finds himself. Alternatively, the child may have true psychiatric illness, but the emergency is not a worsening of symptoms per se but rather that the caretakers are for whatever reason less able to manage those symptoms. A parent may be weakened by illness, divorce, or financial stress, or may lose a key support or structure like an after-school program or grandparent willing to help care for the child; or the child may be removed from the parent and placed in a foster care home where the caretaker is not equipped to care for a child with mental illness. Here, again, the crisis is not psychiatric per se, but rather a breakdown of the caretaking system, which must be shored up if the child is to be discharged safely.

PRINCIPLES OF EMERGENCY PSYCHIATRIC CARE FOR CHILDREN AND ADOLESCENTS

Comprehensive Assessment of the Child

When a patient is in crisis, treatment must start immediately, so the initial assessment must be therapeutic in itself. Given the case complexity of youth presenting to the ED in psychiatric crisis, the first step in the evaluation is gathering essential information. This is more difficult than with adult patients, as information cannot be obtained from the patient alone. When a child or adolescent is brought to the ED, collateral from the parent or guardian is critical to give the facts of the situation that the child is unable to give due to cognitive and emotional immaturity. Collateral also provides crucial information about the child's life at home and at school, their strengths, stressors, medical issues and history (including allergies), history of psychiatric treatment (including response and compliance), developmental history, history of substance use, family history, legal history, social history including any prior trauma exposure, and academic history.

But the assessment should not be based exclusively on the parent or guardian's report, even if the child is very young or intellectually disabled. A careful, curious, and empathic interview of the child is imperative to understand their perspective, the reasons behind their behaviors, their interpretation of what is going on around them, their strengths and cognitive abilities, and the internalizing symptoms such as depression, anxiety, and trauma-related symptoms that often are missed by parents and other adults (Table 36.4–2).

Conducting the interview with an aim to truly understand and empathize with the child's perspective can be very therapeutic for the child. Most children have not had the experience of an adult truly listening to them, striving to understand their experience without judgment or reprimand, and trying to help them. This approach will be more effective than a "checklist" approach to the mental status examination. The interview with the child must include questioning about suicidal and

homicidal ideation, though with the recognition that children and adolescents often minimize or deny suicidal or homicidal ideation or intent, as they fear getting in trouble or being hospitalized. An empathic and nonjudgmental stance to these questions can increase the likelihood of an honest response and also serves to build rapport, even with hostile adolescents. Questions about hallucinations and delusions are also critical, though the clinician should be careful with phrasing these questions as young children or those with developmental delays may misinterpret the question (or their own internal experience) and falsely answer yes, while teens who are truly psychotic may deny such symptoms for fear of being labeled as "crazy." A therapeutic stance to the interview can help young patients to trust the process and the clinician, and starts to break the stigma around mental health treatment.

For very young or otherwise minimally-verbal or nonverbal children (such as those with autism or intellectual disability), the clinician should still attempt to engage the patient to complete a thorough mental status examination. A child with little expressive language may still be able to follow commands, engage in parallel or reciprocal play, and express needs through gestures. The clinician can also observe the child's fine and gross motor skills through drawing and playing, and can assess frustration tolerance, hyperactivity, distractibility, attachment to the parent or guardian (or evidence of fear of the parent), and anxiety with separation. All of these observations will lend diagnostic clarity and provide a therapeutic, calming experience for the child.

Table 36.4–2.
Components of a Comprehensive Assessment

Identifying information
Chief complaint
History of present illness
Past psychiatric history
Current medications and medication history
Past medical history
Substance use history
Trauma history
Social history including trauma and child welfare involvement
Developmental and educational history
Family history
Legal history
Mental status examination including cognitive screen
Medical clearance including physical if indicated

A therapeutic stance is equally important for interviewing parents, foster parents, and other caregivers, who are often exhausted from dealing with frightening and disruptive symptoms and behaviors without a good

understanding of their cause. Treating child psychiatric patients in the ED often feels like having two patients—the child and the family—and approaching both carefully and empathically is crucial to understand the situation and create buy-in for ongoing treatment. A parent's anxiety or agitation can be ameliorated by empathizing with how difficult a child's mental illness can be for a family, and acknowledging that the ED evaluation itself is a difficult process. Reducing the parent's anxiety or anger not only makes the ED evaluation easier, it can also help the parent to be more open to changing their own behavior toward the child and to obtaining treatment. These interviews with both the parent and the child, should be conducted in a quiet, private space free from interruption, so that everyone feels safe and respected when discussing their challenges and expressing painful feelings.

In many cases, a child will be brought to the ED by someone other than their parent (police, EMS, friends, or child welfare workers, for example). The parent should be contacted as quickly as possible, as their involvement will be crucial to the assessment and treatment planning. If the parent or guardian cannot be reached, most states allow clinicians in an emergency to initiate evaluation and treatment of the child, though ongoing attempts to reach the parent should be made. Occasionally, an adolescent will insist that the parent not be contacted. While many states allow adolescents to seek mental health services without the parent being involved or notified, these youth should be encouraged to include their parents in the evaluation, and often with support and empathy of the ED staff a rapprochement can be made between the parent and child.

The initial evaluation does not conclude with an interview with the patient and parent or guardian. A child's teachers and guidance counselors can report on behaviors at school and academic achievements that shed light on the child's cognitive abilities and social skills with peers. Outpatient providers (counselors, case workers, therapists, psychiatrists), and social services workers (child welfare workers, other case managers) can provide very helpful perspective on the child's recent symptoms and mental state, the family's strengths and vulnerabilities, and the resources and supports available to them in the community. The pediatrician can also give an important developmental perspective, having often worked with the child and family for many years, and can identify any concern about compliance, response to treatment, medical issues, physical traumas, and growth which could be a indicative of child abuse or neglect. Consent from the parent or guardian should ideally be obtained before contacting any of these individuals, but in potentially life-threatening situations such as suicidal ideation or concern for child abuse, the safety of the patient outweighs the risk of confidentiality, and the clinician can contact these individuals for information without violating the requirements of Health Insurance Portability and Accountability Act (HIPAA).

By integrating all the information into a comprehensive assessment, the ED clinician can begin to understand the child, family, and contextual factors that are contributing to the crisis at hand. Often the ED clinician will find that the descriptions of symptoms and behaviors and the explanations for such will vary between the child, the parent, and the other informants. These differences may stem from real differences in the child's symptoms and behaviors across different contexts (for example, at home or at school). Alternatively, a parent or other adult may not be aware of or attuned to the child's internal state, and thus may miss internalizing symptoms and over-emphasize externalizing behaviors. The child may have poor insight, may be guarded or minimizing of symptoms, or alternatively may be voicing a major stressor (such as abuse, domestic violence, or school bullying) that the adults are attempting to hide or of which they are unaware. Understanding these sources of variance and integrating them into a clear formulation is necessary to determine an appropriate and effective treatment plan.

Effective Psychotherapeutic and Psychopharmacologic Management of Agitation

Key to ensuring that the initial evaluation is therapeutic is effective management of agitation to avoid restraint and seclusion. Children and adolescents experience restraint and seclusion as frightening, and their perception of time can become distorted such that they perceive themselves as being restrained for much longer than it is in reality. After restraint children are angry at and frightened of staff, which will profoundly limit the staff's ability to fully assess and treat them. While 15 percent of youth in the ED for psychiatric complaints are restrained, much of this can be avoided through proactive engagement to prevent a crisis and by effective verbal and psychopharmacologic de-escalation strategies.

A safe environment is the first step to prevent agitation. Overcrowding, excessive noise, lack of privacy, long wait times, and a tense atmosphere can agitate even a normally quiet child. For a child with impulse control problems, psychosis, trauma history, or autism, such a setting can be catastrophic. A safe ED environment, as described above, will help avert a crisis. Staff who are vigilant to the early signs of agitation and who communicate effectively as a team can notice small shifts like changes in the patient's mannerisms or tone of voice, or their way of interacting with their family, other patients, and the surrounding milieu. When a child is showing these early signs of agitation, the ED staff should work as a team to deescalate the situation. First, the patient should be moved to a safe and quiet area, if they are not already there, and made as comfortable as possible by giving them personal space, separating them from other patients, and either separating them from or rejoining them with preferred family members based on the patient's preference. The patient should be

offered food, a drink, or basic entertainment (such as TV or a video game) to calm and distract them. One member of the staff should approach the patient in a nonthreatening way to listen to their complaint or concern, direct them away from the focus of their anger, and encourage them to verbalize their needs. If the child begins to explain their concern, even if they are still agitated or yelling, staff should empathize by repeating their statement or paraphrasing it back to ensure that the patient's view is understood correctly. As the child makes incremental steps to calm down, for example by talking to staff or by refraining from pacing, staff should praise these positive steps even if the child is still engaging in other negative behaviors (such as cursing or scowling). Offering a child choices, even small ones like which staff to speak to or where to sit, will help the child feel more in control and thus calm down. Most children in the ED are anxious about the process, worried about their parents' reaction and the possibility of hospitalization. Others may be paranoid, may have been abused and thus be hyper-reactive to perceived threats, or may be hungry or in pain. It is important to emphasize that staff wish to understand what happened to the patient to make him react in this way, and not to be judgmental or accusatory. At the same time, staff should be clear that they will work to keep the patient and all others safe and that violence will not be tolerated.

A child's agitation can also stem from a parent's anxiety, anger, or fear. Effective management of child psychiatric patients in the ED requires staff to contain the parent's anxiety, and redirect their response in a positive way. Parents can be anxious in the ED because of concerns about the child's symptoms or safety, fear that the child will be taken away from them (either by child protection or by hospitalization), or worry about missing work or affording the cost of the emergency evaluation or the ambulance that brought the child. They may be fearful about stigma, or they may have had their own negative prior experiences with psychiatric care. If the parent is upset about the child being in the ED, they may express this in a way that agitates the child, either by communicating their fears and anxieties or by blaming or berating the child for being brought to the hospital. The team must listen to and empathize with the parent, emphasize that the parent is not being blamed for the situation, and assure them that the staff will work with the family to ensure the child's safety. If a parent is agitated, it is most often helpful to separate the parent and the child while staff work to calm the parent, to avoid the child becoming agitated as well.

If the patient continues to be agitated and begins to escalate further, perhaps making threats or beginning to destroy ED property or attempt to elope, oral medications should be offered. If the patient is already in psychiatric treatment, carries a diagnosis and is on medication, this can guide the choice of medication for agitation. For example, an adolescent

with known anxiety disorder on a benzodiazepine might benefit from a small oral dose of the same or a different benzodiazepine, while a teen with schizophrenia may require an extra dose of their antipsychotic medication. Medications should be chosen carefully, as the medications most commonly used for agitation in adults can have significant adverse effects on children. Benzodiazepines are often disinhibiting and can cause paradoxical agitation, particularly in young children and those with developmental disabilities or intellectual impairments. Youth who are antipsychotic naive and are given high-potency neuroleptics for agitation, particularly agitation not related to psychosis or mania, are at increased risk for extrapyramidal symptoms. Often the antihistamine diphenhydramine (Benadryl) is the safest medication choice, particularly for young children (though in those with intellectual disability or autism diphenhydramine too can be disinhibiting) (Table 36.4–3).

Oral medication should always be offered before injectable medication (IM), particularly because many children (even ostensibly tough ones) are afraid of needles and can become more agitated when approached with an injection. Often, administering an injection will require a physical hold or restraint, so this should be a last resort for safety after all other interventions have failed. A child who initially refuses an oral medication may accept the oral medication if offered the choice between oral and injectable medication. This not only allows the patient to avoid the potentially traumatic experience of a restraint and IM, but also allows the child to make a choice and begin to demonstrate self-control.

If all of the above techniques to deescalate an agitated child have failed, and the child continues to refuse oral medication and engage in violent or dangerous behaviors, an injectable medication may be indicated for acute chemical restraint. As with oral *pro re nata* (PRN) dosing, if the child is already on an antipsychotic the same medication should be used if it is available in immediate-release injectable form, to avoid the greater risk of adverse effects inherent in concurrent use of two antipsychotics. If the child is not on a standing neuroleptic, the choice of medication should be based on the child's age, size, recent medication administration, medical conditions, and (if known) the psychological cause of their agitation. For younger children, diphenhydramine IM may be preferred as it is sedating and generally well tolerated, though total daily dose should be monitored as over-medication can lead to disinhibition, confusion, or delirium. For adolescents who are agitated due to anxiety, benzodiazepines such as lorazepam (Ativan) or sedating lower-potency antipsychotics such as chlorpromazine (Thorazine) may be effective, while those youth that are agitated due to mania or psychosis will likely require haloperidol or another high-potency antipsychotic. If high-potency antipsychotics are given, they should be given concurrently with diphenhydramine or benztropine (Cogentin) as prophylaxis for acute dystonic side effects, and

the patient should be monitored closely for such. Adding diphenhydramine to haloperidol (Haldol) or chlorpromazine can also magnify the sedating effect of the antipsychotic for a youth who is extremely agitated, particularly when due to mania or psychosis. In general, dosing of IM will be half of the oral dose used, such that for example 50 mg of oral diphenhydramine or chlorpromazine will correspond to 25 mg IM.

Table 36.4–3.
Medications for Agitation

Child (Age <12 or up to 90 lbs):		
Mild Agitation:	**Moderate Agitation**	**Severe Agitation**
Diphenhydramine 12.5–50 mg PO Or Risperidone PO 0.25–2 mg PO	Diphenhydramine 25–50 mg PO or IM Or Chlorpromazine 12.5 mg PO or IM Or Risperidone 0.25–2 mg PO (can be given with Benadryl 12.5–25 mg PO)	Chlorpromazine 12.5–25 mg IM Or Diphenhydramine 25–50 mg IM
Adolescent (Age >12 or >90 lbs):		
Mild Agitation	**Moderate Agitation**	**Severe Agitation**
Diphenhydramine 25–50 mg PO Or Risperidone 0.25–2 mg PO Or Chlorpromazine 25–50 mg PO	Risperidone 0.25–3 mg PO (can be given with Diphenhydramine 25–50 mg PO) Or Chlorpromazine 25–50 mg PO or IM	Haloperidol 1–5 mg IM with Lorazepam 1–2 mg IM (if lorazepam is contraindicated such as patient has intellectual disability or autism, give benztropine 1 mg IM with haloperidol instead) OR Olanzapine 2.5–5 mg IM (do not administer within 1h of benzodiazepine dosing)

In most cases, when injectable medication is required, a physical hold, restraint or seclusion is also necessary for safety. The choice of intervention (physical hold, restraint, or seclusion) should be made based on the regulatory standards of the Center for Medicare and Medicaid Services and The Joint Commission on Accreditation of Healthcare Organizations, state and local governmental and oversight agencies, and the policies of the hospital, as well as the individual patient history. For example, for a child who has been sexually abused, restraint may be deeply re-traumatizing such that seclusion should be chosen instead; a child who is engaging in self-injury may not be able to be safe in seclusion and thus restraint may be more therapeutic. The physician should ensure that the child is safe, physically comfortable, and medically stable in the restraint or seclusion, and should explain to the child the reason for the restraint or seclusion and that they will be released as soon as they can be safe. Regulation and hospital policy will dictate the allowed duration of restraint or seclusion,

but regardless of regulation the child should be removed from restraint or seclusion as soon as possible. Once the child is released, his safe behaviors should be praised and the physician should debrief with the patient to review what upsets the patient and how such episodes can be avoided. While restraints and seclusion can be traumatizing for children if executed poorly, with appropriate support, explanation and debriefing it can be an opportunity for the youth to better express his feelings and understand the roots of his behavioral dyscontrol.

Assessment of Developmental Factors in Psychiatric Emergencies

Children are not just little adults, physically or psychiatrically. When faced with a child in crisis, the interpretation and significance of the child's symptoms will vary greatly depending on the developmental status of the child. The developmental status includes not only the child's chronological or physical age but also any developmental delays, cognitive disabilities, genetic or metabolic syndromes, or deficits in speech, language or learning ability. The ED clinician may not have time for, or access to, a complete developmental history of the child during the initial evaluation, particularly if the biological parent is not present with the child. Nonetheless, by observing the child closely for physical signs of genetic or developmental syndromes such as fetal alcohol syndrome, and determining whether cognitive and emotional skills are appropriate given the child's physical age, the clinician can determine whether a developmental or cognitive delay may be present.

At the most basic level, development influences acute psychiatric symptoms in that symptoms can have different causes or meaning in children of different age and developmental stage. One important example of this is in the assessment of psychosis. A young child may present to the ED with "hallucinations" that are age-appropriate imaginary friends. An adolescent with significant intellectual disability may have a similar presentation, which would be concerning in a child of that age without intellectual disability but may still be normative in the presence of the disability. Sexual behaviors is another important example. Many children are brought to the ED for "sexual acting out," but the interpretation of sexual behavior and the threshold for what is normative differs greatly for a 5-year old or a 14-year old. A 5-year-old child who exposes his genitals to a peer and asks the peer to do the same is actually engaging in normal, common behavior for a child of that age. A similarly-aged child who touches a peer's or adult's genitals is still within the normal range of behaviors for that age, though the behavior may reflect poor impulse control or emotional immaturity. If a 14-year-old boy is sent to the ED from school after touching a peer's genitals without invitation to do so, this could be a predatory behavior, but it is important to assess whether a developmental or cognitive delay is present, as a 14-year old with autism or

intellectual disability may be closer to the 5-year old's developmental maturity than his 14-year-old body would suggest. Children with autism and attention-deficit/hyperactivity disorder (ADHD) are particularly likely to have disparities between their physical age and cognitive ability and their emotional and developmental maturity. Often children present to the ED with concerning behaviors or symptoms that look like psychosis or other acute illness, but a careful developmental history identifies undiagnosed autism or other developmental delay. Identifying developmental problems that are contributing to the current presentation is important to ensure that the child and family are set up with the appropriate services and treatment.

Assessment of Contextual Family and Social Factors Contributing to Psychiatric Emergencies

Children and adolescents present to the ED with a range of acute psychiatric complaints, from recent-onset psychosis or mania to longstanding obsessive-compulsive disorder (OCD) or autism. An important question for any child in the ED is why now—what has led the child to be brought today, and not yesterday or tomorrow, and what were the precipitating factors that contributed to this. Even when a child presents with an acute or new-onset illness such as psychosis or mania, it did not begin just minutes before their arrival to the ED; rather, someone became aware of the child's symptoms or something happened that was the tipping point for the child or family to seek help. Understanding these contextual factors are important to stabilize the crisis. For example, an adolescent may have been abusing opiates for weeks, but today stole money from his mother and became violent toward her. Stabilizing this crisis will require treatment for the child, but also support for his mother if she is to effectively care for him going forward. A young child sent from school for a tantrum may have longstanding ADHD, but the immediate triggers for his tantrum were frustration with schoolwork related to having been transitioned this week from a special education classroom to a mainstream one. His treatment may involve changes in his ADHD medications, but also increased academic supports. A teenage girl with autism is sent to the ED for head-banging and other self-injurious behaviors, but her symptoms are related not only to her autism but also to her caregiver's recent surgery that led to the girl staying with her aunt for three days. A safe discharge for her will be more dependent on psycho-education and support for her aunt than on additional medication for behavioral control.

The key contextual factors to assess are the child's home and family context; educational setting; and social factors. In the home and family sphere, the child's symptoms may be acutely worsened by shifts in the physical environment (moving into a different apartment or shelter, for example), changes in the family makeup (birth of sibling, remarriage,

divorce or death, or a move into foster care), or conflict or violence in the home. These factors may directly impact the child's mental health or may decrease the parent's ability to cope with symptoms, provide structure or supervision, or manage difficult behaviors. A parent may also be suffering from mental illness or substance abuse, or may be abusive, neglectful, or failing to protect the child from abuse or maltreatment. Understanding the child's home and family context can also highlight key strengths and supports for the child that may be useful in treatment and safety planning.

Multiple factors in a child's educational setting can precipitate an ED visit. Many children presenting to the ED are sent from school, often with a mandate for "psychiatric clearance" before the child will be allowed to return. When a child is sent from school, it is important to understand both the general academic context and learning needs of the child, to assess for unmet needs or mismatch, and also the immediate triggers for the child being sent to the ED. For example, for the child with ADHD who has a tantrum after being transitioned from special education to mainstream classes, it will be useful to know as well that the tantrum occurred in math, his worst subject, after he was being teased by peers for being a "retard." This child will have a different treatment plan than a similar boy with ADHD who has a meltdown during a fire drill, when his family recently became homeless after a fire destroyed their apartment building. Each of these boys can be discharged home but are likely to return to the ED with a similar outburst within days or weeks if the contextual factors are not addressed.

Social factors are also important to assess, particularly for adolescents. A child's social milieu can be a crucial support in a crisis, or a trigger for acute pathology. Self-injurious behavior, substance use, risky sexual behaviors, and suicidality can have strong peer effects among adolescents and pre-teens. Conflicts within friendships, romantic breakups, bullying and cyberbullying can precipitate suicidal thoughts and serious violence. Relationship violence and date rape is also unfortunately common among adolescents. Social isolation can be a marker for serious psychiatric illness, be it chronic (in the case of autistic or otherwise "odd" youth) or acute (for depressed, prodromal, or psychotic adolescents).

These contextual factors can be difficult to assess given the time limitations of the ED assessment. The ED clinician is unlikely to go in depth in discussion of each of these areas, but a brief inquiry into home/family, academic, and social life can quickly identify potential problems into which further investigation is needed. As with the other areas of the interview, the clinician's approach should be systematic but flexible, covering all important areas of functioning but focusing the interview based on the presenting concern.

SPECIFIC PSYCHIATRIC EMERGENCIES IN CHILDREN AND ADOLESCENTS

Suicidality and Self-Harm

Assessment. As noted above, suicide is a leading cause of death in adolescents, and is one of the most common psychiatric presentation of youth to the ED. When a child or adolescent presents to the ED after a suicide attempt, medical stabilization is the foremost step. After this, the ED clinician must determine the patient's suicide risk and whether inpatient hospitalization (including potentially 1:1 observation for safety) is required. Assessing suicide risk will include identifying risk factors such as prior suicide attempts or ideation; experience of hopelessness, anhedonia, or command auditory hallucinations to harm self; substance use; prior psychiatric diagnosis (depression, bipolar disorder, substance use and conduct disorders confer particular suicide risk); family history of suicide; and access to firearms and other means of self-harm. A careful assessment of suicidal thinking and behavior is also crucial. The ED clinician should ask about the ideation and planning leading up to the attempt, including the anticipated lethality of the attempt, if the child thought someone would discover or rescue them, if a suicide note or other preparation for death was made, and if the child experienced regret or ambivalence after the attempt and immediately called for help, or took steps to ensure no one would find out or be able to help him. The clinician should also assess current active or passive suicidal thoughts, plans, intent, future orientation, and reasons for living, though with recognition that youth may be motivated to minimize their current suicidal thoughts or intent for fear of being hospitalized or upsetting family members. The mental status examination can identify mental states that confer acute risk for suicide, which may be more difficult for a child to minimize or hide; these including hopelessness, preoccupation with death, severe depression, command hallucinations, and feelings of worthlessness.

It may not be immediately obvious when a child in the ED has made a suicide attempt. Hanging attempts and self-poisonings may have clear suicidal intent, but other youth may present with self-cutting, overdoses of prescription drugs, threats to stab self or jump from high places, attempts to drown in the bathtub, or other acts where the true suicidal intent is unclear. It is important not to dismiss "dramatic" suicidal gestures as related to personality disorder as might be done in adult patients, as in children and adolescents even suicidal gestures and parasuicidal behaviors often demonstrate real risk. Even if the child is repeatedly self-cutting with no current suicidal intent, the fact of engaging in repeated self-injury is a risk factor for later suicide attempts, and even youth who engage in suicidal behavior with ambivalence or for attention can inadvertently hurt themselves (e.g., youth who take overdoses of acetaminophen without realizing its potential lethality).

Management. The first decision in managing a suicidal patient is determining the need for inpatient hospitalization. If a child is on a high risk in one or more of the following ways, they likely require inpatient hospitalization for safety:

- Serious suicide attempt, with or without endorsing persistent or current suicidal thoughts
- Persistent, intense suicidal thoughts or intention
- Suicidal ideation/behavior in the context of severe depression, command auditory hallucinations to harm himself, hopelessness, or self-blame
- Suicidal ideation/behavior in the context of a profound psychosocial stressor, such as recent sexual trauma or disclosure of abuse, severe bullying, relationship loss
- Suicidal ideation/behavior in the context of poor supports (family rejection/stress, no outpatient treatment)

If the clinician is uncertain whether a child is safe for discharge, it is most prudent to hold the child for reassessment of suicidal ideation and for additional collateral history. If the child is not at high risk, a safety plan should still be completed prior to discharge. This involves helping the child identify triggers for suicidal feelings, coping strategies that the child can use if suicidal thoughts present, who the child can call on for support and what those individuals should do to help the child, and how to access professional help or return to the ED if needed. The safety plan should be shared with the parent or guardian. The child should also be set up with prompt (within a week) outpatient follow up for reassessment of suicide risk and to work to stabilize the psychological and social factors that led to the suicidal thoughts and behavior.

If a child presents with self-injurious behavior and the clinician is certain it is without suicidal intent, a safety plan can still be useful, modified to focus on urges to self-harm rather than on suicidal thoughts. It is also helpful to explore the function of the self-harm, which may include internal reinforcement such as relief of strong negative emotions or feelings of numbness, or external reinforcement such as attention from peers or family or release from social situations or conflicts with which the child is otherwise unable to cope. Youth with anxiety disorders, childhood trauma or neglect, and autism may engage in self-injurious behavior for this latter external reinforcement. The ED clinician should view such behavior not as manipulative but as representing an inability to cope or communicate distress and thus demonstrating need for treatment.

Aggression

Assessment. Youth can present to the ED with aggressive behaviors ranging from overblown tantrums to planned, intentional, even lethal

violence. The assessment of such youth starts with managing the child's behavior in the ED, using the techniques described above to deescalate and contain the youth's behavior with verbal interventions, medication, and restraint or seclusion when indicated. The child's response to these interventions will be telling for both diagnosis and risk assessment. An adolescent who is unable to respond to verbal deescalation and seems to be disorganized or paranoid may be psychotic or intoxicated. A child who is brought by police or school safety officers cursing and kicking but is able to speak calmly to the clinician once the uniformed officers have left, may be by contrast an impulsive child with ADHD or PTSD who became agitated due to teasing at school but with no true intent to harm anyone.

Once the initial agitation is addressed, the clinician must attempt to understand the aggressive behavior. Understanding from the child's perspective the triggers for their aggression can make a frightening experience into a therapeutic opportunity. The clinician should assume that there is always a reason for the aggressive behavior, even if the child cannot immediately articulate it. The reason may not be obvious to the clinician or even to the child at first, but empathic and patient questioning can uncover the triggers, both external (such as teasing or other provocative behavior from peers, being told "no," a disruption of routine, being touched by staff or police) or internal (frustration, anxiety, paranoia, command hallucinations, trauma flashbacks). Aggressive acts can be reactive (in response to a trigger or perceived insult) or instrumental (planned with intent to harm or to use aggression to get something). Reactive aggression may be triggered by events that appear benign to adults, like a school staff putting a hand on the child's shoulder to calm her, but which feel intrusive or threatening to the child due to their background and history. Children with autism, intellectual disability, and learning disabilities may become aggressive when frustrated because they lack the verbal skills to solve the problem and express themselves, or because they do not know any other way to ask for what they want.

Management. Once the initial agitation is addressed, the clinician's job is to determine whether the child's risk of future violence is sufficient to require inpatient admission, or if the child can be safely discharged. Risk for future violence depends in part on the nature of the violence, and on the presence or absence of underlying psychiatric illness. Youth with a range of psychiatric illness can be prone to reactive aggression, and the treatment for each must be targeted to the illness or symptoms present. Instrumental aggression is less common in mentally ill youth, but can be seen in conduct disorder and substance use. When aggression is reactive, the treatment involves identifying triggers, teaching skills to cope with those triggers without aggression, and addressing the core symptoms that predispose the youth to aggressive behaviors. When aggression is instrumental, treatment

involves setting clear consequences, often in collaboration with parents and law enforcement, while promoting prosocial behavior with positive reinforcements. The type of aggression and the diagnostic context in which it occurred also helps to determine treatment needs. For example, a girl with ADHD who strikes out impulsively when a peer teases her, or a boy with PTSD who becomes aggressive when told "no" by a teacher who resembles the stepfather that abused him but then feels remorseful, bears a chronically increased risk for future violence due to their psychiatric symptoms but they do not have intent or plan to harm anyone. They can likely be safely discharged, if set up with treatment for their illness and perhaps with some increased supports and monitoring at school. By comparison, a teen who brings a gun to school with intent to harm a girl who romantically rejected him, or who is hoarding knives in his room due to paranoid psychosis, remains at acute risk for violence and requires hospitalization (Table 36.4–4).

Determining whether inpatient hospitalization is indicated depends both on immediacy of risk for further aggression, but also on whether the risk for aggression is due to mental illness and will be helped by hospitalization. There are youth who are engaging in criminal behavior not due to psychiatric illness, and for them inpatient hospitalization may not be helpful; in such cases clinicians should collaborate with the parents and law enforcement to identify other supports to contain the youth's behavior.

Table 36.4–4.
Examples of Psychiatric Illnesses in Children That Can Lead to Aggression

Illness/Symptom	Treatment Focus
ADHD	Address impulsivity
ODD	Set clear limits, reinforce positive behaviors
Psychosis	Treat command hallucinations/paranoia that are triggering aggression
Mania	Stabilize mania to address impulsivity/irritability
Autism or intellectual disability	Promote verbal problem solving and other coping behaviors
Conduct disorder	Set clear consequences for antisocial behaviors and reinforce positive behaviors
Substance use	Increased supervision, motivation enhancement techniques to reduce use

Risky Behaviors and Substance Use

Assessment. Drug use, running away, truancy, risky sexual behaviors including prostitution, gang involvement, and other dangerous behaviors can prompt parents to bring a child to the ED desperate and looking for help. Such behaviors are uncommon in youth and can have serious and even fatal consequences; yet often the child is not immediately "dangerous to self or others." The ED clinician must assess whether the child's

behaviors are age-appropriate limit-testing, a reflection of underlying psychopathology, or a response to problems in the home or failures of supervision, and whether the risk of the behaviors is sufficient that hospitalization is indicated.

Determining safety is, as always, primary; this may involve assessing whether the youth is currently intoxicated with substances or at risk for withdrawal or whether a rape kit or STD testing and prophylaxis are indicated. Some risky behaviors are isolated incidents that the youth will learn from and not repeat. Youth in the ED for such behaviors will usually claim that this is the case, so collateral information is crucial to assess for repeat behaviors, a decline in functioning, or associated psychiatric symptoms. Risky behaviors can be related to a range of psychiatric illnesses, including depression, mania, post-traumatic stress disorder, ADHD, and conduct disorder, and can also be seen in intellectually disabled or autistic youth who may not comprehend the dangerousness of their actions. They can also reflect problems in the child's environment, such as a parent's inability to provide sufficient supervision due to illness or work schedule or the child's reaction to a divorce or other major stressor in the family. In cases of truancy the behavior may be a response to bullying, insufficient academic supports, or an inappropriate classroom placement for a child with special learning needs. Approaching the patient with an empathic and nonjudgmental stance is key to understanding why they are engaging in these behaviors and assessing their motivation to change.

Management. When risky behaviors put the child at immediate risk for harm, or when they are secondary to underlying psychopathology or problems in the environment, further intervention is needed. For a manic youth having promiscuous unprotected sex and abusing drugs, though this youth may not be suicidal or homicidal, he is endangering himself and others and will continue to do so until his mania is treated, so hospitalization is indicated. For an adolescent with intellectual disability who is running away and associating with gang members because his mother is medically ill and unable to supervise him, coordination with child protective services and law enforcement may be required to provide more support or place the child in a residential facility with greater supervision. Bolstering the parent's ability to relate to and engage the child will help them to prevent risky behaviors in the future. Often, the parent is so upset, angry, or anxious about the child's behavior that they are unable to effectively relate to the child, and the ED clinician must help the parent to contain their affect and set reasonable expectations. If the child and parent are unable to agree upon basic rules and behavioral expectations, then outpatient treatment has little chance for success and the ED clinician should coordinate with social work, case management, child protective

services, and any services currently involved with the child to bolster the family's capacity to keep the child safe.

Psychosis

Assessment. Children and adolescents are often sent to the ED from school or from outpatient providers due to concern for psychosis, particularly for command hallucinations to harm self or others. Yet chronic psychotic disorders like schizophrenia are extremely rare in children, instead usually developing insidiously in the late adolescent or young adult years. The ED clinician will often be in the position of discerning whether a child who is sent for "hearing voices" or being "internally preoccupied" is a child with early-onset schizophrenia, in need for inpatient hospitalization, or more likely, that this is a red herring. Young children can report "hearing voices" as a way to express their own thoughts (particularly thoughts that are shameful, uncomfortable, or that might get them in trouble), and older children and adolescents with intellectual disability or autism often do the same. Imaginary friends are also normal in children and again, adolescents with intellectual disability whose cognitive age is much lower than their chronological age may endorse imaginary friends much longer than their neurotypical peers. Children with autism and intellectual disability are also often sent to the ED for being "internally preoccupied" or "responding to internal stimuli," but this may be a symptom of their autism, not of psychosis. Often these children have never been diagnosed with autism or intellectual disability, if the family has not been consistent with medical providers or closely involved with the child's school. Children who have suffered a loss can report hearing or seeing their loved one in the context of grief. Anxiety disorders and OCD can present with thinking that borders on delusional, and post-traumatic flashbacks can look like the child is experiencing hallucinations. Depression and mania can be accompanied with either nihilistic and shameful or grandiose delusions, and at times with hallucinations berating or shaming the patient. An accurate diagnostic assessment is crucial as the treatment will vary greatly depending on the diagnosis and clinical formulation. Collateral information about the child's life, family, functioning, recent stressors, and prior traumas is important, particularly if the child is disorganized or cognitively limited and unable to give coherent answers.

If the clinician determines that the child is truly psychotic, organic causes must be ruled out. A complete physical exam, lab analysis including complete blood count, electrolytes, liver, kidney and thyroid functioning, full toxicology screening, and brain imaging are indicated, as well as other tests (lyme, erythrocyte sedimentation rate, rapid plasma reagin, lumbar puncture for cerebrospinal fluid analysis, etc.) depending on the patient's history and associated symptoms.

Management. Patients who are truly psychotic can be dangerous in the ED as they may act erratically and expose themselves or others to danger. These patients often require a 1:1 sitter for observation and close monitoring. Youth with psychosis can rarely be stabilized in a few hours in the ED and generally require inpatient hospitalization for stabilization. If the psychosis is secondary to substance intoxication, the symptoms may clear when the intoxication subsides, but with the new designer drugs such as synthetic cannabinoids (k2, spice) and substituted cathinones (bath salts), substance-induced psychosis is of much longer duration than with more traditional drugs and may require inpatient hospitalization for safety. If the psychotic symptoms are due to severe depression, mania or OCD, or if the ED clinician lacks the collateral information and time to observe the patient to make a definitive diagnosis, hospitalization may be the best option to keep the child safe and treat him carefully.

If the reported psychotic symptoms are in fact a manifestation of intellectual disability or immaturity, anxiety, grief, trauma, or a normal reaction to stress, the child can likely be discharged with a referral for outpatient treatment and reassurances for the child and family. Families in these cases are often deeply relieved and should be reminded that even though their child is not being diagnosed with schizophrenia, follow up psychiatric care is still important. Depending on the underlying psychopathology, the ED clinician may also consider starting treatment from the ED (for example, medication for anxiety or psychoeducation about trauma and flashbacks).

Youth with Autism and Intellectual Disability

Assessment. Children and adolescents with autism spectrum disorder (ASD) and/or intellectual disability (ID), particularly those with limited or minimal verbal communication skills, are often brought to the ED for behavioral symptoms including aggression, self-injury, inappropriate sexual behaviors, sleep cycle reversal, or running away. These cases can be difficult for the ED clinician, because youth with ASD or ID can be medically and psychiatrically complicated, and also they often have a difficult time in the ED due to the unpredictability and unfamiliarity of the ED, the noise, bright lights, and the need for blood draws and physical exams. Children with ASD or ID often are blocked from admission to inpatient psychiatric units due to their diagnosis, leaving them boarding in the ED for days awaiting an inpatient bed on a specialized unit.

When youth with ASD or ID present to the ED, the first step to keep them safe is to understand what works at home, including preferred toys and caregivers, communication tools (such as picture communication tools and sign language), and soothing techniques. Understanding what typically triggers negative behaviors at home will also help the ED clinician to avoid

outbursts in the ED. When a child with ASD or ID is brought to the ED for problematic behaviors, it is important first to understand if the behavior is longstanding or new. Longstanding behaviors such as self-stimulatory behaviors, impulsive aggression, or head-banging may be related to the underlying ASD/ID and indicate that the community treatments are insufficient or ineffective and should be reevaluated. New behaviors are often triggered by changes in the environment (changes in caregiver or home environment, school vacation, changes in school placement) or physical/medical problems (constipation, dental problems, ear infections, seasonal allergies, pain, fatigue, sedation due to polypharmacy, adverse effects from medication such as akathesia, onset of puberty). More rarely the youth with ASD/ID can have the new onset of a psychiatric disorder such as a mood or anxiety disorder, but environmental changes and medical problems should be ruled out before a new diagnosis is made.

Management. Keeping patients with ASD and ID safe in the ED requires removal of unnecessary stimuli (noise, light, needle sticks), clear communication (simple, concrete, and written or picture-based if possible) of what to expect from the evaluation, attention to physical comfort (pain, fatigue, hunger, constipation), and use of soothing activities or family members when possible. Medication is often used to sedate ASD and ID patients in the ED, however this is dangerous as they may have paradoxical reactions to medications such as diphenhydramine and benzodiazepines yet have little positive effect from antipsychotics. Behavioral interventions, while more complicated to execute, are much more likely to be effective.

Many youth with ASD/ID can be stabilized quickly if the medical or physical etiology of their distress is discovered and resolved. Effective pain control, dental care, management of insomnia and constipation, and resolution of polypharmacy and medication adverse effects can be accomplished in the ED and provide great relief to patients and families. Often when these problems are resolved, families discover that their child who had been increasingly aggressive or difficult to manage for a long time is now calm and comfortable.

As there are few inpatient units that accept youth with ASD or ID (particularly if they are aggressive or engage in self-injurious behaviors), the ED clinician should familiarize herself with community services available for people with intellectual and developmental disabilities. Often home-based and respite services are available to patients who qualify, though families may not know how to access these services.

Child Abuse or Neglect

Assessment. Unfortunately, it is all too common that youth who present to the ED for psychiatric complaints are found to be the victims of child abuse or neglect. Children with psychiatric and developmental

disorders and behavioral disturbances are more likely to be abused and neglected, and abuse and neglect can contribute to the development of a range of psychiatric illnesses. Other risk factors include poverty, single parent households, large family size, social isolation, parental substance use, and personal history of abuse for the parent. Assessing for abuse or maltreatment in the ED is very difficult, because children rarely admit to abuse, due to shame, guilt about betraying the family if the abuser is a family member, or fear of reprisal or removal from home. Clear evidence of abuse is rare. Children can present with medical symptoms such as unexplained physical injuries, signs or symptoms of sexually transmitted diseases, or blood in their underwear, and then the psychiatric clinician consults the pediatric team for further evaluation for abuse. Children who are being abused or maltreated can also present to the ED with a wide range of psychiatric symptoms. Behavioral or externalizing symptoms can manifest as aggression, stealing, hoarding food or eating from the garbage, running away, regression in toileting and other milestones, separation anxiety, or school refusal. Internalizing symptoms can include PTSD and depression but also panic attacks, irritability, inattention, and organizational problems that mimic ADHD, and withdrawal from family, social and academic activities. Adults who know the child has been abused or traumatized in some way often will not connect that maltreatment to the behaviors and symptoms presenting now. And very often, no one but the child and the abuser is aware that any abuse is happening.

The ED clinician must ask in a careful, thorough, nonjudgmental way about any abuse or maltreatment in the home, school, or elsewhere. The child should be interviewed separately from the parent, and should be reassured that he will be safe and protected no matter what he discloses. It is important to interview the child gently, starting with more subtle queries into the child's home life (such as who live in the home, who prepares meals, who helps with homework) and then moving to questions about who sleeps in bed with whom, who gets into arguments and how they are resolved, who yells the most at home, what punishments are for misbehavior, and other contextual questions before asking directly about abuse. Collaboration with the pediatrician if any physical injuries are present can also be helpful as these may be a marker for abuse, or the child may require a genital examination if there is concern for sexual abuse. When child abuse pediatrician consultation services are available, it can be helpful to obtain a specialized interview and physical exam to discover and document evidence of abuse. At the very least, when abuse is suspected, child protective services should be consulted immediately. It is not the ED clinician's job to determine whether abuse has definitely occurred (that is the job of child protective services). But if there is any concern, as a mandated reporter the ED clinician is obligated to call child protection. Parents should be notified that such a call is being made and why; even if

the parent is the perpetrator or failed to prevent abuse, they are often remorseful and looking for help, if the clinician is able to empathize with why the abuse has happened (such as a battered mother unable to prevent the abuse of her children, or an overwhelmed parent struggling to discipline a child with significant behavioral problems). The parent may need help as much as the child does, so maintaining an empathic alliance with the parent will give them and the child the best chance for recovery.

Management. Collaboration with child protective services will help to ensure the child's immediate physical safety, and this may require keeping the child in the hospital until an investigation is done and a safe place is found to which the child can go. The ED clinician can also play an important role in assessing for psychiatric sequelae of maltreatment, providing psychoeducation to the child and family (or foster family), and ensuring that the child receives appropriate psychiatric follow up care. If the child presented to the ED with behavioral problems, helping the family or caregiver to identify how these behaviors may be triggered by or related to the trauma or abuse can help avoid such behaviors (and repeat trips to the ED) in the future. Family therapy can be a very helpful referral in these cases. Anticipatory guidance can also be helpful for both the child and caregiver to understand what types of symptoms may come up in the future and how to access help if needed.

Eating Disorders

Assessment. Eating disorders are a source of significant morbidity and mortality in children and adolescents. When an eating disorder is discovered by a parent or teacher, the adult will often send the child to the ED for medical and psychiatric evaluation due to concern for the medical consequences of eating disorders as well as their association with suicidality and self-harm. The ED clinician may also discover an undiagnosed and unrecognized eating disorder in a child or adolescent who presents to the ED with dizziness, nausea, syncope, suicidal ideation, or self-injury. Younger children and boys may present to the ED with unexplained weight loss, and often no one has asked them about restricting, purging, or excessive exercise because clinicians are unused to seeing eating disorders in prepubertal patients or in males.

Table 36.4–5.
American Academy of Pediatrics Criteria for Medical Hospitalization for Eating Disorders

Anorexia nervosa
Weight ≤75% ideal body weight, or ongoing weight loss despite intensive management
Refusal to eat
Body fat <10%

	Orthostatic changes in pulse increase >20 bpm or blood pressure decrease >20 mm Hg
	Pulse <50
	Temperature < 96.0°F
	Arrhythmia
Bulimia Nervosa	
	Syncope
	Serum potassium concentration <3.2 mmol/L
	Serum chloride concentration <88 mmol/L
	Esophageal tears
	Cardiac arrhythmias including prolonged QTc
	Hypothermia
	Suicide risk
	Intractable vomiting
	Hematemesis
	Failure to respond to outpatient treatment

Management. Children and adolescents with eating disorders may require psychiatric hospitalization for safety due to suicidality or self-harm, or they may require medical admission for medical stabilization. Collaboration with pediatrics is crucial in all cases to determine the treatment plan and need for hospitalization. Assisting the family to identify resources for support and education is also important, as effective treatment of eating disorders is a long-term process that requires close family involvement for greatest success (Table 36.4–5).

Psychosocial Crisis

Assessment. Children are profoundly affected by a parent's state of mind, mental health, and relationships. Parental mental illness, divorce or severe conflict between parents, and in extreme cases medical child abuse (formerly called Munchausen's by proxy) can manifest with emotional and behavioral problems in the child. These stressors put the child in a desperate situation, and for a child with underlying psychiatric or behavioral symptoms, these family crises can be catastrophic. These situations can be difficult to assess. The parent is often unable to objectively reflect the stress on the child or even on the parent's own internal life and struggles. The child may lack the emotional maturity to describe clearly the problems at home, feel guilty, ashamed, protective of the parent, or afraid of being separated from the family. "Listening between the lines" is important, and when the given history does not make sense it can be an indication that hidden stressors at home may be at the root of the child's presenting problem. The child and parents should each be interviewed separately, and the clinician should approach the parent empathically and making it clear that their purpose is to help the child, not to be intrusive, judge the parents, or report them. If parents give deeply discrepant reports or perspectives on the child's symptoms, blame the other parent or the child, or belittle or berate the other parent or child, this

suggests significant conflict in the family that may be triggering the child's symptoms or behaviors or making it impossible for the family to effectively manage those symptoms or behaviors. When speaking with the child, vague or inconsistent statements that seem odd or unusual to the interviewer (such as, a child who states that the parent is sleeping most of the day and cannot be awoken) may serve as "red flags," and reassurance and specific questioning to the child may help them share the problems at home.

Medical child abuse can manifest with exaggeration or fabrication of a child's psychiatric symptoms. This is very rare and difficult to diagnose, but can manifest in the ED with hospital shopping, strange recurrences of symptoms despite good treatment, requests for specific medications, tests or procedures, and refusal to consent for the ED clinician to contact outpatient providers or other key collateral sources. The ED clinician should be cognizant that medical child abuse can present with psychiatric symptoms and should utilize tools for collateral information such as state prescription databases, pharmacy and insurance records, if such an etiology is suspected.

Management. Safety is, as always, the first priority; if a parent is severely mentally ill, the conflict in the home so extreme, or if the clinician is very suspicious that medical child abuse is occurring, then child protective services should be notified. The ED clinician may in extreme cases also need to refer the parent for their own emergency assessment. In less severe cases, with an empathic and strong rapport with the parents, the ED clinician may be able to help the parent to understand their role in the child's symptoms and their need for help and treatment. Getting the parent into individual or family treatment, and helping the child to voice and coping with the stress at home, will reduce the child's distress and the strain on the family.

LEGAL CONSIDERATIONS AND CONFIDENTIALITY

Clinicians working with youth in emergency psychiatric settings should be familiar with the laws and institutional regulations that govern emergency psychiatric treatment and hospitalization, and also those that apply to evaluation and treatment of minors. Many states allow for emergency psychiatric evaluation and treatment of a minor without a parent's consent, and several allow adolescents to access outpatient psychiatric care without the parent's knowledge or consent. If a child requires hospitalization, each state has statutes that dictate a standard for psychiatric hospitalization, generally differentiating between voluntary, involuntary, and emergency or diagnostic admissions. When working with minors, these laws generally dictate that a parent or guardian can hospitalize a child or adolescent under a "voluntary" admission, even without the minor's assent, and often provide a standard by which the decision to hospitalize a child or

adolescent can be made without the parent's consent. Clinicians working in the ED should know these statutes as they apply in their area, as well as the local and institutional policies for consent and hospitalization.

Clinicians should also be familiar about mandated reporting laws for cases of suspected physical or sexual abuse or other maltreatment. If a patient reports serious intent to harm another person, the clinician has a responsibility to warn this individual that supersedes the patient's right to confidentiality. Navigating the child's confidentiality vis-à-vis their parents can also be complicated. If the child is in imminent danger or a danger to others if the parent is not notified, the clinician should tell the parent, but first should attempt to understand the child's desire for secrecy. Often a child fears the parent will react with reprisal, anger, or distress, and may be able to share with the parent with the clinician's support and guidance.

CONCLUSION

Good ED care for children in psychiatric crisis means an accurate, developmentally-informed diagnosis and formulation, stabilization of the crisis, and a treatment plan that helps the child and family to overcome stigma and systems barriers to access the right care. The practical challenges of connecting a patient to appropriate treatment should not be underestimated either. If a patient requires inpatient hospitalization it can be difficult to find an open bed on a psychiatric unit for children and adolescents, but treatment on an adult unit or "boarding" in pediatrics should be avoided as both can be counter-therapeutic. If the child will be waiting in the ED for several days before an appropriate inpatient bed is available, the ED provider should begin treatment (therapy or medication) to the degree that is possible in the ED.

When a patient is safe for discharge, the ED clinician should make every effort to connect the patient to an outpatient provider, not just give the parent a phone number for a provider or for their insurance panel. Connecting to outpatient care can be a very difficult and lengthy process and some parents cannot navigate the system due to insurance issues or the parent's own cognitive or language difficulties. Providing the patient with an actual appointment for follow up has been shown to decrease future dangerous behaviors and so is crucial for safe discharge of high-risk patients. ED clinicians should also familiarize themselves with case management services; child welfare services; community supports such as family resource centers; social services within the school, shelter and family court systems; and respite and crisis services available through the state or city mental health, child welfare, or developmental disabilities services providers. These additional services can be crucial for avoiding a repeat presentation to the ED, particularly if psychosocial or family factors have influenced the current symptoms.

Genetics in Child Psychiatry

ERIKA L. NURMI, M.D., PH.D., MEREDITH A. HANNAN, M.D., PH.D., AND JAMES T. MCCRACKEN, M.D.

INTRODUCTION

Before the completion of the Human Genome Project (HGP) in 2003, the role of genetics in medicine and psychiatry primarily focused on the identification of single-gene mutations that played causative roles in relatively rare Mendelian diseases such as cystic fibrosis, neurofibromatosis, and Tay–Sachs disease. However, classic genetic approaches for Mendelian disease failed when applied to the majority of common human diseases, including neuropsychiatric disorders. Common disorders, while often highly heritable, are complex in nature: caused by the presumed interaction of multiple genetic and environmental influences. While the HGP provided scientists with the 3 billion bases of primary DNA sequence comprising the human genome, assembling the puzzle pieces of complex genetic disease requires an understanding of human variation, DNA regulation, and other complexities that are still incomplete. Due to the efforts of large consortium projects such as ENCODE, the 1000 Genomes Project, and the International Hap Map Project, and fueled by continuing advances in technology, the amount of available genomic information has exploded over the past decade. The challenge remains to leverage these techniques and available data to advance the current understanding of genetic influences in psychiatric illness. Such knowledge, once in hand, should provide opportunities for improved diagnosis, treatment, and prevention. Despite the complexity of childhood-onset neuropsychiatric disorders, definite progress has been made which this chapter will review.

Psychiatric disorders are almost exclusively complex genetic disorders. Heritability and twin studies have consistently demonstrated that genetics play an important, and often major etiologic role in the development of psychiatric disease. Yet identifying susceptibility genes underlying psychiatric illness has proven more vexing than for complex diseases in other areas of medicine (e.g., hypertension, inflammatory bowel disease, diabetes, cancer). One barrier to these efforts is the phenotypic complexity of psychiatric illness, and the likelihood that most categories of psychiatric illness as classified in the DSM-5 are heterogeneous in nature. New research directions, such as the current NIH Research Domain Criteria

(RDoC), attempt to characterize psychiatric illness on dimensional and more objective neurobiological measures. Improved phenotyping is one approach hoped to lead to progress in understanding the genetics of complex illness. Interestingly, most childhood-onset neuropsychiatric disorders appear to be more highly heritable than similar adult-onset phenotypes, suggesting that research to identify genetic influences might be more fruitful in pediatric samples. Likewise, studies of genetic influences on treatment and prognosis may be more revealing in younger, more treatment-naive subjects. As more adult-onset psychiatric disorders are increasingly being conceptualized as neurodevelopmental in nature, with identifiable prodromal and subclinical childhood manifestations, the study of such early phenotypes may represent genetically subgroups more tractable for etiologic investigations.

Genetic information is also being applied in other areas to advance medicine and psychiatry. Knowledge of genetic background for treatment selection and the impact of genetic variation on drug response is referred to as *pharmacogenomics*. *Pharmacogenetics,* now often used synonymously, originally began with genetic determinants of drug metabolism and distribution. Such fields pursue the promise of "precision medicine"—the personalization of treatment based on genetics and other individual factors, which in other areas of medicine has yielded important, widely applied improvements in clinical care. Such efforts are also increasingly being examined in child psychiatry.

With the continued advances in technological, computational, and statistical methods in genetics, it is certain that genetic information will become even more important in understanding and diagnosing psychopathology, and in directing treatment recommendations. Psychiatrists need to appreciate the nature of the genetic discoveries as they emerge and to understand how to interpret and apply them in their practice; to do so requires basic knowledge of the research methods applied and the strengths and limitations of these findings. An update on current findings in the genetics of childhood-onset psychopathology forms a needed background. The goal of this chapter is to highlight progress in genetic research on the etiology of pediatric-onset mental illness as it points to future opportunities to inform clinical practice and treatment practices.

THE GENETIC BASIS OF PSYCHIATRIC DISEASE

DNA Variation

In each individual human genome there are millions of DNA variants, known as *polymorphisms*. Most changes appear to be neutral with respect to human illness but likely are critical for the diversity, robustness, and evolution of the human species. The earliest appreciated disease-associated

genetic variations were cytogenetically visible interchromosomal translocations that disrupt or delete genes or regulatory elements, thus contributing to disease. More recently, large *segmental duplications* (SDs) or *copy number variations* (CNVs), involving extensive duplicated, repeated, inverted, or deleted segments of DNA larger than 1 kilobase (KB) in size, are observed commonly in affected and unaffected individuals. When certain CNVs are observed repeatedly in a population of individuals with a disease, the CNVs can point to disease-causing loci in the genome, such as those CNVs producing the Prader–Willi syndrome (15q11–q13 paternally derived deletions), some cases of syndromic autism (15q11.2–q13 maternal duplications), and William syndrome (7q11.23 deletion). Whereas gross chromosomal derangements typically affect multiple genes and produce rare but characteristic syndromes, subtler variations are more likely to be involved in complex disease susceptibility. CNVs are likely to contribute to disease through changes in gene dosage or disruption of genes or regulatory elements in the genome.

Until recently, little attention had been paid to the role of CNVs in complex psychiatric illness. Surprisingly, CNVs were discovered to be common (about 2 to 12 percent of the genome) and often polymorphic, with individuals carrying from zero to many copies of a given segment of DNA. Small DNA stretches (less than 1 KB) that are deleted or inserted, collectively referred to as *"indels,"* are even more frequent, with more than 400,000 annotated indels in the human genome. CNVs are now appreciated to represent another genetic mechanism contributing to complex disease risk. When compared to typically developing controls, total CNV burden is elevated in individuals with autism and schizophrenia. Although not all CNVs are pathogenic, disease-associated CNVs are larger and more likely to encompass gene-rich regions of the genome.

The simplest and most common type of individual genetic variation is the *single-nucleotide polymorphism* (SNP). SNPs are changes of a single DNA base pair (e.g., adenine [A] to guanine [G]) that occur in approximately one per every 1,200 bases throughout the genome. Public databases catalog millions of SNPs and often include allele frequency and genotyping information because they are widely employed in genetic studies.

DNA Variation and Contribution to Disease Risk. Smaller indels and SNPs can influence disease through more targeted changes in individual genes. SNPs can directly alter protein structure through changes that alter amino acid sequence (nonsynonymous changes) in the gene product or distort start or stop signals. Even synonymous (silent) polymorphisms that do not alter amino acid–coding potential can influence RNA stability, splicing, targeting, editing, and efficacy of translation—many of the effects of these synonymous variants are unknown. Although noncoding changes

are often overlooked due to presumed lack of function, they can exert powerful effects on the regulation of gene expression and transcript processing, as illustrated by the noncoding risk alleles described in macular degeneration and Crohn disease.

Most investigators believe that complex disease susceptibility is driven by a combination of common alleles, each of which carries a small disease risk ("common variants for common disease" model). It is presumed that such alleles arose on an ancestral chromosome long ago and are now common in the population. Recent findings in ASD research have identified evidence that rare, highly penetrant (if present, highly likely to result in disease), loss of function (inactivating) mutations may produce similar disease phenotypes ("rare variants for common disease" model). In this scenario, rare alleles contribute to genetic risk within the context of genetic heterogeneity. Because of their rarity, such causative mutations are challenging to identify. Strides are being made on this front, however, by the introduction of next-generation sequencing (NGS) technology, in which entire genomes of individuals can be completely genotyped, and then scanned for genes that are disrupted and associated with a disease phenotype.

DNA Variation as Markers of Risk Alleles. Neutral polymorphisms, although not directly contributing to the disease phenotype, can serve as markers for functional risk alleles due to the fact that polymorphisms are not inherited independently but in large DNA blocks, a phenomenon known as *linkage disequilibrium* (LD). LD can persist for substantial distances across a chromosome and for numerous generations but decay as a function of the rate of recombination between homologous chromosomes. Therefore, it is not always necessary initially for an investigator to genotype a risk allele directly to find association with disease but merely to genotype one of often many markers "linked" with the risk allele. Although an associated marker may have no direct role in disease etiology, it is present on an ancestral portion of DNA that also contains the disease locus and can thereby pinpoint the genomic location of the disease allele.

Finding Risk Genes

The basic strategy behind studies aimed at disease gene discovery is to identify regions of the genome that are shared between affected individuals; the genes that underlie the disease must reside within these shared regions. The genetic tools best suited to risk mapping depends on the underlying genetic architecture of a given disorder. Common approaches applied to the search for psychiatric risk genes are discussed below, highlighting successful examples.

Linkage Analysis. Linkage analysis is a powerful tool for localizing

genes of single or major effect within a family of related individuals. Historically, hundreds of *microsatellite markers* (polymorphic short tandem repeats) were genotyped across the genome in large families or in many multiplex families in order to identify chromosomal regions that cosegregate with the disease phenotype. Broad loci spanning many megabases could be identified, and explored for candidate genes. With the advent of SNP microarrays, the genomic regions of interest can be further narrowed, and risk variants of large effect can be readily identified. Ultimately, the identified genes responsible for single-gene versions of common disorders (e.g., tuberous sclerosis in autism) may be distinct from common pathways to disease in the population at large. However, this approach may help to identify gene pathways that may be involved in a specific disease, and that information can help to guide treatment and understanding of the overall disease process.

Genome-wide linkage scans have been conducted with the aim of identifying gene loci for many psychiatric disorders. Linkage scans that have focused on a child proband are limited and include attention-deficit/hyperactivity disorder (ADHD), autism spectrum disorder (ASD), Tourette syndrome (TS), obsessive compulsive disorder (OCD), and the eating disorders, many of which share suggestive signals between two independent groups (Table 37–1). Nevertheless, despite more than a decade of linkage studies, relatively few confirmed findings have emerged using this approach, suggesting that the heterogeneity of these disorders is even greater than originally presumed and that even larger study samples, more precise phenotypes, and novel approaches are necessary to identify disorder-linked regions harboring risk genes.

Table 37–1.
Summary of Linkage Data

Disorder	Chromosomal Regions Supported
Attention-deficit/hyperactivity disorder	5p, 6q, 9q, 10q, 12q, 16p, 17p
Autism spectrum disorders (15 studies)	1q, 2q, 3q, 6q, 7q, 11p, 16p, 17q
Schizophrenia	1q, 2q, 6p, 8p, 13q, 18p, 22q
Major depressive disorder	1q, 4q, 7q, 8p, 11q, 12q, 13q, 15q
Obsessive compulsive disorder	1q, 3q, 6q, 7p, 9p, 15q
Tourette syndrome	2p, 4q, 8p, 19p
Bulimia nervosa	10p
Anorexia nervosa	1q, 2p, 13q

Association Mapping. Association mapping identifies regions of the genome shared between affected (but not necessarily related) individuals resulting from a distant ancestral founder who transmitted a risk allele to subsequent generations. Genotype data at selected markers are collected from cases and controls to compare allele frequencies between these

groups. A *family-based association design* (family-based association test, transmission disequilibrium test) examines the frequency of allele transmission to affected siblings, eliminating the problem of *population stratification* (spurious differences due to dissimilar genetic backgrounds in cases vs. controls). Alleles that are found more frequently in cases in a case-control design or preferentially transmitted to affected siblings in a family design implicate specific genes or genomic regions that may be involved in disease. Compared to linkage, association persists across much smaller distances, necessitating greater marker density but also enabling high-precision mapping.

Commonly, genetic studies of association rely on SNP markers because they are densely and regularly dispersed throughout the genome, robust to mutation, easily assayed by automated high-throughput genotyping, and more likely involved directly in disease susceptibility. However, their power is limited by reduced marker heterozygosity and informativeness. This drawback can be overcome by combining SNPs into *haplotypes*—discrete chromosomal fragments defined by a collection of individual SNP alleles. Whereas individual SNPs are biallelic, haplotypes are multiallelic and thus deliver enhanced genetic information by more accurately reflecting genotypic identity at a given locus. A disease-associated haplotype might represent an ancestral chromosome fragment harboring a disease allele.

Evolutionary studies of the genome sequence and structure have revealed that the genome exists as blocks of low recombination (haplotype blocks) flanked by recombination "hot spots." The haplotype alleles that a given individual carries can be identified by genotyping only a small number of key variants ("tag SNPs," or tSNPs) contained within the haplotype. It has been proposed that only five to seven SNPs could capture all the genetic information within an average gene, effectively reducing the number of genotypes that must be measured to study association at a gene locus.

CANDIDATE GENE STUDIES. Typically, studies of allelic association have employed markers residing within disease-relevant candidate genes. The choice of candidates is informed by existing knowledge of pathways or molecules thought to be involved in a specific disease. For example, because monoamine neurotransmission has long been thought to play a role in depression, common choices of candidate genes have included monoamine receptors and transporters. Once a candidate gene is selected, markers mapping within the transcriptional unit are genotyped in case and control populations to screen for deviations in allele frequency. The greatest limitation of candidate gene studies is the rudimentary understanding of disease mechanisms in psychiatry. Which are the correct candidates to test? Researchers have turned to genome-wide association studies (GWAS), to eliminate this bias and provide a comprehensive,

hypothesis-free screen of all genes.

Numerous candidate gene studies have been performed for psychiatric disorders, but very few have been replicated or supported by functional data. A summary of candidate genes most strongly supported as risk factors for specific disorders is shown in Table 37–2. Candidate gene studies are inherently poorly powered due to the low prior probability that any given gene is associated with disease, and therefore the true threshold for significance is very high. Future studies in psychiatric genetics will leverage the genome-wide association approach to thoroughly scan the genome for risk genes.

Table 37–2.
Summary of Replicated Candidate Gene Associations with Childhood Onset Psychiatric Disorders

Disorder	Candidate Genes
Attention-deficit/hyperactivity disorder	SLC6A3 (DAT1), DRD4, DRD5, 5HT1B, SNAP25, DBH, SLC6A4 (5HTT)
Autism spectrum disorders	NLGN3, NLGN4, CNTNAP2, NRXN1, MET, OXTR PDE4, SHANK3, PTEN, GABRB3
Schizophrenia	NRG1, DTNBP1, G72
Major depressive disorder	SLC6A4 (5HTT), BDNF, AVPR1B
Obsessive compulsive disorder	SLC1A1, 5HTT, HTR2A
Tourette syndrome	SLITRK1, DRD4, DRD2
Bulimia nervosa	GHRL
Anorexia nervosa	OPRD1, HTR1D, COMT, DRD2, SLC6A4 (5HTT)

GENOME-WIDE ASSOCIATION STUDIES. Over the last decade, microarray ("gene chip") technology has made ambitious GWAS possible; chips are available that can assay millions of SNPs simultaneously. Evaluating the approximately 10 million SNPs in the human genome is not a practical task and would be fraught with statistical complications. However, the number of SNP genotypes required can be reduced to a more manageable number by typing only tag SNPs within defined haplotype blocks. Currently, the consensus p value for significance in GWAS studies is set at 5×10^{-8}, correcting for the 50,000 predicted false positives that occur when a million tests are performed. While many psychiatric GWAS fail to meet this stringent level of significance, several large consortia have recently been successful by recruiting tens of thousands of participants (Table 37–3).

The most successful GWAS to date have examined schizophrenia in adults and provide a proof-of-concept that large enough sample sizes are indeed able to identify common risk variants of modest effect in psychiatric disease. Due to the cooperation and sharing between several multisite initiatives, tens of thousands of individuals with schizophrenia were analyzed in these studies. The largest psychiatric GWAS to date was

performed by the Schizophrenia Working Group of the Psychiatric Genetics Consortium (PGC), who conducted a meta-analysis of 49 independent datasets totaling 34,241 cases and 45,604 controls, as well as 1,235 parent affected–offspring trios. This well-powered meta-analysis produced 128 statistically independent associations between individual SNPs and schizophrenia diagnosis at 108 loci (including 25 previously reported associations and 83 novel associations). Of interest, at least 75 percent of these loci contained one or more protein-coding genes, many of which were involved in synaptic plasticity and dopamine (DRD2), glutamate (GR1A1, GRIN2A, GRM3), and calcium (CACNAC1C, CACNA11, CACNB2) signaling pathways.

To date, GWAS for other neuropsychiatric illnesses have resulted in limited success, likely due to insufficient sample sizes and substantial disease heterogeneity (especially in the case of major depression and anxiety disorders). Even so, progress has been made on a number of other psychiatric illnesses such as bipolar disorder and major depression, and with further large-scale collaborative efforts, findings are hoped to approximate those seen in schizophrenia GWAS. A total of 9 GWAS of bipolar disorder have yielded at least 17 independent genetic loci that have been replicated and reliably reproduced as risk alleles. In the case of more heterogeneous disorders, such as depression, mood disorders, panic disorders, and posttraumatic stress disorder, findings have been less robust; but the fact that gene loci that cross the significance threshold have been discovered lends credence to the genetic aspects of these disorders. Two large GWAS for major depression have identified four independent loci conferring risk for depression and response to antidepressant treatment, and with increased sample size this list is likely to grow. One GWAS found a single locus associated with mood disorders in general. A GWAS in panic disorder noted two loci associated with panic attacks, and a GWAS for posttraumatic stress disorder also unearthed two independent loci that conferred risk for the disorder.

Table 37–3.
Summary of Neurodevelopmental Disorder GWAS with SNPs That Reach Significance of $p < 5 \times 10^{-8}$

Psychiatric Disorder	Reference	Strongest SNP-Risk Allele	Genomic Region	Mapped Genes	*p* Value

While childhood-onset disorders may reflect greater genetic loading, the majority of GWAS for pediatric psychiatric disorders have resulted in only suggestive associations, most likely due to modest sample sizes. The majority of GWAS in ASD have failed to achieve genome-wide significance, highlighting the probable extreme heterogeneity underlying ASD. GWAS in anorexia nervosa have produced suggestive results, with a few genetic loci approaching the significance threshold. Other child focused GWAS, such as those examining more dimensional traits such as "behavioral disinhibition" and "preschool internalizing problems" have again shown several loci approaching genome-wide significance. GWAS in early-onset bipolar disorder have not yielded any promising results, likely due to small sample sizes and possible unreliable diagnostic criteria for the disorder itself. PGC Working Groups are currently collecting childhood-onset samples to facilitate large GWAS of the magnitude of those successful in adults.

Table 37–4.
Summary of Neurodevelopmental Cross-Disorder GWAS with SNPs That Reach Significance of $p < 5 \times 10^{-8}$

Psychiatric Disorders	Reference	Strongest SNP-Risk Allele	Genomic Region	Mapped Genes	*P* Value
Bipolar and major depressive disorders	Liu (2010)	rs1006737-A	12p13.33	CACNA1C	$3 \times 10^{-}$

Interestingly, cross-disorder GWAS have revealed loci that span diagnostic borders, demonstrating effects in multiple psychiatric categorizations (e.g., schizophrenia and bipolar disorder, or ASDs, ADHD, bipolar disorder, major depression, and schizophrenia; Table 37–4). These cross-phenotype risk genes imply a likely common underlying mechanism for certain aspects, or dimensions, of psychiatric disorders or the presence of resilience genes that confer protection against mental illness.

GWAS approaches are designed to detect common variants of small to moderate effect. As discussed previously, it is plausible that rare variants of larger effect may also be important in psychiatric disease. While some GWAS chips now include rare variants, the most comprehensive method of evaluating rare variation in disease risk is genome sequencing (discussed in the following section).

Comparative Genomic Hybridization and GWAS for Copy Number Variation Analysis. Comparative genomic hybridization (CGH) is a microarray-based technology that can detect CNVs in the human genome rapidly and accurately. *CGH arrays* are glass slides spotted with thousands of probes, from short oligonucleotides to hundred-megabase clone inserts, spanning the genome or focused on a genomic region of interest. Genomic DNA from a test subject and a reference sample are differentially labeled and then cohybridized to the array. Differences in hybridization signals between the test and reference sequences can be detected and decoded to reveal deletions or duplications relative to the reference sample. This method can be used to search for *de novo* (new, noninherited) CNVs in disease populations. CGH has also been used to identify polymorphic CNVs that can be tested for association with disease. Given that local SNPs are frequently in LD with CNVs, it is possible to test association at known CNVs by using nearby SNPs, bypassing the need to measure specific CNV genotypes directly. As an alternative to CGH, GWAS chips can be analyzed for fluorescent signal strength to similarly identify and quantitate CNVs, with increased signal across many adjacent SNPs pinpointing a deletion and increased signal reflecting a duplication.

CNV studies using these microarray-based methods have successfully revealed novel submicroscopic CNVs using advanced computational CNV-predicting algorithms present in populations with intellectual disability, ASD, and schizophrenia. CNVs have been detected in patients with

sporadic ASD at 10 times the frequency in controls, and many CNVs are significantly associated with ASD. A genome-wide linkage study using SNP arrays conducted by the Autism Genome Project Consortium similarly identified a high rate of CNVs in ASD. A screen of the Autism Genetic Research Exchange (AGRE) families by CGH identified a microdeletion and reciprocal duplication at 16p11.2 in approximately 1 percent of cases. Such findings again suggest the prospect of many identifiable subpopulations within larger, heterogeneous ASD samples.

CNV studies have also shed light on biological processes that are affected in schizophrenia. Inherited and *de novo* CNVs associated with schizophrenia more frequently contain genes involved in neurodevelopmental pathways, encoding proteins that function in synaptic architecture, calcium signaling, and glutamatergic neurotransmission. In general, schizophrenia-associated CNVs have large individual effect sizes but are extremely rare in the population, whereas associated SNPs have small individual effect sizes but are common in the population. The aggregate effect of both CNVs (*de novo* and inherited) and SNPs must be considered in order to fully understand genetic risk for psychiatric disease. In addition, smaller *de novo* CNVs have also been implicated in bipolar disorder and ADHD, but at a much lower rate and reduced overall genetic burden compared to ASD and schizophrenia. Table 37–5 summarizes recurrent CNV loci and their association with psychiatric illness.

Next-Generation Sequencing. While GWAS approaches are well suited to examining common genetic variation, genome sequencing studies are able to identify rare variation leading to disease. In the past decade, the advent of NGS, or massively parallel sequencing, made exome (protein-coding regions of the genome) and whole genome sequencing possible. This technology generates millions of overlapping short reads from a DNA template that are assembled and aligned using a reference genome. By comparison to the reference genome, software is used to call genotypes at millions of known and novel variants across the sequenced genome. Since healthy individuals have been shown to carry tens of thousands of novel variants and hundreds of damaging mutations, the signal-to-noise obstacle presented by NGS is staggering. One successful strategy limits the analysis to *de novo* variation by comparing proband to parent genomes. Three independent groups simultaneously published scans of *de novo* variation in ASD in 2012. Collectively, these studies revealed that highly disruptive (nonsense and splice-site) *de novo* mutations in brain-expressed genes are associated with ASD and carry large effects. These *de novo* variants are overwhelmingly paternal in origin (4:1 bias) and positively correlated with paternal age. Multiple independent observations of *de novo* variants within the same gene among unrelated probands and across studies reliably identified several risk genes, including genes involved in sodium transport

(*SCN1A*, *SCN2A*), chromatin remodeling (*CHD8*), and axon guidance (*NTNG1*).

Table 37–5.
Summary of Copy Number Variation Associated with Psychiatric Disorders

Locus	Copy Number Change	Disease Association
1q21.1	Deletion/duplication	SCZ, ID, ASD, ADHD
2p16.3	Deletion	SCZ, ID, ASD
3q29	Deletion	SCZ, ID, ASD
7q11.2	Duplication	SCZ, ID, ASD, ADHD, ANXIETY
7q36.3	Deletion/duplication	SCZ, ID, ASD
15q11.2	Deletion	SCZ, ID, ASD, ADHD, OCD
15q11–13	Duplication	SCZ, ID, ASD
16p11.2	Deletion/duplication	SCZ, ID, ASD, ADHD, ANXIETY, MOOD
16p13.11	Duplication	SCZ, ID, ASD, ADHD
17q12	Deletion	SCZ, ID, ASD
22q11.1	Deletion	SCZ, ID, ASD, ADHD, ANXIETY, MOOD, VCFS
Xq28	Deletion/duplication	ASD

SCZ, schizophrenia; ID, intellectual disability; ASD, autism spectrum disorder; ADHD, attention-deficit/hyperactivity disorder; VCFS, velocardiofacial syndrome.

Pathway Analysis. Individual common SNPs appear to confer only small effects on psychiatric phenotypes, and while they have larger effect sizes, disease-associated CNVs are rare in the population. Therefore, multiple risk alleles in combination are likely required for disease expression.

As the first successful studies identifying risk alleles in psychiatric illness have been published, common pathways impacting specific cellular or neurodevelopmental processes have emerged. Many studies now include pathway analyses to add functional relevance and validity to GWAS or NGS results. Using bioinformatic and gene ontological approaches (such as the DAVID or GO Gene Ontology databases), investigators can determine whether associated genes belong to particular gene networks or cellular processes above chance levels. Using these approaches, scientists can begin to build gene interaction networks based on a priori knowledge of gene function gleaned from the research literature. These data can inform the development of prediction models, generating testable hypotheses about how a particular risk allele might alter a biological process to drive disease risk. An example of how genes cluster in pathways and across diseases is noted in Table 37–6.

PHARMACOGENOMIC EFFECTS ON PSYCHIATRIC TREATMENT IN CHILDREN

Identifying genes that predict treatment response or adverse effects will

improve the safety, tolerability, and effectiveness of psychotropic medication. Thus far, most pharmacogenetic studies in adult psychopharmacology have been limited to investigations of single genes or small numbers of genes and frequently test only single variants within these genes for association with drug response. Research in child and adolescent samples is emerging, especially in the area of ADHD pharmacogenomics. With the increase in large-scale clinical trials in child psychiatry over the last decade, more pharmacogenetic studies are soon to follow. Results from both adult and child studies suggest that genetic testing may hold more promise and initial clinical relevance in the prediction of side effects over efficacy.

Genome-Wide Association Studies

Large-scale GWAS are a particular challenge for detecting pharmacogenomic phenotypes since there may be multiple response "subtypes" which, given the variability in typical outcome measures, may require the strength of repeated assessments throughout a controlled clinical trial in order to detect. No genome-wide significant results emerged from several GWAS conducted for pharmacogenomic predictors of treatment response in adult psychiatry: a meta-analysis of 2,245 individuals of European ancestry with depression (STAR*D, GENDEP, MARS), a depression treatment study of citalopram in 865 adults by the International SSRI Pharmacogenomics Consortium (ISPC), a schizophrenia treatment trial of 738 subjects receiving multiple antipsychotics (CATIE), and a multiple treatment arm study of 458 patients with bipolar disorder (STEP-BD). GWAS for adverse effects have similarly failed to identify compelling signals in adult samples, including antidepressant treatment-emergent suicidality and metabolic, cardiac and movement side effects of antipsychotics.

The few pharmacogenomic GWAS in pediatric populations have been more successful thus far. One success was found in a meta-analysis of a GWAS examining antipsychotic-induced weight gain in youth receiving several antipsychotics identifying a risk allele near the melanocortin 4 (MC4R) gene. When examined in a meta-analysis with three replication cohorts, a genome-wide significant result was reported. GWAS data generated by the OCD Collaborative Genetics Association Study (OCGAS) was used to examine self-reported positive response or nonresponse to serotonin reuptake inhibitors in 804 subjects with childhood-onset OCD; one SNP near DISP1, a gene involved in neurodevelopment, achieved genome-wide significance. Interestingly, enrichment pathway analysis of suggestive associations highlighted the potential roles of glutamatergic and serotonergic neurotransmitter systems. Two small GWAS of response (n = 187) to methylphenidate and stimulant-induced cardiovascular side effects (n = 140) in children with ADHD, however, failed to produce genome-wide

significant results.

Candidate Gene Studies

ADHD Pharmacogenomics. The pharmacogenomics of ADHD represents the area of most research in child psychiatry and reveals the promise, as well as the challenges, of this line of investigation. Studies of ADHD treatment response contain many limitations, including differing study designs, samples of low power to detect genetic effects, short observation periods, retrospective designs, differing medications and delivery systems, varying drug titration protocols, and different response characterizations.

Table 37–6.
Representative Gene Pathways Suggested in Child Psychiatric Illness

Gene	Description	Function	Diseases
CALCIUM SIGNALING PATHWAY			
CACNA1C	Cav1.2 L type calcium channel, voltage-dependent (LTCC), alpha 1C subunit	Calcium signaling in neurons, neuronal gene transcription	Bipolar disorder, schizophrenia
CACNB2	Cav1.2 L type calcium channel, voltage-dependent (LTCC), beta 2 subunit	Calcium signaling in neurons, neuronal gene transcription	Schizophrenia
NCAN	Neurocan, chondroitin sulfate proteoglycan	Calcium ion binding	Bipolar disorder
DOPAMINE SIGNALING PATHWAY			
COMT	Catechol-O-methyl transferase	Degradation of catecholamines (dopamine, epinephrine, norepinephrine)	Depression, schizophrenia
DTNBP1	Dystribrevin binding protein 1, dysbindin	Trafficking of DRD2	Schizophrenia
GLUTAMATE SIGNALING PATHWAY			
GRIN2A	Glutamate receptor, ionotropic, N-methyl D-aspartate 2A	Glutamate receptor activity	Schizophrenia
GRM1, GRM3	Glutamate receptor, metabotropic 1 and 3	Glutamate receptor activity	Schizophrenia
GRM5, GRM7	Glutamate receptor, metabotropic 5 and 7	Glutamate receptor activity	Attention-deficit/hyperactivity disorder
NRGN	Neurogranin	Glutamate signaling, postsynaptic trafficking	Schizophrenia
MAJOR HISTOCOMPATIBILITY COMPLEX/IMMUNE PATHWAY			
MHC	Multiple immune functioning proteins	Immune response	Schizophrenia
SEROTONIN SIGNALING PATHWAY			

SLC6A4/5HTT	Solute carrier family 6, member 4 (serotonin transporter)	Releases serotonin from synapse, neurogenesis	Depression
NEURONAL PROCESSES/NEUROGENESIS			
ANK3	Ankryn-3	Axon guidance, axonogenesis	Bipolar disorder
BDNF	Brain-derived neurotrophic factor	Glutamate receptor activity and trafficking, synaptogenesis	Depression
CNTNAP2	Contactin associated protein-like 2, neurexin family	Neuronal cell adhesion molecule	Autism, schizophrenia
DISC1	Disrupted in schizophrenia-1	Neurite outgrowth, cortical development	Schizophrenia
NRXN1	Neurexin 1	Synaptic maturation	Schizophrenia
ODZ4	Teneurin transmembrane protein 4	Neurite outgrowth, transcription regulation	Bipolar disorder
TCF4	Transcription factor 4	Neurogenesis, synaptic maturation, transcription regulation	Schizophrenia
VIPR1	Vasoactive intestinal polypeptide receptor 1	Neurotransmitter, Neuroendocrine hormone	Schizophrenia
ZNF804A	Zinc finger protein 804A	Putative role in early neurodevelopment	Bipolar disorder, schizophrenia

The DAT1 (*SLC6A3*) gene has been tested repeatedly as a predictor of stimulant response, and several reports have concluded effects from the common 9- or 10-repeat functional 3′-untranslated region (UTR) variable number tandem repeat (VNTR). The 9 allele has been shown to reduce the subjective effects of single-dose administration of d-amphetamine in studies of normal controls, in keeping with the hypothesis that the reduced expression of *SLC6A3* encoded by the 9 allele would be associated with dampening of effects of drugs acting on this target. However, numerous studies in ADHD have yielded varying conclusions where either the 9- or 10-allele predicts favorable treatment response, and a meta-analysis was unrevealing. Taken together, these mostly conflicting reports on *SLC6A3* variants and stimulant response in ADHD are difficult to interpret. Nevertheless, the hypothesized functional importance of *SLC6A3* variants strongly supports further efforts to relate genetic variation, in the context of other genetic or environmental factors, to treatment response.

The dopamine receptor DRD4 gene has also been examined as a moderator of ADHD treatment response. Consistent with the reduced in vitro agonist efficacy produced by the DRD4 exon 3 VNTR seven-repeat allele (*DRD4.7*), one group found that children with this variant showed reduced sensitivity to methylphenidate, as evidenced by a higher-dose requirement for optimal clinical benefit. This result was confirmed by a second pediatric study. The National Institute of Mental Health (NIMH) Preschool ADHD Treatment Study (PATS) sample showed a suggestive negative moderating effect of the DRD4.7 allele, yielding a −0.25 effect size

on methylphenidate response in one analysis. The PATS study also found two copies of the common 240-base pair variant in the DRD4 5′-UTR promoter region to be significantly associated with methylphenidate response, although the effect was not seen in other secondary analyses from the same sample. Illustrating possible epistatic interactions between genes, a small study noted that the *DRD4.7* allele was associated with reduced response to methylphenidate, but only in those individuals who were homozygous for the 5HTT (*SLC6A4*) short variant. Other reports, mostly in adult populations, have found no effect of *DRD4* variants.

SNPs in other catecholaminergic genes posited to play a role in stimulant action have received preliminary study for possible treatment-moderating effects, including adrenergic genes (norepinephrine transporter [*SLC6A2/NET1*] and α-2A adrenergic receptor [*ADRA2A*]). In an RCT study of 82 subjects with ADHD querying functional variation in 7 monoaminergic candidate genes, the serotonin transporter intron 2 (STin2) VNTR was associated with MPH response. Two *DRD4* VNTRs and the 5HTT-linked promoter region (LPR) variant showed gene by dose interactions on math performance. The *COMT* Val/Met SNP and 5HTT-LPR were associated with irritability and vegetative symptoms, respectively. Both dopaminergic (dopamine D2 receptor [*DRD2*]) and adrenergic (*ADRA2A*) variants were associated with response to dexmethylphenidate in the NIMH/CIDAR Translational Research to Enhance Cognitive Control (TRECC) RCT of children with ADHD. The TRECC study screened 120 SNPs capturing complete common variation across 23 candidate genes for ADHD treatment effects. This study was the first to examine pharmacogenomic moderators of guanfacine outcomes, reporting effects of dopamine D1 and D2 receptors on guanfacine treatment response. The TRECC study also identified multiple strong associations ($<10^{-8}$) with growth and cardiovascular side effects of both d-MPH and guanfacine treatment. Several of these effects were in agreement with prior literature showing association of noradrenergic genetic variation (*SLC6A2* and *ADRA2A*) with cardiovascular changes with MPH treatment. In 90 Caucasian children with ADHD, stimulant tolerability was associated with a *DRD1* variant.

Several genes in other systems have some early data. A prospective pediatric study supported involvement of the Val66Met functional polymorphism in brain-derived neurotrophic factor (BDNF). SNAP-25, involved in neurotransmitter release, moderated both methylphenidate response certain side effects, including tics, abnormal movements, and irritability in the NIMH PATS preschool study. A study of *SNAP-25* variants in adults with ADHD was negative. Two reports in children with ADHD found associations at a variant in the latrophilin 3 (*LPHN3*) gene, implicated by linkage in a South American population isolate. While an adult study also found association at this locus, the direction of effect was

reversed.

A potentially important area of pharmacogenetics, relates to genetic effects on drug metabolism and distribution. A combined analysis of four pediatric ADHD clinical trials of atomoxetine (Strattera) identified effects of CYP450 2D6 genotypes on efficacy and side effects. Subjects genotyped as poor 2D6 metabolizers showed significant gains in ADHD symptom reduction with treatment, presumably due to beneficial effects of higher plasma atomoxetine levels despite lower daily doses; although adverse events of anorexia and tremor were slightly greater in poor metabolizers, discontinuation rates did not differ. In a more recent study, 10/100 children receiving standard atomoxetine doses were selected for *CYP2D6* genotyping due to lack of response or prominent side effects. Eight out of 10 of these patients were revealed to have compromised CYP2D6 activity. While in many cases, dose adjustment resolved the issue, the authors relate that in a number of cases, willingness to continue therapy was adversely affected by the initial experience. These data underscore the potential clinical importance of knowledge of CYP genotypes and individual optimization of drug therapy. Drug transporters, such as the multidrug resistance protein (MDR1 encoded by *ABCB1*), can impact transport into the body from the gut and into brain from the blood. In 134 children with ADHD, those homozygous for an *ABCB1* functional variant had 9× greater risk of side effects.

In summary, an understanding of the role of these variants supported by candidate gene approaches will require larger studies, improved controls, objective measures of drug response, and analytic approaches considering potential interactions of multiple variants within and between stimulant target genes. A significant omission in ADHD pharmacogenomics is the absence of information regarding genetic effects on response to other stimulants, as well as second-line ADHD medications besides atomoxetine. Given community practice, which often incorporates a range of medications for ADHD, such knowledge would be important. Finally, incorporating gene by environment interactions can be fruitful when environmental risk factors are known. Two studies incorporating the risk of prenatal exposure to maternal smoking have found support for gene by environment interactions on MPH treatment response. Each study focused on a single candidate gene (*NET1, LPHN3*).

Pharmacogenomics in ASD. The variability in efficacy and side effects of pharmacotherapy targeting ASD symptoms has been widely noted. Given the lack of effective treatments for the core symptoms of ASD, only a few pharmacogenomics studies address genetic moderators of treatment response. Two very small studies have shown nominal associations of *SLC6A4* variants with SSRI response. In a study by the RUPP Autism Network, genetic association with response to MPH treatment for

attentional symptoms in the context of ASD was assessed at 34 variants across 10 monoaminergic loci selected due to their role encoding MPH drug targets. Seven variants (*DRD1*, *ADRA2A*, *COMT*, *DRD3, DRD4, SLC6A3*, *SLC6A4*) showed nominal association with treatment response, a number significantly above that expected by chance, suggesting that many of these associations are in fact true positives. Variants in dopamine D2 and D3 receptors moderated tolerability in the 14 children who discontinued the trial due to side effects.

The rise in use of the second-generation antipsychotics (SGAs) has been accompanied by greater research into their efficacy and safety in pediatric groups. Initial studies of risperidone treatment of severe behaviors associated with autism noted prominent weight gain as a drug-related side effect. Several studies have implicated monoaminergic variants in the moderation of SGA side effects in ASD. The most consistent result, seen in three pediatric populations, has been the association of the serotonin 2C receptor (*HTR2C*) with antipsychotic-induced weight gain (AIWG). The largest pharmacogenomic study in ASD combined the two NIMH RUPP trials of risperidone treatment of 225 children with ASD-associated aggression, and identified numerous gene variants contributing to AIWG, including HTR2C, other monoaminergic variants, and several candidates in the energy balance pathway.

Pharmacogenomics in Other Areas. Dopamine receptor (*DRD2, DRD3*); serotonin receptor (*HTR1A, HTR2A*); and transcription factor ZNF804A, a schizophrenia risk locus, have amassed some support in moderating SGA treatment response in adult schizophrenia. Studies of rare, serious side effects of antipsychotics have resulted in replicated association of *HLA-DQB1* with agranulocytosis and *DRD2*, *HTR2A*, *CYP2D6*, and heparan sulfate proteoglycan 2 (*HSPG2*) in tardive dyskinesia. Children and adolescents, especially those with ASD, appear to be more likely to develop withdrawal dyskinesias with antipsychotics. Studies in children would be valuable to explore risk for motor side effects. Such observations relating to these concerning adverse effects, if robust enough, could potentially inform clinical practice.

The variability in the response of pediatric depression to drug therapy and the heightened sensitivity to adverse events of activation and suicidal ideation/impulses points to another area ripe for pharmacogenetic investigation. In adults, serotonergic and glutamatergic candidate genes have been found to predict adverse events and dropout with antidepressants, and in some instances efficacy differences by genotype. Specific tests of genetic effects on antidepressant-induced mania have encouraged further research. Given the need to improve the benefits and safety of treatment matching for early-onset depression, adult research immediately suggests genetic hypotheses to test in younger depressed

populations.

While the field of psychiatric pharmacogenomics is only beginning, pharmacogenomics studies are likely to differ from categorical disease genetic studies in several ways. Effect sizes are often large, phenotypes can be quantitative and more easily measured (e.g., weight change), and longitudinal data can be leveraged to improve statistical power. Exciting preliminary studies using gene expression profiling suggest that other pharmacogenomic techniques may also facilitate the prediction of drug effect. These analyses seek to identify distinct clusters of transcription patterns associated with drug response. The use of such methods is sure to greatly increase one's ability to better stratify individuals by shared biological features, leading to greater homogeneity in treatment response.

CLINICAL CORRELATIONS

The application of genetics in the practice of child psychiatry is in its infancy, but is growing rapidly. As described below, genetic testing now has a recommended role in many clinical evaluations, and in a greater and greater number of treatment decisions. Given the expected expansion of knowledge in child psychiatric genetics, clinicians need to stay informed, as additional practice implications are sure to follow.

Genetic Testing in Current Child Psychiatric Practice

Published guidelines from the American Academy of Pediatrics and the American College of Medical Genetics both recommend CGH and GWAS analyses as a routine part of the evaluation of any child with suspected ASD and all children with intellectual disability, in an effort to determine molecular diagnoses. In addition, these clinical guidelines include the recommendation for genotyping for the fragile X triplet-repeat mutations and identified mutations in the Rett Syndrome *MECP2* gene. The guidelines note that girls with learning disabilities and suspected other developmental delays have been found to possess these mutations in the absence of full syndromic features. Children with macrocephaly should also be tested for mutations in the *PTEN* gene, given its role in growth pathways and association with head circumference. At present, estimates are that routine genetic testing in ASD as well as intellectual disability results in positive findings in as many as 20 percent of individuals.

Some centers have begun routinely obtaining high-resolution genomic sequencing for suspected Mendelian disorders in place of high-density microarray testing for some patients, hoping to identify more rare variant risk mutations not captured by arrays. Other centers are now collecting genome-wide sequence data for every patient entering their medical system. With the expansion of clinical testing taking place, more and more patients will present with already available genome sequence data,

challenging physicians to identify findings of clinical import. As a result, psychiatrists need to attempt to stay current with the research literature, and develop facility with the many searchable genetic databases to aid their interpretations of patient information.

Pharmacogenomic Testing in Current Clinical Practice

Pharmacogenomic testing has unquestionably entered the clinical practice of child psychiatry. As of mid-2015, the U.S. Food and Drug Administration (FDA) has required the inclusion of pharmacogenomic information of clinical importance for 165 drugs, 30 of which are psychotropics or commonly used and encountered in psychiatric treatment. The FDA provides a comprehensive list of these labels (http://www.fda.gov/drugs/scienceresearch/researchareas/pharmacogenet

The majority of pharmacogenomic labeling pertains to specific drug safety concerns associated with specific genotypes and their corresponding phenotypes. Arguably the most compelling example is the FDA recommendation for *HLA-B*1502* allele testing prior to prescribing carbamazepine (Tegretol) in patients of Asian ancestry. The *HLA-B*1502* allele appears to be primarily restricted to Asian populations and is strongly associated with increased risk for Stevens–Johnson syndrome/toxic epidermal necrolysis, as it has been found to be present in greater than 90 percent of individuals who developed SJS associated with carbamazepine. A majority of other pharmacogenomic considerations relate to genetically mediated drug metabolism differences associated with other safety risks.

Reflecting the growing appreciation of the importance of individual genetic differences in pharmacokinetics and drug distribution, the FDA also approved the first pharmacogenetic test, the AmpliChip CYP450, in January 2005. Test results from this chip provide relatively comprehensive testing of well-defined, clinically relevant polymorphisms in two cytochrome P450 genes (*CYP2D6* and *CYP2C19*) that are known to be associated with large differences in the metabolism of many psychotropic medications. Polymorphisms in the genes encoding these enzymes can result in poor-metabolizer and ultrarapid-metabolizer phenotypes, producing extreme variability in circulating drug levels. An estimate of the US annual treatment cost of adverse antidepressant reaction in CYP2D6 poor metabolizers was $420 million in 1999; consequently, some authors advocate the economic viability of testing CYP genotypes prior to antidepressant therapy. Current guidelines do not endorse standard genetic testing for antidepressants, however, testing is recommended for prescribing of tricyclic antidepressants, as well as specific antidepressants from other classes. These guidelines, available at the Clinical Pharmacogenetics Implementation Consortium website, advise avoidance of tricyclic antidepressants in individuals with ultrametabolizer CYP2D6

status because of potential lack of efficacy and either avoidance or 50 percent dose reductions and monitoring of therapeutic drug levels in individuals with the "poor metabolizer" phenotype of CYP2D6 or CYP2C19. Indeed, genotype-tailored treatment is routinely performed in many other areas of medicine (tamoxifen, warfarin, antineoplastics), and will continue to expand in relation to the safe and effective use of psychotropic therapies. Besides the AmpliChip, a number of commercial laboratories have begun to offer a wider range of genetic tests ostensibly to inform psychiatric practice. Clinicians should also be aware that the supporting evidence for larger-scale pharmacogenetic testing is often limited, and lacks the wider replication required before such tests can be considered "evidence based."

FUTURE DIRECTIONS

As the adoption of clinical genetic testing expands, spurred by future technical and scientific progress, more and more genetic information will become available to clinicians. A number of publically available databases can be accessed by clinicians in their efforts to understand the possible role of genetics at the level of the individual patient. A list of these databases is provided below. As mentioned previously, a number of publically funded websites also include information on the clinical importance of pharmacogenetic differences with clinical import.

Newer scientific methods hold promise too. The field of epigenetics attempts to understand the impact of experience (e.g., environmental influences) on the regulation and expression of genes. Early findings have already shed light on the mechanisms by which early childhood adversity can lead to risk for adult mental disorders (posttraumatic stress disorder, mood disorders) via methylation of genes involved in the stress–response system. As these mechanisms are revealed, they are likely to point to novel prevention and treatment strategies that could be applied to youth, and potentially alter the trajectory of their development and adaptation. Such exciting prospects should encourage close attention to this important area of psychiatric research.

Neuroimaging in Psychiatric Disorders of Childhood

FRANK P. MACMASTER, PH.D., MARIKO SEMBO, B.A., AND DAVID R. ROSENBERG, M.D.

INTRODUCTION

Over the last quarter century, there has been a revolution in the current understanding of the living human brain. The advent of brain imaging has allowed for the noninvasive assessment of brain structure, function, and chemistry. Until the development of brain imaging, the investigation of the neurobiological underpinnings of psychiatric illness in children was stalled compared to adults. Indeed, brain imaging has allowed for tremendous gains in pediatric psychiatric research. Evidence increasingly suggests that abnormal brain development underlies many childhood-onset neuropsychiatric disorders. The application of brain imaging to describe the biology of the illness can lead to improved diagnosis and innovative treatments. Moreover, the study of brain maturation may make it possible to find critical time periods during which brain abnormalities could lead to psychiatric disease. The research findings may also indicate potential "targets" for treatment intervention.

This chapter has three sections. First, core brain imaging methods are described. Second, special considerations (such as gender and development) are addressed. Third, relevant findings from brain imaging studies of psychiatric disorders of childhood are summarized. Disorders include attention-deficit/hyperactivity disorder (ADHD), depressive disorders such as major depressive disorder (MDD), bipolar and related disorders, such as bipolar I disorder (BP-I), anxiety disorders, obsessive-compulsive disorder (OCD), posttraumatic stress disorder (PTSD), Tourette syndrome (TS), childhood-onset schizophrenia, substance use disorders, feeding and eating disorders, autism spectrum disorder (ASD), and specific learning disorders including dyslexia. The purpose of this chapter is to provide an understanding of brain imaging in psychiatric disorders of childhood.

TECHNIQUES AND PRACTICAL CONSIDERATIONS

Neuroimaging Techniques

Twenty-five years ago, the study of the brain was largely limited to postmortem work. However, postmortem studies are not practical for developing an understanding of psychiatric disorders of childhood. Nearly all postmortem brains come from adults. Hence, they are confounded by chronic illness and exposure to treatment. The application of brain imaging techniques has overcome this obstruction to progress.

Morphology/Structure

Morphological studies include the examination of structure, volume, and shape. Early studies in psychiatry began with more of a "radiological" approach—that is, looking for the presence or absence of visible damage or lesions. An example of this is the link between magnetic resonance imaging (MRI) T2 hyperintensities in left frontal stroke and depression. These lesions can be observed with the naked eye. This approach was not adequate, as most psychiatric illnesses do not involve a visible lesion. Hence, the field focused on more quantitative methods.

A measure should be both valid and reliable. Measurement of biological structures is challenging, as many parameters change with development. In the human brain, not all aspects are MR-visible. This is critical when designing an experiment using MRI as the method. The effect must be of necessary scale to be detectable. However, the technology is continually improving and it may someday be possible to evaluate single cells in vivo using MRI-based technologies. In addition to the ability to be detected and measured, the structure must also be clinically of interest. In other words, it should be critically involved in a specific function associated with the psychiatric disorder in question.

The two principal steps in morphological MRI studies are data acquisition and quantification. With both of these steps, bias and error can diminish the validity of the study. Bias can obscure real effects or produce incorrect findings. Error is random variation. Both bias and error can reduce statistical power and result in erroneous findings. There is no single accepted method for reducing bias and error in each of the steps involved in MRI experiments. Furthermore, there is little consensus regarding how to properly perform anatomic quantification, with methods varying considerably. Due to inherent variation in regional brain volumes, it is accepted that large sample sizes are required to demonstrate even moderate effects between groups.

Volume and Shape. A "structure" should be distinct from its neighbors. Within the brain structure, there should be a common aspect to or resultant from the parts comprising the structure. This could be cell type, neurotransmitter receptor distribution, or function. For instance, *caudate* could be a descriptor because it has specific related functions and is contiguous spatially. When trying to understand the brain, you need to

know where functionally specific structures are located, what function they perform, and how the distributed processing of that function is organized. The volume of a brain structure is reflective of the size, shape, and density of its parts. It is reasonable to assume that functional changes are reflected physiologically with changes in cellular composition and/or activity. Consequently, by examining the volumetric properties of a structure one can make inferences about its functionality. Researchers may also study the shape of a brain structure and compare groups and conditions. The quantitative analysis of biomedical shape variation and shape change, while more complicated mathematically, offers useful information on two- and three-dimensional properties of structures that may be relevant to disease states. More recently, the investigation of cortical thickness has become increasingly common in the study of pediatric psychiatric populations. These approaches are typically automated and rely on established templates for the localization of differences.

MRI-based volumetric approaches are a viable tool in basic science studies. As a scientific method, it has served many purposes—mapping developmental trajectories, disease processes, and the effect of treatment. Thanks to its use of nonionizing radiation, MRI allows for repeated measures over time with a high degree of safety. MRI further avoids the physiological changes inherent in the death process and the effects of the lag between death and fixation processing that are part of postmortem studies. Furthermore, for psychiatric diseases of childhood, like OCD and ADHD, there are virtually no postmortem studies. Hence, investigation of psychiatric diseases of childhood has benefited from MRI approaches. It should be noted that MRI is obviously of lesser utility in children with braces or claustrophobia.

Diffusion Tensor Imaging. Diffusion tensor imaging (DTI) is based on the MR signal resulting from the restricted movement of water in brain tissue. DTI allows for the examination of the integrity and directional orientation of white matter tracts (e.g., superior longitudinal fasciculus) in the brain. The fundamental architecture of white matter has the axons running in parallel bundles or tracts. This forces water molecules to move along the main bearing of the tract. This oriented dispersal pattern is termed as anisotropic diffusion. The location, direction, and anisotropy of the white matter tracts can be measured.

Computed Tomography. Computed tomography (CT) was the first imaging method to make routine the direct, in vivo, and noninvasive evaluation of the living human brain. CT is typically used for the assessment of lesions, but also the capability to assess the volume of a structure. CT has limited resolution and contrast between gray and white matter. In practice, MRI has replaced quantitative CT in brain research due

to its improved resolution and tissue contrast. As stated earlier, the use of MRI also avoids the exposure to ionizing radiation associated with CT. This increase in risk (or perception of risk) renders CT's routine use for the study of pediatric conditions less appealing.

Chemistry

Brain imaging methods that evaluate brain chemistry may be more sensitive than structural imaging studies in the identification of localized abnormalities in psychiatric illness. As indicated above, the radiological hallmarks of psychiatric illness (i.e., differences from healthy controls or changes with treatment) are not typically visible to the naked eye. These differences are subtle and require very sensitive methods of detection.

Single-Photon Emission Computed Tomography and Positron Emission Tomography. Positron emission tomography (PET) and single-photon emission computed tomography (SPECT) methods have been critically informative regarding the pathogenesis and mechanisms of treatment response of several neuropsychiatric conditions in adults. These approaches permit the investigation of regional cerebral blood flow, glucose metabolism, and neurochemistry—including specific neurotransmitters, transporters, and receptors. These techniques have only been applied infrequently to pediatric psychiatric disorders. The trepidation arises from the fact that SPECT and PET use ligands labeled with radiation. This risk limits their role in the study of children and adolescents. Institutional review boards frequently disallow such studies in healthy children without neuropsychiatric illness. When deprived of a proper control group, discovering the pathology of childhood psychiatric disease using PET or SPECT is rendered problematic. These radiation concerns make longitudinal studies (e.g., treatment and developmental effects) not viable in children with or without disease. MR-based techniques are free of ionizing radiation and, as such, have rapidly become the preferred means for examining neuroanatomy, blood flow, and chemistry in children.

