fixation titer indicates dissemination. Precipitins detected by immunodiffusion are also valuable because the presence of antibodies to specific H and M antigens correlates well with active or recent infection.[28] A new development, particularly helpful

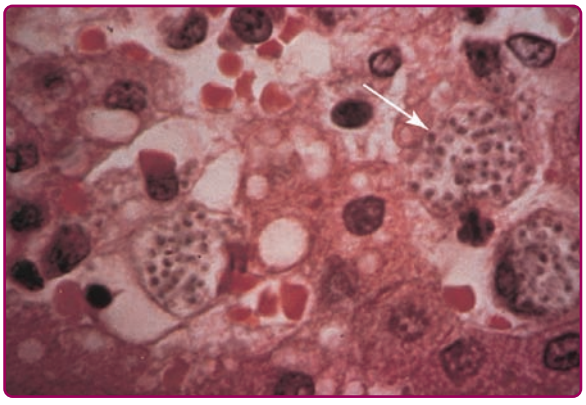

Figure 190-10 Histoplasmosis, disseminated. Lesional biopsy specimen shows dermal macrophages packed with dozens of tiny yeast forms of *Histoplasma capsulatum* (*arrow*).

in AIDS patients, has been serologic or urine tests for the detection of circulating *Histoplasma* antigens.[29] In histopathologic sections, *H. capsulatum* is an intracellular parasite often seen in macrophages. The cells are small (2–4 µm in diameter) and oval in shape with small buds (Fig. 190-10). Mycelial forms are seen rarely in tissue.

PCR based molecular diagnostic methods are available in some centers.

AFRICAN HISTOPLASMOSIS (LARGE-FORM HISTOPLASMOSIS OR HISTOPLASMOSIS DUBOISII). African histoplasmosis is sporadic and uncommon even in AIDS patients.[30] It is seen in patients from areas south of the Sahara and north of the Zambezi River in Africa. Infections seen outside Africa are all imported. The most common clinically involved sites are the skin and bone, although lymph nodes and other organs, including the lungs, may be affected. Skin lesions range from small papules resembling molluscum contagiosum to cold abscesses, draining sinuses, or ulcers. It is not clear if there is an asymptomatic form of African histoplasmosis as in classic histoplasmosis. The diagnosis is confirmed by culture and microscopy (direct microscopy or histopathology). The organisms of *H. capsulatum* var. *duboisii* are different from the smaller *capsulatum* forms. They are usually 10–15 µm in diameter, slightly pear-shaped, and clustered in giant cells. *Histoplasma* serology, using conventional tests, is often negative in African histoplasmosis.

Treatment. The choice of therapy for histoplasmosis depends on the severity of the illness. For patients with some disseminated or localized forms of the disease, oral itraconazole (200–400 mg daily) is highly effective. It also has been used for long-term suppressive treatment of the disease in AIDS patients after primary therapy either with itraconazole or amphotericin B.[31] However, there is now evidence that provided CD4 counts do not fall in patients on highly active antiretroviral therapy (HAART) therapy (see Chapter 198), suppressive treatment can be discontinued. In AIDS, some patients receiving treatment for histoplasmosis, an immune reconstitution syndrome has been reported after commencing HAART therapy with intestinal obstruction, uveitis, and arthralgia. Intravenous amphotericin B (up to 1 mg/kg daily) is given to patients with widespread and severe infections and is the main alternative used. Ketoconazole and fluconazole are effective in some cases. In African histoplasmosis, itraconazole is also the treatment of choice, but once again, in severe cases amphotericin B may be used.[30]

BLASTOMYCOSIS (NORTH AMERICAN BLASTOMYCOSIS)

Blastomycosis is a chronic mycosis caused by the dimorphic pathogen *Blastomyces dermatitidis*.[32] Its chief sites of involvement are the lungs, but disseminated forms of the infection may affect skin, bones, central nervous system, and other sites.

EPIDEMIOLOGY. Blastomycosis is found in North America and Canada.[33] Most cases, though, come from the Great Lakes region and southern states of the United States. It also occurs sporadically in Africa, with the largest numbers of cases coming from Zimbabwe,[34] and cases also have been reported from the Middle East and India.

It is thought that the natural habitat of *Blastomyces* is in some way related to wood debris and is close to rivers or lakes or in areas subjected to periodic flooding. However, it is difficult to isolate *Blastomyces* from the natural environment.[35] Blastomycosis also may affect domestic animals such as dogs.

CLINICAL FINDINGS. As with histoplasmosis, there is a subclinical form of the infection; its prevalence has not been defined in detail because of lack of a commercial *Blastomyces* skin test antigen and the extent of antigenic cross-reactivity with fungi such as *Histoplasma*. Primary cutaneous blastomycosis is also very rare and follows trauma to the skin and the subsequent introduction of fungus, for instance, in laboratory workers or pathologists.[36] After inoculation, an erythematous, indurated area with a chancre appears in 1–2 weeks with associated lymphangitis and lymphadenopathy.

Pulmonary blastomycosis is very similar in clinical presentation to pulmonary tuberculosis.[33,36,37] There may be no symptoms, or there may be low-grade fever, chest pain, cough, and hemoptysis, and unlike histoplasmosis, it often coexists with disseminated disease. Skin lesions are a common presenting feature of disseminated blastomycosis.[36,38] They are often symmetric and usually affect the face and extremities. The early lesion is a papule or nodule, which may ulcerate and discharge pus. With time, this enlarges to form a hyperkeratotic lesion, often with central ulceration and/or scarring (Figs. 190-11 and 190-12). Oral lesions are less common. Multiple skin lesions are often found in disseminated infection. Other patients may present with nodules and abscesses, and in many patients

Figure 190-11 Blastomycosis. Inflammatory plaque with ulceration resembling pyoderma gangrenosum on the calf. (Used with permission from Elizabeth M. Spiers, MD.)

lesions of different morphologies are present. African patients with blastomycosis have a higher frequency of skin and bone involvement.[34] Although blastomycosis can affect almost any organ, other common sites for dissemination include the bone, the epididymis, and the adrenal gland. Less commonly, there is widespread rapid dissemination with multiple organ involvement, and *B. dermatitidis* can produce a form of adult respiratory distress syndrome. Skin lesions in widespread disseminated disease are usually papules, abscesses, or small ulcers. Widespread blastomycosis has been described in AIDS patients, but it is not common.[39]

Figure 190-12 Blastomycosis. Chronic verrucous plaque on the cheek.

Figure 190-13 Direct preparation (potassium hydroxide) of *Blastomyces* (*arrows*).

DIFFERENTIAL DIAGNOSIS. The chronic skin granulomas must be differentiated from those due to tuberculosis, other deep mycoses, nonmelanoma skin cancers, pyoderma gangrenosum, and drug reactions due to bromides and iodides.

LABORATORY FINDINGS. The fungus can be found in KOH mounts of pus, skin scrapings, or sputum as thick-walled, rounded refractile spherical cells with broad-based buds (Fig. 190-13). In culture, the fungus grows as a mycelial fungus at room temperature. It produces small, rounded, or pear-shaped conidia. At higher temperature [37°C (98.6°F)] and on enriched media, it produces yeast forms with the characteristic buds. Molecular probes will confirm the identity. In tissue sections, the typical organisms with broad buds may be found although it may be necessary to search several fields to find the characteristic cells. These are often found in giant cells or surrounded by neutrophils (Fig. 190-14). Precipitating antibodies to *B. dermatitidis* are often present in the sera of infected patients, and a characteristic precipitin line, the E band, has been described in a high proportion of proven cases; there is also an enzyme-linked immunosorbent assay for blastomycosis. There is also an antigen detection system that is most accurate in urine samples.

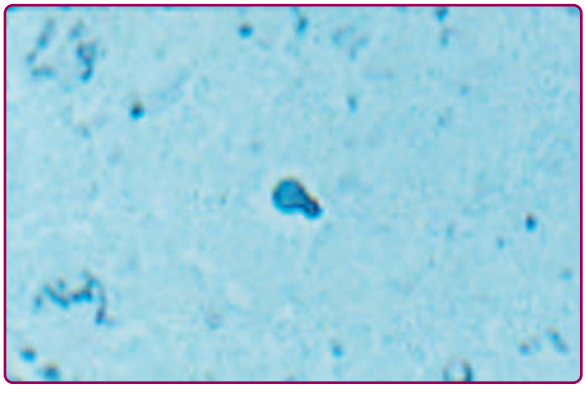

Figure 190-14 Blastomycosis. Lesional biopsy specimen shows a budding yeast form (Gomori methenamine silver stain).

TREATMENT. Treatment is similar to that used for histoplasmosis; itraconazole (200–400 mg daily) is used in the less severe forms of the infection or when there is only localized spread. Voriconazole is also active against this infection. Treatment is usually given for at least 6 months. Follow-up surveillance is necessary because relapse can occur, particularly where there are deep sites of infection or the patient is immunosuppressed. Amphotericin B (up to 1 mg/kg daily) is generally used for the treatment of widespread disseminated forms of blastomycosis.

COCCIDIOIDOMYCOSIS (COCCIDIOIDAL GRANULOMA, VALLEY FEVER, SAN JOAQUIN VALLEY FEVER, DESERT RHEUMATISM)

Coccidioidomycosis is the infection caused by the fungal species *Coccidioides immitis* and *Coccidioides posadasii*; the latter is phenotypically identical and produces identical disease but is mainly found outside California. They shows an unusual form of dimorphism, with a mold form at room temperature and the development of large, spore-containing structures, spherules, in infected tissue. As with other endemic mycoses, there are asymptomatic, acute and chronic pulmonary, and disseminated forms. The disease can affect otherwise healthy individuals or predisposed patients, including those with AIDS.

EPIDEMIOLOGY. *C. immitis* is endemic in some semidesert areas of the Southwestern states of the United States (e.g., California,) and *C. posadasii* elsewhere (Arizona, New Mexico, and Texas) and in parts of Mexico and Central and South America. The climate of the endemic areas is marked by very high summer temperatures and low annual rainfall, demonstrated by a characteristic vegetation with cacti and mesquite bushes. Skin tests with coccidioidin show that the incidence of exposure in endemic areas may be as high as 95%. The fungus is found in soil and can affect other animals as well as humans. Exposure may result from a brief visit to an endemic area, and local weather can determine exposure rates.[40] For instance, dust storms may cause infection in large numbers of individuals. The usual route of infection is respiratory, although direct implantation into the skin can occur rarely.

CLINICAL FINDINGS. As with other systemic mycoses, there is an asymptomatic or subclinical form of coccidioidomycosis that is common in endemic areas, judging by the percentages of skin test reactors to coccidioidin in the healthy population. The primary pulmonary form, which is the most common clinical type, presents as a chest infection with fever, cough, and chest pain. Complications such as pleural effusion may occur. Erythema multiforme or erythema nodosum,[40] often accompanied by arthralgia or anterior uveitis, occurs from the third to the seventh week in about 10%–15% of patients and is more common in females. Sometimes an early, generalized, macular and erythematous rash is seen in some patients.

Figure 190-15 Coccidioidomycosis, disseminated. Two intact and ulcerated papules/nodules are seen on the cheek and nose of this comatose patient with coccidioidomycotic meningitis. (Used with permission from Francis Renna, MD.)

The chronic pulmonary form of the disease presents with chronic cough and resembles tuberculosis. Skin lesions normally do not occur in this phase.

In the rare primary skin infection,[41] after inoculation, there is an indurated nodule that develops 1–3 weeks after local trauma. This is followed by regional lymphadenopathy. Disseminated coccidioidomycosis develops in fewer than 0.5% of infected individuals. It is mainly seen in patients from certain ethnic backgrounds (American blacks, Filipinos, or Mexicans),[40] apparently independent of occupational exposure or socioeconomic class, in pregnant women, and in immunosuppressed patients, including those with AIDS.[42,43] In disseminated disease, lesions may develop in the skin, subcutaneous tissues, bones, joints, and all organs. The skin lesions (Fig. 190-15) are papules, nodules, abscesses, granulomas, ulcers, or discharging sinuses in which there is underlying bone or joint disease. Some lesions appear as flat plaques with central atrophy. Meningitis is an important complication of dissemination and is usually not associated with signs of infection in other sites. In AIDS patients, persistent pneumonia, skin lesions, and widespread dissemination can all occur.

DIFFERENTIAL DIAGNOSIS. Physicians in endemic areas should be aware of the connection between erythema nodosum and coccidioidomycosis. It also may occur in visitors to endemic areas after only a short stay.

LABORATORY TESTS. A characteristic of the laboratory findings is the ability of *Coccidioides* to form spore-containing spherules. These are large (up to 250 μm) and can be seen in KOH mounts of sputum, cerebrospinal

fluid (CSF), or pus. In culture, colonies of *Coccidioides* are mycelial, fast growing, white, and cottony. On microscopy, there are chains of arthrospores at intervals on the older mycelium. *Coccidioides* in the mold phase is highly infectious, and cultures should be handled carefully. There is, as yet, no commercial molecular test for coccidioidomycosis.

A variety of serologic tests are of value in the diagnosis and prognosis of coccidioidomycosis.[44] Precipitins develop in about 90% of infected individuals within 2–6 weeks but are short-lived, complement-fixing antibodies are characteristic of more severe infections and, in active infection, increase to a maximum after 6 months. Skin tests with coccidioidin are of little value in diagnosing infections. Spherulin is an antigen obtained from spherules of *C. immitis* and may be better than coccidioidin for detecting sensitization. However, in severe infections, cutaneous anergy to both is common.

Spherules containing large endospores can be seen in tissue sections, although there are a variety of less distinct intermediate stages in spherule formation that also can be seen. Before endospores form, the cytoplasm of the immature spherule is basophilic and subsequently breaks up into spores. Mycelium is seen rarely in histopathologic sections.

TREATMENT. No specific therapy apart from rest is necessary in the primary pulmonary infection, and there is little evidence that the symptoms are either improved or shortened by giving an oral azole drug, even though it is widespread practice. For disseminated disease, the results of treatment are still variably, but amphotericin B (1 mg/kg daily), itraconazole (200–400 mg daily), or fluconazole (200–600 mg daily) can all be given.[45] Experience with the newer antifungal agents, such as voriconazole and posaconazole, is limited at present. It is important to follow patients carefully, given the frequency of relapse. Meningitis and progressive disseminated infection involving multiple sites are all particularly refractory to therapy. Generally, soft-tissue coccidioidomycosis (skin and joint) has a better prognosis, and the mortality in patients who present with such lesions is low.

PARACOCCIDIOIDOMYCOSIS (SOUTH AMERICAN BLASTOMYCOSIS, PARACOCCIDIOIDAL GRANULOMA)

Paracoccidioides brasiliensis is a dimorphic fungus that causes a respiratory infection with a tendency to disseminate to the mucous membranes and lymph nodes. It is confined to Central and South America.[46]

EPIDEMIOLOGY. Paracoccidioidomycosis has been reported from most Latin American countries, but the infection is found most commonly in parts of Brazil, Colombia, and Argentina. The infection does not occur in the United States, although it has been reported in Mexico. Exposure rates can be estimated by skin test reactivity and appear to be equal in both males and females, although the prevalence of positive reactors in endemic areas seldom exceeds 25%; work with a skin test derived from purified glycoprotein 43 antigen generally demonstrates that exposure rates are higher than previously believed. The active infection is seen predominantly in males. The mechanism is thought to be connected to the presence of a cytoplasmic estrogen receptor on the fungus, and in vitro, estradiol suppresses the conversion of mycelium to yeast.[47] The ecologic niche of the organisms is unknown, but the condition is much more frequent in rural areas; exposure has been associated with proximity to water or areas of high atmospheric humidity.[48]

CLINICAL FINDINGS. There are a number of different clinical patterns of paracoccidioidomycosis infection that depend on the predominant site of clinical involvement. These include the lung (pulmonary form), the mucous membranes (mucocutaneous form), and the lymph nodes (lymphatic form). Many patients have a mixed type of infection with involvement of different organ groups.[46]

Patients rarely present with an acute form of pulmonary infection although this has been observed rarely and reported to subside while dissemination occurs. More usually, pulmonary infection tends to be chronic and slowly progressive with weight loss and chronic cough. The lesions may be bilateral and nodular on chest X-ray, and there is often extensive fibrosis. Other sites of involvement include mucocutaneous areas. Oral or circumoral lesions are common in the mucocutaneous forms of paracoccidioidomycosis; lesions also occur in the nose, conjunctivae, or around the anus. These lesions may be small granulomas or ulcers. They heal with scarring, which may cause considerable deformity.

The cervical lymph nodes are sometimes enlarged, tender, and tethered to the overlying skin; they rarely suppurate. Other systemic sites of involvement include the spleen, intestines, lungs, and liver. Paracoccidioidomycosis is uncommon in AIDS patients, although there is a widespread variety that is a more rapidly progressive form of disseminated infection occurring in young adults or older children without recognizable predisposition.[49]

DIFFERENTIAL DIAGNOSIS. Differential diagnosis includes tuberculosis, leishmaniasis, and other deep mycoses.

LABORATORY TESTS. Sputum, exudates, and scrapings can be screened using KOH. They show numbers of round yeasts with a characteristic form of multiple budding in which a parent cell is surrounded by large numbers of smaller buds. The organism is dimorphic and produces a cottony mycelial-phase growth on primary isolation at room temperature. Once again, the characteristic yeast phase can be induced on enriched media such as brain–heart infusion agar at 37°C (98.6°F). Serology is very helpful in confirming the diagnosis, the main tests being the immunodiffusion assay and a complement-fixation test. Recently, antibodies to pb27 and 87-kDa antigens

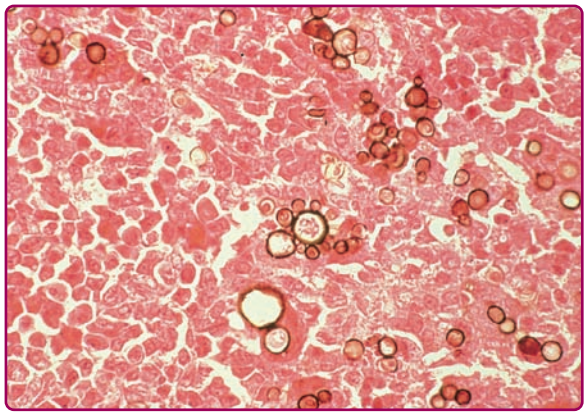

Figure 190-16 Biopsy of oral mucosal lesion showing multiple budding *Paracoccidioides brasiliensis*.

have been found to be highly specific for this infection in immunoblotting. There are also antigen-detection tests useful in monitoring patients with disseminated disease. Histopathologically, there is a mixed granulomatous response with fibrosis. The organisms can be seen with special fungal stains such as methenamine silver (Grocott modification). In tissue, the characteristic budding pattern can be seen, although it may be necessary to search several fields to find the most typical structures (Fig. 190-16). In widespread infections, masses of small yeast forms may be mistaken for *Histoplasma*.

TREATMENT. The treatment of choice in most cases is itraconazole, which can produce remissions in 3–6 months.[50] Voriconazole produces similar responses. Relapses can occur, and, where possible, patients should be reviewed periodically after primary therapy. In very extensive infections and in severely ill patients, such as those with the progressive disseminated type of infection, intravenous amphotericin B may be necessary. Severe pulmonary or intraoral fibrosis may remain after treatment.

INFECTIONS DUE TO *P. MARNEFFEI* (PENICILLIOSIS, *PENICILLIOSIS MARNEFFEI*)

P. marneffei infection is a more recently recognized disease found in Southeast Asia. *P. marneffei* is a member of the common genus *Penicillium*.[51] It shows an unusual pattern of dimorphism in that it develops yeast-like cells that reproduce with septal formation, dividing the cells into two. It is inhaled via the lungs, and it is not known whether there is a primary cutaneous form of the infection.

EPIDEMIOLOGY. The natural source of *P. marneffei* is unknown. Infections are confined to Southeast Asia, particularly Thailand, South China, and Vietnam. However, there are reports in other Asian countries, including Northeast India, and imported cases are seen in Europe and the United States. Natural infections are known to occur in bamboo rats of the genus *Cannomys*, which are large burrowing rodents. The infection affects otherwise healthy individuals as well as those with immune defects and is most common after the rainy season.[52] Patients with AIDS appear to be particularly susceptible to this infection.

CLINICAL FINDINGS. There has been no work to demonstrate that there is a subclinical form of *Penicillium* infection, even though this is likely. Patients usually present with localized pulmonary or disseminated disease. The chest signs are those of chronic pulmonary disease.[53,54] More than 50% of AIDS patients with this infection have multiple skin lesions, which are umbilicated papules that may enlarge and ulcerate. They are usually widely scattered on the face and trunk. Other organs, including the liver, gastrointestinal tract, spleen, and bone marrow, may be affected.

DIFFERENTIAL DIAGNOSIS. The main differential diagnosis is with other disseminated mycoses, such as histoplasmosis and cryptococcosis, which also can be found in the endemic area in AIDS patients. Biopsy and, when necessary, culture will distinguish between the different causes.

LABORATORY TESTS. *P. marneffei* forms characteristic yeast-like cells that are divided by a septum in tissue and are best seen in histopathologic sections stained with methenamine silver. These cells are small (2–4 μm) and difficult to see in blood films or skin or bone marrow smears, but they may be highlighted with stains such as leishmanin. In culture, *P. marneffei* is a green or grayish mold that produces typical *Penicillium* conidiophores and a diffusible red pigment. There is no commercial serologic test as yet, although antigen detection systems and polymerase chain reaction have both been used in diagnosis, the latter for identification of cultures.

TREATMENT. In severe cases, amphotericin B is necessary. In many cases, however, there is a good response to itraconazole (200–400 mg daily). In AIDS patients, this is continued after initial therapy to prevent relapse.[54]

CRYPTOCOCCOSIS

Cryptococcosis is the infection caused by the encapsulated yeast *C. neoformans*. Although the main portal of entry is through inhalation into the lungs, the disease usually presents with signs of extrapulmonary dissemination such as meningitis. Cutaneous lesions can develop as a result of dissemination or, rarely, through inoculation. It is associated with HIV infection.[55]

EPIDEMIOLOGY. Cryptococcosis has a worldwide distribution although exposure rates probably differ markedly in different countries. *C. neoformans* has three variants: (1) *C. neoformans* var. *neoformans*, (2) *C. neoformans* var. *grubii*, and (3) *C. neoformans* var. *gattii*.

These correspond to three clusters of serotypes: (1) D, (2) A, and (3) B or C.[56] The *neoformans* and *grubii* varieties can be isolated from pigeon excreta and are more common in AIDS patients; the *gattii* form is found in the debris of certain eucalyptus trees in the tropics and California, but it is less often isolated from AIDS patients. Two sexual varieties called *Filobasidiella neoformans* and *F. bacillispora* correspond to the *neoformans/grubii* and *gattii* varieties, respectively. Clinically the main differences to be seen are those between the *neoformans* and *gattii* varieties. Patients with certain immunodeficiency states caused by AIDS, malignant lymphomas, sarcoidosis, collagen disease, carcinoma, and those receiving systemic glucocorticoid therapy are particularly susceptible. The incidence of cryptococcosis in patients with established untreated AIDS varied in different countries from 3% to 6% in the United States, to 3% in the United Kingdom, to more than 12% in parts of Africa (e.g., Democratic Republic of the Congo). However, with the widespread use of HAART therapy the incidence has declined. Strains of serotype D are more likely to be found in skin lesions, which occur in 10%–15% of cases of disseminated cryptococcosis.

CLINICAL FINDINGS. The advent of the AIDS epidemic has affected the epidemiology of cryptococcosis considerably, and in areas such as Northern Thailand, it is one of the main secondary complications of HIV infection.[55] There is probably a subclinical form of cryptococcosis because unaffected individuals may have positive skin tests. However, the most common clinical manifestation of disease is meningoencephalitis. This presents with classic signs of meningismus, changes in consciousness, mental changes, and nerve palsies. In AIDS patients, these signs may be only weakly expressed. Pulmonary infection can be found in about 10% of those with meningitis. Chest signs include the appearance of nodular shadows, cavitation, and pleural effusion. Patients with AIDS often present with fever and mild headache and few other features of infection.[55] Cutaneous lesions may develop in about 10% of cases but are seldom pathognomonic.[57–60] Acneiform papules or pustules progressing to warty or vegetating, crusted plaques, ulcers, and hard infiltrated plaques or nodules are characteristic of widespread systemic infection (Fig. 190-17). Cold abscesses, cellulitis, and nodular lesions also occur. In otherwise healthy patients or those with sarcoidosis, lesions may be solitary, and in such patients, they may be the only clinical manifestation of infection.

In primary cutaneous cryptococcosis with direct inoculation of organisms into the skin, the skin lesions are usually solitary nodules that break down and ulcerate. Local lymphadenopathy also develops. The term *primary cutaneous cryptococcosis* is also used loosely to describe solitary lesions of cryptococcosis, but in many such cases there is also evidence of dissemination to other internal organs. It is important to investigate all patients who present with cutaneous lesions for evidence of dissemination to other sites.[58]

DIFFERENTIAL DIAGNOSIS. Cryptococcal skin lesions may mimic a range of other conditions, particularly other systemic mycoses in AIDS patients. It is important to biopsy and culture suspicious lesions in immunocompromised patients.

Figure 190-17 Cryptococcosis, disseminated. Multiple, discrete, skin-colored papules, and nodules resembling molluscum contagiosum are seen on the face of a male with advanced human immunodeficiency virus disease. (Used with permission from Loïs Vaillant, MD.)

LABORATORY TESTS. Cryptococci are large (5–15 μm), budding cells with capsules that are best observed by direct microscopy of India ink or Nigrosin mounts (Fig. 190-18). The organism is not difficult to grow in culture. Various biochemical features, such as the production of urease and the ability to pigment on Guizotia seed medium, are characteristic: or molecular probes can be used to confirm the identity Serologic tests are rapid and specific. The main test is an antigen-detection assay using latex agglutination or enzyme-linked immunosorbent assay, and this is simple and

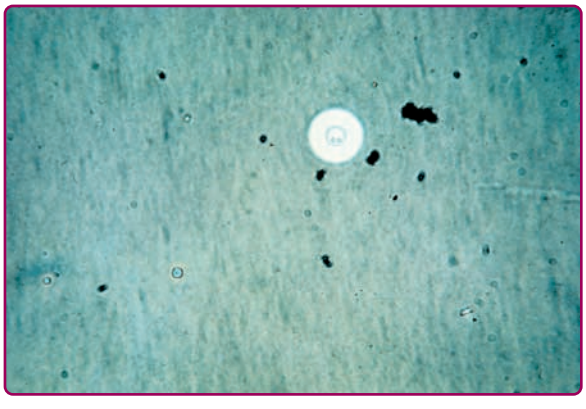

Figure 190-18 Cryptococcosis. India ink preparation of cerebrospinal fluid.

very rapid to perform on blood or CSF. Very high titers are found in AIDS patients in serum and CSF. Non-AIDS patients with single, localized skin lesions are often antigen negative.

In tissue sections, the large pleomorphic yeasts stimulate either a granulomatous reaction or very little inflammation. The capsules of the cells can be stained using the mucicarmine or Alcian blue stains.

TREATMENT. The most frequently used drug regimen in the non-AIDS patient is intravenous amphotericin B combined with flucytosine. In patients with single skin lesions and no other signs of infection, alternatives such as fluconazole or itraconazole can be used. In AIDS patients, there is a very high relapse rate, and the usual policy is to give a 10–14-day course of amphotericin B with or without flucytosine, followed by long-term fluconazole.[61] However, it may be possible to stop long-term suppressive therapy in patients receiving HAART. Fluconazole given on its own is an alternative approach.

CUTANEOUS ASPECTS OF SYSTEMIC OPPORTUNISTIC MYCOSES

Skin lesions are not common with the opportunistic fungal infections, but they can occur in some, particularly in certain predisposed groups. When they occur, their presence may be very helpful because it is possible to biopsy easily accessible lesions in order to establish the diagnosis.

SYSTEMIC CANDIDIASIS

(See Chapters 189 and 198)

Systemic candidiasis follows dissemination of *Candida* sp. from the gastrointestinal tract or via the bloodstream. Skin lesions may occur particularly in two situations: (1) in neutropenic patients, there is often a severe disseminated disease with widespread skin nodules and associated muscle pains,[62] and (2) in intravenous drug abusers, candidiasis may present with a follicular, pustular rash in the beard area and scalp. Other lesions include retinal and vitreal deposits and abscesses around the costochondral junctions.[63]

Systemic candidiasis is usually treated with intravenous amphotericin B (conventional or lipid-associated), caspofungin or fluconazole. Resistance to some azole drugs, such as fluconazole and ketoconazole, is more common with certain non-*albicans Candida* sp., and these antifungal agents should be avoided in infections caused by these species.

MUCORMYCOSIS (PHYCOMYCOSIS, ZYGOMYCOSIS)

Mucormycosis is a rare disease caused by zygomycete fungi such as *Rhizomucor*, *Absidia*, and *Rhizopus*. *Cunninghamella bertholletiae* and *Saksenaea vasiformis* are less common causes. These fungi cause disease in patients with poorly controlled diabetes, neutropenia, or renal disease. Direct invasion through abrasions has been reported following trauma due to a natural disaster (e.g., during a mud slide or tsunami).[64] They can invade necrotic burned areas or involve the facial skin secondary to invasive infection of the paranasal sinuses (Fig. 190-19). Mucormycosis also has been caused by close apposition of the skin with contaminated dressing materials in the case of *R. rhizopodiformis*[65] or with wooden tongue depressors in the case of *R. microsporus*.[66] These fungi have a tendency to invade blood vessels, causing widespread infarction. Infections may respond to intravenous amphotericin, and recent results with lipid-associated amphotericin B formulations have been encouraging.

OTHER OPPORTUNISTIC MYCOSES

Other fungi causing systemic infections also may produce skin lesions in the process of bloodstream dissemination. The best known of these organisms are *Aspergillus*, *Scedosporium*, *Trichosporon*, and *Fusarium*. Skin infection is seen mainly in severely immunocompromised patients such as those with neutropenia.

Aspergillus may produce large necrotic lesions such as ecthyma gangrenosum, but smaller papules and cold abscesses also can occur.[67] *Fusarium* infections may produce widely distributed target-like lesions that may undergo central necrosis and, in some cases, digital cellulitis and superficial white onychomycosis.[68] Treatment for all these infections is usually amphotericin B; although voriconazole is increasingly used with aspergillosis.

LABORATORY FINDINGS. Laboratory confirmation of the diagnosis is fraught with difficulties chiefly because many of the organisms are also commensals in human sites; because they occur in severely ill patients, the capacity to produce diagnostic antibody titers is compromised. The interpretation of laboratory data is consequently difficult and has to be related to the clinical state of the patient. Ideally, a histologic diagnosis should be made, although biopsy may be impossible because of the risk of bleeding.

General Treatment. In many cases, the diagnosis of a systemic mycosis is presumptive, and treatment therefore is given empirically.

ACTINOMYCOSIS AND NOCARDIOSIS

Actinomycosis is an infection caused by filamentous bacteria that form large granules (sulfur granules) in abscess cavities. Draining sinuses communicate from the center of the abscess to the skin or mucosal surface. Nocardiosis is an acute and chronic infection also caused by filamentous bacteria. These lead to localized skin, subcutaneous, and systemic infections. Actinomycosis and nocardiosis are discussed in detail in Chapter 185 and in the online edition.

Viral and Rickettsial Diseases

Chapter 191 :: General Considerations of Viral Diseases

:: L. Katie Morrison, Ammar Ahmed, Vandana Madkan, Natalia Mendoza, & Stephen Tyring

VIRAL DISEASES AT A GLANCE

- Cutaneous lesions are an extremely common and often the only manifestation of viral infections.
- Viruses can produce skin lesions by direct replication in the epidermis, as is the case with papillomaviruses, poxviruses, and several herpesviruses; or as a secondary manifestation of replication elsewhere in the body.
- The direct effects of viral replication on epidermal cells and the inflammatory immune response both contribute to cutaneous lesions.
- Viral latency followed by reactivation occurs with certain viruses. Neoplastic transformation is possible with some latent viruses.
- Laboratory diagnostic techniques include viral culture, microscopy, detection of viral nucleic acids or viral antigens, and serologic testing.
- Many effective antiviral drugs exist, and others are currently in development.
- Preventive techniques are currently the most effective means for decreasing the morbidity of viral infections. Vaccines are a key component of preventative measures.

Cutaneous manifestations are a prominent feature in many viral infections and may arise from a direct result of viral replication in the epidermis or secondarily from viral replication in other organs. In the latter case, the cutaneous manifestations may be the presenting sign of a systemic infection requiring further evaluation. Although most viral infections with cutaneous involvement are mild and self-limited, occasionally severe or life-threatening complications can develop, especially in immunocompromised hosts. Developments in laboratory testing have improved diagnosis of viral infections in the skin. In addition antiviral medications have improved clinical management and outcomes for many of these viral illnesses. While specific diagnosis of the etiologic viral agent is not always feasible, laboratory diagnosis may also be important epidemiologically. Preventive vaccines are available for certain viruses and are currently the most effective strategy for decreasing morbidity and mortality associated with these diseases. Prophylactic vaccines led to the eradication of smallpox, and now include newer vaccines against herpes zoster virus and human papillomaviruses.

DEFINITION

Viruses are unique and fascinating small subcellular agents that require host cells to replicate their genetic material.[1] They contain genomic nucleic acid, a protein coat, and some viruses also have a lipid envelope. Lacking functional ribosomes or other organelles, viruses require host cellular machinery for replication of their genetic material.[1,2] This dependence on the host cell for transcription and replication is why viruses are often referred to as *obligate intracellular parasites*. The intracellular location of the virus provides survival benefit to the virus against some of the host's immune mechanisms.