Magnetic Resonance Spectroscopy. Magnetic resonance spectroscopy (MRS) measures chemicals in the brain. Although many nuclei with odd-numbered protons or neutrons, including phosphorus (^{31}P), carbon (^{13}C), fluorine (^{19}F), sodium (^{23}Na), and proton (^{1}H) compounds, can be detected using MRS, ^{1}H-MRS is the most commonly used technique, providing measures of the following: *N*-acetylaspartate, a neuronal marker; creatine/phosphocreatine, involved in energy metabolism; choline compounds, membrane components; myo-inositol, a secondary messenger involved in signal transduction; and glutamate, glutamine, and γ-aminobutyric acid (GABA)—all of which occur in relatively high

concentrations in brain (Fig. 38–1). ^{31}P-MRS is the second most common approach in developmental populations. ^{31}P-MRS allows for the study of the products of membrane synthesis (phosphomonoesters [PMEs] like phosphoethanolamine and phosphocholine) and breakdown (phosphodiesters [PDEs] like glycerophosphoethanolamine and glycerophosphocholine), along with substrates of energy metabolism. The choice of MRS versus PET/SPECT measures of brain chemistry involves important tradeoffs. First, MRS does not have the power to detect chemicals occurring at lower concentrations, such as monoamines, neuropeptides, opiates, and so on. Second, MRS has relatively poor spatial and temporal resolution as compared to that of PET. However, with data acquisition and spectral editing programs becoming increasingly sophisticated and the increases in magnetic field strength, striking improvements in the spatial and temporal resolution of MRS are being fulfilled.

FIGURE 38–1. Sample proton magnetic resonance spectrum from the hippocampus. Spectra were obtained from a 6.0-mL volume of interest as shown on the magnetic resonance image. Cho, choline; CR, creatine/phosphocreatine; Glx, glutamate/glutamine/γ-aminobutyric acid; mI, myo-inositol; NAA, *N*-acetyl-aspartate. At higher field strengths, distinguishing glutamate from Glx is possible. Angulation of voxels to best accommodate anatomy (like the hippocampus) is also possible. (Figure courtesy of Frank MacMaster, Ph.D.)

FIGURE 38–2. **A:** Functional magnetic resonance imaging (fMRI) data demonstrating activation during a simple finger-tapping task. **B:** Signal intensity from a pixel shows the correspondence with the task paradigm (not tapping/tapping). (Figure courtesy of Frank MacMaster, Ph.D.)

Functional Neuroimaging

The selection of functional magnetic resonance imaging (fMRI) versus PET/SPECT measures of cerebral blood flow also involves tradeoffs. fMRI delivers excellent spatial resolution (1 mm or less) along with potentially superior temporal resolution (about 1 second), compared to the PET/SPECT approaches. Second-to-second temporal resolution is now possible with event-related fMRI. Unlike PET/SPECT, fMRI does not provide an absolute measure of cerebral blood flow. Rather, fMRI can detects changes in blood flow, requiring the use of carefully designed neurobehavioral paradigms during imaging to generate activation signals (Fig. 38–2). New analytical techniques allow for the quantification of

"baseline" or "resting-state" blood flow using fMRI images. The study of so-called default mode networks offers an innovative method for determining differences in brain function between groups and conditions.

Critical Considerations

When acquiring and interpreting data from MR-based neuroimaging studies of children, a variety of factors merit consideration. A concise overview is presented below.

Technical Factors. The capacity of children to remain quiet and still while being scanned is of particular concern to investigators using any imaging technique. Motion artifacts are problematic in studies as they can often render data of such poor quality as to make it unusable. Remaining still can be challenging even for healthy children, let alone those suffering from neuropsychiatric and neurodevelopmental disorders. Children are often naturally curious about the scanning environment. Some children can become quite anxious in the small, confined space of the magnet. Even with earplugs and headphones, the loud noises inherent in certain specific imaging sequences can be disturbing. Pharmacological sedation has been used successfully in children who would be otherwise unable to tolerate neuroimaging in clinical settings, but in research studies, such procedures may entail unwanted side effects and alter the neurobiology being studied. For research studies, sedation and its potential risks are more ethically difficult to justify, especially in healthy control participants. Desensitization to the scanning environment with a "mock scanner" (Fig. 38–3) before the actual scan has been found to reduce subjective distress and heart rate, facilitating the successful completion of the study. Unfortunately, "mock scanners" can be costly and require considerable space in already crowded hospitals. Other means of desensitization, such as careful description of the scanner, videos of its use, and attention to the questions of patients and their parents, may also be helpful in reducing anxiety and habituating children to the scanning environment to facilitate successful MR-based study.

Neuroanatomical Factors. Smaller body size and brain maturation are key technical considerations in performing MR-based neuroimaging research in children. Children may not fit well into head coils designed for adults, leading to increased magnetic field inhomogeneity and decreased signal-to-noise ratios. Greater variability of the cardiorespiratory cycle in children may also contribute to increased physiologic noise during fMRI. Head motion, which is more common in children, can influence functional connectivity measures as well. However, the brain is surrounded by less bony and muscular tissue in children than in adults, so that MR surface head coils lie closer to the brain regions being imaged, possibly enhancing signal detection.

Peak synaptic density within the brain occurs between 4 and 8 years of age. This peak is associated with greater metabolic and perfusion demands, which may lead to more robust increases in regional cerebral blood flow during neuronal activation and/or increased "noise" in fMRI experiments. Furthermore, the networking between brain regions is immature and may result in a weaker, more diffuse fMRI signal. Structurally, greater ratios of gray to white matter and less cerebrospinal fluid (CSF)—occupied free space around vasculature in children may lead to fundamental differences in the generation of MR signal in children versus adults. These factors must be taken into account when attempting to compare subjects of disparate

ages.

The interpretation of fMRI signals in children is further complicated by structural differences, because data processing typically involves the "warping" of study subjects' brains to a standard brain atlas derived mainly from adults. The development of standardized brain atlases for children of different ages offers a solution to this methodological problem. Still, brain volumes may vary during development even in same-aged children, so that the segmentation of brain into gray matter, white matter, and CSF may be necessary to generate individual descriptors of structural differences for use in statistical correction between study subjects. The use of study-specific templates for fMRI and voxel-based morphometry (VBM) is the most logical course. The volumetric MRI study of normal brain development in children and adolescents jointly sponsored by the National Institutes of Mental Health, Child and Human Development, and Neurologic Disorders and Stroke has recently been initiated and will generate a large normative database specific to pediatric structural maturation. Given the aforementioned variation in the developing brain and its effect on analysis methods, the importance of this resource cannot be overestimated.

Cognitive Factors. Another possible confound in the interpretation of certain fMRI paradigms in children relates to their ability to perform the cognitive tasks under investigation. Across development, children vary considerably in cognitive skill and their capacity to sustain attention and remain "on task." Potential tasks need to be vetted thoroughly in children and adolescents before robust interpretations of functional data can be made. Cognitive-based fMRI studies comparing children and adults should account for accuracy and reaction time to avoid falsely attributing performance differences to underlying neurobiology. Assessment of effort should also be considered because some children may guess or give up when a cognitive task is too difficult or too boring. In designing a cognitive paradigm for use in an fMRI study of children, tailoring the level of task difficulty to individual capability may help to ensure consistent performance across subjects at different developmental stages. The possibility that children may use different cognitive strategies on a given task can be examined by correlating task performance with neuropsychological measures. The correlation of activation patterns with performance rather than age may help to identify true functional differences based on brain maturity rather than structural- or performance-based differences, which can vary with age and between same-aged subjects during development.

Functional neuroimaging studies of executive functions, including working memory (the ability to respond to new situations on the basis of stored information) and neurobehavioral response inhibition (inhibition of

context-inappropriate responses), have demonstrated similar regional activation patterns (e.g., prefrontal cortex) in children and adults, with children recruiting larger volumes of activation with greater signal intensity. This suggests a less specific neural network and/or less efficient processing of cognitive stimuli in childhood. Not only may children display different activation strengths in response to stimuli, they may also show regional differences as well. On a task of spatial working memory, adults activated the anterior cingulate, a structure critically involved in arousal and mediating response conflict, whereas children did not. Lower accuracy on the task among children may be related to an incompletely developed anterior cingulate, resulting in a relatively reduced ability to modulate competing responses. In general, the functional connectivity between the anterior cingulate and other cortical and subcortical structures appears to increase with age, as demonstrated in a ^{1}H-MRS study in humans.

Opposite laterality of activation may also distinguish healthy children from healthy adults on tasks of response inhibition and working memory. Children may also recruit subcortical (e.g., basal ganglia, thalamus) and limbic (e.g., amygdala, hippocampus) structures to support incompletely developed prefrontal cortex (PFC) in mediating response inhibition. Moreover, whereas both healthy children and adults show altered activation of the amygdala in response to fearful faces as measured by fMRI, children but not adults show activation for neutral faces, as well as fearful faces, further suggesting that more specific neural processing of information develops with age.

NORMAL DEVELOPMENT

Psychiatric diseases of childhood can only be understood in the context of brain development. Brain size increases considerably in utero through 2 years of age, during which time synaptogenesis is most active. While total brain volume is comparatively static after 5 years of age, there are two dynamic processes that are ongoing through adolescence into young adulthood—synaptic pruning and myelination. Evidence suggests that increased myelination, connectivity, and changing functional activation patterns indicate that more efficient connections between brain regions are being made from childhood through adulthood.

FIGURE 38–4. Schematic showing growth and aging changes in gray matter from childhood through adolescence. Gray mater volume reached a maximum by 9.5 years of age in females (*solid line*) and 10.5 years of age in males (*broken line*) and thereafter declined linearly. This is most pronounced in the frontal and temporal lobes. (Schematic adapted from Giedd JN, Raznahan A, Alexander-Bloch A. Child psychiatry branch of the National Institute of Mental Health longitudinal structural magnetic resonance imaging study of human brain development. *Neuropsychopharmacology*. 2015;40(1):43–49.)

FIGURE 38–5. Schematic adapted from positron emission tomography studies of glucose metabolism as a function of age in children through young adulthood. Note the steep rise through childhood followed by a sharp decline just as puberty and adolescence begins. (Schematic adapted from Chugani HT. Biological basis of emotions: brain systems and brain development. *Pediatrics*. 1998;102(5 Suppl E):1225–1229.)

Gray Matter

Gray matter volumes peak in mid-childhood to early adolescence, earlier in females than males. They then plateau briefly and show a decrease following puberty (Fig. 38–4). This pattern of gray matter maturation parallels changes in local cerebral metabolic rates for glucose in the cerebral cortex as a function of age (Fig. 38–5). These developmental changes most likely represent an increase in the efficiency of neural processing via the pruning of excessive synaptic connections. It is not clear what cellular changes (i.e., loss of neurons, dendrites, axons, and/or neuropil) are responsible for the reduction of gray matter. Indeed, it has recently been shown in 308 healthy children and adolescents that cortical thickness, as measured using MRI, can accurately predict an individual's age.

When considering the developmental basis of normal and abnormal cognitive/emotional function, it is important to note that it is heterochronous. That means that the timing, degree, and rate of cortical and subcortical gray matter change appear to be regionally specific. Gender also plays a significant role in brain development. In a large longitudinal MRI study of cortical volumes in 145 healthy children and adolescents (4 to 20 years of age), gray matter volume was found to peak and then decline after puberty in the parietal, frontal, and temporal lobes but on different time scales (Table 38–1). In contrast, gray matter in the occipital cortex

increased through early adulthood (approximately 20 years of age). With regard to gender differences, the peak for gray matter volume in the frontal and parietal lobes occurs nearly 1 year earlier in girls than boys. This seems to coincide with gender-specific differences in the timing of puberty and suggests the possible influence of gonadal hormones on brain development.

White Matter

The volume of white matter increases roughly linearly in the brain during childhood and adolescence. This is consistent with myelinization during this time (Fig. 38–6). Growth in cortical white matter appears to be regionally specific. The most dramatic increase in white matter occurs in the dorsolateral PFC between 5 and 17 years of age. Consistent with the progressive development of executive function through adolescence and into early adulthood, a segmentation analysis of MRI data found that gray matter reduction in the frontal cortex continued into young adulthood, after gray matter volumes had stabilized in other cortical regions. The "reduction" of frontal lobe gray matter was thus hypothesized to reflect the effects of an increase in myelination (and hence the relative amount of white matter). This interpretation is supported by the inverse relationship of cortical gray matter and brain growth—presumably due to white matter increase—in the frontal lobes. It has been suggested that myelinization may be as important to brain maturation as synaptic pruning. Indeed, the capacity for attention—a function largely attributable to the frontal lobe—has been shown to increase with larger areas of the anterior cingulate cortex over development, possibly the result of increased myelination. The corpus callosum (CC)—the white matter tract connecting the hemispheres—appears to demonstrate a particularly dynamic growth pattern (Fig. 38–7). Unlike the posterior–anterior progression of brain development described in much of the preclinical literature, CC growth occurs in a rostrocaudal wave between 3 and 15 years of age (Fig. 38–7). It may be that CC growth parallels synaptogenesis in associated cortical regions rather than pruning and myelinization. In a large study of 103 healthy participants (5 to 32 years of age), nonlinear development of major white matter pathways was observed. There were significant within-subject changes in the majority of children and early adolescents, with these changes being completed by late adolescence for projection and commissural tracts. In contrast, association tracts demonstrated post-adolescent within-subject maturation of both fractional anisotropy and mean diffusivity.

Table 38–1.
Peak Cortical Gray Matter Volumes by Age and Gender

Cortical Region	Girls (Age in years)	Boys (Age in years)
Parietal	10.2	11.8

Frontal	11.0	12.1
Temporal	16.7	16.5

Data summarized from Giedd JN, Raznahan A, Alexander-Bloch A. Child psychiatry branch of the National Institute of Mental Health longitudinal structural magnetic resonance imaging study of human brain development. *Neuropsychopharmacology*. 2015;40(1):43-49.

FIGURE 38–6. Schematic showing growth and aging changes in white matter from childhood through adolescence. White matter volume increased rapidly until 12 to 15 years of age then slowed to eventually plateau. Males (*dotted line*) females (*solid line*). (Schematic adapted from Giedd JN, Raznahan A, Alexander-Bloch A. Child psychiatry branch of the National Institute of Mental Health longitudinal structural magnetic resonance imaging study of human brain development. *Neuropsychopharmacology*. 2015;40(1):43–49.)

Gender Differences

Gender-specific and age-related differences in gray matter volumes have also been noted in the basal ganglia, hippocampus, and amygdala (Table 38–2). Although reduction of basal ganglia volumes has been demonstrated in both sexes through young adulthood, gray matter loss in this region is most dramatic in boys, especially in the caudate between the ages of 6 to 12 years. It is possible that this maturational difference is related to the preponderance of basal ganglia–associated psychiatric disease (e.g., OCD and ADHD) in boys during this critical developmental

window. In contrast to the basal ganglia and some areas of the cerebral cortex, the volume of the amygdala and hippocampus increases with age. Volumetric and functional abnormalities of these regions have been associated with depression and anxiety disorders, known to occur more commonly in females, particularly after the onset of puberty. The relatively smaller amygdala and larger hippocampal volumes that emerge in girls than in boys around the time of puberty may be particularly relevant in this regard. The preponderance of estrogen receptors in the amygdala and androgen receptors in the hippocampus suggests that gonadal hormones may influence age-specific changes in these regions and possibly the emergence of mood and anxiety disorders in adolescent girls. The pituitary gland also demonstrates a striking gender difference, with females developing a larger pituitary gland than males, particularly during adolescence. This may be associated with the differential timing of puberty in males and females.

FIGURE 38–7. Schematic showing the corpus callosum, its subdivisions, and projections. (Schematic adapted from Thompson PM, Giedd HN, Woods RP, MacDonald D, Evans AC. Growth patterns in the developing brain detected by using continuum mechanical tensor maps. *Nature.* 2000;404(6774):190–193.)

Table 38–2.
Gender Differences in Brain Volumes

Region	Gender Difference (Age in years)

Total brain volume	10% larger in boys (4–18)
Cerebellum	8% larger in boys (4–18)
Caudate and putamen	More dramatic decrease in boys (preadolescent)
Amygdala	Larger in girls (postadolescent)
Hippocampus	Larger in boys (postadolescent)

Data summarized from Giedd JN, Raznahan A, Alexander-Bloch A. Child psychiatry branch of the National Institute of Mental Health longitudinal structural magnetic resonance imaging study of human brain development. *Neuropsychopharmacology*. 2015;40(1):43–49.

SPECIFIC NEUROPSYCHIATRIC DISORDERS

Attention-Deficit/Hyperactivity Disorder

The phenomenology, nosology, and empirically based treatment for ADHD have been well delineated. This makes pediatric ADHD a prime candidate for neurobiological studies of development. ADHD is also relatively consistent in expression across the lifespan. Therefore, the results of studies of the disorder in children, closer to illness onset, are applicable to adult subjects. Various neuroimaging strategies, including PET, fMRI, volumetric/anatomic MRI, and ^{1}H-MRS, have been used to better elucidate the pathogenesis and mechanisms of treatment response in ADHD.

Prefrontal Cortex. Core deficits in attention, arousal, and impulse control characterize children with ADHD. The PFC modulates these functions and is the seat of "executive" control. It is not surprising that the PFC has been implicated in the pathophysiology of ADHD. Smaller prefrontal cortical volumes, particularly of the superior and inferior frontal gyri, have been consistently noted in volumetric MRI studies of children with ADHD. However, one study found girls with ADHD to have normal frontal lobe volumes; this finding may be related to the lower prevalence of ADHD in females than males and an underlying gender difference in the pathophysiology of the disorder. Lower global cerebral metabolism in girls with pediatric ADHD than in male patients and normal controls has been noted, further suggesting gender-specific differences in the neurobiology of ADHD. Smaller PFC volumes correlate with impaired response inhibition in children with ADHD. A recent large-scale study of children with ADHD found that the structural maturation of the PFC lags behind typically developing children by 2 to 3 years. When considering the potential behavioral ramifications of such a lag in development, the implications for the symptoms of ADHD are clear. In addition, using phosphorus magnetic resonance spectroscopy (^{31}P-MRS), lower levels of membrane phospholipid (MPL) precursors were observed in older ADHD children as compared to healthy children. Lower MPL precursor levels suggest a possible underdevelopment of neuronal processes and synapses in ADHD. It was suggested that bottom-up developmental dysfunction, starting in the basal

ganglia, might result in ADHD (Fig. 38–8). During a response conflict task that typically involves the anterior cingulate (AC) in normal subjects, adult patients with ADHD failed to demonstrate a significant AC response. Of interest, both increased and decreased PFC activation during response inhibition has been found in different studies. These discrepant findings may be accounted for by the inverse relationship noted between symptom severity and perfusion in children with ADHD. Specifically, perfusion-based functional neuroimaging studies of "sicker" patients would start from a lower baseline than studies of less symptomatic patients. This may result in a reduction in signal when the PFC is involved.

FIGURE 38–8. Schematic showing membrane phospholipid (MPL) precursor levels as associated with age in children with attention-deficit/hyperactivity disorder (ADHD) (*broken line*) and typically developing healthy children (*solid line*) in the frontal lobe and basal ganglia. (Schematic adapted from Stanley JA, Kipp H, Greisenegger E, et al. Evidence of developmental alterations in cortical and subcortical regions of children with attention-deficit/hyperactivity disorder: a multivoxel in vivo phosphorus 31 spectroscopy study. *Arch Gen Psychiatry.* 2008;65(12):1419–1428.)

Basal Ganglia. Another aspect of the frontal-striatal loop, the basal ganglia, has been repeatedly demonstrated to be abnormal (with regard to volumes and reversed asymmetry) in pediatric ADHD. The deficits in response inhibition and attention noted in children with ADHD have also been associated with smaller volumes and lower activation of the right and left caudate. The basal ganglia has been implicated in ADHD, TS, and OCD, and may account for the high degree of comorbidity among these conditions. ^{1}H-MRS studies have noted lower levels of the putative neuronal marker *N*-acetylaspartate (NAA) and greater levels of choline (Cho), a critical membrane component, in the striatum bilaterally in pediatric ADHD patients. More recently, ^{1}H-MRS studies of pediatric ADHD patients identified greater frontal-striatal glutamatergic levels in medication-free pediatric patients with ADHD 7 to 16 years of age as

compared to age- and sex-matched controls. Lower NAA levels suggestive of reduced neuronal viability may result from excess activity of glutamatergic (Glx) neurons, which can be toxic. Given evidence that changes in Cho, NAA, and Glx may be reversible in other neuropsychiatric conditions; longitudinal ^{1}H-MRS studies of these metabolites in ADHD are critical. As mentioned above, ADHD patients have lower PFC and basal ganglia MPL precursor levels than healthy children. In the basal ganglia, these deficits appear earlier, possibly indicating a bottom-up change in developmental trajectory. No significant differences were noted in the superior temporal region.

Cerebellum and Other Regions. Structural neuroimaging studies have demonstrated smaller cerebellar volumes in girls and boys with ADHD. This smaller volume may be localized to the vermis, a brain region involved in maintaining attention. In an fMRI study of motor function in pediatric ADHD patients, greater impairment in task performance was associated with lower cerebellar activation. Furthermore, motor impairment in ADHD patients was also associated with lower temporal lobe activation but greater thalamic activation. This suggests that complex network-wide dysfunctions might underlie the symptoms of ADHD. This hypothesis is supported by the findings of smaller anterior and poster aspects of the CC in ADHD patients.

Medication Effects on Brain Function in ADHD. Methylphenidate (MPH) is the first-line treatment for ADHD. Studies found that MPH changes frontal-striatal activation in pediatric patients with ADHD, with greater PFC and striatal activation as measured by fMRI demonstrated in ADHD patients. In addition, MPH was found to improve ADHD patient performance on the response inhibition task. Predrug activation during the task was greater among patients than with controls, suggesting that frontal cortical hyperactivity in ADHD may play a compensatory role that is further enhanced by MPH. In the striatum, predrug activation was lower in pediatric patients with ADHD than in pediatric controls. This deficit appeared to be corrected by MPH. MPH-treated healthy children also improved in their ability to inhibit inappropriate response. However, improved performance in healthy children was associated with a distinct pattern of frontal-striatal activation. These differences in MPH-related activation could reflect a fundamental abnormality of frontal-striatal dopamine systems in patients with pediatric ADHD as compared to healthy children. Positive correlation between ADHD symptom severity and increased midbrain accumulation of ^{18}F-dihydroxyphenylalanine (^{18}F-DOPA), a marker of dopamine synthesis, lends further support to the role of dysfunctional dopamine systems in ADHD. There is data suggesting a developmental shift in dysfunction of dopamine from the midbrain in

childhood and adolescence to frontal cortex during adulthood in ADHD. Interestingly in children with ADHD, responders to methylphenidate have greater gray matter concentrations compared to nonresponders in the caudate. This is similar to a larger posterior hippocampus predicting better response to antidepressant in adults with depression. The predictive power of imaging for treatment response has yet to be fully explored in child and adolescent psychiatry.

A recent meta-analysis of fMRI studies of the effect of stimulants on brain function in ADHD examined 14 data sets with 212 children with ADHD. Stimulants consistently enhanced right inferior frontal cortex and insula activation, with a smaller effect on putamen activation. This change in activation was present in those receiving methylphenidate alone. The inferior frontal cortex and insula play a role in cognitive control and an increase in activation may represent the positive clinical response found with treatment.

Depressive Disorders and Bipolar and Related Disorders

Biological studies of depressive disorders and bipolar and related disorders are providing increasingly converging evidence that alterations in medial temporal (e.g., amygdala, hippocampus) and prefrontal-striatal circuits may be involved in the symptomatology of patients with MDD and BP-I (Fig. 38–9). Although the literature is not entirely consistent, it appears that lesions to the left hemisphere are more associated with depression, whereas right-sided lesions tend to be more associated with mania.

Frontal Lobe and Striatum. In both adults and adolescents with MDD, smaller overall frontal lobe volumes have been among the more consistent findings in structural neuroimaging studies. In addition, adolescents with MDD were found to have significantly smaller frontal white matter volumes but larger frontal gray matter volumes than healthy comparison adolescents, even after controlling for age and whole brain. Cortical thickness in the middle frontal gyrus bilaterally and the left caudal anterior cingulate was found to be greater in adolescents with MDD as compared to healthy control participants. Replicating and extending this finding in adults, thicker caudal anterior cingulate was also found with first episode MDD. Left middle frontal gyrus was inversely correlated with age in MDD subjects. This may indicate an altered developmental path in youth with MDD. MRI and PET investigation in adults with MDD and BP-I have reported strikingly localized, left-sided smaller volume in the subgenual region of the prefrontal cortex (SGPFC). This smaller SGPFC was associated with lesser cerebral blood flow. These effects were most prominent in MDD and BP-I patients who had at least one first-degree relative with MDD or BP-I (familial MDD or BP-I). In patients with MDD or BP-I without family history of MDD or BP-I (nonfamilial MDD or BP-I)

no significant differences were observed in the left or right SGPFC. In an additional sample, a smaller left SGPFC volume was also noted in 30 young women with early-onset MDD (18 to 23 years of age) and 18 middle-aged women with recurrent MDD (24 to 52 years of age) than in age-matched controls (19 percent difference).

FIGURE 38–9. Brain regions implicated in the pathophysiology of major depressive disorder.

A study of 22 psychotropic-naive pediatric patients with MDD (9 to 17 years) compared to 22 case-matched controls found that patients with nonfamilial MDD had significantly larger left-sided but not right-sided prefrontal cortical volumes than patients with familial MDD and controls. In both the familial and nonfamilial pediatric MDD subgroups, left prefrontal volumetric abnormalities remained significant after controlling for severity of anxiety. This suggests that this region is integral to the pathogenesis of depression in children. Reduced left-sided prefrontal cortical volume was associated with increased severity of depression in familial but not nonfamilial patients with MDD. Longer illness duration also tended to be associated with reduced left prefrontal cortical volume in familial but not nonfamilial MDD patients. These results, coupled with investigations in adults, suggest that left-sided prefrontal cortical volume reduction in familial MDD patients may reflect degeneration of left prefrontal cortical volume, whereas increased left prefrontal cortical volume in psychotropic-naive pediatric patients with nonfamilial MDD

may reflect alteration in the developmental maturation of the prefrontal cortex.

Left PFC has been further implicated in pediatric MDD in two recent ^{1}H-MRS investigations. Increased left orbitofrontal choline levels were observed in 22 depressed adolescents as compared to 43 control adolescents. Increased orbital frontal choline levels were most prominent in adolescent patients with familial MDD as compared to both nonfamilial MDD patients and controls (Personal Communication, Dr. Perry Renshaw). Increased left but not right dorsolateral PFC choline concentrations were also observed in treatment-naive pediatric patients with MDD as compared to age- and sex-matched controls. Increased choline concentrations in pediatric MDD patients versus controls persisted even after controlling for severity of anxiety. Mean left dorsolateral prefrontal cortical choline concentrations were increased in familial MDD patients as compared to both nonfamilial MDD patients and healthy pediatric controls. Lower choline concentrations were also observed in the right anterior cingulate. Alterations in choline as measured by ^{1}H-MRS have been hypothesized to result from abnormalities in signal transduction involving phosphatidylcholine second messenger cascades and could reflect changes in glucose metabolic rates and/or neuroendocrine function. Increased left prefrontal choline levels may also be consistent with functional neuroimaging studies demonstrating reduced prefrontal cortical metabolism in adults with MDD. Functional neuroimaging studies have demonstrated that reduced prefrontal cortical activation in depressed adolescents and adults normalizes following treatment-induced symptom remission. Because choline alterations in adult patients with MDD appear to be reversible with treatment, the choline resonance may represent a potential target for treatment intervention in pediatric MDD, warranting longitudinal ^{1}H-MRS investigations in these patients. Finally, consistent with findings in adult patients with MDD, lower anterior cingulate Glx concentrations have been noted in pediatric MDD patients than in healthy controls. Glx was also associated with severity of illness in the MDD patients. In addition, distinct differences were noted in familial versus nonfamilial MDD patients. Subsequent investigation, using a more robust spectral fitting method, found that the lower anterior cingulate Glx in patients was due to glutamate but not glutamine. In 20 medication-free youth with MDD, lower anterior cingulate GABA was observed as compared to controls, with this difference being more pronounced in those with anhedonia. Recently, a small case series in adolescents with MDD replicated a finding in adults with MDD that showed an increase in DLPFC glutamate in response to repetitive transcranial magnetic stimulation treatment.

In contrast, recent ^{1}H-MRS investigation in ten medication-free children with BP-I versus ten healthy children found increased glutamate

and glutamine levels bilaterally in the frontal lobes and basal ganglia in children with BP-I. Choline levels did not differ in frontal lobes or basal ganglia in patients with BP-I or controls. Increased lipid levels were also found bilaterally in the frontal lobes of children with BP-I. In contrast, ^{1}H-MRS investigation of anterior cingulate cortex in pediatric patients with BP-I versus healthy pediatric controls found no significant differences in choline, glutamate, glutamine, GABA, or the neuronal marker NAA. Consistent with findings in adults, effective lithium treatment was, however, associated with reduction of the ^{1}H-MRS neurochemical marker myo-inositol in the anterior cingulate cortex of children with BP-I. A recent voxel-based morphometry study found that subjects with BP-I had reduced gray matter volume in the left DLPFC as compared to healthy controls.

In concert with the frontal lobe, the striatum plays an important role in executive and emotional processing. Evidence from adult imaging studies implicates the striatum in the pathophysiology of depressive disorders. A recent study noted that patients with MDD had significantly smaller right striatum (2.3 percent smaller) and caudate volumes (3.9 percent smaller) than healthy subjects. Furthermore, right striatum volumes were inversely correlated with increased severity of depression. These findings provide fresh evidence for abnormalities in the striatum of pediatric MDD and bolster the hypothesis of dysfunction in the cortico-limbic-striatal-pallidal-thalamic circuit in the pathophysiology of MDD.

Amygdala, Hippocampus, and Pituitary. Although prefrontal cortical involvement in pediatric MDD may be specific to depressive state, abnormalities of the amygdala in depressed children and adolescents may be more associated with severity of anxiety than with severity of depression. Ratios of left and right amygdala to hippocampal volume were found to be significantly larger in treatment-naive pediatric patients with MDD than in 23 age- and sex-matched controls. Furthermore, ratios of amygdala to hippocampal volume in pediatric patients with MDD were positively correlated with severity of anxiety but not with severity of depression or duration of depressive illness. Amygdala volumes were larger bilaterally in patients with MDD than in controls. In a magnetic resonance spectroscopic imaging ^{1}H-(MRSI) study of the amygdala in adolescents with depression, lower choline-to-creatine ratios were noted in the left, but not right, amygdala in patients than in controls. This change in cytosolic choline may be secondary to corticosteroid-neuroendocrine–driven changes, given that increases in cortisol can result in lower choline concentrations. Right and left hippocampal volumes were smaller in MDD patients. Not only are comorbid anxiety symptoms and disorders extremely common in patients with MDD, but also excessive fearfulness in adolescence has been found to predict the development of MDD in early adulthood. Smaller left hippocampal volumes have been noted in pediatric

patients with MDD with a familial history of depression than in controls. It may be that patients with a family history of depression are driving the smaller hippocampal volumes noted in previous reports. In a closer examination of the hippocampus using ^{1}H-MRSI, reduced left, but not right, NAA concentration was noted in MDD patients as compared to age- and sex-matched controls. This indicates that neuronal viability may be reduced in pediatric MDD.

In adolescents with MDD, at rest, the amygdala showed lower connectivity with the hippocampus, parahippocampus, and brain stem. This connectivity was inversely correlated with depressive symptoms. Use of emotional facial expressions as fMRI stimuli is common as a probe of affective processing in the amygdala in adults and children. An fMRI study of amygdala response to fearful faces in children with generalized anxiety disorder and panic disorder compared to children with MDD and healthy pediatric controls demonstrated altered activation of the amygdala in both patients with MDD and patients with generalized anxiety disorder/panic disorder, with the magnitude of signal change in amygdala activation being most associated with the severity of the child's rating of everyday anxiety. This increase in amygdala arousal to negative stimuli was recently replicated in 32 adolescents with MDD and 23 age and gender-matched controls.

It should be noted that greater amygdala volume is one of the more consistent findings in adults with BP-I. fMRI studies in adults with BP-I have also demonstrated increased amygdala activation in response to fearful facial affect. More recently, an event-related fMRI study reported that pediatric patients with BP-I demonstrated reduced memory for emotional faces and had increased neural activation in the striatum and anterior cingulate cortex when successfully encoding happy faces, and in the orbitofrontal cortex when successfully encoding angry faces. There were no between-group differences in neural activation during fearful face encoding. Consistent with adult BP-I studies, multiple fMRI studies reported increased amygdala activation in response to fearful faces. Differences across studies of BP-I may have to do with differences in disease state. Longitudinal MRI studies of amygdala volume and function in pediatric patients with MDD are clearly warranted to determine whether increased amygdala volume and altered activation level may serve as potential biomarkers for BP-I.

More recently, larger pituitary gland volumes were noted in adolescents with MDD than in case-matched controls. This was replicated in an independent treatment-naive sample. In the second sample, it was noted that the difference in volume appeared to be driven by nonfamilial MDD patients. Of interest, depressed patients with BP-I demonstrated larger pituitary gland volumes than controls. This was not consistent with a published adult study of BP-I and a pediatric sample. The main difference

between these reports is the disease state (depressed vs. mainly euthymic). This reinforces the need for studies of BP-I across the illness course and the need for further studies to differentiate MDD from BP-I.

Obsessive-Compulsive Disorder

There is a growing literature pointing to a dysfunction in ventral prefrontal-striatal-thalamic and medial temporal circuitry in OCD (Fig. 38–10). The phenomenology, nosology, and empirical treatment for childhood OCD have been well established, rendering it an ideal candidate for developmental neurobiological study. In comparison to depressive and bipolar and related disorders, OCD is more consistent in its expression across the lifespan. This allows investigators to study the illness close to onset, with the results remaining applicable to adult subjects. Studies in pediatric OCD have focused on treatment-naive populations. This minimizes potential confounds such as illness duration and medication exposure. As described in the following sections, evidence is converging that suggests a pharmacologically reversible, glutamatergically mediated thalamic-cortical-striatal dysfunction in pediatric OCD that may serve as a reliable pathophysiological and treatment response marker for the illness (Fig. 38–11).

FIGURE 38–10. Brain regions implicated in the pathophysiology of obsessive-compulsive disorder. (Reprinted with permission from Rosenberg DR, MacMillan SN, Moore GJ. Brain anatomy and chemistry may predict treatment response in pediatric obsessive-compulsive disorder. *Int J Neuropsychopharmacol.* 2001;4(2):179–190.)

Basal Ganglia. Volumetric neuroimaging studies in pediatric patients

with OCD have demonstrated smaller basal ganglia volumes in patients that were associated with OCD symptom severity but not illness duration. In addition, smaller globus pallidus volumes were also noted in treatment-naive pediatric OCD patients than in controls. Recently however, 26 adolescents with OCD showed greater gray matter volume in the bilateral caudate as compared to healthy controls (N = 26). This may reflect fundamental differences in what properties are measured using voxel-based morphometry as compared to the manual tracing technique. Greater caudate glutamatergic concentrations, as measured by ^{1}H-MRS, were also observed in treatment-naive pediatric OCD patients than in age- and sex-matched healthy pediatric controls (Figs. 38–12 and 38–13). No significant differences in glutamatergic concentrations were observed between OCD patients and controls in occipital cortex, a region not implicated in the pathogenesis of OCD. After 12 weeks of treatment with the selective serotonin reuptake inhibitor (SSRI) paroxetine, but not with cognitive–behavioral therapy, caudate glutamatergic concentrations in OCD patients decreased to levels that did not differ significantly from those in controls (Fig. 38–14). Greater pretreatment caudate glutamatergic concentrations predicted a more robust response to paroxetine in OCD patients. More recent investigation suggested that caudate glutamatergic concentrations may persist even after medication discontinuation in pediatric OCD.

Prefrontal Cortex. MRI investigation in treatment-naive pediatric patients with OCD as compared to age- and sex-matched healthy controls demonstrated larger anterior cingulate volumes but not dorsolateral prefrontal cortical volume in the OCD patients (Fig. 38–15). These findings are consistent with findings of increased regional cerebral blood flow and metabolic activity in anterior cingulate cortex in adult and pediatric patients with OCD. Larger anterior cingulate volumes were associated with increased OCD symptom severity but not duration of illness. Pediatric OCD patients also failed to demonstrate the normal age-related growth in anterior cingulate volume seen in healthy controls (Fig. 38–16). Anterior cingulate volumes were inversely correlated with striatal volumes in the OCD patients. It should be noted that two independent studies noted larger anterior cingulate volumes in pediatric OCD, with the more recent study finding differences in the anterior cingulate gray but not white matter. Lower anterior cingulate Glx was also seen in OCD patients than in healthy controls. Of interest, the lower anterior cingulate Glx concentration is associated with the G/G genotype of the glutamate receptor gene polymorphism GRIN2B-rs1019385 in OCD patients. A recent fMRI study found greater activation and connectivity of the medial prefrontal cortex/dorsal anterior cingulate in pediatric OCD patients compared to controls. It was suggested that this might reflect an exaggerated concern for correct performance. Studies of the CC found a larger area and lower signal intensity of the genu of the CC in treatment-naive pediatric OCD patients than in controls. The genu is the region of the CC that connects left and

right ventral prefrontal cortical regions such as anterior cingulate cortex. This provides further evidence for the involvement of ventral prefrontal cortical regions, such as the anterior cingulate cortex, in the pathogenesis of OCD. In right prefrontal white matter, pediatric OCD patients demonstrated greater NAA and Choline concentrations when compared to healthy control participants. The greater NAA concentration correlated with OCD symptoms as well. Using the manual tracing technique, greater right white matter volume in the orbital PFC has also been noted. Indeed, a recent examination of frontal-striatal-thalamic white matter found greater age-related increases in fractional anisotropy in pediatric OCD patients as compared to controls. In the cingulum bundle, this correlated with OCD symptom severity.

FIGURE 38–16. Anterior cingulate volume as a function of age for pediatric patients with obsessive-compulsive disorder (OCD) and normal controls. Opposite neurodevelopmental trajectories in the patients as compared with the healthy subjects may reflect an absence of early neuronal pruning in children with OCD. (Reprinted with permission from Rosenberg DR, Keshavan MS. Toward a neurodevelopmental model of obsessive-compulsive disorder. *Biol Psychiatry.* 1998;43(9):623–640.)

Thalamus. The thalamus acts as the relay station for neuronal input to the cortex and plays a critical role in the circuitry implicated in imaging studies of OCD. In an MRI study of treatment-naive pediatric patients with OCD as compared to age- and sex-matched healthy controls, OCD patients

were found to have larger thalamic volumes. After therapy with the SSRI paroxetine, thalamic volumes decreased in size to the point at which they no longer differed significantly from those of controls (Fig. 38–17). This reduction in thalamic volume was correlated robustly with a reduction in OCD symptom severity (Fig. 38–18). Indeed, a larger pretreatment thalamic volume predicted a better response to paroxetine treatment. When subdividing the thalamus into its component nuclei, the changes in volume were most prominent in medial rather than lateral thalamic regions. With cognitive–behavioral therapy (CBT), no significant changes in thalamic volume were observed before and after 12 weeks of treatment in treatment-naive pediatric OCD patients. This suggests that the reduction in thalamic volume may be specific to SSRI therapy as opposed to a more general treatment effect. In a closer examination of the thalamus in OCD, a ^{1}H-MRS study of treatment-naive pediatric OCD patients and age- and sex-matched pediatric controls was conducted. Lower levels of the neuronal marker NAA were found in OCD patients than in healthy controls. After 12 weeks of drug therapy with paroxetine, an increase in NAA in the medial but not lateral thalamus was seen. Thus, as enlarged thalamic volumes in OCD patients appear to be reduced toward normal after SSRI treatment, lower levels of NAA may be conversely increasing. This suggests a potential neurotrophic effect of SSRI treatment. In addition, significantly greater left and right medial thalamic Cho concentrations were observed in OCD patients than in both healthy control subjects and patients with MDD. Cho concentrations did not differ between patients with MDD and control subjects. This suggests that alterations in medial thalamic Cho differentiate patients with OCD from healthy control subjects and patients with MDD.

Amygdala. Given its role in fear conditioning, the amygdala is believed to be involved in the pathophysiology of OCD. The amygdala is also a target of the SSRIs, the mainstays of pharmacotherapy for OCD. In a recent study, amygdala volumes were evaluated for in vivo volumetric changes in 11 pediatric patients with OCD before and after 16 weeks of monotherapy with the SSRI paroxetine. Eleven healthy pediatric control subjects had baseline and follow-up scans, but none of these subjects received medication. OCD patients at baseline demonstrated significant asymmetry of the amygdala (left greater than right) as compared to healthy controls. The volume of the left amygdala decreased significantly following treatment in the OCD patients. This reduction in volume of the left amygdala in patients correlated significantly with higher paroxetine dose at the time of the follow-up scan and total cumulative paroxetine exposure between the scans. No changes in right or left amygdala volume were noted in healthy

controls over time. There are several possible mechanisms that may account for the paroxetine-mediated change in amygdala volume. Disease progression cannot be entirely ruled out, but this is unlikely, given the degree of change noted and the short time in which these changes occurred. The significant inverse relationship between left amygdala reductions and paroxetine treatment lends credence to the idea that the reversal of hypertrophy is due to treatment. Functionally, in most anxiety disorders, an overactive amygdala is often noted. In pediatric OCD however, amygdala activity is reduced in response to emotional stimuli. Caution is noted due to the small sample sizes involved. Further research is warranted.

Pediatric Autoimmune Neuropsychiatric Disorders Associated with Group A a-Hemolytic Streptococcal Infection

Whereas a smaller basal ganglia appears to characterize patients with early-onset OCD, a larger basal ganglia occurs in the subset of patients with pediatric autoimmune neuropsychiatric disorders associated with group A β-hemolytic streptococcal (GABHS) infection (PANDAS). In PANDAS, it is hypothesized that GABHS-associated antibodies cross-react with neurons in the basal ganglia. This causes the observed symptoms of OCD, as well as tics/TS and ADHD in susceptible children. This hypothesis is supported by evidence indicating larger basal ganglia volumes in some patients with OCD, tics, and/or ADHD that are positively correlated with the incidence of GABHS infection and presence of antibody titers. Furthermore, immunotherapy interventions such as plasmapheresis ameliorate OCD symptoms in some PANDAS patients with marked OCD symptoms. Recovery is also associated reduction in basal ganglia volumes. Of interest, thalamic volumes do not differ between PANDAS patients and controls. Although additional studies are needed, this suggests possible unique neurodevelopmental subtypes of OCD.

Anxiety Disorders

Compared with OCD, there have been relatively few neuroimaging studies of pediatric anxiety disorders.

Generalized Anxiety Disorder

In children with generalized anxiety disorder (GAD), regions associated with fear learning and extinction, mentalization, and amygdala regulation (Fig. 38–19) exhibited greater cortical thickness than controls (Fig. 38–20). These areas included the right inferior frontal gyrus, and the left inferior and middle temporal gyri. Furthermore, amygdala intrinsic functional connectivity is disrupted in children with GAD, affecting the amygdala's connections with the medial prefrontal cortex, insula, and

cerebellum. Functionally, greater left medial PFC and right ventrolateral PFC activation was observed in adolescents with GAD in response to a continuous performance task with emotional distractors. Disrupted connectivity arising from the amygdala was also seen. As discussed earlier (see Depressive and Bipolar and Related Disorders), the amygdala has extensive interconnections with cortical-limbic circuitry and plays a significant role in the processing of anxiety or fear. Indeed, fMRI studies in a combined sample of children with GAD and/or panic disorder compared to healthy children found exaggerated amygdala activation in response to fearful faces in patients with GAD. Furthermore, amygdala volume was significantly larger in pediatric patients with GAD than in healthy controls. In response to treatment with medication or cognitive behavior therapy, right ventrolateral PFC activation related to emotional faces increased. In addition to thicker cortices and larger amygdala volumes, subcortical regions are also affected in GAD. The right putamen was also found to be larger in children with GAD. Interestingly, maltreatment during childhood was associated with larger left thalamic volumes in children with GAD as well. Both the putamen and thalamus have been implicated in other anxiety disorders, but their precise role has yet to be delineated.

FIGURE 38–19. The thalamus, cingulate, amygdala, hippocampus, and the orbital frontal cortex (OFC) are activated in the emotion of fear. (Figure courtesy of Frank MacMaster, Ph.D.)

Posttraumatic Stress Disorder

The amygdala has been implicated in some studies of adult patients with PTSD, and recently hypertrophy of the amygdala in children with PTSD has been observed. In addition, smaller hippocampal volumes have been consistently found in adults with chronic PTSD, but not in children with PTSD. In children with PTSD, smaller whole-brain, prefrontal cortical, and right temporal lobe volumes are associated with an earlier age of onset and longer duration of abuse. More recently, a ^{1}H-MRS study demonstrated lower concentration of the neuronal marker NAA in the anterior cingulate cortex of maltreated children with PTSD than in that of controls.

Consistent with that finding, lower concentration of gray matter has been found in youth with PTSD and an increased activation in response to threat in the anterior cingulate cortex. Given the mixed evidence, discrete neurobiological profiles may be present in pediatric versus adult patients with PTSD. Longitudinal studies to characterize the developmental neurobiology of the illness are needed. Careful assessment for comorbid conditions—for example, anxiety and depression—are also necessary to discern unique neurobiological pathways among different anxiety disorders and depression.

Tourette Syndrome

TS is often comorbid with ADHD and OCD. Indeed, certain brain circuits are common in the pathogenesis of all three conditions.

Cortex. A recent large-scale volumetric MRI study of children and adults with TS found striking abnormalities of cortical development. In the parieto-occipital region, a greater volume was observed in children than in adults with TS. Age-associated reduction in parieto-occipital volumes occurred predominantly in females. In contrast, relatively larger parieto-occipital volumes were observed in older men with TS, suggesting that sexually dimorphic neurodevelopment may contribute to the greater prevalence of TS in males than in females. Larger dorsolateral PFC volumes were found in the younger TS patients but tended to decrease toward adulthood. Because tics often diminish with age, smaller dorsolateral prefrontal cortical volumes in older TS patients were hypothesized to reflect the relatively unusual persistence of tics in the adults participating in the study.

fMRI studies demonstrating increased activation of the PFC during tic suppression in adult TS patients suggest that larger prefrontal cortical volumes observed in children with TS may represent healthy, structural compensation to allow for tic suppression. Functional neuroimaging studies in healthy children and adults have implicated the orbital PFC in the processing of inhibitory control, such that the inverse correlation between orbital prefrontal volumes and tic severity in children and adults with TS likely reflects a fundamental deficit in inhibitory control allowing for the "release" of tics. In the motor and premotor cortices, increased volumes and functional activity appear to occur in adults but not children with TS, possibly reflecting the cumulative effect of years of repetitive, abnormal movements. More recently, it was noted that the normative developmental correlates of activity in frontostriatal circuits that subserve self-regulatory control are disturbed in persons with TS.

Basal Ganglia. Reduced basal ganglia volumes have been observed in both children and adults with TS. Volume reduction has been found to be

particularly prominent in the globus pallidus and putamen in patients with TS, implicating motor pathways within cortical-subcortical circuitry. This is consistent with the motor phenomena of tics. In support of the hypothesized role of gender in the neurobiology of TS, abnormal basal ganglia asymmetry has been demonstrated in boys but not girls with TS. Although volumetric neuroimaging studies of identical twins with TS have generated conflicting findings, one twin study found greater reduction of the caudate in the more severely affected twin, suggesting that the neurobiological underpinnings of TS expression may be influenced by environmental exposure, as well as by gender and genetic predisposition. Enlargement of thalamic volumes have also been noted in children and adults with TS as compared to healthy comparison subjects. Increased apparent diffusion coefficient (ADC) in corticostriatal projection pathways including left external capsule and left and right subcallosal fasciculus pathway have also been noted in children with TS. Based on the efficacy of dopamine receptor blockade in the treatment of TS, one recent PET study of children with TS found evidence for excessive dopamine decarboxylase activity in the left caudate and right midbrain, suggesting subcortical dysfunction of the dopamine system in pediatric patients with TS (Fig. 38–21).

FIGURE 38–20. Cortical thickness in adolescents with generalized anxiety disorder (GAD) as compared to healthy controls. Warm colors (*red to yellow*) indicate greater cortical thickness in adolescents with GAD compared to healthy comparison subjects, and for each region, both cortical and inflated views are presented. Scatter plots are shown for the maximally significant vertex within each depicted region and healthy patients are represented by (•) while adolescents with GAD are represented by (°). The left temporal findings are shown in panel **A**, while the prefrontal differences and occipital findings are shown in panels **B** and **C**, respectively. Finally, an asterisk denotes a statistically significant difference between groups (p = 0.006 for the left temporal differences; p = 0.0004 for the frontal differences and p = 0.0001 for the occipital differences). (See color atlas.) (Reprinted with permission from Strawn JR, John Wegman C, Dominick KC, et al. Cortical surface

anatomy in pediatric patients with generalized anxiety disorder. *J Anxiety Disord.* 2014;28(7):717–723.)

Corpus Callosum. Conflicting results have been observed with regard to the corpus callosum in TS in youth, with reports of larger, smaller, and no difference in area. A study of monozygotic twins discordant for TS using both MRI and DTI methods failed to observe differences with regard to fiber-tracking to the corpus callosum. Fractional anisotropy was lower in the posterior aspects of the corpus callosum in the affected twin however, indicating a less-coherent level of organization.

Other Brain Regions. A recent structural MRI investigation evaluated the association between the size of the cavum septi pellucidi (CSP) and a diagnosis of TS. They found a smaller CSP in children with TS than in healthy pediatric controls. These findings were replicated in an independent sample of adult patients with TS as compared to healthy adults. An inverse association between CSP size and ADHD symptom severity was also noted. In addition, the overall volume of the hippocampus and amygdala was found to be significantly larger in the TS group than in controls. A surface analysis found that the larger volumes in the TS group were derived primarily from the head and medial surface of the hippocampus and the dorsal and ventral surfaces of the amygdala. The volumes of these subregions declined with age in the TS group but not in controls. Hence, the subregions were significantly larger in children with TS but significantly smaller in adults with TS than in controls. Clinically, volumes in these subregions correlated inversely with the severity of tic, OCD, and ADHD symptoms in patients. This suggests that the enlargement of the subregions may have a compensatory effect on tic-related symptoms.

FIGURE 38–21. Effects of postulated dopaminergic hyperinnervation of the striatum. Although some studies have reported normal integrity of striatal dopamine systems, preliminary neuroimaging and postmortem results suggest hyperinnervation of the striatum by dopaminergic neurons, which may contribute to the pathogenesis of tics. Excitatory (glutamatergic) projections are indicated by *solid lines* and inhibitory (GABAergic) projections by *dotted lines.* GABA, γ-aminobutyric acid; Gpe, external segment of the globus pallidus; Gpi/SNr, internal segment of the globus pallidus or the substantia nigra pars reticulata; retic nuc, reticular nuclei of the thalamus; SNc (DA), dopaminergic projections from the substantia nigra pars compacta; Thal, thalamus. Childhood-Onset Schizophrenia

Although it is a rare condition, childhood-onset schizophrenia has recently been the focus of considerable research investigation. It is believed that enhanced understanding of the developmental brain changes in early-onset schizophrenia might lead to an improved understanding of the neurobiology of adult schizophrenia. Indeed, using brain region data as input, machine-learning methods can correctly classify childhood-onset schizophrenia and healthy controls with 73.7% accuracy.

Total Brain Volume, White Matter, and Ventricles. Aside from disrupted hypothalamic–pituitary–adrenal (HPA) axis function in mood disorders, one of the most consistent findings in psychiatry is a reduction in total brain volume and an increase in the volume of the ventricles in adult patients with schizophrenia. In childhood-onset schizophrenia, the smaller total brain volume is even more dramatic than in adult patients. This suggests that childhood-onset schizophrenia may be a rare, more severe version of the disease. Smaller total brain volume in childhood-onset schizophrenia is accompanied by ventriculomegaly. The smaller amount of brain tissue in early-onset schizophrenia may result from a progressive loss of both gray and white matter in periventricular regions, including the posterior cingulate, caudate, and thalamus (Fig. 38–22).

FIGURE 38–22. Top: Left and right hemisphere views showing the three-dimensional renderings of the significant clusters from the gray matter, white matter, and cerebrospinal fluid. Statistical parametric maps (SPMs) were mapped into the average brain space for nine patients with childhood-onset schizophrenia. **Middle:** Significant voxels form the gray matter (voxel threshold $p < 0.01$, corrected at $p = 0.05$), white matter (voxel threshold $p < 0.01$, corrected at $p = 0.05$), and CSF (voxel threshold $p < 0.01$, corrected at $p = 0.05$). SPMs mapped onto three orthogonal slices form the average brain in schizophrenia. **Bottom:** Over the same three slices of the average control brain. (Reprinted with permission from Sowell ER, Toga AW, Asarnow R. Brain abnormalities observed in childhood-onset schizophrenia: A review of the structural magnetic resonance imaging literature. *Ment Retard Dev Disabil Res Rev.* 2000;6(3):180–185.)

In young patients with childhood-onset schizophrenia, slower growth rates were observed in parietal white matter. However, the corpus callosum did not demonstrate any differences from controls with regard to volume and growth trajectory. Furthermore, patients with childhood-onset schizophrenia have demonstrated reduction in fractional anisotropy in the

cuneus when compared to healthy controls. This reduction was also observed in their healthy siblings, possibly indicating some shared genetic risk. This indicates regional effects on white matter with childhood-onset schizophrenia.

Prefrontal Cortex, Insula, and Temporal Lobe. Akin to the aforementioned finding in the cuneus, during a weather prediction fMRI task, siblings of childhood-onset schizophrenia patients demonstrated less activation of the frontal and striatal regions compared to controls. This indicates that impairments in cortical-striatal function may play a role in the liability of schizophrenia. It has been suggested that changes in frontal deficits are modulated in part by polymorphism of the catechol-o-methyltransferase (COMT) gene. Lower levels of the ^{1}H-MRS neuronal marker NAA and gray matter volumes in the frontal and anterior cingulate cortex are found in patients with childhood-onset schizophrenia and unaffected offspring of patients with schizophrenia at increased risk for developing schizophrenia as compared to controls. This suggests that an exaggerated pruning of neurons may be involved in the pathogenesis of schizophrenia. Controlling for medication exposure in neuroimaging studies is critical because typical neuroleptics have been shown to decrease frontal cortical activation, whereas atypical agents (e.g., risperidone) increase frontal activation. The insula plays a critical role in delineating self from non–self-stimuli. Given this function, it has been implicated in the positive symptoms associated with schizophrenia. In 98 patients with childhood-onset schizophrenia contrasted with 100 healthy control participants, smaller right and left insula volumes were noted in patients. Right insula volume correlated inversely with positive symptoms in patients with childhood-onset schizophrenia.

Consistent with studies of adult patients with schizophrenia, smaller volume of the temporal lobe has been reported in childhood-onset schizophrenia, although a contradictory report exists. Within the temporal lobe, smaller superior temporal gyrus volumes associated with increased symptom severity have been observed in patients with childhood-onset schizophrenia as compared to healthy controls. In adult patients with first-episode schizophrenia, volume reduction in the superior temporal gyrus was correlated with duration of pretreatment illness. Superior temporal gyrus volumes appear to increase toward normal after pharmacotherapy, suggesting that this region may be integral to symptom expression in schizophrenia. In a recent report, it was noted that patients with childhood-onset schizophrenia showed significant bilateral deficits (9 to 10 percent) in total hippocampal volume. This smaller volume in such patients remained consistent from age 9 to 26 years. Of interest, subregional maps showed heterogeneous changes, with a loss of hippocampal volume in both anterior and posterior ends, whereas the body of the hippocampus gained in

volume. This suggests that the subunits of the hippocampus are differentially affected in schizophrenia. Indeed, a reduction in the volume of the amygdala–hippocampal formation has also been demonstrated in adults with first-episode schizophrenia, in patients with childhood-onset schizophrenia, and in offspring and siblings of patients with schizophrenia. The reduction in amygdala–hippocampal formation in patients with childhood-onset schizophrenia and high-risk unaffected relatives suggests that it might play a critical role in the pathogenesis of schizophrenia. Earlier onset of illness in patients with traumatic perinatal histories has also been shown to be associated with more severe reduction in amygdala–hippocampal volume. Shape analysis revealed a striking inward deformation in the anterior hippocampus in patients with childhood-onset schizophrenia. These inward deformations were associated with positive symptoms. More recently it has been noted that the younger, healthy siblings of patients with childhood-onset schizophrenia showed significant gray matter deficits in the left prefrontal and bilateral temporal cortices and smaller deficits in the right prefrontal and inferior parietal cortices compared with controls. It may be that a loss in prefrontal and temporal gray matter in childhood-onset schizophrenia is a familial/trait marker of the illness.

Subcortical Regions. Increased caudate volume has been reported in childhood-onset schizophrenia, although this might be due to typical neuroleptic exposure. When typical neuroleptics were replaced with clozapine in patients with childhood-onset schizophrenia, caudate size decreased to normal within 2 years. However, caudate volume reduction has been reported in neuroleptic-naive adult patients with schizophrenia, so that a primary alteration in caudate volume cannot be ruled out. Recently, a shape analysis of the caudate in childhood-onset schizophrenia found an outward displacement in the dorsal aspect of the caudate body. One of the most consistent findings in psychotropic-naive young adults with schizophrenia and childhood-onset schizophrenia is decreased volume of the thalamus. Reduced thalamic volumes have also been found in the primary relatives of patients with schizophrenia.

Substance-Related and Addictive Disorders

Alcohol Use Disorder. Given the high prevalence of conditions such as binge drinking among adolescents, the need for research in this area is great. Consistent with adult studies, a neuroimaging study of alcohol use in adolescents found a significant volume reduction in bilateral hippocampi as compared to healthy pediatric controls. Hippocampal volume reduction correlated positively with age of onset and negatively with duration of alcohol use, suggesting that alcohol may interfere with normal growth of the hippocampus. Smaller prefrontal gray and white volumes have been

noted in adolescents who abuse alcohol. In youth at high risk for alcoholism, a smaller amygdala has been consistently noted. This is suggestive of a possible abnormality in the processing of fearful stimuli. An fMRI connectivity study found differences in resting state synchrony between the left nucleus accumbens and bilateral inferior frontal gyri and the left postcentral gyrus in youth at risk as compared to healthy controls. The results suggested that youth at risk had less segregation between the nucleus accumbens and frontal executive functions, and less integration with reward-related areas like the orbital frontal cortex. In a similar cohort, ^{31}P-MRS has been used to probe for metabolic abnormalities of frontal, occipital, and parietal cortex. In children with both a positive family history of alcoholism and a disruptive behavior disorder, decreased phosphodiester levels were observed, suggesting abnormalities in energy metabolism. These abnormalities were also associated with learning disability. In a longitudinal morphometric study, 40 adolescents were followed over three years. During that period, half initiated heavy drinking. At baseline, subjects who later started drinking heavily had smaller left cingulate, pars triangularis, and rostral anterior cingulate volume as compared to those who did not. Over time, reductions in left inferior and middle temporal gyri, left caudate and brain stem were noted as compared to substance naïve youth. This study suggests that there are pre-existing markers in future drinkers and a further volume reduction over time after alcohol abuse was initiated.

Cannabis Use Disorder. Cannabis using adolescents demonstrate thinner left and right supramarginal, left and right inferior parietal, right pars triangularis, left pars opercularis, left superior frontal, and left superior temporal cortical thickness compared to noncannabis using subjects. Greater cannabis use was also associated with thicker bilateral superior frontal gyri. In adolescents who are regular cannabis smokers, gray matter volume reduction was observed in the medial temporal cortex, temporal pole, parahippocampal gyrus, insula, and orbitofrontal cortex. These are brain regions rich in cannabinoid CB1 receptors and associated with motivational, emotional, and affective processing. In 17 chronic cannabis-using adolescents as compared to 17 healthy controls, reduction in anterior cingulate *N*-acetyl-aspartate, creatine, inositol, and glutamate were observed. Akin to what was observed in childhood onset schizophrenia, changes in prefrontal and insula cortical thickness were observed in adolescent cannabis users. In a resting state connectivity study, heavy cannabis use in adolescents was also associated with middle frontal gyri activity and inversely with the middle temporal gyrus. During an fMRI monetary incentive delay task, adolescent males who use cannabis showed striatal hyperactivity in anticipation of reward. A systematic review of diffusion weighted imaging studies of cannabis use in adolescence found

abnormal white matter microstructure in neocortical association pathways as well as in projection and thalamic pathways. One of the primary problems with studies of cannabis use in adolescents is the limited ability to quantify and control for exposure; with most studies relying on self-report of use with little data on the strength of cannabis used.

Feeding and Eating Disorders

Several studies have documented decreased global brain volume in children and adolescents with anorexia nervosa (AN) that may be somewhat reversible. However, decreased large-scale brain volume loss is probably the result of malnutrition and, is not, therefore, likely to be particularly helpful in elucidating the neurobiologic underpinnings of AN. In adolescents with AN, a lower concentration of frontal NAA have been noted than in controls. Of interest, a lower frontal phosphodiester level was reported as well, indicating a possible decrease in the fraction of membrane phospholipids. However, spectroscopy studies have yielded conflicting results overall. An fMRI study found greater activation in AN patients than in controls when they were viewing food-related stimuli. During working memory tasks, greater activation of temporal and parietal areas was noted in adolescents with AN that resolved with treatment. Functional studies of reward and punishment have also shown that adolescents with AN are especially responsive to losses compared to wins. Studies of bulimia nervosa have also noted reductions in frontal and temporal regions in affected adolescents compared to healthy subjects. Furthermore, fMRI data indicates that adolescents with bulimia demonstrate abnormal patterns of activation during tasks tapping into regulatory control and conflict resolution—with frontal and striatal regions failing to activate.

Autism Spectrum Disorders

The number of imaging studies investigating the underlying neurobiology of ASDs has increased fourfold since 2003 (Fig. 38–23). This tremendous progress occurred despite inherent limitations. First, there have been advances in scanning young children. Early studies into ASD were hampered by being conducted in adults or adolescents. Use of mock scanners and thoughtful approaches to the scanning procedure have allowed very young children to participate. Given that typical onset of ASD is by 3 years of age, studying mostly older patients places the research at an obvious disadvantage. Second, the majority of neuroimaging studies, especially fMRI studies, have been conducted in high-functioning patients with ASD. Differences in study populations, medication exposure, and methodological differences in image acquisition and analysis may have also contributed to the lack of reproducibility of findings.

FIGURE 38–23. Graph showing increase in over time in the number of neuroimaging studies investigating the neurobiology of autism spectrum disorders. (Figure courtesy of Frank MacMaster, Ph.D.)

Global Brain Abnormalities. It is believed that alterations in global brain growth are involved in the pathogenesis of ASD. Greater total brain volume has been one of the more consistent findings in patients with ASD. When examining functional connectivity, it appears that in adolescents and adults with ASD, connectivity is reduced. In younger children with ASD, however, intrinsic functional connectivity is increased. These findings have resulted in a call for research onto the effect of puberty on the neurobiology of ASD. In a large-scale study (N = 717) of children 6 to 10 years of age, those with higher autistic traits (scores on the social responsiveness scale) demonstrated widespread areas of decreased gyrification. Whole-brain serotonin synthesis capacity has been measured in 2- to 15-year-old children with ASD with PET studies using the tracer α-[^{11}C]methyl-L-tryptophan (^{11}C-AMT) for PET. Children with ASD were compared to healthy siblings without ASD and to epileptic children without ASD because using PET to study the brains of healthy pediatric controls is rare. Sedation was required for all of the children with ASD or epilepsy and for many of the siblings without ASD who underwent PET scanning. Disruption in serotonin synthesis capacity was observed in children with ASD compared to their siblings and children with epilepsy. In normal

children, whole-brain serotonin synthesis capacity was greater than 200 percent of adult capacity until age 5 years, and then it declined to adult levels, whereas in children with ASD, serotonin synthesis capacity increased very gradually from age 2 to 15 years to levels 1 to 1.5 times adult normal values.

Regional Brain Alterations. In addition to global brain alterations in serotonin synthesis, comparisons of children with ASD who were otherwise healthy without seizures and their siblings without ASD showed asymmetries in serotonin synthesis in frontal cortex, thalamus, and cerebellum. Lower serotonin synthesis was observed in the left frontal cortex and thalamus in children with ASD (Fig. 38–24). Lesser accumulation of ^{18}F-DOPA in the anterior medial PFC was observed in medication-free children with ASD (Fig. 38–25). Lower levels of dorsolateral PFC phosphocreatine, as measured by ^{31}P-MRS, in high-functioning adolescent and young adult men with ASD suggest altered metabolism and increased membrane degradation in this region and was correlated with neuropsychological and language deficits. The temporal lobe plays a critical role in emotion processing. Hence, it is not surprising that pediatric ASD has been associated with lower metabolic rate, perfusion, and NAA in temporal regions. Volumetric studies of the amygdala and hippocampus have been inconsistent in ASD. In the cerebellum, the dentate nucleus has also been implicated in ASD. The dentate nucleus is involved in the regulation of language and motor output. Abnormal activation of the right dentate has been observed in patients with ASD when performing a language task. In response to sensory stimuli, along with the expected sensory areas, the hippocampus, amygdala, and orbital frontal cortex demonstrate hyperactivity in youth with ASD. Furthermore, greater brain serotonin synthesis has been reported in the right dentate nucleus. Reductions in the neuronal marker NAA in the dentate as measured by ^{1}H-MRS have also been reported.

FIGURE 38–24. Scans from a boy with autism, age 6.8 years **(A–C),** and his brother, age 9.4 years **(D)**. (**A, D**) Positron emission tomography (PET) images using α-[^{11}C]methyltryptophan ([^{11}C]-AMT); (**B**) PET images using [^{18}F]fluorodeoxyglucose scan; (**C**) magnetic resonance imaging scan. *Arrows* denote decreased [^{11}C]-AMT accumulation in left frontal cortex and left thalamus and increased [^{11}C]-AMT accumulation in right dentate nucleus in the child with autism (the left-side image is the right side of the brain).

Specific Learning Disorders

The left hemisphere plays a critical role in the development of reading skills in healthy children. This function appears to be impaired in children with a reading disability, as suggested by lower functional activation in dorsal and ventral regions. Indeed, similar results have been noted in adults with a reading disability, with less functional connectivity between these circuit substrates.

More recently, bilateral prefrontal regions that link brain regions associated with phonological awareness and rapid naming also demonstrated abnormal functional connectivity in children with dyslexia. The planum temporale is associated with a number of auditory and language-related processes. In children with dyslexia, the planum temporale demonstrates a greater rightward asymmetry. Perhaps to compensate for this dysfunction, children and adults with a reading

disability "overactivate" the dorsolateral prefrontal cortex, including the inferior frontal gyrus. Adults with a reading disability also engage the parallel circuitry in the right hemisphere. Right hemisphere activation during reading is normal in children but typically diminishes into adulthood. This suggests a change in the lateralization that characterizes the neural substrates that mediate reading in individuals with persistent reading disability.

FUTURE DIRECTIONS

Although there are unique challenges to conducting neuroimaging studies in pediatric populations, the use of neuroimaging in children with psychiatric disease provides an exciting opportunity to explore the developmental abnormalities that lead to mental illness. Neuroimaging studies in childhood-onset neuropsychiatric disorders that use biomarkers as both moderator (present at baseline) and mediator (changing with treatment) may potentially result in an enhanced mechanistic understanding of the pathogenesis and maintenance of these illness, which could lead to better diagnostic and treatment approaches. Neuroimaging is also well matched with approaches based off the research domain criteria. MR-based technologies are particularly useful in youth because they entail no radiation exposure and can be successfully applied to longitudinal study. Although technological advances will undoubtedly continue to provide more precisely resolved images, investigators must pay special attention to developing consistency in methodological approaches across studies, along with larger sample sizes to account for the high variability of brain volume and function during childhood and adolescence. Exciting times lie ahead in the attempts to unravel the pathophysiology and mechanism of treatment response in various childhood-onset neuropsychiatric disorders.

Temperament: Risk and Protective Factors for Child Psychiatric Disorders

DAVID C. RETTEW, M.D.

Individuals differ in the types and intensity of their emotional and behavioral responses to various environments. Some people are quick to experience anger or anxiety, whereas others are more laid back. Some people seek out new and exciting experiences, whereas others prefer a predictable routine and the comfort of a few familiar friends. Some people are able to delay their impulses and overcome obstacles in the service of working toward a long-term goal, whereas others become quickly distracted or frustrated. These widely recognized human qualities refer to temperament or personality traits that, along with physical and cognitive dimensions, distinguish one person from the next.

Scientists have been observing and studying child temperament and personality development for many years. The bulk of this work has existed beyond the view of most mental health clinicians, under the notion that this area was distinct from clinical psychiatric disorders. More recently, however, accumulating research has demonstrated strong links between various temperamental traits and nearly all types of psychopathology. The prevailing question today no longer is *if* temperament is associated with psychopathology but *how* temperament interacts developmentally in shaping children toward and away from serious psychiatric disturbance. This chapter offers a brief overview of temperament, including its history, definition, core dimensions, stability, and underlying neurobiology. Following these sections is a summary of the known relations between specific temperamental traits and corresponding psychiatric disorders. Finally, the chapter concludes with a discussion of possible mechanisms through which temperamental traits operate to increase risk or, conversely, promote wellness and resiliency throughout development.

HISTORICAL ANTECEDENTS

When most students think of temperament, the two names that often arise are child psychiatrists Stella Chess and Alexander Thomas, who brought the concept of temperament and its role in developmental psychopathology into the spotlight more than 50 years ago. The foundations of temperament

theory, however, can be traced back in time much further. The ancient Greek physician Galen postulated the existence of four temperament types, which he called sanguine (extraverted and stable), choleric (extraverted and unstable), melancholic (introverted and stable), and phlegmatic (introverted and unstable), based on the relative concentrations of four "humors" (blood, yellow bile, black bile, and phlegm). Although this early conceptualization of temperament may appear somewhat comical by today's standards, a thought experiment that substitutes the four humors with modern neurotransmitters such as serotonin and norepinephrine reveals how much of this framework remains intact. Indeed, the very word "temperament," derived from the Latin *temperare*, which means "to mix," conveys this association between the level of important biological substrates in the brain and basic human behavioral and emotional predispositions.

Fast forward to the 20th century and the dawn of modern psychiatry: it is worth noting that Sigmund Freud made few qualitative distinctions between the origins of normal personality traits and the factors responsible for psychiatric symptoms, although the nature of those forces were certainly not described as temperament-based. As the tenets of behaviorism and learning theory gained prominence, there again were few distinguishing features between the postulated mechanisms underlying personality and those that caused the formation of psychiatric disorders.

It was in this climate during the 1950s that Chess and Thomas began their work on temperament. Based on interviewing parents and observing children across many years, they proposed nine basic dimensions of temperament, as shown in Table 39–1, and three temperament types—easy, slow to warm up, and, most famously, difficult. These basic elements of temperament were hypothesized to be substantially heritable rather than based on learning or unconscious conflicts. It was this heritable quality of temperament that ran against the prevailing wisdom of both the psychoanalytic and the behavioral schools of thought, and the work of Chess and Thomas was subjected to intense criticism.

Through the 1980s and continuing today, a medical model of psychiatric illness began to emerge. Under this framework, disorders like depression or panic disorder arise like other medical illnesses such as diabetes or the flu. Genetic variations and environmental pathogens are viewed as important etiological factors in this model, and the disorders are conceptualized as binary entities that a person does or does not possess. While such an approach acknowledges the influence of more innate dispositional factors, this disease model of psychiatric disorders also divorces symptoms from an individual's temperament. A panic disorder, for example, is an illness that "comes out of nowhere" rather than being related to a temperamental proclivity toward experiencing fear.

Table 39–1.
Thomas and Chess Classification of Temperament

Nine temperament dimensions
Activity level
Rhythmicity
Approach–withdrawal
Adaptability
Response threshold
Response intensity
Mood
Distractibility
Attention span/persistence
Three temperament types
Easy
Difficult
Slow to warm up

Thus, researchers and clinicians interested in temperament continue to challenge and be challenged by the changing models and theories of psychiatric disease. The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), while specifically acknowledging the dimensionality of most emotional-behavioral symptoms, retained a disease model of psychopathology in its operational structure. The implications of this decision will be discussed later in this chapter after additional background information on temperament is provided.

DEFINITION OF TEMPERAMENT

Despite the long history of temperament investigation, the precise definition of temperament remains elusive. One prominent temperament researcher, Mary Rothbart, described temperament as "constitutionally based individual differences in reactivity and self-regulation." Although the debate continues, there exists some consensus on key components of a temperamental trait. First, there needs to be a heritable basis to the trait. This quality does not mean that temperament is purely genetic, but rather that there is at least some genetic influence on the phenotypic expression of that trait. Second, a temperament dimension also needs to be relatively stable across time. Similar to the point about genetic influence, stability does not mean inflexibility or, certainly, destiny, but rather that the trait at one time point can predict future time points even many years into the future. Finally, a temperament dimension is expressed early in life, with its rudiments evident as early as infancy. This latter characteristic distinguishes temperament from other important human qualities, such as life satisfaction or generosity, which incorporate higher cognitive functions. These aspects of temperamental traits are summarized in Table 39–2.

MAJOR DIMENSIONS

The core dimensions of temperament continue to be a source of discussion. As previously described, Chess and Thomas hypothesized nine core temperament dimensions and three temperamental types, with the latter referring to a constellation of traits that often coexist. Subsequent testing using different samples and more sophisticated statistical modeling have supported many of these dimensions, whereas others were found in need of modification.

Currently, there exist a number of alternate, even competing, frameworks that have received some empirical support for their reliability and validity. Most temperament taxonomies are structured around basic incentive response systems of approach and withdrawal often merged or crossed with emotional valence (propensities toward positive and negative emotions). Across these various taxonomies, however, there exist named dimensions that overlap somewhat but not completely with a corresponding dimension in another theoretical model. The temperament trait of novelty seeking as described by Cloninger is similar but not identical to a dimension referred to by Rothbart and colleagues as extraversion or surgency. Adding additional complexity is a dimension's relative place along a hierarchical organization from lower- to higher-order traits. Activity level, for example, exists as a component of the surgency dimension in Rothbart's framework but functions as a broad higher-order dimension in the Buss and Plomin model. Furthermore, differences of opinion exist between the conceptualization of temperament traits as quantitative factors that are distributed normally along a continuum versus more binary yes/no designations. All of these variations between the different models of temperament that exist today provide a rich environment for further research and discussion but can be challenging when trying to compare findings across studies.

Table 39–2.
Definition of Temperament

Individual differences in basic reactivity and self-regulation that include the following elements:

1. Heritability: temperamental traits are often passed on from one generation to the next through both genetic and environmental mechanisms.
2. Early appearance: the antecedents if not the full traits are evident in infancy and toddlerhood.
3. Stability: although there is certainly the potential for change, temperamental traits are moderately stable across many years.

Clearly, there is a tremendous amount of overlap between the core dimensions of temperament and personality, and a full discussion of this topic is well beyond the scope of this chapter. Briefly, it is probably fair to say most temperament and personality theorists view temperament as one of the core foundations of personality, with the latter being further developed through additional life experiences, cultural influences, and

cognitive abilities. Because these influences act on children and adults alike, however, a clear boundary between a temperament and a personality trait is obscure and somewhat akin to pinpointing exactly when someone is, for example, an adult. At the same time that some prominent personality researchers such as Costa and McCrae argued that their personality dimensions can largely be seen as temperament, child researchers found evidence that the "Big Five" taxonomy of personality is largely applicable in youth samples. These efforts suggest that at least some of the historical distinction between these two constructs was semantic and based on the age of the sample being studied. These conceptual challenges notwithstanding, several temperament dimensions are fairly consistent across different nomenclatures and constitute the highest level of temperamental traits. These traits are depicted in Table 39–3.

Withdrawal and Propensity to Experience Negative Emotions

Children differ in the threshold required to illicit a negative emotion such as sadness, fear, or anger, the intensity of the emotion when triggered, and the duration of that emotional experience. This trait is found ubiquitously among the different taxonomies and thus has been described using a number of different labels, including negative affectivity, emotionality, and neuroticism. Some researchers have described a similar trait that reflects an underlying sensitivity to signals of punishment and have referred to this dimension as harm avoidance. Gray described individual differences in the behavioral inhibition system (BIS), which responds with fear to signals of punishment or nonreward. Some evidence supports greater separation between the tendency to experience anger and frustration and the tendency to experience fear or anxiety. Nonetheless, components of this dimension often include elements such as worry, shyness, irritability, and difficulty being soothed once aroused. This trait also figured heavily in the Chess and Thomas designation of the "difficult" child.

Table 39–3.
Current Dimensions of Temperament and Personality

Developer/Name	Withdrawal and Propensity to Negative Emotions	Approach Behavior and Positive Emotions	Activity	Sociability	Regulatory Abil
Rothbart	Negative affectivity	Surgency			Effortful Contro
Cloninger	Harm avoidance	Novelty seeking		Reward dependence	Persistence
"Big Five"	Negative emotionality	Extraversion		Agreeableness	Conscientiousne

EAS	Emotionality	Activity		Sociability
Kagan	Behavioral inhibition/disinhibition			Behavioral inhibition/disinhibition

EAS, emotionality, activity, sociability.

Approach and Positive Emotions

The other temperament dimension that exists throughout various taxonomic structures refers to the degree to which a person actively engages the world and other people. This trait often also encompasses a tendency to experience positive emotions such as joy and excitement. Additional components of this dimension according to the various frameworks include elements of dominance, preference for high stimulus activities, and approach behavior. Especially when considered in a more social context, this trait is often referred to as extraversion, whereas from a slightly broader perspective it has been labeled novelty or sensation seeking or the behavioral activating system (BAS).

Emotional Regulation and Constraint

The third dimension common to most temperamental systems relates to emotional and attentional regulation especially in the face of obstacles or in the pursuit of a long-term goal. As a separate dimension, it has been referred to as effortful control, persistence, or, under the "Big Five" framework, conscientiousness. Children with lower levels of this trait are often described as impulsive, distractible, and disorderly. Parallels to more philosophical terms encompassing a person's degree of voluntary control such as "will" are apparent and distinguish this dimension from behavior that is restrained by anxiety in children with high negative affectivity or low approach.

Other Dimensions

A number of other traits have been classified as broad-level traits under some frameworks. In others, however, the dimension is either defined as a facet of one of the three principal dimensions previously described.

Social Affiliation. Although aspects of social affiliation can be subsumed under broad conceptualizations of extraversion, other researchers have viewed a person's tendency toward prosocial behavior as a distinct higher-order trait. Elements of social affiliation are also found in terms such as shyness, although merging these concepts has been seen as problematic by some because it equates the *desire* for social contact with the anxiety or *discomfort* associated with social encounters. As an aspect of temperament, this dimension has been called sociability and reward

dependence, among others, whereas under a personality "Big Five" taxonomy it is related to the trait of agreeableness. In some systems, this dimension encompasses elements such as empathy and the desire and ability to share emotional states with others, as well as with dependency and compassion.

Activity Level. A person's level of motor activity is similarly viewed as a component of extraversion in some models, whereas in others, such as that proposed by Buss and Plomin, it is given additional standing in itself. Its ability to be readily observed by others, genetic influence, and emergence as a distinguishing feature very early conform to some of the core requirements of a temperamental trait.

Temperament Types

As mentioned, an alternative approach to understanding temperament focuses on distinguishing groups of individuals who may possess similar levels of a variety of traits. This emphasis on temperament types should not be considered to be a true substitute to a variable-centered focus but rather a complementary approach, in that these person-centered classifications also rely on specific dimensions to define various classes or types. One potential advantage of using temperament types in research is that this lends itself well to the possibility that the effect of one particular trait depends on the presence of other traits. For example, two people might possess similar levels of novelty seeking but different levels of effortful control. When coupled with high effortful control, novelty seeking might be a very adaptive, whereas without effortful control this same quality could lead to behavioral problems. Understanding these interrelations might provide more meaningful insight than considering each dimension in isolation.

The Difficult Child. Probably the most famous temperamental type is the "difficult" child designation of Chess and Thomas, which was distinguished from the "easy" and "slow to warm up" groups (and notably from children who didn't fit any of the three types). The "difficult" category referred to a cluster of about 10 percent of young children who possessed the particular combination of low rhythmicity, low response threshold and adaptability, and high response intensity. Although not hypothesized to reflect psychopathology per se, it was this group of children in longitudinal studies who were most likely to have poor outcomes and greater psychiatric disturbance.

Behavioral Inhibition and Disinhibition. Another well-studied temperament that referred to people rather than specific dimensions was behavioral inhibition (BI), as well as, more recently, behavioral

disinhibition (BD). BI was defined by the Harvard psychologist Jerome Kagan as referring to a minority of young children—again around 10 to 15 percent—who consistently responded to new situations and people with reticence and fear. He, along with many colleagues, later defined a group of children with the exact opposite response to novelty and referred to them as possessing behavioral disinhibition. As will be discussed in more detail, children who manifest BI as toddlers have been shown to be at risk for psychiatric disorders later in life, in particular social anxiety disorder.

FIGURE 39–1. Temperament profiles as determined though latent profiles analysis. The "moderate" group has average levels across all dimensions, whereas the "steady" group is characterized by low novelty seeking (NS) and high persistence (P). The "disengaged" group has moderately high levels of both novelty seeking and harm avoidance (HA), with low levels of reward dependence (RD). The groups have been found to be related to levels of psychopathology and wellness. (Adapted from Rettew DC, Althoff RR, Dumenci L, Ayer L, Hudziak JJ. Latent profiles of temperament and their relations to psychopathology and wellness. *J Am Acad Child Adolesc Psychiatry*. 2008;47[3]:273–281.)

New Approaches to Temperament Types. Statistical procedures such as cluster analyses and latent profiles analyses can also be used to identify groups of children who manifest similar levels of traits across several dimensions. These analyses can be performed without preconceived theories of how different traits *should* exist together. A latent profiles analysis of a group of children of age to 18 years revealed the presence of three temperament types (Fig. 39–1). The first, as might be expected, contained people who did not have extreme levels of any dimension and was labeled the "moderate" group. A second group was characterized by low novelty seeking and high persistence and was named the "steady" group. Finally, the least common group contained those who possessed high novelty seeking, high harm avoidance, low persistence, and, most

prominently, low reward dependence (low sociability and attachment to others). This last group was labeled the "disengaged" group. As will be discussed, these groups had strong associations with both positive and negative outcomes. Similar efforts by other investigators and using other samples have also tended to find evidence for a relatively small (often around 3 to 6) number of groups distinguishable by their unique temperamental profile.

FEATURES OF TEMPERAMENT

Temperamental traits can be observed in infancy and, according to some, even before birth. Although they contribute to an individual's unique human characteristics, these traits have been widely studied in animals ranging from nonhuman primates to dogs to guppies. Through further understanding of the phenomenology of temperamental traits, it may be possible to advance the knowledge of where temperament and psychopathology share common characteristics and where there are areas of divergence.

Sex Differences

A review and meta-analysis of sex differences using Cloninger's temperament framework showed higher levels of reward dependence and harm avoidance in women than in men, whereas novelty seeking and persistence were found to be roughly equal. Of interest, another meta-analysis of child studies using Rothbart's temperament structure found slightly different results with corresponding dimensions. Specifically, effortful control was found to be higher in girls, surgency was higher in boys, and negative affectivity was roughly equal. These results suggest the possibility that gender differences in temperament may be age-related.

Continuity

By definition, temperamental traits are at least moderately stable across time, and most research supports this assertion. This quality does not mean, however, that a person's temperamental profile should be viewed as unchangeable or as someone's "destiny." Studies that measure how strongly a level of a temperament trait at one time point predicts the same trait in the future routinely find modest but statistically significant correlations even up to decades later. Longitudinal assessments of behavioral inhibition have shown that, while most children do not retain that designation years later, the presence of BI at follow-up can be predicted by initial BI status. In general, increasing stability of a temperament trait has been related to (1) higher baseline age of temperament assessment, (2) shorter time intervals between assessments, and (3) individuals who present initially with more extreme levels of the

trait.

An interesting offshoot of the temperament stability question relates to the possibility that physiological "footprints" of traits persist even in the absence of observable behavior. In one study, adults who at the age of 2 years were classified as being behaviorally inhibited were scanned using functional magnetic resonance imaging (fMRI). When shown pictures of novel faces, the previously inhibited adults showed higher amygdalar activity than adults who were not inhibited as toddlers, despite the fact that these subjects did not report any increased anxiety. This intriguing result and others like it suggest the possibility that the physiology underlying a temperamental trait can linger despite the discrete behavioral correlates being lacking. One mechanism through which this may occur is that other brain areas and circuits, such as those involved in executive functioning, might mature with development and keep a person's behavior more regulated despite enduring internal feelings of discomfort.

NEUROBIOLOGY AND ETIOLOGY

There has been an explosion of research into the neurobiological underpinnings of temperament and personality. Although a thorough review of this literature is beyond the scope of this chapter, many important findings are particularly relevant for understanding the boundaries between temperament and psychopathology. For many years, research on the neurobiology of psychiatric disorders existed in parallel with similar efforts in temperament and personality. As these independent efforts began to reveal similar findings, however, there have been increased efforts to assess temperament and psychopathology concurrently.

Genetic Influences

The genetic influence on temperamental traits, albeit at a magnitude less than many had expected, has been well established through a large number of behavioral and molecular genetic studies. Twin and adoption studies across all ages have generally shown that genetic factors explain about 20 to 60 percent of the variability in temperament scores within study populations, depending on age and the particular dimension being examined. These heritability coefficients tend to be highest in twin studies when temperament is assessed by a questionnaire completed by a single informant (such as a parent rating both twins) and lower in adoption designs or studies that measure temperament using observational protocols. Furthermore, this genetic influence has often been found to be mainly of the additive type, in which multiple genes exert small, independent effects. Nonadditive genetic influence, such as in genetic dominance or epistasis, have also been found to a lesser degree in some studies. Although most studies usually do not find major sex differences in

the *magnitude* of genetic factors, it is not uncommon to find evidence that different genes contribute to a particular dimensions between males and females. One counterintuitive finding that has emerged is that the heritability of some traits appears to be fairly low in the neonatal and early infancy period—a time in which some might expect to find the largest genetic influence. Thus, environmental factors play important roles even in infancy, and new genetic and environmental factors come online to contribute to both temperament stability and change across development. These results are paralleled in the anecdotal reports of many parents who marvel at how different their children's temperaments are from each other despite the children sharing half of their genes and being raised in the same household. Indeed, studies have documented only modest correlations between siblings. Although statistically significant, the moderate level of temperamental differences between siblings suggests that the effects of genetic factors are limited and that individual environmental experiences may play a large role in shaping traits over time.

The question of exactly *which* genes contribute to a particular trait is left for molecular genetic studies that attempt to link temperamental traits to chromosomal regions or known alleles of specific genes. Perhaps the most celebrated, albeit inconsistent, finding in molecular genetic studies of temperament has been the purported link between the dopamine 4 receptor gene and the trait of novelty seeking. As shown in Table 39–4, however, a number of polymorphisms on many other genes have also been linked to specific traits. As is the case of genetic studies of many complex diseases, however, each individual gene typically only accounts for a very small percentage (often about 1 percent) of that phenotype. Nevertheless, these studies give clues about some of the underlying neurotransmitters and pathways that may be related to temperament, which in turn can inform comparative studies on corresponding psychiatric disorders.

Environmental Factors

As mentioned, the other major source of influence for temperamental traits comes from environmental factors. These experiences have been documented to have stronger influences on temperament than many have assumed. From a behavioral genetic perspective, environmental factors come in two main types. The first are those events that have a similar effect on all members of a family and are called shared or common environmental events. Socioeconomic status, parenting practices, and school quality are all potential shared environmental factors to the degree that their effect on siblings in a family is equal and in the same direction. Nonshared environmental factors, by contrast, are environmental events that are not shared by members of the same family and can contribute to making siblings different from each other. Examples here could include a child's peer group or a powerful positive or adverse experience.

Table 39–4.
Selected Candidate Genes for Temperamental Traits

Gene	Description	Temperamental Trait
DAT1	Dopamine transporter	Novelty seeking
DRD4	Dopamine 4 receptor	Novelty seeking
5-HT transporter	Serotonin transporter	Harm avoidance
5-HT-2a	Serotonin 2 receptor	Neuroticism
DRD2	Dopamine 2 receptor	Novelty seeking
MAO_A	Monoamine oxidase A	Neuroticism; reward dependence
NPY	Neuropeptide Y	Trait anxiety
β1-adrenergic receptor	β1-adrenergic receptor	Extraversion
BDNF	Brain-derived neurotrophic factor	Trait anxiety
RGS2	Regulator G protein signaling 2	Behavioral inhibition

Many of the same twin and adoption studies that have shown evidence for genetic influence also show unequivocal evidence for environmental influence, particularly of the unshared type. At the same time, there has been much less support for robust shared environmental effects. This pattern does not necessarily mean that things such as parenting or poverty are unimportant, but rather that they may not affect people uniformly to make them more alike within a family.

Genetic–Environmental Interplay

The old nature-versus-nurture debates assumed that genetic and environmental effects work through mutually exclusive pathways. A child inherits a particular gene or experiences a certain event, and those factors affect behavior directly. Although such a mechanism can occur in various psychiatric and nonpsychiatric diseases, it has become increasingly appreciated that genes and environments have bidirectional influences. Environmental events can control gene expression. Conversely, genetically influenced tendencies can cause certain environments to be more likely to occur (gene–environment correlations), and those environments can, in turn, affect behavior. Finally, the effect of a particular gene can depend on the presence of a particular environment and vice versa (gene–environment interactions). Understanding these complex relations has become a major focus of neuroscience research and has brought with it a new perspective on human development that crosses old boundaries.

Neurotransmitters and Brain Circuitry

Whether behavioral influences are genetic, environmental, or an intricate combination of the two, their ultimate effect is to shape specific brain regions and their connections to other areas. Advances in the knowledge of brain function and its plasticity from environmental factors are rapidly rendering obsolete terms such as “biological” to describe some behaviors

but not others. Nevertheless, there is still much to learn about the specific pathways and neurochemical substrates involved in temperament. Many of the specifics remain unknown, and current models and explanations are acknowledged to be vast oversimplifications.

The trait of negative affectivity and related terms such as harm avoidance and behavioral inhibition have often focused on the amygdala and its multiple afferent and efferent pathways. In a study combining genetic and neuroimaging techniques, researchers found significant associations between reduced amygdala/anterior cingulate connectivity and higher levels of harm avoidance. Moreover, this reduced connectivity was also related to having the short allele of the serotonin transporter gene. Amygdalar hyperreactivity has also been postulated to be one of the core features underlying the trait of behavioral inhibition. Ascending pathways from the reticular activating system to the medial septal area and modulated by the orbital frontal cortex have also been related to passive avoidance and behavioral extinction. Related to these functions, dysregulation of the hypothalamic–pituitary–adrenal (HPA) axis has also been found to be associated with this dimension.

Animal studies have implicated ascending serotoninergic pathways from the dorsal raphe to the basal ganglia, substantia nigra, nucleus accumbens, and amygdala. These pathways can be modulated by γ-aminobutyric acid (GABA), as well as by dopaminergic pathways from nigrostriatal regions. Dopamine pathways have frequently been found to play an important role in the approach behavior and spontaneous activity related to the trait of novelty seeking or extraversion. The mutually interacting systems of harm avoidance and novelty seeking may be related to the typical negative correlation between these two traits. Some brain laterality has also been reported in EEG studies, with left frontal activation being related to more positive emotions and approach, and right frontal activation being related to more negative emotions and withdrawal.

Social affiliation and related traits such as reward dependence are hypothesized to be related to noradrenergic pathways from the locus ceruleus, as well as serotoninergic projections from the median raphe, which innervate a number of areas in the cortex, thalamus, and hippocampus. Neuroactive hormones such as oxytocin may also play important roles in social behavior, as illustrated by the marked behavioral differences between two species of voles that correspond to alterations in the distribution of oxytocin receptors in brain reward centers. Dimensions such as persistence or effortful control are thought to be mediated through many areas of the anterior cortex that modify the function of subcortical regions. Many of these pathways also involve dopaminergic transmission. As previously described, the anterior cingulate gyrus is connected both to limbic structures such as the amygdala and to areas of the lateral cortex, thereby providing a link between key emotion processing and executive

function regions.

In describing candidate genes, neurotransmitters, and neuropathways related to temperament, it becomes quickly apparent that the discussion involves all of the "usual suspects" in psychiatric illness. Realization of this repeated finding has prompted more-systematic efforts to delineate the boundaries between temperamental traits and psychiatric illness in the hope of identifying potential targets of therapeutic intervention.

TEMPERAMENT AND PSYCHOPATHOLOGY

Despite the current conceptualization of psychiatric illness in DSM-5 as binary entities that exist in all-or-none form, there is now overwhelming evidence that most all symptoms of psychopathology exist on a continuum. This spectrum ranges from a large segment of the population who present with few or no difficulties in a particular area to a gradually diminishing number of individuals with higher degrees of symptomatology and finally to a small number of people with extreme levels. Having both a quantitative and dichotomous perspective on a particular disease is not unique to psychiatry. Although all people have a measurable blood pressure, for example, individuals with a pressure greater than 140/90 mm Hg are considered to have the diagnosis of hypertension.

As the dimensional aspects of psychiatric disorders have become increasing appreciated and measured, it is not surprising that people have begun to hypothesize that temperament or personality dimensions may underlie this wide distribution of symptom severity. This realization may have been somewhat inevitable, given hypothesized temperament dimensions such as mood, activity level, and attention span, all of which have descriptive similarities to specific psychiatric conditions. Indeed, when the range of psychiatric instruments is extended to include those on the opposite end of the spectrum (e.g., going beyond the distinction between children with attention problems and no attention problems to being also able to distinguish children with average attentional skills from children with excellent abilities), the distribution of the scores begins to approximate the bell-shaped curve of many temperament traits. This understanding has led to the speculation that what is currently classified as psychiatric disease may actually represent merely the extreme tail of normally distributed traits that exist in the entire population.

To distinguish "true" psychiatric illness from subthreshold or developmentally expected levels of behavior, clinical teaching has dictated that one of most important considerations is *impairment*, that is, whether the behaviors, thoughts, or emotions interfere with a person's daily life and functioning. While theoretically appealing, however, research has demonstrated that this important benchmark also tends to exist along a continuum. People who are severely depressed, for example, are quite impaired, whereas those who are a little depressed are somewhat impaired,

and so on, with no convenient cut-off. Complicating matters further in the field of child psychiatry is the fact that impairment is often not defined by the child but rather by those caring for the youngster. These caretakers may differ in their definition of impairment based on their own strengths, weaknesses, and expectations. In comparing two young boys with exactly the same level of motor activity and impulsivity, for example, one could be viewed as extremely impaired in the context of more orderly parents and teachers with high expectations of the child, whereas the other might be considered not impaired by caretakers with a different set of traits and goals.

As psychiatry continues to accept these strong associations between temperament and psychopathology, several mechanistic hypotheses have been proposed to explain this link. These models are summarized in Table 39–5.

The two most investigated potential mechanisms have been described as the *spectrum model* and the *risk or vulnerability model*. The spectrum perspective postulates that psychiatric symptoms and temperament dimensions lie on a common continuum with no clear qualitative distinctions. The difference between a trait and a disorder, therefore, is simply a matter of degree or magnitude. Implicit in this theory is that there also is common underlying neurobiology between temperament and psychopathology. The factors that determine a child's level of normal developing activity, for example, are the same as those that underlie another child with hyperactivity, albeit perhaps more amplified.

The risk or vulnerability model of temperament/psychopathology relations considers temperamental traits and psychiatric disorder to be qualitatively different entities but with temperament acting as a risk or protective factor for future development. Although it is easy to differentiate conceptually between a risk factor such as sunlight exposure and a disease such melanoma, the description of something like shyness being a risk factor for social anxiety disorder lacks these salient points of obvious divergence. Proponents of this mechanism, however, point out that there are many examples of normally distributed variables that mask a number of very different underlying processes. Intelligence quotient, for example, often shows a normal distribution in large samples. To assume, however, that there is a common quantitative mechanism underlying this distribution would miss, among other things, the small numbers of individuals whose score is related to a distinct and qualitatively different mechanism, such as the trisomy of chromosome 21 that leads to Down syndrome. In addition, there is also a hybrid of the spectrum and risk models that proposes true phenotypic differences between temperament and psychopathology but some common underlying features, such as shared genetics, that are then acted on by other factors, such as specific adverse or positive experiences to create important points of divergence.

Table 39–5.
Possible Mechanisms of Temperament/Psychopathology Associations

Model	Description	Example
Spectrum/continuum	Most psychiatric disorders are best conceptualized as existing on a continuum with temperament or personality traits.	Activity level is a temperamental trait, and people with attention-deficit/hyperactivity disorder are at the end of that spectrum.
Risk/vulnerability	Temperament is different from psychopathology but can increase the risk of its occurrence.	People with high levels of novelty seeking are at increased risk for substance abuse.
Common factor	Temperament and psychopathology share common etiological factors, which are then acted on by other factors that lead some people to develop a disorder.	People with posttraumatic stress disorder share similar genes with temperamentally anxious people but have experienced a severe trauma.
Pathoplastic	Temperament and psychopathology are unique but have bidirectional influences on each other.	The long-term prognosis of depression is better for individuals with high effortful control.
Scar	The pathophysiology of psychiatric disorders can alter temperament.	The plaques and tangles associated with Alzheimer disease cause personality changes that are observed prior to other symptoms.

These three models tend to be the most dominant in the literature when it comes to temperament/psychopathology interactions. However, two other models, both of which preserve the uniqueness of pathophysiological processes, deserve mention. In the pathoplastic model, temperament and psychopathology are distinct but can mutually influence one another. Temperament can increase the chance that a child will suffer a major depression, for example, and that depressive episode can, in turn, exert effects on the child's personality going forward. Finally, the "scar effect" emphasizes the separation of personality and psychopathology but states that psychiatric disorders can modify personality. An example of this effect may be Alzheimer disease. Although personality change is common with this condition and often precedes more specific Alzheimer symptoms, it is thought that the early-developing pathology of plaques and tangles affects personality, rather than the other way around.

Scientists have thus turned to modern research designs and tools to help disentangle these complex relations among temperament, personality, and psychopathology. In so doing, there has been a realization that what were previously thought to be clear boundaries might be much more muddled. What appears to be a continuous trait, like intelligence, may develop from a number of small, discrete causes. Conversely, what appears to be a binary yes/no illness might have more embedded gradations when examined closely. In Huntington disease, for example, the number of

trinucleotide repeats in the huntingtin gene affects the onset and course of illness. It is also important to keep in mind that the various mechanisms are not mutually exclusive. Within a particular trait–disorder pair, there may not be a single mechanism at work across different individuals and perhaps even within individuals. Some individuals with obsessive-compulsive disorder may have strong temperamental correlates, whereas the symptoms of other individuals might be the result of an autoimmune process.

As is clear from these examples, improved understanding of the way illness is conceptualized has important clinical implications. From a research standpoint, it is vital to ensure that any vertical boundaries, should they exist, between temperamental traits and psychiatric illness be delineated because all results downstream of that categorization are likely to be affected. If children who just barely meet DSM-defined ADHD have a brain physiology that is nearly identical to children who just miss the diagnoses, then using the latter group as controls in a functional MRI study, despite their lack of diagnosis, is unlikely to yield fruitful results. Thus, the next section is devoted to describing the current state of knowledge with regard to the existence and mechanism of temperament/psychopathology relations (Table 39–6).

ADHD and Disruptive Behavior Disorders

Attention-deficit/hyperactivity disorder (ADHD) is a prime example of a disorder that at least on the surface appears to be largely in the upward range of temperamental traits related to activity level and attention span. Indeed, it is likely that much of the public controversy surrounding this diagnosis is related to the perception that what is being diagnosed as illness is normal temperament, albeit at somewhat higher levels than are typically observed. As might be expected, low levels of effortful control and persistence have been found, in addition to higher levels of novelty seeking and extraversion, especially among children who meet criteria for the hyperactive-impulsive or combined subtype of ADHD. As mentioned, molecular genetic studies of novelty seeking and ADHD have converged on similar candidate genes, often related to dopaminergic transmission. Furthermore, a recent study of 8,500 twin pairs found evidence for a continuum model of ADHD with nearly identical heritability estimates (around 0.60) for those with diagnostic versus subthreshold levels of behaviors. Another recent study subtyped a group of children with ADHD according to temperament and identified three groups that they labeled mild, surgent (with high levels of approach behavior), and irritable (with higher emotionality and poorer regulatory skills). These temperament-based groups, compared to traditional DSM-based presentations, were shown to provide better cohesion with regard to stability over time, functional brain connectivity, and cardiac physiological parameters.

Table 39–6.
Associations between Temperament Traits and Various Categories of Psychiatric Disorders

	Negative Affectivity	Extraversion	Effortful Control
Attention-deficit/hyperactivity disorder	High	High	Low
Other disruptive behavior disorders	High or low	High	Low
Major depression	High	Low	Low
Anxiety disorders	High	Low	Low
Substance use	High	High	Low
Autism	High	Low	Low
Eating disorders	High	—	High (anorexia) or low (bulimia)

Adapted from Rettew DC. Child Temperament: New Thinking About the Boundary Between Traits and Illness. New York: W. W. Norton & Company; 2013.