Viruses are an important means of horizontal gene transfer and evolutionary genetic diversity.[3,4] Historically, there have been many discussions regarding the etiology and categorization of viruses. Most experts currently view viruses as biological particles that can interact with cells, as opposed to biological organisms or life forms.[3] Viruses have features of both of these groups, which accounts for some of their enigma, but

TABLE 191-1
Selected Virus Groups

Group	Size (nm)	Shape	Envelope	Nucleic Acid	Capsid Assembly	Examples of Viruses
Herpesvirus	120–200	Icosahedral	Yes	DNA	Nucleus	Herpes simplex virus (types 1 and 2), varicella zoster virus, cytomegalovirus, EBV, HHV-6, 7, and 8
Papillomavirus	50–55	Icosahedral	No	DNA	Nucleus	Papillomaviruses
Polyomavirus	45–50	Icosahedral	No	DNA	Nucleus	SV40, JC virus, Merkel cell polyomavirus
Poxvirus	240 × 300	Complex	Yes	DNA	Cytoplasm	Molluscum contagiosum, orf, milker's nodules virus, variola virus, vaccinia virus
Retrovirus	80–120	Spherical	Yes	RNA	Cytoplasm	HIV, HTLV
Paramyxovirus	150–300	Helical	Yes	RNA	Cytoplasm	Measles virus, mumps virus
Togavirus	40–60	Icosahedral	Yes	RNA	Cytoplasm	Rubella virus, Chikungunya virus, some arboviruses
Parvovirus	20	Icosahedral	No	DNA	Nucleus	Parovirus B19 (agent of Erythema infectiosum)
Hepadnavirus	40–50	Icosahedral	No	DNA	Nucleus	Hepatitis B virus
Adenovirus	70–80	Icosahedral	No	DNA	Nucleus	Multiple human serotypes
Picornavirus	20–30	Icosahedral	No	RNA	Cytoplasm	Enterovirus (coxsackievirus, echovirus, poliovirus), rhinovirus
Bunyavirus	90–100	Helical	Yes	RNA	Cytoplasm	Some arboviruses
Arenavirus	85–120	Spherical	Yes	RNA	Cytoplasm	Lassa virus
Flavivirus	40–50	Spherical	Yes	RNA	Cytoplasm	Yellow fever virus, Dengue virus, hepatitis C virus, West Nile virus

lack some of the defining features of living organisms and are not classified taxonomically amongst the kingdoms of life.

The viral nucleic acid contains the genetic information necessary for directing the host cell to replicate the virus. The assembled virus is referred to as a *virion*, and contains a highly organized protein coat or *capsid*.[5] The protein coat protects the viral nucleic acid from extracellular environmental insults such as nucleases and it facilitates virion attachment to the membrane of the host cell.[6] After the virion has infected a cell, the now intracellular viral genetic information is usually found in a nonparticulate form. The various virion components are synthesized in separate pieces within the cell and assembled to form progeny particles. This assembly type of replication is characteristic of viruses.[7]

CLASSIFICATION

Viruses are grouped based upon their type of genomic nucleic acid, DNA or RNA, and by the number of strands of nucleic acid within each virion.[2] Other traditional categorization has focused on viral size, morphology, and presence of an envelope, as shown in Table 191-1. A given family of viruses usually shares functional, genetic, biochemical, and immunologic features as well. Other features that may be evaluated in viral categorization are antigenic cross reactivity and host cell tropism. With the advent of more sophisticated techniques, recent viral classification has focused on relatedness of genome sequences.[8]

On a morphological basis viruses can be grouped as helical, icosahedral, or complex as determined by the type of capsomer and overall shape of the virus.[9] In certain virus families (such as herpesviruses and retroviruses), the capsids are located inside an envelope (composed of lipid, protein, and carbohydrate), which is required for infectivity[5] (see Table 191-1). The viral envelope is sensitive to drying, so that infectivity is lost with drying. The virions of some other viruses (e.g., papillomaviruses) do not possess an envelope, so their capsids are called *naked*. Because the capsid proteins are usually stable in dry environments, viruses whose virions lack an envelope typically remain infectious for long periods after drying.[10]

Figure 191-1 shows examples of virions from the three main families of viruses that multiply in the epidermis and appendageal structures (papillomaviruses,

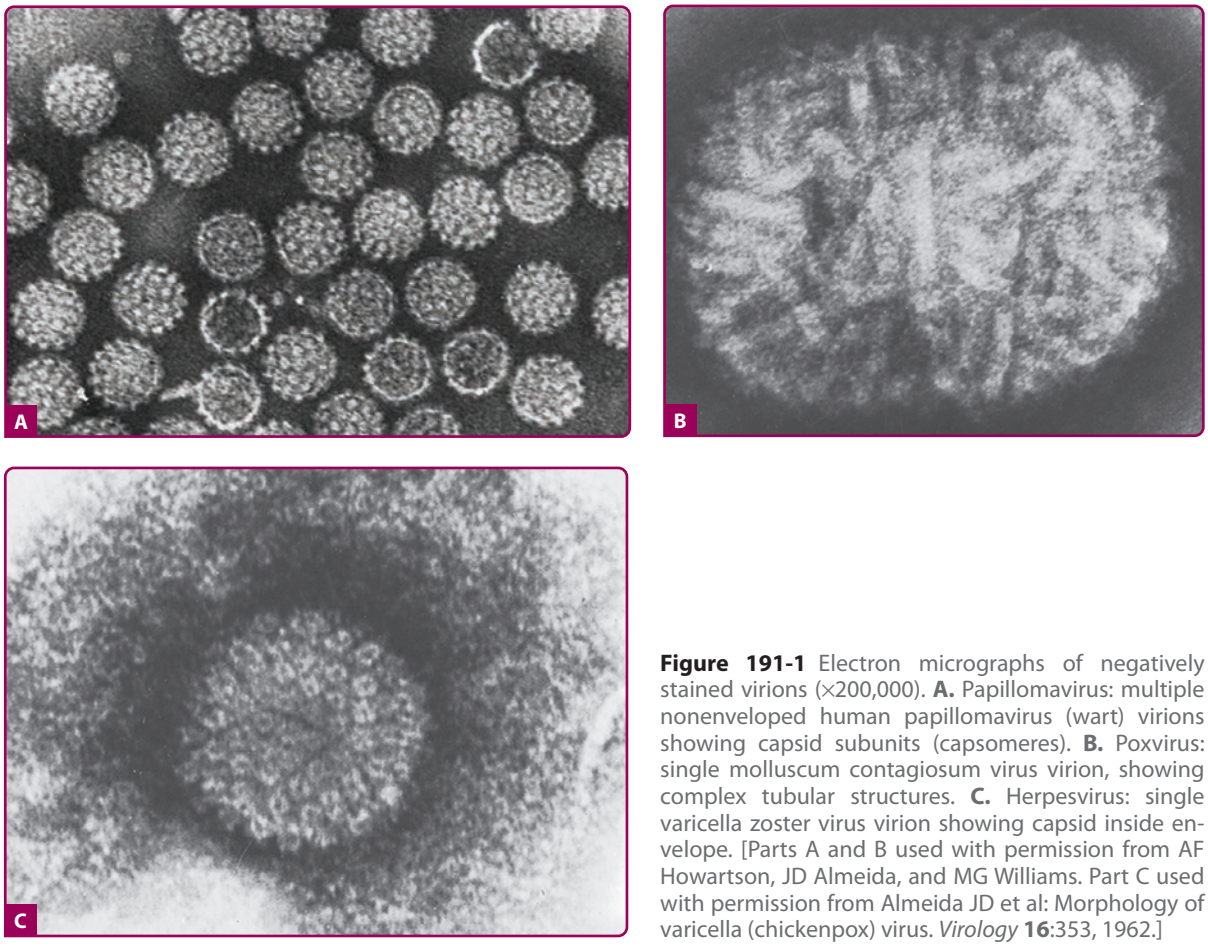

Figure 191-1 Electron micrographs of negatively stained virions (×200,000). **A.** Papillomavirus: multiple nonenveloped human papillomavirus (wart) virions showing capsid subunits (capsomeres). **B.** Poxvirus: single molluscum contagiosum virus virion, showing complex tubular structures. **C.** Herpesvirus: single varicella zoster virus virion showing capsid inside envelope. [Parts A and B used with permission from AF Howartson, JD Almeida, and MG Williams. Part C used with permission from Almeida JD et al: Morphology of varicella (chickenpox) virus. *Virology* **16**:353, 1962.]

herpesviruses, and poxviruses). The viral genomes of these three families are composed of DNA. As noted earlier, papillomaviruses possess naked (nonenveloped) capsids, and herpesviruses have enveloped virions. Poxvirus virions are large, have a very complex structure, and are enveloped, but their envelope is not required for their virions to be infectious. Hence, poxviruses can remain infectious even after drying.[11]

VIRAL REPLICATION

Viral particles do not multiply through cell division because they are acellular. Instead, replication of viruses requires certain host cell genes, proteins, and organelles. The viral replication cycle involves several steps: adsorption, cellular uptake, uncoating, biosynthesis, virion assembly, and release.[5]

Adsorption proceeds with the attachment of virions to cells, involving a specific interaction between the viral capsid, or envelope, and host cell surface receptors. The specificity of this interaction between the viral protein and host receptor defines and limits the species and cell type that a particular virus can infect.[6] Cells that lack the appropriate cell surface receptors for a particular virus are not susceptible to cellular viral entry and infection. For example, human immunodeficiency virus (HIV) enters cells via an interaction between viral envelope protein and two classes of receptors: cellular CD4 receptors and chemokine receptors.[12] While the majority of people are known to be susceptible to HIV infection, rare genetic modifications of specific chemokine receptors have been identified which render hosts relatively resistant to HIV infection or the development of acquired immunodeficiency syndrome.[13,14]

After adsorption, the coat of enveloped viruses may fuse with the host cell membrane and release the virus nucleocapsid into the host cytoplasm. Alternately some viruses may enter the cell through invagination of the cell membrane forming vesicles in the cell cytoplasm.[6] Uncoating subsequently occurs with release of the viral genome from its protective capsid, which begins the nonparticulate phase of the virus life cycle. The nucleic acid can now be transported within the cell.

In the genomic activation or biosynthetic phase, messenger RNA (mRNA) is transcribed typically from viral DNA and translated by the host cell under regulation by the virus. DNA viruses, such as papillomaviruses and herpeviruses typically replicate in the nucleus. (Figs. 191-2 and 191-3) RNA viruses mainly replicate in the cytoplasm. However this is not absolute,

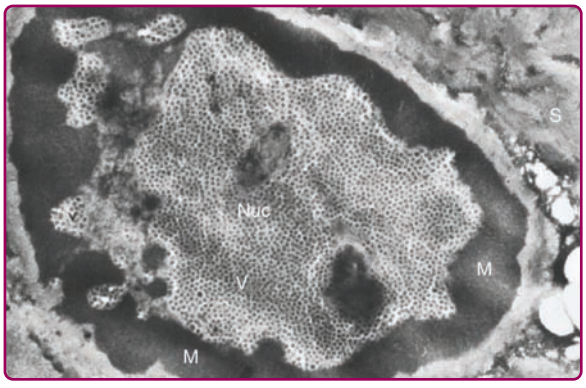

Figure 191-2 Papillomavirus-infected cell. Electron micrograph (×20,000). Nucleus (Nuc) of a stratum corneum cell, filled with papillomavirus virions (V); chromatin is marginated (M). Mature keratin can be seen in an adjacent cell (S).

as exemplified by poxviruses that contains DNA but replicate in the host cell's cytoplasm[15] (Fig. 191-4).

Early viral proteins are usually nonstructural and may code for important enzymes, while later proteins tend to be structural components for the virion. Nonvirion proteins (proteins that are not structural components of the mature virion) of certain viruses may redirect the cell to synthesize proteins required by the virus at the expense of those required for normal function of the cell, essentially hijacking the host's replication and transcription processes.[15]

Assembly of the viral nucleocapsids is the next step. This may occur in the nucleus, as it does with herpes viruses, or in the cytoplasm with polioviruses, or even at the cell surface with viruses such as influenza.[16]

Release of new infectious virions may occur by several mechanisms. The virions of most viruses, including papillomaviruses, herpesviruses, and poxviruses, are released upon cell lysis.[10] Some virions are released by budding from the cell surface and contain a host cell membrane coat. This can occur when virus proteins and nucleic acid condense adjacent to the cell membrane with subsequent budding off of the cell. Virions with resultant cell membranes have a survival advantage of decreased antigenic stimulation and decreased activation of the host's immune system.[10] Alternatively some viruses utilize the host cell's cellular secretory pathway via *Golgi*-derived transport vesicles and fuse with the cell membrane to exit the cell.

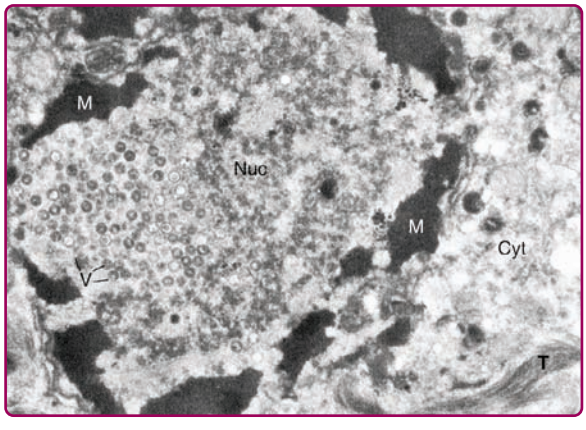

Figure 191-3 Cell infected with varicella zoster virus (a herpesvirus). Electron micrograph (×24,000). Portion of cell of the stratum spinosum. The nucleus (Nuc) contains varicella zoster virions (V). Chromatin is marginated at (M). Virions (V) and tonofilaments (T) are shown in the cytoplasm (Cyt).

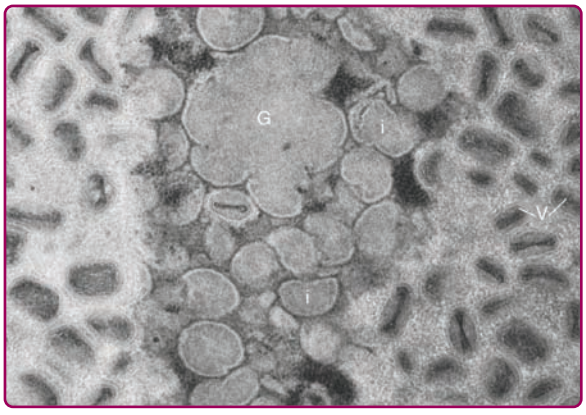

Figure 191-4 Cell infected with molluscum contagiosum (a poxvirus). Electron micrograph (×45,000). Cytoplasm of a spinosum cell filled with mature molluscum contagiosum virions (V), immature virus forms (i), and viroplasm in a gyrate pattern (G).

Typically, hundreds or thousands of new virions are produced from each infected cell, which can then go on to infect other cells. One cycle of viral replication may last from 3 to 36 hours, depending on the virus and cell type involved. Interruption of any step in viral cellular entry, uncoating, synthesis, assembly, or release may prevent the development of new infectious virions. Viruses can also establish several alternate pathways in the host cell, discussed further in the next section.

Each virus has specificity for cell type(s) it can infect. Human papillomaviruses can productively infect a very narrow range of cells, namely, certain differentiating human epidermal cells.[17] Other viruses can infect a much broader range of cells. Herpes simplex viruses (HSVs) can replicate in many different human and nonhuman cell types.[18]

Even within a given tissue, a virus may be infectious only for cells with a specific degree of differentiation. The important role of the differentiated state of the cell in determining whether or not a virus will undergo replication is seen in the skin lesions caused by the molluscum contagiosum virus (MCV). Because MCV particles are sometimes found in cells of the upper dermis, the virus must be capable of attachment to and penetration of these cells. MCV does not, however, replicate in dermal cells, which indicates that an intracellular block to MCV synthesis in the dermal cells. MCV particles are also found in the basal layer of epidermal cells, but synthesis of new viral components does not begin until the cells reach the suprabasal layers, implying that MCV replication can take place only in partially differentiated epidermal cells.[11]

Individual viruses are discussed further in their respective chapters.

CELLULAR CONSEQUENCES OF VIRAL INFECTION

Most viral infections eventually result in the host cell death as a result of cell lysis or alterations to the cell's normal surface membrane leading to cellular apoptosis.[9] Infections of this type are known as lytic or *cytocidal*. However certain enveloped viruses can replicate without causing irreversible damage to the host cell. In noncytocidal infections other possible interactions with the host cell are persistent infection, viral latency, and tumor transformation.[19]

Persistent cellular viral infections without mass cell destruction are possible and occur when there is survival of the infected cell, or only a few host cells are initially infected. This can occur with cytomegalovirus or papillomavirus infections.[17]

Latent infections, via viral integration into the host genome or into the host cell episomally, are another possibility. Viral DNA replication thus proceeds with the cell's genome but does not result in acute mass viral replication or cell lysis.[20] Viral latency is a mechanism for evading the host immune response and may have consequences for the cell. Latently infected cells either produce very small numbers of new virions so that spread to uninfected cells is minimal or they synthesize no virions but retain an intact and potentially inducible viral genome.[20] Ultimately, the state of latent infections can become disrupted with production of new virions. This is commonly seen with herpes viruses HSV-1, HSV-2, and VZV; reactivation of the virus can ensue under conditions that allow viral genome induction.[18]

Tumor viruses possess the ability to alter the normal control of cellular proliferation and transform cells. The phenomenon of latent viral integration with expression of viral proteins known to have an effect on cell cycle regulation has been demonstrated with several viruses, most recently the Merkel cell polyomavirus (MCPyV).[21,22] In many of the genomically evaluated cases to date, the MCPyV DNA sequence has demonstrated a mutation resulting in loss of viral replication ability but retained ability to establish latency in the host cell and express viral proteins.[22,23] Among the viral proteins that have been found to be expressed are those involved in regulation of the host cell, which is a common feature of tumor viruses. Papillomaviruses similarly can encode nonvirion proteins that increase cell growth and lead to inappropriate control of cell division.[17]

The link between certain viruses and cancer was a pivotal discovery in the past century. The viral infectious nature of specific tumors has important implications for prevention, diagnosis, and therapy. Viral induced neoplasia is discussed in greater detail in subsequent chapters.

In addition to complete cellular destruction or transformative consequences for the cell, characteristic effects of a particular virus infection can be microscopically visualized. Cytopathic effects can be pathognomonic for the specific viral infection. These cell effects are typically the result of viral protein synthesis or subcellular degeneration, and can be seen as membrane blebbing, multinucleated giant cell formation, and inclusion body formations, to name a few.

PATHOGENESIS OF VIRAL INFECTIONS IN THE SKIN

Since a virus must grow within a host cell, the virus must be viewed together with its host in any consideration of pathogenesis, epidemiology, host defenses, or therapy. Transmission of an infecting virus to a susceptible individual can occur through several routes. In warts, herpes simplex, primary varicella infections, herpes zoster, molluscum contagiosum, and smallpox, viral shedding from human skin lesions represents an important source in the transmission of virus to other people. For other viruses with cutaneous manifestations, respiratory secretions, blood, genital secretions, or animal vectors are involved in carrying virus to susceptible individuals. Skin involvement may occur by three different routes: direct inoculation, systemic infection, or local spread from an internal focus. The resulting skin lesions may be due to the direct effect of viral replication on infected cells, the host response to the virus, or the interaction of replication and host response.

The viruses of warts, MCV, vaccinia, orf, milker's nodules, and (primary) herpes simplex, all of which infect the skin by direct inoculation, replicate in the epidermis.[10] Their viral cytopathic effects account for the appearance of early lesions. The immune system presumably contributes to the evolution of these lesions by inducing an inflammatory response. The incubation period is generally short, because the lesions develop at the site of inoculation. For warts, however, the incubation period is longer, presumably because the virus replicates slowly or cellular spread of virus is limited.

In systemic infections, the skin is infected during viremia, so that the dermis is generally infected earlier than the epidermis. It is unclear what determines the specific cutaneous distribution of viral exanthemas. In primary varicella infections and smallpox, the lesions seen are a secondary result of the cytocidal damage that the viral infection produces.[18] In contrast, there is some evidence from patients with impaired cellular immunity that suggests that cutaneous manifestations of rubella and measles result at least partly from a cell-mediated immune response to the virus. The basis of most viral exanthemas, such as with enteroviral infections, remains to be established.

Recurrent HSV and herpes zoster represent the local spread of virus to the skin after reactivation of the latent virus present in sensory nerve ganglia. Cytocidal activity is involved in the pathogenesis of these viral associated cutaneous lesions, although the immune response appears to also be an etiologic factor in the blister formation.[18]

HOST RESPONSE

The severity of illness induced by a particular virus has considerable intraspecies variation. The size of the viral inoculum and the portal of entry play some role in the clinical manifestation of disease, but it is believed that host factors usually account for the majority of clinical variation. Both innate and adaptive immunity play key roles in the coordinated immune response to viral infection.[24] Conversely, viral infection may interrupt the normal functioning of the immune system, especially infection with those viruses that target lymphoid cells, such as Epstein–Barr virus and HIV.

Viral proteins have reactive epitopes, which are important for host cellular interaction during infection and replication.[6] The host's defense mechanisms are directed against the viral antigenic epitopes. Antibody responses to viral infection represent the major host defense against reinfection by the same virus. The prophylactic administration of type-specific antibodies can prevent or modify some primary viral infections, even in patients with impaired cellular immunity. There are several mechanisms by which antibodies may inhibit the spread of virus. These include opsonization of virus and prevention of attachment to target cell receptors (which may be increased by complement), enhancement of phagocytic cell activity, and complement-mediated immune destruction of virally infected cells. However, humoral immunity is not believed to contribute substantially to the recovery from most primary viral infections. Viral infections in patients with isolated humoral immune deficiencies usually follow a normal course.

Cell-mediated immunity (CMI) is also elicited during viral infections, controlling viral spread and promoting viral clearance. CMI is a specific response to infection involving T cell recognition of viral fragments displayed on infected cell membranes. This leads to targeting for destruction by natural killer T cells. Some viruses such as HIV can effectively evade CMI by inducing variation in the amino acid sequence of virion surface proteins.[25]

Patients with impaired CMI often have difficulty handling primary or recurrent viral infections. Such patients are at risk of developing severe primary virus infections, problematic reactivations of dormant viruses such as VZV and CMV, and persistent warts, herpes simplex eruptions, and other viral cutaneous lesions. Virus-specific cytotoxic lymphocytes, natural killer cells, and antibody-dependent cell-mediated cytotoxicity all can inhibit infection under experimental conditions and are thought to be the primary players in clearing viral infections. Such genetic alterations in CMI have provided insights into how the immune system responds to viral infections.

Inflammatory cells may produce some of their antiviral effects via the production of interferons, a unique family of closely related cytokines that are active against viruses. Interferon, which can be induced by foreign RNA or DNA (including viral nucleic acids), is secreted into the extracellular fluid. Resistance to viral infection is increased in those cells that come in contact with interferon. Virtually all viruses are capable of inciting an interferon response and are susceptible to its action. However, there is great variability amongst viruses in the degree of interferon induction and the sensitivity to its effects.

Host genetic factors also play a role in the outcomes of viral infection. In animal models, cellular genes greatly influence the susceptibility to viral infection at several levels, including virion attachment to cells, viral replication, and viral-induced immune responses.

CLINICAL MANIFESTATIONS

Viral infections can produce a wide spectrum of mucocutaneous lesions, from single papules to generalized pustulation to large, fungating tumors. Table 191-2

TABLE 191-2
Viral Exanthems

Type of Rash	Associated Virus
Macular/Morbilliform	Rubella Echovirus (especially 9, 16) Coxsackievirus (especially A5, A9, A16, B5) Epstein–Barr virus (infectious mononucleosis) Human herpesvirus 6 (roseola) Rubeola virus Arbovirus (dengue fever) Parvovirus B19 (erythema infectiosum) Hepatitis B and C viruses Human immunodeficiency virus 1
Papular	Human papillomaviruses Orf virus Human herpesvirus 8 (Kaposi sarcoma) Milker's nodule virus Molluscum contagiosum Human immunodeficiency virus 1
Patches	Epstein–Barr virus (oral hairy leukoplakia)
Petechial/purpuric	Coxsackieviruses A5, A9 Hemorrhagic fever viruses Rubella virus (congenital infection) Cytomegalovirus (congenital infection) Echovirus 9 Epstein–Barr virus
Urticarial	Human immunodeficiency virus 1 Hepatitis B virus Coxsackieviruses A5, A9 Epstein–Barr virus
Vesicular/ vesiculopustular	Varicella zoster virus Vaccinia virus Variola virus Herpes simplex virus types 1 and 2 Coxsackievirus (hand-foot-and-mouth disease) (herpangina) Vesicular stomatitis virus Echovirus

lists the viruses that most commonly cause a number of distinguishable skin lesions. Also, for many viruses with cutaneous manifestations, the combination of the exanthem with other clinical and systemic findings, when present, can be characteristic for a specific virus. Human herpesvirus 6 induced roseola subitum in a well appearing child after days of a very high fever or measles exanthem with its characteristic oral lesions, are examples.

There are several cutaneous eruptive diseases for which a virus is highly suspected as the etiologic agent, but this viral causation has not been proven. Asymmetrical periflexural exanthem of childhood and pityriasis rosea are two such diseases (although evidence does link pityriasis rosea to human herpesvirus 7 infection).[26,27]

In certain viral infections the lesions are very specific (e.g., the verrucous papules seen with papillomavirus infection), and a diagnosis can be made without any further testing. However, even during an acute viral infectious episode there is often considerable clinical evolution and variation in the lesions. For example, in many infections due to HSV, VZV, or coxsackievirus, the lesions begin as papules with erythema, progress to frank vesicles, and are followed by pustules, crusts, or shallow ulcers.

In other viral infections the lesions are either rather nonspecific (e.g., urticaria or erythema multiforme) and cannot be accurately distinguished from lesions of nonviral etiology, or semispecific for a limited number of viral diagnoses (e.g., the vesicles seen in HSV, VZV, coxsackievirus, and echovirus infections). In both of these circumstances additional diagnostic procedures may help clarify the cause. Evaluation of systemic signs and symptoms is crucial in formulating a differential diagnosis of skin eruptions and is particularly valuable in infections by viruses that do not replicate in the epidermis, such as Epstein–Barr virus and CMV.

DIAGNOSIS OF VIRAL INFECTIONS

Several laboratory methods are used for diagnosis of viral infections. These are methods based upon viral detection including viral culture and detection of viral antigens, and indirect techniques such as microscopic evaluation and serology. Molecular diagnostic techniques, which are based upon detection of viral nucleic acids, are a newer method increasingly used for laboratory diagnosis of viral infections. The results of any diagnostic method must be interpreted in the context of the clinical setting. Coincidental infection with a virus unrelated to the illness should always be considered. For many viruses, rapid molecular-based assays that are sensitive and specific are now commercially available.

Viral culture is the traditional diagnostic gold standard. If necessary, more precise identification of the cultured virus can be carried out with specific tests for viral nucleic acid or viral antigen. Culture techniques for HSV are quite sensitive, with diagnostic changes in cells often appearing within 1–2 days of inoculation.[18] The closely related VZV is much more difficult to grow in culture, which frequently leads to false-negative results.[18]

When viral culture is of interest, specimens from an acute episode early in the disease process often yield more accurate results than samples taken from the later stages. In vesicular conditions, fluid from an early vesicle is typically a good source of virus. Lesional specimens are less likely to give positive results with nonvesicular exanthemas. Specimens are collected in a sterile tube with 2–5 mL of a buffered isotonic balanced salt solution containing penicillin and streptomycin. Preferably, they should be transported on ice immediately to the laboratory. Alternatively, specimens should be frozen if possible [–70°C (–94°F)]. The suspected pathogen(s) should be indicated, because it may determine the type of cell culture or test animal to be inoculated.[28]

Other diagnostic tests are available that can yield faster results than culturing the virus. This approach may be especially useful for detecting those viruses difficult to propagate in culture and those such as papillomaviruses for which no reproducible culture system is available. Direct microscopic analysis may identify characteristic cells, as with Tzanck smears for herpesviruses (this test will not distinguish between HSV and VZV) or characteristic inclusion bodies with CMV-infected cells. For those lesions that contain large numbers of viral particles, electron microscopy of a lesion or its extract may provide morphologic identification of the virus, although this method is labor intensive, costly, and not readily available.

Rapid diagnostic tests for viral antigens are useful and widely available. Fluorescent antibody detection is commonly used to identify and distinguish between HSV-1, HSV-2, and VZV infections. Radioimmunoassay, enzyme-linked immunosorbent assay, immunoelectron microscopy, and immunoperoxidase techniques are other methods of identifying viral antigen by the use of virus-specific antibody.

Serologic studies to detect viral antibodies may be important for epidemiologic purposes, for identification of infection with viruses such as HIV and hepatitis B virus, and for those situations in which acute sera contain diagnostic antibodies, as with heterophile antibodies in infectious mononucleosis. In general, the most accurate serologic method of diagnosing this acute viral illness is comparison of immunoglobulin G antibody titers from acute and convalescent sera. This comparison is limited to retrospective diagnosis. A single positive titer for immunoglobulin M antibody can also suggest acute illness. Acute specimens should be taken as early in the illness as possible and convalescent specimens 2–4 weeks later. Serum should be separated immediately from the coagulated blood and refrigerated or preferably frozen at –20°C (–4°F) until antibody tests can be run simultaneously on both specimens.[28] A fourfold or greater rise in antibody titer between acute and convalescent sera generally indicates recent infection. A variety of assays are used to measure antibody levels, each detecting a certain type of antigen–antibody reaction, with the type of virus partly determining the utility of any particular assay.

Culture systems possess some virus-specific constraints, but any virus should theoretically be detectable by recognition of viral nucleic acid if sufficient

probes or primers can be obtained for the specific virus(es) of interest. Molecular-based diagnostic assays have had an important impact in direct laboratory identification as well as in improving our understanding of the role of microbes in certain diseases. Most commonly these molecular tests are based upon polymerase chain reaction (PCR) techniques, but many other molecular techniques can be used to diagnosis viral infections including Southern hybridization and in situ hybridization techniques.

Assays based on PCR and related techniques are extremely sensitive, often being able to detect as few as 1 infected cell in 10,000, and highly specific. The main pitfall of PCR is that its great sensitivity makes it very susceptible to yielding false-positive results via cross contamination with minute quantities of viral nucleic acid. Meticulous attention to detail and appropriate controls as well as closed system techniques that are increasingly available can usually overcome this potential liability. In situ PCR, which combines the sensitivity of PCR with histologic localization, is an even more sophisticated technique for viral detection.[29]

Cutaneous manifestations of viral infections are often sufficient for clinical diagnosis. The exact laboratory diagnostic method chosen, if any, will depend on a combination of factors such as resources, clinical disease suspicion, differential diagnosis, immediacy of results, and test accuracy.

THERAPY AND PREVENTION

Viruses are difficult to target therapeutically because of their replication only within host cells, relying on the host cell's biosynthetic processes. Specificity of antiviral therapy to target the virus without consequence to the host can be challenging. Strategies aimed at unique viral functions or proteins are critical for correct diagnosis, treatment, and prevention of disease. Effective treatment requires knowledge of the viral cycle and viral proteins.

More than 40 drugs are approved for the treatment of viral infections, and several of these have a key role in the treatment of cutaneous viral infections. The majority of these drugs are virostatic, not virocidal. Viral enzyme inhibitors, viral receptor inhibitors, chemotherapeutic agents, and immunomodulatory drugs are among the systemic and topical medications used to treat such infections.[10] Our improved understanding of specific viral cycles, the viral interaction with the host cells, and the host immune response, has improved treatment for several viral infections. Specific antiviral treatments are covered in the respective disease chapters.

Although significant progress has occurred in antiviral therapy in recent decades, especially in the treatment of HIV, herpesviruses, and influenza virus infections, strategies aimed at prevention of viral infection have thus far proved more successful than the specific treatment of established infection for most viruses. Vaccines have been extremely useful in the prevention of a variety of viral illnesses and represent one of the premier medical achievements of the twentieth century. In 2006, the US Food and Drug Administration approved two new antiviral vaccines: a prophylactic VZV vaccine for the prevention of herpes zoster in persons 60 years of age and older, and a prophylactic vaccine against genital human HPV infection in women for prevention of cervical cancer caused by HPV-16 and HPV-18 and genital warts caused by HPV-6 and HPV-11. A second vaccine for the prevention of cervical cancer secondary to HPV-16 and HPV-18 (but not HPV-6 or HPV-11) was approved in 2009.[30,31] A number of other vaccines are currently being researched for HSV, cytomegalovirus, dengue virus, West Nile virus, and HIV, among others.[32]

Recombinant DNA techniques are making it possible to develop effective, noninfectious subunit vaccines composed only of viral protein (as with the vaccines against HPV and hepatitis B virus), rather than traditional vaccines, which contain either an attenuated strain of the pathogen or an inactivated preparation of the entire virus. In addition to vaccines that induce active immunity, the passive administration of type-specific antibody soon after exposure is useful in select clinical situations, for example, in immunocompromised children exposed to varicella, and in acute rabies infections. Sensitive procedures for the detection of hepatitis B virus, hepatitis C virus, and HIV in potential blood donors has drastically reduced the incidence of transmission of these agents by transfusion. Public health measures such as safer sex, single use of needles, control of mosquitoes, and proper hand washing continue to be paramount in the prevention of viral disease.