Other disruptive or externalizing disorders include oppositional defiant disorder (ODD), conduct disorder, and, in adults, antisocial personality disorder. All of these entities are rather heterogeneous, making the task of linking specific temperamental traits with these disorders difficult. Aggression, for example, is often divided into more instrumental and reactive subtypes. In the former, sometimes known as type 1 psychopathy, aggressive acts can be planned in advance and without provocation. These behaviors are often associated with individuals who tend to lack empathy and possess what are termed callous and unemotional traits, now incorporated into the conduct disorder diagnosis in DSM-5. Physiologically, many of these individuals have been shown to have an underaroused autonomic nervous system that craves additional stimulation. In reactive or type 2 psychopathy, individuals quickly perceive threat from others and have difficulty modulating their emotional responses. This latter type is more strongly linked to deficits in emotional regulation, as well as to increased negative affectivity. Oppositionality has similarly been found to break into three dimensions, labelled irritable, headstrong, and hurtful. These dimensions show different comorbidity patterns with regard to other DSM disorders.

Mood and Anxiety Disorders

Often collectively referred to as internalizing disorders, mood and anxiety disorders are some of the most common psychiatric conditions in childhood and adolescence. Although they are considered to be separate categories of illness according to current clinical nomenclature, there is good empirical evidence to support their being closely linked. Consistent with this hypothesis is the finding of similar temperamental correlates

common to both mood and anxiety disorders. By far the strongest association is with the dimension referred to as negative affectivity, neuroticism, or harm avoidance. Major depression has also been associated with the combination of high negative affectivity and low approach. Bipolar disorder, especially the purported "broad" phenotype characterized by extreme irritability, explosiveness, and mood lability and with a lack of clear episodes, euphoria, or grandiosity, has been shown to be related to a somewhat unique temperamental combination of high novelty seeking *and* high harm avoidance. This "approach plus avoidance" pattern stands in contrast to the general tendency of novelty seeking and harm avoidance being inversely related to each other.

Especially in the consideration of more generalized and chronic internalizing disorders such as generalized anxiety disorder (GAD), dysthymia, and generalized social anxiety disorder, there again has been speculation that many mood and anxiety disorders are best conceptualized as the high end of a spectrum of negative affectivity. Direct analyses of this hypothesis, however, suggests that such a model is oversimplified. As shown in Figure 39–2, many people who possess even very high levels of harm avoidance do not meet criteria for GAD, whereas some individuals with moderate levels of harm avoidance do. On the genotype level, behavioral genetic studies indicate that approximately half of the genes that contribute to neuroticism are the same genes that contribute to internalizing disorders, whereas half do not. Thus, despite the obvious content overlap between descriptions of anxious temperament and descriptions of anxiety and depressive disorders, the majority of evidence appears to point to temperament dimensions having more complex relations with these disorders rather than simply being a different point along a continuum of a single trait. The cyclic and episodic nature of other types of mood disorders, such as recurrent major depression or panic disorder, further suggests that elements other than temperament need to be incorporated into the current theoretical models.

Low effortful control or persistence has further been associated with internalizing disorders. Indeed, temperamental dimensions relating to regulatory control appear to be a common correlate to most psychiatric disorders, with other dimensions related more to the specific *type* of psychopathology. As mentioned, the construct of behavioral inhibition developed by Kagan and colleagues likely combines elements of high negative affectivity, low approach, or surgency, and perhaps low effortful control. Longitudinally, however, the strongest association has been between BI and generalized social anxiety disorder with a meta-analysis revealing that 43 percent of young BI children meeting criteria for social anxiety disorder later in development.

FIGURE 39–2. Distribution of harm avoidance (HA) scores in children and adolescence. Subjects whose results are given also have generalized anxiety disorder (GAD), according to the criteria of the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV). The pattern reveals substantial but not complete overlap between harm avoidance and GAD, with a few subjects with high HA without GAD, some individuals with moderate HA with GAD, and very few individuals with low HA with GAD. (From Rettew DC, Doyle AC, Kwan M, Stanger C, Hudziak JJ. Exploring the boundary between temperament and generalized anxiety disorder: a receiver operating characteristic analysis. *J Anxiety Disord*. 2006;20[7]:931–945.)

Autistic Spectrum Disorder

To many clinicians observing a nonverbal child with stereotypical behaviors, autism would seem to be one group of disorders that truly is more binary in nature. However, accumulating evidence has demonstrated that many of the core symptom clusters of autism, such as social cognition, communication, and affiliation, as well as the stereotypical behaviors themselves, exist along a continuum when measured quantitatively. Temperament dimensions such as low sociability or reward dependence, high negative affectivity, and low extraversion have all been associated with autism. At the same time, it is important to remember that the finding of a continuous distribution of behaviors does not prove that a common neurobiological mechanism underlies the entire spectrum. Indeed, recent studies showing focal areas of cytoarchitectural disorganization in the neocortex of individuals with autism suggest that, at least for some individuals with autism, a scar mechanism may be at work in which the

pathophysiology of the disorder drives the temperamental differences that are also observed. Further support for the possibility that qualitative differences in brain structure and function exist between individuals who meet criteria for autism and those who possess some of the same traits (albeit at lower levels) comes from the neuroimaging literature, although much more work is needed to explore this intriguing hypothesis.

Other Disorders

Some types of disorders are defined by behaviors that are more binary in nature and thus do not lend themselves as easily to spectrum hypotheses with temperamental traits. Discrete actions such as a binging and purging in eating disorders, hallucinations in psychotic disorders, and the taking of illicit drugs in substance use disorders may fall into this area. Many of these entities also tend to have onsets in adolescence or later and thus have most of the research directed at personality traits rather than temperament per se.

In substance use disorders, the wide variety of substances that are abused, each with unique physiological effects, might be sought after by individuals with different temperamental profiles. Different agents also vary in their legality, which itself could lead to unique associations with particular traits. Alcohol use, for example, is legal for adults but not children and thus may have different temperamental associations by age. One follow-up study of temperament found indications that adult alcohol abuse was associated with being both temperamentally undercontrolled and overcontrolled as a child. Novelty or sensation seeking, especially when defined apart from positive emotionality, has also been associated with increased substance use. Once again, dimensions such as effortful control are related to lower amounts of substance use disorders. An interesting caveat in personality research in substance use acknowledges the shifting cultural perceptions of particular substances over time. Cigarette use, for example, has become viewed as increasingly deviant over the last 50 years across many segments of Western culture. One might expect, consequently, that its use is less associated with traits such as agreeableness over time or compared to cultures in which its acceptance level is greater.

Whereas most individuals with eating disorders regardless of specific diagnosis share a preoccupation with weight and self-image, there also appear to be substantial differences that generally fall along diagnostic lines, particularly between the restricting subtype of anorexia nervosa (AN) and bulimia nervosa (BN), and these may reflect underlying differences in temperament and personality. In particular, low effortful control and persistence has been found with BN but not in AN, in which it has been found in some cases to be higher than in controls. High neuroticism or harm avoidance has also been found for both disorders and parallels the frequent finding of anxiety disorder that can co-occur or precede eating

disorders.

Temperamental associations with psychotic disorders have been less studied, although parallels especially with the negative symptoms of schizophrenia would appear to be a fertile ground for investigation. High harm avoidance has been found in both patients with schizophrenia and their relatives, whereas high novelty seeking may be associated with more violent behavior. While positive symptoms such as hallucinations might be assumed to be relatively rare in the population and be present in more of an all-or-none form, recent research has suggested that lower-level forms of psychotic thinking do exist and are more prevalent than previously thought.

A Case Example

Previous "diathesis–stress" models of psychopathology that include temperament often frame temperamental traits as the diathesis component, which is then acted upon by various stressors, such as parenting behavior, traumatic events, and so on to produce psychiatric symptoms. While data described in this chapter reveal that such a model is likely overly simplistic when it comes to how temperament is conceptualized, certain aspects of this model can still be useful. One of the principal advances from older conceptualizations of the diathesis–stress model is the full appreciation that the stressors often do not act on the diathesis randomly but rather are probabilistically more likely to occur because of those predispositions. As previously discussed in the section on temperament development, these processes have been called genotype–environment correlations and are readily applicable to the understanding of how risk factors like certain temperamental traits contribute toward the creation of environments such as parental behaviors and peer groups that accentuate those initial predispositions. A case example may illustrate this mechanism best.

Kayla was a child who from birth appeared to be more fearful and easily upset than other infants. She cried frequently and forcefully, and as a toddler she was more reluctant to leave her mother's side to play with other children and to explore new situations. Her behavior was a challenge to her mother, who herself struggled with significant anxiety and shyness. Her mother was not prone to seek out activities such as play dates with other parents due to her own social anxiety, and when she did, Kayla's behavior made them frequently go badly. Hoping to avoid another embarrassing scene, Kayla's mother became increasingly overprotective in her efforts to shield her daughter from situations that might provoke discomfort. By the time kindergarten started, Kayla had had significantly fewer opportunities to interact with other children and tended to keep to herself. Throughout elementary school, she avoided team sports and other structured social activities, preferring other activities such as learning to play the piano. She did manage to make some lasting friendships, although they tended to be with other children who were also quiet and reserved. Kayla became an easy target of teasing by others, and as an adolescent she became increasingly self-critical about her demeanor. At the age of 14 years, she saw a psychiatrist for the first time and was diagnosed with social anxiety disorder and major depression.

This illustration demonstrates how insidious the progression can be from temperamental trait to psychiatric disorder and how difficult it can be to ascribe the causation of symptoms as purely genetic or environmental. The case also illustrates the role of other factors in shaping a temperamental trajectory toward more maladaptive outcomes.

OTHER CONCEPTS IN TEMPERAMENT–PSYCHOPATHOLOGY RELATIONS

Parenting Behavior

The fact that some parenting behavior is evoked by children does not mean that it is either unimportant or inevitable. Neither does it mean that suboptimal parenting is the fault of the children. Rather, a more transactional view appreciates the bidirectional influences of children and parents that together can create important home environments with important developmental effects. Research has shown, for example, that parents of anxious children are more likely to teach avoidant rather than prosocial solutions to problems and may facilitate the perception of threat in ambiguous situations. As shown in the case example, these parents can become overprotective, which limits the crucial exposure opportunities that help children to overcome their anxieties. Lack of parental warmth, poor supervision, harsh and inconsistent discipline, and obviously abuse are all important parental behaviors that have been found to be related to various types of psychopathology and serve as critical intermediaries between temperament and psychopathology.

Cognitive Factors

Although some cognitively laden attributes, such as attentional skills, are often included under the temperament umbrella, other aspects, such as intelligence, processing speed, and memory, are generally considered outside of the temperament domain. Nevertheless, these cognitive processes likely also play important moderating roles. Children with relatively diminished attention spans but above-average intelligence, for example, may be able to use that intellectual ability to counteract their attention deficits and prevent the clear impairment required for a diagnosis of ADHD. Other cognitive functions, such as the attributional style that a person applies to interpret themselves and the world around them, also likely shape and are shaped by temperament. These types of appraisals and attributions have been found to be important in a variety of both internalizing and externalizing disorders, from antisocial disorders to mood and anxiety.

Trauma and Adverse Events

Clearly, both single-episode traumas, such as natural disasters and car accidents, and more chronic stressors, such as some forms of abuse and

abject poverty, can propel temperamentally at-risk children toward full-blown psychiatric symptoms. At the same time, it is becoming increasingly clear that one of the strongest predictors of more severe symptoms after a stressful event is poorer functioning prior to that event. Thus, a temperamentally aggressive child might be more likely to develop antisocial behaviors in the face of significant stressors, and a more anxious child might develop posttraumatic stress disorder after a single traumatic event.

Peer Groups and Activities

A powerful behavioral influence, especially for older children and adolescents, comes from their peers and the activities that are done together. Similar to parenting behaviors, it is very likely that peer groups have a bidirectional influence on temperament and personality traits. A high-novelty-seeking child, for example, is likely to have similar-minded friends, who may push each other to ever riskier and more dangerous activities. If many of these group experiences occur within the context of a supervised team or structured activity, there can be additional opportunities to channel temperamental tendencies productively and to provide opportunities to overcome more maladaptive propensities. Research has shown, for example, that adolescents on sports teams are less likely to smoke cigarettes. Given that participation in sports teams appears to have its strongest environmental influence early in life, a possible intervention target emerges for future research.

Temperament and Resiliency

Just as some temperamental traits can mix with the aforementioned variables to generate negative momentum toward psychopathology, other traits can serve as protective factors in the face of adversity and indeed may be important not only for a lack of psychopathology, but also for true mental health and wellness. The previously mentioned study using latent profiles analysis found that compared to a group of children with moderate levels of most temperament traits, the “steady” group, characterized by high levels of persistence and low levels of novelty seeking, performed better at school by parent and teacher report, engaged in more activities, and functioned better socially. Just like the at-risk traits, these dimensions are likely operating with a number of other factors through the same mechanisms of gene–environment correlations and interactions. The Project Competence study, which followed children into adulthood, found robust predictions between child temperament/personality and adult functioning even after controlling for a number of baseline and demographic characteristics. In general, the temperament dimensions did not interact significantly with adversity, again suggesting a wider effect of

temperament than simply guarding against the effects of psychosocial stressors.

Goodness of Fit

Although it is easy to slip into the notion that some temperament traits are good and others are bad, it is important to remember that all traits possess both positive and negative qualities. High novelty seeking, for example, contains generally positive elements of being energetic and spontaneous in addition to being prone toward extravagance and impulsivity. Thomas and Chess popularized the notion of goodness of fit decades ago and it remains a cornerstone of child development theory. Simply put, the idea behind goodness of fit is that particular temperamental traits are not positive or negative per se but become so in an environmental context. A fearful temperament, for example, might be very adaptive in more dangerous settings but becomes less useful when the environment is safer and more predictable.

Research in animals and humans has supported this important hypothesis, although not necessarily at extreme levels. In a study by Rettew and colleagues, certain child temperament traits were related to behavior problems only in the presence of certain parental traits (Fig. 39–3). High child novelty seeking showed no relation to attention problems in families with a low-novelty-seeking mother, but did show a high degree of attention problems when paired with a high-novelty-seeking mother. Indeed, the much maligned short-repeat allele of the serotonin transporter, which has been related to the trait harm avoidance, may be related to environmental sensitivity, thus conveying adaptive *benefit* in some families while having a more negative effect in others.

CLINICAL IMPLICATIONS

It is clear at this point that the benefits of improved understanding regarding precisely how temperamental predispositions push children toward or away from more pathological outcomes have much more than academic implications and may guide major efforts in early identification and intervention. If negative cycles of genetic–environmental interplay leading to disabling symptoms can be identified, they potentially can be stopped, perhaps even reversed. At the same time, more positive cycles can be cultivated and encouraged. Returning to the case example may be worthwhile.

FIGURE 39–3. Relations between child and mother novelty seeking (NS) and attention problems. Children with low NS show few attention problems regardless of maternal NS. In high-NS children, however, a higher degree of attention problems is found in families with a high-NS mother but not in families with a low-NS mother. Results support the construct of goodness of fit in temperament/psychopathology associations. (From Rettew DC, Stanger C, McKee L, Doyle A, Hudziak JJ. Interactions between child and parent temperament and child behavior problems. *Compr Psychiatry*. 2006;47[5]:412–420.)

After diagnosing Kayla with major depression and social anxiety disorder, her psychiatrist recommended cognitive–behavioral therapy to help Kayla overcome her dysfunctional beliefs and provide motivation for her to learn and apply new skills. He also recognized similar symptoms in Kayla's mother and recommended her for psychiatric evaluation, which resulted

in her being prescribed a selective serotonin reuptake inhibitor (SSRI) and receiving individual treatment. Over time, Kayla learned to identify and challenge many of the negative thoughts that surrounded her behavior. Through the use of incentives, she was able to take small risks in approaching others socially. Her therapist recommended that she use her musical skills to an advantage, such using her piano playing as a mechanism through which other people would be encouraged to approach *her*. Her initial gains propelled her to take additional risks, and she joined the school orchestra. Meanwhile, her mother found that the decrease of her own anxiety allowed her to implement the therapist's suggestions more easily. Although Kayla never became a social butterfly, her depressive symptoms resolved, and she graduated from high school with confidence in her abilities and comfort with who she was.

Clinically oriented scientists are working hard to harness the energy that causes temperamentally predisposed tendencies to snowball into full-blown psychiatric syndromes and create pathways that not only will lead out of pathology but also into wellness. Given the complexity of these interactions, it is exceedingly likely that the specific relations between a particular trait and a particular disorder will vary considerably among individuals. Nevertheless, there is tremendous promise that further study of temperament will not only dramatically alter some of the fundamental definitions of psychiatric disorders but also illuminate mechanisms that can improve the lives of children.

Intellectual Disability

BRYAN H. KING, M.D., KAREN E. TOTH, PH.D., NINA DE LACY, M.D., AND DAN DOHERTY, M.D., PH.D.

HISTORICAL OVERVIEW

While centuries of experience have demonstrated that stigma will not disappear with a name change, the field continues to wrestle with how to capture the condition now referred to as "intellectual disability" or "intellectual developmental disorder." For decades, the field has also worked hard to encourage "people first" language. Individuals should not be defined by their illnesses or conditions—for example, John is not a "leper," or a "schizophrenic," or "retarded." Instead, people have illnesses or conditions—for example, John has schizophrenia. Although these lexical and grammatical sensitivities may seem trivial for some, there is no faster way to lose credibility in some settings than to characterize one's patient as "retarded."

Why such heightened sensitivity in this field? While it is well recognized that intellectual gifts have been distributed on a continuum for as long as mankind has walked the earth, the understanding and treatment of persons with intellectual disability has moved like a pendulum between extremes. At one end, persons with intellectual disability have been exalted, and considered "Les enfants du Bon Dieu" ("children of the Good God"). Certain media may convey the message that persons with intellectual or developmental disability are somehow blessed with simpler, more straightforward understandings of basic human truths. And at the other end of the pendulum swing, such persons have also been vilified. The word "cretin" (congenital hypothyroidism), takes its origin from "Christian or Christ-like," even as its modern dictionary definition includes descriptors like "stupid, vulgar, and insensitive." In the introduction to his text on "mental defectives" a century ago, Barr (1904), the chief physician at the Pennsylvania training school for the feeble-minded, observed that: "The terms idiot and imbecile indiscriminately applied for centuries to a despised and neglected class, have naturally, through the mere force of association, become synonymous with and even expressive of opprobrium and reproach. So closely welded has been this association of word and idea, that even the advance of the nineteenth century with all its revelation of true conditions has failed to sunder them" (p. 17).

Evidence for the recognition and treatment of intellectual disability

dates to the earliest of medical writings. Hippocrates described microcephaly and craniostenosis, and Galen actively explored causes of cognitive disability. In the Middle Ages, Avicenna proposed treatments for meningitis and hydrocephalus, and even defined levels of intellectual function.

Esquirol (1838) is credited as the first medical writer to define the disorder and was careful to distinguish intellectual disability from mental illness or disease. He focused on congenital onset in noting that: "Idiocy is not a disease, but a condition in which the intellectual faculties are never manifested; or have never been developed sufficiently to enable the idiot to acquire such an amount of knowledge as persons of his own age, and placed in similar circumstances with himself, are capable of receiving. Idiocy commences with life, or at that age which precedes the development of the intellectual and effective faculties, which are from the first what they are doomed to be during the whole period of existence."

The modern history for the field of intellectual disability begins in the late 18th and early 19th centuries. At that time, Jean-Marc Itard attempted a natural experiment to educate Victor, a "wild-child" discovered in the forests of Aveyron, France. Although Itard himself judged his work with Victor a failure, this famous experiment marked the important consideration that persons with disabilities might be educable. Itard's efforts generated interest in educational and other interventions for persons with disabilities. In some ways, Itard and those that followed provided a bridge from beliefs that individuals with intellectual disability were subhuman (even suggested by Linnaeus to be a separate species in the genus Homo with names like: Juvenis Lupinus Hessensis—a young man found in Hesse among wolves; or Juvenis Hannoverianus—a young man found in Hanover), to a more enlightened appreciation of their humanity and their potential.

Even so, in the preface to his text, Barr (1904) still straddles this divide as he categorically writes off the severely affected, while advocating for the less impaired:

"In endeavoring to emphasize the utter hopelessness of cure, and also the needless waste of energy in attempting to teach an idiot, I have sought to make clear the possibilities that may be attained in the training of the imbecile, the urgent need of preventing the backward child from degenerating into imbecility, and of safeguarding the absolutely irresponsible ammoral imbecile from crime and its penalty."

Howe and Wilbur are credited with introducing the enlightened approach to educating individuals with intellectual disability to the United States with the establishment of training schools like those that were appearing in Europe.

By the turn of the century, there were 30 such institutional settings in 21 states, both public and private, and some reserved for women, and for

individuals with epilepsy. Many of these institutions had residents numbering in the hundreds and gradually the focus shifted away from education and more toward custodial care.

During their peak usage, from 1950 until the late 1960s, institutions were home to approximately 1 per 1,000 Americans.

Since the mid-1960s, many fewer persons with intellectual disability have been institutionalized in the United States. This move toward "deinstitutionalization" has arisen from many sources. First, the overcrowding and neglect common in many large institutions came to light in various exposés during the late 1960s. Blatt and Kaplan's photo story, "Christmas in Purgatory" (reproduced in Look magazine), Geraldo Rivera's television reports, and Robert F. Kennedy's attacks on the Rome and Willowbrook institutions in New York all shocked the nation.

Deinstitutionalization

Other forces also led to deinstitutionalization. Perhaps the most important of these forces was the philosophy of "normalization," the idea that individuals with intellectual disability were entitled to a more normal lifestyle, including a culturally normal rhythm to one's day (school or work, leisure time, sleep), week (weekdays and weekends), and year (vacations, holidays). In 1972, Wolfensberger extended the idea of normalization to the service delivery system itself, calling on all residences, schools, and other services for persons with intellectual disabilities to be as normative as possible. Parent and professional advocacy groups also fought hard for legislative and legal victories to decrease the size of large institutions.

Over the past 50 years, changes in US residential institutions have been dramatic. Several states have closed their institutions, and remaining facilities have become much smaller. Typically, individuals remaining in large or even medium-sized institutions have the most severe impairments; many of these residents also have severe behavior problems, or motor or sensory disabilities in addition to their severe-profound intellectual disability. Overall, from 1967 to 1994, the total institutional population—defined as state-operated institutions with 16 or more residents—decreased by almost two-thirds, from 194,650 to 65,818. In California, the number of persons served by the Department of Developmental Services increased 61.6 percent between January 1992 and December 2001. During this same period however, the State developmental center population decreased by 44.4 percent. In many states, Medicaid funding waivers (the ability to access Medicaid dollars in circumstances in which family income criteria or other eligibility criteria are waived) are in place explicitly to support children with intellectual disabilities who meet "institutional level of care" standards. These so-called "deeming waivers," or "Katie Beckett waivers" are meant to ensure that Medicaid support can follow an individual out of an institutional setting if such a move can be done safely and cost

effectively. Katie Beckett was a young lady in Iowa who became ventilator-dependent following a catastrophic CNS infection, and whose parents discovered that if they took her home from the skilled nursing facility, she would lose her Medicaid coverage. As the costs associated with institutionalization are invariably in the tens of thousands for any individual (ranging from a low of $104,025 per year in Arkansas to a high of $375,000 in Tennessee in 2009), the cost effectiveness criterion is rarely a limiting factor, but clinicians may be called upon to attest to the level-of-care criterion for their patients who are seeking support under this waiver.

School. Schooling is the other major service for persons with intellectual disability. Following the move to "school" all American children that began in the mid-1800s, teachers and administrators soon discovered that a subset of children were having difficulties in performing school lessons. As a result, classes for "problem children" began in many cities and towns in the late 1800s. In 1894, the first classes specifically for children with intellectual disability were formed in Providence, Rhode Island. In rapid succession, special education classes were begun in Springfield, MA (1894), Chicago (1898), Boston (1899), New York (1901), Philadelphia (1901), and Los Angeles (1902).

Local school districts have historically held an ambivalent attitude toward special education classes. Often housed within the least desirable buildings and rooms, these classes were frequently furnished with scarce equipment and materials, and had few specially trained teachers. By 1968, Lloyd Dunn declared that most children with intellectual disability could be "mainstreamed" in classes with age-mates; he questioned the need for segregated special education classes for most children with intellectual disability. Dunn's article took note of the Supreme Court's ruling that "separate could not be equal" in educational settings, that research had not shown that children with mild intellectual disability learn better in special education versus regular education classes, and that educational techniques had advanced sufficiently to allow for the effective schooling of most children with retardation alongside other children.

In both education and living settings, then, the post-1970 era witnessed the strong influence of mainstreaming, community living, and normalization. On the whole, such movements have proven beneficial as persons with intellectual disability increasingly take their rightful place within modern society. Many professionals do, however, question whether normalization has sometimes gone too far. Not every child with intellectual or other disabilities may be able to be schooled optimally with typically developing age-mates, nor might every adult be able to live independently in the community. Indeed, some families are advocating for specialized schools or residential settings for children with autism even as state agencies fear a return to institutional approaches. These issues continue to

be hotly debated among professionals, families, and organizations associated with persons with intellectual disability.

Research

Like service delivery, the modern history of research also begins in the mid-19th century. In 1838, Esquirol differentiated intellectual disability from mental illness, and proposed several levels of impairment. Later in the century, various different classification systems were proposed. Probably the most well-known was a system of "ethnic classifications" proposed by J. Langdon Down in 1866—hence the term "Mongolism" for persons with Down syndrome, the type of intellectual disability he first identified.

In addition to classifying persons with intellectual disability, genetics plays an important historic role in intellectual disabilities research. Unfortunately, early in this century, that role was mainly negative. Spurred by the rediscovery of Mendel's genetic findings, various workers attempted to show that intellectual disability was inherited. Most notorious were Dugdale's (1877) study of the Jukes, and Goddard's (1913) study of the Kallikaks. In both cases, multi-generational families were used to argue that intellectual disability was inherited and that sterilization was necessary for the "preservation of the race." Such eugenic scares led to court decrees and sterilization laws in California and other states during the 1920s.

Also playing an important role in intellectual disability research was the new science of psychological testing. Henry Goddard, the research director at the Vineland Training School in New Jersey, was the first to use Binet and Simon's IQ tests in the United States. After testing Vineland residents over a several-year period, Goddard concluded that "the vast majority of feeble-minded children are not changing and are not improving in their intelligence levels," a finding that another leading worker, Walter Fernald, called "the most significant … and the most discouraging that we have ever known."

Since early in this century, research has progressed in both the behavioral and biomedical fields. Behaviorally, recent work has allowed for better diagnoses and classification. Nearly a century ago, psychologists invented tests of motor, nonverbal intelligence, achievement, adaptive behavior, and other skills. Following similar work with typically developing children, psychologists have recently learned much about the development of cognitive, linguistic, social, and adaptive skills in persons with intellectual disability. In addition, many studies now examine the presence of psychiatric disorders in children and adults with intellectual disability, and families, schools, group homes, and workshops have all received research attention. Much of this work has occurred from the 1960s until today, a time of strong, often federally supported, progress in intellectual disability behavioral research.

But arguably the most important progress has occurred in the

biomedical and genetic fields. As early as 1934, the Norwegian physician, Folling, hypothesized that several of his patients with retardation were unable to metabolize phenylalanine. Such insights later led to a dietary treatment of this inborn error of metabolism; the phenylalanine-free diet, though not perfect, has significantly limited PKU as a cause of intellectual disability in most industrialized countries. In addition, PKU can now be screened at birth through the Guthrie test, after which dietary treatments can be instituted. PKU remains one of the major success stories in intellectual disability even as new treatments for this condition, for example tetrahydrobiopterin, are still being developed.

Modern genetics constitutes another success story in intellectual disability research. In 1959, Lejeune, Gautier, and Turpin discovered that most cases of Down syndrome were due to trisomy of the 21st chromosome. Fragile X syndrome, the second most common genetic cause of intellectual disability, was discovered in 1969, and its cytogenetic diagnosis was refined in the mid-1970s. With the banding techniques of the 1970s and the molecular genetic techniques of the past two decades, exact causes are being described for many of the nearly 1,500 different genetic disorders associated with intellectual disability. The genetic—and, increasingly, the behavioral—characteristics of many of these disorders are now known (see below).

Organizations

The field of intellectual disability is also a history of organizations. The first such organization was the Association of Medical Officers of American Institutions for Idiotic and Feeble-Minded Persons, begun in 1876. As the first professional group devoted exclusively to persons with intellectual disability, the Association of Medical Officers was the forerunner to the American Association on Intellectual and Developmental Disabilities (AAIDD, formerly AAMR), the field's most influential organization. Through its various journals and committees, AAIDD has been at the forefront of research, policy, and legislative advances for persons with intellectual disability.

In addition to AAIDD, other groups have also played important roles, particularly concerning changes in federal policy toward people with disabilities. The Council for Exceptional Children (CEC) was begun in 1922, and continues to champion the profession of special education and the education of all children with disabilities. The Arc, formerly the National Association for Retarded Citizens (NARC) is the main parent-led advocacy group. Arc was particularly influential in the passage of the Education for All Handicapped Children Act of 1975 (PL 94–142), the federal law that for the first time mandated the "free, appropriate public education" of all children with disabilities throughout the United States. Each of these groups was also influential in the passage of the Americans with

Disabilities Act, federal legislation that took effect in 1992, and outlawed discrimination of persons with disabilities. The National Association for the Dually Diagnosed, now simply NADD, was established in 1983, specifically in recognition of the lack of attention by the professional community to the needs of individuals with intellectual disability who also experience psychiatric illness. Over the ensuing years the organization has grown to be the principal association in North America to advance mental wellness for persons with developmental disabilities through the promotion of excellence in mental health care.

Federal agencies constitute an additional category of influential organizations. Begun during the presidency of John F. Kennedy (himself a sibling to a woman with intellectual disability), the National Institutes of Child Health and Human Development (NICHD) have long supported disability research. Other federal programs, including the nationally distributed network of nearly 70 University Centers for Excellence in Developmental Disabilities Education, Research, and Service (UCEDDs), and NICHD-funded Mental Retardation Research Centers (MRRCs), have also played important roles in research and policy. Taken together, professional, parent, and federal organizations provide an important infrastructure to the intellectual disability field.

Before discussing definitional issues, it is worth revisiting terminology. In different countries throughout the world, different terms are used for intellectual disability. In Europe, the term "intellectual disabilities" has long been used, and a major international journal is the Journal of Intellectual Disabilities Research. In Great Britain, alongside "intellectual disability," the term "learning disability" (or learning disabilities) is often used—a term with a very different meaning in the United States.

DEFINITION OF INTELLECTUAL DISABILITY

Over the years, the American Psychiatric Association (APA) has adopted definitions of intellectual disability from the American Association on Intellectual and Developmental Disabilities (AAIDD), previously the American Association on Mental Retardation (AAMR). While the definitions in the third and fourth editions of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM; American Psychiatric Association) are very similar, DSM-5 (American Psychiatric Association, 2013) includes substantive changes to the definition of intellectual disability. For the first time in DSM, for example, the term "intellectual disability" replaces "mental retardation," and the language of DSM-5 is more closely aligned with that of the AAIDD. (The term proposed for ICD-11 [2015] is "intellectual developmental disorders.") Further, severity levels are now classified by adaptive rather than intellectual function or IQ scores. This section reviews the changes (see Table 40–1 for summary).

Intellectual and Adaptive Functioning

Intellectual Functioning. Standardized intelligence tests that meet appropriate psychometric criteria for reliability and validity are commonly used to identify intellectual disability. These instruments are summarized in Table 40–2, along with each test's age range and cognitive domains.

Both in terms of the testing situation itself and in the choice of an appropriate measure, administering such tests to people with intellectual disability is quite challenging. As people with intellectual disability have increased risks of comorbid psychiatric or behavioral disorders, examiners need to ensure that difficulties such as hyperactivity or poor frustration tolerance do not impede optimal test performance. Even in persons without behavioral challenges, certain personality characteristics may interfere with testing. Many people with intellectual disability, for example, look to others for solutions to difficult problems, and are quick to acquiesce, or become easily discouraged by failure. To minimize these problems, examiners can begin with easier tasks to provide success and incentives or rewards for effort.

Table 40–1.
A Comparison of DSM-IV and DSM-5 Diagnostic Criteria for Intellectual Disability

DSM-IV Diagnostic Criteria		
A. Intellectual Function	**B. Adaptive Function**	**C. Onset**
Significantly subaverage intellectual functioning: an IQ of approximately 70 or below on an individually administered intelligence test	Concurrent deficits or impairment in present adaptive functioning (i.e., the person's effectiveness in meeting the standards expected for his or her age or cultural group) in at least two of the following skill areas: communication, self-care, home living, social/interpersonal skills, use of community resources, self-direction, functional academic skills, work, leisure, health, and safety	The onset is before age 18 years.
DSM-5 Diagnostic Criteria		
A. Intellectual Function	**B. Adaptive Function**	**C. Onset**
Deficits in intellectual function, such as reasoning, problem solving, planning, abstract thinking, judgment, academic learning, and learning from experience, confirmed by both clinical assessment and individualized, standardized intelligence testing	Deficits in adaptive functioning that result in failure to meet developmental and socio-cultural standards for personal independence and social responsibility. Without ongoing support, the adaptive deficits limit functioning in one or more activities of daily life, such as communication, social participation, and independent living across multiple environments, such as home, school, work, and community.	Onset of intellectual and adaptive deficits during the developmental period

Data from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 4th

ed. Washington, DC: American Psychiatric Association; 1994; American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*, 5th ed. Washington, DC: American Psychiatric Association; 2013.

For individuals who are nonverbal, there are several measures that can be selected that do not rely on expressive language (see Table 40–2). People with certain genetic syndromes (e.g., Williams syndrome, Down syndrome) also present unique test challenges, as many show syndrome-specific profiles of cognitive strength and weakness that are not easily described by a global IQ score (see phenotype section). Persons with intellectual disability and co-occurring sensory or motor deficits also require adaptation to routine test procedures. Finally, when testing individuals from some minority groups, examiners need to be sensitive to language and cultural issues, and use a multi-method test approach, especially when diagnosing persons with mild intellectual disability.

Adaptive Functioning. Edgar Doll (1935) was the first to develop a formal definition and measure of adaptive behavior. Two decades later, the AAMR (now AAIDD) officially included deficits in adaptive behavior in its definition of intellectual disability. Since that time, deficits in adaptive behavior have been formally included in all definitions of intellectual disability. However, until DSM-5, IQ score alone was used to classify individuals in terms of *severity* of intellectual disability. Table 40–3 illustrates the substantive nature of the changes in severity classification from DSM-IV to DSM-5.

Table 40–2.
Measures for Assessing Intellectual Ability

Measure	Age Range (years)	Domains Assessed
Wechsler Preschool and Primary Scale of Intelligence, 4th edition (WPPSI-IV) (Wechsler, 2012)	2.6 to 7–3	Verbal IQ, performance IQ, full scale IQ
Wechsler Intelligence Test for Children, 5th edition (WISC-V) (Wechsler, 2014)	6 to 16–11	Verbal IQ, performance IQ, full scale IQ
Wechsler Adult Intelligence Scale, 4th edition (WAIS-IV) (Wechsler, 2008)	16 to 90	Verbal IQ, performance IQ, full scale IQ
Stanford–Binet Intelligence Scales, 5th edition (Roid, 2003)	2 to 85+	Verbal, quantitative, abstract/visual, short-term memory, composite score
Kaufman Assessment Battery for Children, 2nd edition (K-ABC-II) (Kaufman & Kaufman, 2004)	3 to 18	Sequential and simultaneous processing, mental processing composite
Kaufman Adolescent and Adult Intelligence Test (KAIT) (Kaufman & Kaufman, 1993)	11 to 85+	Crystallized and fluid scales, composite IQ

Differential Ability Scales, 2nd edition (DAS-II) (Elliott, 2006)	2–6 to 17–11	Verbal, nonverbal reasoning, spatial abilities, general conceptual ability
Raven's Coloured Progressive Matrices (CPM) (Raven, 1998, 2003)	5 to elderly	Figural reasoning; group test
Test of Nonverbal Intelligence (TONI)-2 (Brown, Sherbenou, & Johnsen, 1990)	5–85	Abstract problem-solving: simple matching, analogies, classification, intersections, and progressions
Leiter International Performance Scale, Revised (Leiter-R) (Roid & Miller, 1997)	5–0 to 85–11	Reasoning ability, similarities, differences, relationships
Universal Nonverbal Intelligence Test (UNIT) (Bracken & McCallum, 1998)	5–0 to 7–11	Reasoning, memory, symbolic, and nonsymbolic tasks

Table 40–3.
DSM-IV Severity Criteria for Intellectual Disability (APA, 1994)

Severity Criteria				
Mild	**Moderate**	**Severe**	**Profound**	**Unspecified**
IQ level 50–55 to approximately 70	IQ level 35–40 to 50–55	IQ level 20–25 to 35–40	IQ level below 20–25	When there is a strong presumption of mental retardation but the person's intelligence is untestable by standard tests.

DSM-5 Severity Criteria for Intellectual Disability (APA, 2013)

Severity Criteria	Conceptual Domain	Social Domain	Practical Domain
Mild	For preschool children, there may be no obvious conceptual differences. For school-age children and adults, there are difficulties in learning academic skills involving reading, writing, arithmetic, time, or money, with support needed in one or more areas to meet age-related expectations. In adults, abstract thinking, executive function (i.e., planning, strategizing, priority setting, and cognitive flexibility), and short-term memory, as well as functional use of academic skills (e.g., reading, money	Compared with typically developing age-mates, the individual is immature in social interactions. For example, there may be difficulty in accurately perceiving peers' social cues. Communication, conversation, and language are more concrete or immature than expected for age. There may be difficulties regulating emotion and behavior in age-appropriate fashion; these difficulties are noticed by peers in social situations. There is limited understanding of risk in social situations; social judgment is immature for age, and the person is at risk of being	The individual may function age-appropriately in personal care. Individuals need some support with complex daily living tasks in comparison to peers. In adulthood, supports typically involve grocery shopping, transportation, home and childcare organizing, nutritious food preparation, and banking and money management. Recreational skills resemble those of age-mates, although judgment related to well-being and organization around recreation requires support. In adulthood, competitive employment is often seen in jobs that do not emphasize conceptual skills. Individuals generally need support to make health care–related and legal decisions, and to learn to perform a skilled vocation competently. Support is typically needed to raise a family.

	management), are impaired. There is a somewhat concrete approach to problems and solutions compared with age-mates.	manipulated by others (gullibility).	
Moderate	All through development, the individual's conceptual skills lag markedly behind those of peers. For preschoolers, language and pre-academic skills develop slowly. For school-age children, progress in reading, writing, mathematics, and understanding of time and money occurs slowly across the school years and is markedly limited compared with that of peers. For adults, academic skill development is typically at an elementary level, and support is required for all use of academic skills in work and personal life. Ongoing assistance on a daily basis is needed to complete conceptual tasks of day-to-day life, and others may take over these responsibilities fully for the individual.	The individual shows marked differences from peers in social and communicative behavior across development. Spoken language is typically a primary tool for social communication but is much less complex than that of peers. Capacity for relationships is evident in ties to family and friends, and the individual may have successful friendships and sometimes romantic relations in adulthood. However, individuals may not perceive or interpret social cues accurately. Social judgment and decision-making abilities are limited, and caretakers must assist with life decisions. Friendships with typically developing peers are often affected by communication or social limitations. Significant social and communicative support is needed in work settings for success.	The individual can care for personal needs involving eating, dressing, elimination, and hygiene as an adult, although an extended period of teaching and time is needed for the individual to become independent in these areas, and reminders may be needed. Similarly, participation in all household tasks can be achieved by adulthood, although extended teaching and ongoing supports are needed for adult-level performance. Independent employment in jobs that require limited conceptual and communication skills can be achieved, but considerable support from coworkers and others is needed to manage social expectations, job complexities, and responsibilities such as scheduling, transportation, health benefits, and money management. A variety of recreational skills can be developed but require supports and learning opportunities over an extended period. Maladaptive behavior is present in a significant minority and causes social problems.
Severe	Attainment of conceptual skills is limited. The individual generally has little understanding of written language or of concepts involving	Spoken language is quite limited in vocabulary and grammar. Speech may be single words or phrases and may be supplemented through augmentative means. Communication is	The individual requires support for all activities of daily living (meals, dressing, bathing, and elimination), requires supervision at all times, and cannot make responsible decisions regarding well-being of self or others. In adulthood,

	numbers, quantity, time, and money. Caretakers provide extensive supports for problem solving throughout life.	focused on the here and now. Language is used for social communication more than explication. Individuals understand simple speech/gestures. Relationships with familiar others are a source of pleasure and help.	tasks at home, recreation, and work require ongoing support/assistance. Skill acquisition in all domains involves long-term teaching and support. Maladaptive behavior, including self-injury, is present in a significant minority.
Profound	Conceptual skills generally involve the physical world rather than symbolic processes. The individual may use objects in goal-directed fashion for self-care, work, and recreation. Certain visuospatial skills, such as matching and sorting based on physical characteristics, may be acquired. However, motor and sensory impairments may prevent functional use of objects.	The individual has very limited understanding of symbolic communication in speech or gesture. He or she may understand some simple instructions or gestures. The individual expresses his or her own desires and emotions largely through nonverbal, nonsymbolic communication. The individual enjoys relationships with familiar others, and initiates and responds to social interactions through gestural and emotional cues. Sensory and physical impairments may prevent many social activities.	The individual is dependent on others for all aspects of daily physical care, health, and safety, although he/she may participate in some of these activities as well. Individuals without severe physical impairments may assist with daily work tasks at home, like carrying dishes to the table. Simple actions with objects may be the basis of participation in some vocational activities with high levels of support. Recreational activities may involve music, movies, walks, or participating in water activities, all wit h support. Physical and sensory impairments are frequent barriers to home, recreational, and vocational activities. Maladaptive behavior is present in a significant minority.

Table 40–4.
Common Measures of Adaptive Behavior

Measure	Age Range	Domains Tested
Vineland Adaptive Behavior Scales, 2nd edition (Sparrow et al., 2005)	Birth to 18–11	Communication: receptive, expressive, written; daily living skills: personal, domestic, community socialization: interpersonal relations, play & leisure, coping skills; motor skills: fine, gross
Adaptive Behavior Assessment System, 2nd edition (ABAS-II); (Harrison and Oakland, 2003)	0–89	Assesses conceptual, social, and practical aspects of adaptive behavior, as well as 10 adaptive skill areas.

Scales of Independent Behavior, Revised (SIB-R) (Bruininks, Woodcock, Weatherman, & Hill, 1996)	Birth to 80+	Motor: fine, gross
		Social interaction & communication: social interaction, language comprehension, language expression
		Personal living skills: eating & meal preparation, toileting, dressing, community living skills: time & punctuality, money & value, work
Diagnostic Adaptive Behavior Scale (DABS) (AAIDD release 2015)	4 to 21	Focuses on the critical "cut-off area" for the purpose of ruling in or out a diagnosis of ID or related disability.
Street Survival Skills Questionnaire (SSSQ) (Linkenhoker & McCarron, 1993)	9 to 40+	Administered to person; basic concepts, functional signs, tools, health

Though meanings vary, adaptive behavior is typically viewed as the performance of behaviors required for social and personal sufficiency. Further, adaptive behavior is an inherently developmental and social construct. Adaptive behavior changes as children grow into adolescence and adulthood, and demands for social adaptation are also defined by expectations from others—from one's family, society, and culture. Adaptive skills typically change across various settings; one's adaptive performance on the job or at school may differ from one's performance with friends or at home. Measurements of adaptive behavior, then, need to have a developmental orientation, to be socially and culturally sensitive, and to represent the many settings in which people live, work, and play.

In contrast to Doll's time, many instruments now exist that measure adaptive behavior across multiple domains (e.g., community skills, personal grooming). Table 40–4 summarizes commonly used measures of adaptive behavior, their age ranges, and various domains. Although most of these measures are administered as interviews with parents or other care providers, some measures are administered directly to persons with intellectual disability. Central to all measures of adaptive function is the idea that adaptive behavior is measured by performance as opposed to ability. If people with intellectual disability are able to (possess the skills to) perform certain behaviors, but do not regularly do so or do not do so without prompts, reminders, and assistance, then they necessarily have compromised adaptive functioning.

Severity of Intellectual Disability

There are remarkably variable strengths and competencies of people with intellectual disability. DSM-5 (and similar to AAIDD 2002) provides a classification system based on adaptive functioning across three domains: conceptual, social, and practical. Table 40–3 summarizes the classification

system in DSM-IV (by IQ score) and the DSM-5 system based on characteristics across the three domains and associated with mild, moderate, severe, and profound intellectual disability. As people with intellectual disability can also be classified by the etiology of their conditions, later sections detail how adaptive functioning changes across diverse genetic and other etiological groups.

Mild Intellectual Disability . Mild intellectual disability constitutes the largest group of people with intellectual disability, possibly as many as 85 percent of all persons with ID. These individuals appear similar to unaffected individuals and often blend into the general population in the years before and after formal schooling. Many achieve academic skills at the sixth grade level or higher, and some graduate from high school. As adults, many of these individuals hold jobs, marry, and raise families—yet at times they may appear slow or need extra help negotiating life's problems and tasks.

Robert was a full term infant, the last of three children born to his 38-year-old mother, a high school music teacher, and 40-year-old father, a science teacher. Pregnancy was unremarkable, and Robert's two older sisters were healthy and developing nicely. The family lived in a rural town in the Midwest.

Robert was an extremely fussy newborn, and had extended periods of crying that the pediatrician described as "colic." When Robert was 2 months old, his parents were told that he had supravalvular aortic stenosis, a case that warranted monitoring but no surgeries. Although Robert became less fussy over time, he was a picky eater, refusing solid foods. Robert's parents also noted that he was more "high-strung" than his siblings, often quick to cry or cringe when his sisters played too loudly.

Milestones were slightly delayed, with Robert sitting unassisted at 10 months and walking at 18 months. Language was also delayed, and although his first words appeared at 20 months, Robert had always made his wants and needs known. Although his parents were concerned that he was delayed compared to his sisters, they were reassured by the explanation that boys often had slight delays, and that he was a lively, social boy who would quickly catch up.

When Robert was 3, his parents insisted on a developmental evaluation, which revealed modest delays in cognitive, language, and motor functioning. His developmental quotient was 74 (average range is roughly 85 to 115). He was described as friendly and engaging, a real "charmer," with a cute face that endeared him to many. Robert was enrolled in a special kindergarten, and he remained in a combination of special education and mainstream (general education) classes throughout his academic career. Like the rest of his family, Robert enjoyed listening to music and singing, and he took an active interest in the piano.

At age 7 years, the school psychologist evaluated Robert and felt that he fit a "learning disability" profile. Robert had an overall IQ of 66, but with close to average functioning in short-term memory and expressive language, and pronounced deficits in visual-spatial functioning. He struggled with writing tasks and arithmetic, but loved science and music, and was amazingly conversant to anyone who would listen to him. Indeed, his parents feared he was "too friendly," as well as too active, and with transient, intense interests in unusual items such as vacuum cleaners.

As he entered adolescence, Robert became increasingly anxious, so much so that he occasionally rubbed his hands or rocked, and he "fretted" about day-to-day issues and what would happen next. His long-standing sensitivities to loud sounds seemed to wane slightly, but he developed fears of storm clouds and dogs, and refused to ride on elevators. He became tearful and upset after one of his older sisters left for college, and worried about her health and her ability to watch the weather at college. Although Robert suffered from nightmares, and

would occasionally pace with worry and complain of stomachaches, he attended school, and had a small group of friends in the Special Olympics bowling league. Further, he enjoyed singing with the high school chorus and he was delighted to be frequently selected to play the piano at school concerts.

When Robert was 17 years old, his parents happened to watch a television documentary on Williams syndrome. They were overwhelmed by the similarities between Robert and the people described in the program. They later described the experience like a "jolt." They had always accepted Robert, quirks and all, and had stopped pushing their doctors for reasons "why" when Robert was a preschooler. Nevertheless, they immediately called the informational number offered in the show, and within 2 months, they had the genetic tests done that confirmed their strong suspicion that Robert had Williams syndrome.

While Robert's day-to-day life did not change dramatically after his diagnosis, his parents reported a big difference in Robert's outlook. He met new friends with Williams syndrome at a conference; he applied to go to a summer music camp for young adults with Williams syndrome; and he reported that he felt less alone. Robert's parents reported a mixture of feelings at having such a late diagnosis—disappointment in their doctors, relief in finally knowing, and twinges of guilt. They were energized by having a new community of Williams syndrome families to share their feelings and worries with; like their son, they too felt less alone.

Elisabeth is a 29-year-old widowed Caucasian mother. Elisabeth was the youngest of three children and born to her parents after an unremarkable pregnancy and delivery. Early development was similarly without distinction as she met her developmental milestones as expected. However, in the context of her enrollment in a Head Start program, some cognitive delays were noted. More strikingly, it became clear that Elisabeth had some visual problems evidenced by her falling a lot and stumbling into things. An examination revealed that Elisabeth had significant visual problems prompting patching and other interventions. Elisabeth was routed into special education classes from kindergarten, and although she was described as somewhat of a loner, never really playing with any of her many cousins, behavioral concerns did not really surface until puberty. At that time, she became more withdrawn, into a "fantasy world." Her family recalls that imaginary friends took on new importance such that Elisabeth would carry on animated conversations with them. She would talk to posters on the wall—even kiss them on occasion. Elisabeth began to have increasing difficulties in school around this time as well. Her mother recalls that Elisabeth seemed always to have a level of discomfort with sexuality and, after menarche, Elisabeth would refuse to attend to personal hygiene. Elisabeth was also incapable of eating in the cafeteria with the rest of the students. Her sister recalls that Elisabeth would invariably "start eating like a pig," and because of these behaviors she would be placed in a separate lunchroom by herself.

At the age of 17, a psychological evaluation was done to determine the level of Elisabeth's intellectual ability. The narrative at that time described how Elisabeth had been coded as having mild intellectual disability but that there were other factors that were of concern, notably frequent absences from school and the need to build in extra incentives to get her to attend to tasks. Elisabeth was described in the evaluation at that time as being a cooperative test subject, appearing "healthy in all respects, but she was quiet, somewhat shy and seemed to have difficulty articulating," which was attributed to word-finding difficulties.

Following her graduation from high school Elisabeth found herself in and out of counseling, she became estranged from her family, and at 24 years of age presented to a mental health clinic where she was described as a young woman "with developmental disability who had recently given birth (2 months earlier) to a son." She was described as experiencing symptoms of depression related to the suicide of her husband approximately a year earlier. The story that Elisabeth told at that time was described as chaotic and confusing, including issues relating to her relationship with her parents, sisters and other individuals in her life.

With the birth of Raymond, Elisabeth's first child, the family recalls how they took Elisabeth back into the home to support her and the new grandchild and that they were very concerned about the behaviors they witnessed, including Elisabeth's absolute refusal to change diapers or to wash the baby's genitalia, claiming that such behavior would constitute sexual abuse. They observed her force-feeding the child, and inappropriately dressing him for the

weather. Ultimately, her father overheard a conversation from an adjacent room in which Elisabeth said that she was going to do the same thing that the child's father did (commit suicide) but that she would take Raymond with her. This prompted a call to the authorities and was the proximal event that led to the removal of Raymond from Elisabeth's custody.

Over the next several years, her family describes numerous and volatile interactions with Elisabeth that were consistently characterized by irritability on Elisabeth's part. The family is quite clear in being unable to identify discreet periods of time during which Elisabeth's behavior cycled up or down into specific depressive or manic episodes. The most prominent recollection is of stable and durable preoccupations with fantasy, misinterpretations and even paranoid accusations, recalling recently how she refused to let her brother turn on the lights because she knew that the CIA would be observing the family if the lights were on.

During a recent involuntary hospitalization, the psychiatrist noted that Elisabeth made sporadic eye contact, that her speech was slurred, and that she smiled or giggled inappropriately as though responding to some private thoughts or perhaps "voices." While she denied hallucinations, she was convinced that both her mother and sister intended to kill her if they got the chance, that both had murdered others or had people do the killing for them, and that they were conspiring to make sure that Elisabeth never got her son back. During this admission, Elisabeth was started on risperidone, her first medication trial, at 1 mg per day and subsequently the dose was increased to 3 mg. Elisabeth agreed that the new medicine helped her to think clearly and it was observed that the delusional thinking about her neighbors and the Mental Health Center gradually disappeared during the course of her hospitalization.

Currently, Elisabeth lives on her own in an apartment with close monitoring from community supports. Elisabeth has been cooperative in participating in various programs that have been offered including weekly swimming opportunities as well as participation in an art studio. Staff report that they have not been aware of any changes in Elisabeth's sleep or appetite, no significant changes in her weight, no changes in mood, and no psychotic symptoms.

Historically, people with mild intellectual disability were thought to show relatively few clear-cut organic causes for their delay. However, in recent years there has been an increase in the number of people with genetic syndromes who function in the mild range of intellectual disability. Examples include most people with Prader–Willi syndrome (PWS), as well as some males and most females with Fragile X syndrome.

A more striking finding is that more people with mild intellectual disability come from minority groups and low socio-economic (SES) backgrounds than would be expected from their percentages in the general population. This overrepresentation of minority groups has been used to criticize standardized intelligence tests that are used for placement in special education classroom settings, as well as to highlight the importance of environmental-cultural influences on intellectual development and assessment.

Moderate Intellectual Disability. Moderate intellectual disability is seen in approximately 10 percent of the population with ID, and includes people with more impaired cognitive and adaptive functioning. People with moderate intellectual disability are typically diagnosed in their preschool years, and some show a clear organic cause for their delay. Many persons with Down syndrome, the most common chromosomal cause of ID, often function in this range, as do many adolescents and adults with Fragile X

syndrome. Most children with moderate intellectual disability require special education services, achieving academic skills at the second to third grade level. Need for supportive services continues throughout the lifespan, and with proper supports, many live, work, and thrive in their local communities. In a study by Ross and colleagues, 20 percent of persons with IQs from 40 to 49 lived independently, whereas 60 percent were considered partially dependent and 20 percent totally dependent on others. In a similar way, some individuals in this range are employed in the competitive job market, and need minimal job supervision, whereas others require more extensive supervision on the job, and may work in sheltered workshops or other, more segregated settings.

Bryan is a 17-year-old sophomore with moderate intellectual disability associated with Down syndrome. Bryan had significant cardiac problems in infancy, and eventually required surgery to repair a ventricular septal defect. Although his energy level improved significantly thereafter, he still had some delays in motor and other developmental milestones. Nevertheless, throughout his education, Bryan has been placed in general education classrooms with same-aged peers and with the support of classroom aides. Bryan's IQ is 53, he has some difficulties with articulation, and his language mainly consists of two-to-four-word sentences. Recently, he has made progress in reading and can read 50 sight words. Bryan has had some minor problems with managing his anxiety over the years, and can become somewhat stubborn at times, but he is well-liked by his teachers and classmates, and his parents boast that Bryan has been a charming, pleasant child from infancy. In addition to attending classes at the local high school, Bryan also spends some time learning job skills in the community. He enjoys his position as the assistant manager for his high school's cross-country team and actively participates in Special Olympics.

Severe Intellectual Disability. Severe intellectual disability occurs in about 3 to 4 percent of the population of people with intellectual disability. Individuals at this level often have one or more organic causes for their delay, and many show concurrent motor, ambulatory, and neurological problems, as well as poorly developed communication skills. Most persons with severe intellectual disability require close supervision and specialized care throughout their lives. Some individuals learn to perform simple tasks or routines that facilitate their self-care or their ability to perform in a sheltered workshop or pre-workshop type of setting.

Harrison is a 16-year-old resident at a school for children with severe disabilities. His mother raised concerns early on when at the age of 2.5 Harrison lost acquired language skills. He was seen by a pediatric neurologist, who elected to introduce carbamazepine in the presence of an abnormal EEG. His mother recalls that the carbamazepine not only appeared to improve Harrison's overall function but also seemed to have a positive effect on Harrison's sleep and activity level, both of which were problematic. In fact, the hyperactivity and impulsivity later prompted a trial of methylphenidate and Harrison's mother remembers that while there may have been some initial improvement on this drug, over time Harrison became "an animal" on the medication, resulting in its discontinuation. Indeed, methylphenidate is the only medication that his mother lists when given the opportunity to identify drugs that have been tried in the past that were clearly bad.

On the other side of the equation, his mother lists carbamazepine and other anti-seizure medications as having been consistently helpful over the years. Staff at Harrison's school note

that carbamazepine is unique among the anticonvulsants that have been tried in that there seemed to be benefit with respect to reducing seizure frequency but also significant behavioral benefit. Over the years, the dose of carbamazepine has varied and has been periodically discontinued in favor of trials of newer anticonvulsants because of concerns about Harrison's borderline white blood cell counts. However, because of the unequivocal behavioral benefit that staff and family attribute to the carbamazepine, it is being used again, albeit at doses that may be lower than have been utilized in the past. His mother's recollection is that a number of medication trials have been explored over the years and that each of the medications has conferred only temporary benefit. In addition to carbamazepine and methylphenidate, previous medication trials have included melatonin, clonidine, sertraline, aripiprazole, risperidone, and diphenhydramine.

The behavioral difficulties that have prompted medication changes include agitation, hyperactivity, and mood instability in the form of giddiness, and more recently, inappropriate sexual advances towards female staff. There have also been significant aggressive outbursts in recent years. In addition to the periods of heightened irritability and hyperactivity, there have been periods of diminished activity, and loss of appetite such that Harrison's weight has occasionally dropped into the 120s in spite of his 6′3″ frame. Teachers and Harrison's mother report that during these times his interests also diminish, including his participation in activities that he otherwise enjoys. Observers note that Harrison seems to want to eat but just cannot muster the interest or enthusiasm when food is placed in front of him.

On examination Harrison comes quite willingly into the office setting accompanied by staff and family. He is a tall and slender young man dressed in sweat pants that are loose on his thin frame. Harrison extends his hand to acknowledge the presence of the examiner and does make eye contact on occasion. His psychomotor activity is remarkable for fairly constant stereotyped hand movements and occasionally some vocalizations. Harrison takes a piece of paper from his mother when he sees it, and proceeds to flick it in front of his eyes and to tear small strips from it and place them in his mouth. He readily surrendered these bits of paper upon request. Harrison's affect was full with very clear and bright smiles, especially when interacting with his mother. Later during the visit, he seemed to become more agitated and would occasionally place his hand to his mouth in a self-biting gesture or place his face into the palm of his hand while vocalizing and rocking. Harrison followed simple requests and was able to sign "thank you" after having been given some crackers from the staff who accompanied him.

When Harrison's mother was given a description of bipolar disorder she quite readily recalled all of those symptoms in her older brother, reporting, for example, that he had periods of elevated mood noteworthy for reckless and impulsive behaviors. At other times he would withdraw, become more aloof, and had expressed suicidal thoughts at various times.

Lithium was subsequently initiated, and resulted in a significant improvement in Harrison's irritability, sleep disturbance, and hyperactivity. He remains on a relatively low dose of carbamazepine for control of his epilepsy. His antipsychotic is gradually being tapered toward discontinuation.

Profound Intellectual Disability. Profound intellectual disability affects relatively few individuals (1 to 2 percent) with ID, and involves pervasive deficits in cognitive, motor, and communicative functioning. Impairments in sensory-motor functioning are often seen from early childhood on, and most individuals require extensive training to complete even the most rudimentary aspects of self-care such as eating and toileting. The vast majority of people with profound intellectual disability have identifiable organic causes for their delay, and most require total supervision and care throughout life.

Annalise was born following a pregnancy that was unremarkable—her mother's first. There were significant feeding difficulties in the first few weeks of life, and failure to thrive was considered early on. Annalise was quite hypotonic and her milestones were delayed. She did

not walk until approximately 4 years of age. While she was enrolled in an early intervention program, Annalise's progress was variable and she never used spoken language. She has and uses a few signs to make her needs known, and more recently has begun to use an assistive communication device. Her family reports that Annalise's medical history is extraordinarily complicated. Approximately 2 years ago, Annalise had a life-threatening episode of congestive heart failure requiring intubation and aggressive treatment that now includes a beta-blocker, a diuretic and digitalis.

At that time, it was discovered that Annalise had hypothyroidism, so she has also required thyroid supplementation. Approximately a year ago, the diagnosis of diabetes was made and Annalise is insulin dependent. Her family also reported significant problems with what appears to have been a milk allergy, and wonder whether that may have contributed to some of Annalise's difficulties in gaining weight in her early years. However, when Annalise was approximately 4 or 5 years of age, she began to become completely preoccupied with food, consuming everything in sight, with a particular preference for carbohydrates. Genetic testing for PWS was negative, but subsequent testing revealed a deletion on chromosome 1.

Annalise's history is remarkable for her never having been particularly attentive to the thoughts or feelings of others, literally walking over other children when she was able to do so. The family reports that Annalise has many circumscribed interests, including particular vignettes from Disney videos, which, if she were allowed, she would view repeatedly. She also has had a preoccupation with sorting and stacking objects, and at one point would tantrum if she weren't able to organize stones or pebbles at the local beach. When Annalise was 6 years of age, a methylphenidate trial was initiated. The dose was pushed up to 5 mg three times daily (she was unable to swallow a sustained release capsule intact) and her family reports that over the course of the year that Annalise received that drug, she was less emotionally available and seemed to be more ritual-bound and preoccupied with her limited interests. The family has not observed prominent stereotypic behaviors, merely the preoccupation with objects and with sorting and arranging. Because of Annalise's preoccupation with food, the family has had to lock their refrigerator and cabinets. Her family hopes that medication may help to allay some of Annalise's anxiety and obsessionality that continue to present significant barriers for her full participation in activities, particularly in the community.

These four levels—mild, moderate, severe, and profound—have long-been used to classify severity of intellectual disability, yet have come under attack because of their focus on deficits instead of competencies. How people with intellectual disability are defined and classified—based on strengths, impairments, or some combination of both—has profound implications for studies on the epidemiology of this condition.

PREVALENCE

According to DSM-5, 1 percent of the population has intellectual disability. Indeed, a meta-analysis of 52 peer-reviewed papers has estimated the global prevalence of ID to be 1,037 per 100,000 population. Rates are higher in males. A recent epidemiological study based on a national register in Sweden found that the prevalence of ID in older adults is increasing as a result of medical and social advances, and that approximately 0.5 percent of the population above 55 years of age has ID.

Etiology of Intellectual Disability

As noted by Esquirol in 1845, intellectual disability is not a disease in and of itself, but the developmental consequence of a variety of pathogenic

processes. Intellectual disability results from brain dysfunction, generally due to abnormal brain development or brain injury resulting from genetic and environmental causes (Table 40–5). Many genetic causes of intellectual disability have been known for decades, while modern genetic techniques have identified hundreds of new causes of intellectual disability.

Genetic causes of intellectual disability can result in multiple malformation conditions (e.g., Down syndrome) or what appears to be "non-syndromic" intellectual disability. That said, most genetic causes of intellectual disability are associated with characteristic clinical or neurobehavioral features, if the patients are examined thoroughly. Genetic disorders with intellectual disability display a wide variety of inheritance patterns and genetic mechanisms including chromosome rearrangements (often de novo), autosomal recessive, autosomal dominant (inherited and de novo), X-linked, triplet repeat expansion, and imprinting. The important role for de novo mutations has only recently been appreciated. Knowledge of these genetic mechanisms can aid with diagnosis and is essential for recurrence risk counseling. More and more, the genetic diagnosis influences treatments to implement (e.g., specific melatonin/propranolol treatment for sleep disruption in patients with Smith–Magenis syndrome) and treatments to avoid (e.g., valproate in ornithine transcarbamylase deficiency). In addition, some disorders are associated with health implications for family members (e.g., Fragile X–associated tremor/ataxia syndrome and premature ovarian failure in adult relatives of individuals with Fragile X).

With advances in medicine generally and in molecular genetics in particular, new causes of intellectual disability, or the genetic etiologies of formerly unspecified syndromes, are identified each year. For example, a national database of genetic disorders, *Online Mendelian Inheritance in Man,* lists >2,500 genetic conditions associated with intellectual disability. The most common causes of intellectual disability include Down syndrome, Fragile X syndrome, prematurity, and fetal alcohol syndrome. Variability in patient cohorts and methods for defining etiologies make it difficult to estimate the proportion of patients accounted for by each cause. For example, persons drawn from institutional settings, where severe and profound intellectual disability and visible congenital anomalies are more likely to be found, more commonly have an identifiable chromosomal abnormality than do persons with mild disability residing in community settings.

Table 40–5.
Etiological Classification of Intellectual Disability

Etiology	Examples	Estimated Frequency (%)

A. Prenatal Causes		
1. Genetic disorders		4–28
Chromosomal aberrations	Down syndrome	
Monogenic mutations	Tuberous sclerosis; phenylketonuria and other metabolic disorders; fragile X syndrome	
Multifactorial	"Familial" mental retardation	
Malformation syndromes due to microdeletions	Prader–Willi, Williams, Angelman syndromes	
2. Congenital malformations		7–17
Malformations of the central nervous system	Neural tube defects	
Multiple malformation syndromes	Cornelia de Lange syndrome	
3. Exposure		5–13
Maternal infections	Congenital rubella, HIV	
Teratogens	Fetal alcohol syndrome	
Toxemia/placental insufficiency	Prematurity	
Other	Radiation, trauma	
B. Perinatal Causes		2–10
1. Infections	Meningitis	
2. Delivery problems	Asphyxia	
3. Other	Hyperbilirubinemia	
B. Postnatal Causes		3–12
1. Infections	Encephalitis	
2. Toxins	Lead poisoning	
3. Other postnatal causes	Traumas, brain tumors	
4. Psychosocial problems	Poverty, psychotic illness	
D. Unknown Causes		30–50

Understanding the cause of intellectual disability in an individual person is essential for providing prognostic information, guiding treatment, and educating families about recurrence risk. For instance, distinguishing between a one-time injury such as hypoxia and a genetic neurodegenerative disorder such as a lysosomal storage disorder makes a huge difference in treatment, emotional impact on the family, how they plan their child's life, and how they approach having additional children. A specific diagnosis can also reduce family stress by providing an "answer" for why their child has a significant disability and allowing them to connect with other families affected by the same condition. More and more, an accurate diagnosis will guide more appropriate treatments to maximize neurocognitive function, prevent decline, and direct specific medical screenings or treatments that optimize the patient's health and adaptive function.

In the era of rapidly expanding molecular genetic diagnosis, each provider must decide how to manage the explosion in genetic information and the impact on diagnosis and treatment based on their level of interest, educational background, and access to other subspecialists. At a minimum, psychiatric providers need to know when to suspect an underlying genetic condition and how to ensure adequate evaluation and management (through reference materials and/or consultants). For instance, ornithine transcarbamylase deficiency results from a defect in the urea cycle that can cause encephalopathy due to elevated ammonia levels. Patients can present at any age, and the best way to improve behavioral issues in a patient with undiagnosed or inadequately treated ornithine transcarbamylase deficiency, is to recognize the possibility of the condition, diagnose it using biochemical (plasma ammonia level) and genetic testing (*OTC* gene sequencing), and provide dietary and medication treatment to lower ammonia levels and maintain nutrition. Valproate, haloperidol and other medications should also be avoided, since they have been associated with hyperammonemic crises in these patients. Indeed, the decompensation associated with administration of these medications in an undiagnosed patient can prompt workup and accurate diagnosis of ornithine transcarbamylase deficiency by the vigilant psychiatrist. Genetic diagnosis is now directly influencing treatment choices in a variety of diseases, most prominently cancer, and it is only a matter of time before gene-specific treatments become widespread in psychiatry.

Medical Diagnostic Approach to the Patient with Intellectual Disability

Clinical History and Examination. The elements of a comprehensive clinical evaluation for the patient with intellectual disability are summarized in Table 40–6. As for any patient, a good history is essential, and in many cases collateral information is extremely useful. Family members may be able to fill in important aspects of the family pedigree, providing information about relatives ranging from learning problems to physical anomalies, developmental disabilities, and even response to treatment.

The clinical examination should be performed with particular attention to the presence of minor anomalies, aberrant growth, and physical development (Table 40–6). Increasingly, the examination will look for behavioral symptoms that may comport with a known behavioral phenotype (see later discussion) and help in diagnosis.

Genetic Evaluation. Given the incredible advances in DNA sequencing technologies and other methods for identifying mutations across the entire human genome, clinical genetic testing in patients with intellectual disability is very much a moving target. Currently, patients without an obvious syndrome or extrinsic cause should be evaluated for chromosomal

abnormalities and Fragile X (by chromosomal microarray and Fragile X repeat length testing respectively), since these are the most common causes of "nonsyndromic" intellectual disability. Genetic disorders should still be considered in patients who do not follow the expected course for a presumed environmental cause. Unless a specific aneuploidy (such as Trisomy 21) or a balanced translocation is suspected, a karyotype is no longer the appropriate test when chromosome microarray is available. Beyond these basic tests, expert clinical genetics consultation may be the most cost-effective next step, rather than extensive laboratory testing and imaging. Genetic consultation can help guide diagnostic testing as well as providing counseling about prognosis, surveillance for complications, and recurrence risk.

Table 40–6.
Elements of the Clinical Evaluation of the Patient with Intellectual Disability

Clinical History
Prenatal exposures (alcohol, infections, etc.)
Birth history
CNS infection, traumatic brain injury
Developmental regression
Focal neurological findings, hypertonia, hypotonia, or ataxia
Extra-CNS malformations and medical issues
Visual impairment or hearing loss
Family Pedigree (Three-Generation)
Relatives with learning problems, psychiatric disorders, intellectual disability, abnormal brain imaging findings, neurological or degenerative disorders
Consanguinity
Family resemblance (reduced between family members with and without some genetic conditions)
Physical Examination
Assessment of major and minor physical anomalies including facial features and skin findings
Growth and physical development
Head circumference compared to norms (congenital versus "acquired" microcephaly/macrocephaly)
Growth trajectory (comparison with earlier measures)
Description of facial features (micrognathia, hypertelorism, thin upper lip)
Complete neurological examination
Skin examination for café-au-lait and other birthmarks
Documentation of behavioral phenotype
Adjunct Diagnostics
Hearing evaluation
Ophthalmology evaluation of eye structure, eye movements, and visual function
Psychometric assessments
Laboratory Testing (When Indicated)
Creatine kinase (to evaluate for muscular dystrophies)
7-dehydrocholesterol testing if Smith–Lemli–Opitz syndrome is suspected
Metabolic studies for lysosomal, peroxisomal, and mitochondrial disorders
Urine organic acids, plasma amino acids
Congenital disorders of glycosylation testing
Genetic Testing (When Indicated)
Chromosomal microarray

Fragile X testing
DNA sequencing (single gene, gene panel, whole exome)
DNA methylation testing if Prader–Willi or Angelman syndromes are suspected
Imaging
Structural brain magnetic resonance imaging [MRI]
Functional brain MRI [fMRI] (still largely research-based)
Diffusion tensor brain MRI [DTI]
Other Studies
Muscle biopsy for suspected mitochondrial disease (or muscular dystrophy)

When a specific disorder is suspected, a single gene test may be the best option; however, as genetic testing becomes more widely available, the spectrum of presentations associated with each gene has broadened, so it can be difficult to determine which single gene test to perform. Fortuitously, DNA sequencing has become much more efficient, so panels of genes, or even most of the coding regions in the entire genome (the "exome"), can now be sequenced in a single test. As the cost of sequencing decreased and human sequence variation becomes better characterized, genome-wide sequencing methods will become first-line genetic tests, despite the challenges with interpreting the significance of many DNA variants. It is important to remember that currently available sequencing tests do not detect repeat expansions or imprinting disorders.

Neuroimaging. Neuroimaging is clinically indicated for individuals with intellectual disability in the presence of microcephaly or macrocephaly, abnormal head circumference, seizures, focal neurological signs, and/or progressive cognitive impairment or loss of psychomotor skills. MRI is generally superior to CT unless acute hemorrhage or calcification are suspected. MRI has been useful in elucidating a diagnosis in around 5 percent of people with non-progressive intellectual disability. More commonly, in ~50 percent of patients, subtle and nonspecific structural findings indicating altered neurodevelopment are present such as ventriculomegaly, dysplasia of the corpus callosum, minor abnormalities of white matter signal, cortical gyration, and cerebellar vermis. The American Academies of Neurology and Pediatrics and the American College of Medical Genetics periodically publish updated practice guidelines for the use of brain imaging in the evaluation of patients with intellectual disability. Magnetic resonance spectroscopy is lower-yield and less commonly employed, although it can yield a diagnosis when a metabolic disorder is suspected despite otherwise normal genetic and metabolic work-up. Diffusion tensor imaging holds promise for identifying disorders associated with defects in major axon pathways that do not affect brain morphology; however, it is not yet in wide clinical use. To date, large studies utilizing structural MRI or quantitative methods such as those performed in ADHD or autism have not been performed in intellectual disability, and little has been done in the way of functional MRI (fMRI)

research. Advanced imaging techniques may serve to better elucidate the neurobiology of intellectual disability, resulting in improved diagnostic precision and treatment monitoring in the future.

Electroencephalography. Electroencephalographic investigations, such as waking/sleep video-EEG-polygraphic studies may be useful in patients with a clinical history of seizures and those with severe language deficits and/or specific genetic syndromes such as Angelman syndrome. EEGs are often requested in patients with known cortical malformations associated with high seizure risk (e.g., polymicrogyria) when acute behavioral or cognitive changes have occurred.

Metabolic Testing

EVALUATION FOR INBORN ERRORS OF METABOLISM. The Inborn Errors of Metabolism (IEMs) or biochemical genetic conditions are a large and fast growing group of disorders that are for the most part individually quite rare, but collectively affect 1 to 1.5 percent of the population. These disorders originate from disruptions to genes involved in biochemical and metabolic pathways, many of which are important in brain development and/or function. Generally, symptoms and findings arise from either the accumulation of substances that prove toxic in excess or the inability to synthesize enough of a required product. Well-known IEMs causing intellectual disability include phenylketonuria (PKU), Lesch–Nyhan syndrome, and the Lysosomal and Glycogen Storage diseases. It is important for the practicing clinician to retain the IEMs in the differential diagnosis, since many require specialized treatment to prevent morbidity, progression, and mortality, as well as to optimize development. Frequently, treatment involves supplementation with a deficient enzyme or metabolic intermediate with or without dietary restriction. It should be noted that each IEM may have variant ages of onset such as “infantile,” “juvenile,” or “adult” forms, with concomitantly different mixes of medical and neuropsychiatric symptoms. Later onset forms may manifest in less medically severe findings and a presentation more dominated by neuropsychiatric symptoms. Specific features in each disorder vary, but the child psychiatrist should consider the IEMs in the differential diagnosis of every individual with intellectual disability.

While guidelines published by the American Academies of Pediatrics and Neurology do not recommend routine metabolic testing for all persons with intellectual disability, several studies suggest that IEMs may account for up to 2.5 percent of patients after screening by clinicians. More recent studies have shown that even after broad-based metabolic screening, a second line of testing identified IEMs in 14 percent of patients, many of which were treatable. A careful history should be taken to make sure the

patient received usual newborn screening tests (particularly in the case of immigrants or where the patient lacked usual perinatal care) and whether the testing followed current recommendations (especially in older individuals). IEMs should be particularly considered in the patient with intellectual disability who presents with catatonia, mania, seizures, encephalopathy, and/or visual hallucinations, when symptoms appear exacerbated by physiological stress and illness, occur with abdominal pain or vomiting, or functional regression (Table 40–7).

The authors recommend the following screening labs for patients with intellectual disability when an IEM is suspected: complete blood count, complete metabolic panel (electrolytes, BUN, creatinine, glucose, transaminases), lactate, pyruvate, urine organic acids, plasma amino acids, ammonia, plasma acylcarnitines, and total and free carnitine. Testing during a symptom exacerbation is recommended, since assays may be normal during periods of relative metabolic stability. Referral to a specialist biochemical geneticist is also recommended for evaluation and/or management.

GENETIC INTELLECTUAL DISABILITY SYNDROMES AND BEHAVIORAL PHENOTYPES

Remarkable genetic advances have sparked renewed research interest in the behavioral features of persons with fragile X, Prader–Willi, and other genetic syndromes. In their reviews in the 1970s of behavioral aspects of chromosomal disorders, S. Kessler and R. Moos, for example, discussed only five syndromes. Since that time, the number of disorders for which a "behavioral phenotype" has been suggested has grown considerably. A good working definition of a "behavioral phenotype" is that proposed by Dykens, namely, that of a syndrome in which the probability of the expression of certain behaviors or constellations of behaviors is greater than what would otherwise be expected. Stereotyped hand movements, for example, have been described in many contexts, but a particular form of stereotyped hand wringing is almost invariably seen in Rett syndrome. Hyperphagia and obesity are nonspecific symptoms, but without aggressive dietary intervention, the probability of an individual with PWS becoming obese is nearly 100 percent.

Table 40–7.
Selected Clinical Findings and Laboratory Abnormalities Which Increase Suspicion for Underlying Metabolic Disorder

Growth abnormality
Recurrent, unexplained illness
Exacerbation of symptoms by physiological stress
Seizures
Ataxia

Loss of psychomotor skills
Hypotonia
"Coarse" appearance
Eye abnormalities (cataracts, ophthalmoplegia, corneal clouding, retinal abnormality)
Recurrent somnolence/coma
Abnormal sexual differentiation
Arachnodactyly
Hepatosplenomegaly
Metabolic/lactic acidosis
Hyperuricemia
Hyperammonemia
Low cholesterol
Structural hair abnormalities
Unexplained deafness
Bone abnormalities (dysostosis; occipital horns; punctate calcifications)
Skin abnormalities (angiokeratoma; "orange-peel" skin, ichthyosis)
Brain imaging abnormalities cortical and/or cerebellar atrophy, evidence of stroke, abnormal white matter signal, lactate peak on MRS

Adapted from Curry CJ, Stevenson RE, Aughton D, Byrne J, Carey JC. Evaluation of mental retardation: recommendations of a consensus conference. *Am J Med Genet*. 1997;72:468.

Table 40–8provides a representative sample of syndromes for which behavioral phenotypes have been described—some anecdotally, others with controlled studies. Although the study of behavioral phenotypes is only at its beginning stages, this line of work holds much promise for both clinicians and researchers. Identifying syndrome-specific behavioral patterns helps clinicians to zero in on some diagnostic possibilities over others, and these behavioral profiles also guide intervention and treatment. From a research standpoint, phenotypic work advances the understanding of gene–brain–behavior relationships. To illustrate these advantages, the following subsections review behavioral and genetic features for fragile X, Prader–Willi, Down, and Williams syndromes. Although not representative of all syndromes, these examples amply demonstrate the promise of phenotypic research for both intervention and science.

Examples of Behavioral Phenotypes in Intellectual Disability Syndromes

Fragile X Syndrome. Fragile X syndrome, the most common inherited cause of intellectual disability, results in a wide range of learning and behavioral problems, with males being more often and more severely affected than females. The fragile X gene (*FMR1*) represents a relatively newly identified type of human disease, caused by an amplification (or excessive repetition) of trinucleotide sequences (CGG) that make up DNA. Greater than a certain threshold number of these triplet repeats (about 200), people are fully affected with the syndrome. Numbers of repeats between the normal threshold of 50 and less than 200 are termed "premutations." As many as 1 in 259 women in the general population may carry the premutation, with 1 in 4,000 males and 1 in 8,000 females being

fully affected with the syndrome.

Table 40–8.
Phenotypes of Selected Conditions Associated with Intellectual Disability

As genetic testing has become more widespread, the known clinical presentation for each genetic disorder has expanded beyond the classic presentations described in the early literature. More and more, disorders are being grouped by their shared molecular pathophysiology, e.g., Cornelia de Lange syndrome as a cohesinopathy (defects in the cohesion DNA-binding complex involved in DNA repair, chromosome segregation, and gene regulation) and Neurofibromatosis 1 as a RASopathy (defects in the RAS/MAPK network of genes involved in cell cycle regulation and differentiation).

Disorder	Cause	Inheritance	Prevalence[a]	Recurrence Risk	Testing
Chromosomal					
Cri-du-chat syndrome	5p15.2 deletion	Dominant deletion (usually de novo)	1/20,000–50,000	Very low	Chromoson microarr
Down syndrome	Trisomy 21	Sporadic	1/2,500–1/32 births based on maternal age	Low, unless due to translocation	Karyotype
Smith–Magenis syndrome	17p11.2 deletion	Dominant deletion (usually de novo)	1/25,000	Very low	Chromoson microarr

22q11 Deletion syndrome (Velocardiofacial/ DiGeorge)	22q11 deletion	Dominant deletion (de novo or inherited)	1/4,000	Low if de novo, up to 50% if parent affected	Chromoson microarr
Williams syndrome	7q11–23 deletion	Dominant deletion (usually de novo)	1/7,500	Low if de novo, up to 50% if parent affected	Chromoson microarr
Single gene					
Fragile X syndrome	*FMR1* trinucleotide repeat expansion	X-linked with anticipation	1/4,000 males, 1/8,000 females	Up to 50%	FXS testing length
Rett syndrome	Altered gene expression due to loss of *MECP2* function	X-linked, 99% de novo	1/8,500 females (rare in males)	Low	*MECP2* gen sequenci

Cornelia de Lange syndrome (Cohesinopathy)	*NIPBL, SMC1A, SMC3, RAD21, HDAC8*		1/40,000–100,000		Panel seque exome
Tuberous sclerosis complex 1 and 2	Loss of *TSC1* or *TSC2* function	Autosomal dominant	1/10,000		*TSC1*/*TSC2* sequenci
Neurofibromatosis type[a] (RASopathy)	Loss of *NF1* function	Autosomal dominant (de novo or inherited)	1/2,500–4,000	Low if de novo, 50% if parent affected	*NF1* sequer
Imprinting					
Prader–Willi syndrome (PWS)	Lack of paternal-specific imprinting of 15q11.2-q13	Imprinting (90% sporadic)	1/10,000–30,000	Low, except with paternal mutation	PWS/AS me testing

Angelman syndrome (AS)	Loss of *UBE3A* function via mutation or lack of maternal-specific imprinting of 15q11.2-q13	Imprinting (90% sporadic)	1/12,000–24,000	Low, except with maternal mutation	PWS/AS me testing a sequenci
Metabolic					
Smith–Lemli–Opitz	Loss of *DHCR7* function, defect in cholesterol metabolism	Autosomal recessive	1/20,000–40,000	25%	7-dehydroc level, *DH* sequenci
Phenylketonuria (prototypical biochemical genetic disorder)	Accumulation of phenylalanine	Autosomal recessive	1/10,000	25%	Newborn s plasma a
Mitochondrial	Defects in electron transport chain	Autosomal recessive,	1/5,000	Up to 25%	Lactate, py plasma a

		autosomal dominant, X-linked or maternal			acids, MI biopsy
Lesch–Nyhan syndrome	Loss of *HPRT1* function, accumulation of uric acid	X-linked	1/380,000	50% of sons	Urine urate 24-hr uri *HPRT1* se
Ornithine Transcarbamylase Deficiency	Loss of *OTC* function and ammonia accumulation	X-linked	1/14,000–77,000	Carrier mothers: 50% of sons; Affected fathers: 50% of daughters are carriers	Ammonia le sequenci
Lysosomal storage diseases (diverse group of >50 disorders)	Accumulation of various macromolecules	Autosomal recessive, X-linked	1/5,000–10,000	25%	Enzymatic a sequenci
Toxin					
Fetal alcohol syndrome	Alcohol neurotoxicity	NA	1/3,000 in western countries, 1/300 with fetal alcohol effects	NA	Clinical diag

[a]Estimated prevalence in mixed European populations.

ADHD, attention-deficit/hyperactivity disorder; ID, Intellectual Disability; IQ Intelligence Quotient.

Many of the behavioral features in people with fragile X syndrome are a function of the number of CGG repeats and a cascade of subsequent effects. The number of repeats relates to the degree that the *FMR1* gene is methylated and subsequently silenced, or blocked from transcription and

translation. This, in turn, affects the amount of *FMR1* protein (FMRP) produced, and the range of clinical expression in fragile X syndrome is associated with the amount of FMRP. Fully affected, fully methylated males have no FMRP, whereas high-functioning males, although rare, have some FMRP. In affected females, only one X chromosome carries the *FMR1* gene, whereas the other produces some FMRP. Because all females have one X chromosome that is randomly inactivated in all cells, the degree of involvement in females with fragile X is related to the ratio of normally active X chromosomes to the total active plus inactive X chromosomes. About half of fully affected females thus show mild to moderate intellectual disability, whereas half have average IQ but show learning difficulties and/or social affective impairments. Both males and females with the full syndrome exhibit similar neurocognitive profiles, including deficits in auditory short-term memory, processing of sequential information, and attention, with relative strengths in processing simultaneous information, long-term memory, and distinguishing between one's own and others' representations of the world.

Although fragile X syndrome is a genetic disorder, there is also evidence for environmental contributors to IQ and other specific neurocognitive deficits, including factors relating to the home environment (enrichment opportunities and socioeconomic status). All of these factors taken together —gender, variation in the *FMR1* repeats, and environment—contribute to the significant within-syndrome variability found in fragile X syndrome.

Fragile X Syndrome and Autism. It has been reported that many fully affected males with fragile X syndrome show autistic-like symptoms such as language delay, echolalia, stereotypies, self-injurious behavior, perseveration, poor eye contact, and tactile defensiveness. It is not surprising that early workers wondered whether fragile X syndrome would reveal a common genetic cause of autism.

This flurry of research faded as new studies emerged suggesting that instead of autism per se, many males with fragile X syndrome showed a willingness to interact with others coupled with social and performance anxiety and mutual gaze aversion. Controlled studies and meta-analyses now suggest that only about 5 percent of males with fragile X syndrome have autistic disorder. Instead, the majority of affected males can be placed on a spectrum of social anxiety, shyness, avoidance, and gaze aversion. Although some of these boys have anxiety disorders or autism features, others may simply show slow-to-warm temperament styles, including shyness or social withdrawal.

In addition to these difficulties, hyperarousal, hyperactivity, and attention deficits are seen in the vast majority of boys and girls with fragile X syndrome. Attention-deficit/hyperactivity disorder (ADHD) symptoms are higher among affected boys relative to control subjects, and girls with

fragile X syndrome have lower prevalence rates of ADHD than boys with fragile X syndrome. Among adults, problems in attending and in sustaining effort have been found in the neuropsychological profiles of women with expanded *FMR1* repeats, which may contribute to problems in math, abstract reasoning, and planning.

Fragile X syndrome thus involves vulnerabilities toward shyness, gaze aversion, social anxiety, avoidant disorders, schizotypal disorder, ADHD, PDD-NOS, and, more rarely, autistic disorder. These difficulties vary in severity but are typically found in persons across the IQ spectrum, from those with moderate intellectual disability to those with mild learning disabilities.

Individuals with premutation repeat lengths (typically family members of affected individuals) are also at risk for psychiatric and medical issues including social dysfunction, primarily shyness, gaze aversion, and social anxiety and the adult-onset fragile X–associated tremor/ataxia syndrome (FXTAS). FXTAS is characterized by progressive intention tremor and gait ataxia, with associated dementia and global brain atrophy resulting in significant morbidity and mortality.

Prader–Willi Syndrome. First identified in 1956, PWS affects about 1 in 15,000 births and is best known for its food-related characteristics. Whereas babies with PWS invariably show hypotonia and pronounced feeding-sucking difficulties, young children between 2 and 6 years of age develop hyperphagia and food-seeking behavior such as food foraging and hoarding. Hyperphagia is likely associated with a hypothalamic abnormality resulting in a lack of satiety. Food preoccupations are lifelong, and without prolonged dietary management, affected individuals invariably become obese. Indeed, complications of obesity remain the leading cause of death in this syndrome.

PWS is the first known human disease to show the effects of genomic imprinting, in which genes are modified and expressed differently depending on whether they are inherited from the mother or the father. About 70 percent of PWS cases are caused by a paternally derived deletion on the long arm of chromosome 15. Remaining cases are attributed to maternal uniparental disomy (UPD) of chromosome 15, in which both members of the chromosome 15 pair come from the mother. In either case, there is absence of the paternally derived contribution to this specific region of the genome. When missing information in this same region of chromosome 15 is maternally derived, it results in a completely different and more severe developmental disorder, Angelman syndrome.

Although people with PWS invariably obsess about food, a remarkably high proportion of persons also show nonfood obsessions and compulsive behaviors. These nonfood symptoms include skin picking, hoarding, needing to tell, ask, or say things, and having concerns with symmetry,

exactness, ordering, arranging, cleanliness, and sameness in daily routine. Often these symptoms are associated with distress or adaptive impairment, suggesting marked risks of obsessive-compulsive disorder in this population. Indeed, obsessive-compulsive disorder is many more times likely in people with PWS than in the general population of people with intellectual disability.

In addition, even as compared to others with intellectual disability, children and adults with PWS show high rates of temper tantrums, aggression, stubbornness, underactivity, excessive daytime sleepiness, and emotional lability. Coupled with food seeking, these impulsive behaviors often lead people with PWS to need more restrictive levels of care than would be predicted by their mild levels of intellectual disability.

Psychopathology and cognitive profiles may be associated with an individual's genetic variant of PWS. Thus, research has shown behavioral differences between PWS due to paternal deletion and maternal UPD. Cases with deletions may show lower IQ, especially verbal IQ, and more frequent or severe problem behaviors, such as skin picking, hoarding, temper tantrums, overeating, and social withdrawal. Although a dampening of symptom severity is suggested in many UPD cases, there are occasional cases of more severe problems in UPD, primarily autistic-like features and relatively low IQ. In addition, persons with UPD may do better than their counterparts with deletions on verbal tasks but more poorly on visual-spatial tasks, including solving jigsaw puzzles. Indeed, although many persons with PWS are remarkably skilled in solving puzzles, this unusual strength seems to be limited to those with paternal deletions. The mechanisms that explain such differences in maladaptive behavior and cognition across genetic subtypes are unknown.

Many people with PWS, then, are at increased risk for obsessive-compulsive, impulse control, and affective disorders. Yet even those who do not meet diagnostic criteria for these psychiatric disorders often show significant maladaptive behaviors that interfere with optimal adaptive functioning.

Down Syndrome. Occurring in approximately 1.2 in 1,000 live births, Down syndrome (DS) is the most common chromosomal abnormality leading to intellectual disability. It is most often the result of nondisjunction of chromosome 21. The syndrome has been the subject of considerable investigation.

More than 80 clinical features characterize the phenotype of DS, including cognitive impairments, hypotonia, facial dysmorphisms, congenital heart disease, and other anomalies. Studies of children with DS have shown distinctive cognitive and linguistic profiles. Notable strengths have been highlighted in visual versus auditory processing. Language impairment can be extensive, with particular difficulty in expressive

language, grammar, and pronunciation.

In contrast to the relative overall weakness in the cognitive arena, persons with DS are often described as being particularly socially adept. However, studies of adaptive functioning suggest that these skills are not uniform, with communication scores trailing behind measures of daily living skills and socialization. The stereotype of a "Down personality" as being happy, good-tempered, affectionate, placid, and stubborn has been difficult to verify.

Compared to others with intellectual disability, persons with DS appear to suffer less often and less seriously from psychopathology. Adults with DS appear to be somewhat less prone to psychiatric disturbance than controls. This trend seems to extend to children and adolescents as well, in whom rates of psychiatric and behavioral problems are greater than in the general population but appreciably less than in other groups with intellectual disability. Commonly noted problems include difficulties with attention, impulsivity, hyperactivity, and aggression. In contrast to these problems, depression seems to be less common among children and adolescents than expected norms, although some youth appear to become increasingly withdrawn in their adolescent years. For many, this shift toward increased withdrawal seems gradual and subtle, and it may be an early harbinger of a later onset of depression or dementia in the adult years. Autism and pervasive developmental disorders appear to be relatively rare.

Williams Syndrome. First identified in 1961, Williams syndrome is caused by a microdeletion on chromosome 7 that includes the gene for elastin, a protein that provides strength and elasticity to certain tissues such as the heart, skin, blood vessels, and lungs. The condition affects 1 in 7,500 individuals, and persons with Williams syndrome often show hyperacusis, hypercalcemia, neuromusculoskeletal and renal abnormalities, and characteristic facial features described as elfin-like, cute, and appealing. People with Williams syndrome also typically show cardiovascular disease, especially supravalvular aortic stenosis, and these problems are likely associated with elastin insufficiency.

Apart from these medical issues, recent attention has focused on the interesting, possibly unique, cognitive-linguistic profile shown by many persons with this syndrome. Children with Williams syndrome show relative strengths in verbal short-term memory and language. Indeed, for many years it was thought that these children might even perform at chronological-age levels on a variety of linguistic tasks. Although age-appropriate performance in language has now been found in only small percentages of children with Williams syndrome, these children nevertheless show relative strengths in language, as well as in auditory processing and in some areas of music.

In contrast, many children with Williams syndrome perform especially

poorly on a variety of visuospatial tasks. Mervis and her colleagues found that 47 of 50 children with Williams syndrome showed the pattern of weakness in visuospatial tasks and a relative strength in various measures of language (vocabulary, grammar, and short-term auditory memory). Although not every child with Williams syndrome shows linguistic strengths and visuospatial weaknesses, the large majority present with such a pattern.

Studies have yet to fully examine the personality or psychiatric features of people with Williams syndrome. Early descriptions of people with Williams syndrome hinted at a "classic" Williams syndrome personality, described as pleasant, unusually friendly, affectionate, loquacious, engaging, and interpersonally sensitive and charming. Such qualities may change over the course of development, with adults being more withdrawn and less overly friendly than children.

Use of the Reiss Personality Profiles has shown that, relative to controls, adolescents and adults with Williams syndrome are more likely to initiate interactions with others (87 percent of sample), to enjoy social activities (83 percent), to be kind-spirited (100 percent) and caring (94 percent), and to empathize with others' positive feelings (75 percent) or when others are in pain (87 percent). At the same time, however, these subjects did not fare well in making or keeping friends and were often dangerously indiscriminate in their relating to others. Indeed, although sociability in Williams syndrome has generally been viewed as a strength, these features also seem to reflect the type of social disinhibition that is characteristic of people who are anxious, impulsive, and overly aroused. It is not surprising that salient problems in Williams syndrome include hyperactivity, inattentiveness, and a proneness for ADHD, which may diminish with age.

Recently, attention has begun to focus on anxieties and fears in this population. Generalized anxiety, worry, and perseverative thinking are commonly seen in Williams syndrome, and people with the syndrome appear to show unusually high levels of fears and phobias. Relative to suitably matched controls, fears in persons with Williams syndrome are more frequent, wider ranging, and more severe, and they may also be associated with impaired social-adaptive adjustment. In one study, Dykens compared fears in 120 people with Williams syndrome (age 6 to 48 years) to those with intellectual disability of mixed etiologies. Only two fears—getting a vaccination shot and going to the dentist—were mentioned by more than 50 percent of the group with mixed causes of intellectual disability. In contrast, 50 different fears were mentioned by more than 60 percent of subjects with Williams syndromes. Such fears ran the gamut. Some involved interpersonal issues like being teased, getting punished, or getting into arguments with others. Others involved such physical issues as getting injections, being in a fire or getting burned, or getting stung by a bee. Still others related to these children's hyperacusis or clumsiness (loud

noises such as sirens; falling from high places; thunderstorms). Thus, although not every person with Williams syndrome shows any or all of these fears, the vast majority do appear to be overly fearful compared to most others with intellectual disability.

Smith–Magenis Syndrome

Bryan was a 19-year-old young man with moderate intellectual disability and a history of psychiatric issues including impulsivity, aggressive behaviors, and a striking history of self-injurious behaviors such as self-hitting, skin-picking and pulling out fingernails and toenails. He had been given a diagnosis of autism. Bryan had restricted language abilities but got his basic needs met using a small set of phrases and gestures, though his speech was hard to understand and muffled. He lived at home among a devoted family including his parents and elder brother, and participated in a transitional school program, where he was segregated in a classroom for children deemed "lower functioning" with "behavioral needs." Bryan and his parents visited clinic with the aim of finding a better medication regimen that might be able to support his adaptive functioning, articulating their "dream" that their son might one day live independently or participate more easily in social activities.

At evaluation, Bryan's medication regimen consisted of extended-release dexmethylphenidate, trazodone, buspirone, risperidone, and sertraline, with as-needed lorazepam and additional risperidone for agitation and aggression. These medications were not fully controlling his psychiatric symptoms. A careful history was taken which elicited a history of infantile feeding difficulties, hypotonia and failure to thrive, and a striking pattern of lifelong sleep disturbance. Bryan fell asleep successfully, but woke every night around 2 to 3 a.m., did not go back to sleep, and was sleepy in the afternoons. He was noted to have somewhat heavy and coarse features with brachycephaly and prognathism. Accordingly, first line genetic testing for intellectual disability consisting of chromosome array and Fragile X was sent, revealing a 3.5-Mb interstitial deletion of chromosome 17p11.2, consistent with a diagnosis of Smith–Magenis Syndrome (SMS). SMS is a genetic syndrome with a prevalence of 1:15,000–1:25,000, with disruptions to the *RAI1* gene (located within the deletion) accounting for the majority of features. A number of important studies support the presence of distinctive disruption to melatonergic control of the sleep cycle in SMS and the use of melatonin and beta-blockers to normalize sleep, with resultant improvement in behavioral and cognitive function. Bryan was started on melatonin 3 mg in the evening and propranolol 10 mg in the morning. Over 2 months, these were increased to final doses of 5 mg and 20 mg respectively. His overnight sleep period increased from 4 hours to 8 hours and by the conclusion of the titration, his self-injury was reduced by 90 percent and aggressive behaviors stopped. He began to exhibit new learning, such as starting to search for and complete crossword puzzles, and he displayed an increased interest in social interaction and improved attentiveness. The authors were able to eliminate the use of risperidone, trazodone and all as-needed medications. Importantly, standard-of-care recommended medical screenings for SMS were completed, revealing that Bryan was deaf. He received bilateral hearing aids and speech therapy and began to speak more. A year later, Bryan's adaptive function was significantly improved and he was able to transition to a supported group living situation with two male peers, and began work at a part time job.

Smith–Lemli–Opitz Syndrome

Brianna was a 13-year-old young woman carrying a diagnosis of intellectual disability and Smith–Lemli–Opitz syndrome (SLOS). SLOS is a congenital syndrome characterized by growth retardation, microcephaly and multiple malformations including a distinctive facial appearance. Most affected individuals have moderate to severe intellectual disability but some have normal development and it is increasingly thought that the disorder and carriers may be much more common than previously understood. In SLOS, mutations in the *DHCR7* gene

result in derangement of cholesterol metabolism with elevated serum 7-dehydrocholesterol (7DHC) and low serum cholesterol. Affected individuals almost always display a variety of structural midline and para-midline brain findings, most commonly abnormalities of the corpus callosum. Sterol levels display strong correlation with MRI brain findings and the degree of somatic malformations, supporting a link between altered cholesterol/sterol metabolism, deficient brain myelination, and changes in neurotransmitter function that may underlie the neuropsychiatric phenotype.

SLOS is therefore a specific etiology resulting in intellectual disability, as well as a disorder that may be simultaneously conceptualized as being a biochemical genetic disorder, multiple congenital anomaly syndrome, and/or brain malformation. As with many metabolic disorders, it is thought that dietary supplementation of the deficient substrate, in this case cholesterol, may support ongoing brain development. Brianna received cholesterol supplementation since diagnosis and ongoing dietary optimization, as well as support for learning via an Individualized Educational Plan at school. She received low-dose trazodone to support sleep fragmentation; however, as she entered her teenage years shortly after puberty, Brianna began to exhibit increasing challenges with cognitive control and behavioral dysregulation, becoming much more aggressive towards caregivers and peers and with self-injurious behaviors. Simultaneously, she talked of visual and auditory hallucinations, particularly centered around seeing, hearing, and interacting with a person called "Cassie." These phenomena waxed and waned somewhat on a multiweek or monthly basis, but generally periods of increased aggressive behaviors coincided with what were interpreted as the perceptual or psychotic phenomena.

Olanzapine was started to address aggressive behaviors, self-injury, and presumed psychosis and was titrated to 10 mg twice per day. Brianna's aggressive behaviors declined somewhat but the perceptual phenomena appeared unresponsive and she gained some 40 pounds. With concern for treatment resistance and weight gain, she was switched to haloperidol 5 mg twice per day. With the use of this agent Brianna became more irritable with continuing hallucinations. At this point the treating child psychiatrist sought consultation with a developmental neuropsychiatrist and biochemical geneticist at a specialist center. Laboratory studies revealed that 7DHC levels were elevated. In accordance with best practice guidelines for SLOS, both trazodone and haloperidol, which are contraindicated in this disorder due to their link with 7DHC elevation, were stopped. Brianna was started on valproic acid, which proved effective in reducing her behaviors and addressing psychosis. Melatonin was prescribed for sleep initiation difficulties with good effect.

DEVELOPMENTAL CONSIDERATIONS IN CHILDREN WITH INTELLECTUAL DISABILITY

Throughout the 20th century, children with intellectual disability have been an ongoing topic of developmental research. Small groups of researchers have examined development of various Piagetian cognitive domains, language abilities, social skills, and even morality, but besides providing information about basic milestones or natural histories, these studies aid in understanding the underlying processes of development. Over the past decade, researchers have begun to specify the ordering of development (sequences), the ways in which levels in certain areas relate to levels in other areas (cross-domain relations), and the points at which the speed of development (rate) changes. Such analyses are now being applied to children with different etiologies of intellectual disability.

In addition, developmental analyses have extended beyond studies of children themselves. Many developmental psychologists examine mother–child interactions, family behaviors in families of different-aged children, and the child's interactions with peers, neighbors, and schools. This

section, then, examines both child-related and environment-related aspects of development in children with intellectual disability.

Child-Related Aspects of Development

Overview. Children with intellectual disability traverse the same sequences in their development as do children with typical development, but in the setting of certain forms of intellectual disability there are strengths and weaknesses not generally found in typically developing children. Children with intellectual disability also show certain ages and tasks of particularly slowed development, which seem related to specific types of intellectual disability, although the reasons for such slowings are the subject of ongoing research.