Chapter 192 :: Exanthematous Viral Diseases

:: Leah T. Belazarian, Mayra E. Lorenzo, Andrea L. Pearson, Susan M. Sweeney, & Karen Wiss

MEASLES

EPIDEMIOLOGY

Measles, or rubeola, is a highly contagious disease with worldwide distribution that remains a leading cause of vaccine-preventable deaths in children.[1] The peak incidence of infection occurs during the winter and spring months in temperate areas.[2] The risk of mortality is highest in developing countries, with most deaths due to complications of the disease.[3] In the United States, measles-related deaths occur in 1–3 of every 1,000 reported cases.[2]

Before the development of a vaccine, measles epidemics in the United States usually occurred in preschool and young school aged children.[2,4] A successful immunization program for children and adolescents, particularly in urban areas, has resulted in a greater than 99% decrease in the reported incidence of indigenous measles since the vaccine was first licensed in the early 1960s.[2] Yet, cases of measles continue to occur as a result of viral transmission from importation into the United States.[2]

Improved immunization programs in developing countries have also prevented outbreaks and reduced measles-associated morbidity and mortality. From 2000–2008, global mortality attributed to measles decreased by 78%, from 733,000 to 164,000 deaths.[5] However, the reduction in mortality has leveled off and concerns exist regarding the ability of many countries with a high burden of measles mortality to continue effective measles eradication strategies.

ETIOLOGY AND PATHOGENESIS

Measles virus, a member of the Paramyxoviridae family, is a heat-labile virus with an RNA core and outer lipoprotein envelope.[2,4] Humans are the only natural hosts of the measles virus.[2] Measles is spread by direct or airborne droplet exposure. The incubation period is typically 8–12 days, with patients being contagious from 1 to 2 days before onset of symptoms to 4 days after appearance of the rash.[2] Both humoral and cell-mediated immunity are needed to control measles virus infection. Immunoglobulin M (IgM) antibodies are detected initially with onset of the rash, followed by a rise in measles-specific IgG titers. The humoral response controls viral replication and confers antibody protection, whereas the cell-mediated response eliminates infected cells.[4] A transient immunosuppression occurs during measles virus infection, causing depressed delayed-type hypersensitivity and T-cell counts as well as an increased risk of bacterial infections.[4] This process, as well as long-term immunity against measles, is not well understood but may be due to a weak T helper 1 response to the virus.[6] Measles virus may use dendritic cells to target lymphoid tissue (CD150 lymphocytes) and disseminate virus throughout the body.[7]

CLINICAL FINDINGS

HISTORY. The prodrome is typically characterized by fever (up to 40.5°C), malaise, conjunctivitis (palpebral, extending to lid margin), coryza, and cough (brassy or barking), which may last up to 4 days.[2,4] Koplik spots, the pathognomonic enanthem of measles, begin as small, bright red macules that have a 1–2-mm blue–white speck within them. They are typically seen on the buccal mucosa near the second molars (Fig. 192-1 and eFig. 192-2.1 in online edition) 1–2 days before and lasting 2 days after the onset of the rash (see eFig. 192-1.1 in online edition).[2,4] Individuals with preexisting partial immunity (e.g., patients who received exogenous immunoglobulin) may have less severe symptoms but a prolonged incubation period (14–20 days). Conversely,

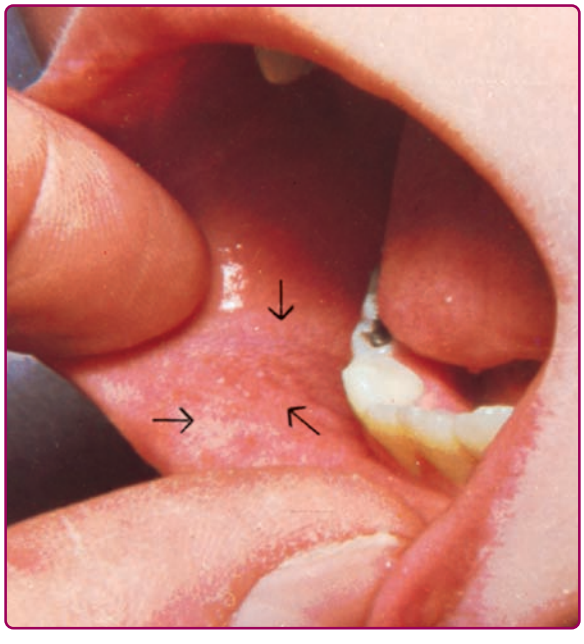

Figure 192-1 The pathognomonic Koplik spots appear as tiny white lesions surrounded by an erythematous halo—"grains of sand." They precede the generalized rash by 1–2 days.

Figure 192-2 The morbilliform eruption of measles in a toddler.

immunosuppressed patients may have more severe disease and can present without the typical rash.[2]

CUTANEOUS LESIONS. The exanthem is characterized by erythematous, nonpruritic macules and papules that begin on the forehead and behind the ears (Fig. 192-2). The rash quickly progresses to involve the neck, trunk, and extremities (Fig. 192-3 and eFig. 192-3.1 in online edition). The hands and feet are involved. Lesions may coalesce, especially on the face and neck (see Fig. 192-3.2 in online edition). The rash usually peaks within 3 days and begins to disappear in 4–5 days. Desquamation may occur as the rash resolves.

Figure 192-3 Measles. Classic morbilliform exanthem with red papules spreading from forehead and postauricular to neck, trunk, and then extremities.

RELATED PHYSICAL FINDINGS. The entire illness may last up to 10 days, with some individuals also having vomiting, diarrhea, abdominal pain, splenomegaly, pharyngitis, otitis media, and generalized lymphadenopathy.[4] Immunosuppressed patients are at higher risk for pneumonitis, acute encephalitis (1:1000 cases), and other fatal complications.[4,8] Viral shedding may also be more persistent in these individuals.[2,9]

Atypical measles infection is rare, but seen in individuals who received formalin-inactivated measles vaccine (1963–1967) and were subsequently exposed to wild-type virus.[4] Symptoms are often more severe with high fever, interstitial pneumonia, pleural effusions, extremity edema, hepatitis, and hyperesthesias occurring more commonly. Coryza, conjunctivitis, and Koplik spots are usually not present. The rash may be maculopapular, hemorrhagic, vesicular, or urticarial and spreads centripetally, making it difficult to distinguish from Rocky Mountain spotted fever.[4]

LABORATORY TESTS

The laboratory diagnosis of measles is based on virus detection or positive serologic findings.[7] During the prodrome stage, virus can be found in nasopharyngeal secretions, blood, and urine. Viral culture has a low sensitivity for finding the virus but viral immunofluorescence tests may quickly detect measles in throat or nasopharyngeal specimens.[10] Indirect enzyme linked immunoassay (ELISA), polymerase chain reaction (PCR), and reverse transcription-PCR assays can detect measles virus in clinical specimens such as nasopharyngeal secretions, oral fluid, serum, dried blood spots collected on filter paper and urine.[7,11] Genotyping of viral isolates can determine patterns of transmission and importation. Genome sequencing can differentiate wild type and vaccine virus infection.[2]

Serologic studies demonstrate measles virus infection with a documented presence of measles IgM antibody and/or a significant increase in measles IgG antibody concentration in paired acute and convalescent titers. IgM antibody increases with the onset of the rash and lasts approximately 1 month. It may be absent or only transient in patients immunized with two vaccine doses.[2,12] As the sensitivity of measles IgM assays may vary during the first 3 days after onset of rash, the test should be repeated in any suspected patient with a negative measles IgM assay and a generalized rash lasting more than 72 hours.[2] IgG antibody appears 2 weeks after rash onset and peaks 4–6 weeks later.[2] In the United States, measles should be reported to the local or state health department.

DIFFERENTIAL DIAGNOSIS

(Box 192-1)

COMPLICATIONS

Age-specific rates of complications are highest among children less than 5 years old and adults over

BOX 192-1 DIFFERENTIAL DIAGNOSIS OF MEASLES

Most Likely

- Drug hypersensitivity reaction
- Rubella

Consider

- Rocky Mountain spotted fever (atypical cases)
- Henoch–Schönlein purpura (atypical cases)
- Other viral infection (parvovirus, enterovirus, adenovirus, human herpesvirus-6, Epstein–Barr virus)

Always Rule Out

- Kawasaki disease
- Graft-versus-host disease (recent bone marrow transplant)

20 years. The most common complications of measles virus infection are otitis media, pneumonia, laryngotracheobronchitis, and diarrhea.[2,13] Hepatitis, thrombocytopenia, and encephalitis occur less commonly. Thrombocytopenia-associated purpura may be severe. Pneumonia is the most common fatal complication of measles in children and the most common complication overall in adults.[4,14] The disease severity is worse in immunocompromised and malnourished individuals, often resulting in the development of Hecht giant cell pneumonia.[15]

Subacute sclerosing panencephalitis (SSPE), a rare degenerative central nervous system disease that occurs 7–10 years after wild-type measles infection, is marked by seizures and behavioral and intellectual deterioration.[2]

PROGNOSIS AND CLINICAL COURSE

Clinical diagnosis of measles is typically made with onset of the characteristic rash as the prodromal symptoms can mimic influenza-like illnesses. Uncomplicated measles is self-limited, lasting 10–12 days. Malnutrition, immunosuppression, poor health, and inadequate supportive care can worsen the prognosis in any patient. In developing nations, measles is a major cause of infant mortality.

TREATMENT

Treatment for measles in the majority of cases is supportive, particularly to maintain good hydration. Patients should be on standard and airborne transmission precautions for 4 days after rash onset (entire duration of illness in immunocompromised patients).[2] Patients with secondary bacterial infections need to be treated with appropriate antibiotics. Ribavirin may be considered, as it has been shown to inhibit measles virus in tissue culture and reduce the severity and duration of measles in some cases.[2,4,16] In trials of patients with subacute sclerosing panencephalitis, however, no benefit was noted with the use of ribavirin.

Malnutrition and vitamin A deficiency can depress cell-mediated immunity in children, increasing the risk and severity of childhood infections. Measles virus infection decreases serum levels of vitamin A and can lead to higher risk of mortality from disease. The World Health Organization (WHO) and the United Nations International Children's Emergency Fund (UNICEF) issued a joint statement that vitamin A should be administered to all children with measles in communities where vitamin A deficiency is known or where measles mortality is at least 1%.[2,17] A 2005 Cochrane review of vitamin A supplementation to treat measles in children found an association between using two doses of vitamin A on two consecutive days and a reduced risk of measles mortality in children less than 2 years old.[2,18]

All individuals at risk (infants less than 1 year of age, pregnant women, unimmunized, and immunocompromised) should receive immunoglobulin prophylaxis within 6 days of exposure to measles virus.[2] If given within 72 hours of exposure, the individual may not be infected with the virus.[4] Healthy individuals should receive 0.25 mL/kg of intramuscular immunoglobulin, and immunocompromised patients require 0.5 mL/kg.[2] Exposed patients (excluding pregnant women and those with impaired immune systems) should also be given the measles vaccine 5–6 months later to confer lasting protection (Box 192-2).

PREVENTION (IMMUNIZATIONS)

The incidence of measles has decreased worldwide as a direct result of immunization. Two doses of the live attenuated measles vaccine (with first dose at or after 12 months of age) produces detectable levels of antibody in 99% of individuals, conferring lifelong immunity.[2,4] Exposure to measles is not a contraindication to immunization. Measles vaccine may even provide protection in some cases if given within 72 hours of the exposure.[2]

Common potential side effects of measles vaccine include fever, local injection site reaction and transient morbilliform rash (7–10 days after vaccination; lasts

2 days) that resolve without treatment. Less common adverse reactions include thrombocytopenia and transient neurologic reactions.[2,19]

Measles vaccine administration is contraindicated in individuals who have a moderate to severe illness as well as those who have had an immediate anaphylactic reaction to a previous measles vaccine. It is also contraindicated in pregnant women and those with impaired immune systems (human immunodeficiency virus infection, immunosuppressive therapy). Hypersensitivity reactions can occur to components of the vaccine such as gelatin, neomycin, or egg white cross-reacting proteins.[2,20]

There have been many unconfirmed, unsubstantiated but widely publicized reports suggesting a potential link between measles-mumps-rubella (MMR) vaccine and the development of autism and possibly inflammatory bowel disease and atopic disorders. Current scientific evidence does not support a causal link between MMR vaccine and autism, inflammatory bowel disease or atopic disorders.[21–25]

RUBELLA

RUBELLA AT A GLANCE

- German measles, 3-day measles.
- Epidemic disease; worldwide distribution.
- Short prodrome; rash of 2- to 3-day duration.
- Enlargement of cervical, suboccipital, and postauricular glands.
- High risk of fetal malformations with congenital infection (microcephaly, congenital heart disease, and deafness), particularly in the first trimester.

EPIDEMIOLOGY

Rubella virus has a worldwide distribution with outbreaks occurring most frequently in late winter and early spring months. Humans are the only hosts for infection.[26] School-aged children, adolescents, and young adults most often develop the disease. Epidemics occasionally occur in developing countries, especially where vaccines are unavailable.

Since introduction of the rubella vaccine in the United States in 1969, the incidences of rubella and congenital rubella syndrome have drastically declined with no widespread epidemics occurring in the United States. Since 2003, fewer than 20 cases are reported annually in the United States.[27] Occasional outbreaks have largely been attributed to failure to vaccinate susceptible individuals. Yet, recent serologic surveys indicate that approximately 10% of the United States-born population >5 years old is susceptible to rubella.[26,27] Epidemiologic studies have identified that individuals born outside the country or in a vaccine-poor area also have an increased risk of rubella.[26]

ETIOLOGY AND PATHOGENESIS

Rubella is an enveloped positive-stranded RNA virus in the Togaviridae family that is spread through direct or droplet contact from nasopharyngeal secretions.[26] Infected individuals shed virus for 5–7 days before and up to 14 days after onset of rash,[28] with viremia unlikely after the rash occurs. In most individuals, infection leads to lifelong immunity.

Congenital rubella occurs when a nonimmunized, susceptible, pregnant woman is exposed to the virus. Transplacental infection of the fetus occurs during the viremic stage. The risk is greatest to a fetus exposed to the virus in the first trimester. Congenitally infected infants may shed the virus through urine, blood, and nasopharyngeal secretions for up to 12 months after birth, thus being a potential source of viral exposure to other susceptible individuals.[26,28]

CLINICAL FINDINGS

HISTORY. Primary rubella infection is typically a mild, subclinical disease, particularly in adults.[26,28] The prodrome is characterized by low-grade fever, myalgias, headache, conjunctivitis, rhinitis, cough, sore throat, and lymphadenopathy; symptoms that may last up to 4 days and often resolve with appearance of rash. Up to 50% of children with primary rubella infection may have a subclinical infection[29] or present only with lymphadenopathy or rash (no prodrome).[28] Conversely, older adults may have more severe and persistent prodromal symptoms that may make distinction from rubeola difficult in some situations. The presence of Koplik spots in the mouth favors rubeola. As the prodrome resolves and the rash begins to appear, some patients develop an enanthem consisting of tiny red macules on the soft palate and uvula (Forschheimer spots).[30] This enanthem is not diagnostic for rubella.

CUTANEOUS LESIONS. The exanthem, occurring 14–17 days after exposure, is characterized by pruritic pink to red macules and papules that begin on the face, quickly progressing to involve neck, trunk, and extremities (Fig. 192-4 and "Rubella At a Glance" image).[28] Lesions on the trunk may coalesce, whereas those on the extremities often remain more discrete. The rash usually begins to disappear in 2–3 days, unlike rubeola, which can be more persistent and clears the head and neck first. Desquamation may follow resolution of the rash.

RELATED PHYSICAL FINDINGS. Lymphadenopathy is usually most severe in the posterior cervical, suboccipital, and postauricular lymph nodes

Figure 192-4 Rubella. Erythematous macules and papules appearing initially on the face and spreading to trunk, arms, and legs within 24 hours.

and is noted up to 7 days before the rash appears.[26] Enlargement of the nodes may persist for several weeks.

Adults, particularly women (up to 70%), may develop arthritis with rubella infection.[26] Both small and large joints may be affected. Joint symptoms often first appear as the rash fades and can last several weeks. In some individuals, the symptoms may become persistent or recurrent. Joint swelling may progress to form a joint effusion.

LABORATORY TESTS

Diagnosis is typically made using serology to detect rubella-specific IgM antibody (up to 8 weeks after infection) or to document a fourfold rise in antibody titer in acute and convalescent-phase serum.[26,30] Hemagglutination inhibition (less common), complement fixation, immunofluorescence assay, and ELISA are some of the methods used to detect antibodies.[11] As with measles, rubella cases should be reported to local or state health departments.

Viral culture (nose, throat, blood, urine, CSF, and synovial fluid) is sensitive but often difficult due to the influence of timing, collection procedure and transport on the specimen.[11] Reverse transcription PCR may be used to detect rubella virus from throat swab or oral fluid with subsequent genotyping of strains to identify a source during outbreaks.[11,31] Complete blood cell count usually shows leukopenia with relative neutropenia. Increased numbers of atypical lymphocytes or abundant plasma cells may be noted as well. Patients with meningeal involvement have lymphocytes in the cerebrospinal fluid (CSF).