When examining child–environment interactions, it is found that mothers act "the same and different" compared to mothers of typically developing children at similar levels of functioning. Mothers of children with intellectual disability are similar in that they shorten their speech, focus on key words, and in other ways structure the environment for their child's development. They seem, however, to be much more didactic in their interactions. Families of children with intellectual disability also differ widely one from another. When the child with intellectual disability shows less maladaptive behavior and when the parent's style of coping is more problem-focused, the result seems to be lessened levels of parent and family stress.

Sequences. Typically developing children show a specific, possibly universal, ordering to their development. For example, in Piagetian cognitive development, children proceed from sensorimotor, to preoperational, to concrete operational, to formal operational thought. Even within these four larger stages, smaller orderings hold: thus, within sensorimotor development, normal infants proceed in order through Piaget's six sub-stages in each of several sub-domains.

Do children with intellectual disability also follow a "similar sequence" to their developments? For almost 30 years, similar sequences have been found for a variety of children over many tasks: in almost twenty Piagetian domains, in symbolic play, and in linguistic grammar and pragmatics. Similar sequences even hold for those children with genetic or other organic causes for their intellectual disability. The only possible exceptions include some children with uncontrollable seizures (where accurate testing is difficult), and some children with autism, who may show different orderings due to their particular disabilities on certain social tasks. For almost all children and for a wide variety of behaviors, development for children with intellectual disability proceeds along similar sequences to those found in typically developing children.

Cross-Domain Relations. If children with intellectual disability proceed in the same developmental ordering as do typically developing children, might they also show the even or flat profiles that groups of typically developing children show from one domain to another? Such a "similar structure" to development was proposed by Zigler in the late 1960s.

Contrary to similar sequences—which hold for all children with intellectual disability—cross-domain structures may differ based on which group one considers. With a few exceptions, children with cultural-familial intellectual disability do show even or near-even performance across various intellectual domains.

In contrast, children with different organic forms of intellectual disability show specific intellectual strengths and weaknesses. For example, three separate groups show weaknesses in sequential (or bit-by-bit, serial) processing compared to simultaneous (i.e., gestalt, holistic) processing. Such sequential deficits are found in boys with Fragile X syndrome, children with PWS, and children with Smith–Magenis syndrome. Children with Down syndrome may have particular weaknesses in expressive versus receptive communication, and specific problems in grammatical abilities. Children with Williams syndrome show extra deficits in visuospatial processing skills, and some subset of these children show heightened abilities in language. Different etiologies of intellectual disability, then, show different characteristic intellectual strengths and weaknesses.

Developmental Rates. A further issue concerns children's rates of development. By definition, children with intellectual disability develop at slower rates than typically developing children. As noted in the Prevalence section, non-specific or mixed groups show reasonably steady rates of development, as shown by stable IQ after the early childhood years. Children with different types of intellectual disability, however, may have periods of accelerated or slowed development.

These periods of accelerated or slowed development seem to be related to either age or task difficulties. For example, boys with Fragile X syndrome show stable developmental rates until the age of about 9 or 10, at which time development slows. Similarly in Down syndrome, both cross-sectional and small-scale longitudinal studies show that these children slow over the 6 to 11 year period. Throughout this age-span, children with Down syndrome slow in their development of linguistic grammar, intellectual skills, and adaptive behavior. In both Fragile X and Down syndromes, it remains unknown why such age-related slowings occur, whether all children with these disorders show such slowings, or if slowings are seen across all domains.

A second type of slowing relates to pronounced difficulties mastering a specific developmental task. These can occur at a variety of ages, whenever children with a particular type of disability reach a specific developmental

task. Consider young children with Down syndrome (who also show age-related slowings from 6 to 11 years). These children show difficulties in acquiring certain tasks of infant intelligence, even after accounting for their already-slower rates of development. Later, toddlers show increasing delays in expressive as opposed to receptive language skills. As a result of both age- and task-related slowings, then, children with Down syndrome generally show their highest IQ scores during the first year of life, after which IQ declines.

Contextual Aspects of Development

Mother–Child Interactions. Following research on interactions between typically developing children and their mothers, mother–child interaction studies in intellectual disability began during the mid-1970s. This research has shown that mothers of children with intellectual disability are both similar and different in their interactions than mothers of typically developing children of the same mental age (MA). Specifically, the two groups of mothers behave similarly on what might be called the structural aspects of behavior. In language, for example, mothers shorten their speech, simplify their vocabularies, raise their pitch, repeat key words, and generally provide the "motherese" typical of mothers of typically developing children. As a result, mothers of typically developing 2-year-olds act almost identically to mothers of children with intellectual disability who are at 2 years MA.

However, compared to mothers of typically developing, MA-matched children, mothers of children with intellectual disability are oftentimes more didactic. They more often initiate the topic of interaction, take longer speaking turns, talk at the same time as their child, and in other ways control the interaction. As a result, the child is allowed fewer opportunities to initiate and control the conversation.

It remains unclear why such stylistic differences occur. The prevailing view holds that mothers of children with intellectual disability are worried about their child's development: in their zeal to teach and instruct their children, these mothers might inadvertently be using a style of interaction that is not the most effective. Although only a few studies exist to date, young children with intellectual disability seem to develop faster when their mothers are less intrusive. One study examined mother-child interactions at 23 months and child outcomes at 36 months. Compared to mothers who were constantly redirecting their child's attention, mothers who simply commented on the object at which the child was looking had higher receptive language ages at 36 months. These studies suggest that the most effective style for mothers might be one that responds to the child's interests and initiatives.

Family Reactions. Over the past two decades, family studies in

intellectual disability have changed enormously, from a predominantly negative to a more balanced perspective. Before the early 1980s, families of children were perceived to be families in crisis. Mothers were examined for their "mourning" reactions, couples for divorce, and mothers, fathers, and unaffected siblings for the presence of depression and other forms of psychopathology.

Since the early 1980s, however, family researchers began to change how they conceptualized families of children with intellectual disability. From an earlier focus on family pathology, these families came to be thought of as families facing increased stress. Children with intellectual disability might therefore add stress to the family system, but now researchers understood that this stress could result in negative or positive adaptations. This changing view implied a more normative view of these families: just as every family faces a variety of stressors in life (e.g., illness, loss of job, etc.), so too do families of children with intellectual disability.

The move from a negative to a stress-coping perspective also has other implications. First, it allows for a change from a predominantly "between-group" research strategy. Previously, most studies compared families of children with disabilities to families of typically developing, nondisabled children of the same chronological age. Recently, however, the between-group focus has been complemented by within-group studies. Given that families of children with intellectual disability vary in their ability to cope, what causes better adjustment in one family and worse adjustment in another? What child, parent, or family characteristics foster better adaptation?

To date, most work has examined child characteristics such as the child's age and degree of impairment. For both variables, findings have been inconsistent. Some studies find it more stressful to parent older children with intellectual disability, and some suggest that families may experience more stress when the child begins puberty (11 to 15 years) and again when the child reaches early adulthood (20 to 21 years). However, other studies do not find such relations between increased family stress and the child's age. Similarly, some studies find that it is more difficult to parent children with more severe levels of disability, whereas other studies do not.

Another characteristic that has been examined is the child's degree of maladaptive behavior. So far, strong connections have been found between child maladaptive behavior and family stress in families of children with mixed etiologies, with PWS, and with 5p- (cri-du-chat) syndrome. Less clear is why such connections occur. Although most researchers feel that child maladaptive behavior leads to increases in familial stress, increased familial stress may also elicit more child behavior problems.

In studies of parent coping style, parents who more actively, constructively attempt to manage their child do better than those parents

who adopt a "palliative" coping style, one that either dwells on or ignores parental emotions. This difference in coping style may help buffer parents and families from the increased stresses of parenting a child with intellectual disability.

Psychopathology in Intellectual Disability

Developmental disability is a significant risk factor for psychopathology in general, and, as may be inferred from the description of causes above, this increased risk may derive from biological vulnerabilities as well as risks that accrue from the environment. Moreover, individuals with IQs below 70 have a two- to fivefold higher rate of psychiatric disorders overall compared with typically developing persons. A host of explanations, highlighted in Table 40–9, have been put forward in efforts to account for this added risk. Included are developmental experiences with which these individuals must contend, including perceived rejection from peers and frustration from parents. The repeated experiences of failure or difficulty achieving what appears to come naturally to typically developing peers, the recapitulation of experiences of failure with each developmental stage, and less well-developed or perhaps less supportive peer groups all take a toll on ego development. In addition to specific biological vulnerabilities, the common comorbidity of intellectual disability with physical illness, for example, epilepsy, may also increase the risk of mental illness.

Moreover, the treatments for epilepsy and other medical conditions may carry some "behavioral toxicity" which can increase the likelihood of diagnosed mental illness. Phenobarbital was widely reported to increase the risk of motoric hyperactivity and disinhibition in children and in individuals with developmental disorders, and phenytoin may cause "cognitive toxicity." While neither of these agents is used as frequently today, similar concerns may obtain for essentially any of the medications that are used for the management of epilepsy or other chronic medical conditions.

Table 40–9.
Possible Contributions to Increased Vulnerability to Mental Disorders in Persons with Intellectual Disability

Neuropathological process(es) responsible for intellectual disability may also cause or increase the risk for mental illness.
There may be an increased likelihood of loss and separation, particularly in out-of-home placements.
Communication deficits may predispose to emotional/behavioral disturbance.
There is vulnerability to exploitation and abuse by others.
There may be inadequate coping skills.
Family stress may be heightened in the presence of a child with developmental disability.
There is a risk of a limited network of social relationships and repertoire of social skills.
There is a risk of reduced opportunities for the development and exercise of recreational and occupational skills.

There is a possible adverse effect of the disability on self-esteem, and possible dysmorphology.

In general, individuals with developmental disabilities may experience the full range of mental illnesses as occur in the general population. A meta-analysis of epidemiological studies of psychiatric disorders in individuals with ID revealed higher rates of psychiatric disorders in children with vs. without ID, and higher rates in children and adults with more severe forms of intellectual disability vs. milder forms. However, evidence of a greater prevalence of psychiatric disorders in adults with *mild* disability as compared to adults in the general population is less clear. Other studies have shown that, in children, there is evidence that the developmental *course* of psychopathology is similar from ages 6 to 18 for children with and without ID. For instance, in general, internalizing behaviors increase with age and externalizing behaviors decrease with age. Specific risk factors for psychiatric disorders in children with intellectual impairments include both family and child characteristics: moderate vs. mild levels of intellectual impairment, adaptive behavior deficits, poor socialization, language impairments, living with one biological parent, and low family SES.

In 2007, the National Association for the Dually Diagnosed (intellectual disability and mental illness), in collaboration with a number of other professional organizations, published a manual to assist clinicians in psychiatric diagnosis with this population. The DM-ID provides a number of explicit examples of adapted diagnostic criteria for each diagnosis and is currently under revision. Additional specific psychiatric disorders as they appear in individuals with ID are reviewed below.

Attention-Deficit/Hyperactivity Disorder. The rates of ADHD in intellectual disability are estimated to between 9 and 18 percent. Although considerable research has been done on the treatment of ADHD, virtually all of these studies have specifically excluded children with ID. Moreover, the diagnosis of ADHD is based upon developmental considerations, namely, hyperactivity, impulsivity, and inattention significantly greater than that expected for a given developmental age, and thus the threshold for diagnosis in persons with severe to profound ID should be elevated.

For persons with intellectual disability, the diagnosis of ADHD is qualified as being excessive for an individual's *mental age*. In the context of profound intellectual disability, attention span, distractibility, or "on-task" behavior are predictably quite variable. Individuals given the diagnosis of ADHD in this context should, in comparison to their peers with similar levels of intellectual impairment, exhibit unusually short attention span, excessive psychomotor activity level, remarkable impulsivity, and so on. In many cases, the clinician will encounter a situation in which an individual does not evidence remarkable psychomotor activity or attentional

difficulties, but may be unusually impulsive. In these situations one should entertain the diagnosis of an impulse control disorder. Such a diagnosis, for example, might be appropriate for an individual who inexplicably strikes out at a peer in the absence of any identifiable environmental stressor.

Impulse Control and Stereotypic Movement Disorders: Self-Injury and Aggression. Every effort should be made to determine and treat the underlying cause of self-injurious behavior (SIB) or aggression, not merely to suppress the behavior. However, in some cases, for example, stereotypic movement disorder with SIB, the symptom is essentially the diagnosis. Aggression and self-injurious behavior are common in ID and increase with greater severity of cognitive impairment. Self-injurious behavior typically takes the form of chronic, repetitive, and frequently stereotyped behavior causing trauma. It occurs in the context of specific genetic syndromes, for example, self-biting in Lesch–Nyhan Syndrome and fingernail pulling in Smith–Magenis Syndrome, but also and more commonly in persons with unknown or nonspecific causes of intellectual disability. DSM-5 added specifiers to the diagnosis of stereotypic movement disorder for these situations.

In a review of psychiatric consultations in an institutional setting, it was reported that SIB was specifically cited as a reason for referral in 36 percent of the 251 cases examined. However, SIB as a presenting symptom is generally unhelpful in predicting the ultimate psychiatric diagnosis.

As SIB and aggression are nonspecific symptoms, one must take into account the presence or absence of a variety of factors to arrive at a presumptive diagnosis. Among these factors are the chronicity of the behavior, what function it serves, whether it is invariant in its topography (e.g., hitting only the right ear suggesting an ear infection), whether it is situational, whether it occurs in concert with regression from a previous level of function, and whether there are associated neurovegetative signs that correlate with its onset.

Oppositional Defiant Disorder/Conduct Disorder . The DSM-5 diagnosis of oppositional defiant disorder or conduct disorder also requires comparisons to others of similar mental age. Further, both diagnoses assume some degree of deliberateness on the part of patients (e.g., disobedience motivated by spite or resentment), which can be very difficult to discern in nonverbal subjects with profound cognitive deficits. As such, there is a lower limit in terms of severity of ID below which the reliability and utility of these diagnoses becomes suspect and an unspecified disruptive or impulse control disorder is likely to be utilized for diagnostic purposes.

Anxiety Disorders. Specific anxiety disorders, for example, separation

anxiety, obsessive-compulsive disorder, panic disorder, generalized anxiety disorder, and so on, rely heavily on an individual's ability to describe the subjective symptoms of anxiety. Patients who are clearly avoidant, who exhibit autonomic arousal in the face of stimuli that most of their peers would not find aversive, who present with other features of anxiety but who cannot articulate their subjective states, might be given a diagnosis of unspecified anxiety disorder.

In some cases in which individuals engage in behavior that appears compulsive or driven, and for whom such behavior seems ego-alien, the diagnosis of unspecified obsessive-compulsive or related disorder might be considered. Oftentimes these patients engage in self-restraint (securing their extremities in their clothing) or cling to their parents or care providers, seemingly to prevent self-injurious behaviors. Simple repetitive behaviors or the insistence on sameness that can accompany autism spectrum disorders should not be given a separate OCD diagnosis. However, it may be useful to organize treatment with an additional diagnosis beyond "autism" if, for example, the focus of treatment is a sleep disturbance, impulsive aggression, anxiety, or the like.

Although common, anxiety disorders appear to be underdiagnosed in persons with ID. The wide variability in prevalence rates, from 1 to 25 percent, is attributed to difficulty in making a diagnosis. Moreover, an individual with ID may not be able to identify subjective anxiety as an underlying cause of distress, and a patient's aggression or agitation may be suggestive of a disorder of impulse control rather than reflective of underlying anxiety. Indeed, common symptoms of anxiety in the population with intellectual disability include aggression, agitation, compulsive or repetitive behaviors, self-injury, and insomnia. Panic may be expressed as agitation, screaming, crying or clinging, which may even appear as delusional or paranoid behavior. Phobias may also occur in this population and may even be more common in persons with developmental disabilities. Experienced clinicians have noted that persons with developmental disabilities are at high risk for abuse, thus placing this population at a greater risk for posttraumatic stress disorder (PTSD). With data suggesting that it may be seen in nearly 8 percent of the general population, PTSD is an important diagnosis to consider in individuals with intellectual disability.

Eating Disorders. Because of the reliance of diagnostic criteria upon subjective experiences, the diagnoses of anorexia nervosa and bulimia are effectively precluded for individuals with severe or profound intellectual disability. For example, one would be hard pressed to identify in nonverbal patients such things as classic distortions in body image, or guilt feelings associated with bingeing. Food refusal or self-induced vomiting would have to be viewed as atypical eating disorders if such symptoms were to occur in

the absence of other diagnosable disorders (e.g., depression, rumination, etc.). Pica is perhaps the most common eating disorder among persons with intellectual disability.

Organic Mental Disorders. One could argue that by definition everyone with intellectual disability has some "organic" cerebral dysfunction, and thus any psychiatric illness should be regarded as organic or due to a general medical condition. In his classic study of psychiatric illness in a sample of institutionalized patients with Down syndrome in the 1970s, Menolascino appropriately argued that psychiatric nosology did not have to be reinvented to accommodate individuals with a "tissue diagnosis." Moreover, he reasoned that patients with so called "dual diagnoses" of mental illness and Down syndrome need to be distinguished from those with Down syndrome alone. Thus, the application of the diagnoses of organic mental syndromes and disorders is best approached as if patients do not have intellectual disability. The same principle should apply to personality disorders. The diagnosis of "organic" personality disorder is probably best reserved for individuals whose pre-existing personality was altered in a pathological way by some additional cerebral insult. In essence, this category has more clinical utility if reserved for patients whose intellectual disability is acquired after a period of typical development, usually secondary to trauma experienced in childhood or early adolescence.

Psychosis. Patients with developmental disorders are at an increased risk for schizophrenia (approximately 1 percent prevalence rate in persons with ID), bipolar disorder and other mental illnesses that may include symptoms of thought disorder and hallucinations. The diagnosis of schizophrenia requires that a patient relate the experience of delusions or hallucinations. Thus, in individuals with profound ID with limited communicative ability, the diagnosis of classic schizophrenia is arguably impossible. Nonetheless, some individuals display presumptive evidence of response to hallucinations (e.g., striking or shouting at empty space, throwing imaginary peers from furniture) or adopt catatonic postures that can appear to be psychotic in origin. In these cases the diagnosis of psychosis should be considered if these signs exist in the absence of sufficient evidence of a supervening mood disorder.

Mood Disorders. Even in profound intellectual disability, the diagnosis of mood disorders is fairly straightforward. Generally, a change in mood from baseline is obvious (recent onset lability, tearfulness, mood elevation, irritability). If coupled with changes in interests, activity level, sleep, appetite, or sexual behavior, of sufficient duration and causing sufficient impairment in adaptive function, the diagnoses of mania or of depression can be made in nonverbal patients.

Mood disorders are not uncommon in persons with ID, although it is unclear from studies to date whether or not mood disorders present at higher rates than in the general population. As noted above, learning problems, social skills deficits and low self-esteem are often associated with developmental disabilities and represent risk factors for the development of mood disorders. There are no striking differences between the expression of mood disorders in persons functioning in the mild and moderate range of ID and their typically developing peers. Differences may emerge among persons with severe to profound disability, but potential equivalents of mood disturbance may be recognizable, including irritability, crying, problems in sleep or appetite regulation, agitation, mood lability, social withdrawal, and isolation. Aggression or self-injurious behavior may also be seen as behavioral manifestations of dysphoria in persons regardless of developmental level.

Other Disorders. The diagnosis of Tourette syndrome is difficult in persons with profound ID. Frequently, these individuals display stereotyped or other movements and it can be challenging to discriminate intentional from unintentional movements or sounds, or to distinguish vocal tics from spontaneous, stereotyped, or echolalic vocalizations in individuals frequently incapable of functional speech. The diagnosis of stereotyped movement disorder might also be considered in such circumstances.

Since elimination disorders require a mental age of 4 or 5 years in order to be considered, the diagnoses of functional encopresis or enuresis are seldom made in the context of severe ID. In some instances, individuals appear to lose previously acquired skills, for example, urinary continence, but such losses typically do not occur in isolation, suggesting alternate diagnoses (e.g., delirium, depression, etc.).

Somatoform disorders, depersonalization disorders, and sexual disorders are less frequently diagnosed in the context of ID, though certainly not precluded. Sleep disorders ultimately require the subjective input of the patient regarding the adequacy of rest, occurrence of nightmares, and so on. Given the frequent history of abuse reported for people with ID as a group, one should not overlook the possibility of PTSD when sleep disturbance is a presenting problem.

Provisional Diagnoses. In many cases individuals with ID may not clearly fall into a single diagnostic category. Comorbidity is common. Additionally, some individuals may have psychiatric symptoms that significantly interfere with habilitative function, but which do not allow for a clear distinction between certain diagnoses. It may be very difficult to distinguish between an impulse control disorder, perhaps characterized by an individual who engages in impulsive aggressive acts, versus an anxiety

disorder, suggested by an individual who strikes out in the context of a stressor that would go unnoticed by most people. The clinician should always make a best effort at a working diagnosis, and be prepared to make modifications as indicated by data gathered through collateral sources and from increasing familiarity with a particular patient.

Approach to Maladaptive Behavior

As with psychiatry in general, there is little specificity that can be attached to a given symptom. Persons with ID will typically be referred for evaluation because of self-injurious, aggressive, impulsive, or hyperactive behavior. Because of the lack of diagnostic specificity for each of these symptoms, a diagnostic decision tree cannot be constructed. Instead, it is perhaps more useful to ask a series of questions about the expression of a particular behavior. If the behavior is of recent onset, one is more likely to consider an acute medical or psychiatric etiology. If the behavior is highly situational, occurring primarily in the context of the stress of task demands, the likelihood of a psychosis or mood disorder is probably reduced. If attempts are made to avoid the behavior by self-restraint, the inference of some ego-dystonic features may be tenable. Assessing the sum of these and collateral data will lead the clinician to a presumptive diagnosis that will form the basis for a treatment plan.

Diagnostic Instruments, Rating Scales

A number of diagnostic and behavioral rating scales have been developed for the population with intellectual disability. While neither diagnostic nor treatment decisions should be based entirely upon the results of a given instrument, the systematic collection of data through such scales is a very useful adjunct to the clinical diagnostic or monitoring process. Among the most common general behavior rating scales are the Aberrant Behavior Checklist (ABC) and the Developmental Behavior Checklist (DBC). The Behavior Problem Inventory (BPI) is particularly useful for self-injurious, aggressive, and stereotyped behaviors. The Diagnostic Assessment of the Severely Handicapped (DASH), the Reiss Screen for Maladaptive Behavior, and more recently the Reiss Scale for Children's Dual Diagnosis are all instruments whose primary utility is to poll for the presence of mental disorders.

TREATMENT

Prevention

Preventive treatment strategies largely focus on specific medical interventions to reduce the prevalence of intellectual disability, and upon mitigating associated complications, for example, treating associated mental disorders. The merits of primary prevention are obvious, and the

successes enjoyed with PKU should continue to provide powerful incentive for the ongoing collaborations of basic scientists and clinicians. Recent evidence suggests that newborn metabolic screening is extremely successful in reducing the incidence and severity of some intellectual disability syndromes. On the other hand, the impact of more recent programs is less clear. For example, although folic acid supplementation appears to significantly reduce the risk of neural tube defects, and may also reduce the risk of autism, compliance with recommendations to increase dietary folate appears to be disturbingly low relative to knowledge that supplementation is beneficial. It also appears that the prevalence of Trisomy 21 is likely to remain unchanged despite the availability of prenatal diagnostic programs. A recent review of the medical literature concluded that while the prevalence of intellectual disability caused by specific medical conditions has decreased significantly over the past 50 years due to medical interventions, only a small dent has been made in the prevalence of ID overall.

Influence of Etiological Factors on Treatment

As suggested above, the approach to treatment begins with the diagnostic process. In some cases, the underlying cause of intellectual disability may be particularly important in considering treatments. For example, in intellectual disability associated with phenylketonuria, a number of attempts have been made to minimize or to attenuate hyperactivity and impulsivity by dietary modification. More recently, as animal models of this disorder are developed and explored, it appears that dopaminergic abnormalities may play a particularly salient role in the expression of maladaptive behaviors and perhaps in the design of specific treatments. Thus, early intervention with dopamine agonists may ultimately play a unique role in the treatment of behavioral and cognitive disturbance associated with PKU.

Abnormalities in serotonergic function have been reported in the context of Down syndrome. This hyposerotonemia led to trials of serotonin replacement with mixed results, but serotonergic drugs may yet hold particular relevance for persons with Down syndrome. In the context of PWS, serotonergic abnormalities are also being reported as responses to serotonergic agents. Taken together, the identification of the underlying cause of intellectual disability has become increasingly important in considering biological treatments. In the same way, the diagnosis of mental disorders or syndromes in persons with ID will guide and influence treatment strategies.

TREATMENT OF MENTAL DISORDERS

Experience over the past decade has made it clear that intellectual

disability is a multidisciplinary problem, and optimal treatment is multimodal. Biological, psychological, social, and developmental dimensions should all be considered when designing a treatment plan for an individual with intellectual disability. Further, an integrative treatment approach should focus not only on ameliorating symptoms, but on restoring mental well-being, and caring for the family system as well. Typically, a treatment plan will include attention to psychoeducational, psychotherapeutic, and psychopharmacological interventions.

Psychotherapy

One should never assume that a person with ID cannot benefit from psychotherapeutic intervention simply because of his or her impairment in intellectual functioning. That being said, there are a number of potential barriers to effective psychotherapeutic treatment approaches, including limited verbal ability, limited cognitive flexibility, psychological-mindedness, and limited self-efficacy. In order to overcome these barriers, certain modifications in approach are beneficial. It is important, for example, that an active therapeutic stance be employed, as well as concrete and supportive interventions and careful attention to the language abilities and developmental level of the patient in treatment. When these types of alterations are made, many patients with ID clearly are able to benefit.

Specific psychotherapeutic approaches that have been shown to be effective include behavioral (in particular, applied behavior analysis models), cognitive–behavioral, psycho-educational, and skills training (e.g., coping skills, social skills). Behavioral therapies are demonstrably effective in managing many maladaptive behaviors, particularly aggression and self-injury, in persons with ID. Interventions that should be considered include environmental modifications, caregiver education, and applied behavior analysis (ABA). There is a large evidence base for ABA, and recent attention has been paid to dealing with low-base-rate behaviors, improving generalization, and incorporating choice-making to improve outcomes. Typically, a behavioral assessment begins with a "functional analysis" of behavior or detailed examination of the variables that reinforce or maintain particular behaviors. One considers the antecedent events and consequences of a behavior in question, and typically must test hypotheses by systematically manipulating key variables. Matson and colleagues have shown that a checklist, called the Questions about Behavioral Function (QABF), can be used successfully to derive clear behavioral functions for most individuals (84 percent) across target behaviors of self-injury, aggression, and stereotypy. Further, when the results of the functional analysis informed the behavior program, subjects improved significantly more than those whose behavior programs were more generic. While screening instruments may thus be quite useful in beginning to identify reinforcing variables for maladaptive behavior, the development and

implementation of an effective behavior program is best conducted by a behavioral psychologist.

In addition to behavior therapies, there is some evidence for use of cognitive–behavioral therapy to treat depression in individuals with mild intellectual disability. Skills training approaches, such as teaching individuals with ID brief relaxation techniques, may be useful in reducing anxiety even in the context of moderate to severe intellectual disability. Parent skills training approaches have been shown to improve developmental, behavioral, and family outcomes. Supportive groups for parents and siblings may also be of particular benefit. Family therapy can be particularly useful and provides a setting for education, for support, and for consolidation of behavioral treatment and other interventions.

An important area of current research is to examine not only efficacy but service delivery. A recent review of a range of psychosocial interventions (behavior analytic, cognitive training and rehabilitation, and parent training interventions) delivered by non-specialist care providers shows that interventions delivered in this way do produce good outcomes compared to no treatment or treatment as usual. This finding is critical given the scarcity of specialists in rural and low-resource areas and countries.

Pharmacotherapy

There is a relative paucity of controlled clinical drug trials that include persons with intellectual disability, particularly individuals with the most severe cognitive impairment. As a result, clinicians must generally extrapolate from the general population with regard to pharmacotherapy in persons with ID. Fortunately, there is little reason to suspect that drugs discriminate on the basis of intellectual ability in terms of their mechanisms of action.

However, because of drug–drug interactions that may affect the availability or effectiveness of concurrent medications, individuals with intellectual disability may require relatively unique dosing strategies. In institutionalized populations, for example, where 30 to 40 percent of persons have epilepsy and as many as 70 percent may have some other medical condition of significance, drug interactions become an increasingly important consideration. At the same time, studies are also making it clear that genetic copy number variants associated with both loss of function and gain of function may be associated with some intellectual disability syndromes. As these data come to inform more personalized or targeted treatment approaches, it is likely to be the case that some medications will emerge as being specifically beneficial or specifically contraindicated in certain ID syndromes relative to the general population.

Antidepressants. Special considerations in the use of antidepressant

medication in ID include the common medical comorbidities as noted previously. Tricyclic antidepressants in particular (e.g., clomipramine) must be used with the knowledge that the risk of lowering seizure threshold is relevant. Although this risk in the general population is in the order of 1 in 1,000, in individuals with intellectual disability this risk may increase to closer to 1 in 5. Cardiac anomalies are common in some intellectual disability syndromes, and the anticholinergic side effects of some medications may be particularly significant in persons with Down syndrome. Individuals with intellectual disability may require lower levels of antidepressant drugs than their normally developing peers, and disinhibition has been described even with typical antidepressant doses of the serotonin reuptake inhibitors.

There are some individuals—particularly a subgroup within the pervasive developmental disorder spectrum—who appear to exhibit extraordinary sensitivity to drugs of this and other classes. This sensitivity, when it occurs, is manifest by disinhibition, and may present as an increase in target symptoms at doses of medication that might otherwise appear quite standard. In this context, individuals may be converted to responders with significant dose reductions, for example, reducing a starting dose of fluoxetine (Prozac) or citalopram (Celexa) from 10 to 2 mg, daily. Moreover, it is increasingly the norm that initiation doses for selective serotonin reuptake inhibitors (SSRIs) in this population are lower, and the rate of dose increase slower, than for the general population.

A subgroup of persons with SIB also exhibit self-restraining behaviors, for example, binding their extremities in their clothing or seeking out helmets to wear for self-protection. Such behavior might indicate an ego-dystonic quality of self-injury and suggests the possibility of SIB as a compulsion. As noted earlier for PWS, obsessive-compulsive disorder occurs more commonly than in the general population, and compulsive skin picking may improve along with other compulsive behaviors with an SSRI.

Given these findings, trials of serotonin reuptake inhibitors in clinical practice are increasingly common among patients with SIB. Favorable experiences have been reported for fluoxetine, paroxetine, sertraline, trazodone, and clomipramine in this regard but all of these reports involve small numbers of subjects. In addition, of these agents, only clomipramine has been shown to be useful in a well-controlled study. Due to its effect of lowering seizure threshold, clomipramine is generally not a first-line treatment for compulsive SIB in individuals frequently comorbid for epilepsy.

Anticonvulsants. Data on the use of anticonvulsant medications for indications other than epilepsy in this population are limited. However, considerable experience suggests that, as for the population in general,

some anticonvulsant drugs may improve cyclical mood disorders and impulsive aggression. Valproate has probably been studied most in this regard. Current prevalence surveys suggest that across all indications, carbamazepine is the most widely prescribed anticonvulsant for persons with intellectual disability.

Crawford and colleagues performed an open-label but randomized, parallel-group, multicenter, add-on study comparing gabapentin with lamotrigine in 109 patients with treatment-resistant focal epilepsy and intellectual disability. Subjects in both the gabapentin and lamotrigine groups experienced a reduction in seizure frequency by nearly half. Both drugs were equally well tolerated. Gabapentin may have had an edge with respect to some behavioral indices, denoted by the investigators as communication, cooperation, and restlessness, but lamotrigine also was credited with improving challenging behavior. Thus, both medications may hold promise for persons with intellectual disability and treatment-resistant epilepsy, and their effects on behavior should be the focus of additional study.

Of interest, there is some experience with a small number of persons with PWS treated with the anticonvulsant topiramate whose skin-picking behavior improved. The mechanism underlying this effect is unknown, and it might even involve peripheral effects of the drug, for example, on sensation, or perhaps even rate of wound healing.

Conversely, SIB and aggression can also dramatically improve with the withdrawal of phenobarbital. The potential behavioral "toxicity" of this and any drug should not be overlooked in designing treatment strategies for persons with intellectual disability. Moreover, medical comorbidity is the rule in individuals with developmental disabilities, and the importance of identifying and treating underlying medical problems or refining that treatment cannot be overstated.

Anxiolytics. Although benzodiazepines are commonly prescribed in treatment for anxiety in the general population, there are unique concerns when they are used in the context of developmental disorders, particularly regarding the possibility of increased confusion, cognitive impairment, unsteadiness, and paradoxical excitement. Barron and Sandman reviewed disinhibition associated with benzodiazepines that occurred in 35 to 68 percent of an institutionalized intellectually disabled population as compared to controls. Nevertheless, alprazolam, clonazepam, and lorazepam are widely used for the treatment of acute anxiety, particularly that associated with procedures. Their use should be considered in the absence of evidence of previous abnormal responses to these agents.

On the other hand, recent findings from animal modeling of haploinsufficiency of the SCN1A gene (Dravet Syndrome) by Catterall and colleagues suggest that activation of GABA(A) receptors with low dose

clonazepam improves behavioral and cognitive impairments in mice. There is growing interest in this mechanism in genetic conditions associated with ID.

Buspirone is another serotonergic agent that has been reported to be of benefit in some persons with developmental disorders. Ratey and colleagues reported the use of buspirone in an open trial in persons with diagnosed anxiety disorders manifested by aggressive and self-injurious behaviors. Typical doses at which patients responded were on the order of 15 to 45 mg per day. In another open trial by King and Davanzo, it appeared that nonresponders to buspirone remained so, even as the medication dose was increased from the levels used by Ratey to 60 mg daily. A study by Verhoeven and Tuinier also explored buspirone in the treatment of anxiety in persons with intellectual disability, suggesting that this agent should be among those considered in treating this population. Moreover, advantages include a relatively benign side-effect profile, specifically the absence of common motor or cognitive toxicities, at doses that are used to treat anxiety.

Antipsychotics. Antipsychotic medications have long been used, arguably indiscriminately, in persons with intellectual disability. These are the most widely prescribed class of psychotropic medication—even more commonly prescribed than anticonvulsant drugs for persons with intellectual disability. Given this ample experience in persons with intellectual disability, such that in residential or institutional settings as many as 50 percent of individuals may be treated with this class of drug, the side effects are well known.

Individuals with intellectual disability appear to be at greater risk of developing tardive dyskinesia than the general population, with recorded rates ranging from 18 to greater than 30 percent following chronic receipt of first-generation antipsychotics. On the other hand, spontaneous abnormal involuntary movements are not uncommon in this population, and this may represent a confound in interpreting rates of neuroleptic-induced tardive dyskinesia. The ascendance of atypical neuroleptic drugs and their use in persons with intellectual disability have reduced the risk of tardive dyskinesia and extrapyramidal symptoms, as well as cognitive toxicity. Considerable evidence is accumulating to support the effectiveness of risperidone in treating severe disruptive behavior in children and adolescents with cognitive disability. Large multisite trials have found that at daily doses ranging from 0.02 to 0.06 mg/kg, children and adolescents with various disruptive behavior disorders, the majority of whom also had attention-deficit/hyperactivity disorder, improved significantly. Sedation and weight gain were the most common side effects. Similar studies exist for aripiprazole although both of the controlled trials were sponsored by the manufacturer. Studies reporting the effectiveness of clozapine,

olanzapine, quetiapine, and sulpiride, through open trials involving small numbers of subjects, also support the use of these agents in individuals with intellectual disability.

There is evidence to support the use of dopamine antagonists in SIB and aggression both in theory and in practice. For thioridazine, in particular, ample experience exists to indicate that both SIB and aggression may improve. Typical doses average less than 300 mg per day, with daily doses as low as 15 mg per day being reported for some children. A "black box warning" about QT prolongation induced by thioridazine and the availability of the atypical neuroleptics have dramatically reduced the use of thioridazine in this population.

Although suggested by some, there is no convincing evidence that the mechanism of action of antipsychotics in SIB or aggression is merely to suppress behavior generally through a nonspecific sedating effect. Such an outcome is clearly undesirable in an individual with pre-existing cognitive impairment, and many of the earliest reports specifically note the absence of sedation.

Psychostimulants. Despite reports of paradoxical responses to stimulant medications in persons with intellectual disability, with higher-than-expected rates of emergent motor tics and emotional lability, a growing body of literature supports the use of stimulant drugs for the treatment of ADHD in the context of intellectual disability. A problem awaiting additional study concerns the likelihood of a response to stimulants in relation to the severity of cognitive disability. Data are mixed with respect to whether IQ negatively or positively predicts treatment response.

Atomoxetine is a nonstimulant that is used for similar target symptoms in the general population. There are no studies specifically examining its effectiveness in ID, but growing evidence suggesting that in autism spectrum disorders, atomoxetine may be useful for target symptoms of inattention, hyperactivity, and noncompliance/oppositionality.

Opioid Antagonists. Some individuals who self-injure appear to have altered pain sensitivity, as was suggested nearly a century ago by Ireland. This observation, coupled with data indicating that opioid antagonists can attenuate stereotypy and self-injury in animal models and data indicating that opioids may modify the function of dopaminergic systems, has fueled interest in this class of drugs. Naltrexone is the opioid antagonist most widely used for SIB, but the literature is mixed. Typical daily doses range from 0.5 to 2.0 mg/kg in children and up to 200 mg in adults. The relatively long half-life of naltrexone, 72 hours in brain, must be kept in mind in designing titration strategies for this drug. On balance, naltrexone appears to be well tolerated in persons with developmental disorders, with

sedation as the side effect most likely to be observed.

Nootropics. Perhaps the "holy grail" of psychopharmacology in intellectual disability would be drugs that positively affect cognition, or nootropic drugs. There is no such drug that has yet to demonstrably improve cognition in ID, but the growing number of strategies that are emerging that "rescue" animal models of specific genetic disorders may redefine this class of therapeutics for the population with ID. Even as some of these novel treatments move in to clinical trials, the question as to whether there are particular developmental windows for therapeutic effectiveness remains important to address.

Other Drugs. There is ample evidence to support an antiaggressive effect of lithium salts in the context of intellectual disability. Similarly, there is evidence to suggest that in the setting of cyclical mood disturbance, lithium may also be helpful. The side effects associated with this agent, particularly the cognitive dulling that is occasionally reported by some recipients without intellectual disability, should raise the threshold for the use of this agent in the setting of cognitive disability.

Beta-adrenergic antagonists have also been reported to be of use in the population with developmental disorders. It is not clear, however, whether the mechanism is central or peripheral. Ratey and colleagues were led to explore this class of drugs based on their perception that many individuals with developmental disabilities appear to have a low frustration tolerance for ambient stimuli. At doses of propranolol upward of 1,000 mg per day, the precise mechanism of action of this drug arguably becomes nonspecific, but lower doses of this and other beta-adrenergic antagonists have also been reported to be beneficial.

A growing appreciation exists for the potential therapeutic utility of drugs acting at glutamate receptor subtypes. Glutamatergic and dopaminergic interactions in the neostriatum are the focus of research on the pathogenesis of a host of neuropsychiatric illnesses, including schizophrenia, obsessive-compulsive disorder, SIB, and aggression. Dextromethorphan, an antitussive agent that also binds to the *N*-methyl-D-aspartate (NMDA) receptor, was reported by Welch and Sovner to have markedly attenuated SIB in a 25-year-old individual with congenital rubella syndrome. The patient was maintained on dextromethorphan for 16 months with sustained benefit. It is surprising and perhaps ominous that no follow-up studies have been reported with this drug in SIB. Lamotrigine is an anticonvulsant drug that also appears to antagonize glutamate by reducing its release. A recent case report suggested that lamotrigine may also be useful in reducing self-injury in the context of a stereotyped movement disorder. A larger study in which lamotrigine was added to the anticonvulsant regimen of children with ID suggested that those with

autism experienced gains that could not readily be attributable to better seizure control alone. A recent double-blind, placebo-controlled trial of lamotrigine in autism, however, was negative.

Amantadine is another drug with affinity at the NMDA receptor. An open trial of the use of amantadine in children with various developmental disabilities and disruptive behaviors was quite promising. A subsequent small multisite, controlled trial in children with autism yielded mixed results. The closely related drug memantine has also shown promise in open trials for agitation in the context of autism.

Sleep disturbance is a little-studied but often significant problem for some persons with intellectual disability. Jan prescribed melatonin openly to children with moderate to severe intellectual disability of mixed etiologies. The children ranged in age from 1 to 11 years. All but two of the children were characterized as dramatic responders based on measures of hours of sleep, nocturnal awakenings, delayed sleep onset, and early-morning awakening. Melatonin was administered as a single 3-mg dose 1 to 2 hours before target bedtime each night. Pillar and colleagues also administered a single 3-mg dose and monitored sleep efficiency, as well as activity (wrist actigraph), in their sample of five children (3.5 to 13 years old) with severe intellectual disability. Sleep was significantly improved in the subjects receiving melatonin, and two of the subjects were still receiving melatonin up to 18 months after the completion of the study. This preliminary evidence suggests that melatonin deserves broader consideration for the treatment of children with intellectual disability and disturbed circadian rhythm of sleep.

Services and Supports

In contrast to even 20 years ago, individuals with ID can now access a wide variety of services. These services can be found throughout the United States and last throughout the lifespan; see Table 40–10 for a listing of some of these services.

Table 40–10.
Service Needs and Resources for Families of Children at Different Ages

	Needs	Resources
Ages 0–3 years		
Child	Evaluation: physical, motor, cognitive, linguistic, social-emotional; early intervention services	Multidisciplinary evaluation, which results in an individualized family service plan (IFSP), with child and family receiving either center- or home-based early intervention services for set number of hours per week
Mother	Emotional support, caretaking behaviors	Support groups by disability, region, and etiology; part of early intervention evaluation, intervention, and IFSP
Family	Support, financial	Support groups; depending on the problem, state

	assistance, information	developmental disabilities or insurance payment for some services; hospitals, agencies, groups
Ages 3–21 years		
Child	Evaluation, referral, and individualized education program (IEP)	School system: involves legal process of evaluation and placement (notification, hearings, appeals if necessary); information on "transition" to adult services as child nears age 21 years (and school services end).
Family	Information, financial assistance, support	Local and national groups; departments in some states, including respite care, camps, art (Very Special Arts) or athletic activities (Special Olympics), scholarships for adolescents with some disabilities (deafness, blindness)
Older than 21 years		
Offspring	Residential services, work	Run by state developmental disability departments; parents and offspring have major say concerning whether residential or work placements are appropriate.
Family	Support, information, guardianship issues	Continuation of many of the services provided during the school years; particularly for individuals with severe disabilities, provisions for residential and work status after parents can no longer serve as offspring's legal guardians

From Hodapp RM. *Development and Disabilities*. New York: Cambridge University Press; 1998:196.

Early intervention and educational services became widespread following the passage of PL 94–142 (the Education for all Handicapped Children Act of 1975); this legislation has recently been extended and modified by IDEA, the Individuals with Disabilities Education Act of 1990, with amendments in 1997 and 2004.

Early Intervention. Early intervention serves young children from birth until a child's third birthday. Such services are supported by the state, with a different "lead agency" coordinating services in each state. Services vary widely from state to state. For instance, in some states, birth to 3 (B-3) care may begin with early intervention specialists providing services, such as speech and language therapy, in the child's home, while in other states B-3 care can also entail center-based services. Once the child is preschool age, most services are center-based and include both one-on-one therapies and small group education services. B-3 and preschool services focus on multiple domains of functioning, including cognitive development, language, motor, social, and adaptive functioning. With the passage of Part H of PL 99–457 (the Education of the Handicapped Amendments of 1986) early intervention services have increasingly emphasized the family's role. Agencies are required to develop an Individualized Family Service Plan (IFSP) for each child and family, focusing on family strengths and needs in caring for their young child with intellectual disability.

School. From ages 3 to 21, specialized education services are provided through local school districts. The Individuals with Disabilities Education Act 2004 requires that public school systems serve all children with

disabilities, and outlines the legal provisions to do so. This process provides for notice that the child is being considered for special services; a formal, scheduled hearing at which the parent(s) and school personnel discuss what is the most appropriate school placement and specialized services; the right to present a defense if parents disagree with school personnel; a written decision given to the parents notifying them of the school's decision; and the parents' right to appeal this decision, first to the school itself, then to district and state educational authorities, and eventually to the court system. This entire process results in an Individualized Education Program (or Plan), called an IEP, which assesses the child's academic performance, provides annual goals and instructional objectives, describes services that the child will receive, and includes starting dates of services and when and how the child's progress will be re-evaluated. Although receiving services for one's child can be complicated, educational services have become a right—not a privilege—for parents of children with intellectual and developmental disabilities.

A further element of education law involves the right to a public education "within the least restrictive environment." This phrase has led to many debates within the special education community about inclusion. Essentially, this debate centers on whether all children should be educated in classes composed primarily of typically developing children. Inclusion advocates conceptualize education alongside typically developing children as every child's right, while proponents of a continuum of care argue that the child's individual educational needs should be paramount.

Special educators have long advocated "non-categorical" approaches to children with ID. Such approaches do not consider the cause of the child's disability, and even knowing about the etiology of the disability has been considered harmful, possibly leading to increased stigmatization.

Over the past few years, however, it has become apparent that the etiology of the child's intellectual disability does influence behavior. As discussed above in reference to Prader–Willi, Fragile X, Williams, and Down syndromes, individuals with each syndrome do differ from others with intellectual disability in maladaptive behavior and psychopathology, but also in relative strengths (or weaknesses) in language versus other abilities and across cognitive domains. Such etiology-related profiles may eventually lead to etiology-related interventions.

Consider Down syndrome. Most children with Down syndrome show particular difficulties in linguistic grammar, expressive language, and articulation, even as their abilities in visual short-term memory appear relatively strong. Thus, when asked to recall a series of hand movements on the Kaufman Assessment Battery for Children (K-ABC), these children perform better than when recalling a series of spoken numbers or words. Using this visual-over-auditory profile, various researchers have become interested in teaching children with Down syndrome to read. In short, one

can use a strength to bootstrap a weakness, using the visual modality as a "way into" language.

Similar suggestions apply to other syndromes. Children with Williams syndrome generally show higher language than visuospatial abilities, while children with either Prader–Willi or Fragile X syndrome show better abilities in simultaneous (i.e., Gestalt) processing compared to sequential (step-by-step, serial) processing. In each instance, educators and test-constructors have already devised ways to help children with a particular learning style, and such specific, tailored educational approaches might prove particularly effective as well for children with different intellectual disability syndromes.

Although such "etiology-based" educational interventions hold promise, such approaches will not necessarily prove effective for every child with a particular syndrome. Not all children with Down syndrome have particular difficulties in language; not all children with Williams syndrome demonstrate especially high language or low visuospatial skills. While etiology-related interventions may be helpful, they need to be considered in light of the child's own specific strengths and weaknesses.

Further, most etiology-related interventions have adopted the approach of "playing to strengths" as opposed to ameliorating weaknesses. To give a few examples, in Down syndrome, visual short-term memory is relatively more advanced compared to auditory short-term memory in the teen than in the grade-school child. Similarly in Williams syndrome, more pronounced patterns of high language and weak visuospatial skills are seen in older as opposed to younger children. In this sense, playing to strengths may reinforce already strong areas, but hopefully in ways that help children to learn a wide variety of information and skills. Despite the ultimate nature of etiology-related interventions, as more information about etiology-related strengths and weaknesses in a variety of syndromes becomes available, such information should gradually become incorporated into more targeted, more effective programs of intervention.

Adult Services. Once an individual with intellectual disability turns 21, service delivery comes under the auspices of each state's department of developmental disabilities. In contrast to educational services, adult services are not federally mandated. States thus vary widely in their services and how they offer them. Services are often spread out across various locations, and qualifying and getting services can sometimes be difficult or impossible.

During the adult years, residential and vocational services predominate. Residential services run the gamut from institutional to community-based, and from constant to no supervision. More restrictive placements involve large or small institutional residences, which mainly serve the lowest functioning, often multiply-impaired individuals. Group homes for 4 to 8

residents are probably the most common residential option; these homes typically exist within residential neighborhoods and provide round-the-clock staff to ensure safety and consistent programming. Supervised living arrangements usually consist of apartments that are shared by a few persons with ID; these residents receive visits from program staff, who often instruct residents in cooking, cleaning, and shopping. Unsupervised apartments, where individuals live by themselves or with a roommate under little supervision, mainly succeed with clients who have lesser intellectual impairments and fewer behavior problems.

Vocational services also range from most to least restrictive. Most restrictive are sheltered workshops, in which individuals with ID assemble or test products next to others with disabilities. Supported employment provides a job coach or other specially trained individual to work with the client to find a job, to learn how to take public transportation to get to a job, and to acquire the technical and social skills needed to handle the job. Competitive employment is the least restrictive job option for adults with intellectual disability. Competitive employment involves a job with the same pay levels and benefits that a nondisabled person would have, but also with the same pressures and responsibilities for work performance. As in unsupervised apartment living, competitive employment is an option for the highest functioning and least behaviorally disordered individuals.

In considering working and living arrangements for any young adult with intellectual disability, one should also consider transitional services. There is a federal mandate requiring youth with disabilities age 16 and older to have an IEP with a postsecondary transition plan. This plan typically includes teaching vocational and adaptive skills in support of long-term life goals. Parents and schools must work together to determine the most appropriate long-term goals for each young adult.

Supports

In addition to services provided by early intervention, school, and adult services, individuals with intellectual disability and their families can also benefit from a variety of other supports. These run the gamut from short- or longer-term respite care (allowing families a break from full-time care), to summer camps, and to sports activity programs such as Special Olympics (see Fig. 40–1). In addition, at several major universities, specialty clinics exist for behavioral and medical management of certain types of intellectual disability.

A wide variety of organized groups are also helpful for affected individuals and their families. Parent groups are available for parents of children with disabilities and for parents of children with specific types of disability. Sibling groups and networks are also available, and the federal government fosters service and advocacy through the University Affiliated Programs (UAP's) in almost every state.

Legal Issues in Intellectual Disability. The Americans With Disabilities Act of 1990 spells out four aims: (1) to provide a clear and comprehensive national mandate for the elimination of discrimination against individuals with disabilities; (2) to provide clear, strong, consistent, enforceable standards addressing discrimination against individuals with disabilities; (3) to ensure that the Federal Government plays a central role in enforcing the standards established in the Act on behalf of individuals with disabilities; (4) and to invoke the sweep of congressional authority, including the power to enforce the 14th Amendment and to regulate commerce, in order to address the major areas of discrimination faced day-to-day by people with disabilities. The ADA represents a major turning point in the assurance of the rights of persons with disabilities who, even 50 years ago were frequently institutionalized and compulsorily sterilized in misguided efforts to protect society from this population. While the pendulum has shifted repeatedly from attitudes of asylum to punishment of persons with disabilities over the centuries, the prevailing paradigms in developed countries are those of community integration and support. Disabilities law over the past three decades reflects these values as articulated in Section 504 of the Rehabilitation Act of 1973, and subsequently the Individuals With Disabilities Education Act (IDEA) of 1990 (originally Pub. L.-94–142 of 1975), with amendments in 1997 and 2004, and the ADA. Collectively, these laws ensure that all children with disabilities receive a free appropriate public education in the least restrictive environment, and that reasonable accommodation is made for the employment of adults. Clinicians working with this population should be aware of their personal obligation to provide an accommodating environment, but should also familiarize themselves with local guardianship, informed consent, and abuse reporting laws in order to best serve this population.

FIGURE 40–1. Athletes competing in activities sponsored by the Special Olympics, whose athletes take the following oath: "Let me win. But if I cannot win, let me be brave in the attempt." The Special Olympics was founded in 1968 by Eunice Kennedy Shriver. The mission of the organization is to provide year-round sports training and athletic competition in a variety of Olympic-type sports for individuals with intellectual disability by giving them continuing opportunities to develop physical fitness, demonstrate courage, experience joy, and participate in a sharing of gifts, skills, and friendship with their families, other Special Olympics athletes, and the community.

Specific Learning Disorder

ROSEMARY TANNOCK, PH.D.

INTRODUCTION

Humans are not born to read, write, spell, or perform arithmetic calculations: These are skills that have to be learned. In contrast to oral language skills, which humans have possessed for over 100,000 years, cultural symbols used to represent specific numbers and speech sounds were invented only a few thousand years ago.[1]

These arbitrary cultural symbols, which are the foundational codes for reading, writing, and arithmetic, are not acquired "naturally" by simple exposure; each human being has to learn these symbols as well as how they map onto specific speech sounds, specific quantities, and numerals. The process of developing these literacy and numeracy skills reorganizes and changes each individual's brain. This is because the human brain did not evolve to accommodate the recent human invention of symbols, which are far too recent to have exerted any evolutionary pressure on brain evolution. Thus, during the human developmental period, existing functions and networks in the brain are "recycled" for the new uses. For example, learning to read involves the creation and automation of an efficient interface between vision and spoken language ("visual word form area" in the left visual cortex); learning arithmetic involves creating connections with nearby areas of the parietal cortex that code for space and eye movement.

Multiple skills are involved in learning to process one's cultural symbol systems. These include the awareness that spoken language can be segmented into smaller units (words, syllables, phonemes) and mapped onto written visual symbols (e.g., letters, characters, numerals); the ability to rapidly identify letters, letter clusters, and words (orthographic awareness); the ability to extract meaning from this written language; and the ability to transcode meaning between symbol systems (e.g., to understand that the symbol "3," the quantity of three dots (***), the spoken word "three" (/th/ /r/ /ee/) and the written word "three"; all represent "threeness" (see Table 41–1 for definitions of key terms related to reading and number sense).

For a surprisingly large subgroup of children (at least 6 percent), this multidimensional developmental task of learning to process and use one's

cultural symbols present major lifelong challenges that are unexpected, given their abilities in other developmental domains. The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) uses the term "Specific Learning Disorder" (SLD) to describe persistent and impairing problems in acquiring and using the cultural symbols that are required for reading, writing, and arithmetic.

Significance of SLD for Psychiatrists

At first glance, the diagnostic category of SLD may appear of lesser importance to psychiatrists and other clinicians in their quest to understand and help individuals suffering from the burden and stigma of mental health problems. However, SLD has high comorbidity rates with other common psychiatric disorders, ranging from ADHD (most common), anxiety, and mood disorders, suicide, to substance abuse (least common). Thus clinicians need to consider the presence of SLD when assessing for these other psychiatric disorders. Also, the burgeoning concern about health literacy and health numeracy in the medical literature highlights the need for clinicians to understand the medical implications of SLD. Health literacy is defined as the ability to obtain, process, and understand basic health information and services needed to make appropriate health decisions; health numeracy is defined as the individual-level skills needed to understand and effectively use quantitative health information (e.g., dose, quantity, probability) to guide health behavior and decision making. Basic reading skills (e.g., letter–sound knowledge and word recognition), reading comprehension, and basic numeracy skills are core attributes that underlie health literacy and numeracy. Poor health literacy and numeracy are independent predictors of health disparities, worse health outcomes, and mortality.

Recent surveys of the readability of patient education materials and medical research consent forms typically indicate that many of these materials have higher-than-acceptable levels of readability for the general public. For example, the American Academy of Pediatrics reported that at least half of their materials manifest unacceptably high readability levels. Few studies have investigated the readability of patient education materials in psychiatry, which is of particular concern, given the low educational attainment of many patients with mental health illnesses. Low numeracy skills constrain patient choice, reduce medication compliance, impair risk communication, and affect medical outcomes. SLD tends to run in families, and so patients and their families may have great difficulty accessing patient education materials and comprehending dosage instructions or nonpharmacological interventions. Clinicians in the workplace may also have SLD themselves (e.g., almost 2 percent of medical students declare a diagnosis of SLD in reading on entry to medical school), which may pose additional challenges in the effective performance of their clinical duties.

Thus an understanding of SLD and knowledge of effective strategies to enhance the clinical performance of clinical trainees and certified clinicians with SLD is of key importance for clinical educators.

To understand SLD, it is necessary to understand how the neuroplasticity of the human brain makes it possible to learn to read, write, and calculate, how the acquisition of literacy and numeracy transforms the brain, and how disturbances in brain development disrupt the normal acquisition of reading, writing, and arithmetic. Two of the most engaging accounts of the history and neuroscience of reading are by neuroscientists, Maryanne Wolf (*Proust and the Squid, 2007*) and Stanislas Dehaene (*Reading in the Brain*, 2009). Likewise, fascinating accounts of the earliest invention of numerals and how the human brain learns to understand and manipulate numbers, are to be found in Stanislas Dehaene's neuroscientific account of number sense (*The Number Sense*: *How the Mind Creates Mathematics*. Rev Upd, 2011), and in a mathematician's (Amir Aczel) personal account of his journey to find the first "zero"—the keystone of our current number system—eventually located on an inscribed stone in an old shed in Cambodia (*Finding Zero*, 2015).

Table 41–1.
Definition of Key Terms Used in Relation to Specific Learning Disorder

Term	Definition
Alphabetic principle	The insight that words are made up of sounds and each sound can be signified by a symbol.
Phoneme	Smallest sound units in a word: The smallest unit of speech that distinguishes one word from another (e.g., the word "peach" has three phonemes: /p/ /ea/ /ch/; the phoneme /p/ distinguishes the word "peach" from "teach").
Phonemic awareness	An explicit awareness that there are discrete speech sounds (phonemes) in speech. It begins to emerge between ages of 2 to 4 years, takes several years to develop, and is crucial to success in reading and spelling. For example, the child must be able to isolate the phoneme /p/ in words such as "pet," "peach," and "pear" to fully understand that the grapheme "p" represents this sound and to associate the sound with this letter when attempting to decode a word like "port."
Phonological awareness	An explicit awareness that spoken language comprises discrete units, ranging from words and syllables to smaller subsyllabic units of onsets and rimes, and phonemes. It includes phonemic awareness.
Phonological coding	Translating the letters or spelling patterns of a written word into speech patterns to identify the word and gain access to its meaning.
Phonics	An instructional approach for teaching children the systematic relationship between letters and sounds and how to use that system (alphabetic principle) to read words. In other words, instruction in phonics requires the child to have some level of phonemic awareness.
Onset-rime	Parts of monosyllabic words in spoken language: These units are smaller than syllables but larger than phonemes. An "onset" is the initial consonant sound of a syllable (the onset of "peach" is "p-"). The rime is the part of the syllable that contains the vowel and all that follows it (the rime of "peach" is "-each").
Orthography	The representation of the sounds of a language by written or printed symbols.

	Patterns link graphemes (letter) to sounds (phonemes). Orthography describes or defines the set of symbols (e.g., graphemes, diacritics) used and the rules about how to write these symbols.
Orthographic transparency	Deep orthographies are writing systems (such as English) that do not have a one-to-one correspondence between the spoken phoneme and the written grapheme. A "shallow" orthography means that the correspondences between letters and sounds (graphemes/phonemes) in the writing system are close to one-to-one (e.g., Finnish, German).

DEFINITION

SLD differs from most other mental disorders recognized by DSM-5, in that not only is it a clinical condition recognized and defined in the medical field, but also it is a discrete category of special educational needs (a.k.a., "exceptionalities") recognized and defined in the field of education. One major challenge for clinicians, educators, parents, and researchers alike, is that the purpose of classification differs in the medical/mental health and educational systems, as do their underlying concepts and definitions of SLD. Thus clinicians who diagnose SLD must understand both the medical and educational definitions, as well as their different implications for accessing school-based supports and intervention services.

Medical/Psychiatric Definition

According to DSM-5, SLD is a Neurodevelopmental Disorder that involves marked and persistent difficulties in learning and using one's cultural symbol systems (e.g., alphabetic letters, characters, Arabic numerals) that are required for skilled reading, writing, and arithmetic. SLD disrupts the normal pattern of learning these essential academic skills and is not simply a consequence of an intellectual disability, sensory deficits, other mental or neurological disorders, lack of opportunity of learning or proficiency in the language of instruction, or inadequate educational instruction. Difficulties learning keystone (foundational) academic skills of reading, writing, and arithmetic may also impede learning in other academic subjects (i.e., history, geography, science) but those problems are attributable to difficulties learning the basic underlying academic skills.

Neurodevelopmental disorders are complex and heterogeneous conditions arising from perturbations of the central nervous system, typically during the pre- and perinatal period, which interfere with the developmental of language and speech, motor skills, attention, behavior, memory, learning, or other neurological functions. Neurodevelopmental disorders are typically heritable, show early onset, persist through the lifespan, and impair academic, social, occupational, and mental health outcomes. DSM-5 delineates six neurodevelopmental disorders, many of which often co-occur: Intellectual Disabilities, Communication Disorder, Autism Spectrum Disorder, Attention-Deficit/Hyperactivity Disorder (ADHD), SLD, and Motor Disorders. The neurodevelopmental disorder of

learning (i.e., SLD) represents the extreme bottom end of normal distributions of culturally acquired skills, rather than a discrete categorical entity.

Like other neurodevelopmental disorders, SLD is understood to be a heterogeneous condition, in which the learning difficulties may be either selective (e.g., occur only with learning one specific aspect of reading such as word decoding) or broad (e.g., occur in learning to decode words, spell, understand what one has just read, as well as in arithmetic calculation), and frequently coexists with other neurodevelopmental (e.g., with Communication Disorders, ADHD) or psychiatric traits or disorders (e.g., with anxiety, anxiety disorders). Moreover, SLD is understood to be a heritable, chronic condition of childhood that typically persists into adulthood, albeit with changes in the ways the learning difficulties manifest.

Medical practitioners must understand that a medical diagnosis of SLD, using the DSM or ICD classification systems, does not necessarily mandate eligibility for special assistance at school.

Federal/Educational Definition

In the field of education, the term "Learning Disabilities" is used to delineate a specific category of "special learning needs," that mandates the provision of special education and other services to permit more equitable access to the curriculum and promote their learning.

In the United States, the conceptualization and definition of "Learning Disabilities" has been strongly influenced by the federal definition adopted by the U.S. Office of Education in 1969, operationalized by the U.S. Office of Education initially in 1977 (Individuals with Disabilities Education Act [IDEA]), and reauthorized in 2006 to determine eligibility for special education services that must be provided by all public schools. The 1977 IDEA definition of a specific learning disability refers to:

"A disorder in one or more of the basic psychological processes involved in understanding or in using language, spoken or written, which may manifest itself in an imperfect ability to listen, think, speak, read, write, spell, or do mathematical calculations. The term includes such conditions as perceptual handicaps, brain injury, minimal brain dysfunction, dyslexia, and developmental dysphasia."

Note that the federal definition of Learning Disabilities includes oral or spoken language impairments, which are classified as Communication Disorders in psychiatric taxonomies and differentiated from SLD. Moreover, the educational definition incorporates notions of presumed etiology (i.e., deficits in underlying psychological processes), whereas psychiatric classification does not.

Identification of specific learning needs in the educational system mandates eligibility for special education services. Due in part to

differences in the purpose of identification, the educational system may identify some children as having special educational needs who would not meet the clinical threshold for a diagnosis of SLD in the medical system.

One substantive problem with the educational definition is that standards of identification of SLD differ across school boards, postsecondary institutions and across countries, so that an individual identified as SLD by one school board, or in one region of the country, or in one country, may not be identified in another. Moreover, as both educational laws and psychiatric taxonomies change over time, different groups of individuals are identified as having SLD or Learning Disabilities, depending on the specific set of criteria applied. Thus, the terms Specific Learning Disorder and Learning Disabilities are not synonymous. To date, there is no consensus definition of this condition: Current assessment and diagnostic practices in both medical and educational systems are varied, often opaque and discriminatory, and therefore vulnerable to legal challenges.

HISTORY AND COMPARATIVE NOSOLOGY

History

The term "Learning Disability" (credited to Samuel Kirk, 1962) was first recognized as a formal category in the field of special education in the 1960s, although the first clinical case of a child's unexplained difficulties learning to read had been described much earlier in the United Kingdom in 1896. In 1963, parents, educators, and policy specialists in the United States, agreed on the term "Learning Disabilities" to refer to a large group of individuals who had unexpected and significant difficulty learning to read, write or do arithmetic, despite average or above intellectual ability.

Kirk defined learning disability as:

> A retardation, disorder, or delayed development in one or more of the processes of speech, language, reading, writing, arithmetic, or other school subject resulting from a psychological handicap caused by a possible cerebral dysfunction and/or emotional or behavioral disturbances. It is not the result of mental retardation. Sensory deprivation, or cultural and instructional factors (Samuel Kirk, *Educating Exceptional Children*, 1962, p. 34).

Early terminology, which focused primarily on difficulties learning to read, included terms such as, reading blindness, word blindness, congenital word blindness, strephosymbolia, specific reading disability, specific developmental disability, unexpected reading failure, specific reading retardation, and garden-variety poor readers, and "dyslexia" (from the Greek *dys* and Latin *lexia*). Descriptions of difficulties learning arithmetic emerged later. For instance, Gerstmann (1957) described an "isolated disability to perform simple or complex arithmetical operations and an impairment of orientation in the sequence of numbers and their fractions" (Gerstmann syndrome). The term "dyscalculia" (from the Greek *dys* and

Latin *calculia*) was used by Cohn (1968) to refer to a "failure to recognize numbers or manipulate them in an advanced culture," and later by Kosc (1974), a Bratislavian, as "a disorder of the special abilities for mathematics without a simultaneous defect in general mental abilities." The first descriptions of *developmental* disorders of written language in the 1960s were based on case studies of isolated impairments of written expression, with other forms of verbal behavior remaining intact. Since these early descriptions involved visual–motor integration, the term *dysgraphia* (literally "difficulty with writing") was the first diagnostic label associated with disorders of written expression. Although it is sometimes used as a synonym for disorder of written expression, the term *dysgraphia* is used more correctly to describe difficulties with the mechanics of handwriting. By contrast, SLD in written expression emphasizes difficulties with accurate and fluent generation and composition of written text.

Terminology and conceptualizations of SLD differ widely among professionals from different disciplines or different countries; they also differ between professionals and the lay public. For instance, in the field of research, the term "dyslexia" is typically understood to refer primarily to problems in decoding single words and is associated with phonological deficits, but lay understanding differs and is broader (e.g., often incorporates concepts such as sensory, perceptual, motor, and emotional difficulties). Also, in Europe, the term "dyscalculia" is used to refer to developmental problems in basic numerical processing, such as automatic or implicit processing of quantities or numbers. By contrast, the term is used rarely in North America, which instead uses terms such as "mathematical disabilities" or "arithmetic difficulties" that implicate a broad array of problems with arithmetic facts, arithmetical procedures, and mathematical reasoning.

Nonetheless, early perspectives of Learning Disabilities shared some commonalities: (a) recognition that impaired academic skills (reading, arithmetic) occur in the context of average or even superior intellectual abilities; and (b) a focus on impairments in specific component skills (e.g., word reading, calculation) rather than viewing an academic domain as a unitary construct. Other important insights were that these disabilities were believed to be congenital, heritable, and manifest more commonly in males than females. However, whether or not learning disabilities could occur either as an isolated domain-specific deficit or be accompanied by deficits in other academic domains remained controversial, as it does today.

The advent of IQ tests in the early 1900s (e.g., Stanford-Binet) permitted direct evaluation of the observed difference in a person's academic skills and intellectual ability. In 1920, the neurologist Samuel Orton postulated a neurological basis for developmental reading difficulties, suggesting that delayed development of specialization of the left

hemisphere for language was potentially causal. However, it was not until the 1970s that an adequate knowledge base was established, which localized the difficulties at the single-word level and pinpointed the cause in most cases as language-based deficits in phonological processing. The 1940s, known as the era of the "brain-damaged child," incorporated a broader array of cognitive deficits into the category of Learning Disabilities, including perceptual, perceptual–motor, and attention difficulties. However, it was not until the 1960s that Learning Disabilities emerged as a formal category and the notion of a discrepancy between IQ and achievement prevailed as one of its defining features. The concept was broadened to include perceptual as well as linguistic processing deficits as underlying learning disabilities.

As previously mentioned, in the 1970s in the United States, the conceptualization of Learning Disabilities was consolidated in the federal definition (U.S. Office of Education, 1977) and in the definitions of professional organizations (e.g., National Joint Committee on Learning Disabilities, 1978), and achieved official federal status as an eligible category for direct services (Public Law 94–192). The notion of underlying deficits in cognitive processing as causal factors was instantiated in the conceptualization of Learning Disabilities and the condition included conditions such as perceptual disabilities brain injury, minimal brain dysfunction, dyslexia, and developmental dysphasia (thereby continuing its earlier conceptualizations), but excluded learning problems resulting from visual, hearing, or motor disabilities, mental retardation, emotional disturbance, or environmental, cultural, or economic disadvantage. Thus this prevailing legal definition restricts the concept of Learning Disabilities to a language-based disorder, and does not include non–language-based learning difficulties, such as dyscalculia, as defined by some researchers. In other words, speech and oral language problems are included in the federal category, but are coded separately as Communication Disorders in psychiatric (ICD, DSM) taxonomies. Thus, the federal/legal and medical categories of Learning Disabilities differ in the range of learning difficulties they encompass as well as in the imputed boundaries between disabilities/disorders.

Comparative Nosology

The first psychiatric/medical descriptions of SLD in reading or mathematics occurred in DSM-III (1980), with SLD in written expression added in DSM-III-R (1987), under the general category of "Academic Skills Disorder" on axis II. These learning difficulties were classified into three separate disorders: *developmental reading disorder, developmental arithmetic disorder,* and *developmental expressive writing disorder,* respectively. By contrast, DSM-IV-TR coded learning disorders on axis I, as does DSM-5. Both of these DSM versions dropped the "developmental"

descriptor that is used by other clinicians and researchers to distinguish between developmental versus acquired learning problems (e.g., as a result of traumatic brain injury, dementia, stroke). There was no compelling logic for the coding shift from axis II to axis I, but the shift may have served to render these impairing learning disorders more salient for diagnosticians, whose clinical practice focuses primarily on other types of mental health problems. The 2013 revision of DSM (DSM-5) no longer recognizes subtypes of SLD distinguished in previous DSM versions. Instead it recognizes an umbrella category of SLD and then uses specifiers for clinicians to use to detail more precisely the range of academic skills that are impaired *at the time of assessment*, thereby recognizing the possibility of changes in manifestation of SLD with development or educational instruction. Specifiers refer to three major academic domains that may be affected (i.e., reading, writing, mathematics) as well as the type of skills impaired. For instance, *SLD in reading* may manifest as difficulties in accurately decoding single words (a.k.a., dyslexia), fluency in reading text accurately, or reading comprehension; *SLD in written expression* may manifest as impairments in spelling words accurately, in accurate use of grammar and punctuation, or in the clarity or organization of written expression; *SLD in mathematics* may manifest as impairments in basic number sense, memorization or retrieval of arithmetic facts, accurate or fluent calculation, or accurate math reasoning.

The DSM-5 conceptualization of "SLD in reading," "SLD in written expression," and "SLD in mathematics"—although comparable with—is not identical to other terms used primarily in the fields of education and in educational and clinical psychology (e.g., "reading disabilities," "developmental dyslexia," "dyslexia," "developmental expressive writing disorder," "written language disabilities," "dysgraphia," "spelling disorder," "math disabilities," "specific disorder of arithmetic skills," "dyscalculia").

The DSM-5 nosology of SLD also differs from that of ICD-10, which differentiates even more specific subtypes of SLD than does any version of DSM. For instance, although ICD-10 distinguishes three subtypes that appear to be similar to those of DSM-IV-TR ("specific reading disorder," "specific spelling disorder," "specific disorder of arithmetic disorder," as well as "mixed disorder of scholastic skills"), they differ in their requirement for the restriction of impairment to that specific academic domain. For instance, the categorical subtype of Specific Reading Disorder excludes individuals who also manifest impairments in arithmetic; Specific Spelling Disorder excludes those who also manifest a reading disorder; individuals who manifest impairments in more than one academic domain are given the diagnosis of Mixed Disorder of Scholastic Skills.

Ongoing concerns about the DSM (and ICD) approach to nosology (e.g., Casey et al., 2013; Greenberg, 2012) have spurred a recent initiative by the U.S. National Institute of Mental Health to focus on alterations in the brain

and its substrates that might signal the location and source of human mental stresses or woes (RDoC: Research Domain Criteria Project; Cuthbert & Insel, 2013). However, this approach is still in the exploratory research phase and has yet to yield clinically relevant syndromes or traits.

EPIDEMIOLOGY

SLD is one of the most frequently diagnosed Neurodevelopmental Disorders. A recent epidemiological study suggested that the lifetime prevalence of SLD is around 10 percent, with the prevalence being greatest among children with special health care needs (28 percent) compared to typically developing children (5.4 percent). However, prevalence rates vary as a function of the definition, cut-offs, and instrumentation used. Moreover, most estimates are based on prevalence of a single manifestation of SLD (e.g., in reading or mathematics) without considering the co-occurrence of SLD across academic domains. Nonetheless, SLD in the domain of reading (particularly at the word level) is the most common and well-studied manifestation, affecting at least 90 percent of all individuals identified as having SLD. It is estimated that two of five children in special education have been placed because of reading difficulties. However, children showing a deficit in one academic domain (e.g., reading) are highly likely to show deficits in other domains as well (e.g., spelling, written expression, mathematics), either concurrently or emerging later, as demands for efficient and fluent use of basic academic skills increase.

To date there are two studies of prevalence of SLD based on DSM-5 criteria. One, conducted in a German school population, found that SLD across several academic domains (and subdomains, such as word reading, fluency, and comprehension) occurred as frequently as an isolated disorder in any one domain. The rates of multiple-domain SLD were high (particularly for co-occurrence of arithmetic and spelling difficulties) even when applying the stricter criteria of achievement scores of 1.25 to 1.5 standard deviations below the mean for age. No sex differences were observed when considering SLD across multiple academic domains, however, more girls manifest problems in arithmetic and more boys had spelling problems and combined reading and spelling problems compared to girls. The second study, conducted in Brazil, a low- to middle-income country, reported that almost 8 percent of the representative sample (about 1,600 second- to sixth-grade children from four geographic areas) manifest SLD across the academic domains (global impairment), 7.5 percent in reading, 6 percent in arithmetic, and about 5 percent in written expression. Moreover, SLD with global impairment was significantly associated with ADHD; SLD in arithmetic was associated with both ADHD and Anxiety Disorders.

Although more cross-cultural epidemiological studies of the prevalence of SLD based on full DSM-5 criteria are needed, the practical implications

of the existing studies are that assessment for SLD should include all three academic domains as well as the subskills. Clinicians are advised to specify the diagnosis of SLD by providing additional information about the learning domains that are affected at the time of assessment (i.e., implementing Specifiers for SLD listed in DSM-5, as described in the later subsection on diagnosis).

ETIOLOGY

Different levels of explanation must be considered in understanding causal influences on learning academic skills. Converging evidence from cognitive, neuroimaging, twin, family, behavioral, and molecular genetic studies indicates that SLD is a multifactorial neurodevelopmental disorder arising from the complex interplay of biological and environmental risk factors that shape the development of brain systems underlying academic learning. Currently, a scientific schism is discernible in etiological research on SLD, in terms of the existence of two contrasting hypotheses: A generalist versus specific risk hypothesis. According to the generalist genes hypothesis, individual differences in academic achievement across the school years from entry to graduation are heritable and attributable to a set of genes that underlie these heritable traits. In other words, the same genes underlie both learning abilities and learning disabilities across various academic domains. By contrast, the specific risk hypothesis presumes that discrete domains of learning disabilities exist (e.g., dyslexia, dyscalculia) with different etiology.

One major challenge to understanding the etiology of SLD is that the research describing its genetics, neurological substrate, cognitive and environmental factors have not only been based primarily on the specific risk hypothesis, focusing on the etiology of specific manifestations of SLD (i.e., in reading, mathematics, or written expression), but also this "disorder-specific" research has been conducted independently of one another, despite the common co-occurrence of various manifestations of SLD across the lifespan. Thus studies continue to focus on genetic, cognitive, and environmental factors associated with specific manifestations of SLD (e.g., on the clinical phenotypic categories of dyslexia or dyscalculia) rather than on the broader category of SLD, often aggregating findings across a wide range of ages, rather than testing for developmental changes in etiological factors. Another challenge is that neither the clinical category of SLD nor its previously delineated subtypes are clear-cut disorders, distinct from normal development. Rather SLD and its impact on subskills, such as word decoding, reading comprehension, spelling, number sense, arithmetic computation, represents the lower tails of normally distributed traits of these learning skills. However, most research have used a categorical approach in sample selection.

Accordingly, based on the research trends, the following sections

summarize findings on etiological factors underlying specific manifestations of SLD. However, readers should be aware of the emerging evidence to support the generalist risk hypothesis, and the likelihood that multiple and interacting genetic factors, brain differences, cognitive deficits, and environmental stressors underlie SLD, each of small effect size.

Genetic Factors

Behavioral Genetics. Family and twin studies indicate that most dimensions of cognition (general intelligence, learning to read, spell, do arithmetic) are moderately heritable: About 50 percent of variance in a given population is attributable to genetic influences, with increases as a function of increasing age. For example, heritability estimates of individual differences in reading skills increase from about 20 percent of variance at age 6 to about 80 percent at age 12. Increases in heritability estimates with age most likely reflect a reduction of environmental influences once children enter formal education and increasing correlations between genotype and environment as with increasing maturity and independence, individuals tend to select environments that fit their abilities (genotype). A recent meta-analysis, based on 5,330 monozygotic and 7,084 dizygotic twin pairs in unselected samples (i.e., typically developing), estimated heritability of academic achievement at 73 percent for reading words, 44 percent for spelling, 49 percent for reading comprehension, 57 percent for mathematics, and 645 for language. Moreover, a common genetic factor has been demonstrated among spelling, reading fluency, and reading comprehension, with genetic influences accounting for around 80 percent of the covariation between core academic skills, such as reading, spelling, and arithmetic, with many of the same genes affecting the learning of various academic subjects independent of intelligence.

Importantly, twin studies involving large samples with diverse abilities (e.g., including typical readers and those with dyslexia) reveal common genetic influences across the range of ability and disability, suggesting that a particular set of genes affects academic learning in both typically developing samples and those with SLD. Also, despite the paucity of behavioral genetic research on SLD in mathematics, family studies indicate that the familial prevalence of dyscalculia is about 10 times higher than expected by chance and that genetic factors contribute to the observed covariance between reading and mathematics deficits.

It is important to note that the preceding findings do not mean that all individuals with SLD inherited the condition since twin studies also reveal that both common and unique environmental influences play a role, as discussed below. However, from a clinical perspective, the high heritability estimates for SLD highlight the importance of probing family history in the assessment for SLD, and ensuring that parents and patients with SLD can

read and comprehend any written reports or information brochures provided to them.

Molecular Genetics. To date, most molecular genetic studies have focused on genes implicated in reading ability and disability, particularly those associated with word reading and spelling difficulties (a.k.a., dyslexia). Several candidate genes have been implicated (e.g., DYX1C1, DCDC2, ROBO1, KIAA0319, and the MRPL19/C2ORF3 locus), with some being replicated in many studies. One problem, is that most of the candidate risk SNPs identified so far for dyslexia have been located in noncoding regions of the genome, which poses a challenge for functional investigations aimed at gaining insights into the molecular mechanisms underlying dyslexia. This is because the biological role of much noncoding DNA is poorly understood, making it hard to design appropriate assays. However, DCDC2 is of interest because of its role in axon guidance and ciliary function: Cilia play a key role in coordinated neuronal migration and placement of interneurons and projection neurons. However, genome-wide association studies have failed to implicate these genes in SLD in reading (dyslexia). Instead, a recent genome-wide scan identified novel candidate genes, one of which (an intronic variant within RBFOX2) is highly expressed in the fetal brain with a role in CNS development. Rare variants and copy number variations have also been reported, but only apply to a minority of cases with SLD in reading. Moreover, recent studies report genetic interactions between two DCDC2 risk haplotypes (READ1 alleles) and the risk haplotype KIAA0319, which influence both reading and oral language, as well as intelligence, with both protective and deleterious alleles. Findings from these studies are consistent with the generalist genes hypothesis and also underscore the close association between Communication Disorders and SLD, which are conceptualized and coded as distinct disorders in DSM and ICD systems.

Molecular genetic studies of SLD in mathematics are sparse and findings inconsistent. For example, two genome-wide association studies failed to identify any significant associations and a third reported a significant genetic component underlying mathematical abilities but did not identify specific risk factors. Another genome-wide association study identified one marker (myosin-18B), that was not only associated with mathematical ability in two independent cohorts selected for dyslexia, but also was associated with brain alterations (reduced depth of right intraparietal sulcus that has been linked with numerical processing) in adults with low mathematical performance. However, this association was not replicated by another group of researchers using independent samples.

As noted above, genetic studies of SLD in written expression have focused on the manifestation of spelling difficulties. A literature search revealed no molecular genetic studies to date on other manifestations of

written expression difficulties.

Neurological Substrate

SLD in Reading. Most research has focused on the neurobiological underpinnings of specific categorical manifestations of SLD, particularly dyslexia. Structural and functional neuroimaging studies have revealed brain regions that are most consistently involved in reading words and which are altered in dyslexia. These regions are typically lateralized to the left hemisphere and include inferior frontal, superior and middle temporal, and temporoparietal regions. Experienced readers also involve an area of the left fusiform gyrus, known as the *visual word form area*, which is activated for orthographic (print) processing. This reading network typically develops with age as children gain automaticity in specific skills required for reading.

Meta-analytic studies have revealed patterns of structural and functional differences in children, adolescents, and adults with SLD in reading words (dyslexia). The most common difference is reduced activation in *left* temporal, parietal, and fusiform (visual word form area) regions. Network analysis has revealed abnormalities in several white matter tracts (e.g., arcuate fasciculus, superior longitudinal fasciculus, inferior fronto-occipital fasciculus, optic radiation, and callosal fibers). Variations in findings may reflect maturational and instructional effects, heterogeneity of SLD in reading, as well as methodological differences.

One challenge has been to ascertain whether the observed brain differences reflect underlying neurobiological etiology or the consequence of years of altered and dramatically reduced reading experience. One approach to dissociating the cause and consequence of dyslexia has been to compare youngsters with dyslexia to “ability-matched” groups (who are at the same reading level but chronologically much younger) as well as age-matched groups. Studies using this approach have found that children with dyslexia exhibit reduced left parietal and occipitotemporal activations compared to both ability- and age-matched groups, suggesting that these differences may be related to the cause of dyslexia, whereas left prefrontal activity tracked ability level. Another approach, in which prereading children at high risk of dyslexia (familial dyslexia) are followed longitudinally, has revealed altered neurophysiological responses to auditory stimuli (e.g., mismatched negativity) that shows potential as an early endophenotype of dyslexia. Some of these biomarkers enhance or even outperform behavioral measures in predicting long-term reading outcomes: But, at present, none of these biomarkers can be used to rule in or rule out the diagnosis of SLD in reading.

SLD in Mathematics. Evidence for the neurological base of mathematical cognition and SLD in mathematics is sparse in comparison

to that for reading and SLD in reading. However, converging evidence from structural and functional imaging studies indicate the *right* intraparietal sulcus as a major (but not sole) locus of brain differences and cognitive deficits in children and adults with SLD in mathematics. Alterations in other interconnected brain regions have also been observed, including posterior regions (bilateral intraparietal sulcus and fusiform gyrus) and prefrontal cortex (premotor cortex and middle frontal gyrus). Also, network analysis reveals multiple dysfunctional white matter circuits, suggesting a neurodevelopmental disconnection condition.

Cognitive Factors

According to the generalist genes hypothesis, shared genetic factors will lead to shared cognitive difficulties across the various manifestations of SLD (and other neurodevelopmental disorders). One domain-general cognitive deficit is executive functioning, which includes the control and coordination of short-term, working- and longer-term memory systems, encoding and retrieval systems, attention, and planning. Working memory, which refers to the ability to temporarily hold and manipulate auditory–verbal and visual–spatial information, while learning new information or problem solving, is believed to be impaired in most individuals with SLD. Thus, individuals with SLD have difficulties suppressing irrelevant information from working memory, as well as simultaneously holding and processing information, which manifests as difficulties updating what they know or have just learned. In other words, the more restricted working memory capacity associated with SLD makes it more difficult for these individuals to suppress irrelevant information and update new knowledge as they learn.

Working memory deficits will impair learning to read new words, which requires the ability to remember letter–sound combinations, their order, as well as the many special rules (e.g., “silent” letters, such as “g” in gnash or height, “e” at the end that changes the vowel sound but itself remains silent, as in “site”). Working memory deficits have an even greater impact on reading comprehension and writing: Reading comprehension requires updating information in working memory to monitor the meaning of each sentence and each paragraph, extract the main ideas, and construct mental images of the emerging situations and events; writing requires the ability to plan, organize, compose and edit, while keeping in mind the writing goals, content, audience, as well as spelling, vocabulary, and grammar. Poor working memory will also impair mathematical abilities, including the ability to retrieve and hold math facts for use in computation, follow arithmetic procedures in calculation, and in math reasoning. A recent meta-analysis indicates the domain-general nature of working memory deficits across the various manifestations and severity of SLD, but with some indication of more severe verbal working memory deficits in

individuals with SLD in reading and more severe deficits in visual–spatial working memory in those with SLD in mathematics.

Slow processing speed is another domain-general factor that has a negative impact on learning. For instance, rapid automatized naming, which refers to the ability to rapidly name familiar alphanumeric (letters, numbers) and nonalphanumeric (colors, objects) stimuli, is impaired in a substantial proportion of individuals with SLD. Although some research has shown distinct rapid naming profiles in students with SLD in reading versus SLD in mathematics (impairment in alphanumeric in the former and in nonalphanumeric stimuli in the later), a recent meta-analysis concluded that rapid naming of nonalphanumeric stimuli is impaired in both manifestations of SLD, whereas alphanumeric naming may be more specific to SLD in reading. However, rapid naming deficits are not unique to SLD: They are also shared with other neurodevelopmental disorders (e.g., ADHD, Autism Spectrum Disorders, Communication Disorders).

Language-based factors, although often linked in the older literature exclusively with SLD in reading (particularly its manifestation as "dyslexia"), are associated with all manifestations of SLD. For instance, oral language difficulties interfere with all aspects of reading, writing, and mathematics, although in the latter domain, the impact is primarily of those aspects of mathematics involving verbal processing. Impairment in a specific language-related skill, phonological processing, is widely recognized as the core cognitive deficit in SLD in word reading. However, some evidence suggests that early phonological deficits may have deleterious effects subsequently on learning arithmetic. For example, one study reported that over 50 percent of children with phonologically based reading difficulties but no apparent difficulties in learning basic arithmetic at age 5 years, manifest learning difficulties in mathematics as well as continued problems in reading at age 7.

An ongoing controversy in the field of SLD is whether SLD in Reading single words (dyslexia) is associated with a unique and potentially diagnostic set of cognitive deficits. However, the conclusions from a large-scale investigation of two population-based samples (US cross-sectional study; international longitudinal study) are that cognitive predictors believed to play a causal role in dyslexia (e.g., phonological processing, rapid automatized naming) are neither necessary nor sufficient for the diagnosis of SLD in reading. Moreover, the investigators concluded that the relationship between the cognitive measures and reading skill is probabilistic not deterministic or diagnostic. Also it remains unclear whether cognitive factors are a cause, consequence, or correlate of SLD. Hence, DSM-5 does not include cognitive processing deficits in the diagnostic criteria for SLD.

Environmental Factors

Twin studies indicate that shared and nonshared environmental factors contribute up to about 40 percent or 50 percent of the variance in academic skill development, and to the development of SLD, but the nature of these environmental factors remains underinvestigated. Candidate risk factors include low socioeconomic status, the prenatal environment, and the postnatal learning environment provides by parents.

Prenatal Environment. Prenatal exposure to toxic substances, such as alcohol, tobacco smoke, lead, and other environmental toxins have been linked to neurodevelopmental outcomes. Prenatal exposure to tobacco smoke remains high despite the overall worldwide reduction in smoking among adults: A recent study reveals that maternal smoking rates during pregnancy range from about 4 to 19 percent in European countries. Known risks of maternal smoking and alcohol intake during pregnancy include premature birth, low birth weight, as well as fetal alcohol syndrome for prenatal alcohol exposure. However, findings for the outcomes in terms of subsequent academic achievement in the offspring are inconsistent, perhaps due to methodological shortcomings of the studies in terms of exposure assessment, measurement of academic outcomes, and inadequate control or consideration of confounding factors. Nonetheless a recent review of 30 studies concluded that both prenatal exposure to the ingredients in tobacco smoke and alcohol can result in a spectrum of adverse developmental outcomes, ranging in severity from intellectual disorders to more subtle negative impact on academic achievement, memory, verbal abilities, and poor executive functioning.

More robust evidence comes from recent studies that postdate the above review. For example, a recent large-scale longitudinal study focusing specifically on reading outcomes of prenatal exposure to tobacco smoke, found that high prenatal exposure to nicotine tobacco smoke (>17 mg nicotine per day) was negatively associated with reading performance, particularly in decoding single words and spelling, with greatest effects on children with poorest phonological skills—suggesting a possible gene X environment effect. Another longitudinal epidemiological study conducted in the United Kingdom examined the health and academic trajectories of children born in the late 1950s—an era in which there was a high rate of maternal smoking during pregnancy (about 30 percent)—from the prenatal period through to age 16. The research revealed that low birth weight, prenatal exposure to tobacco smoke, and poor school-aged health are negatively related to academic achievement in reading and math, suggesting a cumulative effect of early adversities. Also, meta-analysis of the academic outcomes associated with children born very preterm (<32 weeks) or with very low birth weight (<1,500 g) reveals negative effects on IQ scores (by an average of 11 IQ points), and poor academic performance, with greater frequency of SLD in mathematics compared to SLD in reading.

About two-thirds of children born very prematurely or with very low birth weight have special educational needs, especially for SLD in mathematics.

Family Environment. Parents of children with SLD may well have SLD themselves and so may be less able to engage in "code-focused" or "meaning-focused" activities with their children who have SLD: These activities refer to parent–child engagement in rhyming and counting games, teaching letter names and sounds, letter–sound pairs, teaching numbers and how to count (code-focused); and reading stories aloud in an interactive way or playing board games that involve symbol recognitions and counting (meaning-focused). However, although parents of children with SLD report being more stressed than parent of children without SLD, there is no evidence of poorer family functioning in families in which someone has SLD. Moreover, although the home literacy and numeracy environment, including parental SLD predict children's growth in literacy and numeracy abilities in preschool and kindergarten years, by school age, genetic influences as well as basic skills knowledge (e.g., letter and number knowledge) tend to predominate.

Gene X Environment Interaction. The complex interplay between genetic and nongenetic influences has garnered relatively little empirical attention, given the general consensus that SLD arises from gene-by-environment interactions. However, some recent studies provide preliminary evidence for such interactions in SLD in single word reading (a.k.a., dyslexia). For example, one study reports gene X environment effects between adverse prenatal factors (e.g., maternal smoking during pregnancy, low birth weight, socioeconomic status) and a genetic marker associated with dyslexia (DYX1C1-1259C/G) in 165 nuclear families in which at least one member had dyslexia. Findings revealed that the interaction of common "C" allele with lower birth weight was associated with lower reading scores and the interaction between the rare "G" allele and maternal smoking during pregnancy was associated with poorer short-term and working memory scores.

The clinical implications of findings from current research on etiological factors of SLD include the importance of including in an assessment for SLD the family history of SLD, the individual's prenatal and birth history, and for children with suspected SLD, an assay of their home literacy and numeracy environment. Clinicians are advised to be alert to the increased risk for SLD associated with prematurity, low birth weight, and prenatal exposure to tobacco smoke, alcohol, or other drugs.

CLINICAL FEATURES, ASSOCIATED PROBLEMS, AND DIAGNOSIS

Clinical Features

The learning difficulties manifest as an array of observable and persistent behaviors or symptoms that change across the lifespan, many of which are summarized in Table 41–2. These include (but are not restricted to) poor word recognition and difficulties sounding out words, frequently guessing words, reading slowly and hesitantly; difficulty understanding what is read (may get the basic facts, but not the deeper meaning); marked difficulties spelling words correctly; poor sentence and paragraph structure in written work, with numerous punctuation and grammatical errors; difficulties understanding numbers and their relative magnitude and relationships; persistent use of primitive counting strategies (e.g., counting on fingers); difficulties recalling number facts and getting lost in the midst of arithmetic computation; and difficulties applying basic arithmetic concepts to solve quantitative problems.

These observable symptoms are not simply the consequence of an intellectual disorder, sensory deficits or neurological disorders, lack of proficiency in the language of instruction, inadequate educational instruction, or lack of opportunity to engage in full-time formal schooling.

Table 41–2.
Common Risk Factors, Signs and Symptoms of Specific Learning Disorder

Preschool

- Lack of interest in playing games with language sounds (e.g., repetition, rhyming)
- Trouble learning nursery rhymes
- Problems counting correctly
- Frequent use of baby talk and mispronunciation of words
- Failure to recognize letters in own name
- Trouble remembering names of letters, numbers, or days of the week

Kindergarten

- Unable to recognize and write letters, write own name, or use invented spelling
- Trouble breaking down spoken words into syllables (e.g., “cowboy” into *cow* and *boy*)
- Trouble recognizing words that rhyme (e.g., “cat,” “bat,” “hat”)
- Trouble connecting letters with their sounds (e.g., letter “b” makes the sound /b/)
- Unable to recognize phonemes (e.g., does not know which of the set of words {“dog,” “man,” “car”} starts with same sound as “cat”)
- Unable to count in sequence beyond “4” (e.g., “1,2,3,4…um 7,11”)

Primary Grades (Grades 1–3)

- Receives reports of “not doing well in school”
- Continues to have problems recognizing and manipulating phonemes
- Unable to read common one-syllable words, such as “mat” or “top”
- Problems in connecting sounds and letters (e.g., “big” for “got”)
- Unable to recognize common irregularly spelled words (e.g., “said,” “two”)
- Difficulty in sequencing numbers and letters
- Complains that reading is hard, and avoids or refuses to do it
- Difficulty learning simple math facts of 10
- Counting is often inaccurate above about 5 or 6 items
- Unable to identify the relevant numerical information or generate a math equation needed to solve a simple arithmetic word problem

Middle Grades (Grades 4–6)

- ► Mispronounces or skips parts of long, multisyllable words (e.g., says “conible” for “convertible” and “aminal” for “animal”)
- ► Confuses words that sound alike (e.g., “tornado” for “volcano”)
- ► Trouble remembering dates, names, telephone numbers
- ► Trouble reading small function words (e.g., “that,” “the,” “an,” “in”)

Middle Grades (Grades 4–6) Continued

- ► Gets the first part of word correct, then guesses (e.g., reads “clover” as “clock”)
- ► Poor comprehension with or without slow, effortful, and inaccurate reading
- ► Trouble completing homework or tests on time
- ► Fear of (refuses) to read aloud, avoids reading
- ► Terrible spelling; unable to recognize correct spelling from plausible alternatives (e.g., necessary/necessery; friend/frend)
- ► Continues to rely on finger counting for simple arithmetic
- ► Difficulties mastering basic math facts (e.g., cannot remember that 3 + 2 = 5)
- ► Shows high levels of anxiety around any activity requiring basic arithmetic

High School, College, Work

- ► Slow, effortful reading of single words and connected text
- ► Trouble pronouncing multisyllable words
- ► Frequent need to reread material to understand or get the main point
- ► Trouble making inferences from written text
- ► Avoids activities that demand reading (reading for pleasure, reading instructions)
- ► Terrible spelling; same word misspelled in different ways within one piece of work
- ► Excessive problems generating written text: short, immature, not representative of the student’s knowledge or creative ideas
- ► Avoids writing activities; written expression is very short, immature, and disorganized
- ► Great difficulties in using arithmetic in functional activities (e.g., calculating tip percentage, calculating amount of change required after a purchase, monitoring bank account)

General

- ► First-degree relative (parents, sibling) with current or history of SLD
- ► Slow learning to talk
- ► Anxious and embarrassed when asked to read or work out a problem in public (e.g., in class, workplace)
- ► Avoidance or refusal to read, write or do arithmetic
- ► Reluctance to go to school

Signs and Symptoms of SLD in Reading. The most common and earliest manifestation of SLD in reading, particularly in the English language, is inaccurate, effortful and slow reading at the word level (a.k.a., “dyslexia”). Common signs of this difficulty include reluctance and resistance in reading aloud; reads hesitantly, slowly, and inaccurately, often with visible effort and discomfort (e.g., sighing, squirming, becoming flushed); guesses based on the sound of the first letter; may recognize a few words by sight, but is unable to “sound out” unfamiliar words; or an inability to reconstruct the word having sounded out its component parts (e.g., sounds out /b/ /a/ /n/ /k/, but cannot reconstitute to “bank”); adolescents and adults may read accurately but so slowly and with such effort that reading is not functional for everyday use, and so may avoid reading.

Lack of automaticity in letter–sound mapping not only interferes with

reading at the word level, but will also make it difficult for the person to understand what has just been read at the level of the sentence, paragraph, or entire text. However, some individuals with SLD in reading at the word level may have very little difficulty in comprehending connected text (sentence, paragraph, entire text) if the need to decode words is bypassed by having the text read aloud at a reasonable pace (e.g., by using text–speech software).

These observable behaviors are due to an underlying difficulty in learning how the letters (graphemes) and speech sounds (phonemes) of one's language map on to one another and being able to do so automatically. The general consensus in the scientific community is that the problems with letter–sound conversion arise from an underlying deficit in processing phonemes—the elementary constituents of speech sounds.

Common features of SLD in reading comprehension include reading text aloud with a flat intonation and no modulation to acknowledge punctuation marks (e.g., no pauses at commas or periods; no change in pitch to represent a question mark or exclamation point); may read the text accurately and fluently—often too fast—but is unable to extract and use the inherent meaning (e.g., may not grasp the sequence of events, relationships among events or people, may not be able to draw inferences from text or process the deeper meaning of the text); tends to simply reread the text without using effective strategies before restarting to read (e.g., does not predict, scan for or review unfamiliar words), during reading (e.g., does not make notes or self-question to check one's understanding; does not create visual images of the scenarios), and after reading (e.g., does not check the accuracy of understanding; does not make a synopsis).

Over time, these challenges in reading comprehension tend to result in a reduction in or avoidance of reading print (e.g., newspapers, novels, nonfiction, lengthy texts regardless of format such as digital or paper). In turn, restrictions in the amount of reading will have a negative impact on vocabulary growth, so that the individual's range of vocabulary use and understanding is noticeably reduced.

Signs and Symptoms of SLD in Written Expression . One of the most common clinical features is noticeable and persistent poor spelling for age —often described as "atrocious spelling" (e.g., often adds, omits, or substitutes vowels and consonants; may spell phonetically but incorrectly, such as "pikchr" for "picture"). Sentences are often very short or incomplete and contain grammatical errors, omission of words, and little or no use of punctuation, as well as spelling errors. Also written paragraphs are often short, poorly constructed and organized (e.g., does use a starting sentence to introduce the topic; includes several topics in one paragraph without a logical order; does not maintain the correct verb tense, incorrect use of pronouns) and their intended meaning is unclear. A common

complaint from teachers (and parents) is of "procrastination": The youngster fails to start writing, writes very little, and with great effort and reluctance. In general, the person's written work does not accurately reflect that individual's knowledge, creativity, or depth of understanding of an issue: The person's spoken or visual presentations are often very much better than the written one. Also, essential written activities, such as note taking, pose major challenges. This is because note taking requires the physical act of writing or typing notes to occur simultaneously with a complex web of other cognitive processes involved in listening, comprehending, retaining key information while continuing to process incoming and new information, and summarizing key points in a legible and organized format.

Signs and Symptoms of SLD in Mathematics. One common sign that persists across the lifespan is the sole reliance on finger counting for simple addition and subtraction that is inappropriate for age. Note that typically, children start to switch from finger counting to more efficient calculation strategies, such as retrieval of math facts from memory, by about age 8 or 9 (e.g., see the interview of an accomplished author and Defence correspondent, describe his lifelong struggles with SLD in mathematics, including his use of finger counting under the boardroom table! http://www.mathematicalbrain.com/qt/paul.mov).

Other common features include a poor sense of numbers in terms of their magnitude and relationship; inaccurate counting and calculation; failure to attend to key mathematical symbols (e.g., symbols for addition, subtraction, multiplication, division); difficulty with identifying the previous or next item in a sequence (e.g., difficulty identifying the name of previous or next day, month, or number, despite being able to rote list those items); difficulty understanding the concept and use of "zero" or decimal points; and "gets lost" in the middle of multidigit calculation and may switch procedures or apply them incorrectly (e.g., in the problem 57 – 38, may start to subtract 7 from 8 instead of 8 from 7, then either subtracts 3 from 5 without considering the trading procedure, or may switch to adding 5 and 3). Many struggle with understanding the "language" of mathematics, especially in *word problems*, that are emphasized in current curricula across all grade levels. Word problems consist of two interwoven semiotic layers: A narrative about some event or sequence of events in the real world, and a latent web of mathematical relations typically expressed in words, and related by a question involving concepts of quantity such as "more," "more than," "less than," "altogether." Thus, many individuals with SLD in reading have great difficulty with the language-based demands of word problems. Moreover, older children, adolescents, and adults manifest difficulty understanding and using money, telling the time, using calculators, and remembering numerical PIN codes.

Math anxiety is another common feature that persists across the lifespan. Often described as "a feeling of tension, apprehension, or fear that interferes with math performance," it may manifest as sweaty palms, a racing pulse, breaking out in a cold sweat, or choking feeling in the back of the throat, when required to perform mathematics in everyday life (e.g., answer math questions in class; complete math homework, counting out money to buy something, splitting a restaurant bill or calculating the tip, entering specific numbers for cash withdrawal or deposit at an ATM machine).

General Signs and Symptoms of SLD. In school-aged children, the typical presenting problem concerns difficulty in learning at school ("not doing well at school—and we don't know why"). The puzzling picture for parents and teachers is that the child appears intelligent and often succeeds or even excels in other aspects of the curriculum (e.g., oral discussions, art, drama, sports) that do not depend on the core academic skills.

In addition to the domain-specific features summarized above, SLD imposes a great emotional toll. For example, other common features include embarrassment and low self-esteem; and extreme discomfort or even refusal when asked to read, write, or spell. Children and adolescents may be reluctant or refuse to go to school; may report being exposed to daily criticism, taunting, or bullying; they may look anxious, stressed, sad, depressed, or express despair or suicidal ideation.

Associated Problems

SLD is commonly, but not invariably, associated with a developmental history of problems in speech and language, attention, and motor skills. Moreover, SLD commonly, but not invariably, co-occurs with other neurodevelopmental (e.g., Communication Disorders, ADHD) and mental health disorders (e.g., Anxiety and Mood Disorders). These associated problems are clinically important because the diagnosis of SLD cannot be confirmed until the child has started school and been exposed to formal academic instruction, but Communication Disorders in particular are likely to be apparent and diagnosed earlier and so indicate a risk for later SLD. Likewise, a developmental and family history of SLD may indicate a risk for later anxiety and mood disorders in adolescence and adulthood.

Speech and Language Impairments. Oral language constitutes an essential foundation for abilities in written language. Thus it is not surprising that a developmental history of Communication Disorders (Speech Sound Disorder, Specific Language Impairments, alone or in combination) in preschool years is a common precursor of SLD, particularly for poor skills in reading words and reading comprehension, spelling, arithmetic fact retrieval, and calculation. (Speech sound disorder,

defined as problems in producing sounds on one's language accurately and intelligibly, whereas language impairments refer to problems in developing the structural aspects of language, such as grammar [syntax] and vocabulary [semantics]). For example, one longitudinal study of a community-based sample of children identified with pervasive speech/language disorders in kindergarten were found to have an estimated three- to sixfold greater risk for SLD (all manifestations alone or in combination) in young adulthood compared to typically developing youngsters. Moreover, according to a recent population-based study, the cumulative risk of SLD in written language by age 19 is about 64 percent in youngsters with speech/language impairments compared to 18 percent in those without.

Attention-Deficit/Hyperactivity Disorder. Epidemiological and clinical studies indicate that the overlap between SLD and ADHD is greater than expected by chance alone. For example, around 20 to 45 percent of children with ADHD also meet diagnostic criteria for SLD, but the strongest link appears to be between the inattention dimension of ADHD and SLD, particularly SLD in reading and writing. Inattention in the classroom (even at subclinical levels), as rated by teachers, is a robust predictor of concurrent and subsequent poor academic outcome, as well as a poor response to evidence-based academic intervention. Importantly, there is little robust evidence that medication treatment for ADHD (including stimulant and nonstimulant medications) have any substantial effect on SLD, despite its positive effects on the behavioral symptoms of ADHD and academic productivity (i.e., completing more arithmetic problems in a specified time frame). By contrast, preliminary evidence suggests that intensive educational intervention may improve (but not normalize) the behavioral problems. The clinical implications of these findings are that assessment for SLD should include assessment for ADHD and vice versa: Youngsters with SLD who have coexisting inattention or ADHD require multimodal intervention including intensive educational intervention, since medication for ADHD will not address the SLD and intervention for SLD will be less effective if the inattention remains unaddressed.

Emotional Problems, Anxiety and Mood Disorders, Suicide Risk. Individuals with SLD are highly likely to manifest concurrent social, emotional, and mental health problems. For example, they are only too aware of their academic difficulties, leading to low self-esteem and these negative self-perceptions are very difficult to change and contribute to their problems in social and academic functioning. Avoidance of or reluctance to engage in activities requiring the academic skills is common in children, adolescents, and adults. Also, recent meta-analyses confirm that the

majority of youngsters with SLD (about 70 percent) have higher rates of anxiety and depressive symptoms compared to non-SLD peers. Episodes of severe anxiety or anxiety disorders (including somatic complaints or panic attacks) are common across the lifespan and accompany both the circumscribed and broader expression of learning difficulties. Moreover, SLD is associated with increased risk for suicidal ideation and suicide attempts in children, adolescents, and adults. The co-occurrence of internalizing symptoms and disorders is clinically significant whereas SLD is treated primarily in the field of education, these internalizing symptoms often remain unaddressed. Thus psychiatrists and other mental health practitioners play an important role in identifying, monitoring, and treating the concurrent internalizing problems.

Criteria for Diagnosis

There are no biomarkers to date for SLD. Thus, SLD is a clinical diagnosis, which is best made by an experienced clinician, based on a comprehensive assessment with careful clinical synthesis of information from multiple sources, including developmental, medical, educational, and family history; school reports; teacher observations, including response to classroom instruction and other intervention provided at school; as well as direct standardized psychometric assessment of the individual's academic skills—including reading (accuracy, fluency, comprehension), spelling, written expression, and arithmetic (number sense, counting, algorithmic computation). The DSM-5 diagnostic criteria for SLD are presented in Table 41–3.

This diagnostic category is indicated by using one overarching term "Specific Learning Disorder," which incorporates difficulties in learning academic skills, such as reading, writing, and mathematics, which were classified as separate disorders in previous versions of DSM and in ICD-10. The generic term reflects the evidence from behavior–genetic studies show that learning difficulties in the various academic domains share genetic variance, and from clinical and epidemiological studies that individuals showing a deficit in one academic domain frequently show deficits in other domains as well, although deficits isolated to one academic domain may occur. Using this overarching term, diagnosticians can then specify the details of the areas of learning difficulty and their severity, as manifest at the time of assessment.

Table 41–3.
DSM-5 Diagnostic Criteria for Specific Learning Disorder, with ICD-9-CM Codes (ICD-10 codes are shown Parenthetically)

Diagnostic Criteria
A. Difficulties learning and using academic skills, as indicated by the presence of at least one of the

following symptoms that have persisted for at least 6 months, despite the provision of intervention that targets those difficulties:

1. Inaccurate or slow and effortful word reading (e.g., reads single words aloud incorrectly or slowly and hesitantly, frequently guesses words, difficulties sounding out words)
2. Difficulty understanding the meaning of what is read (e.g., may read text accurately but not understand the sequence, relationships, inferences, or deeper meanings of what is read)
3. Difficulties with spelling (e.g., may add, omit, or substitute vowels or consonants)
4. Difficulties with written expression (e.g., makes multiple grammatical or punctuation errors within sentences; employs poor paragraph organization; written expression of ideas lacks clarity)
5. Difficulties mastering number sense, number facts or calculation (e.g., poor understanding of numbers, their magnitude, and relationships; counts on fingers to add single-digit numbers instead of recalling the math fact like peers; gets lost in the midst of arithmetic computation and may switch procedures)
6. Difficulties with mathematical reasoning (e.g., severe difficulty applying mathematical concepts, facts, or procedures to solve quantitative problems)

B. The affected academic skills are substantially and quantifiably below those expected for the individual's chronological age, and cause significant interference with academic or occupational performance, or activities of daily living, as confirmed by individually administered standardized achievement measures and comprehensive clinical assessment. For individuals aged 17 years and older, a documented history of impairing learning difficulties may be substituted for the standardized assessment

C. The learning difficulties begin during school-age years but may not become fully manifest until the demands for those affected academic skills exceed the individual's limited capacities (e.g., as in timed tests, reading or writing lengthy complex reports for a tight deadline, excessively heavy academic loads)

D. The learning difficulties are not better accounted for by Intellectual Disabilities, uncorrected visual or auditory acuity, other mental or neurological disorders, psychosocial adversity, lack of proficiency in the language of academic instruction, or inadequate educational instruction.

Note: The four diagnostic criteria are to be met based on a clinical synthesis of the individual's history (developmental, medical, family, educational), school reports, and psychoeducational assessment.

Coding Note: Specify all academic domains and subskills that are impaired. When more than one domain is impaired, each one should be coded individually according to the following specifiers.

Specify if:

315.00 (F81.0) With impairment in reading:

Word reading accuracy

Reading rate or fluency

Reading comprehension

Note: *Dyslexia* is an alternative term used to refer to a pattern of learning difficulties characterized by problems with accurate or fluent word recognition, poor decoding, and poor spelling abilities. If dyslexia is used to specify this particular pattern of difficulties, it is important also to specify any additional difficulties that are present, such as difficulties with reading comprehension or math reasoning.

315.2 (F81.81) With impairment in written expression:

Spelling accuracy

Grammar and punctuation accuracy

Clarity or organization of written expression

315.1 (F81.2) With impairment in mathematics:

Number sense

Memorization of arithmetic facts

Accurate or fluent calculation

Accurate math reasoning

Note: *Dyscalculia* is an alternative term used to refer to a pattern of difficulties characterized by problems processing numerical information, learning arithmetic facts, and performing accurate or

fluent calculations. If dyscalculia is used to specify this particular pattern of mathematic difficulties, it is important to also specify any additional difficulties that are present, such as difficulties with math reasoning or word reasoning accuracy.

Specify current severity:

Mild: Some difficulties learning skills in one or two academic domains, but may of mild enough severity that the individual may be able to compensate or function well when provided with appropriate accommodations or support services, especially during the school years.

Moderate: Marked difficulties learning skills in one or more academic domains, so that the individual is unlikely to become proficient without some intervals of intensive and specialized teaching during the school years. Some accommodations or supportive services at least part of the day at school, workplace, or at home may be needed to complete activities accurately and efficiently.

Severe: Severe difficulties learning skills, affecting several academic domains, so that the individual is unlikely to learn those skills without ongoing intensive individualized and specialized teaching for most of the school years. Even with an array of appropriate accommodations or services at home, school, or workplace, the individual may not be able to complete all activities efficiently.

The manifestation of learning difficulties *at the time of assessment* is coded by adding *Specifiers* to the generic diagnosis of SLD to provide more precise information about the domains that are affected. Specifiers are deficits in reading, deficits in writing, deficits in mathematics, each of which can be further specified by detailed descriptions (e.g., SLD with impairment in reading [currently manifests as problems in word reading accuracy, reading fluency, and comprehension] and impairment in mathematics [currently manifests as problems with memorization of math facts, as well as in accuracy of calculation]). Use of the terms "dyslexia" and "dyscalculia" to refer to problems in learning to read or do arithmetic, respectively, is permitted according to clinician and patient preference, but detailed coding of the manifestation of SLD should still be completed. Severity ratings (mild, moderate, severe), which reflect the dimensional nature of SLD, permit further description by considering the range of learning difficulties and impairments, as well as the likely need for accommodations and support to best promote ongoing learning. DSM-5 specifies a set of four diagnostic criteria, all of which must be met to confirm a clinical diagnosis of SLD.

Criterion A. This criterion lists a range of observable descriptive behaviors or symptoms (Criterion A1 to A6, Table 41–3) which may be observed, probed during the clinical assessment, and confirmed by evidence from the school reports, teacher observations or ratings, previous psychoeducational assessment reports, and current performance scores on standardized achievement tests. At least one of these symptoms must be present. Moreover, Criterion A also requires evidence that the symptoms have persisted for at least 6 months despite the provision of intervention that targets each of the affected academic domains. For children, the term

"*persistent*" is confirmed by evidence of restricted progress in mastering the affected academic skill, over at least 6 months, despite the provision of intervention that targets that affected skill. For older adolescents and adults, persistent difficulties refer to ongoing difficulties with literacy or numeracy skills that first manifest during the school years, as confirmed by school reports, evaluated portfolios of past and current work, or previous assessments.

The term "*intervention*" refers to extra help at school or home, small group or individualized instruction, using any instructional approaches available at the school that focus on the affected skill. DSM-5 does not require the provision of intensive evidence-based (research-based) intervention—as specified by a current educational model in the United States (Response-to-Intervention [RTI]). RTI is a multitiered approach to academic and behavioral intervention designed to provide early, systematic, and appropriately intensive assistance to children who are at risk or already underperforming academically or behaviorally, compared to grade-appropriate standards. To date the RTI approach, while laudable in its goals, not only lacks a strong evidence base but also is not consistently available within the United States and is rarely available outside of the United States.

Criterion B. This comprises two components: (i) academic achievement that is well below average and (ii) impairment resulting from the learning difficulties. In terms of low academic achievement, the DSM-5 applies the "average-person standard" that has been applied in disability discrimination laws for years. An individual's scores on standardized, individually administered, culturally sensitive academic achievement tests are compared to the population mean for chronological age, not to IQ or to achievement scores of subsets of the population, such as peers attending university, medical, or law school. Examples of commonly used standard achievement tests are shown in Table 41–4.

DSM-5 does not specify what cut-off scores to use for determining low academic achievement within the diagnostic criterion itself, but provides guidelines within the text. One suggested guideline for below-average academic performance is to require evidence that scores on standardized academic achievement tests fall at least 1.5 standard deviations below the general population mean for age: This cut-off score is equivalent to a standard score >78 or >7th percentile. Standardized tests vary in the number and composition of items relevant to age, as well as in the particular aspect of reading, arithmetic, spelling, written expression. Moreover, it is important to recall that standardized testing occurs in rather artificial situations (quiet space, minimal noise or other distraction, use of a standardized procedure that often precludes repetition of a question by the examiner), performance may be influenced by factors other

than academic skill level, such as motivation and effort, familiarity with the testing situation, anxiety, hunger, and sleep status, etc. Thus, greater diagnostic certainty is established by evidence of low scores on more than one test or subtest.

A second guideline suggests that more lenient cut-off scores may be used (1.0 to 1.5 standard deviations below mean for age) when supported by other converging evidence of learning difficulties, such as academic history, other test scores, school reports, teacher observations, etc.

For individuals aged 17 and older, a documented history of long-standing and impairing learning difficulties (based on self-reported history of difficulties learning to read, spell, do arithmetic or written work; previous standardized testing; school reports; previous systematic clinical assessments for SLD) may be substituted for the standardized assessment. The goal of this substitution is to avoid the time and expense needed for unnecessary repeated standardized assessments, based on the evidence that childhood-onset SLD typically persists into adulthood.

Identification of SLD in individuals in postsecondary education poses challenges. DSM-5 does not preclude the possibility that an individual with high IQ, giftedness, or attending postsecondary education may have SLD. Evidence required for greater diagnostic certainty in this situation includes previous or current reports (from school, significant others), self-reported history of marked learning difficulties, manifestation of self-report of an extraordinary effort required or dependence on the provision of support and accommodations needed to attain/maintain performance; previous evaluated portfolios of academic work; previous clinical assessments indicating SLD; family history of SLD; or current evidence of low academic scores (e.g., below the population mean for age). Extensive testing is rarely required: Research evidence indicates that tests of fluent word reading, reading comprehension, word spelling, number sense, and fluency of arithmetic computation, suffice.

In the absence of available culturally appropriate and normed standardized academic achievement tests (as occurs in many low- to middle-income countries, or non–English-speaking countries), converging evidence of markedly low academic performance must be derived from careful clinical review of scores on locally available tests, school reports, and clinical assessment. (See Tables 41–1 to 41–4 for a description of commonly used tests.)

Moreover, Criterion B emphasizes impairment, in requiring that the learning difficulties cause significant impairment in academic, occupational, social functioning, or in activities in daily living that requires the academic skills. Thus, low academic scores per se are not sufficient to meet the specifications of Criterion B: Evidence of associated impairment is required. This component is in line with the standard of US “Americans with Disabilities Act (ADA)” for determining a disability.

Criterion C. This third criterion requires evidence that the symptoms of SLD manifest in the school years—most reliably interpreted as during the elementary (primary) school years. Symptoms of SLD may manifest in preschool years, but a diagnosis cannot be confirmed until the individual has received formal instruction in the core academic skills. However, a diagnosis of SLD can be made for the first time in adolescence of adulthood. This is because the manifest learning difficulties may have been overlooked, not assessed, or attributed solely to concurrent emotional behavioral difficulties. Also, some individuals (particularly those with higher adaptive and intellectual functioning, or in highly supportive environments) may have coped with the demands for the core academic skills during the school years, albeit by putting forth extraordinary effort, or by using compensatory skills, that no longer suffice in later years, when high demands on accurate and fluent academic skills (e.g., reading or writing lengthy complex reports for a tight deadline, excessively heavy academic or occupational loads) start to exceed the individual's limited capacities and compensatory mechanisms. In such cases, greater diagnostic certainty is established by converging evidence from comprehensive clinical assessment, and the ability to rule out loss of previously acquired academic skills as a result of a major medical event or condition.

Table 41–4.
Examples of Commonly Used Standardized Tests of Reading, Written Expression, Arithmetic and Related Skills

Name of Standardized Test	Reading Skills
Comprehensive Test of Phonological Processing (CTOPP); standardized. Ages: 5 years to young adulthood	Basic reading skills (e.g., phonological awareness, phonological coding, working memory, rapid naming)
Woodcock Johnson-III Achievement battery	Letter-Word Identification, Word Attack and Reading Fluency, Reading Comprehension
Test of Word Reading Efficiency (TOWRE); Ages: 5 years to young adulthood	Single-word reading efficiency (e.g., speedy and accurate naming of single words and pseudowords)
Gray Oral Reading Test; Nelson–Denny Reading Test; Gray Silent Reading Test	Reading fluency and comprehension (e.g., rate of reading connected text for meaning)
	Written Expression Skills
Wechsler Individual Achievement test (WIAT-II) Ages: 5–19 years	Spelling, written expression
Test of Written Language (TOWL; 3rd edition) Ages: 7.5–17.9 years	1. Elicited writing, including vocabulary, spelling, capitalization and punctuation, logical sentences, sentence combining 2. Spontaneous writing combining
Test of Early Written Language (TEWL; 2nd edition)	Basic, global, and contextual writing

Ages: 3–11 years	
Test of Written Spelling (TOWS; 4th edition)	Spelling of phonetically regular and nonregular words
Ages 6–18 years	
Woodcock–Johnson Psychoeducational Battery	Dictation, proofing, writing fluency, writing samples
Ages: 5 years–adult	
	Mathematics Skills
Woodcock–Johnson Achievement Battery-III	Math fluency, calculation, quantitative concepts, applied problems
Test of Early Mathematical Abilities —3rd edition Age: 3–0 to 8–11	Numbering skills, number-comparison facility, numeral literacy, mastery of number facts, calculation skills, and understanding of concepts
Test of Mathematical Abilities Age: 8–0 to 18–11	Mathematical symbols and concepts; computation; mathematics in everyday life; word problems; attitude toward math
Teacher Academic Attainment Scale (TAAS)	Subjective rating scale of student academic achievement (7 items)
Math Anxiety Questionnaire	Math anxiety
Abbreviated Math Anxiety Scale	1. Learning anxiety: anxiety related to learning math 2. Testing: anxiety related to being tested in math
Subjective Numeracy Scale	Subjective rating of one's health numeracy
Test of Functional Health Literacy in Adults (s-TOFHLA)	Objective measure of health literacy
Rapid Estimate of Adult/Adolescent Literacy in Medicine [REALM])	Objective measure of health literacy

Criterion D. The fourth criterion refers to a range of exclusionary conditions. These include intellectual disability, other major mental or neurological conditions, uncorrected visual or auditory acuity, severe psychosocial adversity, lack of proficiency in the language of instruction (for adults, lack of proficiency in the language of the workplace or social community), lack of or inadequate educational instruction, as may occur for children excluded from education for various reasons (e.g., because they are girls; living in war zones, no schools, no teachers, etc.). These exclusionary criteria are evaluated by means of the comprehensive clinical assessment.

As of 2012, UNICEF reports that about 58 million children are excluded from primary school education and 63 million from lower secondary school education (http://www.uis.unesco.org/Education/Pages/out-of-school-children.aspx). Certainly it makes no sense to make a diagnosis of SLD in immigrant children who previously have been excluded from education. The issue of excluding from the SLD category those children whose low academic scores may be due to instructional factors (inadequate instruction; limited opportunity to learn) is important, but has been challenging for clinicians to operationalize. One component of Criterion A attempts to address this challenge, by requiring evidence that symptoms of learning difficulties have persisted for at least 6 months despite the

provision of intervention that targets the affected academic skills. As noted previously, the RTI approach was not adopted by DSM-5 due to insufficient evidence and lack of universal availability of RTI approaches. However, in many countries, the quality of teacher training has improved over recent years (especially in teaching children to read), affording some assurance that a student's limited progress is not due to inadequate instruction and so SLD is a possibility.

Identification of SLD in individuals whose first language (mother tongue) differs from the language of instruction is challenging. Greater diagnostic certainty is accorded by evidence of the following: The individual has a history of language delay or disability in the native language; the individual has had difficulty developing literacy or numeracy skills in the native language (assuming adequate instruction in the native language); there is a family history of SLD in parents, siblings, or other close relatives, the individual is not making adequate progress over 6 months compared to other nonnative speakers, despite the provision of targeted intervention.

Does Information from Tests of Intellectual Capacity or Cognitive Processing Assist in the Diagnosis of SLD or Guide Educational Treatment?

Intelligence testing (and IQ profiling using various subtests) with the requirement for a significant discrepancy between intellectual and academic achievement has been the primary and often sole criterion for the diagnosis of SLD in previous versions of the DSM, continues to be used internationally to determine eligibility for special education services and accommodations, and figures strongly in the understanding of SLD by various stakeholder groups (e.g., teachers, psychologists, parents and parent organizations, lobby groups and researchers). Moreover, this "discrepancy" model has become ingrained in clinical training and practice, despite the several decades of research evidence against its validity for diagnosis or utility in guiding educational instruction. For example, discrepancy scores are unreliable, and children with learning difficulties who do and do not meet the IQ-achievement discrepancy do not differ in symptomatology, associated cognitive deficits, or response to intervention. In other words, the purported differences between those with discrepant and nondiscrepant IQ-achievement scores have not proven to be clinically or educationally meaningful. Thus, a measure of intelligence is not required for a diagnosis of SLD (unless there are concerns about the individual's intellectual ability and adaptive behavior).

Accordingly, based on the available scientific evidence, DSM-5 eliminated the requirement for a significant discrepancy between the IQ score and an achievement score for the diagnosis of SLD. The DSM-5 does not prohibit the inclusion of intellectual assessment in the diagnostic assessment of SLD: Occasionally information from an IQ test might be

helpful in changing a teacher or parent's overall view of the child and their misunderstanding of the child's intellectual ability. However, when formulating a diagnosis of SLD, clinicians should also keep in mind the DSM-5 changes to the conceptualization and criteria for Intellectual Disability: Specifically, poor adaptive and intellectual functioning, with the latter suggested by IQ score less than 70 ± 5 standard points. This means that individuals with an IQ score of greater than 70 ± 5 standard points and adequate adaptive functioning, could potentially—but not necessarily—meet criteria for SLD, since the differential diagnosis of Intellectual Disability can be ruled out.

In recent years, testing of cognitive processes (e.g., phonological processing, rapid automatized naming, auditory and visual processing, processing speed) and executive functions (e.g., working memory, inhibitory control, cognitive flexibility, sustained attention) has been incorporated increasingly in assessment for SLD, in addition to IQ testing. The goal of such testing is to document patterns of cognitive strengths and weaknesses to inform the development of differentiated and more effective educational instruction and intervention. However, it is unclear whether the relationship between SLD and these processes or executive functions is causal or correlational. There is little or no robust evidence that training these cognitive processes and executive functions will boost academic learning particularly in students with SLD. Also, recent meta-analyses conclude that effect sizes of the magnitude of the relationship between children's cognitive characteristics and response to intervention were small and unable to improve clinical prediction from measures of academic skills per se. Moreover, there is little evidence the cognitive profiles are valuable for planning intervention (i.e., little evidence for Aptitude X Treatment interactions). Thus current recommendations are for assessment and intervention for SLD to focus on educational rather than cognitive factors—a position that is understandably threatening to clinicians and other professionals trained in the psychometric tradition and who might lack expertise in curricular and pedagogical practices. Hence the DSM-5 criterion B does require the use of individually administered standardized tests of academic achievement in reading, writing, and arithmetic, where possible.

DIFFERENTIAL DIAGNOSIS

SLD can be distinguished from normal variation (individual differences) in learning academic skills due to other internal and external factors by the severity of the learning difficulties, the specificity of the difficulties in the presence of intact intellectual abilities, and their persistence in the presence of adequate educational opportunity and receipt of the same instruction as the peer group, targeted home or school-based intervention, competency in the language of instruction (even when different from one's

mother tongue).

A diagnosis of SLD is not usually made before the child is about 7 years old because evidence of failure to learn to read, write, or do arithmetic is required. Difficulties in learning the foundational academic skills may occur for a variety of reasons (e.g., lack of adequate exposure to print, limited education) and are associated with numerous mental health conditions, including mental retardation, developmental coordination disorder, communication disorders, ADHD, conduct disorder, hearing or visual problems, and prematurity. The most common distinguishing feature of SLD in reading is a persistent impairment in phonological processing and spelling; that of SLD in mathematics is a persistent impairment in number facts. In a child with visual or hearing deficits, the learning problems must be in excess of the difficulty typically associated with these sensory disorders. In a child with learning difficulties in the presence of low intellectual abilities (i.e., IQ score of 70 ± 5), it is important to assess adaptive behavior to be able to rule out Intellectual Disabilities.

SLD is distinct from Intellectual Disabilities: Individuals diagnosed with intellectual disability have reduced cognitive capacity that has a global impact on learning and adaptive functioning in everyday life. By contrast, individuals with a diagnosis of SLD have at least average intellectual capacity but exhibit significant difficulties in one or more *academic* areas, while coping well or even excelling in other areas of academic, sporting, or artistic achievement. Moreover, SLD is distinguished from "learning difficulties," which is a broader term that encompasses difficulties learning as a consequence of a range of causes, including intellectual disabilities, physical or sensory deficits (e.g., hearing or visual impairments), emotional or behavioral difficulties, inadequate environmental experiences, or appropriate educational opportunities.

SLD in Reading, Mathematics, or Written Expression is frequently associated with ADHD, and a concurrent diagnosis is not only permissible, but is also essential. An explicit statement should be made concerning the presence of both clinical conditions to ensure that the child can access the relevant and effective interventions. Moreover, even if the individual does not meet full criteria for ADHD but does manifest persistent symptoms of inattention (particularly in the school setting), clinicians should report these problems, given the increased risk conferred for poor response to intervention if inattention is not targeted in the treatment plan.

It might be possible to determine inadequate instruction as the primary explanation for reading problems through detailed interview with parents and teachers. Probes for the number of schools attended, absenteeism (voluntary due to illness or vacation; required due to class or school suspensions and expulsions), and type of reading instruction provided at the school(s) in the primary grades may be informative. However, differential diagnosis may be complicated by parental history or current

manifestation of SLD, given that parents with SLD would be less likely to be able to provide the necessary early reading or numerical experiences for the child.

COURSE AND PROGNOSIS

Converging evidence indicates that SLD is persistent and does not remit with increasing age in the absence of effective intervention. SLD tends to be a persistent and chronic condition that remains with the individual his or her entire life, albeit with developmental changes in its manifestation.

Onset, recognition, and diagnosis of SLD usually occurs during the first few years of elementary school when children are expected to learn to read, write, spell, and do basic arithmetic. Precursor signs (e.g., delayed onset of talking; difficulties with counting or rhyming; problems with fine motor skills required for writing) commonly occur in preschool years before the start of formal schooling. Moreover, preschoolers with poor phonological short-term memory (STM) skills and specific language impairment (SLI) are highly likely to meet diagnostic criteria for SLD in reading at school age. However, referral and formal diagnosis rarely occurs until a couple of years later in second grade, when the children have failed to respond to formal classroom instruction in reading.

SLD in elementary school-aged children (grades 1 to 3) typically manifests first as marked difficulty learning to connect letters with the sounds they make (particularly in English-speaking children), to recognize and read common one-syllable words (e.g., mat, top) or common but irregularly spelled words (e.g., said, two). Reading aloud is slow, inaccurate, and effortful. Some children may also (or instead) show problems in learning to count, remember math facts, and perform simple single-digit arithmetic. Recent evidence suggested that it is possible to estimate an individual child's risk for SLD in reading at school age from the following factors measured in preschool years (age 3.5 years): Familial history of reading problems, poor letter and object naming speeds, and poor phonological awareness.

In the middle grades (grades 4 to 6), children with SLD may not only continue to show problems with word reading and basic number sense, but also may manifest problems with spelling, writing, and understanding word problems in mathematics. Others may gradually be able to sound out words, but their reading is slow and effortful, they have difficulty understanding what they have just read, and also problems start to manifest in their written work (e.g., poor spelling, poor punctuation, words left out of sentences, short disconnected sentences, illegible and disorganized writing). Some youngsters continue to count on their fingers since they cannot remember math facts. It is not uncommon, even at this young age for children to dread going to school and to try and avoid reading, writing, or arithmetic.

By adolescence, some youngsters may show improved word recognition and the ability to sound out words, but reading remains slow and effortful, often with poor comprehension, and so they cannot keep up with the increasing demands for reading complex material. They often need to reread material to get even the main point and have great difficulty making inferences from written text. Written work is markedly impoverished: numerous spelling errors, illegible writing, with poor sentence and paragraph structure. Those who showed problems in basic number sense at a younger age, may use long and inefficient strategies to work out even simple arithmetic, such as "7 × 8" (e.g., draw 8 groups of 7 items, and then counting all of the items). Ongoing dread of and failure in school may result in high-school dropout, anxiety, and depression.

Longitudinal investigation of a 1990 US cohort of children, reveals that individuals with SLD in word reading (a.k.a., dyslexia) show an achievement gap in reading that is discernible upon school entry in grade 1 (about age 6) and that persists throughout childhood and adolescence. It remains unknown whether early reading intervention (i.e., kindergarten, grade 1) will eliminate the observed persistent difference in growth trajectories in reading. Likewise, a longitudinal investigation of a large sample of kindergarten children recruited in 1998 to 1999 and followed through 8th grade, revealed that children with SLD in mathematics enter kindergarten with lower skill levels and the achievement gap persists through grade 8.

Young adults with persistent problems in both reading accuracy and fluency appear to develop compensatory mechanisms to cope with reading, such as greater reliance on memory-based rather than analytic strategies to assist in word identification. By adulthood, many individuals try to hide the fact that they cannot read, spell, or do arithmetic by avoiding both leisure and work-related activities that require these skills, or use alternative approaches to access print (e.g., text-to-speech or speech-to-text software, audiobooks, audiovisual media).

The clinical course of SLD is often complicated further by comorbidity with other mental health problems, such as ADHD or conduct disorder, as well as with low self-esteem, anxiety, depression, and increased risk for suicidal ideation and suicide attempts. The causal relationships between SLD and the various comorbid disorders are unknown and longitudinal epidemiological studies suggest that the relationships are complex.

On a more positive note, a recent study reported that adults with SLD in reading (a.k.a., "dyslexia") are overrepresented among entrepreneurs and manifest higher levels of visual problem-solving skills compared to peers with average reading abilities. This subgroup of individuals attributed their success to an admixture of high self-motivation, educational accommodations, and a supportive social network, particularly parents.

Juan P, a 20-year-old Hispanic college student, presented at the primary care clinic in his home city, with complaints of increasing problems sleeping, inability to concentrate or manage his college schedule, failing some courses, and feeling "down" most days. Clinical history indicated a normal birth, slowness in learning to talk, childhood problems with concentration, hyperactivity and angry outbursts, as well as struggles learning to read, at school. Family history was positive for ADHD (older brother) and SLD (father, now deceased, was reported to have had "dyslexia" and dropped out of school early). He had been diagnosed with ADHD, Predominantly Combined Type, at age 9, but did not meet criteria for SLD, since the discrepancy between his intellectual capacity and reading achievement was deemed not to be "substantial" as required by DSM-IV and his local school board.

During the clinical interview, JP reported that since starting college a year ago, he had been unable to remain focused while reading or listening to lectures, felt overwhelmed, and was unable to complete written assignments on time. He complained of feeling restless, agitated, exhausted, and often in a "blue mood." He denied any substance use or suicidal thoughts. He stopped taking medication for ADHD when he was aged 12, and had not sought registration with Student Disability Services at his college, for help with his ADHD, because he thought he could get through college by himself. Current psychoeducational assessment confirmed that JP's reading fluency and comprehension, spelling and written expression, were substantially and quantifiably below that expected for age and was causing significant impairment.

Diagnostic formulation: *Attention-Deficit/Hyperactivity Disorder*, with predominantly inattentive presentation, of mild to moderate severity; *Specific Learning Disorder*, with impairment in reading (fluency, comprehension) and written expression (spelling, organization of written expression), all currently of moderate severity; depressive symptoms but did not meet criteria for a mood disorder.

TREATMENT

Treatment focuses almost exclusively on academic intervention and rarely includes mental health services despite the fact that students with SLD experience higher levels of inattention (and ADHD), anxiety, and depression than their non-SLD peers. Moreover, treatment of SLD is typically carried out in education settings or specialized psychology clinics, and so is not the primary responsibility of psychiatrists or primary care providers.

The primary role of medical health care providers is that of coordinator, which, as a first step, includes the provision of psychoeducation about the disorder and its longer-term implications. Thus, physicians need to be able to explain what Specific Learning Disorder is and refer parents (or the adult patient) to organizations, websites, or reading materials that will help (see the References for some useful websites). Also, parents may need help in understanding their child's needs and rights under the Individuals with Disabilities Education Act, including possible need for accommodations. Given that Specific Learning Disorder tends to run in families, physicians may need to modify how any numeric health information is communicated (prevalence rates, risk ratios, dosage, etc.), as well as to check that the individual or caregivers are able to comprehend any relevant printed or website material.

A second critical step is to establish a monitoring plan with the patient and family, to permit early detection and management of commonly associated mental health problems, such as ADHDs, anxiety, and

depression, as well as to ascertain whether recommended accommodations have been put in place along with intensive, individualized, explicit instruction. Moreover, the need for transitional planning is essential to help individuals with SLD through major developmental and life transitions (e.g., transition from elementary to secondary school; from secondary school to the workforce or postsecondary education; marriage, parenthood, etc.) and facilitate access to services.

One of the major problems is that the standard instruction in regular classrooms is too little, too general, and nonsystematic. For example, one large-scale study found that children receiving special education over a 1-year period advanced in reading by only 0.04 standard deviations per year, which means that it would take at least 8 years to raise these students' scores from the 5h to the 9th percentile. By contrast, students with SLD in reading who received 1 to 2 hours daily of intense and focused intervention for a total of 35 to 70 hours of instruction showed dramatic gains in performance on standardized measures of both decoding and comprehension, which were maintained for several years after intervention. The instruction programs were very explicit and visible, conducted in small, interactive groups of children matched for reading abilities, which promoted engaged and repeated reading of connected text presented in a way that controlled task difficulty, and included instruction in basic reading abilities (e.g., teaching phoneme-to-grapheme correspondences), as well as the application of metacognitive strategies for decoding unfamiliar words and comprehending connected text. Of note, preliminary evidence suggests that intense and focused instruction may in fact alter the aberrant brain activation profiles observed in children with SLD. Thus, clinicians need to be aware that recommendations for placement in special education may not be sufficient to improve reading or arithmetic skills. Rather, they need to advocate for the provision of intense, focused, and explicit instruction in each of the affected academic domains.

Also, given the importance of literacy and numeracy skills in health, clinicians are advised to screen for and monitor health literacy and numeracy in all patients (and parents of pediatric patients), regardless of their referral problem. Low literacy or numeracy cannot be inferred reliably on the basis of the patient's education level, intelligence, or other observable behaviors. Reliable short screening forms can be used to assess health literacy and numeracy in adolescents and adults and to guide health communication.

Developmental Coordination Disorder

CAROLY SUE PATAKI, M.D., AND WENDY G. MITCHELL, M.D.

Developmental coordination disorder (DCD) is a neuromotor disability emerging in the early developmental period which can affect both fine and gross motor skills, interfering with daily activities. Children with DCD have motor performance which is typically slower, less accurate, and more variable than peers of the same age. DCD is estimated to occur in 5 to 6 percent of children aged 5 to 11 years, and 1.8 percent of children 7 years of age exhibit severe DCD. DCD affects boys more often than girls, most recent population studies report ratios of male:female of about 2:1. Children exhibiting DCD often show impairment in gross motor skills such as jumping, hopping, and running, fine motor skills including handwriting, tying their shoelaces, or using utensils, and balance. Motor coordination disorder is comorbid up to 50 percent of the time with attention deficit/hyperactivity disorder (ADHD). Other disorders that may co-occur with DCD are communication disorders and specific learning disorders. Delayed motor milestones may be the first sign of DCD, in the absence of intellectual disability. Without intervention, DCD often continues to cause impairment throughout childhood and adolescence, leading to significant consequences physically, educationally, socially, and psychiatrically.

DEFINITION

The essential feature of DCD according to DSM-5 is impaired motor skills leading to deficits in coordination compared to children of the same chronological age and intellectual level, interfering with activities of daily living, social activities, and school productivity. Key symptoms are marked delays in achieving motor milestones, such as walking, crawling, and sitting; constantly dropping objects; inability to catch or throw a ball, and poor handwriting. Children with DCD perform motor coordination tasks slower and less accurately than those peers of the same chronological age and intellectual capacity. Specific manifestations of DCD are detailed in Table 42–1.

HISTORY

In the early 1900s, childhood motor clumsiness was termed motor *deficiency syndrome*. This syndrome was characterized by awkward

voluntary actions, excessive tendon reflexes, mild hypertonicity, and neurological overflow movement. The term *clumsy child syndrome* first appeared in the literature in the 1930s to describe a set of symptoms associated with clumsy motor behaviors of unknown etiology, not associated with a known neurological disorder. The observation was made that many children with motor coordination difficulties also exhibited ADHD, communication disorders, and specific learning disorders. During the 1940s, remedial programs were established in an attempt to improve academic learning deficits through treatment of coordination difficulties observed in children.

By the 1960s, the *clumsy child syndrome* was officially distinguished from other categories of learning disorders. From this period to the mid-1980s, significant investigations were conducted into perceptual–sensory causes for motor impairments, as well as social and emotional problems associated with such impairments. Children with clumsy behavior were noted to have deficits, rather than solely delayed fine and gross motor coordination skills.

COMPARATIVE NOSOLOGY

Many terms have historically been applied to the description of *clumsiness* in a child. Terms used in the past that overlap with a description of DCD include congenital maladroitness, choreiform syndrome, psychomotor syndrome, developmental apraxia, developmental dyspraxia, congenital clumsiness, developmental agnosia, and developmental dyspraxia–dysgnosia. It is only appropriate to make a diagnosis of DCD after any suspicion of a neurological disorder is ruled out. In the DSM-5, DCD is not diagnosed if symptoms are attributable to intellectual disability or a neurological condition such as cerebral palsy, muscular dystrophy, or a degenerative disorder. Although, currently, this syndrome is still occasionally referred to as clumsy child syndrome, DCD and specific developmental disorder of motor function are more appropriate terms.

Table 42–1.
Manifestations of Developmental Coordination Disorder

Gross motor manifestations
Preschool age
Delays in reaching motor milestones, such as sitting, crawling, and walking
Balance problems: Falling, getting bruised frequently, and poor toddling
Abnormal gait
Knocking over objects, bumping into things, and destructiveness
Primary-school age
Difficulty with riding bikes, skipping, hopping, running, jumping, and doing somersaults
Awkward or abnormal gait
Older

Poor at sports, throwing, catching, kicking, and hitting a ball
Fine motor manifestations
Preschool age
Difficulty learning dressing skills (tying, fastening, zipping, and buttoning)
Difficulty learning feeding skills (handling knife, fork, or spoon)
Primary-school age
Difficulty assembling jigsaw pieces, using scissors, building with blocks, drawing, or tracing
Older
Difficulty with grooming (putting on makeup, blow-drying hair, and doing nails)
Messy or illegible writing
Difficulty using hand tools, sewing, and playing piano

DCD has been included as a diagnosis in DSM-III-R and appears in essentially the same form in DSM-5. The tenth edition of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) also includes the disorder, but the slightly more formalized definition requires an intelligence quotient of at least 70 and performance at least two standard deviations below the mean on a standardized test of motor coordination. In 1994, an international Consensus meeting, held in London, Ontario agreed on the term DCD to describe children with a heterogeneous set of motor impairments that caused impairment in performing motor tasks compared to same age peers.

Although DSM-5 and ICD-10 view the disorder as a unitary undifferentiated syndrome, several investigators have suggested that there may actually be several distinct subtypes. Supporting that view is the individual variation in symptomatology, only some of which is clearly age related. One recent attempt to reclassify DCD proposed subtypes, such as ataxic syndrome (marked by unsteadiness and mild tremors), hypotonic syndrome (characterized by below-average resting muscle tone), tension syndrome (manifested by constant and excessively high levels of muscle tone), dyspraxic syndrome (identified by the inability to link a series of submovements necessary to execute smooth motor movements), manual–graphic syndromes (two separate manual syndromes, one marked by inadequate dexterity but adequate ability to reproduce written symbols and the other characterized by adequate dexterity but inability to reproduce written symbols accurately using fine motor movements), visual–perceptual clumsiness (ranging from ocular–motor problems involving inefficient movement of eye muscles to severe retinal deterioration), and mixed syndromes (a combination of symptoms already presented under the aegis of the previous six classifications). It is always important to keep in mind that significant ataxia, hypotonia, or any asymmetry between left and right side muscle function may be an indicator of a neurological disorder and requires a neurological assessment.

EPIDEMIOLOGY

The prevalence of DCD has been estimated to be approximately 5 to 6 percent among school-aged children. DCD has been noted in Europe, Asia, Africa, Australia, and North America. Clinical studies of children with DCD have historically found greater rates in boys than girls, of up to 7:1. More recent population studies have found less disparity, and report rates of approximately 2:1, male to female.

ETIOLOGY

A meta-analysis of performance deficits in DCD by Wilson and colleagues (2013) found that several clusters of deficits in learning motor skills emerged, suggesting that brain networks including parietocerebellar and cerebellar regions are involved. The clusters of motor skills dysfunction include "internal modeling of action" (predictive control of motor skills), rhythmic coordination and timing of motor movements, executive function, and dynamic control of posture and gait. The result of insufficient internal models, due to deficits in neural pathways in DCD leads to a lack of fluency and efficiency in coordinated movement. That is, the sequence of a complex motor movement in children with DCD is not properly or efficiently ordered, leading to awkward motions. Poor ability to coordinate a sequence of motor movements in DCD may be attributable to dysfunction in the corticocerebellar brain region. In terms of executive function deficits, impaired attention, working memory, and inhibition may contribute to poor action planning, and exacerbate overall poor motor coordination. The exact etiology of DCD is not yet clear, however, it is likely to include heritable factors, with potential prenatal and prenatal developmental contributions. There is much heterogeneity in the expression of DCD. Motor control is dependent on numerous skills, including perception of objects in space, regulation of muscle activity, and balance. Children with DCD appear to be less proficient and less consistent in regulating muscle activity in heterogeneous ways. Some children with DCD are poor in manual skills, while exhibiting proficiency in balance, and for others, the opposite is true.

Developmental Coordination Disorder and ADHD

Epidemiologic surveys have documented the comorbid occurrence of DCD in 30 to 50 percent of children diagnosed with ADHD. A recent study of children comorbid for ADHD and DCD in the Netherlands by Fliers et al., in 2007 confirmed previous research demonstrating a consistent increased risk of each of these disorders based on the presence of the other one. This study also investigated the association between the various types of motor coordination problems and inattentive versus hyperactive or impulsive subtypes of ADHD. In this study, data suggested that inattentive rather than hyperactive or impulsive symptoms were related to higher measures

of motor coordination symptoms on the Developmental Coordination Disorder Questionnaire (DCD-Q) that was filled out by parents. This finding lends support for hypotheses that deficits in information processing are contributing problems underlying both ADHD and DCD. Although parents report that motor coordination problems often diminish with age, half of adolescents comorbid for ADHD and DCD continue to be impaired by coordination problems. One possible commonality between DCD and ADHD is a deficit in cerebellar activity. The coexistence of DCD and ADHD may reflect a shared heritable disturbance of the dopamine pathway. These two disorders may also share dysfunction in the basal ganglia and the prefrontal cortex.

Developmental Coordination Disorder and Premature Birth

Evidence indicates biological and cognitive-developmental correlates of DCD. The biological–organic factors associated with the disorder include various birth and perinatal problems, such as low birth weight, prematurity, hypoxia, and neonatal malnutrition. A study by Marlow and colleagues investigated motor and "executive" cognitive function in 241 children who were born severely prematurely, at less than or equal to 25 complete weeks of gestation. These children were assessed at a median age of 6 years and compared with 160 classmates born at full term. Children underwent assessment of cognitive and neuromotor skills, including the Kaufman Assessment Battery for Children (K-ABC) and the NEPSY (a teacher-based assessment of academic achievement). Motor function was assessed by clinicians using the following items from the Movement Assessment Battery for Children (MABC): Heel-toe walking (15 steps), 1-leg balance (more than 20 seconds), and time to post 12 coins. Results from this study indicate that compared to classmates, children born severely prematurely and in the absence of cerebral palsy exhibited high prevalence of impairment in gross motor function at early school age, in addition to impaired visual–spatial, perceptual–motor attention, and executive function. In each of the above impairments in motor skills or executive functions, at least half of the deficits were not accounted for by limitation of the overall cognitive score. Thus, motor and executive function disturbances in extremely prematurely born children are not due to compromised intellectual function but more specifically associated with perceptual deficits. Children who were born extremely prematurely were observed to need more time for tasks compared to full-term classmates, and they were noted to have greater difficulty inhibiting associated movements and maintaining secure postural basis during activities. As many as 7 percent of extremely prematurely born children were unable to balance on one leg for 20 seconds (compared to 1 percent of classmates). This study showed that extremely prematurely born children did not differ significantly from classmates on observed off-task motor behavior (17

percent vs. 25 percent), mirror movements (32 percent vs. 46 percent), and overflow movements (45 percent vs. 69 percent). Some investigators have postulated a continuum of reproductive casualty. There are also suggestions of incomplete cerebral dominance or lateralization, neurochemical abnormalities in the brain, and structural lesions in the parietal lobes.

Developmental Coordination Disorder and Psychiatric Comorbidities

DCD frequently occurs concurrently with speech–language disorders, and specific learning disorders, including reading disorders and dyslexia. A study showed that more than half of children with severe dyslexia exhibited motor coordination impairments severe enough to warrant intervention. Reading disorders, dyslexia, and speech and language disorders have been hypothesized to be associated with cerebellar involvement as has DCD. One longitudinal study of children with language impairments revealed a continuing correlation between peg-moving performance and language performance. Another study found that fine motor skills, response speed, and upper limb speed were associated with language disturbances, whereas gross motor coordination and visual–motor control were not. Furthermore, evidence indicates that articulation problems are related to motor impairment, although the motor impairment is not necessarily dyspraxia.

DIAGNOSIS AND CLINICAL FEATURES

In 2012, The European Academy of Childhood Disability (EACD) published an interdisciplinary clinical guideline for the assessment, diagnosis, and treatment of children with DCD. The essential feature of DCD is poor skill in daily motor activities for a given child's age and intellectual level. Impairments may be observed in gross motor activities, such as running, kicking, or catching a ball, as well as in fine motor coordination, resulting in poor ability to write letters neatly, to drink from a cup, or to use a knife and fork well. Children with DCD exhibit a heterogeneous pattern of impairments and thus function more competently in some motor task areas than others.

Assessment Instruments for Developmental Coordination Disorder

The Developmental Coordination Disorder Questionnaire. The DCD-Q is a 17-item parent questionnaire developed in Canada and validated to identify motor coordination problems in children from 8 years to 14½ years by Wilson et al. (2000) validated in children 4 to 8 years of age. For each item, parents rate the degree of coordination in their child compared to others of the same age on a 5-point scale. By adding the scores for each item, a total DCD-Q score can be calculated. In the study validating this instruments for young children, a score of less than or equal to 53 (15th

percentile) was used as the criterion for DCD. The 17 items on the DCD-Q are:

1. Throw ball
2. Catch ball
3. Hit ball
4. Jump over
5. Run and stop
6. Plan activity
7. Writing speed
8. Writing legibly
9. Pencil pressure
0. Cutting
1. Team sports
2. Avoids sports
3. Rides bicycle
4. Learns skills
5. Clumsy
6. Awkward
7. Fatigues easily

The Movement Assessment Battery for Children. The The MABC-second edition, was introduced by Barnett, Henderson, and Sugden in 2007, and provides an indication of gross and fine motor skills for children 4 years to 16 years of age. The MABC has two parts: a checklist and a performance test. On the MABC checklist, teachers rate the motor performance of children on 48 items reflecting everyday activities in the lives of children from 4 to 12 years. The checklist is divided into 4 sections with 12 items in each section. On the performance test, there are four age-related item sets, each consisting of eight items that measure manual dexterity, ball skills, and static and dynamic balance. The checklist is a reliable instrument within sections and overall. Since the nature and severity of problems in DCD is very broad, an instrument meant to screen children with DCD must be able to measure a wide variety of motor skills.

Bruininks–Oseretsky Test of Motor Proficiency for Identifying Children with Motor Impairment. The Bruininks–Oseretsky Test of Motor Proficiency (BOTMP) assesses motor skills in children from 4½ to 14½ years old and provides a comprehensive index of motor proficiency as well as individual measures of gross and fine motor skills. In addition to the long form (LF), there is also a short form (SF), which consists of 14 items from the long form that have been validated. A recent study of the BOTMP in the assessment of preschoolers investigated the correlation between the long form and the short form of the instrument. Although the correlation between the two forms were high, short form total scores were found to be

significantly higher than long form scores, identifying less children as having motor impairment. Therefore, although the long form has been validated for young children, the short form is questionable in its ability to identify motor impairment in very young children.

Additional tests include the Frostig Movement Skills Test Battery, the Slosson Drawing Coordination Test, the Southern California Sensory Integration Test, and the Stott Test of Motor Impairment, which provide a comparative measure of a child's abilities.

Symptoms of DCD may be broken down into the following categories: dyspraxia, synkinesia, hypotonia, hypertonia, tremors, impersistence, and asymmetries. *Dyspraxia* describes a child's difficulty in exhibiting sequenced, coordinated motor movements when presented with an oral request. Movements identified as *synkinesia* are best described as unintentional muscle movements, also termed *motor overflow*. Mirror movements, such as finger twitching on the opposite hand when the child is asked to perform a finger opposition task or facial grimaces when the child is asked to make hand movements, are examples of synkinetic motor actions.

Two categories that describe muscle tone abnormalities are *hypotonia* and *hypertonia*. Hypotonia can be observed in all parts of the body and is characterized by a flaccid or sleepy quality in the child's facial expression and general muscle tone. Children with this condition may exhibit poor posture and obesity. Children with hypotonia often appear to be floppy and weak, but, on actual muscle strength testing, they may have normal muscle strength. *Hypertonia* describes generally high levels of muscle tone in a child. For example, a child with hypertonic movement cannot finish drawing a line at a given point, instead overshooting the intended stopping point. Another example is a child who tends to throw a ball too hard and inaccurately at short distances.

The movement category of *tremors* is marked by irregular unsteadiness in motor movements observed in tasks requiring walking, drawing, or both. For example, legibly formed letters might reveal, on closer inspection, rapid tremors in the actual lines themselves. Unsteadiness might be exhibited in the child's gait as high-amplitude fluctuations in leg muscle movement.

The category of *impersistence* refers to the child's inability to sustain and maintain various body postures for reasonable periods of time. Asking a child to stick out his or her tongue is an example of a task used often to investigate impersistent motor movements. In this example, the clinician would keep track of how long the child could maintain this tongue position.

The final movement category, *asymmetries*, describes motor behaviors that affect only one side of the body. This category includes unusual flexions or muscle weakness, or both, on one side of the body or general muscle weakness in the limbs on one side. These asymmetrical muscle

movements can be observed by requiring a child to move laterally in a rapid manner ("like a basketball player on defense, not crossing your feet"). If the child executes the movement more fluidly on one side than the other, it might indicate an asymmetry. A child who is observed to have asymmetrical motor movements is likely to be referred for a magnetic resonance imaging (MRI) study to rule out an organic cause for this symptom. If the neurological work-up is negative, then this symptom may be considered as part of a DCD.

Specific manifestations vary across individuals; thus, there is no typically clumsy child. In some instances, manifestations may be quite specific; one case report describes a child who could sew and do jigsaw puzzles without difficulty but could not write neatly.

The most common way to identify DCD is through the observation of delays in achieving motor milestones (e.g., sitting, standing, crawling, and walking). Gross motor coordination manifestations may be seen in difficulties with activities, such as sitting, walking, running, balancing, throwing, and kicking. Fine motor coordination manifestations may be identified through difficulties in performing tasks, such as using utensils, tying laces, buttoning or zipping clothing, drawing, and, especially, printing or writing. During motor tasks, children with DCD may exhibit overflow movements in unsupported limbs, mirror movements, slight abnormalities of reflex, or poor ability to make movements smooth.

Some manifestations of DCD are age dependent. Young children show symptoms, such as delayed development, in early motor milestones and delayed acquisition of self-help skills, such as self-dressing (i.e., tying ties, fastening snaps, zipping zippers, buttoning, and unbuttoning) or self-feeding (handling a knife, fork, or spoon). Preschool-aged children may also have balance problems, awkward gait, and a history of frequently bumping into objects, falling down, and getting bruised. Problems with balance, hopping, jumping, catching and bouncing a ball, and tracing appear to be among the more common symptoms of school-aged children with DCD. A common sign of DCD among school-aged children is avoidance of sports activities because of poor performance or teasing by classmates.

Table 42–2.
DSM-5 Diagnostic Criteria for Developmental Coordination Disorder

A. The acquisition and execution of coordinated motor skills is substantially below that expected given the individual's chronological age and opportunity for skill learning and use. Difficulties are manifested as clumsiness (e.g., dropping or bumping into objects) as well as slowness and inaccuracy of performance of motor skills (e.g., catching an object, using scissors or cutlery, handwriting, riding a bike, or participating in sports).
B. The motor skills deficit in Criterion A significantly and persistently interferes with activities of daily living appropriate to chronological age (e.g., self-care and self-maintenance) and impacts

academic/school productivity, prevocational and vocational activities, leisure, and play.

C. Onset of symptoms is in the early developmental period.

D. The motor skills deficits are not better explained by intellectual disability (intellectual developmental disorder or visual impairment and are not attributable to a neurological condition affecting movement (e.g., cerebral palsy, muscular dystrophy, degenerative disorder).

In addition, children with DCD frequently have comorbid communication and learning difficulties. Among the more common of these difficulties are expressive language disorder, mixed receptive–expressive language disorder, phonological disorder, reading disorder, disorder of written expression, and mathematics disorder.

Secondary complications for children with DCD often involve rejection from peers who are critical of their poor abilities in sports activities and other tasks. Over time, children who are chronically "picked last" for sports teams and who are unable to keep up physically with their peers may become demoralized or depressed. The DSM-5 diagnostic criteria for DCD are listed in Table 42–2. The ICD-10 diagnostic criteria for specific developmental disorder of motor function are presented in Table 42–3.

Differential Diagnosis

Informal observation by parents, teachers, and clinicians of gross motor coordination (e.g., hopping, jumping, and standing on one foot), fine motor coordination (e.g., finger tapping and shoelace tying), and hand–eye coordination (e.g., catching a ball and copying letters) is the most common initial screen for identification of coordination difficulties. However, given the vast normal variation in motor skills, it is often not easy to make a diagnosis of DCD. When coordination difficulties interfere with academic achievement or activities of daily living, however, formal testing and evaluation of these skills are recommended (Table 42–4).

Table 42–3.
ICD-10 Diagnostic Criteria for Specific Developmental Disorder of Motor Function

A. The score on a standardized test of fine or gross motor coordination is at least two standard deviations below the level expected for the child's chronological age.

B. The disturbance described in Criterion A significantly interferes with academic achievement or with activities of daily living.

C. There is no diagnosable neurological disorder.

D. Most commonly used exclusion clause. IQ is below 70 on an individually administered standardized test.

Table 42–4.
Motor Signs and Symptoms Indicating Referral for Comprehensive Neurological Evaluation

Hypertonia	Chorea
Hypotonia	Weakness
Ataxia	Asymmetry
Tremor	

Ruling Out Neurological Disorders. Children with developmental motor disorders progress in gross and fine motor landmarks, although at a slower rate than peers. They do not regress. Thus, a child who previously walked, ran, and climbed at age-appropriate levels, but who no longer does these activities well should be evaluated for neurological disorders. A child whose balance has deteriorated needs further testing to determine the cause of the change. Similarly, a child whose fine motor development was at age expectation but who stopped using a hand, switched apparent hand dominance, or lost previous abilities should be assessed for other medical conditions. Even a child whose initial motor landmarks were delayed should be carefully investigated if he or she loses previously established abilities.

Family history is important in the consideration of neurodegenerative conditions such as spinocerebellar degeneration, Huntington disease, peripheral neuropathies, or other neuromuscular disorders. Further investigation should be pursued even if the positive family history is of onset in adulthood. Many dominantly inherited neurodegenerative conditions show "anticipation," presenting in subsequent generations at earlier ages, even early childhood.

A physical examination, including neurological examination, should be performed. Skin stigmata, for example, may suggest a neurocutaneous syndrome (i.e., multiple café-au-lait spots, axillary or inguinal freckles suggesting NF1, depigmented macular lesions, sebaceous nevi, facial adenoma sebacea suggesting tuberous sclerosis). Excessive diffuse skin pigmentation, particularly in nonsun-exposed areas, is a clue to possible corticotropin excess, seen in boys in the early phases of adrenoleukodystrophy, at a time that the only other complaints may be loss of adept motor skills and behavior problems. Dysmorphic features, even subtle, may suggest an etiology. The presence of scoliosis, or a dimple, bulge, or hair tuft over the spine, or limb asymmetries may suggest that the motor findings are due to a structural spinal cord abnormality. Examination of the ocular fundi is sometimes challenging in small children, but is particularly important if loss of motor landmarks is accompanied by other symptoms such as headache or vomiting.

Screening evaluation of cranial nerve function in young children is most easily assessed by observation of eye movements, facial movements, listening to quality of speech, and watching the child swallow. For example, a child who cannot easily swallow water from an open cup or who coughs or gags when doing so may need to have gag reflex formally tested. The extremities should be evaluated for muscle bulk, tone, and symmetry of length and girth. Asymmetric extremity size suggests either structural brain or spinal cord lesion. In young children, strength is best assessed by observation of the child performing specific activities, such as rising from the floor, climbing onto a stool, reaching overhead for a toy, jumping, and hopping. Diffuse or symmetric muscle atrophy or weakness may suggest a neuromuscular disorder (i.e., muscular dystrophy, congenital myopathy, and neuropathy), malnutrition, or systemic illness. For example, boys with early manifestations of Duchenne muscular dystrophy may appear motor delayed and maladroit well before there are obvious complaints of weakness. Although testing of tendon reflexes may yield somewhat inconsistent results in young children, consistent asymmetries, complete absence of reflexes, or frank hyperreflexia, clonus, or extensor plantar responses mandate further investigation. Gait should be observed in multiple ways: Watch the child walking, running, tandem walking, skipping, and walking on heels and toes. In addition to watching the gait pattern, the examiner should pay attention to posture and movement of upper extremities as the child walks or runs. Abnormalities such as asymmetric arm swing or dystonic posturing of one or both hands are sometimes only appreciated with activity. Balance can be assessed both watching the child perform ordinary activities such as rising from the floor, walking, or turning, and by more structured tasks such as standing on one foot. Frank ataxia, as opposed to immaturity and delay in acquiring skills, should mandate additional investigations. Many different genetic conditions present with truncal ataxia, with or without other deficits. Initial presentation may be relatively subtle. Fine motor abilities can be observed both directly (i.e., finger to thumb tap, thumb to sequential finger tap) and by watching the child during age-appropriate activities. For example, watch the child pick up a toy, color, write, use a hand-held computer game, tablet-type computer, drink from a cup, or use a spoon. Look for asymmetries, dystonic posturing, or tremor. Look for tremor or dystonic posturing of the outstretched arms.

Poor motor coordination frequently coexists with learning disorders and disruptive behavior disorders, such as ADHD, particularly in children with high levels of impulsivity. A child may meet criteria for DCD and ADHD. The tendency for children with DCD to be accident-prone, to fall down, to hurt themselves, and to break objects may, at times, be construed as destructiveness. In the school setting, a child's motor difficulty with holding a pencil and writing legibly may result in great frustration for the

child and the teacher. For children whose impaired writing ability and poor production are inadvertently interpreted as lack of motivation, demoralization is common, and an evaluation for special educational services may be warranted. Children with DCD are at higher risk for poor social skills and are often victimized by bullies.

Jimmy was referred for evaluation to determine his need for adaptive physical education (PE) age 9 years of age. Jimmy was failing PE, was unable to run a mile, and he could not throw or catch the ball, and was generally slow motorically. His classmates laughed because he looked so "funny" while running, and he always seemed to be getting hit with the ball instead of catching it. Jimmy was always picked last for team sport games and was beginning to be bullied by his classmates for his poor physical skills. Jimmy already had an accommodation for more time on tests due to his previously diagnosed ADHD. He was being treated with Vyvanse which was working well. A developmental history revealed that Jimmy was born prematurely at 31 weeks, and his motor milestones were all delayed, although verbal milestones were right on time. Currently, Jimmy was unable to tie his shoes correctly, and he struggled to hand write letters correctly, but his parents were hoping that he would outgrow those problems. Upon questioning about Jimmy's current motor skill, it became apparent that not only was he having coordination problems, but that he was now being rejected by peers and had become quite socially isolated. At home, Jimmy's parents had accepted the fact that he was just a clumsy boy and noted that Jimmy constantly spilled his drinks and was awkward when he used a fork. His food often fell off a fork or spoon before it reached his mouth, and he had great difficulty using a knife and a fork. A comprehensive assessment of fine and gross motor skills yielded the following results: Jimmy was able to hop, but he could not skip without briefly stopping after each step. He could stand with both feet together but could not stand on tiptoe. Jimmy held a ball bounced to him at chest level, and he could not catch a ball bounced to him on the ground from a distance of 15 ft. Jimmy's agility and coordination were measured with the BOTMP, which revealed functioning levels commensurate with those of an average 7-year-old child.

Jimmy was referred to a neurologist for a comprehensive evaluation to rule out neurological disorders. On neurological examination, Jimmy was found to have no signs of a specific neurological disorder. Neurological examination was negative for conditions that could account for his poor motor skills. Based on the history and finding on the BOTMP, Jimmy was given a diagnosis of DCD. Jimmy's symptoms included gross and fine motor impairments, poor balance, and mild hypotonia. Based on an individualized educational plan (IEP) meeting with his school, it became evident that Jimmy required an adaptive physical education program and other specific learning disorders. In addition to his known ADHD, Jimmy was found to have a writing disability. A treatment plan was developed that included twice weekly with an occupational therapist who used perceptual–motor exercises to improve his fine motor skills, targeting particularly writing and use of utensils. Jimmy was also enrolled in a treatment program using motor imagery training to improve clumsiness and was also referred to a social skills group to help him deal more effectively with his peers.

Jimmy was relieved to be receiving help, especially for his handwriting and physical education class, which he had been close to failing. Over a period of 4 months of treatment, Jimmy showed some improvement in the legibility of his handwriting, although he remained a slow writer. He was responsive to the stimulant medication and his academic achievement improved as his attention span increased. Jimmy was receiving more praise from his teachers than ever before, and his classmates were teasing him less. As he began to feel better about himself, he began to try to play sports informally with his peers, although not competitively. He was given a modified physical education program in school, and he was not required to play on teams, but he practiced throwing and catching a ball and was allowed to walk his mile at a slower time. Jimmy continued to exhibit some impairment in fine motor skills over the year, and he was cooperative with the therapeutic interventions, showed some continual improvement, and was demonstrating improved peer relationships.

COURSE AND PROGNOSIS

Children with DCD represent a heterogeneous group with a variety of impairments in gross and fine motor behaviors needed for everyday living as well as in static balance. The profile of specific deficits for a given child is individual and has been shown in recent studies to be modified positively by specific motor skills interventions. The outcome of motor coordination disorder is influenced by the severity of the impairment, the age of initiation and duration of therapeutic interventions, and the presence of comorbid disorders. A recent study of preschool children with DCD at 7 to 8 years of age revealed that those children who had significant impairment at 5 years of age continued to show impairment 1.5 years later. Longer-term studies have shown that motor coordination improves over the long term in at least 50 percent of children when they reach adolescence. A 2-year follow-up study of children of primary school age who had failed a motor test battery revealed motor performance that, although improved, was still inferior to that of controls. The children with motor impairments also showed poorer educational performance than controls.

A 10-year follow-up of clumsy children and their age-matched, sex-matched peers was done in children over a period of 8 to 9 years. When first identified, the clumsy children were approximately 6 years of age; at follow-up, they ranged from 15 to 17 years of age. Follow-up testing indicated that the clumsy children were still significantly below the controls in most motor skills (e.g., dexterity, ball skills, and balance, cutting with scissors, catching, and walking backward) and in global ratings by physical education teachers. The clumsy adolescents showed higher rates of dysgraphesthesia, dysdiadochikinesis, and motor slowness. In addition, the educational achievements of the clumsy adolescents were significantly poorer, and they had significantly lower perceived social competence than their nonclumsy peers. That finding substantiates reports of continuing secondary problems, including peer problems, low self-esteem, and academic struggles in children and adolescents with significant coordination difficulties.

A long-term follow-up of children with DCD and those with ADHD and DCD at 22 years of age suggests that there are psychosocial ramifications into adulthood. Psychosocial adjustment difficulties present in the young adults with only DCD and those who were comorbid for ADHD included unemployment, use of substances, continued difficulties with reading, and legal problems.

DCD tends to improve in most individuals over time, and those with more severe impairment at a younger age, as well as those comorbid for additional psychiatric disorders, have the poorest prognoses.

TREATMENT

Interventions for developmental motor coordination can be divided into three major categories: (1) *Task-oriented* approaches such as Neuromotor

Task Training (NTT) and Cognitive Orientation to Occupational Performance (CO-OP); (2) *Process-oriented* approaches such as Sensory Integration (NI) and kinesthetic training; and (3) *traditional physical and occupational therapy* such as perceptual–motor training, and therapist-guided parent or teacher intervention. A meta-analysis of interventions to treat DCD in children by Smits-Engelsman and colleagues (2013) found that the strongest evidence of effective treatment for DCD was for task-oriented approaches and traditional motor training therapies, with process-oriented therapy yielding only weak efficacy.

Task-Oriented Approaches

Task-oriented therapies focus on learning particular motor skills with a focus on the aspects of the movements that pose the greatest difficulties for the child. NTT is a hybrid of practicing specific problematic specific motor skills with the addition of cognitive behavioral strategies to increase motor planning, reduce anxiety, and increase incentive for trying. Cognitive Orientation to Occupational Performance (CO-OP) is another form of task-oriented therapy which directs a child to form a mental model of how a particular set of movements will be accomplished, and then review with the therapist how well the mental image fit the actual motor task trials. CO-OP consists predominantly of cognitive behavioral problem solving approaches, and utilizes cognitive behavioral strategies proposed by Donald Meichenbaum.

Computer gaming with virtual physical motor tasks has been found to benefit children with DCD often without explicit instructions or learning. A study of children with DCD playing a computer game designed in which children need to catch a ball virtually on the screen, showed that they used visual cues to help them virtually catch the ball without even realizing it. These children were able to improve their computer score implicitly by practicing the game and to make use of a perceptual cue without having to be specifically instructed on how to improve. This has implications for treatment in that, in addition to providing direct instruction to children with motor coordination problems, improvement can also occur with practice through environmental cues that are not necessarily identified.

A newer task-oriented strategy is Nintendo Wii Fit Training (Wii training). The Nintendo Wii is a gaming system that combines motion sensor technology in handheld controls and a balance board provides both aspects of biofeedback and virtual reality to the player. In this way, an interactive videogame can serve as a therapeutic tool for motor skills improvement.

A study of 56 children between 6 years and 10 years with DCD, compared NTT (n = 37) to Wii training (n = 19) by Ferguson and colleagues (2013). Children in the NTT group were provided two sessions per week (45 to 60 minutes) for 9 weeks in which they played games such as soccer, tag,

and netball under the guidance of therapists who facilitated learning of motor skills, provided positive feedback, and manipulated the environment when necessary. Children in the Wii group, participated in 30 minutes of gaming three times a week for 6 weeks under the supervision and guidance of therapists who encouraged, praised, and motivated the children. Games included sports such as cycling, soccer, skateboarding, and skiing. Games required that the children shift their weight from side to side, and jump over virtual objects, and some games required twisting of arm movements. The results found mean motor performance scores in both groups improved during the course of the study. The NTT group showed greater improvement in overall motor performance, functional strength and cardiorespiratory fitness, while the Wii group showed significant improvement in anaerobic performance. Thus, this study suggests that both NTT and Wii training can provide valuable therapeutic gains.

Overall recommendations for first-line interventions for children with DCD include task-oriented therapies of various types. Younger children can benefit from NTT, for problems such as handwriting, that is, writing letters, even before they learn to read. Older children and those with verbal skills may be able to benefit from CO-OP approaches which incorporate more verbal planning. Nintendo Wii and other gaming interventions can be beneficial for children with DCD of all ages.

Process-Oriented Approaches

There has been only a weak suggestion from studies that process-oriented approaches are effective therapies for DCD, however, they are often used in conjunction with other strategies. Process-oriented interventions aim to target neural structures such as the cerebellum for improving balance, or sensory processes, such as proprioception in children with DCD. Interventions aim to enhance and remediate sensory input processing, for example, sensory integration therapy (SIT). SIT approach was introduced in the work of Ayres in the late 1970s who focused remediation on enhancing sensory information processing in order to achieve more accurate motor execution. Sensory integration programs are often delivered as a related service to children with DCD under the direction of occupational therapists. These programs prescribe specific physical therapies that attempt to modify the motor and sensory functioning of these children. These therapies are based on the notion that sensory integration disorders interfere with body movements and body awareness. Activities are designed to target the tactile, vestibular, and proprioceptive systems. A sensory integration program that addresses disorders affecting the proprioceptive system (bumping into walls and inability to button, to skip, or to write) might involve using scooter boards to improve balance and body awareness. Multisensory modalities, including visual, auditory, and tactile materials, are utilized in this form of treatment. Motor imagery

training for clumsiness in children, have received attention recently, based on results from controlled investigations of this modality compared to perceptual–motor interventions. A recent study used a successful motor imagery intervention through CD-ROM, which contained six main training components for children with coordination difficulties. The components included visual imagery exercises involving predictive timing, relaxation and mental preparation, visual modeling of fundamental motor skills, mental rehearsal of skills from an external perspective, mental rehearsal of skills from an internal perspective, and overt practice. This model of treatment is based on the notion that deficits in a child's ability to internally represent the movement tasks contribute to poor motor coordination. The ability for visual imagery of objects is not typically impaired in children with DCD. The previously mentioned training exercises were designed to improve the timing and accuracy of a given child's ability to visualize motor tasks, as well as to reduce muscle tension while imagining completing the given motor task. Finally, the children were trained in mentally rehearsing the task before actually practicing it.

Traditional Physical and Occupational Therapy

Traditional physical and occupational therapies target actual activities of daily function and seek to improve the execution of these motor behaviors. A variety of cognitive motor approaches have been utilized to improve the planning and execution of motor skills. One cognitive motor approach to improving functional skills by Sugden and Hendersen has been updated and labeled ecological intervention, which places emphasis on the actual control of movement and is done in a real-life setting.

Traditional perceptual–motor training consists of a combination of gross motor, fine motor, and perceptual–motor activities related to a child's actual daily motor tasks, such as hopping, skipping, jumping, climbing and moving through hoops, climbing ladders, and jumping on a trampoline, to practice competency. Specific tasks addressing fine motor skills, for example, handwriting training, includes activities to improve grip of a pencil, wrist rotation, and posture. The results of the previously mentioned study were extremely notable in that the mental imagery treatment was as efficacious as traditional perceptual–motor training exercises in improving a given child's coordination.

An example of functional skill intervention would be those that address impairment in handwriting. It is estimated that between 10 and 30 percent of children exhibit persistent impairment in handwriting, a skill that remains a critical means of communication even in the face of the pervasive use of computers. Handwriting impairment is associated with academic skills disorders. Handwriting treatment approaches may include perceptual–motor, visual–motor, motor control, individualized interventions or exercises, and supplementary handwriting instruction.

Few controlled studies have examined which techniques are most efficacious, and a survey of 50 pediatric occupational therapists found that 90 percent of them advocated an eclectic approach to interventions for handwriting improvement. A study of a school-based occupational therapy intervention for school-aged children with poor handwriting legibility showed efficacy in improved legibility of letters. Children with handwriting difficulties in this study received direct traditional perceptual instruction on writing letters for approximately 30 minutes per week for approximately 7 months. This consisted of a variety of handwriting interventions, such as using vibration or resistance to writing to increase appropriate grip and writing on a chalkboard or a vertical surface to increase arm strength and stability while writing. At the end of this period, children made significant gains in handwriting legibility, compared to a control group that did not receive the intervention. Handwriting speed in the children who received the treatment increased from 32 to 37 letters per minute. Although this was a trend toward speed, this did not represent a statistically significant increase in speed. Some students in the treatment group wrote their letters with a greater degree of deliberate care, and, although this increased legibility, it may have actually diminished their speed. Overall, the increase in legibility applied to letters more than numbers but did not significantly increase writing speed.

43 Communication Disorders

▲ 43.1 Language Disorder

EMIKO KOYAMA, PH.D. AND JOSEPH H. BEITCHMAN, M.D.

INTRODUCTION

Communication disorders are among the most common problems exhibited by young children. Nonetheless, communication disorders often go unrecognized, particularly when they cooccur with other emotional or behavioral problems. Thus, child psychiatrists, psychologists, and other clinicians need to be alert to the potentially damaging impact of communication problems on a child's overall well-being. Proficiency in verbal communication is critical to success in virtually all human activities and is therefore highly valued in society. Individuals with communication disorders may be unable to participate fully and competently in everyday interpersonal, learning, and occupational situations. Limited participation in such key life activities may further restrict growth in communication and related domains.

To develop effective communication, children must master language, the conventional code used to express ideas about the world and speech, the complex and rapid motor movements that translate such ideas into spoken words. Children need to also learn how to use language and speech appropriately in a given social context. The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) recognizes five diagnostic categories for communication disorders. One category concerns a disorder in language (language disorder), two categories relate to disorders in speech (speech sound disorder and childhood-onset fluency disorder), one category is associated with language use (social [pragmatic] communication disorder), and the final category covers communication disorder not otherwise specified.

DEFINITION AND COMPARATIVE NOSOLOGY

Individuals with language disorders show persistent impairments in the

expression and reception (production and comprehension) of language. These impairments will manifest across different modalities including speaking, writing, and sign language. The expressive difficulties may include limitations in vocabulary size, sentence complexity, and coherence in discourse. These expressive problems, however, are of less overall concern than the receptive difficulties. Children with receptive problems may manifest deficits in basic auditory processing skills, such as auditory discrimination, detection of rapid sound changes, association of sounds and symbols, and memory for sound sequences. They may be slow to learn word meanings, especially those that are uncommon or abstract. They may not understand the questions or comments of others and may misinterpret complex directions and explanations. They may have difficulty following conversations or learning from lectures. Because of comprehension failures, individuals with language disorders may give illogical or inappropriate responses. Furthermore, their comprehension problems may go unrecognized and instead may be misattributed to inattention, stubbornness, or other psychological or behavioral problems. Because of these problems, individuals with a language disorder would often have limitations in academic achievement, occupational success, and other social participation.

The definition of language disorder in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) combines elements of both the expressive and mixed receptive-expressive language disorders of the revised fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR) and the 10th edition of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10). Both the DSM-IV-TR and the ICD-10 conceptualized the expressive and receptive subtypes as being mutually exclusive language disorders, characterized by significant language problems, despite normal levels of nonverbal intelligence. DSM-IV-TR, however, differentiated between the developmental and acquired subtypes, whereas the ICD-10 only recognizes the developmental type, and acquired language problems such as acquired aphasia with epilepsy are listed under separate categories.

EPIDEMIOLOGY

The prevalence estimates of language disorder differ greatly from roughly 3 to 15 percent. Receptive problems are thought to be somewhat less common than expressive problems. The variation in prevalence estimates is most likely due to differences in language measures used to define the disorder, the age of the children surveyed, and the nature of the sample tested (community or clinic referred).

Language disorders are more common in boys than in girls. Various studies have yielded sex ratios as high as 5:1 and as low as roughly 2:1.

Familial aggregation is characteristic of language disorders. A variety of

methods (aggregation, pedigree, twin, adoption, and linkage studies) have provided clear evidence of genetic influences on language disorder. Complementary work also points to environmental input as a key factor that likely contributes to familial aggregation.

Approximately 10 to 15 percent of children younger than 3 years of age show delayed onset and slow initial progress in language development. Because of the large range of normal variability in the language production skills of young children, it is not yet clear whether an initial delay consistently warrants a diagnosis of language disorder. The majority (50 to 80 percent) of these children eventually acquire language skills within the normal range, but some show persistent language difficulties into adulthood. Children who continue to exhibit language problems after age 4 are more likely to experience long-term language deficits which may persist into adulthood, although the specific language profiles may change over time.

ETIOLOGY

There are no known causes for language disorder. Various factors have been shown to correlate with language disorder, but none has yet been established as causal. Language disorder most likely has multiple determinants, including various biological and environmental factors. Different factors or combinations may be implicated in some cases and not others, as suggested by the heterogeneity in the population. At least seven general types of possible causal factors have been investigated: (1) brain abnormalities, (2) genetic factors, (3) environmental influences, (4) neurodevelopmental immaturity, (5) general cognitive factors, (6) specific linguistic factors, and (7) auditory processes. Each of the proposed factors enjoys some empirical support, but none has gained widespread acceptance as a plausible account for all cases of language disorder. Moreover, the factors are not mutually exclusive and may interact in complex ways.

Structural or functional brain abnormalities can now be studied in a sophisticated fashion with advanced neuroimaging techniques. Such abnormalities have long been considered possible causal factors in language disorder, because (1) language characteristics of language disorder resemble those of acquired language disorders that result from known neurological insults, and (2) children with language disorders show elevated rates of soft neurological signs (e.g., mixed cerebral dominance, attention problems, or fine motor difficulties). Neuroimaging studies of children with language disorders have demonstrated structural and functional abnormalities, often in brain regions known to be crucial for language processing (e.g., left hemisphere or certain subcortical structures). Nonetheless, many questions remain. Both the language disorder phenotype and the techniques used to examine the brain abnormalities differ greatly among the studies, making it difficult to draw

conclusions about how brain abnormalities contribute to language disorder. Furthermore, because of the important role that experience plays in brain development, it is not clear whether some of the abnormalities noted are the cause or the result of language disorder.

Genetic factors have now been clearly implicated in language disorder, but it is far less clear just what these factors are and how they operate. Loci on chromosomes 13, 16, and 19 have been tentatively linked to aspects of language disorder in several studies. Although these regions are unlikely to be the sole determinants of genetic influences on language, their investigation may yield important insights. For example, some recent linkage studies have suggested that chromosome 16q may be associated with phonological short-term memory and chromosome 19q with expressive language. Work also continues to refine or broaden the language disorder phenotype to accurately identify possible subtypes and modes of transmission. An interesting possibility suggested by several lines of evidence is that autism and language disorder may share some relevant genetic characteristics. Genetic factors may also be important in understanding the origin of the brain abnormalities noted earlier.

Various environmental factors may also be critical, at least in some cases of language disorder. Children from families of low socioeconomic status (SES) are at elevated risk for language disorder. Low SES, in turn, correlates with other known risk factors, such as single-parent family status, large family size, lower parental education, pregnancy and birth complications, and lack of appropriate learning materials in the home, and abuse and neglect. Children from low SES families are also at risk for malnutrition, other health problems, increased exposure to known toxins (e.g., lead), and limited educational and social opportunities. The amount and quality of linguistic input available to children have also been shown to vary dramatically across families, with some children hearing as few as 700 utterances a day and others as many as 11,000! Furthermore, and not surprisingly, these variations in input were strongly related to language development as measured by standardized tests. In adverse conditions, supportive extended family and neighbors may act as protective factors assisting the children's language development. Further work is needed to clarify whether or how various environmental and input factors may interact with one another and, perhaps, with biological factors to cause language disorder.

Neurodevelopmental immaturity may also underlie language disorder. Proponents argue that language development generally follows a normal sequence and course but at a slower rate; that is, it is delayed rather than deviant. Delayed maturation of neural structures or slow myelinization of neural pathways might also account for associated characteristics that are common in children with a language disorder, such as attention and motor problems and other behavioral difficulties. Furthermore, such

neurodevelopmental immaturities may occur more often in boys than in girls. A related view is that children with language disorder simply have language skills that fall at the lower end of the normal distribution. The only reason that these children are perceived as handicapped is because language skills are so essential for success in a literate society. When other less crucial abilities, such as musical talent, fall in the lower end of the normal distribution, children are not perceived as handicapped, because musical proficiency is not expected of all members of society.

A variety of general cognitive factors have also been proposed to account for language disorder. Speed of cognitive processing is one such factor. Children with a language disorder typically perform slower than their peers without the disorder on a variety of linguistic (e.g., naming or grammatical judgments) and nonlinguistic (e.g., fine motor or visual-spatial) tasks. This slower processing speed might somehow interfere with language learning. Some research studies, however, failed to show significant correlations between processing speed and language achievement, casting doubt on this suggestion. Others propose that phonological working memory, the immediate maintenance and manipulation of verbal information, is a key cognitive factor in language disorder. Children with a language disorder show deficits in phonological working memory, which have been linked to deficits in vocabulary learning and reading proficiency. However, strong causal inferences about the role of phonological working memory are not yet possible based on the available correlational evidence.

In contrast to the neurodevelopmental immaturities and general cognitive delay perspectives, that imply that children with a language disorder experience an overall delay but nevertheless follow a typical course of language development, some researchers have argued that children with language disorders may show specific lingering deficits in certain aspects of language that a young child with otherwise matched language ability may not show. For example, children with language disorders have particular difficulty in learning certain grammatical features (e.g., verb tense markers or pronouns in English) to the extent that their use of these features is even poorer than that of younger children at the same level of language development. Much-needed cross-linguistic work in languages with varied grammars is helping theorists hone in on the commonalities and differences in the grammatical features that pose particular problems for children with language disorders who are learning different languages. At this point, however, these linguistic theories are primarily descriptive rather than explanatory.

Auditory problems have also been investigated as possible causes of language disorders. One concern is otitis media, an inflammation of the middle ear that results from ear infections or allergies. Otitis media is often accompanied by mild hearing loss, which is usually temporary if the

underlying infection is treated. Repeated episodes of otitis media and associated hearing loss are common in young children during the earliest stages of language development. Although otitis media alone is not sufficient to cause language disorder, it may contribute in combination with other risk factors. A second concern centers on auditory perception of sounds. Many (but not all) children with language disorders have difficulty perceiving small sound differences and rapid auditory transitions, which are aspects of the acoustic signal thought to be important in understanding speech. It has proven difficult, however, to develop convincing theoretical and empirical links between auditory perceptual skills and the various language difficulties shown by children with language disorder.

DIAGNOSIS AND CLINICAL FEATURES

The hallmark of language disorder is impairment in receptive and expressive language development. The rate of language growth is slower in children with language disorder than children with typical language development. The receptive and expressive language characteristics of affected children may be largely similar to those of younger children who are acquiring language in a typical fashion. Certain language features, such as the grammatical marking of tense, aspect, number, gender, or case may be especially difficult for children with language disorders to acquire. They may have difficulty learning the correct use of auxiliary or modal verbs (e.g., is, were, could), plurals (e.g., cats, geese), verb tense endings (e.g., -ing, -s, -ed), and pronouns (e.g., he, she, they).

Comprehension often varies with the complexity of the language. For example, words for familiar, concrete objects, actions, or relations may be comprehended (e.g., *wagon*, *apple*, *walk*, *give*, *in*, *over*), but those with less familiar, abstract meanings may be unknown (e.g., *neuron*, *freedom*, *receive*, *pretend*, *between*, *when*). Similarly, sentences with simple grammatical forms may be understood (e.g., "The boy is smiling." "The phone rang."), whereas those with more complex structures may be misinterpreted (e.g., "The car that rammed the bus was towed to the garage." "Before she finalized the arrangements, she consulted with her lawyer."). Complex or lengthy instructions, questions, and explanations may not be comprehended. When children with language disorders misconstrue the language and intentions of others, they may inadvertently make inappropriate responses or comments during conversations. Their comprehension failures may also contribute to confusion or inaccuracy in telling stories, relating events, and giving explanations, problems that may be further exacerbated by their expressive language limitations. When their comprehension difficulties are not recognized, children with language disorders may be mistakenly thought to be inattentive, lazy, or uncooperative.

The specific manifestations of language disorder vary with age. Some

children with language disorder eventually acquire language skills within the normal range, but the overall prognosis is poorer for children with severe receptive language problems than for children with just expressive language difficulties. The expressive and receptive features adversely affect personal interactions and academic achievement because spoken language is poorly expressed and understood.

Amy was a sociable, active 5-year-old who was diagnosed with a language disorder. She often played with Lisa, her kindergarten classmate. During pretend play one day, each girl told the story of Little Red Riding Hood to her doll. Lisa's story began: "Little Red Riding Hood was taking a basket of food to her grandmother who was sick. A bad wolf stopped Red Riding Hood in the forest. He tried to get the basket away from her but she wouldn't give it to him."

By contrast, Amy's story illustrated her marked difficulties in verbal expression: "Riding Hood going to grandma house. Her taking food. Bad wolf in a bed. Riding Hood say, what big ears, grandma? Hear you, dear. What big eyes, grandma? See you, dear. What big mouth, grandma?

Eat you all up!"

Amy's story contained many features characteristic of children with language disorders at her age, including short, incomplete sentences, simple sentence structures, omission of grammatical function words (e.g., is and the) and inflectional endings (e.g., possessive -'s and present tense verb -s), problems in question formation, and incorrect use of pronouns (e.g., her for she).

Nevertheless, Amy performed as well as Lisa did in understanding the details and plot of the Riding Hood tale, as long as she was tested with methods that did not involve verbal responding. Amy also demonstrated adequate comprehension skills in her kindergarten classroom, where she readily followed the teacher's complex, multistep verbal instructions (e.g., "After you write your name in the top left corner of your paper, get your crayons and scissors, put your library books under your chair, and line up at the back of the room.").

Julio was a quiet, sullen 8-year-old whose language problems were no longer obvious in casual, social conversations. His speech now rarely contained the incomplete sentences and grammatical errors that were so evident when he was younger. His expressive problems, however, still surfaced in tasks involving elaborate or abstract uses of language, like those required in much of his third-grade academic work. An example was Julio's explanation of the outcome of a recent science experiment: "The teacher had stuff in some jars. He poured it, and it got pink. The other thing made it white." Although each sentence was grammatical, his explanation as a whole was difficult to follow, because key ideas and details were omitted or poorly explained. Julio also showed problems in word finding, that is, in using specific words for the concepts and actions he was describing. Instead, he relied on vague and nonspecific terms, such as thing, stuff, and got.

In early elementary grades, Julio had kept pace with his classmates in reading, writing, and other academic skills. By third grade, however, the increasing demands for written work began to negatively affect his overall academic standing. His written work was characterized by problems similar to those noted in his oral expression, such as poor organization and lack of specificity. Classmates also began to tease him about his difficulties, and he reacted quite aggressively, sometimes to the point of fighting. Nonetheless, Julio continued to show relatively good comprehension of spoken language, including classroom lectures concerning abstract concepts. He also comprehended sentences that were grammatically and conceptually complex (e.g., "The car the truck hit had hubcaps that were stolen. Had it been possible, she would have notified us by mail or by phone").

Susan was a pleasant 2-year-old who did not yet use any spoken words. She made her needs known with vocalizations and simple gestures (e.g., showing or pointing) like those typically used by younger children. She seemed to understand the names for a few familiar people and

objects (e.g., *mommy*, *daddy*, *cat*, *bottle*, and *cookie*). However, compared to other children her age, she had a small comprehension vocabulary and showed limited understanding of simple verbal directions (e.g., "Get your doll." "Close your eyes."). Nonetheless, her hearing was normal, and her motor and play skills were developing as expected for her age. She showed interest in her environment and in the activities of the other children at her day care.

Min was a shy, reserved 5-year-old who grew up in a bilingual home. Min's parents and older siblings spoke English and Cantonese proficiently. Her grandparents, who lived in the same house, spoke only Cantonese. Min began to understand and speak both languages much later than her older siblings had. Throughout her preschool years, Min continued to develop slowly in comprehension and production. At the start of kindergarten, Min understood fewer English words for objects, actions, and relations than her classmates did. She showed difficulties in following classroom instructions, particularly those that involved words for concepts of time (e.g., *tomorrow*, *before*, or *day*) and space (e.g., *behind*, *next to*, or *under*). It was also hard for Min to match one of several pictures to a syntactically complex sentence that she had heard (e.g., "It was not the train she was waiting for." "Because he had already completed his work, he was not kept after school."). Min occasionally tried to speak with other children. However, these conversations usually broke down because she misinterpreted what others said or could not express her own thoughts clearly. Consequently, her classmates generally ignored her, preferring instead to play with more verbally competent peers. Min's infrequent interactions further limited her opportunities to learn and to practice her already weak language skills. Min also showed limited receptive and expressive skills in Cantonese, as revealed by an assessment conducted with the assistance of a Cantonese interpreter. Nonetheless, her nonverbal cognitive and motor skills were within the normal range for her age. She showed no difficulties in solving spatial, numerical, conceptual, or analogical problems, provided they were presented nonverbally.

Fred received a diagnosis of language disorder when he was a preschooler. By 8 years of age, he had also received the comorbid diagnoses of specific learning disorder and attention-deficit/hyperactivity disorder (ADHD). This combination of language, learning, and attention problems made it virtually impossible for Fred to succeed in school. His comprehension and attention difficulties limited his ability to understand and to learn important information from classroom instructions, discussions, and lectures. Because the unlearned information was critical to the understanding of future academic lessons, Fred fell further behind his classmates. He was also disadvantaged by the fact that he could read only a few familiar words. This meant that he could not learn other academic information that his classmates acquired by reading textbooks, library books, newspapers, and other written materials. His poor reading ability also limited his opportunities to learn the new vocabulary, complex sentence forms, and sophisticated ideas that other children absorbed from reading. Despite his academic problems, however, Fred continued to show nonverbal intellectual skills within the low normal range, although his scores were somewhat lower than those he had earned as a preschooler.

The disorders of speech, learning, and development may cooccur with language disorder. The two most frequently cooccurring disorders are speech sound disorder and specific learning disorder. Speech sound disorder, which is characterized by difficulty in correct production of speech sounds, occurs in roughly 40 to 60 percent of preschoolers with language disorder. Specific learning disorder, especially difficulties in reading, occurs in approximately 50 to 90 percent of school-age children with language disorder and most frequently for children with receptive language problems. Difficulties in learning to read may be apparent early or may not surface until later in the learning process when knowledge of

sophisticated vocabulary and sentence structures is required to support reading comprehension. Because of this high comorbidity between language disorders and reading problems, some researchers have theorized that language impairment and reading difficulties may be different manifestations of the same underlying problems that manifest itself at different ages. Genetic studies also suggest that families with known risk of language disorders also tend to be at higher risk for reading problems and vice versa. However, other researchers suggest that reading and language problems should be considered separate disorders, as children with language problems manifest problems that go beyond phonological awareness and include syntax and semantics. Future studies in molecular genetics may help clarify this debate. A few children with language disorders also experience stuttering and developmental coordination disorder.

The risk for concomitant psychiatric disorders is also high for children with language disorder, especially when receptive language is impaired. Estimates vary, but comorbid psychiatric disorders may affect as much as 70 percent of school-age children with language disorder who have severe receptive language problems. The most common comorbid condition is ADHD, occurring in 30 to 60 percent of cases. Internalizing disorders are also noted but not as often as ADHD. Boys are at particular risk for externalizing disorders. Behavior difficulties tend to occur most frequently in children who have concomitant language and reading problems. Girls with language disorders may be withdrawn and quiet, making detection of language disorders more difficult.

Most children with language disorder do not show frank neurological symptoms (e.g., tremor, paralysis, or seizures). As a group, however, children with language disorders show elevated rates of mild to moderate abnormalities (e.g., in reflexes or fine motor function) on careful neurological examination. They are also more likely than typically developing children to show mild to moderate abnormalities in measures of brain function or structure, such as electroencephalographic (EEG) readings or magnetic resonance imaging (MRI) and functional MRI (fMRI) scans. Furthermore, the number of abnormal neurological signs may be associated with the severity of language difficulties.

PATHOLOGY AND LABORATORY EXAMINATION

There are no laboratory tests that can provide a diagnosis of language disorder. Neuroimaging techniques, such as MRI and fMRI, sometimes reveal structural or functional brain abnormalities associated with language disorder. However, such abnormalities have neither been found in all cases nor have their possible etiological or diagnostic values been determined.

DIFFERENTIAL DIAGNOSIS

Standardized evaluations of expressive and receptive language and nonverbal intellectual functioning are the key elements for differential diagnosis of language disorder. Receptive language testing is particularly important because comprehension deficits may be less obvious than expressive difficulties. Receptive and expressive language performance must fall substantially below the range of normal language performance expected for a child's age. In addition, the severity of the receptive and expressive language problems must hinder academic performance or social communication. Speech–language pathologists often use observational techniques and analyses of spontaneous language to assess the functional impact of language difficulties and to complement information obtained from standardized language tests. A thorough functional assessment of language abilities may also be substituted when appropriate standardized tests are not available (e.g., if a child speaks a language for which tests have not yet been developed).

A significant discrepancy between receptive language and nonverbal abilities precludes the alternate diagnoses of selective mutism and intellectual disabilities. In selective mutism, receptive language and nonverbal performances usually are similar in level and markedly higher than expressive language skills. In intellectual disabilities, performance is impaired substantially in all three areas of receptive language, expressive language, and nonverbal abilities, relative to age-level expectations.

Deficits in receptive language may also be evident in cases of hearing impairment, environmental deprivation, or autism spectrum disorder. A hearing test should be part of the assessment of all cases of suspected language disorder. Collection of a careful history can usually identify severe environmental deprivation. Observations of disturbed social interaction, limited communicative intent, and unusual repetitive behaviors suggest autism spectrum disorder. A concurrent diagnosis of language disorder may be made when receptive and expressive language deficits exceed those expected for the degree of intellectual disabilities, hearing impairment, or environmental deprivation.

Differential diagnosis requires attention to other comorbidity issues. Speech sound disorder is a possible comorbid diagnosis when difficulties in speech sound production accompany language disorder. School-age children identified with either language or specific learning disorder should be screened for difficulties in the other area because the two disorders frequently cooccur. Similarly, children with psychiatric diagnoses, particularly ADHD, should be screened for language disorder because it is known that a high proportion of children referred for psychiatric assessment shows previously undetected comorbid language disorders. Sometimes a child shows expressive language that is so difficult to follow and so disorganized that the practitioner questions whether it should be

considered disordered thinking symptomatic of schizophrenia.

Illustrative of this concern is the case study presented here with a brief excerpt from a conversation with Max, a highly anxious 9-year-old with language disorder who had just visited the dentist. The stream of language in this case study raises serious concerns about a possible diagnosis of schizophrenia. However, a child with language disorder may produce language this disorganized, especially in situations of heightened anxiety. Diagnosis can usually be clarified by reassessment when the child is less anxious and by careful attention to the presence or absence of comorbid symptoms.

What do you suppose you'd like to do today?

Taking a dentist appointment ...

[You're taking a dentist appointment.]

Yeah, he has a little cavity ...

[He has a little cavity.]

... and I'm going to take it from him cause he's stuck there he sure doesn't like it but he knows there is too far (mumbled)...

... too far and so he was losing a lot of hair so he needs a new way ... sounds like he's bald ... so he has everything (mumbling) a guy who's not recep ... teaching he will have to it's important like he will or he won't.

Acquired language problems may result from a variety of neurological insults, including (1) cerebral vascular accidents, such as strokes; (2) infections, such as encephalitis or meningitis; (3) severe respiratory problems that result in intraventricular hemorrhage or anoxia; (4) near drownings; (5) closed head injuries from falls, motor vehicle accidents, or other blows to the head; (6) open head injuries, such as those from gunshot wounds; (7) toxins, such as lead or household poisons; (8) damage from tumors or radiation treatment; or (9) seizure activity. Landau–Kleffner syndrome (acquired aphasia with epilepsy) is a rare condition marked by an abrupt loss of language skills, which is often associated with the onset of seizures or abnormal EEG activity.

Acquired language problems vary considerably in their language symptoms as a function of the nature and severity of the underlying neurological condition. Acquired disorders also show distinctive language characteristics as well as some features shared with language disorder. For example, closed head injury, which often occurs in motor vehicle accidents or falls, typically results in sparing of basic skills in vocabulary and grammar (after initial recovery stages), whereas more complex skills, particularly in discourse, remain markedly impaired. Comprehension for lengthy or complex discourse may be limited. Likewise, expression in discourse may be disrupted by disorganized, tangential, inappropriate, and illogical comments, even if basic vocabulary and sentence structures are used correctly. Communication effectiveness may be further hindered by accompanying deficits in memory, attention, affect, behavior, and motor skills.

Landau–Kleffner syndrome also shows a unique pattern. Children with Landau–Kleffner syndrome seem to be developing normally until around ages of 3 to 7 years, when they start to have trouble with expressive and

receptive language with no apparent reason. The decline in language ability may be sudden or gradual. Hearing loss is usually suspected by parents; however, laboratory tests disconfirm this suspicion. In about 80 percent of children with Landau–Kleffner syndrome, one or more episodes of epileptic seizures occur, typically during sleep. Behavioral problems such as hyperactivity, aggressiveness, or depression may cooccur.

Elliott, 4 years of age, was a cheerful, talkative preschooler who suddenly experienced a series of seizures for no apparent reason. His language skills, which had been excellent, simultaneously showed a precipitous decline. He no longer understood words, commands, and sentences that had posed no difficulty for him before the seizures. He also lost his expressive skills and began using shorter, less sophisticated sentences, which became increasingly incoherent as he omitted or misused important words. He also developed significant memory and attention problems. Nonetheless, he continued to show nonverbal intellectual skills that were grossly within the normal range. Although Elliott's seizures were eventually controlled with medication, he experienced persistent problems in comprehension and production of language, which never fully resolved.

Course and prognosis are also variable for children with acquired language problems. Some spontaneous recovery generally occurs rapidly within days or weeks of the neurological insult, but additional improvements may show a protracted course over months or even years. Approximately two-thirds of children with acquired disorders eventually recover language functioning that is broadly within the normal range, although subtle deficits may persist. Those who do not attain normal language functioning show persistent language and cognitive deficits of varying severity. Prognosis depends on many factors, including the severity, extent, and location of brain damage, the specific etiology, the age of onset, the extent of preinjury language development, and the existence of other preinjury disorders.

Language disorders also occur in children from diverse linguistic and cultural backgrounds. A difficult diagnostic challenge is to differentiate language errors that are a normal part of acquiring a new language from those that are indicative of disorder. A valid assessment usually requires the cooperation of a well-trained informant from the same cultural and linguistic background as the child. The informant assists in collecting and interpreting history information, assessing the child's skills in the other language, and discussing assessment results and recommendations with the family.

COURSE AND PROGNOSIS

Language disorder is characterized by considerable variability in severity, course, and outcome. Individuals who had mild to moderate language disorders are less likely to suffer from significant long-term mental health problems than individuals who had severe language disorders. Youngsters with early receptive language delays show higher rates of persisting

disorder and less favorable long-term outcomes than those with early expressive-only delays. Some, however, do eventually attain language functioning within the normal range. Better outcomes are generally associated with higher levels of early gestural communication, receptive language, and nonverbal intelligence.

Children with persistent language disorders continue to develop language comprehension and production skills during the preschool and school-age years. However, the rate of development may be quite slow, causing them to fall further behind peers who are developing language at a normal rate. Overall, the communicative prognosis for children with persistent language disorders continues to be poorer than for those with expressive-only disorders.

Children with language disorders are also at risk for academic problems once they enter school. A negative spiral of poor academic performance, low self-esteem, reduced motivation, and social isolation may stem from the language comprehension difficulties, particularly when they are coupled with attention or reading problems. Fortunately, some progress has been made in using performance on early language-related tasks to predict which kindergarten children may be at risk for later reading difficulties. Moreover, interventions to improve phonological awareness, a key skill for early reading, have proven successful with children with language disorders, at least in the short term.

Many adolescents and young adults with a history of language disorder continue to show problems in communicative effectiveness, academic performance, and social functioning. These problems may limit vocational choices and social participation. Individuals with language disorder are also at heightened risk of being bullied or victimized in general, including sexual assault or abuse for girls and women. Serious psychiatric problems, such as social anxiety disorder or antisocial personality disorder, may also develop in some individuals. The societal consequences are significant, as evidenced by the high rate of language difficulties in adults who live in poverty, commit crimes, incur psychiatric illnesses, and achieve limited literacy.

TREATMENT

Experts disagree about the timing of intervention for language disorder. Some advocate a wait-and-see attitude for young children with early expressive delays (late talkers), because most acquire normal language functioning during the preschool years. They argue that intervention should be provided only to those with persistent expressive delays at 4 or 5 years of age. Others suggest that early intervention might prevent or minimize later language, academic, and behavioral difficulties. Unfortunately, few relevant data are available on the efficacy of early- versus late-language intervention.

Direct and mediated interventions have been shown to promote short-term language growth in children with language disorders. In direct interventions, the primary intervention agent is a professional (usually a speech–language pathologist) who works directly with the child to improve language functioning. In mediated interventions, the primary intervention agents are parents, teachers, or paraprofessionals, who have been taught by the speech–language professional to deliver the intervention to the child. Mediators are encouraged to incorporate language facilitation techniques into daily activities and routines, thereby providing regular, naturalistic opportunities for children to use newly learned language features.