CONGENITAL RUBELLA SYNDROME

Women who are infected with rubella during pregnancy may only exhibit minor clinical symptoms. The effects, however, of rubella infection on the fetus can be profound,[28] with the greatest risk of fetal malformation in the early stages of pregnancy. Up to 85% of fetuses exposed to rubella within the first 12 weeks of gestation develop serious sequelae such as: microcephaly with mental retardation, congenital heart disease (ventricular septal defect, patent ductus arteriosus, pulmonary artery stenosis), sensorineural deafness, cataracts, glaucoma, low birth weight, and fetal death.[27,28,30] Neonatal manifestations of congenital infection include: growth retardation, interstitial pneumonitis, radiolucent bone disease, hepatosplenomegaly, thrombocytopenia, and dermal erythropoesis "blueberry muffin lesions."[26]

Diagnosis of congenital rubella infection is obtained by isolating rubella virus in the throat, cataracts, urine, or CSF of the affected neonate. Serologic testing is not as sensitive but is easily available for confirmatory testing. IgM antibody can be detected from birth to 1 month of age; IgG antibody titers may be stable or increase over several months. Laboratory confirmation of congenital infection in children >1 year old is difficult as viral isolation is rare.[26,28]

DIFFERENTIAL DIAGNOSIS

(Box 192-3)

COMPLICATIONS

Rarely, rubella infection may lead to encephalitis (1 in 6,000 cases),[30] with mortality rates varying from 0% to 50%.[30] Other rare complications include: peripheral neuritis, optic neuritis, myocarditis, pericarditis, hepatitis, orchitis, and hemolytic anemia.[28] Transient thrombocytopenia has been described in 1 in 3,000 children (usually girls); first appearing within days of rash onset and lasting days to months.[28,32] Recently, cases of rubella-associated hemophagocytic syndrome

BOX 192-3 DIFFERENTIAL DIAGNOSIS OF RUBELLA

Consider
- Other viral infection (enterovirus, adenovirus, parvovirus, human herpesvirus-6)

Always Rule Out
- Streptococcal scarlet fever

For differential diagnosis of congenital rubella syndrome with blueberry muffin lesions, see Box 192-9.

and encephalitis have been described.[33,34] Congenital rubella syndrome may predispose patients to developing diabetes mellitus.[35]

PROGNOSIS AND CLINICAL COURSE

Rubella is typically a self-limited disease. Infants who have congenital rubella are infectious until viral shedding from the nasopharynx and urinary tract ends. The majority of infants (85%) infected in utero excrete virus in the first month of life; 1%–3% continue to excrete virus in the second year of life.[26,30] Pregnant women caring for these infants are at risk for developing rubella. Clinical course depends on how severely affected the fetus is from intrauterine infection.

TREATMENT

Treatment of primary, uncomplicated rubella is supportive. Standard and droplet precautions are recommended for patients with rubella for 7 days after rash onset.[26] In nonpregnant individuals, rubella vaccine administration within 3 days of exposure may theoretically prevent illness, though this is yet to be proven.[26] Limited data indicate that intramuscular immune globulin (0.55 mL/kg) as postexposure prophylaxis of rubella-susceptible patients may decrease infection, viral shedding and rate of viremia.[26] However, absence of clinical signs after administration of immune globulin in a pregnant woman does not assure that congenital infection did not occur. IgM antibody can be used to detect maternal infection after exposure, even after immune globulin administration.[26]

Neonates with congenital rubella syndrome require supportive care as well as appropriate attention to significant health issues. These infants are contagious and should be isolated to prevent transmission to susceptible individuals.[26,28] Contact isolation is recommended for these infants until they are at least 12 months old or if repeated cultures are negative after 3 months of age.[26]

PREVENTION (IMMUNIZATIONS)

Rubella vaccine is typically administered as part of a threefold vaccine (MMR) or fourfold vaccine (MMRV) at 12–15 months of age and again at 4–6 years of age. Seroconversion after a single dose of MMR vaccine occurs in 95% of individuals.[26,27] It is imperative that individuals at risk for rubella infection are immunized, such as health care workers, military recruits, college students, and recent immigrants.[26] Individuals are considered immune to rubella if they have documented vaccination with a live MMR on or after their first birthday, serologic evidence of rubella immunity, or were born after 1957 (except women of child-bearing age).[26,30]

Potential adverse reactions to rubella vaccine occur in susceptible individuals and include: fever (6–12 days after vaccine), morbilliform rash, lymphadenopathy, and arthralgia.[26] Febrile seizures occur more frequently in children 1–2 years old when receiving the first MMR vaccine.[26]

Pregnant women should not receive the rubella vaccine due to theoretical risk to the fetus.[36] Any woman receiving the rubella vaccine should not become pregnant for 28 days. Infants of vaccinated breast-feeding mothers may become infected with rubella via breast milk. Typically, they develop a mild erythematous exanthem of macules and papules with no serious effects.[30] As rubella infection confers lifelong immunity, a woman who is reexposed during pregnancy has a low risk of having her fetus contract congenital rubella. Concern about possible infection can be addressed by looking for IgM antibodies in fetal serum (cordocentesis).

ERYTHEMA INFECTIOSUM AND PARVOVIRUS B19 INFECTION

PARVOVIRUS B19 AT A GLANCE

- Causes erythema infectiosum, fifth disease.
- Fifth disease in children with "slapped cheeks" followed by an erythematous, lacy eruption on the trunk and extremities.
- Symmetric polyarthritis, particularly of the small joints.
- Causes papular purpuric gloves-and-socks syndrome with pruritic erythema, edema, and petechiae of the hands and feet, fever, and oral erosions in adolescents.
- Aplastic crisis in patients with increased red blood cell turnover, chronic anemia in immunocompromised persons, and fetal hydrops.

EPIDEMIOLOGY

Erythema infectiosum (fifth disease) is worldwide in distribution, can occur throughout the year, and can affect all ages. It tends to occur in epidemics, especially associated with school outbreaks in the late winter and early spring. Serologic studies show increasing prevalence of antibodies with age. Various studies indicate that from 15% to 60% of children 5–19 years of age and 30%–60% of adults are seropositive.[37] Seroprevalence increases to greater than 90% in the elderly.[37] Previous infection with B19 seems to confer lifelong immunity.

The incubation period for erythema infectiosum is from 4 to 14 days.[38] After intranasal inoculation of parvovirus-infected serum to healthy volunteers, low-grade fever and nonspecific complaints occurred at the time of viremia, 6–14 days after inoculation, and the rash appeared at day 17 or 18.[39] Parvovirus B19 is thought to be transmitted primarily by the respiratory route via aerosolized droplets during the viremic phase, and B19 DNA has been found in respiratory secretions of viremic patients.[39] After the rash of

erythema infectiosum appears, B19 is not found in respiratory secretions and is usually not present in the serum. This suggests that persons with erythema infectiosum are infectious only before the onset of the rash.

The virus seems to be effectively spread after close contact. The secondary attack rate among susceptible household contacts is approximately 50%. Transmission may occur via blood transfusion, from blood products, and vertically from mother to fetus.[40] The transmission of B19 through blood transfusion is particularly problematic because the nonenveloped virus is not killed by the solvent detergents or heat that are used to inactivate HIV and hepatitis viruses.[41]

ETIOLOGY AND PATHOGENESIS

The B19 virus belongs to the family Parvoviridae and the genus *Erythrovirus*.[42] B19 lacks an envelope and contains single-stranded DNA. It is the smallest single-stranded DNA-containing virus known to infect humans, measuring 18–26 µm in diameter. Parvoviruses are widespread in veterinary medicine, but animal parvoviruses are not thought to be transmissible to humans.[41]

The pathogenesis of erythema infectiosum is unknown, but the mechanism may involve immune complexes. The more serious manifestations of parvovirus infection relate to the fact that the virus infects and lyses erythroid progenitor cells. Evidence suggests that the blood group P antigen (globoside) is a receptor of parvovirus. Because some individuals lack P antigen, they are not susceptible to infection with B19.[43] In patients with increased red blood cell destruction or loss who depend on compensatory increase in red cell production to maintain stable red cell indices, B19 infection may lead to transient aplastic crisis. Such patients include those with anemia associated with acute or chronic blood loss. When parvovirus infects the erythroblasts in a developing fetus with decreased red cell survival, the result may be hemolysis and anemia.[44] Anemia may trigger congestive heart failure, edema (fetal hydrops), and possibly fetal death.

CLINICAL FINDINGS

PARVOVIRUS B19 IN CHILDREN. Most infections caused by B19 are asymptomatic and unrecognized. Fifth disease, the most common clinical picture associated with the virus, usually begins with nonspecific symptoms such as headache, coryza, and low-grade fever approximately 2 days before the onset of the rash.[45] Patients may have headache, pharyngitis, fever, malaise, myalgias, coryza, diarrhea, nausea, cough, and conjunctivitis coinciding with the rash. Approximately 10% of children with erythema infectiosum develop arthralgias or arthritis. Large joints are affected more often than small joints.[45] Occasionally, children may present with chronic joint complaints suggestive of juvenile idiopathic arthritis.[46]

The characteristic rash begins with confluent, erythematous, edematous plaques on the malar eminences, the "slapped cheeks" (Fig. 192-5). As the facial rash fades over 1–4 days, pink to erythematous macules or papules appear on the trunk, neck, and extensor surfaces of the extremities. These lesions have some central fading, giving them a lacy or reticulated appearance (Fig. 192-6).[45] The rash can be morbilliform, confluent, circinate, or annular, and there have been reports of palmar and plantar involvement.[38] The eruption typically lasts 5–9 days, but can recur for weeks or months with triggers such as sunlight, exercise, temperature change, bathing, and emotional stress. In some outbreaks, pruritus is a major feature of the rash in children.[38]

Figure 192-5 Erythema infectiosum. Child with the characteristic "slapped cheeks."

There have been occasional reports of parvovirus B19 associated with vascular purpura, including Henoch–Schönlein purpura.[47] An enanthem consisting of erythema of the tongue and pharynx and red macules on the buccal mucosa and palate can occur.

PARVOVIRUS B19 IN ADULTS. Acute arthropathy is the primary manifestation of B19 viral infection in adults.[48] It occurs mainly in women and affects the small joints of the hands and, knees. Other joints, such as the spine and costochondral joints, are occasionally involved. This symmetric polyarthritis is usually of sudden onset and is self-limited but can be persistent or recurrent for months. It may mimic Lyme arthritis or rheumatoid arthritis.

The constitutional symptoms are usually more severe in adults than in children.[49] Fever, adenopathy, and a mild arthritis without a rash is the usual course. Women are more likely than men to have joint complaints and rash, whereas men often present with only a flu-like illness.[48] Some adults may have fatigue, malaise, and depression for weeks after the infection. Asymptomatic infection can certainly occur in adults

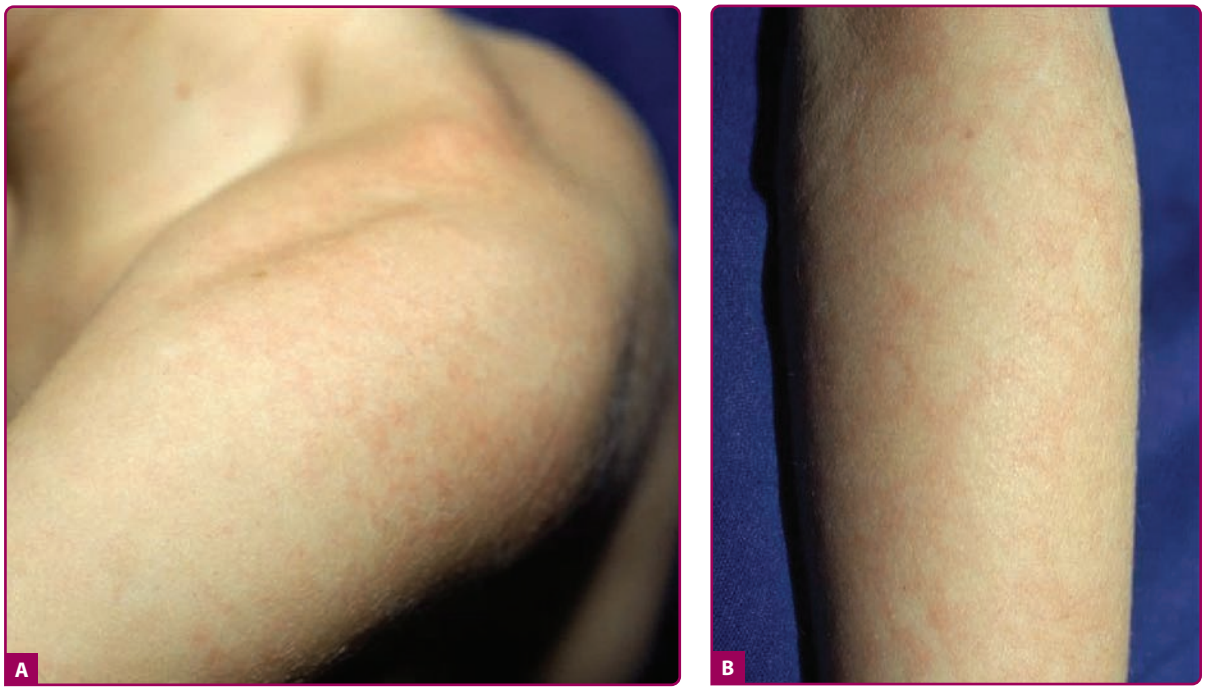

Figure 192-6 **A** and **B.** Erythema infectiosum. **A**. Lacy, reticulated macules and papules on proximal extremities. **B**. Lacy macules on leg.

as well as in children. In one outbreak, 26% of adults were reported to be asymptomatic.[48] Parvovirus B19 can cause numbness and tingling of the fingers with or without other features of fifth disease.[50] Pruritus that is sometimes severe can occur with or without a rash. It has been suggested that if pruritus is a complaint in a patient with acute-onset arthritis, parvovirus should be considered as a possible cause.

The rash in adults, if present at all, is usually macular and blotchy or lacy, often on the extremities, and rarely demonstrates the characteristic slapped-cheek appearance.[48] Other cutaneous manifestations associated with B19 infection in adults include purpura, vesicles and pustules, palmoplantar desquamation, a morbilliform exanthem with Koplik spots, and livedo reticularis.

PAPULAR PURPURIC GLOVES-AND-SOCKS SYNDROME. In 1990,[51] a unique syndrome of pruritic erythema and edema of the hands and feet with petechiae, fever, and oral erosions was described. This rare exanthem, now known as *papular purpuric gloves-and-socks syndrome,* seems to affect teenagers and adults. However, it can affect children also.[52] Patients usually have mild prodromal symptoms of fatigue and low-grade fever, myalgias, and arthralgias. Subsequently, itchy, painful, symmetric edema and erythema of the distal hands and feet occurs.[53] Purpuric papules appear on the hands and feet with abrupt demarcation at the wrists and ankles. The enanthem, if present, arises on the lips, soft palate, and buccal mucosa. The syndrome resolves spontaneously within 2 weeks. Although many viruses have been implicated as causative agents for papular purpuric gloves-and-socks syndrome, B19 is the virus proven to cause the syndrome.[54] Importantly, papular purpuric gloves-and-socks syndrome is contagious when the eruption is present, in contrast to erythema infectiosum.

LABORATORY TESTS

In patients with erythema infectiosum, laboratory results are usually normal, including reticulocyte count, hematocrit, and tests of liver and renal function. Patients with aplastic crisis have reticulocytopenia and anemia, the severity of which depends on the degree of underlying anemia. Reticulocytopenia, anemia, lymphopenia, neutropenia, and thrombocytopenia can occur in healthy individuals with B19 infection, although these are usually not significant enough to cause clinical symptoms. The erythrocyte sedimentation rate is rarely elevated, and rheumatoid factor has been positive in some cases of parvovirus-associated arthritis.

Detection of recent infection is usually performed with assays for IgM antibody. Radioimmunoassay or ELISA techniques can detect IgM within a few days after onset of illness. IgM can be measured for up to 6 months in many cases, although there is a decline in titer in the second month after onset. IgG can be identified with the same techniques by the seventh day of illness and lasts for years and is therefore best for documenting past infection. Parvovirus antibody is often not detectable in immunodeficient persons.

SPECIAL TESTS

Histologic examination of various tissues demonstrates homogeneous, intranuclear inclusions with peripheral condensation of chromatin in erythroid precursor

cells.[55] Electron microscopy of these inclusions reveals parvovirus-like particles.[55] In fetal tissues, a leukoerythroblastic reaction may also be seen. The histopathologic changes in the skin of patients with erythema infectiosum include a sparse superficial perivascular lymphocytic infiltrate that is not considered diagnostic.

PCR is used to detect B19 DNA.[56] This technique is considered one of the most sensitive approaches for detection of the virus within a number of different specimens including serum or plasma, amniotic fluid, placental or fetal tissue, or bone marrow. It is considered the test of choice in an immunocompromised patient. Immunohistochemical techniques can be used to detect B19 parvovirus antigen in a number of different tissues.

DIFFERENTIAL DIAGNOSIS

(Box 192-4)

COMPLICATIONS

As more attention is focused on parvovirus B19, an increasing number of complications are recognized. Subclinical infection is quite common. However, this virus can be responsible for a variety of hematologic, rheumatologic, and neurologic abnormalities.