Further research on treatment efficacy is needed to address important outstanding issues. For example, studies are required to assess (1) the ways in which interventions might be tailored to address the specific language needs of individual children, (2) the long-term merits of early intervention for children with expressive delays, (3) the extent to which the benefits of intervention achieved in laboratory studies can also be demonstrated in routine community-based interventions, and (4) what the potential harms of early screening or intervention for language delays may be, including the risk involved in false-positive and false-negative results, labeling, parent and child anxiety, and unnecessary evaluation and intervention. One recent study of routine early interventions suggests that systematic efforts may be required to improve their effectiveness.

Children with language disorders are generally recommended for intervention to address their receptive and expressive language needs. Various language intervention techniques and programs have been developed, but some have not been rigorously evaluated to demonstrate their efficacy. The available efficacy literature, however, suggests that language intervention can foster short-term progress toward specific communicative goals, a conclusion that extends to various intervention techniques and programs. Unfortunately, there has been limited study thus far of the possible long-term benefits of language intervention in limiting or reversing the negative impacts of language disorder on linguistic, academic, and psychosocial outcomes.

Interventionists have, however, begun to focus on long-term, broad-based outcomes. Preschoolers with language disorders are receiving interventions designed to promote not only oral language outcomes but also social communication and early literacy skills. Kindergartners with language disorders are being taught certain key prereading skills, which may prevent the early reading failure that is linked to subsequent academic and psychosocial problems. More attention is being given to enabling peers, parents, and teachers to learn methods for fostering frequent, natural, and optimal communicative interactions with children who have language disorders. In schools, there are efforts to coordinate the various types of interventions that may be required by a child with a language

disorder (e.g., language intervention, special reading help, special education support, or behavioral interventions). Despite some initial promising results from these efforts, much remains to be learned concerning optimal goals, techniques, and programs for language intervention.

Language disorders may also necessitate modifications to other interventions that rely heavily on language as a medium (e.g., psychotherapy or cognitive behavioral modification). Comprehension can be facilitated by simplification of vocabulary, sentence structure, questions, and verbal instructions and by repetition of verbal information as required. Compensation for expressive difficulties can be achieved by using nonverbal response modes to supplement verbal responses. Ambiguous or unclear responses should also be clarified. Assessment procedures that depend heavily on language (e.g., projective tests or diagnostic interviews) may require similar modifications.

▲ 43.2 Social (Pragmatic) Communication Disorder

INTRODUCTION

Social (pragmatic) communication disorder is a new diagnostic category introduced in DSM-5. The main characteristic of social (pragmatic) communication disorder is the persistent deficit in the social use of nonverbal and verbal communication and difficulty using the linguistic context to make inferences and to resolve ambiguities. The symptoms include deficits in understanding and applying social rules concerning verbal and nonverbal communication, difficulty adapting one's language according to the needs of the listener or situation, problems following the rules of conversations (such as turn taking) and storytelling, and difficulty understanding ambiguous and nonliteral language through integrating the linguistic context and prior knowledge. Social (pragmatic) communication disorder has significant overlaps in symptoms with autistic spectrum disorder and language disorder. However, unlike individuals with autism spectrum disorder, individuals with social (pragmatic) communication disorder do not exhibit clinically significant restricted interests or repetitive behaviors. Although social (pragmatic) communication disorder can cooccur with other communication disorders such as language disorder, the social communication and pragmatic deficits must exceed what would be expected from structural language deficits alone. The diagnosis of social (pragmatic) communication disorder cannot be made along with autism spectrum disorder.

HISTORY

Although social (pragmatic) communication disorder was not included until DSM-5, there has been a long-standing debate regarding the diagnostic status of children with deficient social communication and pragmatic skills. In fact, children who have social communication and pragmatic deficits have been documented in the speech and language literature for over 30 years. In the early 1980s the term semantic-pragmatic deficit syndrome was introduced to characterize children who demonstrated problems with verbosity, word-finding deficits, unusual word choice, and poor topic maintenance. A similar term introduced in the late 1980s was semantic-pragmatic disorder, which was thought to occupy the diagnostic space between autism spectrum disorder and specific language impairment. Both of these terms reflect the idea that semantic (i.e., the meaning of an expression) and pragmatic (i.e., the use of language in context) difficulties tend to cooccur. In the 1990s, however, research started to emerge showing that semantic deficits did not necessarily cooccur with pragmatic deficits, and that semantic abilities did not reliably differentiate between typically developing and clinical groups. As a result, the term pragmatic language impairment was coined and became the

generally accepted term used in the speech and language literature.

The addition of social (pragmatic) communication disorder to the DSM-5 is closely associated with the changes made to the diagnostic criteria concerning autism spectrum disorder. In DSM-IV-TR, the umbrella term, pervasive developmental disorders, was used to cover autistic disorder, Asperger syndrome, and pervasive developmental disorder—not otherwise specified. The pervasive developmental disorder—not otherwise specified was applied to individuals who were on the autism spectrum but did not meet the full criteria for either autistic disorder or Asperger syndrome. Therefore, children or adults who showed core deficits in one area such as social deficits, but did not meet the diagnostic criteria for other symptoms such as restrictive, stereotypical, and repetitive behaviors would have been given the diagnosis of pervasive developmental disorder—not otherwise specified. Research has shown that more than half of the children diagnosed with pervasive developmental disorder—not otherwise specified were given the diagnosis due to the fewer restrictive and repetitive behaviors they exhibited.

In DSM-5, the diagnostic category of autism spectrum disorder replaced the pervasive developmental disorders of DSM-IV-TR. The major reason for this change was due to the lack of reliable and meaningful differentiation in the subclassification under pervasive developmental disorders, even among experts. One of the consequences of this change was that the pervasive developmental disorder—not otherwise specified was removed as a diagnostic classification, and that the diagnosis of individuals who showed social interaction deficits but mild or no restrictive and repetitive behaviors were given the new diagnosis of social (pragmatic) communication disorder under the diagnostic classification of communication disorder in the section of neurodevelopmental disorders.

Social (pragmatic) communication disorder is thought to largely align with the pragmatic language impairment discussed in the research literature. However, various definitions of pragmatic language impairment exist, and the traditional definitions do not include impairments in nonverbal communication. Therefore, precaution needs to be taken when making inferences from the previous literature regarding the social (pragmatic) communication disorder.

DIAGNOSTIC FEATURES

Individuals with social (pragmatic) communication disorder have difficulties with pragmatics—the rules that govern social conventions of verbal and nonverbal language that allow people to relate to one another in socially appropriate ways. While most children pick up these social rules intuitively, children with social (pragmatic) communication disorder may find it difficult to learn the basic rules of social communication, such as when to start talking, when to listen, how to phrase a question, stay on

topic and know when the talk is over. As a result of deficits in pragmatics, individuals with social (pragmatic) communication disorder may struggle with holding conversations, may interrupt frequently, monopolize the conversation, or not talk at all. They may say things that are inappropriate or unrelated to the conversation at hand. This can make it difficult for individuals with social (pragmatic) communication disorder to develop meaningful social relationships, and communicate well with others at school or in the workplace. The symptoms of social (pragmatic) communication disorder include the following:

1. Problems using nonverbal and verbal language such as greeting and sharing information, in ways appropriate for the social context.
2. Impairment in changing communication to match the context or the need of the listener such as speaking differently in the classroom than on the playground, or talking to a child than to an adult.
3. Difficulties following social conventions of conversation and storytelling, such as taking turns in conversations, rephrasing when misunderstood, and knowing how to use verbal and nonverbal signals to regulate the interaction.
4. Difficulty making inferences when something is not explicitly stated, and difficulty understanding the meaning of nonliteral or ambiguous language, such as idioms, humor, and metaphors, and when there are multiple meanings depending on the context.

These deficits experienced by individuals with social (pragmatic) communication disorder impede effective communication, social participation, academic achievement, or occupational performance. Difficulties with social interactions are manifest early in life, although the impairments may not become fully apparent until social communication requirements become more demanding. The symptoms of social (pragmatic) communication disorder should not be attributable to another medical or neurological condition. The deficit in social communication should not be solely attributable to problems in the mechanics of language as is the case for individuals with language disorder. The deficits should not be better accounted for by intellectual disability, global developmental delay, autism spectrum disorder, or any other mental disorders.

As is the case with autism spectrum disorder, individuals with social (pragmatic) communication disorder may show little interest in social interactions. They may have difficulty adapting language to different listeners (for example, talking the same way to an adult and to a child), and to different situations (for example, talking the same way in a classroom as on the playground). They may have trouble making inferences and understanding things that are implied and not stated explicitly. They may not give background information when they are speaking to an unfamiliar person. They may have trouble properly greeting people, making requests,

or getting attention. They tend to be overly literal and not understand riddles or sarcasm. They may have difficulty understanding nonverbal communication such as reading others' facial expressions. Due to the difficulties in making inferences, understanding the nuances and social subtleties, some children may have trouble with reading comprehension, despite being able to develop phonemic awareness. As a result, their reading issues may not be noticed until mid-elementary school, when children move from learning to read to reading to learn.

Some experts suggest that social (pragmatic) communication disorder usually never occurs by itself. Language disorder is the most commonly occurring disorder associated with social (pragmatic) communication disorder.

Attention-deficit/hyperactivity disorder is a common comorbidity associated with social (pragmatic) communication disorder. The hyperactivity and inattention problems can aggravate the problems of pragmatic competence. In addition, a lack of social pragmatic skills may lead to children becoming frustrated and acting out.

Jonny was a 6-year-old boy who often spoke out of context and had great difficulty playing with other children. He would make associations with a word or phrase and continue to perseverate. He would respond inappropriately to questions, for example, in the midst of a totally unrelated discussion, he might shout: "The toilet is cracked and white stuff is coming out." One of his favorite statements was, "what a lovely bouquet," which he would repeat, usually without reference to anything that was happening at the time. People were puzzled by him and found it difficult to communicate with him. While he appeared able to make grammatically correct sentences, and had no evidence of problems with articulation or speech, he seemed to have little appreciation of the meaning of his statements or that his comments were often totally out of context.

N is a 17-year-old youth with a long history of physical confrontations with other youth. He presented with a flat affect and no facial expression. He was prone to misinterpret others' intentions and found himself easily provoked. Although he said he could discern others' emotions, his history of misjudging others' intentions contradicted this belief. His emotional reactions were extremely difficult to assess because of the absence of facial expression. He has had difficulty making friends and staying in relationships. He does not get along with peers his own age and seeks friendship with individuals 4 years older than him. He has difficulties in social situations and would like to change his interactions. He plans on ignoring the "sly friends" and only engaging in physical altercations if they provoke him first even if they are joking. There was no evidence of symptoms suggestive of an autism spectrum disorder, no history of current or past repetitive, restricted interests or behaviors.

As this vignette demonstrates, individuals with social (pragmatic) communication disorder may show signs of deficits in nonverbal communication despite relatively intact structural language.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis should take into consideration the relationship between social (pragmatic) communication disorder and other psychiatric

disorders, especially autism spectrum disorder and language disorder. Many children referred to clinics for psychiatric or psychological assessment have been found to show some form of social communication or pragmatic language deficits. The rate of comorbidity is especially high for children with language disorder, attention-deficit/hyperactivity disorder, conduct disorder, and traumatic brain injury. Differential diagnosis can be challenging due to overlaps in symptoms among various psychiatric disorders and lack of well-validated assessment tools with high reliability.

Social communication is one of the core deficits of autism spectrum disorder. Children with autism spectrum disorder may show adequate structural language abilities, yet have difficulty with pragmatic language such as overly formal speech, verbosity, and turn taking in conversations. For children with autism spectrum disorder, these pragmatic language and social communication difficulties are part of a larger social deficit which includes restricted interests and repetitive behaviors. The past and/or present symptoms of clinically significant specialized interests and restricted, repetitive behaviors can help differentiate autism spectrum disorder from social (pragmatic) communication disorder.

Because a diagnosis of autism spectrum disorder can be given to individuals with just a history of fixed interests and repetitive behaviors, individuals who only show significant social and pragmatic language deficits but no present behavioral patterns characteristic of autism spectrum disorder may still be given a diagnosis of autism spectrum disorder. Complicating the differential diagnosis further, stereotyped language, which was considered one of the symptoms of pragmatic language impairment, is now considered part of the repetitive and restrictive behaviors required for giving a diagnosis for autism spectrum disorder. Finally, some children may show an increase in repetitive behaviors and specialized interests as they grow older, further complicating the differential diagnosis.

Children with language disorder show deficits in word knowledge, grammar, and discourse. As discourse includes conversational exchange and narrative, deficits in these areas tend to manifest in social communication problems. For children with language disorders, however, social and pragmatic language deficits are thought to be a result of, or secondary to, the structural language impairment. A strong association between language results and measures of social deficits would support the diagnosis of language disorder.

Some studies have shown group differences in symptom profiles of social communication and pragmatic deficits, although making differential diagnosis based on these symptom profiles may prove difficult. For example, children with attention-deficit/hyperactivity disorder as a group may show problems with inappropriate initiation (such as talking about a

topic that no one is interested in). One study examining children with William syndrome and children with autism spectrum disorder showed that children with William syndrome tend to have fewer problems with stereotyped language, nonverbal communication, social relations, and coherence compared to children with autism spectrum disorder. An observational study comparing children with social (pragmatic) communication disorder and children with language disorder has found that, as a group, children with social (pragmatic) communication disorder tend to have more problems with turn taking in conversations, provide no response or inappropriate responses to the communication at hand, and make little use of nonverbal signals compared to a group of children with language disorder. More work is needed examining the sensitivity and specificity of these social and pragmatic language profiles for the purpose of differential diagnosis, and how the risk factors associated with different clinical populations affect the course and prognosis of social and pragmatic language development.

There is overlap in symptoms between social (pragmatic) communication disorder and social anxiety disorder. Some children with severe social anxiety disorder may be misdiagnosed with autism spectrum disorder due to their apparent uneasiness in social situations and lack of eye contact. The timing of the onset of symptoms may help to differentiate between these two disorders. Children with social anxiety disorder have typically developing social communication skills, yet do not utilize them due to anxiety associated with social interactions. Children with social (pragmatic) communication disorder, on the other hand, would have never had effective social communication.

ETIOLOGY

There is no published research examining the heritability and environmental factors associated with social (pragmatic) communication disorder using the DSM-5 criteria. There is accumulating evidence, however, which suggests that a family history of autism spectrum disorder, language disorder, or specific learning disorder may increase the risk of having social communication and pragmatic language deficits. Studies are also emerging, associating the impairments in pragmatic language with some common gene variants. These gene variants, however, are not specific to pragmatic language impairments but are also found to be associated with other neurodevelopmental and psychiatric disorders including autism spectrum disorder, intellectual disorders, and language disorder. More research is needed examining the familial aggregation and genetic factors associated with social (pragmatic) communication disorder. Although the causes of social (pragmatic) communication disorder still remains unknown, several theories have been proposed regarding the underlying deficits related to social (pragmatic) communication disorder. The social

inference theory suggests that individuals with social (pragmatic) communication disorder, much like individuals with autism spectrum disorder and conduct disorder, may have deficits in social cognition, especially in theory of mind (ToM), which involves making inferences about a person's mental state and using that information to understand and predict the other person's intentions and behaviors. It is often theorized that this type of understanding and representation of other people's mental states precedes the development of social communication. However, it is also possible that an understanding of others' mental states develops as a result of social communication. A third possibility is that individuals with social communication problems have a core deficit in relating to others, which may affect both social communication and forming mental representations of others' intentions. The weak central coherence theory posits that social communication deficits may be associated with a more general processing problem of integrating different sources of information. This theory suggests that social communication deficits occur as a result of individuals with social communication problems narrowly focusing on inappropriate or less crucial aspects of the communication while ignoring the bigger picture, which in turn makes it difficult for them to use linguistic and social context to derive meaning. The executive dysfunction theory suggests that individuals with pragmatic language and communication issues have a more general issue with executive functioning. Executive functions are associated with (but not limited to) the activity of the prefrontal regions of frontal lobes of the brain, which is associated with high-level cognitive functioning such as impulse control, behavior monitoring, flexibility of thinking, abstract thinking, concept formation, problem solving, and planning. The executive dysfunction theory helps explain the great heterogeneity in pragmatic language difficulties experienced by individuals with social and pragmatic difficulties. While executive dysfunction has been implicated in psychiatric disorders such as autism spectrum disorder and attention-deficit/hyperactivity disorder which is associated with pragmatic deficits, more research is needed to examine the hypothesized causal mechanism between high-level processing and social communication or pragmatic language deficits among individuals with social (pragmatic) communication disorder.

EPIDEMIOLOGY

Although there are no reliable prevalence estimates for social (pragmatic) communication disorder, it is acknowledged by clinicians that children with social communication and pragmatic language deficits are one of the fastest growing groups being referred for speech and language interventions. How demographic factors such as age, gender, and socioeconomic backgrounds may correlate with the prevalence estimates

also remains to be investigated. One study in the United Kingdom found that 22 percent of the children attending a language clinic had pragmatic language impairment. However, due to the differences in diagnostic criteria, it is unclear what percentage of these children will also meet the diagnostic criteria for social (pragmatic) communication disorder.

Another study examining a sample of children with autism spectrum disorder found that roughly 1.5 percent of the sample showed signs of social communication deficits without meeting the criteria for fixed interest and repetitive activities and behaviors. Another estimate showed that over 50 percent of the children who were given the diagnosis of pervasive developmental disorder—not otherwise specified showed signs of social communication deficits without clinically significant specialized interest and repetitive behaviors. However, neither of these studies used the DSM-5 criteria for social (pragmatic) communication disorder and therefore the prevalence rate is likely to differ from that of social (pragmatic) communication disorder.

A field trial comparing the prevalence rate of autism spectrum disorder using the DSM-5 criteria and pervasive developmental disorders using the DSM-IV criteria showed a decrease in the prevalence of autism spectrum disorder in one site. Nevertheless, when the prevalence rate of autism spectrum disorder was combined with the prevalence rate of social (pragmatic) communication disorder, the prevalence rate was not significantly different from that of pervasive developmental disorder of DSM-IV. This suggests that the decrease, if any, in the estimated prevalence of autism spectrum disorder may be accounted for by the inclusion of social (pragmatic) communication disorder in DSM-5.

DEVELOPMENT AND COURSE

The diagnosis of social (pragmatic) communication disorder is rarely given before 4 years of age, as an adequate development of speech and structural language is necessary before making a diagnosis of social (pragmatic) communication disorder. By 4 or 5 years of age, most children should have developed sufficient social communication and language skills to make a diagnosis. Some milder forms of social (pragmatic) communication disorder may not be manifest until adolescence, when the social communication and language demands intensify. Although social (pragmatic) communication disorder requires a relatively intact structural language and impaired social communication, there is great heterogeneity in the severity and patterns of manifestation among those who are diagnosed with social (pragmatic) communication disorder. As a group, children with autism spectrum disorder tend to have more severe social communication and pragmatic language deficits than children with social (pragmatic) communication disorder. Children with language disorder, in turn, tend to show milder symptoms of social and pragmatic language

deficits than children with social (pragmatic) communication disorder. The outcome of social (pragmatic) communication disorder differs greatly. Some children's social and pragmatic skills improve considerably while others experience social deficits into adulthood. In general, studies suggest that children with pragmatic language difficulties tend to perform better in academics compared to children with structural language problems. Nevertheless, children with social communication deficits may struggle with written expression and reading comprehension. In addition, there is some evidence suggesting that pragmatic language difficulties in elementary school years may be associated with emotional and behavioral difficulties, higher rates of referral for psychiatric and psychological assessments, and longer duration attending special education. Social (pragmatic) communication disorder may continue into adulthood, making it difficult to form and maintain close social relationships.

Social communication problems rarely occur in isolation, absence of other psychiatric disorders. Cooccurring disorders, as well as other risk factors, are likely to affect the developmental course and prognosis of social (pragmatic) communication disorder.

TREATMENT

Social (pragmatic) deficits rarely occur without other cooccurring behavioral or emotional difficulties. These behavioral and emotional problems may serve as risk factors for further social communication difficulties, and social difficulties in turn may accentuate the cooccurring behavioral and emotional problems.

Several treatment options have been proposed for children with social communication and pragmatic language difficulties who also present behavioral/emotional problems. Several behavioral interventions and cognitive-behavioral treatment programs have been proposed, involving multiple collaborators that include speech–language therapists, mental health professionals, family members, teachers, and peers.

Functional communication training is a behavioral technique that has commonly been used to treat problem behaviors. After a functional analysis is conducted to identify the environmental trigger that evokes the problem behavior in various settings, socially acceptable communicative responses are taught, reinforced, and subsequently applied in different social settings. Cognitive-behavioral therapy is also a popular intervention technique used to modify maladaptive cognitive patterns, emotional responses, and behaviors.

High-quality, randomized controlled trials of social communication interventions specifically targeting social (pragmatic) communication disorder are very rare, however, and more research is required to examine the effectiveness of these treatments. One randomized controlled trial examined the social outcomes of children with social communication

deficits (both with symptoms of social (pragmatic) communication disorder and autism spectrum disorder) who received intensive, individualized, multifaceted interventions as compared to children who received treatment as usual. The intervention focused on developing (1) social interaction skills and social understanding, (2) verbal and nonverbal pragmatic skills, and (3) language processing skills. The children received up to 20 sessions from specialized speech–language professionals and trained assistants. The children who received the experimental intervention showed significant improvement in blind ratings of communication skills, teacher ratings of learning behaviors, and parental ratings of social and pragmatic skills. There were, however, no significant changes in the standardized assessment measures of social communication, which may be due to the lack of sensitivity of these measures to detect change.

Didactic training in social skills on its own, however, has met with little meaningful social changes. This is likely due to the fact that individuals with social (pragmatic) communication disorder do not generally have impaired knowledge of social norms and appropriate behaviors. Interventions targeting underlying deficits, developing strategies to minimize distracting information or make explicit important verbal and nonverbal cues may be more beneficial.

▲ 43.3 Speech Sound Disorder

EMIKO KOYAMA, PH.D., AND JOSEPH H. BEITCHMAN, M.D.

INTRODUCTION

Children with a speech sound disorder do not correctly produce the speech sounds that are expected for their age, developmental stage, and dialect. Sounds may be omitted (e.g., saying *hou* for *house* or *dum* for *drum*), substituted for other sounds (e.g., saying *tup* for *cup* or *yewo* for *yellow*), or distorted because they are produced in an atypical way (e.g., saying /sh/ with too much air escaping from the sides of the mouth or producing /s/ or /z/ with the tongue protruded). Often, the speech sound errors occur in systematic patterns. For example, consonants that should involve a steady airflow instead have an interrupted airflow (e.g., *pat* for *pass* or *bacuum* for *vacuum*) or consonants that should appear at the end of words are instead omitted (e.g., *be* for *bed* or *ro* for *rose*). In severe cases of speech sound disorder, speech may be completely incomprehensible to others.

As with other aspects of language, children must gradually learn the regularities of phonology. Not surprisingly, then, speech sound disorder is similar in many ways to other communication disorders. The affected communication skills generally develop in a typical sequence, but with a delayed onset and slow rate of growth.

Linguistic and motor learning, as well as their integration and coordination, is essential for speech sound development. Linguistically, children acquire knowledge about the individual sounds that comprise a particular language and their permissible contrasts and combinations. Children also induce the regularities governing syllable and word stress, and the intonation patterns (melody) of speech. In other words, linguistic learning presumably involves gradual and implicit acquisition of a complex rule system that underlies the representation, perception, and production of speech. It is not yet clear whether such rules explain or merely describe the nature of phonological knowledge.

Speech sound development also involves considerable motor learning.

Speech production entails the quick, accurate, and coordinated actions of the many muscles that support breathing, voicing, and articulation of speech sounds. Eventually, adults learn to control the complex coordination of these fine motor activities well enough to enable the production of intelligible speech at rates as high as 250 words per minute.

Speech sound development normally proceeds in a systematic fashion. The first words that children use generally consist of simple sequences of consonants (C) and vowels (V) that comprise syllables of the forms CV (e.g., bye), VC (e.g., up), or CVC (e.g., dog) and short repetitive sequences of the form CVCV (e.g., dada). More complex syllable and word shapes are gradually mastered, such as those with multiple, nonrepetitive syllables and consonant cluster sequences, such as /thr-/, /kl-/, /-rst/, or /-nt/. Vowels are generally thought to be acquired early, and most studies suggest that vowel production is relatively accurate by 2 years of age. As such, numerous vowel errors made beyond age 2 years may be early warning signs of impaired speech. Early words generally include consonant sounds designated as the *early eight* (/m/, /b/, /y/, /n/, /w/, /d/, /p/, and /h/), which are also commonly used during the babbling stage from about 6 months of age. As development continues, the *middle eight* consonant sounds (/t/, /ng/, /k/, /g/, /f/, /v/, /ch/, and /j/) are mastered gradually, followed by the *late eight* (/sh/, /th/ [two variants], /s/, /z/, /l/, /r/, and /zh/). Children may not achieve full mastery of the late eight consonant sounds until 7 or 8 years of age. Throughout the course of typical development, children may produce speech sounds incorrectly and inconsistently. Three types of errors are common: omissions (e.g., *ha* for *hat*), substitutions (e.g., *fin* for *thin*), or distortions (e.g., a slurpy-sounding /s/).

Speech sound errors may also be described in terms of phonological processes or rules that encompass a pattern of errors. For example, young children often use a phonological process of final consonant deletion in which they regularly omit consonants at the end of words. This deletion process is used often by young children but usually disappears from their speech by 3 years of age. Similarly, there are other common processes that gradually disappear during normal development, including reduplication (repetition of a syllable to form a multisyllabic word, e.g., *bahbah* for *bottle*), unstressed syllable deletion (omission of a syllable that is not stressed, e.g., *nana* for *banana*), stopping (use of an interrupted airflow for sounds that should have a continuous airflow, e.g., *tee* for *see*), consonant harmony (e.g., using a sound similar to one that occurs elsewhere in a word, e.g., *tat* for *cat*), and consonant cluster reduction (omitting or simplifying sounds in a consonant cluster, e.g., *top* for *stop*). These phonological processes all occur regularly in the speech of young children but all are usually overcome before 5 years of age.

Even if a child mispronounces words, it may not affect the overall

comprehension of the child's utterances. If a child's spoken word or phrase cannot be understood, the child's speech is said to be *unintelligible*. Intelligibility is influenced not only by the produced speech sounds but also by other factors such as pragmatic context and the complexity of the sentence. In normal speech development, roughly half of children's speech is considered intelligible at about 2 years of age, roughly 75 percent is intelligible by 3 years of age, and by age 4 years, nearly all of the child's spoken language becomes intelligible. If less than two-thirds of the child's utterances are intelligible by age 4, clinical attention may be warranted.

COMPARATIVE NOSOLOGY

Speech sound disorder in the 5th edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) largely corresponds to phonological disorder in the revised 4th edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR). The designation of *speech sound disorder* is typically reserved for speech sound problems with no known cause, which are thought to reflect difficulties in learning the regularities of phonology (the sound system of a language). The 10th edition of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) provides the category of *specific speech articulation disorder* for speech problems of unknown etiology and designates a different category for speech impairment arising from sensory, structural, or neurological conditions. In the research literature, terms such as (developmental) phonological disorder, (functional) articulation disorder, developmental verbal dyspraxia, and childhood apraxia of speech are commonly used in association with speech sound disorder.

EPIDEMIOLOGY

The prevalence of speech sound disorder is at least 3 percent in preschoolers, 2 percent in 6- to 7-year-old children, and 0.5 percent in 17-year-old children. Estimates however vary widely in the research literature, reflecting the diverse criteria and samples that have been used across studies. Slightly more than half show problems only in speech sound production; the remainder also had language difficulties. Overall, speech sound disorder occurs far more frequently than speech impairment with known structural or neurological origins.

Speech sound production difficulties occur more often in boys. The literature includes estimates for sex ratios as high as 4:1 and as low as 1.5:1. Speech sound disorder also shows high rates of familial aggregation. Approximately 20 to 40 percent of children with speech sound disorder have at least one immediate family member who is also affected. There is evidence in favor of genetic contributions to familial aggregation, but environmental factors may also play a role. Familial risk factors such as low maternal education have also been identified as a potential risk factor.

ETIOLOGY

Speech sound disorder has no known cause. Proposals regarding causation typically focus on many of the same factors considered as possible causes for language disorders, including subtle brain abnormalities, genetic influences, environmental factors, neurodevelopmental immaturity, linguistic factors, and auditory processes. In addition, speech motor control and speech mechanism factors have also been entertained as possible causes.

Speech sound disorder most likely has multiple causal determinants. Although some evidence supports each proposed determinant, no single one is implicated in all cases of speech sound disorder. The idea that brain abnormalities may be responsible for speech sound disorders is supported primarily by indirect evidence, which includes reports of associated soft neurological signs at higher than normal rates and findings of structural or functional brain abnormalities in children with related disorders, such as language disorder and reading disorder. The evidence in support of genetic factors comes from a variety of methods, including pedigree, twin, adoption, and linkage studies. Recent studies have found susceptibility of speech sound disorder genes in chromosomes 3, 6, and 15, which are also thought to be candidate regions for dyslexia. The advancement of work on genetic influences will probably stimulate corresponding advances in the understanding of environmental determinants. At present, however, no conclusive evidence links specific environmental factors to speech sound disorders, although it is reasonable to assume that such factors contribute in as-yet unspecified ways. Neurodevelopmental immaturity is suggested by the fact that children with speech sound disorder usually follow the same sequence in speech sound development as children without the disorder, albeit at a slower rate. Additional indirect support comes from findings of soft neurological signs and subtle deficits in motor skills. Children with speech sound disorders may also have linguistic deficits that interfere with efficient learning of the regularities of phonology (e.g., permissible sounds, combinations, or positions of occurrence) from the available language input. Difficulties with auditory discrimination and perception or temporary hearing losses may also contribute to some cases of speech sound disorder. Children with speech sound disorder also show elevated rates of subtle abnormalities in the structure and function of the speech mechanism, but it is not yet known whether these abnormalities are causes or just correlates of the disorder.

DIAGNOSIS AND CLINICAL FEATURES

A diagnosis of speech sound disorder is given when a person experiences persistent difficulties in speech sound production due to different degrees of impairment in phonological knowledge and coordination of movements

involved in speech. The speech sound production is impaired for what is expected based on the speaker's age and dialect, and cannot be attributed to medical or neurological conditions such as cerebral palsy, cleft palate, traumatic brain injury or hearing impairment. A further criterion is that the speech sound difficulties must interfere with social communication, academic achievement, or occupational success. Speech sound disorder ranges in severity from mild, in which errors occur on one or two sounds and speech intelligibility is hardly affected, to severe, in which errors occur on most sounds and speech intelligibility is significantly impaired.

A delayed onset and slow rate of speech sound development are typical of most children with speech sound disorders. However, the course and sequence of development usually resemble those of typically developing children. Simple syllable and word shapes are gradually elaborated to include more complex shapes. The rate of acquisition may be slow, but the early eight consonant sounds usually develop first and are followed, in turn, by the middle eight and then the late eight consonant sounds. The errors in speech sound production resemble those that occur in normal development, but the relative distribution of omissions, substitutions, and distortions may be somewhat different. Children with speech sound disorder generally use phonological processes that also occur in normal development but may use these processes well beyond the age at which they normally disappear. Children with speech sound disorder also sometimes use unusual or idiosyncratic phonological processes that are not observed in normal development.

Ramon was a talkative, likable 3-year-old with virtually unintelligible speech, despite his normal hearing and language comprehension skills. Ramon's level of expressive language development could not be determined because his speech was so difficult to understand. The rhythm and melody of his speech, however, suggested that he was trying to produce multiword utterances, as would be expected at his age. Ramon produced only a few vowels (/ee/, /ah/, and /oo/), some early developing consonants (/m/, /n/, /d/, /t/, /p/, /b/, /h/, and /w/), and limited syllable shapes (V, CV, and CVCV). This reduced sound repertoire made many of his spoken words indistinguishable from one another (e.g., he said *bahbah* for *bottle*, *baby*, and *bubble*, and he used *nee* for *knee*, *need*, and *Anita* [his sister]). Moreover, he consistently omitted consonant sounds at the end of words and in consonant cluster sequences (e.g., /tr-/, /st-/, /-nt/, and /-mp/). On occasion, Ramon reacted with frustration and tantrums to his difficulties in making his needs understood.

Kent was a pleasant, cooperative 5-year-old boy, who had been diagnosed with a speech sound disorder when he was a preschooler. His hearing and language comprehension skills were within normal limits. However, he showed some mild expressive language problems in the use of certain grammatical features (e.g., pronouns, auxiliary verbs, and past-tense word endings) and in the formulation of complex sentences. He correctly produced all vowel sounds and most of the early developing consonants but was inconsistent in his attempts to produce later-developing consonants (e.g., /r/, /l/, /s/, /z/, /sh/, /th/, and /ch/). Sometimes, he omitted them; sometimes, he substituted other sounds for them (e.g., /w/ for /r/ or /f/ for /th/); occasionally, he even produced them correctly. Kent had particular problems in correctly producing consonant cluster sequences and multisyllabic words. Cluster sequences had omitted or incorrect sounds (e.g., *blue* might be produced as *bue* or *bwue*, and *hearts* might be

said as *hots* or *hars*). Multisyllabic words had syllables omitted (e.g., *efant* for *elephant* and *getti* for *spaghetti*) and sounds mispronounced or even transposed (e.g., *aminal* for *animal* and *lemon* for *melon*). Strangers were unable to understand approximately 80 percent of Kent's speech. Fortunately, Kent often spoke more slowly and clearly than usual when he was asked to repeat something, as he often was.

Natasha was a shy, reserved 8-year-old girl, with a history of significant speech delay. During her preschool and early school years, she had overcome many of her earlier speech errors. A few late-developing sounds (/r/, /l/, and /th/), however, continued to pose a challenge for her. Natasha often substituted /f/ or /d/ for /th/ and produced /w/ for /r/ and /l/. Overall, her speech was easily understood despite these minor errors. Nonetheless, she was often reluctant to speak in front of others because of the teasing she received from her classmates about her speech.

Other language, learning, and developmental disorders may cooccur with speech sound disorder. Language disorder, especially deficits in expressive language, frequently cooccur with speech sound disorder. Children who have both speech sound disorder and language disorder are at increased risk for other problems, such as reading and other learning disorders, attention-deficit hyperactivity disorder, and perhaps, developmental coordination disorder. Children with isolated speech sound disorders are at a relatively small risk for severe academic, behavioral, or psychiatric disorders. Children who continue to display severe speech errors by the time they enter school may, however, be at increased risk of developing reading and spelling problems.

PATHOLOGY AND LABORATORY EXAMINATION

There are no laboratory tests that can provide a diagnosis of speech sound disorder. When necessary, specific laboratory tests may help identify and document an underlying neurological condition that is responsible for apraxia or dysarthria.

DIFFERENTIAL DIAGNOSIS

The most important task in diagnosis of speech sound disorder is to judge if speech sound production is inappropriate for the age and dialect of the speaker. The judgment may be challenging because the speech of children with speech sound disorder often resembles that of younger children who are developing normally. The same speech errors that may indicate disorder in a 6-year-old child may also indicate typical development in a 4-year-old child. Thus, it is critical to compare carefully a particular child's pattern of speech sound errors to the normal patterns of speech sound development in children.

One must also carefully consider the dialect spoken by the child. Sound differences that may be quite acceptable in one dialect may suggest disorder in another. For example, the production of *caht* for *cart* is acceptable for speakers from Boston but not for those from most other

parts of North America.

One of the challenges facing clinicians is how to diagnose speech sound disorders in bilingual children. Depending on such factors as the child's first language background and the timing of acquisition of the second language, even typically developing bilingual children may exhibit more frequent and atypical phonological error patterns compared to their same-age monolingual peers. Research is needed to establish the typical and atypical speech patterns of children acquiring a second language. Meanwhile, an assessment of speech sound production skills in English and the child's other language, accompanied by a careful history, may lead to a correct diagnosis.

The diagnostic assessment should also include a hearing test and an oral examination. The hearing test identifies temporary or permanent hearing difficulties that may require medical or other interventions to enhance the prognosis for the development of understandable speech. The results from the oral examination may help clarify whether the speech sound production problems are developmental, structural, or neurological in origin. For example, children with neurological conditions may be slow or inaccurate in performing various speech and nonspeech movements (e.g., sequencing syllables, as in *putuku*; protruding the tongue; or rounding the lips) or may show signs of muscle weakness or paralysis. Drooling, feeding, or swallowing problems, suggestive of dysarthria, may also be observed or reported in the history. During the oral examination, the diagnostician may also identify structural abnormalities in the mouth, such as tumors or submucous clefts of the palate, which may need to be considered in overall management of the child.

Selective mutism is an anxiety disorder that is characterized by the consistent failure to speak in specific social settings. Children with speech sound disorder may not speak due to embarrassment about their speech impairments. However, children with selective mutism typically exhibit normal speech in settings where they feel "safe," such as with family or close friends.

Screening for possible cooccurring communication disorders is also important for children diagnosed with speech sound disorders. When intellectual developmental disorder is suspected, a cognitive assessment may help confirm or rule out this diagnosis. In cases in which speech difficulties are in excess of those expected for a particular degree of intellectual disability, a diagnosis of cooccurring speech sound disorder may be made.

A practitioner should make a referral to a speech–language pathologist for assessment of speech sound production skills when (1) a 2 year old uses little or no speech, (2) a 3 year old is poorly understood by familiar members of the family, (3) a 4 year old is poorly understood by peers and strangers, (4) a child of any age seems to be withdrawing from social

interactions as a result of teasing or frustration associated with speech difficulties, (5) a parent or teacher is concerned about a child's speech, or (6) a child (or adult) experiences a sudden deterioration in speech production skills. The last may be the first warning sign of a developing neurological condition and therefore also warrants referral for neurological examination.

COURSE AND PROGNOSIS

Diagnosis may occur as early as 2 years of age in severe cases of speech sound disorder, which may be accompanied by cooccurring language involvement. However, diagnosis around 4 years of age is more usual. Speech sound disorders show considerable variability in severity, course, and outcome. In approximately 75 percent of mild-to-moderate cases, speech sound production skills normalize by 6 years of age, with or without intervention. Thus far, no specific predictors of normalization have been identified from among the various speech, hearing, oral, cognitive, linguistic, or psychosocial variables that have been investigated. For children whose speech has not normalized by 6 years of age, speech sound development proceeds in spurts and plateaus until 8 or 9 years of age. If normalized speech has not been achieved by then, residual articulation problems often persist into adulthood unless successfully treated. These residual errors usually involve distortions of later-developing sounds, such as /l/, /r/, /s/, /z/, /sh/, /ch/, and /th/. Distortions of the sounds /s/, /z/, /sh/, and /ch/ are termed *lisps*. Residual errors often have little effect on speech intelligibility but may influence others to erroneously perceive a speaker as lazy, immature, or of low intelligence.

Children with mild-to-moderate speech sound disorders are at relatively little risk for adverse long-term outcomes. Although speech typically normalizes by 8 to 9 years of age, subtle deficits in the speed and accuracy of articulation during complex speech tasks (e.g., rapid pronunciation of multisyllabic words) may remain detectable into adulthood but have little functional impact. Overall, language, cognitive, academic, psychosocial, and psychiatric outcomes are usually within the normal range for adults with a history of mild-to-moderate speech sound disorder.

Children with severe speech sound disorders that persist to school age are at a greater risk for poor outcomes. They may not develop adequate phonological awareness skills (perception, identification, and mental manipulation of speech sounds), which, in turn, may lead to problems in learning to read and spell. Parents and teachers should monitor carefully the reading and spelling development of school-age children with severe, persistent speech sound problems. If required, reading and spelling performance can then be fostered through explicit instruction in phonological awareness. It is not yet clear whether severe speech sound disorders are associated with increased risk for adverse psychosocial or

psychiatric outcomes.

Children with cooccurring language disorders are, however, known to have elevated risk for adverse long-term outcomes in communicative, academic, psychosocial, or psychiatric functioning. Those with receptive difficulties are at the greatest risk.

TREATMENT

Treatment is typically recommended for children with moderate-to-severe speech sound disorders. A speech–language pathologist may provide the treatment directly to the child or indirectly through paraprofessionals, parents, teachers, peers, or other volunteers who are taught how to provide treatment for the child. Although there are many intervention techniques, styles, and programs that have been advocated, two main approaches to treatment are discernible.

The *traditional approach* is typically used with children who produce substitution or distortion errors for just a few sounds. In this approach, the child participates in activities that highlight the auditory and motor characteristics of a particular sound. The child then practices the production of the sound, while the clinician provides feedback and cues concerning the correct placement and movement of the articulators. Treatment is discontinued once the child produces the new sound accurately in spontaneous speech.

A *phonological approach* is usually chosen for children with patterns of multiple speech sound errors that are described by phonological processes (e.g., final consonant deletion or consonant cluster reduction). In this approach, the child participates in activities that demonstrate the communicative value of correctly using certain classes of sounds, such as final consonants or consonant clusters. The child then practices the production of various final consonants or clusters in meaningful communicative situations until the targeted groups of sounds are incorporated into the child's phonological system. Treatment is discontinued once the child uses the new classes of sounds correctly and consistently in everyday speech.

Traditional and phonological approaches have proven effective in accelerating the rate of speech sound development. However, not all variations of these approaches have yet been subjected to rigorous investigations of their efficacy. Additional research is also needed to compare the relative merits of various techniques for children with different profiles of speech errors, although some work of this nature has begun to appear in the literature. Overall, treatment success depends on whether the new speech skills become established as automatic patterns of production. A key factor in achieving this goal may be the extent to which a child or adolescent is motivated to change existing speech patterns.

In addition to speech sound intervention, children with cooccurring

language disorder may need interventions to promote language or fluency. Few studies have systematically evaluated the efficacy of such joint interventions. It is possible that speech production gains may occur as an additional benefit of language intervention that did not focus specifically on speech sound production.

▲ 43.4 Stuttering

ROBERT M. KROLL, PH.D., AND JOSEPH H. BEITCHMAN, M.D.

DEFINITION

Stuttering is a condition in which the flow of speech or fluency is disrupted by involuntary speech motor events. Stuttering may include a variety of specific dysfluency types, such as sound and syllable repetitions, sound prolongations, dysrhythmic phonations, and complete blocking or unusual pauses between sounds and syllables of words. More severe forms of stuttering are frequently accompanied by a variety of struggle behaviors, commonly referred to as *accessory*, or *secondary*, features of the disorder. These struggle behaviors may be observed at the respiratory, phonatory, or articulatory level of the speech mechanism and may manifest themselves in

disordered breathing, glottal fry (abnormal voice quality), lip pursing, and tongue clicking. Additional behaviors, such as eye blinks, facial grimacing, head jerks, and abnormal body movements may be observed before or during instances of disrupted speech. In addition to the core and secondary physical symptoms of stuttering, the intended communication is often altered or distorted by linguistic avoidance due to anticipatory sound or word fears. Linguistic avoidance is a commonly observed feature of stuttering, which results in word substitution and circumlocution as the individual approaches the feared sound or word during the communicative attempt. Furthermore, it has been reported that varying levels of both utterance length and temporal complexity function to modulate stuttering frequency in adult stuttering speakers. Similarly, situational avoidance is often characteristic of chronic stuttering, and the type of communicative situation often influences the amount and severity of stuttering. Stuttering patterns are extremely variable, ranging from mild, occasional dysfluencies in speech to severe stuttering that renders communication all but impossible for the affected individual and often results in serious psychological difficulty and social withdrawal. Moreover, the person who stutters may exhibit widely fluctuating periods of fluency and dysfluency during the course of a day, depending on the communicative situation, anxiety level, fatigue level, and many other associated variables. It is to be noted that stuttering severity is not solely a measure of the frequency of observed stuttering instances, but is usually a function of the communicative hardship that it places on the speaker. In other words, an individual employed in an office setting who exhibits a stuttering rate of 15 percent may feel less handicapped than an airline pilot who is 4 percent dysfluent but whose fluent communication is critical. Most recently, treatment efficacy studies of stuttering have begun to utilize measures of functional communication and quality of life to supplement traditional data gathered from counts of stuttering frequency.

HISTORY AND COMPARATIVE NOSOLOGY

Psychiatric syndromes can be defined from the point of view of the observer or the patient. Depressed individuals may not look depressed, but if they report subjective symptoms sufficient to meet criteria, a diagnosis of a depressive disorder can be made. Likewise, stuttering can be defined from the point of view of the listener or the speaker. The speaker's sense of subjective distress or loss of control of the speech apparatus reflects an approach to nosology that focuses on the speaker's experience. The *Diagnostic and Statistical Manual of Mental Disorders* (DSM), on the other hand, focuses on the observer's point of view—that is, on the observable behaviors.

In both DSM-III and DSM-III-R, stuttering was placed in the category of disorders usually first evident in infancy, childhood, or adolescence. In

both of these systems, stuttering was coded on axis I, along with clinical psychiatric syndromes. This remains controversial, as stuttering is not commonly viewed as a psychiatric disorder among speech–language professionals, and speech–language pathologists have argued that it should not be included in DSM at all.

In DSM-IV-TR, stuttering is categorized as a communication disorder. This is consistent with the speech–language pathology classification, in which all speech and language disorders are kept within the same category. However, it remains to be shown that it belongs in this category; aside from the similarity of causing communicative difficulties, stuttering may differ fundamentally from the other communication disorders in this category. The 10th revision of the *International Statistical Classification of Disease and Related Health Problems* (ICD-10) separates stuttering (stammering) from the speech and language disorders and places it in the category of other behavioral and emotional disorders with onset usually occurring in childhood and adolescence. The diagnostic criteria in ICD-10 are similar to the DSM-IV-TR diagnostic criteria, but a few differences are notable.

DSM-IV-TR requires that the disorder interfere with academic or occupational achievement or social communication, whereas the ICD-10 diagnosis applies only if it is severe enough to cause marked disturbances in fluency. ICD-10 requires a minimum duration of 3 months; DSM-IV-TR has no duration criterion. DSM-IV-TR further specifies that the disturbance must exceed what is appropriate for the individual's age, and, if a speech–motor or sensory deficit is present, the speech difficulties must exceed those usually associated with these problems. ICD-10 has an additional category for cluttering, which is not accorded separate status in DSM-IV-TR.

According to the DSM-5, stuttering is defined by a disturbance in the normal fluency and patterning of speech that are inappropriate for the individual's age and language skills, persist over time and are characterized by frequent and marked occurrences of one (or more) of the following: sound and syllable repetitions; sound prolongations of consonants as well as vowels; broken words (e.g., pauses within a word); audible or silent blocking (filled or unfilled pauses in speech); circumlocutions (word substitutions to avoid problematic words); words produced with an excess of physical tension; monosyllabic whole-word repetitions (e.g., "I-I-I see him").

The disturbance causes anxiety about speaking or limitations in effective communication, social participation, or academic or occupational performance, individually or in any combination.

The onset of symptoms is in the early developmental period. The disturbance is not attributable to a speech–motor or sensory deficit, dysfluency associated with neurological insult or another medical condition, or better explained by another mental disorder.

EPIDEMIOLOGY

Surveys conducted chiefly in the United States and Europe indicate that the prevalence of stuttering in the general population is approximately 1 percent. Although data regarding incidence vary widely, most specialists would agree that the likelihood of an individual ever exhibiting some form of stuttering is between 3 and 4 percent. Of those who begin to stutter, the majority stop by adulthood. The estimated percentages of spontaneous recovery in stuttering, again, vary widely because of differing definitions of stuttering and normal nonfluency, age groups studied, and data collection techniques. Several studies have estimated spontaneous recovery to be as high as 80 percent. Stuttering is more prevalent among boys than girls, with the ratio of boys to girls among US schoolchildren being approximately 3:1. Current studies have challenged the above estimates of prevalence, incidence, and gender ratios. Among other factors, it has been postulated that most of the risk for stuttering onset is over by age 5. Even in its earliest stages, stuttering has been shown to be both qualitatively as well as quantitatively different from normal dysfluency.

A high familial incidence is indicated by the presence of stuttering among the relatives of approximately 50 percent of individuals who stutter. Additionally, a high degree of concordance of stuttering exists in identical twins. Individuals who stutter appear to have normal developmental histories, except for speech and language. Numerous studies have demonstrated that young stuttering children are somewhat delayed in early language and articulation development; however, studies of older stuttering children appear to demonstrate that language skills are once again age appropriate. With regard to personality and social and emotional adjustment, children who stutter are often regarded by their parents or primary caregivers as nervous and prone to specific fears. They are often described as overly sensitive to their environment. Adults who stutter tend to be somewhat more anxious and emotionally reactive than their nonstuttering peers. For the most part, studies relating intellectual ability to stuttering are inconclusive; however, there is a significantly higher prevalence of stuttering in the developmentally delayed population.

ETIOLOGY

There has been growing agreement by researchers and clinicians that stuttering is a multifactorial disorder. Specifying the level of causation can facilitate understanding the etiology of stuttering.

The first of these levels pertains to underlying causation, which refers to the genetic, neurophysiological, and psychological factors that may predispose a child to fluency disruption. Research in these areas has been rather cyclic since the 1940s, and various models implicating psychological, learning, and neurophysiological variables in stuttering have been

presented.

One early psychoanalytic theory of stuttering postulated that disrupted speech represents part of the individual's psychological history, such as disturbed early parent–child interaction. Empirical support for this psychoanalytic model is largely lacking, and studies investigating personality factors associated with stuttering have not revealed anything suggesting emotional disturbance or neurosis as a possible cause.

Later psychological models of stuttering have drawn on the principles of classical and operant conditioning to explain stuttering. Several behaviorally oriented researchers offered a model of operant conditioning in which the early dysfluencies of the child were subject to an intermittent schedule of reinforcement, resulting in incipient stuttering. The two-factor theory of stuttering posited that fluency failure resulting from negative emotion becomes associated with speech-related stimuli through a process of classical conditioning. The individual's response to the fluency failure, the repetitions, sound prolongations, and attempts to terminate the instance of disruption are instrumentally conditioned. Perhaps the best known of modern psychological theories of stuttering is the diagnosogenic (semantogenic) model. This theory postulates that stuttering is caused by parents' diagnoses of the developing child's normal dysfluencies as stuttering.

The large proportion of stuttering individuals who have relatives with a similar speech disorder and the high concordance for stuttering in identical twins have long suggested that biological inheritance plays some part in stuttering. Current models of genetic transmission that can account for familial patterns of stuttering provide strong evidence for the biological inheritance of stuttering. Moreover, research utilizing the most current genotyping technologies has confirmed the evidence for a strong genetic factor in stuttering. However, these genetic models point to a complex interaction between heredity and environment. Most recent studies have pointed out several possible specific candidate genes. However, it is too early to declare that specific genes underlying stuttering in the general population have in fact been identified. Moreover, at this point in time, it remains unclear as to which specific combinations of motor, linguistic, temperament, or other aspects of speech are being transmitted.

The theory of cerebral dominance, proposed in the late 1920s, was one of the earliest neurophysiological models used to explain the cause of stuttering. This theory postulated that stuttering resulted from the lack of an appropriately developed hemispheric dominance of speech and language function.

The theory of incomplete or atypical cerebral lateralization for speech has received varying amounts of support, but not until relatively recently did advances in electrophysiological techniques and brain imaging begin to yield more definite data on cortical and subcortical processing of speech in

stuttering. Much of the earlier research into the nature of these hypothesized brain processes was based largely on the use of behavioral observations and electromyographic measures. Relevant observations included the effects of auditory delayed feedback on the speech fluency of nonstuttering and stuttering speakers; differences in dichotic listening and dual task interference performance between stuttering and nonstuttering speakers; and articulatory discoordination and oral kinesthetic deficiencies in stuttering individuals. These observations, among others, represented indirect evidence of differences in neural processing between stuttering and nonstuttering individuals.

Most recently, several brain-imaging techniques used to measure regional cerebral blood flow have been applied to the investigation of stuttering. Data from these initial studies using single-photon emission computed tomography (SPECT) and positron emission tomography (PET) point to differential activation patterns in stuttering during both oral and silent reading and even immediately after treatment for stuttering. Findings from these studies have reported a general overactivation in several regions of cortical and subcortical motor systems in individuals who stutter. Recent functional imaging studies have reported increased activation in the right frontal-lateral cortex and the medial-anterior cingulate during silent and oral reading in stuttering individuals. Moreover, the neural activation in stuttering adults is characterized by a more generalized bilateral recruitment of cortical and subcortical neural resources involved in both language formulation and speech production.

Data coming from studies investigating effects of treatment seem to suggest that behavioral treatment initially results in an even further increase in recruitment of resources, including cerebellar activity, after an intensive 3-week treatment period, followed by a significant reduction in the overall amount of activation after 1 year. At the 1-year mark, the overall activation pattern observed in the stuttering speakers is very similar to that observed in the normally fluent speakers. This finding has been interpreted as signaling increased automaticity in the application of learned speech motor skills.

A recent study attempted to establish whether disconnections between speech-related cortical areas were the structural basis for stuttering. The investigation reported that stuttering subjects showed disturbed patterns of activation in the premotor and motor cortices, particularly below the laryngeal and tongue representations in the left sensorimotor cortex. Further evidence pointing to anomalous anatomical cortical structures in stuttering has been reported in a study using volumetric MRI scans. The study found that anomalous anatomical configurations of perisylvian cortical speech–language areas are more common in adults with stuttering. In addition to several other findings, the authors report that both the right and left planum temporale were significantly larger in the stuttering

subjects compared to the controls, and planar asymmetry was reduced, implicating speech and language laterality. The authors point out that the left planum temporale is composed of auditory association cortex, which is important in higher-order processing of linguistic information and is structurally larger than its homologous counterpart in healthy adults, thus the resulting leftward asymmetry. Researchers have speculated that the left planum temporale may be the neuroanatomical substrate for language, and there is some evidence of a relationship between planar asymmetry and language laterality. Additional structural anomalies have been reported in recent studies examining the neuroanatomical differences in speech-related cortex between stuttering and nonstuttering individuals using voxel-based morphometry. Results revealed significant differences in localized gray and white matter densities of left and right hemisphere regions involved in auditory processing and speech production.

The past decade has seen an exponential growth in the numbers of peer-reviewed articles investigating both functional and structural brain differences in stuttering individuals. While there appears to be much in the way of unclear or conflicting evidence, there have been some consistent findings.

First, several studies have demonstrated that people who stutter demonstrate greater activity in the right hemisphere cortex (gray matter) than nonstuttering individuals. Such overactivation is observed particularly in an area of the right frontal lobe which is homologous to Broca's area of the left hemisphere. Structural studies have further demonstrated that white matter differences between stuttering and fluent speakers, located primarily in the right primary auditory and frontal cortices, were observed contralateral to the gray matter differences. The implication from these studies is that structural deficits are compensated for by the contralateral region through the formation of new white matter pathways. In a recent study of stuttering children, reduced gray matter volumes in the bilateral-inferior frontal gyri and left putamen were observed. These stuttering children also demonstrated increased gray matter volumes in right ventral premotor and superior-temporal gyri relative to fluent children. These findings are interpreted as reflecting developmental factors resulting in a deficit in speech motor learning. A number of studies have also reported that stuttering subjects show significantly increased activation in the cerebellum, which is critical for integrating sensory and motor functions early in the acquisition of motor skills.

A second etiological level of stuttering involves the precipitating causes —that is, when, where, and under what conditions stuttering is most likely to occur. At this level, concern is with the loci of stuttering and the specific speaking situations affecting fluency. Linguistic factors associated with stuttering have led some theorists to view it as a higher-level cognitive dysfunction. The vast majority of stuttering occurs mostly on the initial

sounds of words or syllables. Fluency-facilitating conditions include choral reading, repeated reading of the same material, whispering, and speaking under conditions of altered auditory feedback or masking noise. Based on these and other phenomenological features of stuttering, new theories have implicated higher-level linguistic processes as the fundamental causal elements for speech disruption in stuttering. These processes involve the planning or adjustments of linguistic plans via internal monitoring loops. One such theory, the covert repair hypothesis, emphasizes the role of internal monitoring in detecting and correcting phonological errors in speech planning and production. The theory uses elaborate models of internal monitoring, self-repair, and priming in attempts to explain both the type of dysfluency and the conditions that facilitate speaking.

A third level of causation and an area of active investigation concerns the motor speech and vocal tract dynamics characteristic of stuttering. The vocal tract events generating disrupted speech patterns have been the focal point of much of the physiological research in stuttering since the early 1980s. It is reasoned that increased knowledge of vocal tract events and the component behaviors of stuttering will ultimately have a direct impact on the assessment, measurement, and modification of these behaviors. Much information is available on the respiratory, laryngeal, and articulatory dynamics of stuttering. Physiological studies indicating differences between stutterers and nonstutterers are closely scrutinized because they may in fact be dealing only with peripheral events surrounding stuttering, not with underlying causation. The above argument notwithstanding, individuals who stutter, as a group, exhibit relatively longer laryngeal, respiratory, and articulatory reaction times. It has been speculated that the speech motor systems of people who stutter are limited in their skill or ability to prepare and perform the motor actions that are required to implement the various demands imposed by linguistic, cognitive, emotional, and motor aspects of speech.

The final level of causation involves the environmental factors associated with the onset and development of stuttering. Much information has been collected on personality traits of young children who stutter and their parents, as well as the psychodynamic, sociological, and conditioning factors influencing stuttering and their interaction with linguistic development. Considerable inconsistency exists in data obtained from research on the personality of stutterers. There is little (if any) conclusive evidence that stutterers, as a group, exhibit a definable character structure or predictable set of personality traits. This inconsistency is further evidenced in a series of recent articles investigating temperament, emotional regulation, and emotional reactivity in young children who stutter. Some of these studies suggest that greater emotional reactivity experienced by preschool children who stutter, together with their relative inability to regulate their emotions and control their attention, may lead to

fluency breakdown. Other studies have been unable to distinguish between the children who stutter and those who do not, on these variables. Moreover, there appears to be much overlap in overall adjustment profiles between stutterers and nonstutterers, with lower social adjustment and self-esteem scores characterizing individuals who stutter. These traits are most often explained by the impact of the stuttering itself on these individuals and their environment.

DIAGNOSIS AND CLINICAL FEATURES

Stuttering is typically characterized by involuntary disruptions in the fluency of verbal expression. These disruptions may be audible or silent and are usually characterized by repetitions or prolongations of sounds or syllables, or by tense pauses or the complete cessation or blocking of speech sounds.

Accessory, or secondary, features frequently accompany instances of stuttering. These secondary behaviors involve both the speech mechanism and related or unrelated body structures. Such behaviors may include eye blinks, facial grimacing, lip and tongue tremors, tics, vocal fry, head jerks, abnormal movements of the limbs, and breathing irregularities. Linguistic and situational avoidance behavior is often observable with confirmed stuttering. The affected speaker will often scan the intended utterance to predict stuttering and then attempt to avoid such disruption by substituting words, revising phrases, circumlocutions, or stopping the entire communicative process. Situational avoidance is often reported, such as speaking in front of a group or on the telephone. Most adult stutterers report specific sounds, words, or situations that increase stuttering. Most of this information comes from studies carried out on chronic adult stutterers. Children who stutter have not been studied extensively, but it is generally accepted by clinicians that stuttering in its earlier forms is more often restricted to simpler types of dysfluency, such as repetitions and prolongations, and less often involves the more severe struggle and avoidance behaviors. Definitions of *stuttering* vary widely and are usually based on listeners' observations of the disrupted speech pattern. However, some authors emphasize that the affected individual's sensations of the stuttering moment are crucial to any complete definition. Many forms of stuttering are so subtle that they are undetectable by the listener and are only perceived by the speaker.

Although stuttering varies markedly in terms of frequency and severity, both within and among individuals who stutter, some fairly predictable events or situations are commonly observed that either facilitate fluency or result in a deterioration of the stuttering (e.g., choral reading, singing, whispering, speaking in the presence of masking noise or under conditions of delayed auditory feedback, speaking when alone). Conditions commonly observed to increase stuttering include talking on the telephone, talking to

groups, making introductions and saying one's own name, talking to authority figures, and attempting to communicate during stressful situations such as job interviews or formal presentations.

Although severe forms of stuttering are most often observed in adults, children and adolescents can be similarly affected. Stuttering can have a significant impact on the individual's quality of life, causing significant social, emotional, educational, and vocational problems. The preschool and young school-age stutterer frequently develops social and school-related anxiety. The adolescent who stutters tends to withdraw from normal social interaction. The young adult stutterer often reports feelings of restricted academic and career choices and often forgoes the opportunity to develop specific talents and career paths.

Adam was a pleasant and likable 8-year-old boy in the second grade. He had a younger brother and older sister whose speech developed normally. Adam's speech was also developing normally until around the age of 3½ at which time he began to show numerous repetitions of words, syllables, and sounds. Adam's pediatrician felt that the dysfluent speech was only a phase that Adam would soon outgrow. Adam's speech grew progressively worse and he began to show signs of struggle as he tried to force his words out on many occasions. The family remained convinced that the physician's predictions would in fact be borne out and that Adam would eventually grow out of the problem. By the time Adam was in the second grade, his speech was characterized by severe stuttering taking the form of silent blocks lasting up to 20 seconds. These blocks were associated with generalized upper body tension and breathing abnormality just prior to the instance of disruption. In addition to being visibly frustrated by his inability to communicate at school and with his friends, Adam became withdrawn and socially isolated. He would not participate in class and would often refuse to go to school if he knew that he would be called on during a certain activity. Adam's mother also reported that there had been several instances of bullying and teasing by two of Adam's classmates. On several occasions, Adam returned home from school crying because of the remarks made concerning his speech. At this point, Adam's mother consented to having the school speech–language pathologist perform a full assessment and begin therapy sessions in order to provide Adam with the relief and support that he had been lacking.

The case study of Adam illustrates two commonly observed scenarios with regard to children's early speech development. First, childhood dysfluent speech patterns are often mistakenly interpreted as normal developmental phenomena. Although it is true that many young children will pass through periods of disrupted speech patterns and will spontaneously recover from these, a significant minority, estimated as high as 30 percent, of these children will continue to exhibit disrupted speech patterns, and if left unattended, they will develop confirmed stuttering. Recent studies point to the importance of early clinical intervention and, at the very least, referral for assessment by a speech–language pathologist to determine whether treatment is indicated. The case study highlights a second frequently observed social impact on children who stutter, teasing and bullying. Recent studies have demonstrated that more than 80 percent of children who stutter have at some point experienced bullying, usually in the form of teasing or name-calling. Children who stutter will often

experience feelings of shame and reduced self-esteem as they are identified by their peers as different and vulnerable. They will often be excluded from their peer group activities and become increasingly withdrawn and socially isolated. Because they feel inadequate as communicators, these feelings of inadequacy quite often evolve into generalized feelings of low self-worth.

Susan is a 28-year-old bilingual speaker of English and Bengali. At the time of her assessment, her speech was characterized by severe amounts of hard glottal attacks, sound prolongations, and laryngeal blocks. Secondary behaviors observed included eye blinks and lip tremor. She reported that she regularly used avoidance strategies such as starters, fillers, and word switching to avoid stuttering in public, whenever possible. Susan also reported that she avoided speaking with unfamiliar listeners and speaking in group situations. Susan reported that she had participated in treatment at the age of 8 and 10 with some success in structured settings, but her gains had been difficult to maintain.

Based on her assessment, it was recommended that she participate in an adult group intensive treatment program focusing on fluency-shaping strategies. Susan was judged to be an excellent candidate for this model of treatment based on the following criteria: First, she demonstrated through her assessment interview and reading sample that she possessed the intellectual capacity to manage the rigorous demands of the intensive nature of the program. Second, she demonstrated through her oral mechanical examination and trial therapy probe that she was capable of managing the physical demands of altering her motor movement patterns. Third, she evidenced the emotional readiness to benefit from group therapy and to address the cognitive restructuring requirements of the program. Fourth, she evidenced a high level of motivation to successfully complete treatment and participate in a long-term maintenance program.

Susan's treatment program included 3 weeks of daily clinic sessions lasting for close to 5 hours per day. She further dedicated between 2 and 4 hours to the completion of home assignments each evening.

In addition to successfully acquiring the motor skills required for fluent speech, Susan responded well to the cognitive restructuring goals of the program. She took to heart the suggestion that optimal success in treatment cannot be achieved without a genuine acceptance of one's self as a person who stutters. She gained a level of comfort and openness about stuttering by completing a number of assignments that required her to practice with a variety of partners outside the group. This afforded her the opportunity to discuss her speech condition and therapy program with a number of family members, friends, and coworkers.

Susan is currently in the maintenance phase of her treatment program. She has taken many positive steps to creating a lifestyle that supports her goal of long-term fluency maintenance. Susan carefully completes her daily schedule of maintenance practice. When she neglects her practice, she realizes the negative effect on her speech but manages these ups and downs with a positive attitude. She thoughtfully selects short-term goals at each follow-up meeting that will support her long-term goal of successful maintenance. Most recently, she revealed that she has been accepted to a graduate program in speech–language pathology.

DIFFERENTIAL DIAGNOSIS

The ability to produce fluent speech is a skill that develops as the young child grows, and it depends on such factors as motor coordination and timing and linguistic and cognitive development, as well as emotional development and maturity. Fluent speech production results when the motor skills to produce a desired message occur sequentially and synchronously in a smooth manner. This requires a fully developed system composed of respiratory, phonatory, resonatory, and articulatory components acting interdependently to produce fluent speech. Given that

these systems are not fully developed at 3 or 4 years of age, preschool children quite commonly exhibit dysfluency in speech during their communication efforts. The factors that distinguish normal nonfluency from incipient stuttering involve both the type and frequency of the observed disrupted speech patterns. Children who stutter exhibit predominantly part-word repetitions, voiced or unvoiced sound prolongations, and broken or fragmented words, whereas the normally nonfluent child is more likely to demonstrate whole word and phrase repetitions and revisions. Several researchers have emphasized the degree of speech fragmentation as the distinguishing factor between stuttering and normal nonfluency. The child who is developing normal speech patterns usually does not evidence more than 10 percent of any type of dysfluency in speech, whereas the stuttering child often exhibits higher amounts of speech disruption. Another distinguishing factor is the presence or absence of struggle during speech attempts. The child who is stuttering often exhibits difficulty in initiating or maintaining breath flow or voicing during speech attempts. The normally developing child is more likely to evidence easy, effortless speech, even if it is intermittently marked by repetitions of whole words or phrases. Unlike the stuttering child, the normally developing child produces speech, voice, and airflow in a continuous, uninterrupted fashion.

The discussion thus far has centered on developmental stuttering, the disorder of fluency most commonly observed in children and adults. It should be noted that there are other types of speech dysfluencies that may be observed in clinic populations, two of which will be mentioned here.

Acquired neurogenic stuttering is a condition that can appear for the first time in adulthood and is usually associated with a variety of temporary, progressive, and nonprogressive neurological disorders, such as traumatic brain injuries, strokes, and extrapyramidal diseases. In addition to adult cases of neurogenic stuttering, there have also been reports in which childhood stuttering worsened or reappeared with the onset of the neurological disorder. Several features of neurogenic stuttering help to distinguish it from developmental stuttering: general annoyance with the problem but no apparent anxiety, instances of dysfluency occurring in any part of the utterance, lack of secondary symptoms, stuttering on small grammatical words and substantive words with approximately equal frequency, and reduced variability of stuttering across different communicative situations.

Cluttering is another disorder of fluency characterized by rapid speech, reduced intelligibility, and frequent telescoping of words. Cluttering is often marked by grammatical and syntactic errors and is not typically associated with any specific sound or word fears or even limited awareness of the speech disorder. Cluttering has often been associated with a central language imbalance, and some authors have suggested that cluttering exists

when an individual presents with one or more impairments in each of five broad communicative dimensions reflecting cognitive, linguistic, pragmatic, speech, and motor abilities. One of the features differentiating cluttering from developmental stuttering is self-monitoring and general awareness. Whereas the person with developmental stuttering is usually hypersensitive to the sound of his or her own speech, the person who clutters is often only vaguely aware of the aberrant speech pattern. Prognosis for improvement with treatment for cluttering is usually guarded, in large part because of the individual's general lack of awareness of the speech pattern.

COURSE AND PROGNOSIS

The onset of stuttering can occur anytime between the ages of 2 and 7, peaking at approximately age 4. Most of the risk for the onset of stuttering is usually over by the age of 5. The stuttering fluctuates in severity initially, so that the course of development is not steady. Initially, days or weeks may go by with little or no speech difficulty, only to be followed by a sharp increase in the amount and type of stuttering behavior. The stuttering pattern changes with time. Despite fluctuations in severity, young children who begin to demonstrate signs of true stuttering do not continue to be dysfluent in the same manner in which they began. As children begin to demonstrate more struggle and fragmentation of words and syllables, the stuttering pattern becomes more complex. Moreover, although the stuttering is usually episodic in the beginning, it becomes more chronic as it progresses. In its most advanced form, speech disruptions are accompanied by secondary behaviors such as those previously described. Complete recovery from stuttering is rare after puberty. As many as 80 percent of stuttering children experience spontaneous recovery, with girls more likely to become spontaneously fluent than boys. Investigations of prognosis in therapy for the older, confirmed stutterer have focused primarily on the influence of personality factors in treatment; subjects with less favorable speech attitudes were less likely to obtain long-term benefit from behaviorally oriented speech therapy for stuttering.

TREATMENT

The vast majority of treatment techniques for stuttering have been conducted on adults. Speech–language pathologists have traditionally practiced two distinct forms of therapy. The first deals directly with the psychological aspects of the problem—that is, the attitudes, feelings, and emotions displayed by the individual who stutters. Treatment procedures use various types of psychotherapy directed at self-acceptance, attitude change, and avoidance or anxiety reduction. The second major speech therapy approach involves modification of the stuttering response to fluent-sounding speech by the application of systematic steps and rules of

speech mechanics. In this framework, therapy procedures attempt to reconstruct the respiratory, phonatory, and articulatory gestures used in speech production, either by stuttering modification or fluency-shaping techniques. Therapy formats for adults who stutter have been intensified, and several major stuttering treatment programs now offer full-time treatment approaches administered in blocks of several weeks. Current research and clinical efforts are directed at maintenance of fluent speech in the posttreatment environment. A significant number of individuals have been reported to exhibit either partial regression or even total relapse of stuttering without continued practice of speech skills after treatment.

Varying definitions of stuttering and of successful treatment have largely hindered measures of treatment efficacy. Current therapies report success rates ranging from 60 to more than 90 percent when the sole dependent variable is perceived fluent-sounding speech immediately after treatment. However, thorough treatment outcome measures for stuttering should include three elements: (1) a significant positive change in speech output is produced, (2) the change is generalized across speaking situations, and (3) the change is maintained over time.

Far fewer studies have been done on the effects of speech therapy for young stuttering children. Clinicians tend to be somewhat divided on the issue of direct therapeutic intervention for the preschooler who stutters. Many advocate an indirect approach, incorporating parent counseling and environmental manipulation to treat the dysfluent child. This approach incorporates such techniques as parental modeling of relaxed, unhurried speech and reduction of communicative stressors in the home environment. A second approach trains parents of very young children to apply behavioral techniques of verbal contingencies to stuttering and to verbally reinforce stutter-free speech in the child's everyday speaking environment. If it is determined that these indirect approaches are not sufficient to fully address the stuttering, direct techniques of speech modification or fluency shaping, such as respiratory control and gentle phonatory onsets, are taught in a manner similar to those used with older populations.

▲ 43.5 Unspecified Communication Disorder

TIM BRESSMANN, PH.D., AND JOSEPH H. BEITCHMAN, M.D.

INTRODUCTION

The section on Communication Disorders in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) focuses mainly on developmental speech and language disorders, which is consistent with previous versions. The category unspecified communication disorder is open ended and may capture other notable aspects of a patient's symptomatology as they relate to verbal communication.

In order to fill the diagnostic category unspecified communication disorder with life and illustrate its possible application, this chapter, similar to previous editions of the *Comprehensive Textbook of Psychiatry,* will focus on voice disorders. Beyond the linguistic information that is conveyed through a speaker's voice and speech, the voice quality gives important information about the speaker's emotional and physical status. The patient's voice quality and quantity can be an important clinical sign in the anamnesis of a range of psychiatric conditions, and psychiatric and voice symptoms can sometimes interface in interesting ways. Voice disorders can equally be an outlet or a cause for stress and emotional turmoil. The boundary between structural and functional (psychological) etiologies is often blurred.

The voice is part of the speech production mechanism. Speech is a complex physiological phenomenon that relies on the coordination of multiple anatomical systems. Airflow from the lungs causes the vocal folds to vibrate periodically. This vibration generates a raw sound that is amplified and modulated in the pharynx. The velopharyngeal sphincter functions like a valve that can direct the airflow orally to produce oral speech sounds. If the velum is lowered, speech sounds will be nasal. The movement of the lips, jaw, and tongue creates differentiated, meaningful speech sounds. Accordingly, the subsystems of speech can be broken down as follows: respiration (airflow from the lungs), phonation (sound generation in the larynx), resonance (shaping of the sound quality in the vocal tract), oral–nasal balance (direction of airflow into the oral or nasal direction at the level of the velopharyngeal sphincter), articulation (modulation of the sound stream into consonant and vowel sounds with the tongue, jaw, and lips), and suprasegmentalia (speech rhythm, loudness, and intonation).

DEFINITION

In the DSM-5, unspecified communication disorders are described as

"presentations in which symptoms characteristic of communication disorder that cause clinically significant distress or impairment in social, occupational, or other important areas of functioning predominate but do not meet the full criteria for communication disorder or for any of the disorders in the neurodevelopmental disorders diagnostic class." The wording of this descriptor is somewhat unfortunate because it implies that unspecified communication disorders do not reach a threshold of criteria to qualify as proper communication disorders. The DSM-5 definition goes on to state that the category is applicable "in situations in which the clinician chooses not to specify the reason that the criteria are not met for communication disorder or for a specific neurodevelopmental disorder, and includes presentations in which there is insufficient information to make a more specific diagnosis." In reality, the DSM-5 categories are not broad enough to capture the full range of communication disorders. Important and frequent acquired communication disorders such as aphasia (acquired language disorder), dysarthria (neurogenic motor speech disorder) as well as structurally related speech disorders related to head and neck cancer, to name but a few, are omitted in the DSM-5. The clinician may make a diagnosis of an unspecified communication disorder not because of insufficient information but simply because of lack of a more appropriate diagnostic category.

Examples of disorders that lend themselves to the diagnosis of unspecified communication disorder include voice disorders but also structurally related disorders such as oncological pathologies (laryngectomy or glossectomy). Because the latter occur only rarely during childhood and are rather self-evidently related to surgical resections, this section is focused on voice disorders. Voices are as varied and as individual as faces. What is considered acceptable as a normal voice quality, loudness, and pitch may vary markedly between languages or in different cultures. The clinician will therefore try to determine whether a client's voice is appropriate (rather than "normal") with regard to the speaker's physical makeup, culture, and language. A voice may be considered disordered when the speaker experiences marked functional limitations, such as a voice that does not project well or gives out. The vocal quality may attract negative attention and may be perceived as unpleasant by the speaker or the environment. Speaking may be uncomfortable or painful.

HISTORY

The beginnings of modern vocology can be dated to the late 19th century. Much of the research during this time was conducted by singing teachers. The early 20th century saw a rapid improvement in laryngeal imaging methods and a more thorough understanding of the vocal mechanism. During this time, researchers also observed that many voice disorders are the result of chronic hyperfunctional misuse, and that the voice can be a

target of psychosomatic processes. These findings roughly coincided with the development of early psychoanalysis. As a result, functional voice disorders were generally interpreted as a manifestation of a suppressed personal conflict, resulting in a conversion dysphonia. However, in recent decades, voice scientists and speech–language pathologists have begun to differentiate more carefully between true psychogenic dysphonias and the functional voice disorders that are related to excessive muscle tension. Patients with muscle tension dysphonia will experience voice problems chiefly because of poor musculoskeletal alignment. The muscle tension dysphonia can be treated on its own merit, and a psychodynamic interpretation of the disorder is no longer regarded necessary or helpful.

COMPARATIVE NOSOLOGY

Human communication disorders are as complex and as varied as psychiatric conditions. The DSM-5 continues to recognize the relevance of communication disorders to the psychiatric profession. However, it is neither the aim nor the scope of the DSM-5 to provide the level of detail and differentiation that a speech–language pathologist would bring to the diagnosis and treatment of communication disorders. There are manifold communication disorders that cannot meet the relatively narrow criteria for the types of developmental communication disorders laid out by the DSM-5. Consequently, the DSM-5 category unspecified communication disorder is a diagnostic wild card.

EPIDEMIOLOGY

There are few reliable epidemiological estimates for the prevalence of voice disorders, and the available figures vary considerably between studies. In part, this is due to uncertainty about the concept of the healthy voice: The acceptability of different vocal qualities and quantities varies considerably in different cultures, languages, and on different socioeconomic levels. Voice quality is an auditory–perceptual impression, so what is considered to be or not to be pathological is very much in the ear of the beholder. The estimated prevalence for pediatric voice disorders ranges from 6 to 23 percent. The prevalence of adult voice disorders has been estimated between 3 and 10 percent. The available epidemiological reports vary in group sizes and compositions as well as in methodology. It is also difficult to estimate how many of the speakers who have been identified as having a pathological voice quality will require treatment. The need for behavioral, surgical, or pharmaceutical intervention can probably be estimated to be closer to the lower, more conservative end of the prevalence estimates.

The occurrence of voice disorders varies across the lifespan. In children, boys tend to have more voice disorders, probably due to more aggressive vocal behavior and boisterous vocal play. By adolescence, the prevalence is roughly balanced between the sexes. In adults, voice disorders are more

frequent among men than women. However, women seek help more often and sooner than men. The highest prevalence for voice disorders in adults is found in the age group of 45 to 64 years. Overall, most voice disorders are benign in nature (vocal nodules, polyps, edemas, functional dysphonias).

ETIOLOGY

The precise etiology of a voice disorder is often difficult to determine and needs to be evaluated based on the nature of the pathology, the patterns of voice use, the emotional and physical states, and the underlying or accompanying medical conditions of the individual patient. Sudden onsets tend to denote acute processes, which are mostly reversible, and slow progressive onsets tend to denote longer-standing vocal trauma or degeneration that may require more comprehensive behavioral interventions, often in combination with phonosurgery. Voice disorders are characterized by deterioration in vocal quality and quantity. A lesion on the free margin of the vocal fold results in incomplete vocal fold closure and a breathy, rough, or hoarse voice quality with a decreased loudness and pitch range. A referral to the otolaryngologist is necessary if a persistent change in vocal quality and quantity is observed. The otolaryngological examination always comprises a visual inspection of the larynx in order to rule out potential malignant lesions, such as squamous cell carcinoma.

Voice disorders can be congenital or acquired. The relatively rare congenital disorders of the larynx include laryngomalacia (softness of the cartilages of the larynx and the epiglottis), subglottal stenosis or laryngeal webbing between the vocal folds, and rare laryngeal clefts. The primary concern in infants with these pathologies is to keep the airway patent and ensure the patient can breathe.

The majority of voice disorders are acquired. Acquired voice disorders present as a hen-or-egg problem: It is difficult to determine whether abusive vocal behavior has led to a vocal pathology, or whether a pre-existing pathology has triggered a vicious cycle of maladaptive behavior. Consequently, voice therapy and vocal re-education are paramount in all vocal pathologies.

In both children and adolescents, acquired voice disorders can be caused by a number of factors. The most important factor that causes injury to the vocal folds is vocal misuse or abuse (vocal hyperfunction) through excessive yelling, singing, talking, or abusive behaviors such as excessive throat clearing or aggressive vocal play. Voice disorders related to vocal misuse and abuse are often labeled as hyperfunctional voice disorders. Acute and traumatic vocal abuse and misuse can lead to lesions in the vocal fold, such as acute inflammatory (usually bilateral) vocal nodules, acute vocal fold polyps, or acute vocal hemorrhage. If these conditions are the consequence of a singular event (e.g., a spectator sports

event), they are usually easily reversible by vocal rest and vocal hygiene. Protracted vocal abuse requires more comprehensive behavioral and possibly surgical interventions.

Long-standing voice misuse or abuse may result in chronic, fibrotic vocal nodules or chronic, indurated polyps. The delicate and supple superficial layer of the vocal fold (Reinke's space) is particularly prone to irritation and swelling, resulting in chronic inflammatory edema of the vocal folds (Reinke's edema, chronic laryngitis, polypoid degeneration). Granulomas or contact ulcers on the arytenoid cartilages may be a consequence of low-pitched, strained phonation. Many of these pathologies will be accompanied by excessive muscle tension, which is often visible and palpable in the extrinsic strap muscles of the larynx. This tension leads to an elevated position of the larynx during phonation. Muscle tension dysphonia can be a symptom that accompanies an organic pathology, or it can be a voice disorder by itself.

Excessive muscle tension is also often found in psychogenic dysphonias. Patients with psychogenic voice disorders can present with severe dysphonia or even complete aphonia (loss of voice) although the larynx is free of any visible pathology. The symptoms in the psychogenic dysphonias can be variable: Patients may claim a total loss of voice and present with only whispered or breathy phonation, or they may present with an excessively rough and hoarse voice quality, often accompanied by pain and discomfort when speaking. In some psychogenic dysphonias, the ventricular folds (false folds) are adducted together with the true vocal folds. The ventricular folds are situated above the true vocal folds. This mixed glottal–ventricular phonation can be visualized endoscopically and results in a rough, low-pitched voice quality (comparable to the singing technique used by Louis Armstrong). The onset of the psychogenic dysphonias is mostly sudden, sometimes related to a bout of cold or laryngitis in combination with a high level of life stress or emotional upheaval. According to reports, patients with psychogenic dysphonias are predominantly female, but men and children may also be affected. A specific psychogenic dysphonia of the age of adolescence is the postmutational falsetto, in which the prepuberty pitch and voice quality are retained by the patient. The result is an age-inappropriate high-pitched, shrill voice quality. It is more obvious in men than in women since the male voice drops about an octave (12 semitones) in puberty, compared with about a terce (three semitones) in females. This voice disorder is called postmutational falsetto (in men) or juvenile voice (in women). It is idiopathic but may be associated with resistance to adolescence and adulthood or a feminine self-identification (in men). It is often possible to elicit a more physiological pitch from these speakers during nonspeech maneuvers such as coughing, throat-clearing, and laughing. The discrepancy between the pitch of the speaking voice and the laryngeal pitch

during nonspeech tasks can be an indicator of a psychogenic dysphonia or of postmutational falsetto.

The complete refusal to vocalize or speak is called selective mutism. This disorder is predominately observed in younger children. These children acquire normal speech and language but at some point refuse to use it because of emotional or psychosocial distress. Most children with selective mutism limit their interaction to a small number of immediate family members with whom they have close relationships. The incidence of prolonged mutism (i.e., longer than 6 months) has been estimated at less than 1 child in 1,000. Girls are more prone to this disorder than boys. The DSM-5 classifies selective mutism as an anxiety disorder.

A disorder that is difficult to categorize in children as well as in adults is idiopathic paradoxical vocal fold movement. Patients with this disorder are frequently misdiagnosed with either asthma or with a panic disorder. The patients experience spontaneous respiratory distress, often related to strenuous physical activity, in a fashion that is similar to an asthma attack. However, no swelling of the bronchi and the trachea occurs in an episode of idiopathic vocal fold movement. The patient experiences isolated involuntary laryngospasms with a complete closure of the vocal folds. Consequently, asthma medication will not provide the necessary relief. This disorder will instead respond to behavioral therapy in most cases.

Viral infection with the human papilloma virus can affect the respiratory tract in children and adults and lead to multiple lesions. In order to prevent the spreading of the papillomatosis into the trachea and lungs, the lesions are surgically removed. Although this treatment is effective for the viral infection, it may result in severe scarring of the larynx and the vocal folds. An incomplete or irregular vocal fold closure with a hoarse and breathy voice may result.

Neurogenic voice disorders are related to lesions or degenerative processes in the central nervous system. Peripheral vocal fold paralyses can be caused by strokes, degenerative disorders, mechanical or surgical trauma, or viral infections. The peripheral paralysis can be uni- or bilateral, and the location of the lesion along the nerve will determine the position of the affected fold and the consequences for breathing, swallowing, and speech. Lesions in the central nervous system have a more generalized impact on the whole speech motor system on all levels: respiration, phonation, resonance, articulation, and prosody. Depending on the localization of the lesion along the central motor pathways, a spastic, hyperkinetic, hypokinetic, ataxic, or pseudobulbar movement disorder will result. The associated motor speech disorders are labeled accordingly (as spastic, hyperkinetic, and so forth dysarthrias) and roughly reflect the nature of the underlying movement disorder. Apraxia of speech is a motor speech disorder that is characterized by deficits in the muscle coordination and sequencing of speech gestures. This also affects the coordination of the

laryngeal voicing and devoicing for voiced and unvoiced speech sounds (e.g., to differentiate /f/ and /v/).

Spasmodic dysphonia is an insidious neurogenic voice disorder that is considered to be a focal dystonia (like torticollis or blepharospasm), possibly caused by small lesions in the basal ganglia. In spasmodic dysphonia, voicing is interrupted by adductor (adductor spasmodic dysphonia) or abductor spasms (abductor spasmodic dysphonia). The voice quality in spasmodic dysphonia is unsteady and often effortful, marked by a chaotic pattern of vocal fold adduction and abduction. Visceral voice production during coughing or throat clearing is often unimpaired. However, during conscious, purposeful speech, the spasms become obvious. Spasmodic dysphonia is very rare in children and adolescents but occasional cases have been reported.

An aggravating factor for all voice disorders can be insufficient hydration of the vocal folds. The vocal folds can be dehydrated by insufficient intake of fluids, active and passive smoking, or exposure to irritating or toxic chemical fumes in the work or home environment. Dehydration makes the vocal fold less flexible and more vulnerable for mechanical trauma caused by loud singing, shouting, aggressive throat clearing, and so forth. Medications can also contribute to vocal fold dehydration. Bronchodilators can influence airflow and air passage. Diuretics, corticosteroids, and decongestants can reduce the fluid level in the vocal fold. Antihistamines, antitussives, and antirefluxiva can reduce pharyngeal and laryngeal secretions. Long-term hormonal therapies (especially with testosterone) can change the vocal fold structure and permanently lower the pitch. Acid reflux from the esophagus can lead to esophagitis (gastroesophageal reflux disease, GERD) with ulcerations or granulomas on the posterior aspect of the vocal folds or the arytenoid cartilages and a resulting voice disorder. Reflux esophagitis with irritation of the larynx may also be the result of self-induced vomiting in bulimic patients. A number of psychotropic drugs can cause xerostomia and have dehydrating effects on the vocal folds, including tetracyclic, tricyclic, antipsychotic, and anxiolytic drugs. Usually, the level of oral secretions is a good predictor of the laryngeal secretions and the lubrication of the vocal folds. If marked xerostomia is observed, the patient should be counseled about hydration by a speech–language pathologist before he or she develops voice problems.

The perceived subjective impairment resulting from a voice disorder is highly variable across patients. Voice disorders may cause anxiety and depression and may impact the patient's work and social interactions. Anxiety about the restitution of the premorbid voice quality is usually highest among professional voice users, such as singers and actors. Professional voice users are often very emotional about even minor changes in their vocal quality and range. Voice problems in professional voice users

may sometimes be related to unrealistic or unhealthy artistic demands on the voice, such as prolonged singing or shouting with a deliberately rough and loud voice. In this sense, the vocal folds of a professional voice user are like the knees of a professional basketball player: Irrespective of the talent, the body has individual physiological limits for every organ. Some rock music singers have a seemingly endless vocal stamina and never sustain vocal injury, even though they abuse their vocal folds every night on stage. Other singers hit the physiological limits of their larynx a lot sooner, despite a correct singing technique.

A population with unique voice therapy needs are transgender patients who strive to adjust their voice quality and speech to their new gender role. In female-to-male transgender patients, the male hormone therapy will lead to a thickening of the vocal folds which will lower the speaking pitch. The vocal tract size will still be female and the patient will have to work with a speech–language pathologist on developing convincingly male-speaking mannerisms. The transition is more difficult for a male-to-female transsexual patient. The patient must learn to raise the speaking pitch and develop more feminine speaking habits. However, the larger male vocal tract size makes it more difficult for many male-to-female transgender patients to convincingly portray the new female personality. For the transgender patient's satisfaction with the treatment outcomes and quality of life, the voice change can be more relevant than the physical appearance. Therefore, it is important to ensure that the patient is referred to a speech–language pathologist who is competent in voice therapy for gender-reassignment patients.

A final etiology that needs to be mentioned in this section is velocardiofacial syndrome (22q11 microdeletion syndrome). This congenital syndrome is related to a microdeletion on the long arm of chromosome 22 and has highly variable symptoms. As a result, patients are sometimes not identified at birth but only later when symptoms become manifest. Many of the patients show various developmental delays, especially with regard to speech and language development. In childhood, attention-deficit/hyperactivity disorder, anxiety disorders, phobias, or emotion regulation disorders are considerably more frequent than in the general population. In adulthood, schizophrenia and schizoaffective disorders are frequently observed. As part of the syndrome, many patients present with cleft palate, which leads to hypernasality (too much air and sound emitted through the nose during speech). The cleft palate in this population is often isolated so that it does not affect the lip and the alveolar ridge and is not visible in the patient's face. It may even be submucous (hidden under a lining of mucosa) and hidden to a casual oral inspection. Patients with velocardiofacial syndrome are a prime example of the importance of interdisciplinary treatment of complex disorders. The members of the craniofacial treatment team need to be aware of the

patients' risk for mental health problems during the lifespan. On the other hand, a psychiatrist who notices hypernasal speech in a patient who has not been followed by a craniofacial team should make the appropriate referral.

DIAGNOSIS AND CLINICAL FEATURES

Any unexplained change in voice quality, especially when it involves hoarseness or pain and persists longer than 2 weeks, should be examined by an otolaryngologist. The diagnosis of voice disorders relies on a number of different components. An important component is the perceptual evaluation of the voice disorder by an experienced otolaryngologist or speech–language pathologist. This evaluation assesses the patient's voice quality and quantity. Accepted general descriptors of voice quality are breathiness (resulting from incomplete closure or hypoadduction of the vocal folds) and roughness (irregular vocal fold vibration resulting from lesions on the vocal fold or hyperadduction of the vocal folds). *Hoarseness* is defined as a mixture of roughness and breathiness. Additional descriptors include strain or asthenia. Vocal quantity can be described in terms of the pitch and dynamic range of the voice. If pitch is inappropriate, a speaker's voice is too high or too low for his or her age, maturation, and sex. If the dynamic range is inappropriate, a patient may speak too loudly or too softly or may have difficulties raising his or her voice. Associated perceptual assessments concern the patient's oral–nasal balance, which may make speech sound hypernasal or hyponasal, or may add a muffled or twangy quality (however, it is important to note that hyper- or hyponasality are not voice disorders per se). Finally, suprasegmental features of speech (prosody, speech melody) are assessed. Pathological prosodic patterns include monotonous, unmodulated voice versus exaggerated inflections, excessively slow or fast speech, and inappropriate or uneconomical breaks for inhalation during speech. Quantitative instrumental measures of voice quality, voice range, or airflow can supplement the perceptual diagnosis. This is combined with a detailed interview that assesses the voice usage and medical history together with health practices, social and occupational circumstances, and psychological considerations. In pediatric patients, developmental and family information will be included.

PATHOLOGY AND LABORATORY EXAMINATION

Most lesions of the vocal folds are benign and do not require detailed histological analysis. However, suspicious lesions should be biopsied and analyzed in order to rule out malignancies. The malignant laryngeal tumors are usually of the squamous cell carcinoma type. Irrespective of the clinical presentation of the voice disorder, the vocal folds should always be examined visually by an experienced otolaryngologist in order to correctly assess or rule out any organic causes of the problem. This can be done with a simple mirror examination, but ideally, a flexible endoscopy or a

videostroboscopy should be performed. The videostroboscopic examination allows the physician to slow down the display of the vocal fold motion so that the patterns of vocal fold vibration can be observed. High-speed video kymography allows the physician to film vocal fold motion in real time, with a temporal resolution of several thousand exposures per second. Although a complete and comprehensive assessment of a patient's vocal structures and voice quality is crucial to determine the correct treatment, many otolaryngologists tend to be content with only superficial investigations, especially of pediatric clients. Malignancies of the pediatric larynx are extremely rare, while on the other hand a videostroboscopic examination of a small child can be very tedious. However, this wait-and-see attitude may sometimes delay appropriate treatment. Voice disorders in pediatric and adolescent populations have to be taken just as seriously as adult voice disorders.

DIFFERENTIAL DIAGNOSIS

Today, most voice centers use videostroboscopy or flexible endoscopy. With these methods, organic voice disorders can be readily detected. However, the challenge in voice diagnosis is to identify the behavioral components of the voice disorder. In particular, the differential diagnosis between hyperfunctional voice disorders and psychogenic voice disorders can often be difficult for otolaryngologists and speech–language pathologists. As a result, the necessary referral to psychiatric services may be delayed. Psychogenic voice disorders often have a characteristic onset. They come about suddenly, often related to a minor viral infection. The discrepancy between visceral vocalizations such as yawning and voice production in speech is often informative. If voice can be produced during coughing, throat clearing, humming, yawning, and sighing but not in speech, then it is likely that the patient can be helped back to a normal voice quality by a short course of voice therapy. After a normal voice has been restored, the patient should be referred for a psychiatric follow-up. On the other hand, if the patient presents with a total loss of voice but does not cooperate with the therapist's efforts to restore voice production, a different disorder to consider in pediatric patients is selective mutism.

One of the most difficult diagnoses for an otolaryngologist or a speech–language pathologist is spasmodic dysphonia, which is often diagnosed by exclusion of other applicable pathologies. In particular, psychogenic and neurogenic voice disorders must be ruled out. Since not every clinician is aware of spasmodic dysphonia, many patients undergo prolonged diagnostic and therapeutic odysseys before the correct diagnosis is finally made. The voice breaks in spasmodic dysphonia may sometimes resemble the tonic blocks of a person who stutters. While the onset of spasmodic dysphonia is in adulthood, stuttering begins during childhood. Another difficult diagnosis is that of idiopathic paradoxical vocal fold motion, which

can very much resemble an asthmatic attack. However, the airway constriction in these patients will be restricted to the level of the larynx and will not include the bronchi and the trachea. Finally, patients with velocardiofacial (22q11 microdeletion) syndrome may often present with hypernasality as well as a variety of psychiatric disorders throughout their lifespan. Therefore, it is important to ensure that any psychiatric patient with hypernasality of unclear etiology is referred to a craniofacial team for multidisciplinary assessment and genetic testing.

COURSE AND PROGNOSIS

As voice disorders may be caused by many different conditions, there is a high degree of variability in the long-term prognoses and treatment success. Acute organic processes that are associated with a onetime event of vocal abuse usually have a good prognosis. Examples for such pathologies are acute nodules or polyps. Vocal nodules in children are sometimes not removed by surgery as the vocal fold expands during puberty and the nodules tend to resolve spontaneously. Organic pathologies that are related to long-standing vocal abuse will require more comprehensive therapeutic interventions that also address the associated abusive behaviors. Examples for such pathologies are chronic nodules, chronic polyps, and Reinke's edema. If there is persistent voice abuse combined with aggravating factors such as smoking or alcohol abuse, the long-term prognosis is poorer. Lesions such as nodules may recur quickly after a surgical resection if the maladaptive behaviors cannot be modified. Voice disorders with a pronounced psychogenic component have to be addressed with a combined effort by the speech–language pathologist and the psychiatrist. Although the voice disorder can usually be managed effectively in speech therapy, the underlying emotional or psychosocial factors that have contributed to the voice disorder have to be evaluated by a psychiatrist.

TREATMENT

Intervention in voice disorders is dependent on the nature of the problem. Organic pathologies are typically managed surgically with laser surgery or microsurgery, followed by a course of voice therapy. In functional voice disorders, the speech–language pathologist will counsel the patient about the nature of the disorder and commence a course of vocal re-education, aimed at modifying or eliminating vocal abuse. If psychological factors contribute to the genesis or the persistence of the voice disorder, a referral to psychiatric services will be necessary.

There are many different approaches to voice therapy. Most of these fall within five main streams of voice therapy: symptomatic, physiological, psychogenic, hygienic, and holistic. This distinction is largely academic because the boundaries between the different approaches are blurred. Most voice therapists will move between these different schools of thought and

pursue a more personal eclectic approach to achieve optimum outcomes for their patients. *Symptomatic* voice therapy uses interventions and voice exercises that are geared toward the voice symptoms of the individual patient. *Physiological* voice therapy draws on concepts from physical therapy such as respiration or posture exercises to achieve the foundations for a physiological voice production. *Psychogenic* approaches to voice therapy draw on the cognitive behavioral approach to behavior modification in order to change the way in which a patient reacts to life stresses with a change in voice quality. This type of therapy also uses relaxation techniques such as progressive muscle relaxation. *Hygienic* voice therapy is a supplement rather than a standalone therapy approach. The basic concept here is a maximum hydration of the vocal folds. Hydration results in clearer, healthier secretions and well-lubricated, soft vocal folds that are less prone to mechanical trauma. Finally, a number of schools of voice therapy are *holistic,* in that they try to achieve goals on multiple levels through a fixed program of exercises. The *vocal function exercises* treat the vocal muscles like other muscles in the body and provide a number of "stretching" exercises to increase the vocal range and stamina. The *accent method* uses a combination of controlled respiration, chanting, and dancing to elicit relaxed phonation. *Resonant voice therapy* aims at maximizing oral resonance and achieving good voice projection through a combined program of vocalizing and increasing self-awareness.

Marvin was a boy of 4 years of age whose speech, language, and overall development had been within normal range. At the age of 4 years, he suddenly became aphonic and started using a whispered voice for all verbal communication. After a while, the family grew concerned and asked the family doctor for advice. The family doctor referred Marvin to an otolaryngologist who did not find any visible pathology on his vocal folds. A speech–language pathologist and a clinical psychologist were also consulted but neither was able to coax Marvin into using his voice again. The ensuing months were a period of anguish for the family until the boy started speaking normally again. It was only years later that Marvin felt that he was able to share what had prompted him to use the whisper voice: His older brother had told him one night that he was talking too much and that this was dangerous because there was only a limited amount of voice for his lifetime. He had advised Marvin not to waste his voice so that he would not run out of it in a few years, so Marvin had come up with the solution of whispering instead.

Steven was a 17-year-old teenager who was referred to the speech–language pathologist because of his high-pitched voice. Steven had experienced teasing and negative comments about his voice in the classroom and in other social situations. He was very motivated to change the pitch of his voice. The patient was of normal height and built for his age. An otolaryngological mirror examination had ruled out the presence of a vocal fold web (patients with a laryngeal web often have a high pitch because the vibrating edge of their vocal folds is shorter). Upon palpation, the larynx was normal in size and had a normal movement range when Steven was asked to swallow (laryngeal elevation) and to yawn (laryngeal lowering). An acoustic measurement revealed a fundamental frequency of around 230 Hz, which was twice as high as the appropriate pitch for a male speaker. When the patient was asked to throat-clear and to hum, the fundamental frequency dropped to an appropriate range. The speech–language pathologist used gentle vocalization exercises such as chanting in combination with manual circumlaryngeal massage in order to help the patient relax his larynx and lower his

fundamental frequency. Steven required only six sessions with the speech–language pathologist to change the pitch of his voice. However, he was apprehensive about using the new voice with his classmates at school. He was worried that the change was quite startling and that he would be ridiculed for seeing a speech–language pathologist. Steven decided that he would spend the Christmas holidays with his family and avoid seeing his friends during these days. When he went back to school in the new year, he told his classmates that he had been sick with flu and that the associated cough had done some damage to his voice box and changed his voice.

The patient described here was very motivated to change his voice to an age-appropriate pitch. However, some patients may initially resist the speech–language pathologist's efforts. Speaking with a different fundamental frequency changes a physical activity that is deeply engrained, and that is as difficult to change as one's posture or gait. Patients may sometimes complain that the new way of phonating feels uncomfortable, hurts their larynx, or even affects their breathing. These initial complaints are usually overcome, and postmutational falsetto should be resolved with a short course of voice therapy. The effect on the patient's appearance in social situations can be stark, so it is important to help the patient develop strategies to gently introduce the environment to the new voice.

Autism Spectrum Disorder and Social Communication Disorder

FRED ROBERT VOLKMAR, M.D., AMI KLIN, PH.D., ROBERT T. SCHULTZ, PH.D., AND MATTHEW W. STATE, M.D., PH.D.

OVERVIEW

Autism spectrum disorder (ASD) includes a range of conditions (the "spectrum") characterized by early onset of severe delay and deviance in the development of social and communicative and unusual response to the environment (repetitive behaviors, difficulties with change, and unusual sensitivity to the inanimate environment). In DSM-5, criteria are included for ASD (which essentially corresponds to disorders previously grouped within the pervasive developmental disorder class); DSM-5 also includes a new category of social communication condition. The DSM-5 approach is a marked change from that employed in DSM-IV.

AUTISM SPECTRUM DISORDER

Definition

This condition encompasses a number of concepts, all previously subsumed under the overarching pervasive developmental disorder category. Of these conditions the DSM-IV autistic disorder, also known as childhood autism, infantile autism, and early infantile autism, is, by far, the best known and, in important respects, the definition proposed in DSM-5 probably is closest to this older concept. In DSM-5, the previously used triad of impairments in social interaction, communication, and repetitive and restricted interests/behaviors was collapsed into two domains: social communication and restricted and repetitive behaviors. The four criteria included in the social communication group all must be met (see Table 44–1), while in the restricted and repetitive behaviors domain, two of four criteria must be met. The latter category includes, for the first time, a criterion reflecting sensory difficulties (over- or undersensitivity to the environment). The four symptoms must be present in early childhood. Because of concerns (noted subsequently) that a large number of individuals might lose service eligibility, an exception rule allows individuals with Asperger disorder and pervasive developmental disorder-not otherwise specified (PDD-NOS) and

higher-functioning autism to retain their diagnosis, thus effectively maintaining the DSM-IV system for individuals who already had a diagnosis so that, effectively, two systems will remain in use for some time.