TRANSIENT APLASTIC CRISIS. Parvovirus B19 is the most common cause of transient aplastic crisis in patients with chronic hemolytic anemias.[57] This has been demonstrated in sickle cell anemia, hereditary spherocytosis, heterozygous β-thalassemia, pyruvate kinase deficiency, and autoimmune hemolytic anemia, as well as in other conditions of decreased red cell production or increased red cell destruction. The aplastic crisis may be the initial manifestation of the underlying hematologic disease.[58] Patients typically have fever and constitutional complaints, followed 1 week later by fatigue, pallor, and worsening anemia.[59] Cutaneous manifestations are rarely seen with the aplastic crisis. The hemoglobin may fall below 4 μg/dL and is not associated with reticulocyte production. Bone marrow examination shows hypoplasia or aplasia of the erythroid series. Red blood cell transfusion may be necessary, and most patients recover in 1 week, although the problem can be fatal if untreated. Transient red cell aplasia can occur in healthy persons without underlying hematologic abnormalities.[60] It is likely that the aplasia is missed in individuals without disorders of shortened erythrocyte survival because the hemoglobin does not drop low enough to cause symptoms.

CHRONIC B19 INFECTION. In immunocompromised patients, B19 infection can cause a serious, prolonged anemia from persistent lysis of red blood cell precursors.[60] Parvovirus-related chronic anemia has been reported in HIV-infected patients, as well as in transplant recipients and those with congenital immunodeficiencies, acute leukemias, lupus erythematosus, and during the first year of life without immunodeficiency. These patients respond dramatically to intravenous γ globulin, suggesting that antibody is the main defense to human parvovirus infection.[61]

FETAL B19 INFECTION. Fetal infection with B19 may result in either an unaffected fetus or spontaneous abortion (especially in the first half of pregnancy), hydrops fetalis in the second half of pregnancy, congenital anemia, and even late fetal death.[62] Nonimmune fetal hydrops is the most common complication of intrauterine infection with B19. Because B19 virus can infect erythroid precursors, extensive hemolysis can occur in the fetus, leading to severe anemia, tissue anoxia, high-output heart failure, and generalized edema. The fetus may show ultrasonographic evidence of subcutaneous edema, ascites, pleural effusion, pericardial effusion, placental edema, and polyhydramnios. The overall risk of fetal death is not clearly known, but recent studies suggest that this risk is approximately 6.5% with maternal infection.[62] The risk of fetal death for a woman with unknown serologic status is estimated to be less than 2.5% after a household exposure and less than 1.5% after a significant work exposure. It seems that in B19-infected pregnant women, most fetuses are not infected; if they are infected, usually there is not an adverse outcome.[63] Furthermore, approximately one-half of women of childbearing age are immune to parvovirus infection because of prior infection.

Because parvoviruses are known teratogens in animals, there has been much concern about whether they cause birth defects in humans. In sera collected from 253 infants with a wide range of congenital abnormalities, there was no parvovirus-specific IgM detected to suggest recent infection.[64] There has been one report of a B19-infected abortus with eye abnormalities,[65] and another of

BOX 192-4 DIFFERENTIAL DIAGNOSIS OF PARVOVIRUS B19 INFECTION

Most Likely
- Erythema infectiosum
- Drug reaction
- Enteroviral infection
- Erysipelas on the cheek
- Papular purpuric gloves-and-socks syndrome
- Hand-foot-mouth disease

Consider
- Erythema infectiosum
- Roseola
- Rubella
- Measles
- Collagen vascular disease (systemic lupus erythematosus, dermatomyositis)
- Papular purpuric gloves-and-socks syndrome
- Atypical measles

Always Rule Out
- Scarlet fever
- Rocky Mountain spotted fever
- Kawasaki disease

an infected abortus with cleft lip, cleft palate, and micrognathia.[66] Rare reports describe cardiac abnormalities.[67] neurologic problems,[68] and "blueberry muffin" nodules.[69] It has been concluded from these few studies that parvovirus B19 is not a common cause of birth defects.

OTHER COMPLICATIONS. There are reports of B19 infection causing encephalitis, meningitis, brachial neuritis, a myasthenia-like syndrome, and motor weakness. Parvovirus infection has been blamed for a granulomatosis with polyangiitis (Wegener's) illness,[70] polyarteritis nodosa,[71] Kawasaki disease,[72] and a systemic lupus erythematosus-like picture.[73] In addition, there are reports of other hematologic complications including idiopathic thrombocytopenic purpura, transient neutropenia, myocarditis, a hemophagocytic syndrome, and the Blackfan–Diamond syndrome.

PROGNOSIS AND CLINICAL COURSE

Parvovirus B19 infection in healthy individuals is self-limited. The eruption of erythema infectiosum and the parvovirus arthropathy usually resolve in 1–2 weeks, but can recur or persist for months. If untreated, transient aplastic crisis can be fatal, but most patients recover in 1 week. Chronic anemia from B19 usually resolves if treated with γ globulin. Fetal hydrops can lead to fetal death if not treated.

TREATMENT

There is no specific treatment available for parvovirus B19 infection. Erythema infectiosum is a benign condition, and usually no treatment is necessary. Supportive therapy for relief of fatigue, malaise, pruritus, and arthralgia may be needed. The chronic anemia of persistent B19 infection may be treated successfully with commercially available intravenous immunoglobulin, which contains neutralizing anti-B19 antibodies. Transient aplastic crisis, which can be life threatening, may require oxygen therapy and blood transfusion.

Serologic testing for B19 IgG and IgM should be offered to pregnant women who are exposed to parvovirus B19. Infected pregnant women are followed by frequent ultrasonograms. Evidence of hydrops fetalis warrants umbilical cordocentesis to check for anemia, viral DNA, IgG, and IgM. The management of infected fetuses is controversial. Some physicians advocate observation because spontaneous resolution is common. Fetuses with severe anemia and compromise are usually managed with intrauterine exchange transfusion, but this procedure does carry risk (Box 192-5).

PREVENTION

There is currently no vaccine to prevent parvovirus B19 infection. Candidate vaccines are in clinical trials.[74] It is not known whether immunoglobulin given around the time of exposure prevents infection or alters the course of the disease.

BOX 192-5 TREATMENTS FOR PARVOVIRUS B19 INFECTIONS

▪ Erythema infectiosum	Supportive treatment of fatigue, malaise, pruritus, arthralgias
▪ Chronic anemia	IV immune globulin
▪ Transient aplastic crisis	Oxygen and/or blood transfusion may be necessary
▪ Hydrops fetalis	Possible intrauterine exchange transfusion

Because patients with erythema infectiosum are no longer infectious by the time they develop the illness, control measures directed toward these individuals are not likely to be effective. If these persons are hospitalized, no special precautions need to be taken. Because the virus is transmitted before the rash appears, the disease is easily spread in situations of close prolonged contact such as schools, day care centers, workplaces, and homes.

Patients with aplastic crisis or immunosuppression with chronic B19 anemia may have high-titer viremia and are particularly infectious. These individuals should be placed in respiratory and contact isolation if hospitalized, and pregnant health care providers should not care for them directly. Hospital workers are at risk of contracting nosocomial infections from these patients[75] and could spread the virus to patients if adequate precautions are not taken.

EPSTEIN–BARR VIRUS

EPSTEIN–BARR VIRUS AT A GLANCE

- Human herpesvirus 4.
- In developed countries, primary infection most often occurs during adolescence/early adulthood.
- Infectious mononucleosis characterized by the triad of fever, lymphadenopathy, and pharyngitis.
- Morbilliform exanthem with primary infection; most common after administration of ampicillin/amoxicillin.
- Oral hairy leukoplakia, nasopharyngeal carcinoma, Burkitt lymphoma, Hodgkin disease, Kikuchi histiocytic necrotizing lymphadenitis, and certain types of cutaneous T-cell lymphoma associated with Epstein–Barr virus infection.

EPIDEMIOLOGY

Epstein–Barr virus (EBV) is a worldwide pathogen with more than 90% of adults latently infected.[76] In developed countries, most cases of primary infection occur during adolescence or early adulthood, and clinically may present as infectious mononucleosis.[77] Primary infection may occur during childhood; however, is often subclinical, probably because children are better able to clear the infection. In developing countries, most of the population is infected during childhood, thus infectious mononucleosis is much less common.

EBV is transmitted primarily by saliva through close contact.[78] Viral replication occurs during primary infection, allowing infectious viral particles to be shed from the oropharynx. There are also reports of EBV acquired via blood transfusion.[79] It is also thought that EBV may be transmitted through breast milk[80] and genital secretions.[81]

ETIOLOGY AND PATHOGENESIS

EBV, also called *human herpesvirus 4 (HHV-4)*, belongs to the Herpesviridae family and is approximately 180–200 nm in diameter.[78] The double-stranded DNA genome encodes approximately 100 proteins and is enclosed within a capsid. The capsid is surrounded by an envelope, composed primarily of glycoprotein gp350. CD21 is present on the surface of B cells and binds with gp350, allowing entry of EBV into the cell.

EBV infects B lymphocytes directly within the oral mucosa or infects mucosal epithelial cells, which then infect the B lymphocytes.[82–84] The infected B cells are activated, and their population is expanded. These B lymphocytes allow dissemination of the virus throughout the lymphoreticular system.[85] A clonal expansion of cytotoxic T lymphocytes allows recovery from primary infection and is the source of the atypical lymphocytes associated with EBV infection.[86] Symptoms likely result from this immunologic response.

EBV establishes an indefinite latent infection within the B cells, during which time low levels of the latent proteins are produced.[86] The previously linear DNA forms a circular structure, called an episome. Thereafter, B cells may reactivate and reinfect the oropharynx; replication and shedding of the viral DNA allows transmission of the virus to new hosts.[78,85]

CLINICAL FINDINGS

HISTORY. There is an incubation period of 30–50 days. Primary infection with EBV in adolescents and adults typically results in infectious mononucleosis, or the "kissing disease." The classic triad of fever, lymphadenopathy, and pharyngitis are noted in more than 50% of patients.[78] The fever may range from 37.5°C (99.5°F) to 40.5°C (104.9°F) and lasts 1–3 weeks. Lymphadenopathy is tender and characteristically found in the posterior cervical chain. Examination of the posterior pharynx may vary from mild erythema to grossly enlarged tonsils with white exudates.[85]

CUTANEOUS LESIONS. Seventy percent to 100% of patients with infectious mononucleosis develop an eruption when antibiotics, specifically ampicillin, are administered.[83] Similar rashes have been reported with other antibiotics, such as amoxicillin, cephalexin, erythromycin, and levofloxacin. The rash typically begins 7–10 days after the initial administration of antibiotics. A pruritic, erythematous, morbilliform, or scarlatiniform eruption is noted on the trunk and extremities. The rash has been described as copper colored. Coalescence may be observed on the extensor surfaces and dependent areas. (Fig. 192-7 and see eFig. 192-7.1 in online edition). The palms, soles, or oral mucosa may be involved. Clearance, which is usually within 7 days,[87] is accompanied by prominent desquamation.[86] The rash is thought to be a result of EBV-induced antibodies that are produced in response to the administered drug; these antibodies subsequently form immune complexes, which fix complement.[83] This exanthem does not usually indicate a permanent allergy to the medication.[87]

An exanthem due to EBV alone occurs in a minority of cases (approximately 5%–15%),[83,87] and can similarly be morbilliform and pruritic; however, usually it commences during the first few days of illness and resolves faster, typically in 1–6 days.[86,87] Periorbital and eyelid edema may be seen in up to 50% of those with infectious mononucleosis.[89] In approximately 25% of cases, an enanthem is noted. Six to 20 petechiae, measuring 0.5–1.0 mm, may be visualized at the junction of the hard and soft palate. Lesions may coalesce forming larger lesions.

Erythema multiforme, erythema nodosum, acrocyanosis, erythema annulare centrifugum, pityriasis lichenoides, palmar dermatitis, cold urticaria, and granuloma annulare have all been reported during infection with EBV.[86]

Genital ulcers may occur during primary infection with EBV (Fig. 192-8).[90,91] They may occur prior to the onset of other features of infectious mononucleosis or occasionally after the fever and lymphadenopathy.[92] They are well circumscribed, painful, and deep with a red-violaceous border. The base of the ulcer can be clear, seropurulent, or with granulation tissue. They frequently occur on the labia minora.[93] If bilateral, they are often symmetric with a "kissing" pattern. It is unclear at this point whether the ulcer is caused directly by the virus or whether it is due to a host immune response. Biopsy is typically nonspecific and nondiagnostic. The ulcers heal in approximately 2–3 weeks, and treatment is symptomatic.

EBV is currently the most common cause of Gianotti–Crosti syndrome.[94] In children, primary infection with EBV is often mild or asymptomatic; as a result, typical features of infectious mononucleosis are usually not observed.[86]

RELATED PHYSICAL FINDINGS. Associated symptoms and signs may include fatigue, rigors, headache, and hepatosplenomegaly.[95]

Figure 192-7 **A**. Epstein–Barr virus mononucleosis. Copper-colored papules on trunk and extremities after taking oral amoxicillin. **B**. Closer view of rash with Epstein–Barr virus mononucleosis. (Used with permission from Helmut Hintner, MD.)

LABORATORY TESTS

Most patients with infectious mononucleosis demonstrate lymphocytosis, with lymphocytes often accounting for more than 50% of the absolute white blood cell count.[96] Atypical lymphocytes are a hallmark, and typically represent more than 10% of total lymphocytes; most of these cells represent activated T cells responding to infected B cells.[78] Mild, transient neutropenia[97] and thrombocytopenia[98] are common. Transaminases are elevated in more than 80% of patients with infectious mononucleosis.[99]

Figure 192-8 Two scrotal ulcerations in a patient with documented EBV infection.

The presence of heterophile antibodies confirms most cases of infectious mononucleosis.[100] Heterophile antibodies recognize antigens on the erythrocytes from a number of different species, including horses, sheep, bulls, and humans; however, they do not recognize EBV. They are thought to be a result of polyclonal stimulation during the viral infection,[101] and can occasionally be detected (false positives) in other illnesses such as lymphoma, hepatitis, or autoimmune disease.[100] Heterophile antibodies typically appear within 1 week of the onset of symptoms, peak within 2–5 weeks, and may persist for up to 1 year. They are not the ideal diagnostic test in children less than 4 years old, as sensitivity is quite low.[95] In the past, the Paul–Bunnell test had been used with sheep erythrocytes.[100,96] Currently, the more sensitive monospot test is used, which is a latex agglutination assay with horse erythrocytes to look for heterophile antibodies. Up to 10% of patients with EBV mononucleosis never develop heterophile antibodies; this is referred to as heterophile-negative mononucleosis.

A number of antibodies specific to EBV develop in the course of disease as well.[100,95] Measurement of these specific antibodies may be warranted if infectious mononucleosis is suspected and heterophile antibodies are negative. IgM and IgG antibodies form to viral capsid antigen (VCA) and are both present at onset of disease. IgM VCA antibodies wane after approximately 3 months; IgG VCA antibodies persist for life and are a marker for previous infection. IgG antibodies to EBV nuclear antigen develop 6–12 weeks into the course of disease and also persist for life. IgG to early antigen develops at the onset of disease and is made up of two subsets of antibodies, anti-D and

anti-R. The presence of anti-D antibodies suggests recent infection, although 30% of patients do not produce antibodies at all. Anti-R antibodies have no clinical significance. Thus, primary infection may be most easily diagnosed in the presence of IgM and IgG VCA antibodies as well as negative IgG EBV nuclear antigen antibodies.[102]

HISTOPATHOLOGY

The morbilliform exanthem associated with EBV demonstrates nonspecific histopathologic findings.[103] There is usually a mild perivascular infiltrate of inflammatory cells. Specific cutaneous manifestations may show their characteristic pathologies.

DIFFERENTIAL DIAGNOSIS

(Box 192-6)

COMPLICATIONS

Complications of infectious mononucleosis occur in approximately 20% of patients and include airway obstruction, autoimmune hemolytic anemia or thrombocytopenia, neutropenia,[85] myocarditis, and hepatitis.[80] Neurologic complications occur in approximately 5% of patients.[85] Examples include encephalitis, meningitis, and Guillain–Barré syndrome.[78] The risk of splenic rupture is estimated at 0.1% and is spontaneous in greater than one-half of cases.[104] Between 3% and 30% of patients with infectious mononucleosis also have concomitant group A streptococcal pharyngitis.[96] Finally, in some patients, fatigue and hypersomnia can persist up to 6 months.[105]

BOX 192-6 DIFFERENTIAL DIAGNOSIS OF INFECTIOUS MONONUCLEOSIS

Most Likely
- Group A streptococcal infection
- Cytomegalovirus mononucleosis
- Toxoplasmosis

Consider
- Viral hepatitis
- Measles
- Rubella
- Enterovirus
- Adenovirus

Always Rule Out
- Primary exanthem of human immunodeficiency virus
- Drug rash with eosinophilia and systemic symptoms syndrome

PROGNOSIS AND CLINICAL COURSE

Recovery from infectious mononucleosis is typically over 2–3 weeks without specific treatment.[100] Disease may be more protracted in older adults. Chronic active EBV infection occurs rarely.[78] It begins as a primary EBV infection and persists for more than 6 months with severe illness and histologic evidence for organ disease. EBV DNA or antigens can be demonstrated from tissue, and usually EBV antibody titers are significantly elevated.