Other changes in the DSM-5 approach involved the overarching decision to abandon use of not otherwise specified categories and the multiaxial approach to diagnosis that had been in place since DSM-III. In DSM-5 a series of specifiers are provided, for example, if a known etiological factor is present. A second specifier allows for description of required levels of support and impact on levels of functioning for the two criteria domains. These severity specifiers range from levels 1 to 3, indicating a need for support, substantial support, or very substantial support, respectively. It is made explicit that severity specifiers do not correspond directly to qualification for or need for services because they do not account for a person's profile of abilities or an individual hierarchy of intervention objectives. A third specifier can be used to indicate the presence of associated intellectual disability and a fourth to indicate whether language impairment is present. A final specifier allows for indication of the presence of catatonia (Table 44–2).

The changes introduced with DSM-5 have been the source of considerable controversy. Clinically the work group sought to preserve the strengths of DSM-IV while improving on its limitations—notably the controversies surrounding the validity of categories like Asperger disorder and PDD-NOS in DSM-IV and also to improve the applicability of the criteria to infants and very young children. In contrast to DSM-IV, where a large international field trial was undertaken in conjunction with the ICD-10 revision, the decision was made to analyze a large body of data collected from standard interviews of parents and an individual assessment specifically designed for individuals with autism. Although the original DSM-5 report suggested 10 percent of cases might "lose" their diagnosis a series of studies, using a range of different samples, suggested that a significant number of cases would lose their diagnoses—these estimates varied depending on the nature of the sample but suggested that more cognitively able individuals with autism (as diagnoses in DSM-IV) and also Asperger and PDD-NOS (as diagnosed in DSM-IV) were at risk—with perhaps 80 percent or more of such cases losing their diagnoses. Young children with autism were also noted to be at risk. A more recent study using an epidemiologically representative sample suggests that overall, perhaps 20 percent of cases might be at risk of losing their diagnoses more. The utility of the various proposed modifiers remains to be established but concern has been made over the reliability of ratings of severity since in children with autism needs can be dramatically different depending on the environmental context within which observation is made.

History

In 1943, Leo Kanner described 11 cases of what he termed autistic disturbances of affective contact. In these cases, there was a congenital "inability to relate" to people in usual ways. Kanner also noted unusual responses to the environment, which could include both stereotyped motor mannerisms and resistance to change or insistence on sameness, as well as unusual aspects of the child's communication skills, such as pronoun reversal and a tendency to echo language (echolalia). Kanner's phenomenologically based description of this condition remains worthy of review. However, at the same time, he was mistaken about some aspects of the condition, and his early misconceptions took some time to clarify. For example, Kanner believed that the condition was not associated with mental retardation because the children were not dysmorphic and looked "intelligent" and did well on some parts of intelligence (IQ) tests. As time went on, it became clear that many function in the intellectual deficient range if the entire test is administered. However, consistent with Kanner's original observation, it continues to be the case that marked scatter in skills —with occasional areas of ability ("splinter skills") or even unusual ability ("savant skills")—is often observed. In his original paper, Kanner mentioned that parents of affected children were unusually well educated or successful in their occupations. This led to the notion that autism might somehow result from pathological patterns of care. Considerable evidence suggests this is not the case and his impression resulted from ascertainment bias. There is no particular difference in terms of social class distribution of autism if factors that control for case ascertainment are controlled and if potential effects of lack of parental awareness are figured in. It is also the case that parents of autistic children do not exhibit specific deficits in parenting or other aspects of child care and are not likely to have other psychiatric disabilities at an increased rate, with the exception of anxiety/mood disorders and a range of developmental difficulties. Finally, Kanner's use of the term autism was reminiscent of Eugen Bleuler's earlier use of the term to describe the quality of self-centered thinking seen in schizophrenia. Although Kanner originally believed that autism and schizophrenia were unrelated, his use of this word became a source of confusion for many years. There was an assumption of continuity based on severity—that is, because autism was so severe, it was assumed to somehow be on a continuum with schizophrenia.

Table 44–1.
Autism Spectrum Disorder

Diagnostic Criteria
A. Persistent deficits in social communication and social interaction across multiple contexts, as manifested by the following, currently or by history (examples are illustrative, not exhaustive, see text):

1. Deficits in social–emotional reciprocity, ranging, for example, from abnormal social approach and failure of normal back-and-forth conversation; to reduced sharing of interests, emotions, or affect; to failure to initiate or respond to social interactions.
2. Deficits in nonverbal communicative behaviors used for social interaction, ranging, for example, from poorly integrated verbal and nonverbal communication; to abnormalities in eye contact and body language or deficits in understanding and use of gestures; to a total lack of facial expressions and nonverbal communication.
3. Deficits in developing, maintaining, and understanding relationships, ranging, for example, from difficulties adjusting behavior to suit various social contexts; to difficulties in sharing imaginative play or in making friends; to absence of interest in peers.

Specify current severity:

Severity is based on social communication impairments and restricted repetitive patterns of behavior (see Table 44–2).

B. Restricted, repetitive patterns of behavior, interests, or activities, as manifested by at least two of the following, currently or by history (examples are illustrative, not exhaustive; see text):
   1. Stereotyped or repetitive motor movements, use of objects, or speech (e.g., simple motor stereotypies, lining up toys or flipping objects, echolalia, idiosyncratic phrases).
   2. Insistence on sameness, inflexible adherence to routines, or ritualized patterns or verbal–nonverbal behavior (e.g., extreme distress at small changes, difficulties with transitions, rigid thinking patterns, greeting rituals, need to take same route or eat food every day).
   3. Highly restricted, fixated interests that are abnormal in intensity or focus (e.g., strong attachment to or preoccupation with unusual objects, excessively circumscribed or perseverative interest).
   4. Hyper- or hyporeactivity to sensory input or unusual interests in sensory aspects of the environment (e.g., apparent indifference to pain/temperature, adverse response to specific sounds or textures, excessive smelling or touching of objects, visual fascination with lights or movement).

Specify current severity:

Severity is based on social communication impairments and restricted, repetitive patterns of behavior (see Table 44–2).

C. Symptoms must be present in the early developmental period (but may not become fully manifest until social demands exceed limited capacities, or may be masked by learned strategies in later life).
D. Symptoms cause clinically significant impairment in social, occupational, or other important areas of current functioning.
E. These disturbances are not better explained by intellectual disability (intellectual developmental disorder) or global developmental delay. Intellectual disability and autism spectrum disorder frequently co-occur; to make comorbid diagnoses of autism spectrum disorder and intellectual disability, social communication should be below that expected for general developmental level.

Note: Individuals with a well-established DSM-IV diagnosis of autistic disorder, Asperger disorder, or pervasive developmental disorder not otherwise specified should be given the diagnosis of autism spectrum disorder. Individuals who have marked deficits in social communication, but whose symptoms do not otherwise meet criteria for autism spectrum disorder, should be evaluated for social (pragmatic) communication disorder.

Specify if*:*

With or without accompanying intellectual impairment

With or without accompanying language impairment

Associated with a known medical or genetic condition or environmental factor (Coding note: Use additional code to identify the associated medical or genetic condition.)

Associated with another neurodevelopmental, mental, or behavioral disorder (**Coding note:** Use additional code[s] to identify the associated neurodevelopmental, mental, or behavioral disorder[s].)

With catatonia (refer to the criteria for catatonia associated with another mental disorder, pp. 119–120, for definition) (**Coding note:** Use additional code 293.89 [F06.1] catatonia associated with

autism spectrum disorder to indicate the presence of the comorbid catatonia.)

Kanner's original report emphasized the centrality of deficits in social relatedness, as well as unusual behaviors in the definition of the condition. During the 1960s, there was much confusion about the nature of autism and its etiology but by the 1970s, a considerable body of evidence began to accumulate suggesting the neurobiological basis of the disorder. This included high rates of seizures as children were followed over time, and the observation of persistent neurological signs and symptoms. Follow-up studies of large groups of "psychotic" children also revealed a bimodal distribution of onset of this poorly defined set of cases. The early-onset group, noted by Israel Kolvin, Michael Rutter, and others, appeared to have many of the characteristics described by Kanner. Children with later-onset "psychosis" (after age 5 or 6) seemed to resemble those with schizophrenia in that they had delusions, hallucinations, and so forth. Family history also discriminated the late-onset groups with higher rates of schizophrenia in family members. A landmark in classification occurred in 1978 when Rutter synthesized Kanner's work and subsequent research in a new definition that served, in many respects, as the basis for that used in DSM-III. In DSM-III, the condition was first recognized and placed in a new class of disorders—the pervasive developmental disorders.

Table 44–2.
Severity Levels for Autism Spectrum Disorder

Severity Level	Social Communication	Restricted, Repetitive Behaviors
Level 3		
"Requiring very substantial support"	Severe deficits in verbal and nonverbal social communication skills cause severe impairments in functioning, very limited initiation of social interactions, and minimal response to social overtures from others. For example, a person with few words of intelligible speech who rarely initiates interaction and, when he or she does, makes unusual approaches to meet needs only and responds to only very direct social approaches.	Inflexibility of behavior, extreme difficulty coping with change, or other restricted/repetitive behaviors markedly interfere with functioning in all spheres. Great distress/difficulty changing focus or action.
Level 2		
"Requiring substantial support"	Marked deficits in verbal and nonverbal social communication skills; social impairments apparent even with supports in place; limited initiation of social interactions; and reduced or abnormal responses to social overtures from others. For example, a person who speaks simple sentences, whose interaction is limited to narrow special interests, and how has markedly odd nonverbal communication.	Inflexibility of behavior, difficulty coping with change, or other restricted/repetitive behaviors appear frequently enough to be obvious to the casual observer and interfere

		with functioning in a variety of contexts. Distress and/or difficulty changing focus or action.
Level 1 "Requiring support"	Without supports in place, deficits in social communication cause noticeable impairments. Difficulty initiating social interactions, and clear examples of atypical or unsuccessful response to social overtures of others. May appear to have decreased interest in social interactions. For example, a person who is able to speak in full sentences and engages in communication but whose to-and-fro conversation with others fails, and whose attempts to make friends are odd and typically unsuccessful.	Inflexibility of behavior causes significant interference with functioning in one or more contexts. Difficulty switching between activities. Problems of organization and planning hamper independence.

Comparative Nosology

In the first and second editions of DSM (DSM-I and DSM-II), autism was not officially recognized; rather, it was viewed as being on some continuum with schizophrenia. It is now recognized that childhood schizophrenia, particularly very early-onset childhood schizophrenia, is quite rare.

Although the definition of autism in DSM-III was based largely on Rutter's synthesis of Kanner's original description and subsequent work, both the name of the disorder "infantile autism" and the criteria proposed reflected a certain lack of developmental orientation (e.g., criteria for the condition were monothetic and most appropriate to younger children with autism); a category, residual infantile autism, was available for children, adolescents, and adults who had once met the criteria for the condition but no longer did so. The latter concept was problematic in several respects since older children and adults still exhibited significant difficulties and needed services.

In DSM-III-R, there was more attention to developmental concerns and a set of 16 very detailed criteria were provided, grouped in the traditional three categories of social disturbance, communicative disturbance, and restricted and repetitive behaviors. An additional change in DSM-III-R was the multiaxial placement of autism and other pervasive developmental disorders. In DSM-III-R, the condition was moved to axis II, and only the two diagnoses of autistic disorder and PDD-NOS were included. It quickly became apparent that the diagnostic concept had been unintentionally broadened.

The term pervasive developmental disorder was the topic of some debate. It was originally coined in 1980 as a new term for the class of disorders to which autism was assigned. The term was chosen to reflect the fact that multiple areas of functioning are affected in autism and related conditions. However, some investigators and clinicians objected to it since it seems to imply a greater degree of severity than is always present.

However, it is clear that, by the time of DSM-III-R, the term had come into general usage and was used as a category for the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10).

In ICD-9, the category of psychoses with onset in childhood included the subgroup of infantile autism, among others. The use of the term psychosis in ICD-9 perpetuated the mistaken impression that autism was related to adult schizophrenia. In ICD-10, the pervasive developmental disorder category includes childhood autism, atypical autism (in which there is a failure to meet the behavioral or onset criteria), Rett syndrome, other childhood disintegrative disorder, overactive disorder with mental retardation and stereotyped movements, Asperger syndrome, other pervasive developmental disorder, and pervasive developmental disorder unspecified. In contrast to DSM-IV-TR, there was an even greater attempt to differentiate subgroups of pervasive developmental disorders. However, the validity of these conditions has been the topic of some debate, and definitive data are lacking. Despite the concerns about such distinctions, the working group responsible for DSM-IV decided, partly on the basis of a large international field trial, to try to achieve as much consistency with ICD-10 as possible. In the end, this was largely achieved, although there were some differences in terms of emphasis.

For DSM-IV, potential new criteria, as well as DSM-III and DSM-III-R and pending ICD-10 criteria, were evaluated in an international, multisite study including nearly 1,000 cases evaluated by more than 100 raters at 20 some sites around the world. In DSM-IV and DSM-IV-TR, autism was defined on the basis of behavioral features and age of onset (age of onset must be before 3 years). Behavioral difficulties must include some feature of social disturbance, communicative disturbance, and restricted interests or repetitive behaviors. The definitions of autism in both ICD-10 and DSM-IV-TR were conceptually identical. There was an explicit attempt to avoid the over inclusiveness of DSM-III-R criteria for autistic disorder. In addition, the disorder was returned to axis I. The number and detail of criteria were also reduced in length. Interrater reliability was assessed for autism and related conditions and was generally good to excellent, particularly for experienced clinicians. The DSM-IV-TR provided updated text for autism and related disorders particularly for Asperger disorder. As noted previously DSM-5 takes a markedly different approach.

Epidemiology

Prevalence. The first epidemiological study of autism was conducted by Victor Lotter in 1966, who reported a prevalence rate of 4.5 in 10,000 children among the entire 8- to 10-year-old population of Middlesex, a county northwest of London. Since then many epidemiological studies have appeared (Table 44–3). The median prevalence rate of these studies is 8.7

in 10,000. However, rates tend to be higher in studies with smaller samples and also tend to be higher more recently. If one excludes smaller and older studies, the median rate is slightly higher—approximately 9.5 in 10,000. Variability among studies reflects methodological issues, such as sample size, syndrome definition, and study design. Increased awareness of the condition on the part of health professionals and educators may also have contributed to increased case detection. Possible reasons for the increased rate in more recent studies involve the adoption of definitions of autism more applicable to the entire range of syndrome expression, as well as use of smaller target populations. Some studies have focused on the broader pervasive developmental disorder spectrum rather than on autism more narrowly defined. It is reasonable to say that approximately 1 in every 800 to 1,000 children may have strictly defined autism, with a larger number (1 in 150) exhibiting some features of the condition. The issue of whether autism is increasing in frequency—that is, if there is truly a secular change in rates of autism—has been the object of much debate. Unfortunately, the data available to address this issue are limited. There are marked variations in prevalence, even for studies conducted at the same point in time. It is clear that at least some of the apparent increases may be accounted for by other factors including diagnostic substitution; prospective surveillance data are needed to address this issue. It does appear likely that the new DSM-5 approach will significantly reduce diagnostic rates for newly diagnosed cases; cases with "well-established" previous diagnoses are automatically allowed to keep them.

Sex Ratio. Studies based on both clinical and epidemiological samples have repeatedly noted a higher incidence of autism in boys than in girls, with ratios reported averaging around 3.5 or 4.0 to 1. This ratio varies in relation to intellectual functioning. Some studies have reported male to female ratios of up to 6.0 or higher to 1 in individuals with autism without mental retardation, whereas ratios within the moderately to severely mentally retarded range have been reported to be as low as 1.5 to 1. It is still unclear why females are underrepresented in the normal IQ range. One possibility is that males have a lower threshold for brain dysfunction than females, or, conversely, that more severe brain damage would be required to cause autism in a female. According to this hypothesis, when the person with autism is a girl, she is more likely to be severely cognitively impaired.

Social Class. Although a few early studies supported Kanner's impression of an association between autism and upper socioeconomic status, most epidemiological studies published in the 1980s and 1990s have failed to reveal such association. In addition to the bias for more educated and successful parents to seek referral or the autism label for intervention purposes ("diagnostic substitution"), it seems likely that families from

disadvantaged backgrounds are still underrepresented in clinically referred samples. Outreach initiatives are still needed to provide equal access to diagnostic and intervention services to children from all socioeconomic backgrounds. Autism clearly is seen in all social classes and in all countries.

Etiology

Psychosocial Theories. Kanner's speculation that emotional factors might be involved in the pathogenesis of autism led others to conclude that the condition was always caused by the experience of a "refrigerator" mother who was not responsive to the child's emotional needs. In this view, intensive psychotherapy was needed for mother and child, or, sometimes, the child was removed from the family in an attempt to remediate the presumed deficits. Unfortunately, there was no evidence that such efforts were efficacious. A generation of parents were traumatized by the experience of being blamed for their child's condition.

Biological Theories. As children with autism were followed, various factors suggested a biological basis of the condition. These included the high rates of mental retardation and seizure disorders and the recognition that various medical and genetic conditions were sometimes associated with autism. The current consensus is that autism is a behavioral syndrome caused by one or more factors acting on the central nervous system (CNS). Although the underlying biological abnormalities of autism are unknown, efforts are now under way to delineate more precisely testable neuropathological mechanisms.

Table 44–3.
Selected Epidemiological Studies of Autism

Study, Year	Country	Size of Target Rate Population	Criteria Used Based on	Prevalence (per 10,000)
Lotter, 1966	UK	78,000	Kanner, 1943	4.5
Wing et al., 1976	UK	25,000	Kanner, 1943	4.8
Gillberg et al., 1984	Sweden	128,600	DSM-III, 1980	4.0
Cialdella and Mamelle, 1989	France	135,180	DSM-III, 1980	4.5
Gillberg et al., 1991	Sweden	8,106	DSM-III-R, 1987	9.5
Fombonne et al., 1997	France	325,347	ICD-10, 1992	5.3
Baird et al., 2002	UK	16,235	ICD-10, 1992	30.8
Chakrabarti and Fombonne, 2001	UK	15,500	ICD-10, 1992	16.8
Croen et al., 2002	USA	4,950,333	Full syndrome Autism	11.0
Fombonne et al., 2006	Canada	27,749	DSM-IV	21.9
Isaksen et al., 2012	Norway	31,015	ICD-10	14

Genetic Factors. Family and twin studies demonstrate that genetics plays a central role in the etiology of ASD. Approximately 60 percent of monozygotic twins share a diagnosis of strictly defined autism while 80 to 90 percent are concordant for the broader spectrum. When compared to the dizygotic concordance rate, the cumulative data from these types of studies suggest that genes account for a greater share of the liability for ASD than does the environment, though both contribute substantially to population risk.

For several decades, despite a strong consensus that genes play a significant role in autism, defining the specific nature of that risk proved to be quite challenging. However, over the past several years, with the availability of large patient and family cohorts, rapidly advancing genomic technologies, and a wholesale move toward large-scale collaborative studies, there has been very rapid progress in illuminating the genetic architecture of autism and related conditions.

Several important themes have emerged: first, the majority of progress so far has been a consequence of a focus on mutations that are rare in the population, are often new (or de novo) in the affected individual, and carry relatively large biology effects; second, while there is substantial evidence that polymorphisms that are common in the population convey risk, unlike disorders such as schizophrenia and bipolar disorder, so far, no specific common genetic variants have been reproducibly associated with ASD using genome-wide association strategies, the current gold-standard methodology for this type of analysis. This is almost certainly a consequence of still underpowered patient cohorts and the small individual effects conveyed by these types of genetic variations. Third, while recent studies have underscored an exceptionally high degree of genetic heterogeneity underlying ASD, so far, the genes that have been discovered appear to converge on a much smaller number of biological processes. To date, multiple studies have highlighted the role of, for example, chromatin modification, synaptic proteins, and targets of fragile X mental retardation protein (FMRP) as playing important roles in pathophysiology and underscored the importance of mid-fetal human cortical development. Fourth, there is incontrovertible evidence that rare, de novo variations in the submicroscopic structure of chromosomes, also called copy number variations (CNVs), carry risk for ASD. Moreover, it has also been repeatedly shown that the identical CNV in different individuals may increase the liability for a very broad range of neurodevelopmental disorders, ranging from schizophrenia, to epilepsy, intellectual disability, or specific language impairment. These findings raise important questions about the specificity of genetic risks underlying ASD. Finally, while the relative contribution of genes is thought to be quite large, influences other than variation in the deoxyribonucleic acid (DNA) sequence are likely to turn out to be

important as well, including epigenetic mechanisms and environmental factors. Indeed, one of the most important outcomes of the successful search for autism transcripts will be the light it will shed on nongenetic, potentially modifiable risks.

Other Medical Conditions and Autism. ASDs have also been associated with other conditions with a strong genetic component, for example fragile X syndrome and tuberous sclerosis. In fragile X, a marker X chromosome is noted to be "fragile" in that, when grown in a special medium deficient in folic acid, there is a site that commonly fractures. The fragile X mutation typically involves a triplet repeat of cytosine–guanine–guanine in the regulatory domain of the gene *FMR1*, which may amplify with succeeding generations. Physical signs of the condition include characteristic facies, enlarged testicles, associated mental retardation, and autistic features. Behavioral difficulties include attention problems, impulsivity, and anxiety. Recent data suggest that between 20 and 30 percent of boys with fragile X meet diagnostic criteria for autism spectrum conditions, and between 1 and 8 percent of boys with idiopathic autism will be found to carry a fragile X mutation.

Given the marked increase in risk for ASD among those with abnormal expression of the fragile X gene and recent findings suggesting that many genes carrying risk for "typical" ASD are targets of the FMR protein (FMRP), recent advances that have begun to illuminate the biology of this molecule may turn out to have important implications for understanding more common causes of autism. FMRP is an RNA-binding protein that has been found to interact with multiple transcripts and to repress gene translation, to contribute to neuronal plasticity through involvement in the process of long-term depression (LTD) at the synapse, and to help regulate the function of group I metabotropic glutamate receptors (mGluR). Loss of FMRP leads to increased mGluR5 signaling activity and adversely affects synaptic plasticity. Such findings have led to novel and unanticipated avenues for potential intervention: In animal models of fragile X syndrome, use of glutamate receptor antagonists (such as MPEP [2-methyl-6-(phenylethynyl) pyridine] or lithium [Eskalith]) can rescue some of the phenotypic features resulting from the loss of FMRP expression. Whether these insights will lead to improved intervention for fragile X, with or without autistic features, is not yet known.

Tuberous sclerosis (TS) is characterized by abnormal tissue growth, or benign tumors (hamartomas), which affect various organ systems. This autosomal dominant disorder is associated with a range of phenotypes, including intellectual disability and seizure disorder. Studies of individuals with autism find TS in between 0.4 and 2.8 percent of cases, a significant elevation over the rate of TS in the general population.

The mutations that lead to TS are found in the genes encoding the TSC1

(Tuberous Sclerosis Complex 1) and TSC2 (Tuberous Sclerosis Complex 2) proteins which are members of the mTOR (mammalian target of rapamycin)/Akt (a.k.a., Protein Kinase B) intracellular signaling pathway, involved in multiple cellular processes including proliferation, growth, cell survival, and mobility. Interestingly, other ASD-risk genes, such as PTEN (phosphatase and tensin homolog) are also members of this pathway. The specific manner in which mTOR/Akt pathway dysregulation leads to ASD is not fully understood. However, as is the case with FMRP, restoring the normal function of the signaling pathway in model systems carrying ASD-related mutations has led to restoration of function, even in adult animals.

PRE-, PERI-, AND NEONATAL FACTORS. Several studies have shown increased rates of pre-, peri-, and neonatal complications in children with autism. Much of the difference relates to observation that something unusual is noted about the child at birth. This may reflect the operation of genetic as well as perinatal factors. The genetic predisposition to autism may interact with perinatal factors in producing the syndrome.

OTHER ETIOLOGIES. Various reports have associated autism with a host of other conditions. To date, many of these reports are in the form of single case reports or case series rather than controlled studies and their significance is difficult to interpret. Moreover, controlling for potential confounds when investigating the prevalence of ASD in neurodevelopmental syndromes accompanied by significant intellectual impairment, can be challenging. Several associations have been of particular interest; for example, autism associated with neurofibromatosis and congenital rubella. In the former case, there have been several lines of recent compelling biological evidence supporting this observation. In the latter case, it has become clear that when children with congenital rubella, who were initially thought to have autism, were followed over time, their "autistic-like" features tended to diminish. Also, such children exhibit a range of sensory deficits and intellectual disability, both of which complicate the diagnostic process.

There has been much interest in recent years regarding whether the reported increase in the prevalence of autism might be the result of environmental or other factors. There clearly is some role for environmental contributions although precise mechanisms remain to be specified. The combination of advances in the genetics and neurobiology with well-designed prospective epidemiological studies will help clarify which specific environmental risks are most relevant and, importantly, modifiable. Of note, to date, despite multiple focused investigations, there is no evidence that vaccinations play a role in the environmental liability for ASD.

Postmortem and Neuroimaging Studies

NEUROIMAGING AND BRAIN DEVELOPMENT. ASD is a neurodevelopmental condition that emerges early in life. Much has been learned about ASD from postmortem, model system, and neuroimaging studies over the last few decades. However, of these, MRI studies have provided the largest contribution to the current understanding of attributes of brain structure and function associated with autism. This section will review the main themes of this research, focusing on neuroanatomical studies using structural MRI (sMRI) and brain functioning using functional MRI (fMRI).

Neuroimaging as a tool and as an approach to understanding brain-based disorders emerged on the research landscape in the 1990s, with the arrival of fMRI to complement sMRI, which became a useful research tool about a decade earlier. Imaging in autism research, however, did not gain traction until the late 1990s, after which it accelerated rapidly, as it did in all subfields of neuropsychiatry. The dominant research approach has been the case-control design, which considers individuals with autism as categorically distinct from other groups, including typically developing controls (TDCs). Thus, studies focus on describing how the brain is different in autism than TDCs, at what ages those differences emerge, and how specific brain features map onto to phenotypic elements of autism, genetic risk variants, and outcome measurements. Recent data, however, demonstrate that ASD is extremely heterogeneous, both in its core features, with severity ranging from the boundary of typical development to profoundly impaired, and with respect to many frequently co-occurring conditions such as intellectual disability, epilepsy, anxiety, and attention-deficit hyperactivity disorder (ADHD). This is relevant to understanding the neurobiology of autism research literature because often studies do not replicate upon follow-up, and thus they cannot provide reliable information. This is inherent both to the heterogeneity that accompanies the current conceptualization of the essence of ASD, as well as to the practice of publishing results based on inadequate sample size, for example, where case and control groups have less than 20 or 30 individuals each. Inadequate sample size is an acknowledged problem across all of neuroscience because it leads to failed replications, undermining the ability to accumulate a stable base of knowledge. Thus, the review of studies herein is confined to research where there have been several studies arriving at similar conclusions, with a bias away from describing studies based on small samples.

DEVELOPMENTAL NEUROANATOMY. The observation that individuals with autism tend to have enlarged heads dates back to the origin of the diagnosis itself. Although subsequent studies of head circumference confirmed this observation, it did not receive much attention until the advent of MRI, which provided the excellent soft tissue contrast needed for more precise quantitation of brain morphology. The first MRI study from the middle of

the 1990s, found total tissue volume of individuals in the autism to be about 6 percent larger than the control group. Subsequent studies suggested that the size increase includes both gray and white matter. Courchesne et al. were the first to report that megalocephaly was observable as young as 2 years of age (but was not present at birth). This has been replicated and extended several times. Most recently Hazlett et al. showed that while gray matter volume and cortical surface area is enlarged in ASD, cortical thickness is not, which is an important observation because it constrains the possible biological mechanisms that could account for these size differences.

The Infant Brain Imaging Study (IBIS) promises to bring greater precision to the current understanding of the earliest signs of developmental brain differences. IBIS is a multisite, national study collecting data prospectively on at-risk baby siblings of youth with autism, with the first brain MRI between 3 and 6 months of age, repeated at regular intervals up until 24 months of age. The first IBIS results showed that axonal fibers had a blunted development in ASD between 6 and 24 months of age, with results clustering in brain regions implicated by fMRI study as part of the "social brain." These data suggest that autism begins to develop neurobiologically before the end of the first year of life in those who go on to a formal diagnosis at older ages (e.g., age 3). This is consistent with emerging data from very careful behavioral testing which also shows significant deficits in the first year of life for those who go onto develop autism. Another IBIS study found white matter microstructural abnormalities at 7 months of age in the group who went on to have ASD, in fiber bundles associated with visual orienting and with the ability to disengage attention. These data help pinpoint brain circuits that appear to underlie a "sticky attention," a phenomenon in autism that causes significant behavioral management issues, and undermines learning. Both studies confirm the brain connectivity is an early feature that goes awry in autism. A third IBIS study has focused more explicitly at how the white matter's individual axonal fibers are organized in autism using diffusion tensor imaging (DTI). This study found significant fiber network inefficiencies in the brains of toddlers with ASD at 24 months of age. Thus, a developing theme is that white matter shows aberrant organizational properties in the first year of life, which accentuate with time, and subserve core features of ASD.

While most studies have not tried to localize areas of the brain that may be disproportionately enlarged, those that have often find frontal and temporal regions most enlarged. In addition, Dawson et al. discovered early overgrowth of the amygdala, a structure vital to emotional processing and memory, in a sample with an average age of 4 years. Subsequent studies have verified and extended these findings showing associations between degree of overgrowth and severity of clinical symptoms. However, findings

are confined to preschool ages, as increases are noted later in childhood and adolescence. Several MRI studies have suggested that the brain's white matter is disproportionately enlarged in autism, which is viewed as supportive of more recent conceptualizations of autism as involving disrupted connectivity. However, not all white matter fiber tracts are enlarged. For example, numerous studies have found decreased cross-sectional width of the corpus callosum. Moreover, there is evidence that later myelinating areas in particular, contribute the most to the increase in brain volume in ASD relative to TD controls (i.e., frontotemporal and frontoparietal regions). Allometric models of cerebral development suggest that doubling the number of neuronal processing units (the gray matter "minicolumn") supports a fourfold increase in neuronal connectivity, potentially generating a fourfold increase in white matter volume. However, even though white matter enlargement seems a bit disproportionate compared to gray matter enlargement in ASD, it may be that the white matter enlargement is less than would be expected under model assumptions. The implication is that the bigger brains in autism are actually less well connected than smaller brains among TDCs.

The neurodevelopmental trajectory of ASD was refined by subsequent studies that found that ASD increases in head size were observable only below age 12, after which group differences disappeared. This observation has been replicated many times, but the finding is not without opposing results. The single largest and best controlled study to date, albeit on head size (an imperfect proxy for brain size), found significant head circumference enlargement regardless of age. This study is remarkable for its very large sample size (n = 1,889 individuals with ASD from young childhood to young adulthood), and for controlling known confounds such as age, body size, and IQ measurements, as well as familial effects on head size, since both parents and an unaffected sibling were also included in the analyses (total n = 7,225). In summary, the brain growth and volume literature suggests that brain overgrowth begins in the first few years of life in ASD, and that by adolescence brain size is much more typical. This abnormal pattern of growth across infancy and childhood is presumed to have very important implications for the functional properties of the brain and to likely perturb functional organization of systems that support typical social–emotional and cognitive skills. This atypical growth pattern also provides clues as to the possible cellular–genetic bases of autism, especially mechanisms that govern neural numbers.

Consistent with this summary, a postmortem study of brains of those with ASD recently pinpointed a possible mechanism for brain volume differences in autism. This study found good evidence for early deficits in neural pruning in autism. While relatively small by MRI standards, the 20 brains analyzed (about half with ASD) represents one of the larger published postmortem studies. Samples came from individuals who died

between 2 and 20 years of age. Synaptic pruning after the first year of life is well known as a normal developmental process, which is presumed to yield improved computational efficiencies. While typical controls lost about 40 percent of their dendritic spines (that part of a neuron that receives signal transmissions) across the age span, those with ASD lost half that much. The investigators also used a mouse model of autism to study possible causes of this pruning failure. They found that mTOR, a key protein in brain function and development, was hyperactive, which impaired the ability to prune synapses. Overactivity of the mTOR pathway led to blockage of autophagy processes, reduction in pruning and resulted in mice with ASD-like social behaviors. Significantly, the investigators were able to correct the pruning deficits and ASD-like behaviors in mice through use of an immunosuppressive drug, rapamycin, which inhibits mTOR activity. While this is unlikely to become a standard treatment in humans, owing to its very serious side effects, mTOR is currently being tested in clinical trials for a special subgroup of ASD (those with tuberous sclerosis), where the risk has been judged appropriate. Finally, the investigators also found in the human postmortem tissue proteins that reflect deficient autophagy and synaptic pruning malfunctioning. Collectively, these data are consistent with growing evidence of neural connectivity abnormalities in autism, especially regional overconnectivity. Given that a great many of the known ASD genetic risk variants interact with the mTOR pathway, deficits in synaptic pruning provide plausible mechanisms contributing to the development and maintenance of autism. Lack of pruning would also lead to an abundance of synapses, which would create the opportunity for seizures, a common comorbidity of ASD.

Recently attention has focused on neuroanatomical changes later in adolescence and adulthood. One particularly relevant study matched a very large number of cases and controls (age 7 to 25 years) on age, gender, and IQ, and found significant, widely distributed reductions in cortical thickness with age in ASD relative to TDCs. These declines were concentrated in the same areas of the brain shown in other studies as exhibiting hypertrophy early in life—frontal and temporal lobe regions, suggesting a unique inverted U-shaped developmental growth trajectory. Prefrontal cortex and the anterior temporal lobe also showed significantly reduced surface area with age (an age by group interaction). These results are consistent with several other recent studies that showed accelerating cortical thinning with age, including in the temporal lobe. Collectively, these data raise the concern that there might be undetected declines in cognitive and social–emotional functioning as individuals with ASD move into adulthood.

FUNCTIONAL IMAGING. fMRI studies of ASD have painted a complex portrait of differences in brain functioning in autism. While MRI studies of

neuroanatomy focus on measurements of a trait of a person, fMRI study results are influenced both by enduring personal traits (e.g., some people are very good at recognizing faces or others are not), and also mental and emotional states at the time of the assessment. Because the MRI experience can vary between individuals (e.g., stress provoking for some, sleep provoking for others), measurement signal can be influenced by state factors. The signal analyzed from fMRI comes from fluctuations in the magnetic field with different blood oxygen levels that accompany changes in neural activity. While the measurement is in this way indirect, fMRI has advantages over other neuroimaging techniques because of its ability to localize activity very precisely to different parts of the brain, with resolution in most studies of about 3 mm^3 (voxel size). Although this is precise by many standards, it is important to recognize that an average cortical gray matter voxel contains about 630,000 neurons.

fMRI studies can be of different types. Some are task based, and have focused hypotheses about regions of the brain (e.g., the amygdala) that are hypo- or hyperactive in autism. This type of study, based on a specific task (e.g., showing emotionally engaging images versus neutral images with the participant providing a judgment that is recorded by a button press), has expectations that specific brain "modules" will be differentially engaged has dominated the literature particularly the early literature. This approach has been successfully used to test a range of theories about the primary deficits in autism. The social, communication, and behavioral problems that occur with ASD suggest that the syndrome affects a functionally diverse and widely distributed set of neural systems. At one point or another, disturbance in nearly every neural system in the brain has been proposed to be a fundamental mechanism causing autism. These theories are typically derived from beliefs about the most salient behavioral and psychological features of the disorder, sometimes with explicit consideration of developmental course. For example, those who emphasize difficulty with complex information processing as the principal characteristic of autism, postulate widespread cortical abnormalities sparing early sensory and emotional processes as the neural basis of autism. Such cortical abnormalities, when present from early in life, would impair learning and contribute to developmental features of autism. On the other hand, those who focus on the social reward and saliency deficits and their role in social difficulties, often highlight the limbic system and reward system circuitry in the pathogenesis of autism. Less sensitivity to social reinforcement and drive for social engagement would curtail social development. Theory-driven research is able to articulate specific hypotheses and to pursue programmatic research that accumulates knowledge across time. Table 44–4 summarizes the knowledge about brain functioning that has been gained with this type of approach. Replicated studies that support a role of specific brain areas whose functions are

atypical in autism are represented in this table.

Table 44–4.
Brain Regions of Potential Importance in Autism

Brain Area	Function
Amygdala	Emotional arousal, emotion perception, and emotional learning
Extended amygdala, ventral striatum, and nucleus accumbens	Social reward circuitry
Fusiform gyrus (especially lateral aspect of the right fusiform)	Face (person) recognition
Posterior, superior temporal sulcus	Interpreting nonverbal communications, action observation, and theory of mind
Orbital prefrontal cortex	Emotional learning
Medial prefrontal cortex	Social cognition (interpreting what others might be thinking and feeling)

Table 44–4reflects the literature and the strong interest in the field in localizing specific functions related to social ability to discrete locations in the brain. Perhaps the best studied process and brain region involves face perception and fusiform gyrus (see Fig. 44–1). The fusiform has a specific role in person identity from visual images. Numerous studies show that it is often under active in autism, paralleling difficulties on psychological tests of face recognition. The fusiform is functionally synchronized with the limbic system, and in particular the amygdala. The amygdala, along with the reward system, is believed to play a role in directing a person's attention to socially relevant things in the environment such as people and their social interactions. Both the amygdala and the reward pathway have been shown to be hypoactive in ASD, though the amygdala's social responsiveness is confounded by its role in signaling anxiety and fear. There has recently been considerable speculation regarding the relationship between ASD symptoms and a constellation of brain areas referred to as the mirror neuron system (MNS). MNS has proven responsive to both the perception and implementation of specific body movements. The posterior part of the superior temporal sulcus has been highlighted in many fMRI studies of social perception (especially recognizing nonverbal cues, such as facial expressions, gestures, and eye gaze direction), as well as part of larger systems for representing the intentions of others (i.e., for generating a theory of mind of others). The hub of theory of mind activity, however, is generally localized to the medial prefrontal cortex. Orbital prefrontal cortex represents the value of experiences and of rewards and as such it plays a key role in emotional learning.

FIGURE 44–1. Composite functional magnetic resonance image comparing a group of 14 normal controls (NCs) and 14 individuals with autism or Asperger syndrome (autism), matched on age and intelligence quotient. Composite images show areas preferentially activated by faces (**A,C**) and nonface objects (**B,D**). Note that the fusiform "face area" has been defined by a green box in **A**. Among individuals with autism or Asperger syndrome, there is significant underactivation of the fusiform gyrus during face perception and compensatory activation of a region lateral to the fusiform. This more lateral region was most strongly activated by the object task among the NCs. Hypoactivation of the fusiform face area is the best replicated functional neuroimaging finding in the literature. (See color atlas.) (Adapted from Schultz RT, Gauthier I, Klin A, et al. Abnormal ventral temporal cortical activity during face discrimination among individuals with autism and Asperger syndrome. *Arch Gen Psychiatry*. 2000;57:331–340.)

In the past 5 years, there has been increased attention given to task-free fMRI studies, most notably what has been termed resting state fMRI (rsfMRI). With this approach, participants are not required to engage in any specific mental activity. Rather fMRI signal is gathered continuously during a rest period, generally of about 5 minutes long and often with more than one rest session. This approach has been most valuable in the context of functional connectivity studies of brain systems, an approach which examines the cross correlation of disparate regional brain activity fluctuations. In essence, the approach searches for synchronous fMRI activity in order to create networks of regions that appear to be working together in a time-locked fashion. This approach has yielded numerous

study findings, but many have not been consistently found across studies, and these therefore await larger studies. Those that are consistent often identify brain system differences associated with ASD that can be supported by lesion studies, or task-based fMRI (e.g., as described in Table 44–4). rsfMRI is an important component of a major NIH initiative—the Human Connectome Project. This multicenter program of research is collecting imaging data on 1,200 participants. The Human Connectome and related endeavors will allow connectivity matrices derived from graph theory on resting state and diffusion data from individuals with ASD to be compared to several other groups, including, for example, typical development, Alzheimer's, and ADHD. These publicly available resources will generate the large samples needed to make gains in characterizing neural circuits with multimodal imaging in basic cognitive neuroscience and in ASD. This is significant given other lines of evidence support the general theory of underconnectivity of the brains of individuals with ASD. This approach, along with increased implementation of multimodal imaging studies (where sMRI, fMRI, and other techniques are combined to address hypotheses about the neural architecture of ASD), promise to allow important advances in the understanding of ASD in the coming years.

Neurochemistry. Beginning in 1961, a number of studies have reported that approximately one-third of children with autism have increased peripheral levels of the neurotransmitter serotonin. This has been the focus of much research, but the significance of this finding remains unclear, as the finding is not specific to autism, and the relation of peripheral levels to central levels of serotonin is unclear.

Another line of work has focused on other neurotransmitters such as dopamine. A hyperdopaminergic functioning of the brain might explain the overactivity and stereotyped movements seen in autism. This would be consistent with the general observation that administration of stimulants, which increase levels of dopamine, sometimes worsens behavioral functioning in autism. Studies of cerebrospinal fluid (CSF) of dopamine metabolites and catecholamine metabolites have been inconsistent. It is clear that agents that block dopamine receptors are effective in reducing the stereotyped and hyperactive behaviors of many autistic children.

The endogenous opioids have been investigated, given the possibility that these compounds—enkephalins and endorphins—might lead to social withdrawal and unusual sensitivities to the environment. This was the rationale for use of opioid antagonists such as naltrexone (Depade) in treating children with autism. Although it does appear that there may be a modest effect of these agents on the high levels of activity and agitation overall, results have been disappointing. More recently, work has centered on potential use of agents like oxytocin that may impact attachment and social brain systems more directly.

Immune Theories of Autism. Some work has suggested a possible role of immunological factors in autism. There has been a suggestion that maternal antibodies directed against the fetus may be produced in utero. There also have been reports of autism associated with viral infections. Considerable controversies have arisen over the question of whether exposure to the measles–mumps–rubella (MMR) immunization might be a causative factor. This assumption rests largely on case reports that link the apparent onset of autism with the immunization; however, it has long been known that a small number of children with autism present with a developmental regression, and the bulk of the available evidence does not support a causative association with immunization. The potential negative effect of an increase in children not immune to measles is considerable.

Diagnosis and Clinical Features

In DSM-5 a diagnosis of autism required three essential social communicative features and at least two restricted/repetitive features. The social communicative deficits are in the areas of social interaction across settings, deficits in social–emotional reciprocity, and deficits in nonverbal communicative behaviors used in social interaction, for example, difficulties with eye contact and so forth. All three features must be present. In addition at least two of four restricted and repetitive behaviors must be present. These four features include: (1) stereotyped motor mannerisms; (2) restricted interests and insistence on sameness including difficulties with change and overreliance on routine; (3) highly restricted interests abnormal in focus or intensity, for example, overattachment to an unusual object; and (4) hypo- or hypersensitivity to sensory input. The symptoms must be present in early development (although their severity may change over time) and symptoms must cause clinically significant impairment. As noted previously, a variety of additional codes can be used to indicate the presence of specific features such as intellectual delay and catatonia. The symptoms cannot be better explained by intellectual difficulty. As noted earlier, individuals with previously "well-established" DSM-IV diagnosis of autistic disorder, Asperger disorder, or PDD-NOS should be given the diagnosis of ASD. Finally, for persons with major problems in social communication but who do not meet criteria for autism the new category of social communication disorder can be considered (see below).

DSM-5 provides a number of specific developmental/behavioral examples but does note that the clinician is not limited to these. Clearly there is a marked range of syndrome expression in ASD over both age and intellectual and communicative level. For the lowest cognitive level, often the child is typically largely or entirely mute, is isolated from social interaction, and makes few social overtures. At the next level, the child may accept social interaction passively but does not seek it out. At this level, some spontaneous language may be observed. Among the higher-

functioning and somewhat older children, the child's social style is different, in that he or she may be interested in social interaction but cannot sustain it in typical ways. The social style of such individuals has been termed "active but odd," in that they often have difficulty regulating social interaction once it has commenced. This last group may pose the greatest challenge diagnostically in use of DSM-5. Given the range of syndrome expression and variations in presentation with age, there is considerable potential for misdiagnosis. Evaluation of the child with autism should include a detailed history, comprehensive medical and developmental examination, and psychological testing. Practice guidelines for screening, assessment, and treatment are available.

Age of Onset. The onset of autism is by definition early in life. As shown in Figure 44–2, parents typically become concerned between the ages of 12 and 18 months as language fails to develop. Although there may be concern that the child is deaf, the parents also note the child may respond quite dramatically to sounds in the inanimate environment; occasionally, parents report, in retrospect, that the child was "too good," made few demands, and had little interest in social interaction. This is in stark contrast to normally developing infants for whom the human face and social interaction are among the most interesting and salient features in the world. Occasionally, parents report that the child seemed to develop some language, and, then, his or her language either plateaued or was lost. Such a history is reported in perhaps 20 to 25 percent of cases. Often, detailed review of early developmental history or of videotapes of the child at a younger age will reveal some earlier abnormality, and true regressive autism (i.e., with a dramatic onset of symptoms after previously normal development) is clearly much less common. The DSM-IV diagnosis of childhood disintegrative disorder applied in instances where a marked and profound developmental regression and development of autistic like behaviors occurred after a clear period of normal development. This rare condition is of considerable interest, for example, it might represent the action of specific genetic or other mechanisms. It is unclear how many such children who now come to diagnosis will receive an ASD diagnosis, since the mean age of onset is approximately 4 years. Similarly individuals who exhibit a pattern of social difficulties more consistent with the DSM-IV Asperger diagnosis may present problems given the emphasis on early onset and their higher-cognitive levels. In such cases social interest is often very present although pragmatic skills are typically weak while vocabulary and other aspects of language may be quite advanced. Table 44–5 summarizes some of the features important in differentiating autism from other disorders in the first years of life.

FIGURE 44–2. Age of recognition in autism in a series of 174 consecutive cases.

Impairments in Social Communication. Normally developing infants have a marked interest in social interaction and the social environment from birth. This predisposition is an important foundation for development of other skills. In infants and young children with autism, the human face holds little interest; disturbances are seen in the development of joint attention, attachment, and other aspects of social interaction. For example, the child may not engage in the usual games of infancy, may have difficulties with imitation, and may lack usual play skills. These deficits are highly distinctive and are not just due to associated developmental delay.

Table 44–5.
Symptoms Differentiating Infants and Toddlers with Autism Form Typical and Developmentally Delayed Peers

	Social Interaction	Communication	Stereotypical and Repetitive Behaviors
First year	Limited ability to anticipate being picked up	Poor response to name	Excessive mouthing
	Low frequency of looking at people	Infrequent looking at objects held by others	Aversion to social touch
	Little interest in interactive games		
	Little affection toward family members		
	Content to be alone		
Second	Abnormal eye contact	Low frequency of verbal or	Hand/finger mannerisms

and third years		nonverbal communication	
	Limited social referencing	Failure to share interest (e.g., by pointing, giving, showing)	Inappropriate object use
	Limited interest in other children		Repetitive interests/play
	Limited social smile		Unusual sensory behavior (hyper/hyposensitivity to sounds, texture, taste, or visual stimuli)
	Low frequency of looking at people	Failure to respond to communicative gestures (showing, pointing, giving)	Poor response to name
	Limited sharing of affect/enjoyment	Use of other's body as tool (takes hand to get object without making eye contact as if hand is agent)	
	Limited range of facial expressions	Unusual vocalizations	
	Unusual attachment object (hard not soft, the specific object less important than object less important than category of object)		
	Little interest in interactive games		
	Limited functional play		
	No pretend play		
	Limited motor imitation		

Adapted from Chawarska K, Volkmar FR. Autism in infancy and early childhood. In: Volkmar F, Klin A, Paul R, Cohen D, eds. *Handbook of Autism and Pervasive Developmental Disorders*. 3rd ed. Hoboken, NJ: John Wiley & Sons; 2005:230.

Social interest may increase over time. There is often a developmental progression, with younger and more impaired individuals being avoidant or aloof from interaction, whereas somewhat older or more advanced individuals are willing to passively accept interaction but do not seek it out. Among the most able individuals with autism, there is often social interest, but the person has difficulty in managing the complexities of social interaction; this often leads to an unusual or eccentric-appearing social style.

In terms of communication as many as 30 to 40 percent of individuals with autism never use language for communication (e.g., they never speak or only echo or repeat statements of others). Delays in the acquisition of language are the most frequent presenting complaint of parents. Usual patterns of language acquisition are observed (e.g., children with autism may not babble or may take the parent's hand to obtain a desired object

without making eye contact, as if the hand, rather than the person, is obtaining the item). In contrast to the child with a language disorder, there is no apparent motivation to engage in communication or attempt to communicate via nonverbal means.

When individuals with autism do speak, their language is remarkable in various ways. They may echo speech (echolalia). Speech tends to be less flexible, for example, there is no appreciation that change in perspective or speaker requires pronoun change; this leads to pronoun reversal. Speech may be nonreciprocal in nature, for example, the child produces language that is not meant as communication. Although the syntax and morphology of language are relatively spared, vocabulary and semantic skills may be slow to develop and aspects of the social uses of language (pragmatics) are particularly challenging. Thus, humor and sarcasm may be a source of confusion, as the person with autism may fail to appreciate the speaker's communicative intent, resulting in an overly literal interpretation of the utterance. Although typically developing babies acquire the prosody of their mother language during the first year of life, for more able individuals with autism, this aspect of language may not develop, and often, intonation is monotonic and robot like. Nonverbal behavior, as used in social interaction, is very impaired with individuals oblivious to clear social cues, for example, talking at great length about topics of interest to them but not their conversational partner.

Deficits in play may include a failure to develop usual patterns of symbolic–imaginative play. The autistic child may explore nonfunctional aspects of play materials (e.g., taste or smell) or use aspects of materials for self-stimulation (spinning the tires on a toy truck).

Restricted Activities and Interests. Children with ASD often have difficulty tolerating change and variation in routine. For example, an attempt to alter the sequence of some activity may be met with what appears to be catastrophic distress on the part of the child. Parents may report that the child insists that they engage in activities in very particular ways, and changes may elicit great opposition or upset. The child may develop an interest in a repetitive activity, for example, collecting strings and using them for self-stimulation, memorizing numbers, or repeating certain words or phrases. In younger children, attachments to objects, when they occur, differ from usual transitional objects in that the objects chosen tend to be hard rather than soft, and, often, it is the class of object, rather than the particular object, that is important. For example, the child may insist on carrying a certain kind of magazine around with him or her. Stereotyped movements may include toe walking, finger flicking, body rocking, and other mannerisms; these are engaged in as a source of pleasure or self-soothing. The child may be preoccupied with spinning objects, for example, he or she may spend long periods watching a ceiling

fan rotate. This group of behaviors tends to be one of the last to develop and may be minimal until the child is around three years of age.

Associated Features. In contrast to Kanner's early belief that children with autism had good cognitive potential, approximately 31 percent have intellectual disability and 23 percent have IQs in the borderline, below average range. The profile on psychological testing is marked by significant deficits in abstract reasoning, verbal concept formation, and integration skills and on tasks requiring a degree of social understanding. For example, on the Wechsler scales, weaknesses are usually obtained on the similarities and comprehension subtests, while relative strengths are usually observed in tasks involving rote learning and memory skills. Visual–spatial problem solving is often a strength, particularly if the task can be completed piecemeal, that is, without having to infer the context, or gestalt, of the task. The typical preference for rote and sequential, rather than conceptual and integrative tasks usually carries the implication that individuals with autism fail to see "the trees from the leaves," a difficulty that cuts across functioning modalities—from cognitive testing to language and communication, to style of social interaction. Given that verbal deficits are common in autism, performance on the Wechsler scales is also usually characterized by higher perceptual reasoning than verbal comprehension scores, particularly in the individuals scoring within the range of intellectual disability. However, the opposite pattern is sometimes seen in individuals with above average or gifted intelligence.

Several influential psychological theories of the social dysfunction in autism have been proposed. One hypothesis posits that there is a lack of a central drive for coherence, with the consequent focus on dissociated fragments rather than integrated "wholes," leading to a fragmentary and overly concrete experience of the world. Another hypothesis posits deficits in executive functioning, defined as the capacity for abstracting rules, inhibiting irrelevant responses, shifting attention and profiting from feedback, and maintaining a focus on multiple aspects of information in decision making. As executive functions are thought to be mediated by frontal brain areas, this hypothesis has historically highlighted some similarities between autism and conditions resulting from acquired frontal lobe lesions. Yet another influential hypothesis posits that autism results from the child's inability to attribute mental states (such as beliefs and intentions) to others. Devoid of such a "theory of mind," individuals with autism are presumed to be unable to infer the thoughts and motivations of others, thus failing to predict their behavior and to adjust accordingly. This results in lack of reciprocity in communication and social contact, and great challenges in successfully navigating social situations that require contextual understanding of implicit social mores and of nonliteral speech such as humor and irony. In the past decade or so, eye-tracking technology

has been used to study social–visual engagement in a highly quantitative fashion, with a focus on abnormalities of skills such as preferential visual orientation to salient aspects of social stimuli that typically facilitates social engagement (Fig. 44–3). This line of research has documented significant impairments in social orientation and motivation skills, skills that are both developmentally early emerging and evolutionarily highly conserved. Examples include preferential orientation to biological motion (or movement of living beings) and eye gaze, both of which are essential components of joint or shared attention, which in turn is a key component of reciprocal social engagement and communication. These findings suggest that social development is likely derailed very early on in the lives of children with autism, leading to a cascade of developmental events that have an impact on subsequent social cognitive milestones and on brain specialization. More recently, investigators have capitalized on the high recurrence rates of autism within sibships, following prospectively and longitudinally the developmental trajectories of large cohorts of younger siblings of children with autism. One to two in five among the younger siblings either meets criteria for autism or exhibits subthreshold levels of autism-related symptoms. Using eye tracking, EEG, sMRI, fMRI, and DTI methods, prodromal markers of autism have already been identified in the first year of life of children later diagnosed with autism.

FIGURE 44–3. Eye tracking data from a typically developing young adult (*top line*) and a young, high-functioning man with autism (*bottom line*). The man with autism focuses almost exclusively on the mouth of the person speaking, avoiding the upper part of the face and not noticing the emotional responses of the listener. (From Klin A, Jones W, Schultz R,

Volkmar F, Cohen D. Defining and quantifying the social phenotype in autism. *Am J Psychiatry*. 2002;159(6):895–908, with permission.)

Although all of these hypotheses have informed clinical practice and guided a surge of research into the neuroscience of social dysfunction in autism, challenges remain in tying these primarily descriptive findings to specific mechanisms of pathogenesis and pathobiology. Critically, there is still a vast gap between advances in molecular genetics research, which has implicated hundreds of genetic variants in the etiology of autism, and the still limited understanding of the developmental unfolding of autism symptoms in the first 2 years of life. The next generation of studies is likely to advance gene–brain–behavior research by probing specific brain systems known to be affected in autism via coregistration measurements of genetic and epigenetic liabilities and of their instantiation as behavioral or brain endophenotypes.

One of the most fascinating cognitive phenomenon in autism is the presence of so-called islets of special abilities or splinter skills, which are preserved or very highly developed skills in specific areas that contrast with the child's overall deficits in cognitive functioning. It is not unusual, for example, for children with autism to have great facility in decoding letters and numbers, at times precociously (hyperlexia), although comprehension of what is read is much impaired. Perhaps as many as 10 percent of individuals with autism exhibit a form of "savant" skill, that is, high, sometimes prodigious performance on a specific skill in the presence of mild or moderate intellectual disability. This fascinating phenomenon usually relates to a narrow range of capacities—memorizing lists or trivial information, calendar calculation, visual–spatial skills such as drawing, musical skills involving a perfect pitch or playing a piece of music after hearing it only once. Interestingly, individuals with autism represent a disproportionate majority of all savant persons. Individuals with normative or gifted IQs often display highly circumscribed interests, typically expressed in memorization of vast amounts of factual information. Such narrow interests can interfere with learning more generally and can also result in a one-sided, nonreciprocal style of communication with others.

MOTOR AND SENSORY ABNORMALITIES. One of the prototypical aspects of autism is the display of motor stereotypies such as hand flapping, body rocking, finger twiddling, or waving in front of the eyes, as well as other repetitive and purposeless motor mannerisms such as toe walking and the assumption of odd postures. Stereotypies are also seen in other conditions, particularly severe intellectual disability and sensory impairments such as blindness and deafness, but are clearly more common in autism, often emerging around the ages of 3 or 4 although more subtle expressions have been reported as early as the second year of life. They often decrease in adolescence and adulthood, and are less common in individuals with

normative levels of intellectual functioning. Some children with autism may copy other people's motor movements (echopraxia) without necessarily learning the purpose of that movement. This is, to some extent, the motor equivalent of echolalia. Normative motor skills are usually preserved relative to the child's intellectual level, although this may not be the case over time, as the social aspects of motor activity become more important as the child becomes older. In fact, older and higher-functioning individuals are often perceived as motorically "clumsy" or awkward. Over activity is common in autism, particularly in the preschool years. At the same time, a lack of curiosity in the environment and passivity or hypoactivity, may also be observed in children with autism. The two may alternate for the same child in different settings or in relation to different activities. Task engagement and attention are important considerations in educational programming.

Both hypo- and hypersensitivity to sensory stimuli are typical of children with autism as they are in other developmental disorders. Children with autism may be acutely sensitive to some sounds (hyperacusis); they may, for example, cover their ears when hearing a dog bark or the noise of a vacuum cleaner. Other children may appear oblivious to some loud noises or to people calling them, and yet may be fascinated by the faint ticking of a wristwatch or the sound of crumpling paper. Bright lights may be distressing, although some children are fascinated by light stimulation and may, for example, move an object back and forth in front of their eyes. There may be extreme sensitivity to touch (tactile defensiveness), including major reactions to specific fabrics or social or affectional touch, and yet many children appear insensitive to pain and may not cry after a severe injury. There is often a fascination with certain sensory stimuli, such as spinning objects or toy parts that can spin, and some children enjoy vestibular sensations such as twirling, engaging in this action without apparently becoming dizzy.

Physical Characteristics

With autism, there is a higher incidence of minor physical anomalies such as ear malformations. Such anomalies may reflect the embryological period in which the factors responsible for autism act, for example, ears are formed at around the same time as older regions of the brain develop. However, most young children with autism are often described as attractive and do not exhibit any forms of stigmata. Physical attractiveness may diminish in adolescence and adulthood, as the various disabilities and unusual behaviors have an impact on physical appearance. A significant number of toddlers with autism develop macrocephaly.

Pathology and Laboratory Examination

Electroencephalography and Seizure Disorders. A variety of electroencephalographic (EEG) abnormalities may be seen in autism, including diffuse and focal spikes, paroxysmal spike-and-wave patterns, multifocal spike activity, and a mixed discharge. The incidence of EEG abnormalities in autism (in the absence of a clinical seizure disorder) ranges from 10 to 83 percent and depends on the number of recordings and the nature of the sample obtained (Fig. 44–4). The incidence of abnormal EEGs is significantly higher in mentally retarded autistic individuals. The finding of high incidence of EEG abnormalities and seizure disorders in autism was one of the first compelling pieces of evidence supporting a biological basis for the condition.

Both early and more recent studies on auditory brainstem–evoked potentials in autism indicate that if children with underlying neurological conditions are excluded and age and gender are controlled, there is no evidence for abnormalities in the auditory brainstem pathways. However, abnormalities of cognitive potentials, particularly the auditory P300 (which represents the brain's processing of sensory stimuli), have been shown to be abnormal in autism. This presumably reflects abnormalities in higher auditory processing and neural pathways. A growing body of research uses EEG to explore issues like recognition of faces with characteristic patterns observed in individuals with autism as compared to TDCs.

FIGURE 44–4. Rates of first seizure (incidence rate per 1,000) in samples of individuals with autism. (Data from cases with autism from Volkmar F, Nelson D. Seizure disorders in autism. *J Am Acad Child Adolesc Psychiatry*. 1990;29:127–129; and from cases with autism/pervasive developmental disorder from Deykin EY, MacMahon B. The incidence of seizures among children with autistic symptoms. *Am J Psychiatry*. 1979;136:1310–1312; as compared to rates in a normative sample from Cooper JE. Epilepsy in longitudinal survey of

5,000 children. *Br Med J*. 1965;1:1020–1022.)

The development of epilepsy in autism occurs in approximately 10 to 25 percent of the autistic population by young adulthood, based on the occurrence of readily identifiable major motor seizures. Although there is evidence of seizure onset at all ages, early childhood and adolescence have been reported to be the peak periods. Lower-functioning individuals are at increased risk. The onset of seizures may be associated with deterioration.

Neuroimaging Studies. As noted previously, a growing body of work has emerged on the neuroanatomical and neurophysiological substrates of autism using neuroimaging and other techniques. However, neuroimaging studies are not routinely needed as part of the evaluation of a child with potential autism in the absence of a specific indication.

Laboratory Studies. As indicated by history and examination various laboratory tests may be relevant as part of the assessment process. These include screening for conditions known to be more frequently associated with autism, for example, fragile X and tuberous sclerosis. Increasingly sophisticated genetic testing is also now available; indications are summarized in practice guidelines provided in the reference list. It should be noted that knowledge in this area is evolving rapidly and recommendations are frequently updated.

Differential Diagnosis

ASD must be differentiated from a range of other problems (some of which are, at times, associated with it). These include neurodevelopmental disorders such as intellectual deficiency or language–communication disorders. Visual and hearing impairments must also be considered. A variety of useful and well-developed instruments are available to aid in diagnosis—these include both parent interviews and direct assessment of the individual. It should be noted that some of these require extensive training and results should not replace clinical judgment. Selected instruments are summarized in Table 44–6.

In mild to moderate intellectual deficiency (mental retardation), social skills are usually consistent with abilities in the areas of cognition and communication. In individuals with severe and profound retardation, the frequency of both autism and autistic-like behaviors increases. A common source of diagnostic error is the confusion of stereotypies in such individuals. In higher-functioning individuals, there is potential confusion relative to those personality disorders that involve social isolation.

Table 44–6.
Summary of Selected Assessment Instruments for Autism Spectrum

Disorder

Scale (See Legend)	Uses	Age Range	Method of Administration	Population Studied	Scale Characteristics	References
ABC	Screening	Children	Teacher/parent	AD	57 items, scale 1–4	Krug et al., 1980
CARS II	Screening	3 to adult	Clinician rated	AD	15 items, severity ratings	Schopler & van Bourgondian, 2010

and treatment of children and adolescents with autism spectrum disorder. *J Am Acad Child Adolesc Psychiatry*. 2014;53(2):237–257.

In obtaining a history, the use of videotapes or other aids to memory may be helpful. It also may help if the parent is asked to recall the child at certain particular dates (e.g., third birthday). In most cases of autism, there is not a history of normal development, although in a small group of cases (20 to 25 percent), parents may report an apparent period of normal, or near-normal, development before either developmental stagnation or developmental regression. A careful review is indicated in these cases. Many times, some abnormality in development or behavior will have antedated parental concern. A history of clearly normal development raises the possibility of selective mutism, Rett syndrome, the DSM-IV childhood disintegrative disorder, language disorder, schizophrenia, and degenerative CNS disorders. Typically, children who have experienced severe neglect exhibit delayed or deviant social skills, but other features of autism are not present and the social deficits remit with appropriate care. In childhood-onset schizophrenia, there usually has been a long period (many years) of normal or near-normal development before the onset of characteristic delusions, hallucinations, and so forth. In some instances, the diagnosis can be clarified with certainty only over time.

John was the second of two children born to middle-class parents after normal pregnancy, labor, and delivery. As an infant, John appeared undemanding and relatively placid; motor development proceeded appropriately, but language development was delayed. Although his parents indicated that they were first concerned about his development when he was 18 months old and still not speaking, in retrospect, they noted that, in comparison to their previous child, he had seemed relatively uninterested in social interaction and the social games of infancy. Stranger anxiety had never really developed, and John did not exhibit differential attachment behaviors toward his parents. Their pediatrician initially reassured John's parents that he was a "late talker," but they continued to be concerned. Although John seemed to respond to some unusual sounds, the pediatrician obtained a hearing test when John was 24 months old. Levels of hearing appeared adequate for development of speech, and John was referred for developmental evaluation. At 24 months, motor skills were age appropriate, and John exhibited some nonverbal problem–solving skills close to age level. His language and social development, however, were severely delayed, and he was noted to be resistant to changes in routine and unusually sensitive to aspects of the inanimate environment. His play skills were quite limited, and he used play materials in unusual and idiosyncratic ways. His older sister had a history of some learning difficulties, but the family history was otherwise negative. A comprehensive medical evaluation revealed a normal EEG and computed tomography (CT) scan; genetic screening and chromosome analysis were normal as well.

John was enrolled in a special education program, in which he gradually began to speak. His speech was characterized by echolalia, extreme literalness, a monotonic voice quality, and pronoun reversal. He rarely used language in interaction and remained quite isolated. By school age, John had developed some evidence of differential attachments to family members; he also had developed a number of self-stimulatory behaviors and engaged in occasional periods of head banging. Extreme sensitivity to change continued. Intelligence testing revealed marked scatter, with a full-scale IQ in the moderately retarded range. As an adolescent, John's behavioral functioning deteriorated, and he developed a seizure disorder. Now an adult, he lives in a group home and attends a sheltered workshop. He has a rather passive interactional style but exhibits occasional outbursts of aggression and self-abuse.

Course and Prognosis

Autism is generally a lifelong disability, with most individuals needing significant family and community support. Although increasing claims for cure are reported (and indeed more individuals appear to be entering college and the work force), even in the most able individual, some social oddities persist. Changes in outcome likely reflect early diagnosis and intervention preventing or minimizing some of the barriers that ASD presents for typical learning. The first outcome studies were rather pessimistic regarding long-term outcome with perhaps 5 percent of cases achieving independence and self-sufficiency and two-thirds or more need high levels of intensive support. Over time these numbers have changed (as have diagnostic and intervention practices) but it is clear that more individuals are able to achieve adult self-sufficiency.

In other instances some support is needed in adulthood. Even in more cognitively challenged individuals, most will exhibit some improvement in social relatedness, communication, and self-help skills, and a major long-term goal should be used to facilitate acquisition of important adaptive skills, with the aim of maximizing the potential for independence.

Various factors predict long-term outcome. These include, in particular, the presence of some communicative speech by the age of 5 or 6 and higher nonverbal–intellectual level. Overall cognitive ability in the normal range is a positive prognostic sign. The relationship of severity of autistic symptomatology in early childhood to adult symptoms is somewhat less clear. With early intervention, some children make significant gains, whereas other children provided with such intervention may not. Several groups have now shown the potential for observable brain changes in response to treatment using EEG or fMRI response to social stimuli.

Gains in social compliance and communication are often made during elementary school years, particularly if structured, individualized, and intensive interventions are in place. During adolescence, some autistic children may exhibit behavioral deterioration; for a minority among these, the decline in language and social skills may be associated with the onset of a seizure disorder. Various interactional styles can be observed, ranging from aloof to passive to eccentric (e.g., children who make attempts to initiate contact with others but do so in a very awkward or rigid fashion). These styles are related to the developmental level. Depressive and anxiety symptoms may appear in higher-functioning adolescents, who become painfully aware of their inability to form friendships despite a desire to do so and begin to experience the cumulative effect of years of failed contact with others and teasing by peers.

Treatment

The goals of treatment for children with autism are to reduce disruptive behaviors and promote learning, particularly in the areas of language acquisition, communication, and self-help skills. These goals are best achieved based on a comprehensive assessment to determine a profile of strengths and needs, and an individualized and structured program is implemented by professionals experienced in working with children who are autistic. A recent review of several treatment studies highlighted the importance of intensive and early intervention in individual outcome. Treatment goals should be updated regularly, as different issues should be prioritized as a function of the child's rate and profile of progress and age (e.g., vocational training and independent living skills should be aggressively promoted in adolescence). Additionally, psychopharmacological treatments may be beneficial when specific indications are present.

Educational Approaches. Autistic children require intensive and highly structured special education from as early as the child is able to tolerate a school routine. Given the challenges involved in teaching children with autism, a classroom setting with a low student to teacher ratio is usually essential. For the more impaired children, a typical hierarchy of priorities should include the ability to: (1) tolerate individual adult guidance in performing tasks; (2) consistently follow a daily routine; (3) develop communication intent and communication means; and (4) move from associative to conceptual learning. Learning should take place in an environment that minimizes distractions (e.g., nearby windows, richly decorated walls). For the more challenged children, individual workstations and forceful adult intrusion may be necessary. The use of highly predictable and consistent routines is necessary to eventually promote the child's own internal sense of order, scheduling, and organization of experiences, thus promoting more systematic learning. Children with autism must be helped to generalize skills, for example, using new words acquired at home as well as in school. Both the ability to better predict impending activities and the ability to better express one's wishes and protests are usually beneficial in reducing frustration and associated disruptive behaviors. A number of well-established evidence-based treatment models are now available. These include approaches relying on applied behavior analysis (ABA), models using a more developmental approach (The Early Start Denver Model [ESDM]), hybrid approaches in which developmental models inform behavioral treatments as in pivotal response therapy, and eclectic approaches drawing on a range of intervention methods.

The focus of speech–language–communication therapy is on the use of words for the purpose of meaningful communication. Children with autism may acquire a considerable vocabulary that is dissociated from the act of

communication. Therefore, language acquisition should go hand in hand with the promotion of the child's intent to communicate with others. For this purpose, the focus of vocabulary expansion should be on words that are relevant to everyday life. Children who do not vocalize should be engaged in programs focused on alternative forms of communication, including signs, communication boards, or other forms of augmentative communication. The use of nonvocal forms of communication should not preclude the simultaneous use of words in children whose vocalizations are just emerging and for whom vocal communication is a realistic goal. For older or higher-functioning children, the core of the educational program should be an intensive focus on social and communication skills training. Positive actions in frequently troublesome situations may have to be rehearsed and scripted. Concrete social and communication skills—including eye gaze, voice modulation, gestural communication, posture, proximity, greeting behaviors, rules of conversation, and social expectations—may have to be taught in a very explicit fashion. The setting for the social and communication skills therapy may have to alternate between small group instruction (in which appropriate behaviors can be practiced and supportive feedback can be gained) and naturalistic settings (in which the newly acquired skill can be put to practice or additional problematic behaviors can be identified for practice in the small setting). Successful techniques used for this purpose include modeling of behaviors by an instructor, self-observation, role playing, and the use of individualized social stories. The advent of numerous computer interventions and applications adaptable to the individual's situation and levels of functioning are now available.

Behavior Therapy. This treatment, based on learning theory principles, uses behavior-modification techniques to establish desired behaviors and eliminate problem behaviors. Most educational programs for children with autism use behavioral management techniques, although they vary in terms of how integrated these procedures are in the comprehensive educational program. Such techniques can be particularly useful in the management of disruptive behaviors that impact on the child's ability to engage in remedial educational intervention. After a functional analysis of the target behavior is performed and patterns of reinforcement are identified, techniques such as shaping, prompting, and extinction are used to promote the desired behavioral alternative, which is then reinforced by increasingly mature rewards. Behavior therapy is also used for the facilitation of learning, including the promotion of early cognitive skills such as categorization and elicitation of vocalization and speech. It is clear that many children, although not all, will significantly benefit from behavior therapy; other forms of teaching can also be used particularly for more intellectually able children.

Psychotherapy. With the shift from a psychogenic to a biological understanding of autism, it became clear that psychodynamic psychotherapy and unstructured play therapies, in general, were not appropriate in the treatment of young children. Individual psychotherapy may be appropriate for higher-functioning individuals who may present with anxiety and depressive symptoms as they grow older and become more aware of their differences and difficulties relating to others. In these cases, psychotherapy should focus on rather explicit problem-solving skills rather than being insight oriented, with the goal to promote better adjustment and self-satisfaction. New approaches that include modified CBT specific to individuals with ASD should be considered.

Psychopharmacology. No pharmacological agent has proven curative, but certain medications may be of benefit with regard to specific symptoms although work is now ongoing on agents that might have this potential, for example, oxytocin. Such target symptoms may include self-injury, aggression, stereotyped movements, and over activity. Because individuals with autism are often enrolled in educational and behavioral programs, it may be possible to have staff participate (e.g., by collecting behavioral data that can be used to monitor effectiveness of the drug). As with all medications, the potential benefits and side effects should be considered (e.g., with the major tranquilizers, there is potential for over sedation, which can be mistaken for a positive therapeutic response). Before beginning drug treatment, baseline laboratory studies (tests of liver and renal function, electrocardiogram [ECG], urinalysis, blood count, weight, and blood pressure) should be conducted. Typically, an examination for abnormal movements is performed (typically using the Abnormal Involuntary Movement Scales [AIMS]).

MAJOR TRANQUILIZERS. Major tranquilizers have been the most extensively studied agents in autism. At relatively low doses, they may decrease stereotyped behaviors and agitation and may help the individual profit from remedial programming. Some data suggest that the combination of these agents with behavior therapy is more effective than either treatment alone. Side effects may limit the usefulness of these agents (e.g., sedation, withdrawal, and tardive dyskinesia). The higher-potency neuroleptics have often been used given the lower likelihood of sedation, although these agents do carry increased risk for dystonias. Recent interest has centered on the atypical neuroleptics, and these agents appear to offer considerable potential promise. A large double-blind, placebo-controlled study of one of these agents has shown significant benefit in reducing agitation and other problematic behavioral difficulties and risperidone (Risperdal) has now been approved for use in autism.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS. Several reports suggested the potential usefulness in autism and related conditions of the selective serotonin reuptake inhibitors (SSRIs). The potential use of such agents was suggested by the observation of higher peripheral serotonin levels in autism. In several controlled studies, these medications have proven superior to placebo relative to symptoms such as repetitive behaviors and impulsive aggression. There is a suggestion that seizure disorders may be exacerbated in some cases. Occasionally, children become agitated on these agents.

CLONIDINE. Given the apparently high levels of arousal in autism, use of clonidine (Catapres) was suggested. This agent, an α_2-adrenergic agonist, reduces noradrenergic activity. There may be a modest effect on activity levels, although sedation and hypotension can present serious side effects.

STIMULANTS. Individuals with autism, particularly school age children, may exhibit significant problems with attention that respond to traditional stimulant and related medications. Unfortunately the level of side effects is higher than in the regular ADD population.

OTHER AGENTS. Various other agents have been reported to sometimes be effective in treating at least some of the symptoms of autism. Such evidence is usually based on single case reports, and controlled studies are often lacking. Lithium is generally not clearly helpful unless there is a personal or family history of bipolar illness. Although the available data are limited, it appears that, in general, stimulants exacerbate behavioral difficulties in autism, probably acting through their effect on dopamine. β-Blockers have been used in several open trials concerned with reducing aggressive, self-injurious, and impulsive behaviors. These agents may act to decrease arousal levels, and positive responses have been noted, although the potential for serious side effects has limited their more general use.

Parents often are interested in alternative treatments, including diet and vitamin therapy, among others. Although the focus of much interest, substantive data are lacking. Usually, a single case report or uncontrolled study is reported, and tremendous enthusiasm follows, but controlled studies do not substantiate the claims made. This was recently observed for secretin, a gut peptide, which, in a series of double-blind, controlled studies, failed to offer significant improvement over placebo. Various somatic treatments have not proven clinically useful. In general, pursuit of unproven treatments should be avoided, particularly if they are pursued at the expense of educational and behavioral interventions that are known to be efficacious. In some instances, treatments that pose actual danger to the child have been proposed and, clearly, should be avoided. Given the relatively poor prognosis associated with autism, parents are easily attracted by treatments that propose a rapid cure. Parents should be

encouraged to pursue treatments with known efficacy.

SOCIAL (PRAGMATIC) COMMUNICATION DISORDER

Definition

This condition, newly recognized in DSM-5, is characterized by persistent difficulties in the use of social and nonverbal communication. The problems must be obvious in social contacts, include difficulties in matching the communication to the context or conversational partner, problems in following or conducting a conversation, and in understanding implicit meanings. These difficulties must appear in the developmental period, cannot be due to another condition, and must be the source of some functional limitation in effective social communication.

45 Attention-Deficit Disorders

▲ 45.1 Attention-Deficit/Hyperactivity Disorder

ALMA M. SPANIARDI, M.D., LAURENCE L. GREENHILL, M.D., AND LILY I. HECHTMAN, M.D.

INTRODUCTION

Attention-deficit/hyperactivity disorder (ADHD) is the most common childhood behavioral disorder diagnosed in outpatient settings in the United States. It is a chronic disorder which can cause impairment into adolescence and adulthood. In 2007, Polanczyk and colleagues estimated worldwide prevalence of ADHD in children and adolescents to be 5.29 percent using a comprehensive meta-analysis including hundreds of articles and more than 100,000 patients. Similarly, a meta-analysis from 2012 by Willicut using full DSM-IV diagnostic criteria found the prevalence of ADHD to be 5.9 to 7.1 percent. It has been suggested that the prevalence of ADHD is higher in males and younger children. The National Survey of Children's Health (NSCH), which showed that 11 percent of US school-aged children had been diagnosed with ADHD by 2011, an increase of 42 percent since the previous survey in 2003. It has been suggested that the increasing rates of diagnosis and treatment may be due to increased awareness and access to care as opposed to an increase in the number of children in the population meeting criteria for ADHD.

HISTORY

ADHD first was described by George Still in 1902, who wrote about children who were restless, impulsive, and inattentive, with intense affective responses and conduct problems. After the influenza pandemic and the epidemic of encephalitis lethargica in 1919 to 1920, children who survived the flu frequently developed severe behavior problems and are now thought to have suffered organic brain damage. For that reason, the childhood condition was termed "minimal brain damage syndrome," even though brain damage could not be proven. In the early 1960s, the condition was renamed "minimal brain dysfunction." Not only did these terms

postulate unproven etiological mechanisms, they were also stigmatizing. The ninth revision of the *International Classification of Diseases and Related Health Problems* (ICD-9) and the second edition of the DSM adopted the same descriptive term for the condition—hyperkinetic syndrome of childhood. The 1980 version of the APA classificatory system, DSM-III, renamed this diagnosis attention-deficit disorder (ADD) due to research suggesting that the main disability was the difficulty of maintaining sustained attention and impulsivity. Much of the diagnostic criteria for ADHD has remained the same between DSM-IV in 1994, the text revision, DSM-IV-TR in 2000, and the most recent version, DSM-5, released in May 2013.

DIAGNOSIS AND DEFINITION

The fifth edition of the American Psychiatric Association's (APA) *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5), published in May 2013, describes ADHD as a pattern of inattentive and/or hyperactive–impulsive behavior inconsistent with developmental level which interferes with functioning in social, educational, or work settings. Symptoms are divided into two categories: inattention and hyperactivity and impulsivity. There are five main diagnostic criteria: (1) onset before age 12 years old; (2) duration greater than 6 months; (3) children must have at least six symptoms from the inattention and/or hyperactive/impulsive symptom list, while older adolescents and adults must have at least five; (4) several symptoms must be present in two or more settings and interfere with functioning; and (5) symptoms that do not occur exclusively during the course of schizophrenia or other psychotic disorder and are not better accounted for by another mental disorder, such as depression. DSM-5 has no exclusion criteria for those with Autism Spectrum Disorder (ASD), allowing both Autism and ADHD to be diagnosed simultaneously in the same patient. Possible specifiers for the disorder in DSM-5 include combined presentation (criterion met for both inattention and hyperactivity–impulsivity), predominantly inattentive presentation or predominantly hyperactive/impulsive presentation. Other specifiers describe current severity of the disorder being mild (few to no symptoms in excess of those required), moderate or severe (many symptoms in excess of those required), or to specify if the disorder is in partial remission (fewer than full criteria met in past 6 months, but still result in impairment).

The inattention symptom criteria list includes: (a) Often fails to give close attention to details or makes careless mistakes in schoolwork, at work, or during other activities; (b) Often has difficulty sustaining attention in tasks or play activities; (c) Often does not seem to listen when spoken to directly; (d) Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace; (e) Often has

difficulty organizing tasks and activities; (f) Often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort; (g) Often loses things necessary for tasks or activities; (h) Often easily distracted by extraneous stimuli (or unrelated thoughts for adolescents and adults); and (i) Often forgetful in daily activities.

Hyperactivity and impulsivity symptoms criteria include: (a) Often fidgets with or taps hands or feet or squirms in seat; (b) Often leaves seat in situations when remaining seated is expected; (c) Often runs about or climbs in situations where it is inappropriate; (d) Often unable to play or engage in leisure activities quietly; (e) Often "on the go," acting as if "driven by a motor"; (f) Often talks excessively; (g) Often blurts out an answer before a question has been completed; (h) Often has difficulty waiting his or her turn; and (i) Often interrupts or intrudes on others.

In the DSM-5 enhanced item descriptors were added to diagnostic criteria to demonstrate symptoms across the lifespan. For example, motor hyperactivity appears far less frequently in affected adolescents and adults, who continue to have attentional and organizational problems, poor anger management, job instability, and problems with social relationships and self-esteem. All 18 of the DSM-IV-TR symptoms of ADHD were retained in the DSM-5, but enhanced elaborators of each were added to better describe difficulties experienced by adolescents and adults. For instance, the inattention criteria "Often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort" now includes specific examples of this symptom "(preparing reports, completing forms, reviewing lengthy papers)" to be applied to older adolescents and adults in addition to "(schoolwork or homework)" which is primarily specific to children.

Concerns about Changes in DSM-5

DSM-5 addresses limitations in the prior edition. There is a concern that the decision in DSM-5 to increase the age of onset allowed for diagnosis from 7 years old to 12 years old may inflate the prevalence of positive diagnoses in adults. The onset criterion of age 7 used in three prior editions of the DSM lacked empirical validation. The aim of the 5-year extension in upper age limit for diagnosis was to improve diagnosis of adults, while still maintaining ADHD as a neurodevelopmental disorder with childhood onset. However, there is concern that the prevalence of ADHD will increase as a result, especially in older children, adolescents, and adults (McKeown et al., 2015). The prevalence rate may also increase in individuals with inattentive subtype, as inattention has been found to have a later onset. A recent study by Matte et al. has suggested a 27 percent increase in the expected prevalence of ADHD among young adults when comparing DSM-IV to DSM-5 criteria while Polanczyk et al. found that the age adjustment to 12 would have minimal impact.

COMPARATIVE NOSOLOGY

Clinicians in Europe use a very different diagnostic description of ADHD than that in the DSM-5: The ICD-10 diagnosis of "hyperkinetic disorder (HD)." The differences include the extent to which medication should be used and the algorithm used to diagnose the disorder. The DSM-5 diagnosis of ADHD and the ICD-10 diagnosis of HD are based on the same 18 symptoms, but the two systems use different decision rules. Fewer children are classified with ADHD using ICD-10 than in DSM-IV. For example, investigators in the United Kingdom applied an algorithm to the 579 children with DSM-IV ADHD Combined Subtype who had been recruited into the National Institute of Mental Health (NIMH) Multimodal Treatment Study of Attention-Deficit/Hyperactivity Disorder (MTA trial) in order to generate an ICD-10 diagnosis of HD. Only 25 percent of the MTA sample continued to meet the diagnostic criteria for HD. This suggests that cultural differences in referral practices and clinician preferences play a role in determining international differences in diagnoses of ADHD and HD.

ETIOLOGY

ADHD is a complex disorder of multifactorial etiology, thought to have multiple genetic and environmental variables of small effect acting together to produce vulnerability to ADHD. Although the etiology of ADHD yet has to be determined, there is a growing consensus that the condition involves functional and anatomical dysfunction in the brain's cortico-basal ganglia-thalamo-cortical circuitry. These areas support the regulation of attentional resources, the programming of complex motor behaviors, and the learning of responses to reinforcement. Theories involving these areas have been examined in series involving neurobiological studies of healthy humans, humans with ADHD, and animal models.

Genetics

Twin, sibling, adoption, and family studies all suggest a strong genetic component in the development of hyperactivity, inattention, and impulsivity, with heritability index estimated to range from 0.6 to 0.98. Heritability estimates include both genetic influences, as well as the effects of gene–environment interaction. ADHD-like behaviors have been reported in rare genetic disorders such as fragile X syndrome, neurofibromatosis type 1, DiGeorge syndrome, tuberous sclerosis, Turner syndrome, Williams syndrome, Angelman and Prader-Willi.

Twin Studies. Twin studies suggest that 76 percent of the variance in the transmission of ADHD is attributable to genetics, making ADHD one of the most heritable psychiatric disorders. Monozygotic twins have been

found to be more concordant for ADHD symptoms of hyperactivity, inattention, and impulsivity than are same-sex dizygotic twins. The concordance rate among monozygotic twins ranges from 59 to 92 percent, whereas the concordance rate in dizygotic twins ranges from 29 to 42 percent.

Sibling and Half-Sibling Studies. MRI studies have found reduced volumes in right prefrontal gray matter and left occipital gray and white matter in both ADHD subjects and their unaffected siblings. An early study compared the incidence of ADHD symptoms in 29 full-sibling and 22 half-sibling pairs for evidence of minimal brain dysfunction. Each pair had been raised together by a common mother. More than half (10) of the 19 full-sib pairs were concordant for ADHD, compared with only 2 of the 22 half-sib pairs, a significant difference, supporting the genetic influence on the transmission of ADHD in families.

Adoption Studies. Studies have found that the biological relatives of hyperactive children are more likely to be hyperactive themselves. This relationship is not seen in adoptive relatives of hyperactive children. Adoptive relatives of children with ADHD have risk of ADHD similar to relatives of control children, while the biological relatives of children with ADHD are more likely to have ADHD or associated disorders. In a study of international adoptees aged 10 to 15 years, Van den Oord and colleagues estimated that genes accounted for 47 percent of the variance of inattention scores on the Child Behavior Checklist. Eighteen percent of biological relatives of adopted-away children with ADHD were found to be at risk for the disorder versus 6 percent of the child's adopted relatives.

Family Studies. Family studies have shown that first-degree relatives of children with ADHD are two to eight times more likely to have the disorder. First-degree relatives of children with ADHD have a 20 to 25 percent risk for ADHD, compared with 4 to 5 percent for relatives of controls. If a parent has ADHD, 50 percent of his or her offspring are likely to have that condition. The increased incidence of ADHD is also extended to second-degree relatives.

Mode of Inheritance. Several hypotheses of ADHD's mode of transmission have been advanced. Omenn explored the possibility of sex-linked transmission because of the male preponderance in the condition. Other theories include a polygenetic inheritance model, including those of Morrison and Stewart, but limitations in sample size made this hard to prove. Rhee and colleagues postulated a polygenetic multiple threshold model after analyzing sex differences in an Australian twin and sibling-pair study. However, differences in fit between genetic models were modest, as

is true for comparisons of multifactorial and single-gene inheritance. This led to the suggestion that symptoms of ADHD may be caused by several interacting genes of modest effect. This hypothesis is consistent with ADHD's high population prevalence and high concordance in monozygotic twins, but modest recurrence risk for first-degree relatives. However, diagnostic uncertainty impedes progress in developing genetic models of inheritance.

Molecular Genetic Studies. There has been increasing interest in attempting to identify the specific "risk" genes that may be implicated in the development of ADHD. This search has yielded generally inconsistent results due to complexity of the trait and heterogeneity across studies. Candidate genes have been chosen for study based on theoretical considerations related to their function and the majority of studies have concentrated on dopamine-related genes given the implication of dopamine dysfunction in ADHD. Candidate genes discovered so far are responsible for less than 5 percent of genetic variation in ADHD. Genome-wide association studies (GWAS) of ADHD have not yet revealed any genome-wide significant association to common variation, indicating that the effect sizes of risk variants are likely very small.

The dopamine transporter gene (DAT1) codes for a sodium-dependent dopamine transporter protein that regulates reuptake of dopamine from the synaptic cleft. Cook et al. were the first to show an association between ADHD and DAT1 with 480–base-pair allele. Several studies have indicated that DAT1 might be more strongly associated with the hyperactive/impulsive or combined subtypes of ADHD. Another early gene studied was the dopamine type D2 receptor gene (DRD2). The gene is not specific to ADHD and is not believed to be a primary cause of the disorder. The dopamine 4 receptor seven-repeat allele gene (DRD4) has been linked to novelty seeking and connected to the impulsivity seen in ADHD. DRD4 has also been related to the inattentive subtype of ADHD. The synaptosomal-associated protein 25 gene (SNAP25) codes for a protein involved in neurotransmitter regulation and axonal growth. McGough et al. found an association between SNAP25 and sensitivity to methylphenidate (MPH) adverse events in preschoolers with ADHD. Genes that code for dopamine β-hydroxylase (DBH), catechol-O-methyltransferase (COMT), dopamine 5 receptor gene, norepinephrine transporter gene (SLC6A2), serotonin transporter gene (SLC6A4), α-2A adrenergic receptor (ADRA2A), thyroid receptor B gene, androgen receptors and factors in immune function and regulation have also been reported to correlate with ADHD symptoms. Subsequent studies and meta-analysis have not sufficiently supported the association between ADHD and these genes.

Neuroanatomical Aspects

Investigators have postulated the presence of an anterior attention network for promoting multiple aspects of attention, including focusing, executing, sustaining, and shifting functions. The attention networks are widespread through the cortex of the brain and are closely related to the default mode network described by Castellanos and others. MRI studies suggest that there are structural abnormalities in the brains of children with ADHD, including differences in the frontostriatal areas, temporoparietal lobes, cerebellum, basal ganglia, corpus callosum, amygdala, hippocampus, and thalamus. A meta-analysis of voxel-based morphometric (VBM) studies by Nakao and colleagues of children and adults with ADHD found global reductions in gray matter volumes, especially the right lentiform nucleus extending to the caudate nucleus, with slightly larger gray matter volumes in the left posterior cingulate cortex. These areas were demonstrated to normalize with age as well as with stimulant medication treatment. Developmentally, children with ADHD have a 3- to 5-year delay in cortical thickness maturation, particularly in the frontal and temporal brain regions. Diffusion tensor imaging (DTI) studies show white matter tract abnormalities and dysfunctional connectivity in ADHD during rest and while engaging in cognitive tasks.

Deficits in neural activity within frontostriatal and frontoparietal circuits are consistent findings in ADHD. fMRI studies using cognitive tasks to target the neural circuits show significantly reduced frontal lobe activity in subjects with ADHD compared to controls. Meta-analysis shows hypoactivation in the frontoparietal and ventral attention networks in children with ADHD, areas which control goal-directed executive processes and decision making. Hart and colleagues found that right dorsolateral prefrontal cortex activation was reduced in medication-naive patients, but normal in long-term stimulant-medicated patients. Electroencephalography (EEG) studies have reported an elevated theta/beta ratio (TBR) in subjects with ADHD versus controls, however, increased theta band activity has also been associated with substance use and bipolar disorder. Recent meta-analysis determined that excess theta and elevated TBR was not a reliable diagnostic measure for ADHD, but could have prognostic value for treatment outcome.

Neurotransmitters in ADHD

The nonspecific catecholamine hypothesis of ADHD posits that the psychophysiology of ADHD symptomatology emerges from an imbalance among various neurotransmitters, including norepinephrine, epinephrine, and dopamine. Human studies investigating the catecholamine hypothesis of ADHD produced conflicting results, possibly due to the difficulty of measuring brain levels of these neurotransmitters in peripherally obtained samples.

Dysfunction in brain norepinephrine systems, particularly a lack of

inhibition of locus coeruleus neurons, could explain the inattention, cognitive deficits, and higher levels of gross motor activity seen in children with ADHD. Randomized clinical trials (RCTs) have suggested that the norepinephrine reuptake inhibitors (NRIs), tricyclic antidepressants (TCAs) and atomoxetine, are effective in reducing ADHD symptoms by restoring a more normal ratio of epinephrine and norepinephrine. Molecular genetic studies have targeted genes that code for dopamine receptors and PET scans in adults with ADHD have provided imaging data that correlate stimulant-driven increases in dopamine concentration. There is weak evidence for serotonin's role in ADHD. Medications that exclusively affect serotonin function, such as the selective serotonin reuptake inhibitors (SSRIs), have no efficacy in the treatment of children with ADHD. For that reason, serotonin is thought to play a secondary role in the pathology of ADHD.

Environmental Factors

ADHD has been associated with numerous environmental factors, although it is difficult to conclusively determine causality. In utero risk factors include prenatal exposure to alcohol, nicotine, recreational drugs, glucocorticoids, the toxins hexachlorobenzene and polychlorinated biphenyls (PCBs), poor maternal diet and maternal stress during pregnancy. Perinatal ADHD risks include prematurity, low birth weight, and obstetric complications. ADHD has been associated with childhood illnesses such as meningitis, encephalitis, cardiac disease, thyroid disease, epilepsy, head trauma, and autoimmune and metabolic disorders. High blood lead levels have also been linked with ADHD diagnosis, however, this is likely not a major factor in the disorder. Psychosocial adversity including poverty, childhood maltreatment, negative parenting, family discord, and bullying have all been associated with ADHD. It has been difficult for investigators working with children affected by adversity to determine whether their ADHD symptoms reflect a response to negative parenting, a harsh environment, a genetically influenced biological problem, or some interaction among these factors.

Dietary Influences. Dietary factors as a cause and possible treatment of ADHD are controversial. There have been reports of a connection between ADHD and nutritional deficiencies of iron, zinc, and essential fatty acids (omega-3 and omega-6), but the beneficial effects of supplementation are inconclusive. Some studies have indicated that a small subset of children may have sensitivity to certain foods, additives, excess sugar or nutritional deficiencies, causing behavioral effects. There has been some support for elimination diets to treat ADHD, such as the Feingold (additive and salicylate-free) diet, oligoantigenic (hypoallergenic) diet, and ketogenic diet. In 2011, the U.S. Food and Drug Administration determined that

existing data do not support a causal link between additives and behavioral disturbance in children.

DIAGNOSIS AND CLINICAL FEATURES

The diagnosis of ADHD requires the integration of data from multiple sources, including clinical interview, direct observation, behavioral rating scales, and the subjective observations of parents and teachers. Most children with ADHD are referred for care because of impairment in academic, family, and/or peer relationship functioning. Symptoms of impulsivity, overactivity, and inattention drive this impairment across the lifespan.

Clinical Features

DSM-5 Diagnostic Criteria. DSM-5 diagnostic criteria for ADHD defines three types of presentations based on two criteria lists of nine symptoms of inattention and nine symptoms of hyperactivity/impulsivity. Children with six or more symptoms of inattention and fewer than six symptoms of hyperactivity–impulsivity are diagnosed with ADHD predominantly inattentive presentation, while those with six or more symptoms of hyperactivity/impulsivity and fewer than six symptoms of inattention meet criteria for ADHD predominantly hyperactive/impulsive presentation. ADHD combined presentation is diagnosed if full criteria from both lists are met. Older adolescents and adults require only five symptoms from either (or both) of the two criteria lists. For formal diagnosis of ADHD it is necessary for symptoms be present prior to age 12, persist for at least 6 months, have a negative impact on social, academic, or occupational activities and be present in two or more settings. The diagnosis is not appropriate if the symptoms occur exclusively during the course of another primary psychotic, mood, anxiety, or substance or personality disorder, but ADHD may coexist with pervasive developmental disorder. DSM-5 has included expanded item descriptors of symptoms to better represent the experience of adolescents and adults of ADHD across the lifespan. There are specifiers available to indicate severity of the disorder as mild, moderate, or severe.

Hyperactivity. Hyperactivity describes the inappropriate excessive motor activity observed in ADHD, including restlessness, fidgeting, and appearing to be “driven by a motor.” These behaviors are often first noticed when the child is a toddler, but can be normative before age 4. The level of gross motor activity usually decreases with age, however, the inner sense of restlessness may continue into young adult life. Children with ADHD display sustained levels of high activity in different settings such as home, school, and playgroup. Activity increases occur during sleep as well.

Hyperactivity may be absent in novel situations or when child is engaged in an activity they find particularly engrossing such as playing videogames.

Impulsivity. Impulsive actions occur without forethought about consequences and may be associated with desire for immediate rewards or to avoid delay. Impulsivity might be seen when the child engages in dangerous activities, yells out in class, or interrupts or intrudes on others during games or conversations. Impulsive behavior might also result in trouble with parents, teachers, or other children, including verbal or physical fights. Children with ADHD can demonstrate overly quick and error-prone performance on standardized tasks. Symptoms of impulsivity can persist into adulthood, even after hyperactive symptoms have diminished.

Attentional Difficulties. Inattention includes difficulty sustaining focus, trouble maintaining organization, and being easily distracted by extraneous stimuli. The symptoms of inattention often become prominent in elementary school when the child is approximately 8 to 9 years old and symptoms can be lifelong. Attentional difficulties are most often seen in routine settings in which the youth with ADHD must sit and carry out tasks that involve repetition under conditions of low levels of reinforcement and external motivation. Sluggish Cognitive Tempo (SCT) is a type of attentional difficulty that has been closely associated with the inattentive subtype of ADHD. SCT describes a constellation of symptoms such as daydreaming, staring, tendency toward confusion, mental fogginess, sleepiness, apathy, and physical hypoactivity. There is growing evidence suggesting that SCT is a condition distinct from ADHD, however, SCT is currently not considered a separate disorder or diagnostic subtype.

Associated Factors. Children with ADHD might have areas of impairment that are not listed under the DSM-5 symptom criteria covered exactly by the 18 symptom exemplars of hyperactivity, impulsivity, or inattention. Children and adolescents with ADHD often show difficulty with time management and do not develop an internal sense of pace in planning tasks. This poor sense of time leads to problems in estimating the actual difficulty of waiting in line, planning how much time a task requires, or even knowing when to come home when out playing with other children. Children with ADHD often lack persistence and can become bored playing interactive games with peers. They also find it difficult to delay gratification.

Neuropsychological testing has found that individuals with ADHD demonstrate impaired executive functioning including abnormal response inhibition. On any given measure of executive function, less than half of children with ADHD have been found to be impaired. Executive

functioning problems also occur in other psychiatric disorders of childhood, such as depression, and are not specific to ADHD. It has been shown that academic functioning is more strongly affected by an impulsive need to get through tests quickly, a deficit closely linked to poor behavioral inhibition, rather than poor executive functioning.

ADHD is often associated with problems in emotion regulation, resulting in temper outbursts, mood lability, and reactivity. Moods can change dramatically with no obvious connection with what is going on in the environment. Social skills are often significantly impaired in children with ADHD compared to controls. Individuals with ADHD may have problems accurately interpreting nonverbal social cues and have trouble cooperating with other children and following rules in games. Peers identify these individuals as intrusive, bossy, and insensitive to the needs of others. Children with ADHD often overreact and respond to frustration in social situations which can lead to verbal or physical aggression. This is a strong stimulus for peer rejection, which has been shown to be a reliable long-term negative predictor of development, particularly in adolescence.

MEDICAL AND LABORATORY EXAMINATION

Children with ADHD should be given a medical evaluation, including a thorough history and physical examination, to rule out physical disorders that can mimic the symptoms of ADHD. The medical history should cover the prenatal, perinatal, toddler, and preschool phases of development. Inquiries should be made about pregnancy complications, such as maternal illness (eclampsia, diabetes), maternal smoking, alcohol, or illicit drug use. The perinatal period should identify the presence of labor problems, delivery complications, prematurity, jaundice, and low birth weight. Feeding and sleeping routines during the perinatal and postnatal periods need to be described. Developmental milestones, illnesses, injuries, and symptomatology need to be reviewed. A detailed family, medical, and psychiatric history should be completed.

The medical examination can identify physical problems (such as arrhythmia, tachycardia, or hypertension) that can increase the risk of serious adverse events should a stimulant medication treatment be initiated. Height and weight at baseline should be recorded. Physical examination of a child with ADHD may reveal nonlocalizing neurological signs, such as poor coordination, dysrhythmias, and overflow movements. Medical problems that might aid in the differential diagnosis, such as petit mal epilepsy, hearing and vision difficulty, thyroid dysfunction, and hypoglycemia, all need to be ruled out. There are no blood, genetic, or neuroimaging tests available to diagnose ADHD.

RATING SCALES

Many standardized behavioral rating scales for ADHD have been

developed. Rating scales should not be used independently to diagnose ADHD, but can be particularly helpful in establishing the presence of core ADHD symptoms in more than one setting. ADHD-specific scales have been found to have greater than 90 percent sensitivity and specificity if used in the correct population. Commonly used rating scales for ADHD include Conners Rating Scales for parents (CPRS-R) and teachers (CTRS-R), Conners Wells Adolescent Self-Report Scale, Vanderbilt ADHD Diagnostic Parent and Teacher Scales, Swanson, Nolan and Pelham (SNAP-IV), and Brown ADD Rating Scales for Children, Adolescents, and Adults. Only the Conners Comprehensive Behavior Rating Scales and the ADHD Rating Scale IV have been validated in preschool-aged children.

DIFFERENTIAL DIAGNOSIS

A clinician must make a differential diagnosis when judging whether a patient meets criteria for ADHD. The distinction between differential diagnosis and comorbidity is not well defined in the DSM-5. If the impairing condition is best accounted for by another disorder, that other disorder rules out ADHD. For children with intellectual disability, inattention may be a natural accompaniment of the intellectual limitations, so the diagnosis of ADHD should only be applied if that symptom is excessive for the mental age of the child. Children from chaotic, disorganized, or inadequate home environments may also show symptoms of overactivity or inattention. The symptoms of children with oppositional defiant behavior must be distinguished from the reluctance and resistance that children with ADHD exhibit when they avoid effortful mental tasks. Symptoms of impulsivity, gross motor hyperactivity, or inattention may appear during the use of medications, such as the akathisia that accompanies second-generation antipsychotics or from bronchodilators. Such children should not receive a diagnosis of ADHD, but one of Other Substance-Related Disorder.