TREATMENT

Treatment for uncomplicated infectious mononucleosis is symptomatic (Box 192-7).[95] Acetaminophen or nonsteroidal anti-inflammatory agents may be useful in treating the fever or throat discomfort. Because splenomegaly is often an associated finding, contact sports should be avoided until the spleen has returned to its normal size to avoid splenic rupture.

Systemic corticosteroids may decrease the duration of fever or pharyngeal symptoms, but in general, are not recommended for uncomplicated disease.[77]

There have been complications such as encephalitis or meningitis associated with steroid treatment of infectious mononucleosis. Oral steroids may be considered in patients showing signs of impending airway obstruction, thrombocytopenia, or hemolytic anemia.

A meta-analysis of five randomized controlled trials evaluating acyclovir in the treatment of infectious mononucleosis showed that there was decreased oropharyngeal shedding of the EBV; however, there was no overall clinical benefit demonstrated.[106] A multicenter, double-blind, placebo-controlled study involving 94 patients with acute infectious mononucleosis revealed that acyclovir and prednisolone also reduced oropharyngeal replication of virus but did not affect duration of symptoms.[107]

BOX 192-7 TREATMENT FOR EPSTEIN–BARR VIRUS INFECTIOUS MONONUCLEOSIS

First line	Fever, throat discomfort, myalgias, headache. Splenomegaly	Acetaminophen/nonsteroidal anti-inflammatory drugs. Avoid contact sports until spleen size normalizes to prevent splenic rupture
Second line	Impending airway obstruction, thrombocytopenia, hemolytic anemia	Systemic corticosteroids

PREVENTION

Because infectious mononucleosis is often mistaken for a bacterial infection, antibiotics may initially be used to treat. Antibiotics should be avoided in infectious mononucleosis as an exanthem is much more likely to occur in this setting.

Vaccinations are currently being investigated and may prove to be helpful in preventing EBV infections in the future, particularly in high-risk patients.[78]

LYMPHOPROLIFERATIVE DISEASE AND MALIGNANCY

The latent infection established by EBV has been linked to the development of several malignancies, including nasopharyngeal carcinoma, Burkitt lymphoma, and Hodgkin lymphoma.[78] EBV-associated malignancies occur mainly in patients who are immunocompromised due to HIV infection, congenital immunodeficiencies, or those who receive immunosuppressant therapy such as organ transplant recipients. It is thought that the latent infection of B cells allows transformation and immortalization, allowing the development of a neoplasm to occur.[114] Different EBV genes are expressed in each type of malignancy and the biology is quite complex.

Nasopharyngeal carcinoma occurs sporadically in the United States and in Western Europe, is common among Alaskan Eskimos, and is endemic in Southern China, Southeast Asia, and in the Mediterranean basin.[115] This neoplasm may clinically present with bloody nasal drainage, otitis media, or cranial nerve palsies. Metastasis to the lymph nodes occurs early; thus lymphadenopathy of the head or neck may be the initial presentation. Skin metastases can rarely be the presenting sign, usually appearing as dermal or subcutaneous nodules.[116] Clubbing and dermatomyositis have rarely been reported in association with nasopharyngeal carcinoma. EBV is present in the malignant epithelial cells yet is not found in the lymphocytes.[78]

African Burkitt lymphoma is a mature B-cell neoplasm endemic to Equatorial Africa that involves overexpression of the c-myc oncogene.[117] It typically affects children and presents with tumors of the jaw or facial bones.[117,118] A sporadic subtype in Western Europe or the United States demonstrates abdominal involvement. The immunodeficient subtype typically occurs in HIV-positive patients and appears most frequently in the abdomen. Virtually all cases of endemic Burkitt lymphoma are associated with EBV as well as a previous malarial infection, whereas the sporadic variant is associated with EBV is less than 20% of cases.[118,119] Dissemination to the skin is extremely rare; however, marked lymphadenopathy is commonly observed.[118] Biopsy of lesions show a neoplasm of medium-sized cells with abundant basophilic cytoplasm, as well as apoptotic debris and macrophages ingesting apoptotic tumor cells, creating the "starry sky" appearance.

Hodgkin disease is a malignant lymphoma with bimodal age distribution.[120] In developed countries, the peaks are in young adulthood and in older adults. In developing countries, children as well as older adults are more frequently affected. EBV is associated with Hodgkin lymphoma in 30%–50% of cases. EBV is linked to Hodgkin disease more commonly in developing countries, in children, and in the setting of immunodeficiency. The majority of patients have a painless mass, frequently in the neck.[121] Hodgkin disease has associated skin lesions in 17%–53% of patients.[122] The majority of cutaneous findings are nonspecific and considered paraneoplastic in nature. Examples include severe pruritus, eczema, ichthyosis, urticaria, erythroderma, erythema nodosum, and associated mycosis fungoides. Cutaneous infiltration by Hodgkin disease is rarer, and typically occurs in the setting of advanced disease. Findings may include ulcerated nodules, plaques, tumors, papules, or erythroderma. Pathology consists predominantly of an inflammatory infiltrate with scattered characteristic Reed–Sternberg cells, which are $CD30^+$, $CD15^+$, binucleate large cells with eosinophilic nuclei.[120] Treatment is radiotherapy, chemotherapy, or a combination.

Certain types of cutaneous T-cell lymphoma have been found to be associated with the EBV. Chronic ulcers, subcutaneous nodules, and violaceous tumors have been noted in patients with angiocentric T/natural killer-cell lymphomas, T large-cell lymphomas, and systemic T-cell lymphoma with cutaneous involvement.[123] Necrotic nasal masses, which may affect surrounding skin as well, can also occur in angiocentric T/natural killer-cell lymphomas. EBV may also be associated with subcutaneous panniculitic T-cell lymphoma, which clinically presents as a panniculitis.[124] Histologically, there are atypical lymphocytes in the lobules of the fat as well as phagocytizing "beanbag cells" (eFig. 192-8.1 in online edition).

Vesiculopapular lesions on the face of a child, resembling hydroa vacciniforme, may be associated with EBV and have a malignant potential. Hypersensitivity to mosquito bites with erythematous swellings or ulcers may also be linked to latent EBV infections. This phenomenon may indicate high risk for progression to a malignant neoplasm.

GIANOTTI–CROSTI SYNDROME

GIANOTTI–CROSTI SYNDROME AT A GLANCE

- Papular acrodermatitis of childhood.
- Common, self-limited dermatosis.
- Monomorphic dome-shaped or flattopped papules symmetrically distributed on face and extensor extremities.
- Associated with multiple viral triggers and immunizations.
- Historically associated with hepatitis B infection, but now more often triggered by Epstein–Barr virus.

EPIDEMIOLOGY

Gianotti–Crosti Syndrome, also known as infantile papular acrodermatitis and papular acrodermatitis of childhood, is a common, self-limited dermatosis seen worldwide. It affects infants and children between the ages of 6 months and 12 years with the peak age of presentation being 1–6 years of age. Cases have a seasonal predilection, most often occurring in spring and early summer. In children, there is neither an ethnic nor sexual predilection.[129,130] There have been only scattered case reports in adults, exclusively in women.

ETIOLOGY AND PATHOGENESIS

GCS is a cutaneous reaction pattern associated with viruses, bacteria, and vaccines. The exact pathogenesis is unclear. However, there is some suggestion that immunizations or immune imbalance may enhance the risk of developing the exanthem following certain infections. A recent study showed an increased incidence of a personal or family history of atopy in children with GCS.[131]

Historically, it was thought to be induced exclusively by hepatitis B, but over time other infectious triggers have been identified. When hepatitis B is the causative agent, subtype ayw is most frequently seen.[132] However, with widespread immunization against Hepatitis B, most cases found in Europe, India, the United States, and Canada are not associated with Hep B infection. EBV is the most common cause in the United States and can be due to initial infection or reactivation.[133] Other associated viruses include cytomegalovirus, enterovirus, respiratory syncytial virus, rotavirus, adenovirus, echovirus, pox virus, poliovirus, coxsackie virus (A16, B4, and B5), parvovirus B19, HIV, hepatitis A, hepatitis C, mumps virus, HHV-6, vaccinia virus, rubella virus and parainfluenza virus. Bacterial pathogens include *Mycoplasma pneumoniae*, *Borrelia burgdorferi*, *Bartonella henselae*, and group A β-hemolytic streptococcus. Immunizations that have been associated include influenza, diptheria-pertussis-tetanus (DPT), bacillus Calmette–Guérin, *Haemophilus influenzae* type b, MMR, hepatitis B, Japanese encephalitis and oral polio vaccine. Although many groups have tried using both electron microscopy and immunohistochemistry, neither viral particles nor viral antigens have been demonstrated in skin lesions of GCS.[134,135] Thus, today it is accepted that the mechanism of lesion development does not involve a direct local interaction between viral antigens and immune-competent cells in the skin.

CLINICAL FINDINGS

HISTORY. Before the onset of the exanthem, a nonspecific prodrome of upper respiratory tract symptoms with fever and pharyngitis plus lymphadenopathy may be present.

CUTANEOUS LESIONS. Regardless of the cause, the clinical features in all cases tend to be the same. Typically, patients abruptly develop multiple coalescing, monomorphous, flat-topped or dome-shaped, red–brown papules and papulovesicles (Fig. 192-9 and see eFig.192-9.1 and eFig. 192-9.2 in online edition). Lesions can be pruritic and, rarely, hemorrhagic. Papules vary from 1 to 10 mm in diameter (see Fig. 192-9B) and are distributed symmetrically on the cheeks, extensor surfaces of the extremities, and the buttocks. The trunk, palms, and soles are usually, but not always, spared. Occasionally, the small papules coalesce into large plaques. Cutaneous lesions evolve over a few days and last for 2–8 weeks.

RELATED PHYSICAL FINDINGS. Constitutional symptoms, including malaise, low-grade fevers, and diarrhea, are sometimes seen at time of presentation, but are usually mild. Patients can develop lymphadenopathy, especially of the cervical, axillary, and inguinal chains.[136]

LABORATORY TESTS

In most patients, the diagnosis is established on clinical findings and no further diagnostic testing

Figure 192-9 **A** and **B**. Erythematous edematous monomorphous dome-shaped papules on the extensor extremities in an toddler with Gianotti–Crosti syndrome.

BOX 192-8 DIFFERENTIAL DIAGNOSIS OF GIANOTTI–CROSTI SYNDROME

Most Likely
- Papular urticaria
- Pityriasis rosea

Consider
- Erythema multiforme
- Lichen planus
- Lichenoid drug eruption
- Pityriasis lichenoides et varioliformis acuta
- Molluscum contagiosum
- Hand-foot-mouth disease
- Follicular eczema
- Erythema infectiosum

Always Rule Out
- Infectious mononucleosis
- Henoch–Schönlein purpura
- Scabies

is necessary. In patients with hepatomegaly, further diagnostic testing, including complete blood cell count and liver enzymes, may be warranted. Lymphocytosis or lymphopenia are common and do not require further diagnostic evaluation. If there are elevations in the liver enzymes, evaluation for hepatitis or EBV should be performed. If hepatitis is suggested, checking anti-hepatitis A IgG and IgM, hepatitis B surface antigen and core antibody, and anti-hepatitis C IgG is indicated.

DIFFERENTIAL DIAGNOSIS

(Box 192-8)

COMPLICATIONS

Complications are rare with the majority of cases having a self-limited and mild course. On rare occasions, when GCS is associated with hepatitis B infection, chronic liver disease with subsequent liver failure can occur.[137]

PROGNOSIS AND CLINICAL COURSE

In the vast majority of cases, GCS is a self-limited, benign process that usually resolves within 3–4 weeks. The course is quite variable, with the skin findings lasting anywhere from 5 days to 12 months.[136,138] Lesions heal without scarring, and, rarely, postinflammatory hypopigmentation or hyperpigmentation is seen. Lymphadenopathy can last for several months.[132] In cases associated with hepatitis B, an anicteric viral hepatitis evolves and may not be seen until 2 weeks after cutaneous lesions are seen. Most of the time, the hepatitis is self-limited.

TREATMENT

No treatment is necessary in the majority of cases. In some patients, medium potency topical steroids may decrease the duration of lesions when applied once daily for 1–2 weeks. However, patients should be monitored closely because worsening of findings with topical steroid use has been documented.[139] In severe cases, systemic, pulsed corticosteroids may be administered.[140] Oral antihistamines or topical anti-itch lotions may diminish severe pruritus.

PREVENTION

There is no known way to prevent GCS.

HUMAN CYTOMEGALOVIRUS

CYTOMEGALOVIRUS AT A GLANCE

- Human herpesvirus 5.
- High prevalence in the population.
- Establishes latent infection and capable of reactivation in immunosuppressed states.
- Primary infection is mainly asymptomatic; it is the cause of severe morbidity and mortality in utero and in immunocompromised patients.
- Petechiae and blueberry muffin syndrome with congenital infection.
- Congenital infection is major cause of hearing loss.
- Infected cells are cytomegalic with intranuclear inclusions.

EPIDEMIOLOGY

Human cytomegalovirus (HCMV) is ubiquitous around the world. The seroprevalence in the population increases with age, with 10%–20% of children infected before they reach puberty.[141] By adulthood, the prevalence of HCMV is 40%–100%. For unclear reasons, there is a higher prevalence in developing countries and areas of low socioeconomic status. HCMV is the most common congenital viral infection in humans with an incidence of 0.2%–2.2% of live births in the United States.[142] Five percent to 17% of congenital infections exhibit neurodevelopmental sequelae.[143] Nearly all HIV-infected patients are infected with HCMV.[144] It is a significant cause of morbidity in bone marrow

transplant (BMT) and solid organ transplant (SOT) patients, with 50%–90% of patients infected.[142]

CLINICAL FINDINGS

CONGENITAL HUMAN CYTOMEGALOVIRUS INFECTION

History. Congenital HCMV (cytomegalic inclusion disease of the newborn) occurs mostly in children of primiparous women with primary infection during pregnancy. Fifty-five percent of maternal primary HCMV infections results in intrauterine HCMV infection of the fetus, and approximately one-third of those are symptomatic.[149] Reactivation or secondary HCMV infection of a HCMV-immune woman during pregnancy rarely results in symptomatic HCMV infection for the baby.[149]

Cutaneous Lesions. Cutaneous findings in the newborn include a petechial rash secondary to thrombocytopenia, jaundice due to hepatitis and blueberry muffin lesions (Fig. 192-10) from dermal erythropoiesis. In one study, approximately 70% of children with symptomatic congenital HCMV infections had petechiae and jaundice.[150] Dermal erythropoiesis, also known as thrombocytopenic purpura or blueberry muffin syndrome, can also be seen with congenital rubella,[151] toxoplasmosis, and blood dyscrasias. These purpuric lesions are present at birth and evolve during the first 24–48 hours of life. They are papular and range from 2 to 10 mm in diameter. Lesions are initially dark blue to violaceous and fade to red or copper–brown. They regress during the first 6 weeks of life despite continued presence of the virus. Histology shows plaque-like aggregates of nucleated cells and nonnucleated erythrocytes in the reticular dermis.[152]

Figure 192-10 Newborn with congenital HCMV infection: "blueberry muffin baby." (From Groark SP, Jambel RM: Violaceous papules and macules in a newborn. Dermal erythropoiesis associated with congenital cytomegalovirus infection. *Arch Dermatol* **114**:116, 1989, with permission.)

Related Physical Findings. Related findings include hepatosplenomegaly in virtually all newborns, microcephaly, periventricular calcifications, ventriculomegaly, encephalitis, chorioretinitis, hearing loss or neurodevelopmental sequelae, intrauterine growth retardation, and postnatal failure to thrive. Studies show that 22%–65% of symptomatic and 6%–23% of asymptomatic children have hearing loss after congenital HCMV infection.[153]

PERINATAL HUMAN CYTOMEGALOVIRUS INFECTIONS

History. Perinatal infection with HCMV is very different from congenital HCMV infection, without diffuse visceral or central nervous system involvement.[149] Transmission of the virus occurs via cervical secretions, breast milk, or blood transfusions between 4 and 16 weeks of age. It is usually asymptomatic, although it may be manifested by self-limited lymphadenopathy, hepatosplenomegaly, or afebrile pneumonitis.

Cutaneous Lesions. There are usually no cutaneous findings with perinatal HCMV infection. Uncommon presentations for HCMV infection in infants and children include scleroderma, Giartti–Crosti syndrome[128,154] gray pallor, hepatosplenomegaly with self-limited respiratory deterioration in preterm infants,[155] and cutaneous vasculitis.[155] Perineal ulcers have been reported in an immunocompetent preterm infant.[156]

HUMAN CYTOMEGALOVIRUS INFECTION IN IMMUNOCOMPETENT ADULTS AND CHILDREN