COURSE AND PROGNOSIS

Parents often notice very high levels of gross motor activity when the child with ADHD is a toddler, just when the child has learned to walk independent of the parent's help. However, the energy, oppositionality, and curiosity of toddlers can be confused with the excessive, almost random motion of older children with ADHD, so that one must be cautious when applying the ADHD diagnosis to a preschooler. Usually, the ADHD diagnosis is first applied in primary school, during grades 1 to 6, when adjustment to the sedentary learning style is compromised. Thus the school-aged child often experiences academic failure and peer rejection. Behavior problems at school and at home are not infrequent with oppositional defiant disorder (ODD) being a common comorbidity.

In childhood 65 to 75 percent of children with ADHD have one or more

comorbid conditions, which in addition to ODD, can include conduct disorder (CD), anxiety and mood disorders, tics or Tourette syndrome, learning disorders, and autistic spectrum disorders. Many of these comorbidities continue into adolescence.

In adolescents, the external overactivity lessens but the internal restlessness does not. The adolescent with ADHD continues to have academic and social problems, which erode his/her self-esteem and at times promote the gravitation to a negative peer group. Thus, adolescents with ADHD who are untreated, compared to peers with no mental disorder, have a threefold increase in substance use and abuse, more frequent delinquent acts and trouble with the law, and increased rates of car accidents when they begin to drive. Adolescents with ADHD also start sexual intercourse earlier with a higher number of sexual partners and greater frequency of unprotected sex with corresponding higher rates of sexually transmitted diseases and unwanted pregnancy. The rate of depression and anxiety also increases in adolescence because of the many functional problems.

Approximately 60 percent of children with ADHD continue to be impaired well into adult life with prevalence estimates suggesting that 4 percent of adults may suffer from ADHD. In adulthood, hyperactivity may be expressed by inner feelings of restlessness, inability to relax and excess talkativeness, fidgeting, and inability to remain seated for long periods of time, for example, meetings, symposia, church. Impulsivity may be expressed in impatience, interrupting others, acting without thinking, ending or starting ventures on impulse, for example, jobs, relationships, and at times sensation-seeking behavior.

Inattention is seen in distractibility, disorganization, chronic lateness, or missing appointments. The distraction and disorganization often results in careless mistakes and forgetfulness. Procrastination is another important problem. Even when things are started, they are often not finished and so deadlines are thus missed.

The inattention and distractibility also make it appear that the adult with ADHD is not interested and not listening to what is being said. This can strain relationships at home and at work. Some adults with ADHD also suffer from labile moods and “short fuses.” These characteristics coupled with the problems described above result in more frequent losses of jobs and relationships. The consequences of this are lower job status and lower income and a sense of underachievement or failure on the part of the adult with ADHD. The inattentiveness and impulsivity also increases the likelihood of driving accidents and infractions, other types of accidents are also more prevalent. Generally, adults with ADHD may have an unhealthy lifestyle, with smoking, alcohol, and drug abuse risky sexual behavior, and chronic sleep problems frequently seen.

In adulthood, comorbidity is the rule, with more than 75 percent of

adults with ADHD having at least one comorbid condition. Anxiety, depression, substance abuse, and some personality disorders are the most common comorbidities. Gambling and other addictions are also frequently seen.

It should be noted that even though the male/female ratio in children with ADHD can be 3–4:1, in adulthood it is 1:1. It is possible that many girls who tend to be less disruptive are not identified or referred in childhood but have significant impairment as adults and seek help then.

TREATMENT OF ADHD

The efficacy of both medication and psychosocial interventions for the treatment of ADHD has been well established. The preferences of families and availability of services largely guide the choice of treatment.

Stimulants

Stimulants are considered first-line agents to treat ADHD symptoms based on decades of proven safety and efficacy. Therapeutic effects of stimulants include a decrease of hyperactivity, impulsivity, and inattention, as well as improvement in associated behaviors. The two groups of stimulant medication that have received U.S. Food and Drug Administration (FDA) approval for the treatment of youth with ADHD are amphetamines and MPHs. Many stimulants are available in both generic and branded versions. Stimulants are classified with drugs that can be abused or cause dependency under the category of schedule II controlled substances by the United States Drug Enforcement Agency (DEA) (Table 45.1–1).

Pharmacology and Pharmacokinetics. Both MPH and amphetamine can be described as psychostimulants, which refers to their ability to increase central nervous system activity in brain regions and increase blood pressure and pulse in the periphery. Although the exact mechanism of action is not completely understood, stimulants increase the concentration of dopamine and norepinephrine in the synaptic cleft. MPH appears to act primarily as a dopamine–norepinephrine reuptake inhibitor, while amphetamines block the reuptake of both norepinephrine and dopamine as well as facilitate dopamine release through reverse transport. Berridge et al. showed—during in vivo microdialysis in rodents—that low-dose MPH substantially increased norepinephrine and dopamine reflux within the prefrontal cortex (PFC) while enhancing PFC-dependent cognitive functioning.

Table 45.1–1.
Stimulant Drugs, Doses, and Pharmacodynamics

| | | |

Medication	Forms	Pediatric Dose, Start/Typical	Effect (hours)	Duration of Action (hours)
Dexmethylphenidate				
Short-acting	2.5-, 5-, 10-mg tabs	2.5 mg AM/10 mg b.i.d.	1–4	5–6
Long-acting	5-, 10-, 15-, 20-, 25-, 30-, 35-, 40-mg caps[a]	5 mg AM/10 mg AM	1–4	12
Dextroamphetamine				
Short-acting	2.5-, 5-, 7.5-, 10-, 15-, 20-, 30-mg tabs, 5 mg/5 mL[b] oral solution	5 mg b.i.d./10 mg b.i.d.	1–3	4–6
Long-acting	5-, 10-, 15-mg caps[c]	5 mg AM/15 mg AM	1–4	6–8
	20-, 30-, 40-, 50-, 60-, 70-mg caps[d]	30 mg AM/70 mg AM	2–3	up to 12
Methylphenidate				
Short-acting	5-, 10-, 20-mg tabs[e]	5 mg b.i.d./10 mg t.i.d.	1–3	3–5
	2.5-, 5-, 10-mg chewable tablets[e]	5 mg b.i.d./10 mg t.i.d.	1–2	3–5
	5 mg/5 mL, 10 mg/5 mL[e] oral solution	5 mg b.i.d./10 mg t.i.d.	3–3	3–5
Immediate-acting	10-, 20-mg[f]	10 mg b.i.d./30 mg AM	3	3–8
Long-acting	10-, 15-, 20-, 30-, 40-, 50-, 60-mg tabs/caps[g]	10 mg AM/30 mg AM	5	8–12
	18-, 27-, 36-, 54-mg tabs[h]	18 mg AM/36 mg AM	8	10–12
	10-, 15-, 20-, 30-mg transdermal patch[i]	10-mg patch on 9 hours, off 15 hours 30-mg patch on 9 hours, off 15 hours	7–9	10–12
	5 mg/5 mL oral solution[j]	20 mg AM	5	10–12
	20-, 30-, 40-mg chewable tabs			up to 13
Mixed salts of amphetamine				
Short-acting	5-, 7.5-, 10-, 12.5-, 15-, 20-, 30-mg tabs[k]	5 mg b.i.d./10 mg b.i.d.	1–3	4–6
Long-acting	5-, 10-, 15-, 20-, 25-, 30-mg caps[k]	5 mg AM/30 mg AM	1–4	8–10
	3.1-, 6.3-, 9.4-, 12.5-, 15.7-, 18.8-mg orally disintegrating tabs[l]	6.3 mg AM/18.8 mg AM	5	8–10
	2.5 mg/mL oral suspension[m]	2.5 mg AM/20 mg AM	3.9	up to 13

b.i.d., twice daily; t.i.d., thrice daily.

[a]Focalin, Focalin XR; [b]Dexedrine, Zenzedi, ProCentra solution; [c]Dexedrine Spansule; [d]Vyvanse (Lisdexamfetamine); [e]Ritalin, Methylin chewable, Methylin oral suspension; [f]Metadate ER; [g]Metadate CD, Ritalin LA, Aptensio XR; [h]Concerta; [i]Daytrana. The four patch sizes deliver 10-, 15-, 20-, and 30- mg over 9 hours, respectively, supplied in sealed trays containing 10 to 30 patches in individual pouches.; [j]Quillichew ER, Quillivant XR oral solution; [k]Adderall and Adderall XR; [l]Adzenys XR-ODT; [m]Dyanavel XR.

FORMULATIONS

The racemic form of MPH is d,l-threo-methylphenidate, with d-threo-methylphenidate (d-MPH) being the more active isomer. Both racemic MPH (including Ritalin, Metadate, and Methylin) and the monoisomer d-MPH (Focalin) are commercial products. MPH is available in immediate-release tablet, chewable and liquid formulations.

Extended-release MPH is available in many different preparations. It is manufactured using beaded technology, consisting of both immediate- and delayed-release beads which are equivalent to two doses of immediate-release medication given 4 hours apart. The beads can be sprinkled on food for children who have difficulty with swallowing pills. MPH is also available as a transdermal patch (Daytrana), which has onset of action of 60 minutes and can be worn up to 9 hours per day. MPH utilizing an osmotic-release oral system (OROS-MPH or Concerta) releases the stimulant via an osmotic pump in an ascending dose curve over a 10- to 12-hour period. This allows for a single-dose product that is consistent with the effect of a three times per day dose of immediate-release MPH hydrochloride. The newly available MPH hydrochloride extended-release liquid suspension (Quillivant XR) has demonstrated efficacy in reducing ADHD symptoms for up to 12 hours, is well tolerated and is especially useful in children who have difficulty swallowing pills.

Amphetamine is manufactured as immediate-release formulations, including mixed amphetamine salts, which is a mixture of d- and l-amphetamine, or in the dextro isomer. With regard to just the dextro isomers, dextroamphetamine (d-AMP) is 1.5 times more potent, milligram for milligram, than is d-MPH. Another popular product, mixed salts of amphetamine (MAS), is marketed as Adderall, and combines four different salts of amphetamine, including both d-AMP and l-AMP. One small study showed that there are no efficacy differences between d-AMP and MAS.

AMP is also available in extended-release beaded formulations, as the isomer d-amphetamine sulfate (Zenzedi) and as a liquid (Procentra). Lisdexamfetamine dimesylate (Vyvanse) is a therapeutically inactive prodrug that is converted by enzymatic hydrolysis to inactive l-lysine and active d-amphetamine predominantly by red blood cells, with a smaller amount converted in the gastrointestinal tract. This formulation was developed to decrease the potential for abuse, as lisdexamfetamine used intranasally or intravenously has similar effects to oral administration.

Although absorption of MPH products is generally not affected by foods, some long-duration preparations of d-AMP show decreased concentrations when taken with high-fat meals. Whereas MPH is metabolized in the gut wall and plasma by esterases, the metabolism of d-AMP and MAS takes place in the liver. Variants in the humans CES-1 gene coding for the hydrolyzing enzyme have led to interindividual variations in MPH metabolism and plasma level.

Amphetamine product package inserts approved by the FDA warn that urinary excretion of AMP metabolites can be increased by foods of acidic content (vitamin C and orange juice), thus lowering plasma concentration. Conversely, foods that shift urinary pH higher reduce excretion and thus increase the plasma concentration of d-AMP or MAS.

Efficacy. Efficacy studies of stimulants consistently show high numbers of children who are responders (Storebø et al., 2015). The MTA study found that 77 percent responded to MPH, and an additional 10 percent of MPH nonresponders responded to d-AMP. Teacher rating scales showed significant reductions in ADHD symptoms for stimulants compared with placebo, with effect size ranging from 0.8 to 1.0 standard deviation (SD) on behavioral measures and 0.5 SD for cognitive measures for those children randomized to active drug. Placebo response rates in controlled studies have tended to be low, generally less than 20 percent of those randomized to that condition. The Preschool ADHD Treatment Study (PATS) determined that preschool-aged children require a lower optimal doses of IR methylphenidate, experienced much higher rates of adverse events, do not respond as robustly showing a lower effect size, and had slower clearance of the drug than school-aged children (Vitiello et al., 2015).

Amphetamines and MPHs both share the ability to reduce gross motor overactivity, increase sustained attention on tasks, and reduce impulsive responses on laboratory measures. These characteristics have been shown in more than 200 short-duration, double-blind, placebo-controlled clinical trials involving patients with ADHD across a wide age range, including preschoolers, school-aged children, adolescents, and adults. Some individuals respond preferentially to MPH, whereas others respond preferentially to the amphetamines. The majority of evidence indicates that MPH and amphetamine are equally efficacious.

Cognitive and Behavioral Effects. Greater effects due to stimulants are found to occur in behavioral domains rather than in cognitive areas. Psychostimulant medications have been shown to reduce gross motor overactivity, out-of-seat behavior, calling-out in the classroom, disruptiveness, impulsive behavior, and noncompliance while improving self-perception, academic productivity, peer nominations of the child and mother–child interaction. Stimulants have been shown to improve vigilance and reaction time and reduce variability, short-term memory, and learning of verbal and nonverbal material in children with ADHD. The MTA Titration Trial showed a linear dose–response curve for behavioral measures between 0.5 and 1.0 mg/kg/day. Although earlier studies showed no long-term academic benefit from stimulant treatment, recent controlled trials revealed improvements in school-based productivity and accuracy in

children with ADHD consistently treated with stimulants.

Adverse Effects

SHORT-TERM ADVERSE EFFECTS. Common side effects of the stimulant medications include decreased appetite, weight loss, delayed onset of sleep, headaches, stomachaches, and small increases in blood pressure and pulse. Most of the short-term side effects can often be dealt with by changing the time or dose of medication, or both.

Infrequent side effects include motor tics, the unmasking of Tourette syndrome, and late withdrawal effects, sometimes called rebound. Rebound presents the sudden return of more severe overactivity, impulsivity, and inattention in the late afternoon or evening than present at baseline off medication. Attempts to demonstrate their presence in full-day, laboratory classrooms have been unsuccessful, so these effects may be generated as the child interacts with task demands in his or her natural environment. Long-acting psychostimulant preparations or a small dose of immediate-release medication may be given before onset of the rebound to reduce this problem.

Stimulants rarely produce visual and tactile hallucinations, priapism, choreiform movements, and self-directed behavior, such as lip licking, nail biting, and rubbing of sores. These problems are first treated by discontinuing the medication until the adverse event disappears.

Two large recent studies in children and one in adults found that ADHD medications are not associated with an increased risk of severe cardiovascular events. General cardiac side effects of stimulant drugs are increase in heart rate of approximately 1 to 2 beats/minute and increase in systolic and diastolic blood pressure of 3 to 4 mm Hg. Stimulants have not been found to induce clinically significant changes in electrocardiographic parameters. The evidence suggests a potential for severe adverse cardiac events in some children with certain forms of congenital heart disease or arrhythmias. Routine electrocardiograms are not recommended prior to initiating stimulants in the absence of concerning physical examination findings or personal or family cardiac history.

Long-Term Adverse Events

EFFECTS ON GROWTH. The use of stimulants in children has been associated with growth suppression in some studies, but methodological issues prevent a clear conclusion to be drawn. Two large-scale NIMH-supported randomized, clinical trials have shown that MPH can reduce the rate of height and weight gains in developing children with ADHD. This suppression effect, which may be dose related in some children, has been more pronounced in those children treated with d-AMP and occurs predominately in the first year of treatment. The reductions in linear

growth have been minimal (approximately 1 cm in height and 2.5 kg in weight during the first year of treatment with stimulants). There is growing evidence of that this decrease in growth velocity diminishes after the first year treatment. The effects on growth are thought to be secondary to appetite suppression and reduction of caloric intake. Small, single-site studies are discordant concerning whether psychostimulants suppress human growth hormone (HGH) or effect prolactin levels. Some researchers have suggested that the growth deficit may be associated with the disorder itself, rather than stimulant medication. Clinicians are recommended to regularly monitor height and weight of children with ADHD treated chronically with psychostimulant medication. It is also encouraged to institute drug holidays during summer vacations to increase the probability of growth rebound.

SUBSTANCE ABUSE. There is no evidence to suggest that the use of stimulants in young people increases the risk for later substance use disorders (SUD). A meta-analytic study by Wilens and colleagues suggests that stimulant treatment in childhood has a protective effect, bringing the risk down to the level of the general population. Other studies have revealed that stimulant therapy neither increases nor decreases the risk for subsequent SUD in children and adolescents with ADHD. Clinicians should take into consideration if family members are currently abusing prescription medication before prescribing stimulants for ADHD.

Stimulant medication can be misused or diverted for the purpose of academic performance enhancement or euphoric effects, with immediate-release stimulants more often misused compared to extended-release formulations. A systematic review of 21 studies indicated prevalence of psychostimulant misuse in the year prior to the study ranged from 5 to 9 percent in grade and high school–aged children and 5 to 35 percent in college-aged individuals. Close monitoring, pills counts, or switch to nonstimulant medication should be employed by the clinician if misuse or diversion is suspected.

Summary of Stimulant Medication. Continuous treatment of children with ADHD with psychostimulants is both effective and safe over the first 2 years. Long-acting preparations provide the convenience of once-daily dosing, reduce stigma associated with taking medication at school and can decrease the potential for abuse. Short-acting forms are useful for younger children who often require smaller doses than is available in extended-release preparations. Many adverse events can be handled by adjustment of dose and/or the time of administration of the medication. Long-term adverse events such as growth rate suppression concern parents but may be managed by instituting drug holidays to permit growth rebound.

Nonstimulant Medication in the Treatment of Children with ADHD

Whereas psychostimulants constitute the first-line treatment for children with ADHD, other medications need to be used for nonresponders or those who experience moderate to severe adverse events. Some nonstimulant medications, such as atomoxetine and long-acting clonidine or guanfacine, have been approved by the FDA for the treatment of ADHD in children and adolescents. Other nonstimulant medications are used off-label but are less efficacious than the stimulants in treating ADHD symptoms. Advantages of nonstimulant medications include a longer duration of action and the absence of psychostimulant effects such as behavioral rebound or delay of sleep onset.

Atomoxetine HCl. Atomoxetine (ATX), an NRI marketed under the name Strattera, is an approved alternative to stimulants. It may be considered first line in individuals where parents have a personal objection to stimulants, or the child has comorbid anxiety symptoms or severe stimulant side effects. Atomoxetine is well absorbed after oral administration and is minimally affected by food. Maximum plasma concentrations are reached approximately 1 to 2 hours after ingestion and typical duration of action is 10 to 12 hours. Ninety-eight percent of circulating ATX is bound to plasma protein, mainly albumin. ATX is dosed by weight, with RCTs showing no benefit from exceeding total daily doses of 1.4 mg/kg. The time to therapeutic effect is in the range of 1 to 4 weeks, with full response at 6 to 12 weeks.

ATX has been shown to reduce ADHD behaviors in children, adolescents, and adults with a medium effect sizes of 0.5 to 0.7. Common adverse events associated with ATX involve abdominal discomfort, nausea, decrease in appetite, sedation, daytime sleepiness, headache, dizziness, vertigo, irritability, and mood swings. Daytime sleepiness and gastrointestinal tract problems may be diminished by titration to full dose over 1 week in twice-daily dosing. Minor increases in blood pressure and pulse have been reported and thus should be regularly monitored. Rare adverse events in youth include priapism, disturbances in sexual functioning, increased suicidality and liver toxicity.

ATX is metabolized by the cytochrome P450 (CYP) 2D6 hepatic enzyme system. A fraction of the population are poor metabolizers of CYP 2D6–metabolized drugs. Such individuals may experience elevated plasma concentrations and extended plasma half-life, therefore very slow initial titration may be required to prevent excessive dosing of these patients. Patients taking other medications metabolized by CYP 2D6, such as fluoxetine (Prozac), paroxetine (Paxil), and quinidine (Cardioquin), might show signs of competitive inhibition, namely increased plasma levels of both ATX and the competing drug.

α -Adrenergic Agonists. The α-adrenergic agonist agents were initially approved for the management of hypertension in adults. The long-acting α-adrenergic agents guanfacine ER (Intuniv) and clonidine ER (Kapvay) have been FDA approved as monotherapy and adjunctive treatment of ADHD in children 6 to 17 years old. The immediate-release clonidine (Catapres) and guanfacine (Tenex) have not been approved to treat ADHD, although they are commonly used off-label. The supposed mechanism of action of the α-adrenergic agents involves stimulating α (alpha) receptors in the PFC leading to improvement inattention, impulsivity, and hyperactivity. The α-adrenergic agonists are clearly less efficacious than the psychostimulants with several meta-analyses suggesting a moderate effect size. However, a small multisite, double-blind, RCT showed that children and adolescents comorbid for ADHD and Tourette syndrome benefited from clonidine alone or in combination with MPH, in both cases significantly better than placebo. Guanfacine has proven efficacy in reducing oppositional symptoms in children with comorbid oppositional behaviors and ADHD.

Common side effects of the α-adrenergic agents are sedation, fatigue, somnolence, headache, hypotension, syncope, and bradycardia. There have been rare reports of hallucinations in children treated with guanfacine. Clonidine is very sedating and has been used to treat sleep difficulties of children with ADHD, as well as to offset the delay in sleep onset caused by stimulant medications. It is initiated at low doses, 0.05 mg at bedtime. Guanfacine is a more selective α-adrenergic agonist and is slightly less sedating than clonidine. It is used in higher total daily doses than clonidine, between 1 and 3 mg. The α-adrenergic agonists need to be discontinued very slowly to prevent rebound adrenergic overdrive, with hypertension, agitation, fever, headache, tachycardia, chest pain, sleep disturbance, nausea, and vomiting. This can create a problem if a family goes on holiday and the parents forget the child's medication.

Tricyclic Antidepressants. TCAs have data supporting their use in ADHD, but are used infrequently as they have a much more serious side-effect profile. Spencer reviewed 29 studies of children and adults treated with TCAs (imipramine, desipramine, and nortriptyline) and found significant reductions in ADHD symptoms in 22 of the studies. There are many adverse events associated with TCAs, including cardiovascular adverse events, such as slowing of cardiac conduction and increasing the electrocardiographic PR and QRS intervals indicating increased risk of cardiac arrhythmias and heart block. There have been reported sudden deaths in patients on stable therapeutic doses of TCAs. For that reason, electrocardiograms at baseline and after each dose adjustment are necessary for routine monitoring. Other side effects commonly experienced with TCAs include lowering of seizure threshold and cholinergic side

effects, such as constipation, dry mouth, or blurred vision. When discontinued, TCAs should be tapered over several weeks.

Bupropion. Bupropion is an antidepressant with dopaminergic and noradrenergic properties that has shown modest efficacy in ADHD, but is less effective than stimulants or atomoxetine. It is available in extended-release preparations (Wellbutrin SR, Wellbutrin XL) that permit once-daily dosing. It might be more effective in adolescents and is not recommended for children. Starting dose for young adolescents is 75 mg twice a day to a maximum of 200 to 300 mg/day. The doses can be increased once weekly until improvement is noted. Bupropion usually takes 4 to 6 weeks to show effect.

Side effects of bupropion include fatigue, dry mouth, insomnia, headaches, nausea, vomiting, constipation, tremor, and skin rash. Seizures will reliably occur if the adolescent's dose exceeds 400 mg/day. This medication is FDA approved for the treatment of depression and smoking cessation, but not ADHD, in individuals older than 18 years of age. Bupropion is considered a second-line, off-label treatment for ADHD.

Other Alternative Medications. Anticonvulsants, including carbamazepine (Tegretol), lithium (Eskalith), SSRIs have not been shown to be effective for the treatment of ADHD. Second-generation antipsychotic medications such as risperidone have been shown to be effective for the treatment of aggression when combined with parent training and MPH, but not when used as the sole therapeutic agent. Modafinil (Provigil), an antinarcoleptic stimulant agent, was shown to be effective in three double-blind, placebo-controlled RCT, but the manufacturer withdrew its application to the FDA because of a severe Stevens–Johnson skin rash that might have occurred in one patient and reported visual hallucinations in registration trials. In summary, then, these medications might be useful in treating some comorbid conditions that children with ADHD often have.

Summary of Medication Treatments. Most children with ADHD respond to stimulant medication, so it continues to be the first-line treatment choice for reducing the symptoms of ADHD. However, if stimulants are ineffective, practice parameters first suggest turning to the serotonin–norepinephrine reuptake inhibitor atomoxetine. Alternatively, one can combine a stimulant medication with an α-2 agonist when the youth shows only partial response to a stimulant. If the child shows severe adverse events on stimulants, off-label medications can be tried. One must keep in mind that bupropion is less effective than either the TCAs or stimulants and carries a risk of seizures at high doses. Clonidine and guanfacine are sedating and have significant cardiovascular side effects. For all these drugs, careful monitoring and slow, cautious discontinuation

are essential. TCAs are not routinely used for the treatment of ADHD due to the numerous side effects and high toxicity.

Treatment of ADHD Comorbidities

Tic Disorder. Stimulants alone or in combination with clonidine, guanfacine, and atomoxetine appear to reduce ADHD symptoms in individuals with both ADHD and Tourette syndrome or tic disorders. Although stimulants have not been shown to worsen tics in most patients with tic disorders, they may exacerbate tics in some individual cases. In these instances, decreasing the dose of stimulants or treatment with α-agonists or atomoxetine may be an alternative. Cognitive behavioral therapy (CBT) with the use of opposing muscle contractions to address tics has also shown some efficacy and can be considered to address problems with tics.

Seizure Disorder. Children with seizure disorders may also suffer from ADHD. Although there are concerns about psychostimulants, particularly MPH, lowering the seizure threshold, experiencing a first seizure when starting a psychostimulant is extremely rare. Studies of EEG epileptiform activity, seizure rates, or interactions between antiepileptic drugs (AEDs) and psychostimulants have not shown any additional seizure risk. On the contrary, studies have shown that children with ADHD and a seizure disorder that is adequately controlled on an AED show reduced ADHD symptoms and no change in seizure frequency.

Aggression, Oppositional Defiant Disorder, and Conduct Disorder. Individuals with ADHD and comorbid Aggression, ODD and/or CD require comprehensive intervention which includes pharmacotherapy and psychosocial treatments. Stimulants have been shown in randomized, controlled trials to improve ADHD, aggression, ODD and CD symptoms. α-Blockers (guanfacine and clonidine) alone or as adjuncts to stimulants have also been shown to decrease ADHD, aggression, and oppositional symptoms. Stimulants also reduced negative social interactions and covert antisocial behavior (stealing and vandalism but not cheating). However, one cannot solely rely on medication to treat children with ADHD and these comorbid conditions. A comprehensive treatment approach which may include parent training, social skills training, and anger management for the child as well as an appropriate academic program and support may also be needed. Treating Aggression, ODD, and CD early and effectively is critical as long-term consequences of these disorders include later drug and alcohol abuse and antisocial behavior with involvement of the criminal justice system.

Anxiety Disorder. It had been suggested that children with ADHD and

comorbid anxiety may be less responsive to and experience more side effects with stimulant medication (Coughlin et al., 2015). The large Multimodal Study of ADHD (MTA) did not find this to be the case. However, children with ADHD and anxiety disorder seemed to benefit significantly from psychosocial treatment as well as medication. Thus for children with ADHD and comorbid anxiety, slow and careful titration of stimulant medication for the ADHD symptoms is recommended and psychosocial treatments such as parent training, social skills training, and/or CBT for the child combined with an appropriate academic program and academic support is suggested. However, should all these measures prove inadequate, addition of SSRIs (fluoxetine [Prozac] or sertraline [Zoloft]) to address the anxiety can be added.

Mood Disorder. In community samples, major depressive disorder (MDD) in youth with ADHD is more than five times higher than in youths without ADHD. Depressive disorders in youth with ADHD usually occur several years after the onset of ADHD and may be due to the cumulative effects of ADHD-related impairments and negative environmental circumstances they need to cope with. Youths with depression and ADHD have greater levels of psychosocial impairment than those with either condition alone. For individuals with both disorders, depressions start earlier, last longer, are more likely to recur and have higher rates of suicides and hospitalizations than those who have depression alone.

A combination of pharmacotherapy and psychosocial interventions is recommended for patients who have both ADHD and major depression. Generally, as per the Texas Children's Medication Algorithm Project (CMAP), it is suggested that the clinician begin with the most effective medication for the most impairing condition for the patient. Only after the full effect of this medication is determined for both conditions, should a second medication be added to deal with residual symptoms of the second condition. Thus, in some cases of the combination of ADHD and mood disorders both stimulants and SSRIs may need to be used.

Psychosocial interventions both for the depression, for example, CBT, and the ADHD, for example, organizational, study skills remediation, and appropriate academic and/or vocational program may all be needed.

The question of ADHD and Bipolar Disorder is being resolved with the introduction of the clinical entity of Disruptive Mood Dysregulation introduced in DSM-5. As a result, mainly classical symptoms of Bipolar Disorder such as severe elation of mood, grandiosity, racing thoughts, and hypersexuality are used to confer the bipolar diagnosis. In these circumstances, the Bipolar Disorder needs to be stabilized with mood stabilizers and/or antipsychotics before stimulant treatment can be introduced.

Developmental Disorders. ADHD symptoms of inattention and hyperactivity are seen in children with mental retardation and ASD. Stimulants have been shown to be beneficial in both groups, particularly in those children with IQs greater than 50. A recent randomized, controlled trial found that MPH was more effective than placebo in reducing symptoms of ADHD in children with autism, while few effects were seen on ASD symptoms.

Some studies suggest that these populations may be more susceptible to adverse events of psychostimulants. While other studies do not suggest this. However, if severe side effects occur, for example, severe agitation, irritability, fearfulness, or stereotyped behavior, a low dose of second-generation antipsychotic medication may need to be added.

There are few randomized, double-blind controlled trials with other medications for patients with ADHD and ASD. Atomoxetine has been shown to have some positive effects on ADHD symptoms with little effect on ASD. The side effects associated with Atomoxetine appear to be less problematic than with stimulants. There are some clinical suggestions that some anticonvulsant medications and guanfacine may also be beneficial for the ADHD symptoms in these populations but no well-controlled trials have been reported to date. Although psychosocial interventions are also suggested, again data on the efficacy of these approaches is also lacking.

Psychosocial Treatment of Children with ADHD

Psychosocial treatment of children with ADHD refers to nonmedication treatment. This type of treatment includes different modalities, such as psychoeducation, academic organization skill teaching and remediation, parent training, behavior modification, CBT, social skills training, and individual therapy. Of these modalities, parent training, intensive behavior modification, social skills training, and academic organizational skills have shown efficacy for children with ADHD in controlled trials.

Among nonpharmacological treatments, direct contingency management uses systematic manipulation of punishments and rewards, often in specialized settings. Although it can produce impressive effects on behavior and performance in the classroom, its effects tend not to generalize or be maintained outside of the settings in which they are applied. In addition, published outcomes are achieved through single-case designs. In the field, behavior therapy often is carried out in consultation with teachers and parents regarding in-school and home management. Published trials often depend on parent and teacher ratings of improvement but do not include independent evaluators. However, a recent review showed that even with blinded assessments, significant effects persisted for improving parenting and decreasing childhood conduct problems. Although controlled studies of systematic combinations of direct contingency management plus intensive behavior therapy have yielded

significant improvement, effect sizes of clinical change are smaller than those found with stimulant medication.

Intensive behavioral interventions are based on a number of principles. These begin with psychoeducation about the course, risk factors, and long-term outcomes of ADHD. Second, the parents are encouraged to attend more carefully to their child's behavior, particularly when the child complies. Third, the parents are trained to use time out effectively. Fourth, the parents are instructed in establishing a contingency management or token economy system at home. Then the parents learn how to manage noncompliant behaviors in public settings. Finally, advances in prosocial behavior in school are supported by use of a daily report card.

It is crucial to evaluate the parents and family for dysfunction related to the child's ADHD. Parental ADHD may interfere with behavioral modification programs, indicating that treatment of the affected parent may be necessary before the child's intervention can be successful. Other dysfunctions might be present in the family as well, such as marital problems, substance abuse, or parental depression.

Behavior modification has been successfully applied to the classroom, with a meta-analysis of 70 studies showing an effect size of 0.6 SD compared to an attention control condition. In contrast, CBT has not been shown to be effective (Vidal et al., 2015). Practice parameters published for child and adolescent psychiatrists strongly suggest that behavior therapy in the form of behavioral parent training and behavioral classroom management be added to psychopharmacological treatment if the child is shown to be a partial responder to stimulant medications or exhibits a comorbid psychiatric disorder whose impairment does not respond to the medication.

SUMMARY AND CONCLUSIONS

ADHD is a prevalent condition which begins in childhood but often continues into adolescence and adulthood. It is accompanied by significant academic, occupational, social, and emotional impairment. The patients with ADHD are often comorbid with other conditions. These comorbidities include oppositional defiant, conduct, learning, and anxiety disorders in childhood, and anxiety, depression, and substance use and abuse in adolescence and adulthood.

Treatment must include the ADHD and the various comorbidities. Thus, pharmacotherapy and psychosocial treatment as well as appropriate academic programs and support are needed for optimal outcome. It must be stressed that ADHD is a chronic condition for which ongoing long-term monitoring and treatment is required to optimize functioning.

SPECIFIC CASE OF CHILDHOOD ADHD

Ben is an 8.5-year-old African-American adopted boy who lives with his parents and 11-year-old brother. He attends third-grade regular education in his local public school and received special services including speech, physical, and occupational therapy. Although his drug screen at birth was negative, Ben's biological mother was said to have used crack and methadone during her pregnancy. No information was available about his biological father. Ben had suffered several upper respiratory infections at age 2 years requiring several rounds of antibiotics. Developmentally, some motor delays were reported, with crawling by 1 year and walking by age 2 years. He was speaking one word by his first birthday, but by age 3½ years his expressive language was behind his peers in fluency. He demonstrated difficulties following multipart directions, even though his hearing tested in the normal range.

Ben has had difficulty with daydreaming and wandering about since kindergarten. His teachers complained that Ben did "not seem to listen," had "poor concentration," and was constantly "out of his seat." Ben had never had close friends and other children seemed to avoid him because he could not stick with an activity for very long and he was always "in their space." Ben's adoptive parents were drained from the nightly battles over homework and discouraged by his lack of focus and "spaciness." His inattention and impulsivity put him in danger and caused injury. He had run into traffic on several occasions, even after being hit by a truck with resulting injuries.

Ben's parents and his third-grade teachers completed the SNAP Rating Scale. Clinician assessment revealed seven symptoms of inattention. His mother also endorsed all nine symptoms of hyperactivity/impulsivity. These symptoms were moderately to severely impairing across multiple settings, including home, peer relations, personal safety, and during athletics.

Ben was started on extended-release MPH at 18 mg daily which was later increased to 27 mg daily. His teachers reported improvement in attention and hyperactive behavior at school. Homework was no longer such a struggle and he was noted to play quietly with his toys in the evenings.

▲ 45.2 Adult Manifestations of Attention-Deficit/Hyperactivity Disorder

JAMES J. MCGOUGH, M.D., M.S.

Although attention-deficit/hyperactivity disorder (ADHD) was originally conceptualized as a developmental delay of childhood, it is now defined as a lifespan neurodevelopmental disorder and adult manifestations are widely recognized. Longitudinal studies suggest that a majority of school-age children diagnosed with ADHD continue to have clinically meaningful symptoms and impairment into young adulthood. Numerous lines of epidemiological evidence reveal that prevalence rates of adult ADHD are among the highest of all psychiatric disorders. Clinical investigations indicate that adults with ADHD have patterns of psychiatric comorbidity and neurocognitive deficits similar to children, but suffer with a much broader array of functional impairments. Both structural and functional brain imaging studies demonstrate distinct abnormalities in groups of adults with ADHD compared to those without, and genetics studies conducted in adults have replicated pediatric findings. Adult ADHD is associated with significant medical, occupational, economic, and social impacts, and has emerged as a major public health concern.

DEFINITION

ADHD was classified as a Neurodevelopmental Disorder in the 5th edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), reflecting the disorder's initial emergence in childhood and common cooccurrence with other early-onset brain-based syndromes. In a departure from previous editions, DSM-5 fully acknowledged the persistence of ADHD across the lifespan and modified diagnostic criteria for older adolescents and adults to improve symptom sensitivity to developmental changes with increasing age. While criteria in younger patients require evidence of six or more inattentive or hyperactive/impulsive symptoms of either inattention or hyperactivity/impulsivity, this threshold was reduced to five symptoms in either domain for diagnosis of patients aged 17 years and older. This modification recognized that the population prevalence of ADHD symptoms decreases with increased age, but adults with as few as four symptoms suffer significant clinical impairments compared with similarly aged peers. As with younger individuals, symptoms must have been present for a minimum of 6 months and exceed what is expected for a given patient's expected developmental level. Additionally, there must be some evidence that symptoms occurred prior to age 12 and have manifested in multiple life settings, such as home, school, work, social relationships, or personal activities. Symptoms must currently lead to clinically meaningful impairment in social, academic, or occupational functioning. Symptoms cannot occur exclusively during an episode of schizophrenia or other psychotic illness, and cannot be better attributed to other psychiatric conditions such as mood, anxiety, dissociative, or substance use disorders.

DSM-5 eliminated ADHD subtypes. Instead, *specifiers* describe the overall clinical presentation evidenced in the prior 6 months. Adults with at least five symptoms of inattention and hyperactivity/impulsivity exhibit the combined presentation. Those with five or more inattentive but fewer than five hyperactive/impulsive symptoms exhibit the inattentive presentation. Those with a minimum of five hyperactive/impulsive but fewer than five inattentive symptoms exhibit the hyperactive/impulsive presentation.

Other specifiers describe disorder severity. *Mild ADHD* is specified when the minimal number of symptoms required for diagnosis occur and functional difficulties are at the threshold for clinical significance. *Severe ADHD* is specified when there are many symptoms in excess of the required threshold, or in the presence of marked functional difficulties in one or more settings. Moderate ADHD is specified when the number of symptoms and associated degree of impairment falls between "mild" and "severe."

DSM-5 further permitted the diagnosis of "other specified ADHD" when an individual exhibits significant impairment due to ADHD symptoms, but fails to meet full diagnostic criteria. In this instance, the clinician should

specify which criteria are not met, for example, "other specified ADHD with insufficient symptom number." Clinicians may also assign the diagnosis "unspecified ADHD" if they choose not to specify which criteria are lacking.

HISTORY

For the first half of the 20th century, the condition now recognized as ADHD was variably referred to as minimal brain damage (MBD), minimal brain dysfunction, or hyperkinesis. While these terms conveyed some expectation that the disorder arose from underlying brain pathology, the syndrome was principally viewed as a developmental delay that was most often outgrown during adolescence. This position was maintained in the second edition of the DSM (DSM-II), published in 1968, which placed the diagnostic category named *hyperkinetic reaction of childhood* within the grouping "Behavioral Disorders of Childhood and Adolescence." Unique among editions of the DSM, DSM-II further implied that core features of short attention span, restlessness, and hyperactivity were a reaction to unsupportive environments and/or inadequate parenting.

In the 1970s, concurrent with development of the third edition of the DSM (DSM-III), seminal work by Paul Wender and colleagues at the University of Utah identified a group of adults with persistent childhood ADHD symptoms. Wender asserted that symptoms under consideration for inclusion in the DSM revision were developmentally inappropriate for older patients. He proposed the Wender Utah Criteria for Adult ADHD, empirically derived from extensive experience with older patients, as an alternative to the DSM. Wender Utah Criteria required (1) retrospective diagnosis of childhood ADHD made on the basis of patient interview and, when available, confirmation by a third-party informant; (2) evidence of ongoing impairment in adulthood from hyperactive and impulsive symptoms adulthood; and (3) the presence of additional symptoms felt to be typical of adults with the disorder, including mood lability, irritability, impulsivity, disorganization, and poor stress tolerance. The diagnosis could not be made in the patients suffering from severe depression, psychosis, or severe personality disorders.

DSM-III, published in 1980, continued to define attention deficit disorder as a childhood condition. However, with some deference to work by Wender and others, DSM-III allowed the diagnosis of attention deficit disorder, residual type, for adults previously diagnosed as children who had ongoing evidence of some symptoms. This category inherently implied that adults could not meet full diagnostic criteria. Text of the revised third edition (DSM-III-R) allowed that ADHD might continue through adulthood in up to 30 percent of affected children.

Throughout the 1980s and 1990s, and in the absence of clearly applicable DSM criteria, Wender Utah Criteria were used widely in clinical practice as well as research studies of adult medication response, brain

imaging, and genetics. Concurrently, longitudinal follow-up studies of adults previously diagnosed with childhood hyperactivity reported ADHD persistence in 40 to 60 percent of cases. These converging lines of evidence influenced subsequent DSM conceptualizations of the disorder and increased recognition of ADHD in adults. Although the Wender Utah Criteria had tremendous impact in promoting initial acknowledgment and study of adult ADHD, their use was largely abandoned as DSM criteria were increasingly applied outside of pediatric age groups.

In the 1990s, emerging research reports and several best-selling lay publications spurred widespread public awareness of adult ADHD. These studies and concomitant increases in public demand for clinical services catalyzed growing interest in the phenomenology, causes, and potential treatments of adult ADHD. Interestingly, although the fourth edition (text revision) of the DSM (DSM-IV-TR) provided some further leeway for adult diagnosis, it continued to maintain that for most cases ADHD symptoms resolved by late adolescence.

Revisions in DSM-5 incorporated more than two decades of research and clinical experience in adults. Enumerated ADHD symptoms remained unchanged from those previously identified in field trials of school-age children, but text clarifications were added to improve recognition of developmental changes that occur with increasing age. The age of onset criterion from previous editions of the DSM was modified from requiring evidence of symptoms and impairment prior to age 7 to requiring some recognition of symptoms alone prior to age 12. In response to studies that demonstrated an overall decline in symptom prevalence rates in older populations as well as associated functional impairments seen in adults with as few as four ADHD symptoms, only five symptoms in either the inattentive or hyperactive/impulsive domain were required for individuals aged 17 and older. Finally, descriptions of typical impairments associated with ADHD were broadened to include the range of difficulties frequently seen in adults, notably problems with work, personal activities, social relationships, and general health maintenance.

Comparative Nosology

In the 10th revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10), the entity defined as ADHD is subsumed under the category hyperkinetic disorders. Similar to DSM-5, ICD-10 requires impaired attention and overactivity that are developmentally inappropriate for a person's age. Unlike the DSM, both symptoms of inattention and overactivity are required, making it more difficult to apply the diagnosis to adults who generally exhibit fewer problems with hyperactivity. Also unlike DSM-5, but similar to previous versions of the DSM, ICD-10 retains the requirement that ADHD symptoms must have been generally present before 6 years of age. ICD-10

divides ADHD into subtypes based on the presence or absence of conduct disorder.

Epidemiology

Epidemiological studies demonstrated that ADHD is the most common behavioral disorder of childhood, with prevalence estimates ranging from 5 to 10 percent of school-age children. Results from the National Comorbidity Survey Replication estimated a 4.4 percent prevalence of ADHD among adults in the United States. International studies found slightly lower but comparable rates. These epidemiological studies are consistent with findings from longitudinal reports that describe persistence of ADHD in over 70 percent of adolescents and 50 percent of young adults. These converging reports confirm that significant numbers of adults suffer from ADHD and related impairments. Unlike other common psychiatric conditions such as mood and anxiety disorders that are typically episodic, adults with ADHD are apt to experience chronic and unremitting symptoms that require ongoing management.

Etiology

ADHD is best viewed as a neurodevelopmental disorder that arises from interplay of genetic and environmental factors. Twin and family genetic studies demonstrated that the mean heritability of ADHD exceeds 75 percent, approaching the estimated heritability of height and exceeding that seen in other psychiatric disorders such as schizophrenia and anxiety. Approximately one-third of adults with ADHD have at least one child with the disorder, and similarly, one-third of children with ADHD have at least one affected parent. Evidence suggests that ADHD is a complex behavioral phenotype resulting from multiple genes, each contributing additive risk for the condition. Early molecular genetic studies identified numerous candidate genes, particularly ones involved in brain catecholaminergic activity, with demonstrated associations with ADHD. Meta-analyses of these studies confirmed positive associations for several candidates, but none predicted substantial ADHD risk. Similarly, initial genome-wide association studies (GWAS) of ADHD failed to identify genomic regions with major risk polymorphisms. However, a related GWAS investigation found several regions likely to harbor common risk alleles for ADHD, depression, bipolar disorder, autism spectrum disorder, and schizophrenia. Other studies suggested individuals with ADHD have greater numbers of rare copy number variants (CNVs) throughout their genomes, suggesting that the sum of individual mutations better predicts disorder occurrence than specific mutations within given sets of genes. Ongoing investigations will further elucidate the genetic, environmental, and gene-by-environment interactions that affect ADHD risk.

Structural and functional brain imaging studies consistently demonstrated significant differences between adults with and without ADHD. It is unclear if these differences are primary causes of ADHD or secondary effects. Comparisons using computerized tomography (CT) and magnetic resonance imaging (MRI) found smaller total brain volumes, particularly in frontal and cerebellar regions. Positron emission tomography (PET) studies of adult parents of ADHD-affected children revealed decreased glucose metabolism in premotor and superior prefrontal cortices. Several studies utilizing single-photon emission tomography (SPECT) demonstrated increased dopamine transporter (DAT)-binding densities in the striatal regions. This is a particularly interesting finding given that methylphenidate (Ritalin) blocks DAT activity, possibly leading to normalized DAT functioning, and is consistent with reports implicating the DAT gene with ADHD. In more recent investigations that examined dysfunctional patterns and altered connectivity across multiple neuronal networks, adults with ADHD exhibited decreased activation in frontoparietal systems and overactivation in the visual, dorsal attention, and default networks.

Several environmental variables contribute increased risk for development of childhood ADHD, notably maternal use of nicotine or alcohol during pregnancy, birth prior to completion of 32 weeks' gestation, and increased serum lead levels. Adverse factors such as paternal incarceration, parental mental illness, financial stress, foster care, and child abuse increase risk for more severe adult outcomes, while higher intelligence and consistent structure at home and school decrease risk. Adults with concomitant executive functioning deficits generally exhibit more severe difficulties than those without. Nonetheless, while up to 50 percent of diagnosed children fail to manifest adult ADHD, the factors that contribute to remission or persistence of ADHD are not identified. Further elucidation of specific risk factors for adult persistence might facilitate development of preventative strategies and improved long-term outcomes.

Table 45.2–1.
DSM-5 Symptoms and Adult Correlates

Inattention		Hyperactivity and Impulsivity	
Younger Individuals	**Older Individuals**	**Younger Individuals**	**Older Individuals**
Fail to notice small details, make careless errors	Careless, inaccurate work	Frequently fidget, tap hands or feet, squirm while seated	Often fidgety or restless
Difficulty maintaining attention	Problems staying focused on boring work, mind often wanders, trouble with extensive reading	Frequently get out of seat or have trouble staying seated	Can't sit long at meetings or other activities where seating is required

Seem not to listen even when spoken to directly	Trouble retaining what people say even when addressed directly	Often run or climb at inappropriate times	Often feel internally restless or unsettled
Trouble finishing work or following through on instructions	Sidetracked easily, problems following directions or finishing tasks	Have trouble playing quietly; often too loud	Often louder than necessary or appropriate
Problems with organization	Can't prioritize, procrastinate, messy, miss deadlines, and bill payments	Often "on the go," as if "driven by a motor"	Difficulty unwinding or relaxing; always needing to be busy
Avoid activities that require sustained concentration	Delay and avoid work and other activities that are boring or repetitive	Get in trouble for excessive talking	Talk too much in social settings, don't tolerate silence
Lose or misplace things frequently	Often misplace things needed at home, work, or other activities	Often blurt out answers before questions are finished	Finish others' sentences or answers before questions are completed
Distracted easily when interrupted	Easily distracted by surrounding noises, interruptions, or extraneous thoughts	Have difficulties when waiting for turn or standing in line	Frustrated when needing to wait
Frequently forgetful	Fail to remember appointments, deadlines, and other obligations	Frequently interrupt or intrude	Interrupt others' conversations and activities, socially intrusive

DIAGNOSIS AND CLINICAL FEATURES

Although parents and teachers generally serve as primary informants in the assessment of pediatric ADHD, adult patients themselves are usually the primary sources of information in their own assessments. Unfortunately, research showed that young adults are frequently poor reporters of ADHD symptoms and associated difficulties, although reliability is much improved when patients reach their late 20s. Studies also revealed that both adults with ADHD and parents of these adult children exhibited poor retrospective recall of problems related to childhood ADHD, often reporting ages of onset up to 4 years later than documented in prospectively collected data. As with children, optimal assessment of adult ADHD depends on the clinical synthesis of all available information, including reports of childhood and current difficulties, symptom reports from parents and significant others, school and occupational reports, and a review of pertinent medical records.

Consideration of an ADHD diagnosis should be given to any adult with long-standing difficulties from inattention or distractibility. A single DSM symptom, "Is often distracted by extraneous stimuli," correctly differentiated 97 percent of ADHD-affected adults compared with 98 percent of community controls. One additional symptom, "Avoids tasks requiring sustained mental effort," correctly identified 89 percent of ADHD cases when compared with other clinical cases without ADHD.

As with children and adolescents, diagnosis of ADHD in adults is based on DSM-5 criteria. DSM-5 acknowledged developmental changes observed in adults by requiring only five inattentive and/or hyperactive/impulsive symptoms for diagnosis, compared with six for younger individuals. ADHD symptoms in DSM-5 are identical to DSM-IV and were initially derived from field trials conducted in school-age children. However, text descriptions in DSM-5 provided adult correlates for these symptoms and allow greater applicability to older patients, as summarized in Table 45.2–1.

ADHD assessment requires careful consideration of potentially comorbid psychopathology as well as a broad range of functional impairments. Common cooccurring conditions include lifetime histories of disruptive behavior and antisocial activities, nicotine dependence, substance use disorders, anxiety disorders, depression, risky behavior, and poor health maintenance. Typical impairments include difficulties in academic, occupational, social, and family functioning.

Diagnosis is based principally on information derived from a clinical interview with the adult patient. A self-administered questionnaire, the Adult ADHD Self-Report (ASRS), developed under the auspices of the World Health Organization, is useful for screening. Table 45.2–2 summarizes additional rating scales and structured diagnostic interviews used in adult assessment. Some clinicians remain highly skeptical of the validity of adult ADHD and have a general view that adults seeking the diagnosis are malingering or drug seeking. Clinical corroboration of self-reported ADHD symptoms and related difficulties with past records, third-party informants, and an overall life course consistent with the natural history of the disorder, remains the best approach for establishing the adult diagnosis.

Laboratory Studies

There are insufficient data to support the use of neuropsychological tests, computerized tests of attention (CPTs), or brain imaging modalities in the diagnosis of adult ADHD. Neuropsychiatric testing can be useful in differentiating ADHD from specific learning disabilities and other cognitive impairments, particularly with a predominance of inattentive symptoms or history of school failure. Nonetheless, neuropsychiatric testing has no demonstrated value in assessment of ADHD itself. Research studies using

electroencephalography (EEG), functional magnetic imaging (fMRI), PET, and other imaging modalities reveal distinct features in groups of adults with ADHD compared with nonclinical controls. However, these findings have poor predictive value in assigning diagnoses to individual patients and no evidence supports their utility in clinical settings. As with children and adolescents, adult ADHD remains a clinical diagnosis derived through careful history taking, adherence to clinical criteria, and differential diagnosis of other psychopathology.

Table 45.2–2.
Rating Scales and Diagnostic Instruments for Adult DSM Attention-Deficit/Hyperactivity Disorder (ADHD)

Rating Scales	Structured Interviews
Barkley Adult ADHD Rating Scale-IV (BAARS-IV)	Brown Adult ADHD Diagnostic Interview
Brown Adult Attention Disorders Scale	Conners' Adult ADHD Diagnostic Interview (CAADID)
Conners' Adult ADHD Rating Scales (CAARS): self and observer reports	Diagnostic Interview for ADHD in Adults (DIVA)
World Health Organization Adult ADHD Self-Report Scale (ASRS)	Adult ADHD Clinical Diagnostic Scale (ACDS)

Differential Diagnosis

Clinicians should consider a diagnosis of ADHD in any adult patient complaining of pervasive difficulties with inattention, hyperactivity, or impulsivity. Several ADHD symptoms, such as problems with sustained attention, motor restlessness, increased speech, and acting "on the go," are common in other psychiatric disorders. Clinicians must distinguish ADHD from other psychiatric syndromes while remaining sensitive to a high probability of coexisting psychopathology.

Depressive disorders are differentiated from ADHD in that problems with concentration and motor restlessness occur only during periods of dysphoric mood, anhedonia, or increased irritability. The occurrence of discrete episodes of somatovegetative symptoms, such as appetite changes and alterations in sleep patterns, further confirms a diagnosis of depression. Patients with both ADHD and depression will report ongoing difficulties with core ADHD symptoms that persist outside of discrete mood episodes. Similarly, patients with bipolar I disorder report racing thoughts, rapid speech, and impulsive behaviors only in the context of sustained periods of elevated or irritable mood. Somewhat more controversial is the overlap of ADHD with hypomania and rapidly cycling bipolar disorder. A clear past history of discrete depressive episodes or strong family history might assist in clarifying the diagnosis, but in many cases patients will meet criteria for both conditions. Anxiety disorders are distinguished from ADHD by subjective worry that is either generalized

and difficult to control, or specific to a particular situation or stimulus. Patients with substance use disorders and ADHD should have histories of ADHD symptoms that precede initiation of substance use. Patients with histories of early school difficulties and childhood conduct disorder are likely to be comorbid for both ADHD and substance use. Adults with ADHD and a childhood history of conduct disorder frequently exhibit antisocial personality disorders.

Adults with histories of school difficulties and inattentive symptoms in the absence of hyperactivity or impulsivity should be evaluated for specific learning disabilities or other executive functioning deficits. This generally requires a battery of neurocognitive tests to measure academic aptitude and achievement. Patients with significantly idiosyncratic interests and impaired social functioning might also be diagnosed with autism spectrum disorder.

Although considerable research has addressed the occurrence of significant psychiatric comorbidity in adults diagnosed with ADHD, far less attention has been paid to prevalence rates of ADHD cooccurring with other adult psychiatric disorders. Emerging evidence suggests that up to 16 percent of adults currently suffering from major depression have childhood histories of ADHD, and that in approximately 13 percent of adults with current mood disorders, 10 percent with current anxiety disorders, and up to 25 percent with current substance use disorders meet ADHD criteria. In view of its high overall adult prevalence and associated developmental risk for comorbid psychopathology, all adult psychiatric assessments should include routine diagnostic consideration of ADHD.

A 42-year-old woman obtained an evaluation for distractibility and general nervousness. The patient had spent the past 16 years at home caring for her children. Her youngest child recently began elementary school, and she obtained part-time work as an assistant manager in a large retail department store. She was excited about the position, particularly the flexible work hours and the opportunity to earn extra income for the family. However, she reported particular difficulty remaining focused on her job, had general trouble organizing her time, and was in danger of losing her job due to her failure meeting several deadlines. She was tense, irritable, had trouble relaxing, and described difficulty falling asleep because she was worried about what she needed to do the next day. She complained that her "mind goes completely blank" when overstressed. She denied depressed mood, loss of pleasure in her usual activities, change of appetite, or suicidal preoccupations.

The patient reported that she was considered a bright student, particularly in elementary school. She liked school, but was generally shy and uncomfortable in unfamiliar social situations. Beginning in middle school and throughout college she felt increasingly bored, easily distracted, and particularly frustrated with long reading assignments. She graduated with a 3.0 grade point average and subsequently worked for 2 years as a retail clerk. She became pregnant soon after her marriage and left her job to raise her family. She described her marriage as "typical," generally stable and satisfying with occasional marital tension due to financial stresses and child-rearing. Her middle child, a 12-year-old boy, had been diagnosed with ADHD and successfully managed with stimulant therapy and behavioral techniques learned through parent training.

On a self-completed ACDS Rating Scale, the patient endorsed six

inattentive and two hyperactive/impulsive symptoms. An ADHD-IV Rating Scale completed by her husband reflected a similar symptom pattern. Clinical synthesis of all available information supported an ADHD diagnosis with a retrospectively determined age of onset in middle school, a history of impairment at school, work, and home, and a comorbid diagnosis of generalized anxiety disorder.

The treating clinician outlined several options for medication therapy, specifically an initial stimulant trial with subsequent selective serotonin reuptake inhibitor (SSRI) treatment for residual anxiety versus atomoxetine (Strattera) monotherapy. The patient agreed to a medication trial with main target symptoms of distractibility, nervousness, and sleep disturbance.

On stable medication, she reported improved focus at work, better general organization, less general anxiety, and improved sleep. She was followed with monthly medication visits for 3 months and then visit frequency was reduced to every 3 months. After 6 months of medication treatment, the patient was pleased to report that she recently finished reading a novel, her first since college. She resolved her initial difficulties at work and had been given a commendable employment evaluation. She was feeling less stressed at home, but remained troubled by what she viewed as her inadequacies and inability to manage all her responsibilities. In response, her physician referred her for a brief course of cognitive-behavioral therapy (CBT) to address residual anxiety symptoms and organizational skills.

COURSE AND PROGNOSIS

The prevalence of ADHD symptoms declines with age. Many children with the combined presentation of ADHD exhibit fewer hyperactive-impulsive symptoms by mid-adolescence and subsequently exhibit the inattentive presentation as adults. Given the age-related decline of ADHD symptoms in the general population, adults can remain significantly impaired relative to same-age peers with fewer symptoms than are required for diagnosis in childhood. This suggests that reported rates of ADHD remission are more a function of syndrome definition than true syndrome remission. Long-term outcome studies of ADHD-affected children are limited, and there are insufficient data to draw conclusions regarding the developmental course of ADHD from early to middle adulthood. Between 30 and 45 percent of ADHD children do not suffer ADHD-related impairments as adults. Nonetheless, many adults with ADHD continue to struggle with the consequences of the disorder throughout their lives.

Adults with ADHD demonstrate significant rates of cooccurring psychopathology and limitations in adaptive functioning when compared with unaffected peers. Adults with ADHD exhibit higher rates of childhood conduct disorder with a subset having antisocial personality disorder.

Significantly higher rates of substance use disorders are consistently reported compared with unaffected adults. There is no clear evidence that adults with ADHD prefer one type of recreational drug compared with another, but those who develop drug dependency have a more difficult time achieving sobriety than individuals without ADHD. Similarly, adults with ADHD initiate nicotine use at earlier ages, demonstrate higher rates of lifetime nicotine addiction, and have more difficulty in maintaining smoking cessation. Adults with ADHD suffer high rates of lifetime mood and anxiety disorders. The differential impact of comorbid psychopathology on long-term ADHD outcome has not been adequately studied.

ADHD confers significant risk for lifetime functional impairments. Lower self-esteem, poorer lifetime academic achievement, less successful work histories, and more failures in long-term relationships are evident. Adults with ADHD often make poor choices regarding personal health, including participation in high-risk activities, unprotected sex, and unsafe driving. Conversely, some of these succeed in making lifestyle adjustments that minimize evidence of impairment. Individuals find occupations for which they are well suited, can live alone or find suitable close relationships, or can utilize other talents that compensate for ADHD-related difficulties. Additional research is required to identify predictive factors that mitigate these impairments.

A 26-year-old man obtained an evaluation for severe distractibility after being involved in a minor traffic accident. In early grade school he had particular difficulties making careless mistakes on tests, forgetting his assignments, and sitting still in class. Although he was considered intelligent, his grades were average and he had no aspirations for college. After high school he had several short-term jobs in the construction industry, which were enjoyable because he spent most of his time outdoors. In the past year he had obtained part-time work as a wedding videographer and found himself increasingly interested in making and editing videos.

During his clinical interview, the patient described ongoing difficulties maintaining his attention on uninteresting tasks, easy distractibility, problems with time management, generally feeling restless, and frustration when required to sit for extended periods. He endorsed six inattentive and five hyperactive/impulsive symptoms on a DSM-5 ADHD checklist of current symptoms. The patient was diagnosed with the combined presentation of adult ADHD.

After discussing the nature of ADHD with his physician and receiving additional educational materials, the patient agreed to a medication trial. A once-daily extended-release preparation of stimulant medication was prescribed in escalating doses over several weeks to determine the optimal dose that maximized symptom reduction and minimized side effects. At his follow-up visit, the patient admitted to robust improvement in his ability to focus and surprise at his increased motivation to attend to the technical details of video editing. After several months of treatment, he enrolled in a community college to pursue formal coursework in video production.

TREATMENT

Good long-term clinical care is contingent on adequate patient education about the nature of the disorder and effects of treatment. Once a diagnosis

is made, clinicians should provide sufficient information to assist adult patients in choosing treatment options that meet individual patient needs. Given the degree of misinformation about ADHD available from the Internet and other lay sources, patients are well served when physicians guide them to appropriate reference materials. Many patients are relieved to understand that they have a biologically based condition that is shared by a significant number of other adults. National organizations such as Children and Adults with ADD (CHADD, www.chadd.org) or the National Alliance for the Mentally Ill (NAMI, www.nami.org) provide access to local support networks and reliable educational materials.

Pharmacotherapy remains a treatment cornerstone. Medications found to be useful in the treatment of childhood ADHD are generally shown to be effective in adults. FDA-approved medications for adult ADHD include stimulant and nonstimulant medications, as summarized in Table 45.2–3. Other medications used off-label in adults with ADHD include immediate- and extended-release forms of the alpha-2-agonists, guanfacine and clonidine; tricyclic antidepressants, buproprion; and the wake-promoting agents, modafinil and armodafinil. Stimulant medications are the most frequently prescribed. The greatest clinical effect from stimulants is seen with robust dosing. A particular difficulty in clinical management of adults is the frequent necessity for multiple daily dosing, even with extended-release formulations, in order to provide adequate relief from ADHD symptoms throughout the day. Many clinicians remain reluctant to prescribe stimulant medication due to concerns about abuse, misuse, and illicit diversion. Several studies have reported widespread diversion of prescribed stimulants among college students, although in most cases the medications are used to enhance academic performance as opposed to recreational use. Several lines of evidence suggest that prodrug and certain extended-release stimulant formulations are less likely to create abuse liability than older immediate-release forms. Nonstimulant medications remain an option in patients at high risk for abuse or misuse of ADHD stimulants.

Table 45.2–3.
FDA-Approved Medications for Adult Attention-Deficit/Hyperactivity Disorder (ADHD)

	Brand Name	Typical Single Dose	Approved Maximum Dose (mg/day)
Stimulants			
Methylphenidate	Ritalin	5–20 mg	60
	Metadate CD	20–60 mg ER	60
	Ritalin LA	100–40 mg ER	60
	Concerta	18–72 mg ER	72
Dexmethylphenidate	Focalin	2.5–10 mg	20

	Focalin XR	10–40 mg ER	40
Dextroamphetamine	Dexedrine	5–30 mg	60
	Dextrostat	5–30 mg	60
	Dexedrine Spansule	5–40 mg SR	60
Lisdexamfetamine	Vyvanse	20–70 mg	70
Mixed amphetamine salts	Adderall	5–30 mg	40
	Adderall XR	5–30 mg ER	60
Nonstimulants			
Atomoxetine	Strattera	40–100 mg	100

ER, extended release; SR, sustained release.

Although many adults have significant lifetime histories of other psychiatric disorders, there have been few treatment studies for comorbid ADHD. Current evidence suggests that clinicians should first initiate therapy for the condition (i.e., ADHD vs. other psychopathology) that is causing the most distress. One example is sequential pharmacotherapy with either a stimulant or SSRI for cooccurring ADHD and anxiety or depression. A particular vexing problem is whether stimulant medications should be provided to patients with known histories of substance use disorder. It is essential that physicians maintain proper documentation of patients' diagnostic assessments and prescription medication records. Some clinicians are comfortable initiating ADHD pharmacotherapy in the presence of intermittent alcohol or cannabis use, but are advised against stimulant pharmacotherapy in those patients with chronic use or use of other psychoactive agents such as opioids or methamphetamine.

There is growing support for certain nonmedication treatments in adult ADHD. The strongest evidence exists for CBT, which has been administered successfully both in individual and group settings. Well-controlled blinded investigations of omega-3 fatty acid supplementation have also yielded small but significant positive effects on ADHD symptoms. Other nonmedication approaches, such as ADHD coaching, mindfulness training, meditation, yoga, cognitive remediation programs, EEG neurofeedback, and use of digital technologies such as electronic scheduling and reminder systems remain popular, despite a lack of sufficient scientific data to support their general use. Individuals are best served when psychosocial interventions are individually tailored to their own specific difficulties. For example, patients who suffer from marital or relationship difficulties might be referred to couples therapy. The emphasis in this treatment should be the couple's relationship problems, not the individual's ADHD. Parents might benefit from participation in a parenting course, particularly if they themselves have children with ADHD. Insight-oriented psychotherapy might be useful for some patients with significant self-esteem or interpersonal difficulties.

Proper management of adult ADHD is also likely to include appropriate

educational planning and consideration of academic and occupational accommodations. Occupational counseling and vocational training can be better options for some individuals than insistence on attending a 4-year college. Adults who attend college should be referred to their school's office for students with disabilities. The Americans with Disabilities Act (ADA) has particular implications for adults with ADHD. Regulations implementing the ADA require that *reasonable* accommodations be made in areas of education and employment for individuals with documented disabilities. Colleges and universities develop their own guidelines for provision of special accommodations based on Federal mandates. At higher-grade levels and for standardized testing at the college level and beyond, it is generally necessary to conduct formal neuropsychological testing to document ADHD-related learning impediments prior to granting accommodations. In occupational settings, the ADA requires that reasonable accommodations be made for persons with disabilities, but does not require that anyone be hired for a position who is not otherwise qualified. It is essential that thresholds for disability be determined in reference to population or societal norms, and not speculations about the individual's potential capabilities. *Reasonable* accommodations should have minimal impact on employer expectations, job performance, and coworkers.

A 19-year-old woman was evaluated at a drug rehabilitation center for methamphetamine dependence. In early grade school she was extremely hyperactive, reckless, and prone to impulsive judgments. Her father suffered from alcohol dependence and was physically abusive to her and her mother. She began smoking cigarettes at age 11 and using alcohol and marijuana at age 12. At age 13, she was raped by a high school senior that she had been dating. Two years later, she quit high school and ran away from home. She began smoking crystal methamphetamine the previous year, and was court ordered for drug evaluation after an arrest for prostitution.

A careful history of early school experiences revealed significant problems with distractibility, completing assignments, sitting still in class, and general irritability. On a DSM checklist assessing childhood symptoms, she endorsed six inattentive and eight hyperactive/impulsive symptoms. Currently, she endorsed nine inattentive and nine hyperactive/impulsive symptoms, general dysphoria, fatigue, anhedonia, and suicidal preoccupation.

The patient enrolled in a long-term, court-funded residential treatment program for drugs and alcohol. After several weeks her mood symptoms diminished, but she continued to suffer from marked inattention, distractibility, and restlessness. After careful consideration, her physician initiated nonstimulant medication treatment for ADHD. At 1-month follow-up, she described good response to treatment and had begun studying to obtain a general equivalency diploma (GED). At discharge, she had resolved to stay in outpatient drug treatment and obtain part-time work. Her physician continued to monitor her on a monthly basis with intermittent, unannounced drug testing to monitor ongoing sobriety.

FUTURE DIRECTIONS

Ongoing advances in neuroscience are apt to increase acknowledgment of adult ADHD as a biological syndrome. Changes in clinical practice increasingly reflect a shift from viewing adult ADHD as a unique and rare

phenomenon to routine consideration of ADHD both alone and as potentially comorbid with other traditional adult psychopathologies. There will be ongoing interest in developing medication treatments with less perceived potential for abuse and longer durations of effects. Concurrently, there will be sustained efforts to develop effective nonmedication therapies. Although revisions made to ADHD criteria for DSM-5 better reflect the developmental aspects of the behavioral phenotype, ongoing research will increasingly focus on identification and modification of underlying dysregulation in brain neural networks. Such discoveries would raise the possibility of early identification of risk and treatments that target specific dysregulated systems in individual patients.

Disruptive Behavior Disorders in Children and Adolescents

DANIEL F. CONNOR, M.D.

Oppositional defiant disorder (ODD) and conduct disorder (CD) are grouped as the disruptive behavior disorders and included in the DSM-5 chapter on disruptive, impulse control, and CDs. These conditions involve individual problems in emotional and/or behavioral regulation that either bring the individual into significant conflict with authority figures (ODD and CD) or violate the rights of others and/or societal norms (CD). Although ODD frequently overlaps with CD and their symptoms show high correlation, these two categorical disorders are relatively distinct dimensions of psychopathology, with some separate correlates, sequelae, and prognoses. Consistent with DSM-5, in this chapter ODD and CD are considered separately.

When behaviors and emotions are considered dimensionally rather than categorically, these disorders are associated with an externalizing spectrum that includes the personality dimensions of disinhibition, low constraint, and negative emotionality. The disruptive behavior disorders generally have an onset in childhood or adolescence, and are usually more common in males than females.

Considered together, these disorders are one of the most frequent reasons for mental health referral, accounting for between a third-and-half of all child and adolescent psychiatry clinic referrals. These disorders are compelling to understand and treat because they are common and because they are associated with high rates of morbidity, high rates of associated psychiatric illness and psychopathology, and are very costly for society, being associated with higher rates of public expenditure than for youngsters with other neuropsychiatric conditions. These disorders are frequently comorbid with or linked to increased risk for the development of other psychiatric disorders such as depression, bipolar disorders, anxiety, attention-deficit/hyperactivity disorder (ADHD), substance use, and/or antisocial personality disorders. Many societal institutions that serve children and adolescents including the family—the educational system, juvenile justice systems, community and public health systems, primary care systems, and mental health systems—experience the impact of

youngsters with early-onset disruptive behavior disorders.

OPPOSITIONAL DEFIANT DISORDER

Definition

The essential features of ODD are a frequent and persisting pattern of angry/irritable mood, argumentative/defiant behavior, or vindictiveness that is clearly more frequent, more intense, and more persistent across the child's development than is typically observed in individuals of similar age and developmental level. Argumentative and defiant behaviors are expressed by persistent stubbornness, resistance to directions, and unwillingness to compromise, give in, or negotiate with adults or peers. Defiance may also include deliberate or persistent testing of limits, usually by ignoring requests or commands, arguing, and failing to accept blame for misdeeds. Irritability can manifest as anger or aggression and can be directed at adults or peers. Temper outbursts and aggression generally involve the expression of verbal aggression, usually without the more serious physical aggression seen in CD. Symptoms of the disorder are typically more evident in interactions with adults or peers whom the individual knows well. Usually individuals with this disorder do not regard themselves as oppositional or defiant, but justify their behavior as a response to unreasonable demands or circumstances. Symptoms generally begin early in life and are usually more prevalent and severe at home in the child's interactions with the parents. Only with more severe and pervasive ODD and later in the course of illness, does the disorder tend to generalize out of the home with angry/irritable and argumentative/defiant symptoms expressed toward authority figures at school or in the community.

ODD is not recognized if symptoms only occur during the course of a psychotic, bipolar, and depressive or substance-use disorder. In these cases, the symptoms of ODD are felt to be part of the underlying disorder. Disruptive mood dysregulation disorder (DMDD) shares symptoms of chronic negative mood and temper outbursts with ODD. However, symptoms are much more severe, frequent, and chronic in individuals meeting criteria for DMDD than in those with ODD. In individuals who meet diagnostic criteria for both ODD and DMDD, only the more severe disorder is diagnosed, and a diagnosis of ODD is not given.

CD and ODD are both related to disruptive behaviors and externalizing symptoms that bring the individual into conflict with parents or other authority figures. The symptoms of ODD are generally less severe than those of CD and typically do not involve overt aggressive behaviors toward others or a pattern of deceit or theft. Furthermore, ODD includes problems with emotional regulation (irritability, anger) that are not found in the diagnostic criteria for CD. When criteria are met for both ODD and CD, both diagnoses can be given.

History

ODD emerged as a distinct diagnosis separate from CD for the first time in the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III). Previously, the Group for the Advancement of Psychiatry had suggested the concept of childhood oppositional personality in 1966, emphasizing the symptoms of disobedience and pervasive negativism. Early conceptualizations of the disorder emphasized the passive-aggressive nature of the oppositional symptoms. With the introduction of DSM-III in 1980, the idea of an oppositional disorder was first introduced and links to the notion of a passive-aggressive personality were retained. Subsequent editions of the DSM added a defiant label and expanded the ODD symptom list from two of five possible items (DSM-III), to five of nine items (DSM-III-R), and finally to four of eight items (DSM-IV, DSM-IV-TR, and DSM-5). As evidence mounted that early-onset oppositional behaviors were linked to increased risk for later antisocial behaviors, ODD became grouped with CD under the disruptive behavior disorders and links to passive-aggressive personality traits were dropped. Limited field trials supported the diagnostic criteria for ODD in DSM-III-R. More extensive field trials and secondary data analyses were performed in support of ODD in DSM-IV. Evidence from the DSM-IV field trials indicated that the diagnostic criteria of four of eight possible ODD items possessed adequate internal consistency, positive predictive power, and negative predictive power. Four of eight symptoms remain required for the diagnosis of ODD in DSM-5. Subsequent research supports the reliability and validity of the ODD category as separate from the more severe diagnosis of CD, and this distinction is retained in DSM-5.

Although the eight ODD symptoms found in DSM-5 are the same as for DSM-IV-TR, they are now grouped into three categories (i.e., angry/irritable mood, argumentative/defiant behavior, and vindictiveness). Recent research has shown that outcomes may differ depending on which grouping of ODD emotional/behavioral symptoms is most predominant. For example, the angry/irritable mood category predicts an increased risk for internalizing disorders, the argumentative/defiant behavior category predicts risk for disruptive behavior disorders, and the vindictiveness category may be associated with risk for instrumental aggressive behaviors. Thus, in DSM-5, ODD is now conceptualized as a disorder with both emotional and behavioral dimensions and contained in a new chapter on the disruptive, impulse control and CDs.

Comparative Nosology

Compared with DSM-IV-TR, the grouping of DSM-5 ODD symptoms into three categories suggests that subgroups of ODD children exist and can be identified each with differing risk for the development of associated

psychopathology. This may enhance differential provision of clinical treatments.

The DSM-5 and the 10th edition of the *International Classification of Diseases* (ICD-10) include similar symptoms in the criteria lists for making the diagnosis of ODD and CD. However, while DSM-5 treats each disorder separately and both disorders may be diagnosed in an individual, if criteria for both disorders are present, ICD-10 considers ODD jointly with CD. In DSM-5, ODD is specified as a separate disorder from CD with four of eight symptoms in three categories required for a diagnosis (Table 46–1). The symptom criteria for ODD are substantially different from the symptom set for CD, supporting the idea that they are separate disorders. However, the notion that ODD might be related as a less severe developmental precursor to CD is built into the DSM-5 criteria by grouping together argumentative/defiant behaviors as a subcategory of ODD symptoms that predicts increased risk for disruptive behavior disorders including CD.

ICD-10 includes a 23-item symptom list very similar to the combined symptom lists of DSM-5 ODD and CD, but divides them into 15 more severe items appropriate for the diagnosis of CD and eight less severe items equivalent to the DSM ODD symptoms (Table 46–2). A diagnosis of CD is made similarly in both systems using three or more of the more severe items in ICD-10. However, unlike the DSM system, ICD-10 treats ODD as a subtype of CD and requires a total of four or more symptoms from the full list of 23 items to be met, but where no more than two items come from the list of 15 more severe conduct symptoms. This results in an ICD-10 diagnosis of CD and ODD subtypes. As a result, all children who meet DSM-5 criteria for ODD also meet ICD-10 criteria for the disorder. However, not all children who meet an ICD-10 diagnosis of CD and ODD subtype (e.g., four ODD + CD symptoms combined total) will meet DSM-5 ODD diagnostic criteria (e.g., four ODD symptoms and no symptoms of CD required). Recent studies have shown that the DSM criteria may exclude from the diagnosis, children who meet criteria for an ODD diagnosis by ICD-10 criteria and that these omitted children are substantially impaired. Many of these omitted children may be assigned a DSM-5 diagnosis of other specified or unspecified disruptive, impulse control and CD. As a consequence, population prevalence rates in epidemiological studies of ODD may differ because of the different diagnostic systems utilized with the DSM system at risk for underestimating the true rate of ODD compared to ICD-10.

Epidemiology

The prevalence of disruptive behavior disorders varies according to age, gender, socioeconomic status, neighborhood, and degree of urbanicity. Evidence suggests that the population prevalence of ODD may be higher than CD during childhood and remains constant or declines somewhat

during adolescence (when CD prevalence begins to rise). The disorder appears more prevalent in males than females (1.4:1) prior to adolescence. The male preponderance disappears in adolescents and in adults with ODD. The criteria used to make the diagnosis also cause prevalence to vary. For example, studies have shown that the prevalence of ODD decreased as more stringent diagnostic criteria were applied from 1980 to 2013 across DSM-III to DSM-5. In nonreferred epidemiological samples, the prevalence of ODD varies between 4.5 and 15.4 percent in males and between 1.5 and 15.6 percent in females aged 7 to 21 years old. DSM-5 cites an average overall prevalence estimate of 3.3 percent for childhood ODD. Recent studies in adults have reported a 12-month ODD prevalence of 1 percent and a lifetime prevalence of ODD of 8.5 percent in the United States. Good data on the prevalence of ODD in the preschool population are presently lacking. ODD appears to be more prevalent among children and adolescents from families of low socioeconomic status living in inner city disadvantaged neighborhoods.

Etiology

Presently, there is little scientific investigation into the origin of ODD as a separate and discrete disorder. More is known about the etiology of CD and the general categories of disruptive behavior disorders, delinquency, and antisocial behavior than is understood about the specific causes of ODD. Most theories favor a cumulative risk model arising out of a complex interplay between biological and environmental risk and protective factors as the child interacts with caregivers, authority figures, and the environment across development. As risk factors accumulate and begin to outweigh protective factors, risk for the initiation of ODD increases. Most experts agree that single cause or main effects models are inadequate to explain the complexity inherent in the origin of ODD. Vulnerability gene by environmental interactions and dynamic, interactive models examining reciprocal interactions between the child and their caregivers over time as development unfolds appear best suited to eventually provide a clearer understanding of the etiology of ODD. Understanding the etiology of ODD is important because as risk aggregates, the impact of prevention interventions and treatments may diminish.

Biological. Biological investigations into the disruptive behavior disorders have generally combined CD and ODD together or focused on larger categories of disruptive behaviors such as conduct problems, aggression, delinquency, criminality, or antisocial behavior. When specific diagnoses are investigated, more studies have investigated the biological correlates of CD than those of ODD. Few studies have specifically examined the biological etiology of ODD. Neurobiological markers associated with CD such as lower heart rate and skin conductance reactivity to environmental

stimuli, reduced basal cortisol reactivity, and functional imaging abnormalities identified in the prefrontal cortex and amygdala are also correlated with ODD. It is presently unclear if there are neurobiological markers specific to ODD.

Table 46–1.
ICD-10 Diagnostic Criteria for Research

F91 Conduct Disorders

G1. There is a repetitive and persistent pattern of behavior, in which either the basic rights of others or major age appropriate societal norms or rules are violated, lasting at least 6 months, during which some of the following symptoms are present (see individual subcategories for rules or numbers of symptoms).

Note: The symptoms in 11, 13, 15, 16, 20, 21, and 23 need only have occurred once for the criterion to be fulfilled.

The individual:

1. Has unusually frequent or severe temper tantrums for his or her developmental level;
2. Often argues with adults;
3. Often actively refuses adults' requests or defies rules;
4. Often, apparently deliberately, does things that annoy other people;
5. Often blames others for his or her own mistakes or misbehavior;
6. Is often "touchy" or easily annoyed by others;
7. Is often angry or resentful;
8. Is often spiteful or vindictive;
9. Often lies or breaks promises to obtain goods or favors or to avoid obligations;
10. Frequently initiates physical fights (this does not include fights with siblings);
11. Has used a weapon that can cause serious physical harm to others (e.g., bat, brick, broken bottle, knife, gun);
12. Often stays out after dark despite parental prohibition (beginning before 13 years of age);
13. Exhibits physical cruelty to other people (e.g., ties up, cuts, or burns a victim);
14. Exhibits physical cruelty to animals;
15. Deliberately destroys the property of others (other than by fire setting);
16. Deliberately sets fires with a risk or intention of causing serious damage;
17. Steals objects of nontrivial value without confronting the victim, either within the home or outside (e.g., shoplifting, burglary, forgery);
18. Is frequently truant from school, beginning before 13 years of age;
19. Has run away from parental or parental surrogate home at least twice or has run away once for more than a single night (this does not include leaving to avoid physical or sexual abuse);
20. Commits a crime involving confrontation with the victim (including purse snatching, extortion, mugging);
21. Forces another person into sexual activity;
22. Frequently bullies others (e.g., deliberate infliction of pain or hurt including persistent intimidation, tormenting, or molestation);
23. Breaks into someone else's house, building, or car.

G2. The disorder does not meet the criteria for dissocial personality disorder, schizophrenia, manic episode, depressive episode, pervasive developmental disorders, or hyperkinetic disorder. (If criteria for emotional disorder are met, the diagnosis should be mixed disorder of conduct and emotions.)

It is recommended that the age of onset be specified:
Childhood-onset type: Onset of at least one conduct problem before the age of 10 years;
Adolescent-onset type: No conduct problems before the age of 10 years.

Specifications for possible subdivisions

In addition to these categorizations, it is recommended that cases be described in terms of their scores on three dimensions of disturbance:

Hyperactivity (inattentive, restless behavior);

Emotional disturbance (anxiety, depression, obsessionality, hypochondriasis); and

Severity of conduct disorder:

Mild: Few if any conduct problems are in excess of those required to make the diagnosis, and conduct problems cause only minor harm to others;

Moderate: The number of conduct problems and the effects on others are intermediate between "mild and severe";

Severe: There are many conduct problems in excess of those required to make the diagnosis, or the conduct problems cause considerable harm to others—e.g., severe physical injury, vandalism, or theft.

F91.0 Conduct Disorder Confined to the Family Context

The general criteria for conduct disorder (F91) must be met.

Three or more of the symptoms listed for F91 criterion G1 must be present, with at least three from items 9–23.

At least one of the symptoms from items 9–23 must have been present for at least 6 months.

Conduct disturbance must be limited to the family context.

F91.1 Unsocialized Conduct Disorder

The general criteria for conduct disorder (F91) must be met.

Three or more of the symptoms listed for F91 criterion G1 must be present, with at least three from items 9–23.

At least one of the symptoms from items 9–23 must have been present for at least 6 months.

There must be definitely poor relationships with the individual's peer group, as shown by isolation, rejection, or unpopularity and by a lack of lasting close reciprocal friendships.

F91.2 Socialized Conduct Disorder

The general criteria for conduct disorder (F91) must be met.

Three or more of the symptoms listed for F91 criterion G1 must be present, with at least three from items 9–23.

At least one of the symptoms from items 9–23 must have been present for at least 6 months.

Conduct disturbance must include settings outside the home or family context.

Peer relationships are within normal limits.

F91.3 Oppositional Defiant Disorder

The general criteria for conduct disorder (F91) must be met.

Four or more of the symptoms listed for F91 criterion G1 must be present, but with no more than two symptoms from items 9–23.

The symptoms in criterion B must be maladaptive and inconsistent with the developmental level.

At least four of the symptoms must have been present for at least 6 months.

F91.8 Other Conduct Disorders

F91.9 Conduct Disorder, Unspecified

Childhood:

- ► Behavioral disorder, NOS
- ► Conduct disorder, NOS

From World Health Organization. *The ICD-10 Classification of Mental and Behavioral Disorders: Diagnostic Criteria for Research*. Geneva: World Health Organization; 1992.

Table 46–2.

DSM-5 Diagnostic Criteria for Conduct Disorder

A. A repetitive and persistent pattern of behavior in which the basic rights of others or major age-appropriate societal norms or rules are violated, as manifested by the presence of three (or more) of the following 15 criteria in the past 12 months from any of the categories below, with at least one criterion present in the past 6 months.

Aggression to people or animals

1. Often bullies, threatens, or intimidates others.
2. Often initiates physical fights.
3. Has used a weapon that can cause serious physical harm to others (e.g., a bat, brick, broken bottle, knife, or gun).
4. Has been physically cruel to people.
5. Has been physically cruel to animals.
6. Has stolen while confronting a victim (e.g., mugging, purse snatching, extortion, armed robbery).
7. Has forced someone into sexual activity.

Destruction of property

8. Has deliberately engaged in fire setting with the intention of causing serious damage.
9. Has deliberately destroyed others' property (other than by fire setting).

Deceitfulness or theft

10. Has broken into someone else's house, building, or car.
11. Often lies to obtain goods or favors or to avoid obligations (i.e., "cons" others).
12. Has stolen items of nontrivial value without confronting a victim (e.g., shoplifting, but without breaking and entering; forgery).

Serious violations of rules

13. Often stays out at night despite parental prohibitions, beginning before age 13 years.
14. Has run away from home overnight at least twice while living in parental or parental surrogate home (or once without returning for a lengthy period).
15. Is often truant from school, beginning before age 13 years.

B. The disturbance in behavior causes clinically significant impairment in social, academic, or occupational functioning.

C. If the individual is age 18 years or older, criteria are not met for antisocial personality disorder.

Specify whether:

Childhood-onset type: Individuals show at least one symptom characteristic of conduct disorder prior to age 10 years.

Adolescent-onset type: Individuals show no symptom characteristic of conduct disorder prior to age 10 years.

Unspecified-onset type: Criteria for a diagnosis of conduct disorder are met, but there is not enough information available to determine whether the onset of the first symptom was before or after age 10 years.

Specify if:

With limited prosocial emotions: To qualify for this specifier, an individual must have displayed at least two of the following characteristics persistently over at least 12 months and in multiple relationships and settings. These characteristics reflect the individual's typical pattern of interpersonal and emotional functioning over this period and not just occasional occurrences in some situations. Thus, to assess the criteria for the specifier, multiple information sources are necessary. In addition to the individual's self-report, it is necessary to consider reports by others who have known the individual for extended periods of time (e.g., parents, teachers, coworkers, extended family members, peers).

Lack of remorse or guilt: Does not feel bad or guilty when he or she does something wrong (exclude remorse when expressed only when caught and/or facing punishment). The individual shows a general lack of concern about the negative consequences of his or her actions. For example, the

individual is not remorseful after hurting someone or does not care about the consequences of breaking rules.

Callous—lack of empathy: Disregards and is unconcerned about the feelings of others. The individual is described as cold and uncaring. The person appears more concerned about the effects of his or her actions on himself or herself, rather than their effects on others, even when they result in substantial harm to others.

Unconcerned about performance: Does not show concern about poor/problematic performance at school, at work, or in other important activities. The individual does not put forth the effort necessary to perform well, even when expectations are clear, and typically blames others for his or her poor performance.

Shallow or deficient affect: Does not express feelings or show emotions to others, except in ways that seem shallow, insincere, or superficial (e.g., actions contradict the emotion displayed; can turn emotions "on" or "off" quickly) or when emotional expressions are used for gain (e.g., emotions displayed to manipulate or intimidate others).

Specify current severity:

Mild: Few if any conduct problems in excess of those required to make the diagnosis are present and conduct problems cause only minor harm to others (e.g., lying, truancy, staying out after dark without permission, other rule breaking).

Moderate: The number of conduct problems and the effect on others are intermediate between those specified in "mild" and those in "severe" (e.g., stealing without confronting a victim, vandalism).

Severe: Many conduct problems in excess of those required to make the diagnosis are present, or conduct problems cause considerable harm to others (e.g., forced sex, physical cruelty, use of a weapon, stealing while confronting a victim, breaking and entering).

Studies have estimated the genetic and environmental contributions to oppositional defiant behavior from mother, father, and teacher reports using rating scales in twin samples. These studies find support for additive genetic, unique environmental, and shared environmental influences on oppositional behavior and for both boys and girls. These studies generally support the idea that vulnerability to oppositional and defiant behaviors has a genetic basis that interacts with the child's environment in complicated interactional ways across development to result in the expression of ODD as a disorder. This research supports the clinical observation that oppositional and disruptive behaviors frequently cluster in siblings and biological relatives of the ODD child proband.

Temperament is defined as the characteristic style of emotional and behavioral response of an individual in a variety of differing situations and to a variety of differing environmental stimuli. Temperament is thought to be a constitutional facet of child development that may be observed early in life and generally persists over time and across situations. As the child grows older, temperamental characteristics shade imperceptibly into personality traits. Individual differences in infant and child temperament have long been recognized. Temperament has heritable and biologically based, as well as environmentally mediated aspects. Temperamental characteristics are presumably derived from a combination of genetic,

intrauterine, central nervous system, and postnatal environmental factors. Although not rigid and fixed, an individual's temperament style is likely to be relatively constant over time, especially when interplay between the individual and his or her environment is relatively stable across development.

A cluster of temperament dimensions described as the "difficult temperament" has been shown to correlate with concurrent and future behavioral adjustment in children of varying ages and social and ethnic groups. Although many definitions exist, the difficult temperament is generally characterized by infant or young child qualities of overactivity, undercontrol, high intensity of responses, inattention, predominantly negative mood, and low adaptability to new situations. Cross-sectional studies document a relationship between difficult temperament and generalized psychopathology, including oppositional defiant and conduct problems in childhood, adolescence, and adulthood. Longitudinal studies assessing the relationship between difficult temperament initially assessed early in the preschool years and behavior problems later in life are also largely consistent in finding a relationship with increased risk for generalized psychopathology, including externalizing behavioral problems such as oppositional defiant and CD, delinquency, aggression, and antisocial behaviors. This risk appears for both boys and girls, but may be stronger for boys. It should be noted that difficult temperament by itself is a relatively weak predictor of the development of oppositional defiant and conduct problems. When a negative child temperament is combined with family dysfunction, marital conflict, poverty, upbringing in a high-crime neighborhood, or parental psychopathology, prediction for disruptive behavior disorder is stronger.

Other temperament dimensions with relevance for oppositional defiant and disruptive behaviors have been described. One is novelty or sensation seeking. These children are described as outgoing, actively seeking stimulation, impulsive, and lacking in anxiety and fear. Because they are driven to seek stimulation and lack fear, they may have a more difficult time learning from experience and inhibiting their behaviors than children who do not exhibit these temperamental qualities. These children may appear undercontrolled, defiant, and oppositional. Other temperamental dimensions associated with risk for development of ODD include low levels of prosocial behavior and impulsivity and a lack of persistence. Temperamentally undercontrolled children at age 3 years have been found at age 18 years to have personality traits characterized by impulsivity, danger seeking, and aggression, and at higher risk for more aggression, antisocial behaviors, conduct problems, and criminal involvement compared to youth low on these temperament dimensions. The temperament dimension of novelty seeking may have a genetic basis. In molecular genetic investigations, polymorphisms in dopamine D_2 and D_4

receptors are significantly associated with personality traits of novelty seeking in population-based studies.

Psychological. A very influential theory in the causation of oppositional defiant and conduct problems in children is coercion theory. Coercion theory posits that parents and children in families with behavior-disordered children behave in such a way that oppositional and conduct-problem behaviors are behaviorally reinforced. This theory integrates contextual variables, parent variables, and child variables into an integrated understanding of oppositional and antisocial children that has the support of much empirical evidence. Coercion theory focuses on learning theory, specifically negative reinforcement of antisocial behavior. A behavior is negatively reinforced when it allows an individual to escape from a noxious, aversive, anxious, or unpleasant situation or task. In coercion theory, the negative behavior of one member of a parent–child dyad serves to terminate the ongoing negative behavior of the other, thereby negatively reinforcing the first member's original negative behavior. Over time, the child learns that aversive behavior "works" to solve social problems and may begin to generalize learned aversive and oppositional interpersonal behavior out of the home to interactions with authority figures at school and in the community.

Social learning theory posits that children learn by modeling the behaviors of caregivers and important others in their lives. To the extent that parents demonstrate coercive, aggressive, angry, and oppositional defiant behaviors and attitudes as a means of social problem solving, their children may learn that hostile behavior is an acceptable means of interacting with others.

Although the quality and pattern of an infant's attachment to a caregiver contributes to the development of individual personality and risk for psychopathology later in life, a link between attachment and oppositional defiant behaviors has yet to be conclusively demonstrated. The behavioral manifestations of insecure attachment, especially anxious–avoidant attachment, may be similar to the clinical characteristics of disruptive behavior disorders. In these cases, oppositional behavior is seen as a child's attempt to gain attention from an unresponsive parent.

Sociological. Ecological and environmental variables have long been noted to be associated with risk for the development of disruptive behavior disorders, including ODD and CD. Family characteristics, including poor family cohesion, family discord, inconsistent discipline practices, poor parental monitoring of the child's whereabouts, family stress, and poverty, all contribute to risk for child disruptive behaviors. Poverty appears to be a risk factor, although it does not appear to be a proximal or direct risk factor. Rather, low socioeconomic status is associated with disruptive

behavior disorders through family interactions and stress. Poor parents may have less time, patience, or energy to invest in parental monitoring and involvement with their children because of the increased daily hassles and stress associated with poverty. For similar reasons, parental psychopathology such as maternal depression is associated with child disruptive behaviors. Studies of the relation between maternal depressive symptomatology and the development of externalizing behavior problems in children find that maternal–child interaction quality partially mediates this association, even when the effects of social class are taken into account. Depression may adversely affect parenting ability such that increased negative interactions including irritability or hostility may occur between the child and caregivers, or parental monitoring and supervision of offspring may break down.

Diagnosis and Clinical Features

ODD is a disorder of emotional/behavioral regulation. A pattern of angry/irritable mood, argumentative/defiant behavior or vindictiveness lasting at least 6 months and occurring during interaction with at least one individual who is not a sibling, are the essential features of the disorder. A minimum of four symptoms total from any of the three ODD categories are required for diagnosis. The first ODD category is angry/irritable mood consisting of the symptoms—often losing temper, is often touchy or easily annoyed, and is often angry or resentful. The second category is argumentative/defiant behavior and encompasses the symptoms often argues with authority figures including parents and adults, often defies or refuses to comply with requests from authority figures or with rules, often deliberately annoys others, and often blames others for his/her mistakes. The final ODD category is vindictiveness including the symptom has been spiteful/vindictive at least twice in the past 6 months. The symptoms of ODD cause distress in the individual or others in his or her social environment and create disturbance in at least one domain of child functioning, including social, family, academic, or occupational functioning. Problems with angry/irritable mood include loss of temper, being easily annoyed, and frequent angry and resentful moods. Argumentative and defiant behaviors include arguing with adults, actively refusing to comply with requests or rules, and deliberately annoying others during which the individual often externalizes responsibility for his or her actions onto others in the environment. Vindictiveness refers to behaviors that suggest a petty desire to harm or humiliate others and/or that the individual seeks revenge on others perceived to have wronged him or her. Unlike in CD, in ODD the basic rights of others or age-appropriate societal rules are not violated.

To meet the threshold for clinical diagnosis, oppositional and defiant behaviors must be more severe than would be expected for the child's

developmental age. Criteria for distinguishing a behavior that is symptomatic from a behavior that is within normal limits for age and development include persistence and severity of symptoms. For children younger than five years of age, ODD behaviors should occur on most days for a period of at least 6 months. For older individuals, the behaviors should occur at a minimum frequency of once per week for a period of at least 6 months. For example, defiant behavior and temper tantrums are usual for a 2 year old and oppositional behavior is normative in early adolescence. For a diagnosis of ODD to be given, the behaviors are more extreme than is found for others of the same developmental age and cause daily impairment in functioning.

The diagnosis is not limited to a particular age group, but most commonly emerges between the ages of 4 and 8 years old. Studies have shown that ODD suggests a more circumscribed disturbance of lesser severity than other disruptive behavior diagnoses such as CD or ADHD. Problem behaviors are usually evident at home in relationships with those most familiar to the child and may not appear upon clinical examination in the office setting. In more severe cases, ODD symptoms may occur outside the home, usually in situations where authority figures set limits or place demands on the child. The ODD child generally does not see his or her behaviors as a problem and generally places blame on others for any problems. Thus, the clinical evaluation should include multiple reporters such as parents or teachers in addition to the child.

William is a 7 year old whose mother complained that he was frequently out of control at home, especially when asked to do simple chores such as helping to clean up his room or when limits were placed on him such as asking him to turn off the television at dinnertime. His mother reported that she frequently gave in to him in order to prevent more serious escalations of his temper, but no matter how many times he got "his way," his behaviors did not seem to improve around the house. Occasionally she reported getting "so mad" that she spanked him. Then his behavior would improve, but "only for a little while." He becomes easily frustrated and argumentative with his younger siblings. His parents divorced when William was 3 years old. Mother is a single parent with two younger siblings in the home. She does not work and supports the family on welfare. Social and parenting supports for the family are few. Mother reports that she divorced William's father because "he drank too much." She worries that William is "just like his dad ... he never listened either." After the divorce, mother was treated for an episode of depression. Although William appears to be progressing at school in the first grade, he struggles with reading and has few friends. Teachers describe him as somewhat withdrawn in the classroom. However, with peers he is described as bossy and frequently interrupting of others, often leading to conflicts that require teacher intervention. William is in good physical health, with normal vision, hearing, and physical development. Mother described him as an irritable infant who was frequently demanding of her attention.

Pathology and Laboratory Examination

No laboratory investigations are available for the diagnosis of ODD. The disorder is diagnosed on criteria established by clinical examination and by history. Several validated rating scales are available for oppositional and

defiant behaviors. These document symptom severity relative to same age and gender peers. Rating scales may assist in treatment planning by identifying specific targets for interventions and by documenting baseline disorder severity and subsequent response to treatment. Rating scales to measure the degree of functional impairment caused by symptoms are also available. These scales may assist the clinician in establishing that the oppositional and defiant symptoms exhibited by a particular child exceed those of children of the same gender and of similar developmental age, cause daily impairment, and thus help in establishing that a diagnosis of ODD exists.

Differential Diagnosis

ODD must be distinguished from disruptive behaviors that occur as part of normal development. Generally, ODD is distinguished from normal oppositional behaviors by its severity, impairment, and persistence across development. Because of the need to distinguish the disorder from disruptive behaviors occurring normally as part of development, the reliability and validity of ODD has not yet been established for preschool children. ODD as a diagnosis generally becomes clear around 4 to 8 years old. New-onset oppositional and defiant behaviors in early adolescence may be due to the process of normal separation or individuation. Defiant and disruptive behaviors may occur after a stressor such as a traumatic event or the loss of a loved one. If the disturbance lasts less than 6 months, adjustment reaction is the more appropriate diagnosis. In persons with intellectual disability, a diagnosis of ODD is only given if the oppositional behaviors are markedly greater than is commonly observed among individuals of comparable age, gender, and severity of cognitive disability. Irritable, defiant, and oppositional behaviors are common associated features of mood disorders such as depression, dysthymia, or anxiety disorders such as obsessive-compulsive disorder or separation anxiety disorder in young children. Bipolar disorder presenting in those younger than 18 years is often characterized by severe aggression, disruptive behaviors, defiance of authority, oppositionality, and irritability. Oppositional behaviors may be a feature of psychotic illness in youngsters. As such, ODD is not diagnosed separately if the symptoms occur only during the course of a mood or psychotic disorder. Refusal to follow the directions of authority figures needs to be distinguished from disorders of hearing and language. Children with hearing loss or receptive language disorders may look oppositional on the basis of a failure to hear or understand spoken commands.

In children, the diagnosis of ADHD may frequently be accompanied by a diagnosis of ODD. Children and adolescents with ADHD are often disruptive as a result of the core ADHD symptoms of inattention to tasks requiring sustained vigilance and deficits in impulse control. The willful

defiance of children with ODD must be distinguished from the poor compliance of children with ADHD.

The disruptive behaviors of individuals with ODD are of a less severe nature than those youngsters with CD. ODD typically does not involve violation of the basic rights of others, violation of age-appropriate social norms, severe aggression toward people or animals, recurrent destruction of property, or a pattern of covert theft or deceit. In DSM-5 ODD is identified as a distinct diagnosis from CD. Research has shown that the three categories of ODD (i.e., angry irritable mood, argumentative/defiant behavior, and/or vindictiveness) identify symptom clusters that overlap yet are substantially separate from CD. Longitudinal studies have established that the different ODD categories identify differing prognoses and risks across development. Thus, if criteria for both disorders are met, both diagnoses may be assigned to an individual.

DMDD shares with ODD, symptoms of negative mood, depression, irritability, and temper outbursts. However, as conceptualized in DSM-5, DMDD is a more severe disorder than ODD. In DMDD the severity, frequency, and persistence of aggression, irritability, and temper outbursts lead to more severe symptoms, greater impairment, and a worse prognosis than for ODD. Thus, if criteria for both DMDD and ODD are met in an individual, DMDD is diagnosed as the more severe condition and ODD is not diagnosed.

Comorbid Conditions

Children and adolescents with ODD appear to have higher rates of comorbidity with other psychiatric disorders relative to psychiatric comparison subjects. In addition, significantly greater family dysfunction and social impairments are found in youths with ODD compared to psychiatric controls. Population-based studies find that in cases of ODD, 14 percent of children have comorbid ADHD, 14 percent have accompanying anxiety disorders, and 9 percent have depressive disorders. Learning impairments and language disorders are also common in ODD youngsters. In studies ascertaining comorbidity in clinically referred samples, rates are much higher. The major comorbidity issue in clinically referred ODD children is with ADHD. Studies have shown that 60 to 80 percent of ODD youngsters assessed in clinics may meet criteria for ADHD, and about 50 percent of ADHD elementary school children will meet diagnostic criteria for ODD. Approximately 15 to 20 percent of clinically referred children and adolescents with ODD have comorbid depression, bipolar disorder, anxiety disorders, or language disorders. Concurrent substance abuse and cigarette use should be considered especially in teenagers with oppositional defiant disorder and/or ADHD.

Course and Prognosis

The course and prognosis of ODD varies by the age of onset of ODD, by symptom severity, with the presence of comorbid psychiatric disorders, and by the predominant ODD symptom cluster present. ODD often precedes the development of CD. An earlier age of onset of the disorder and more severe baseline ODD symptoms convey a poorer prognosis in terms of risk for progression to CD. The combination of early-onset ADHD and ODD also confers more risk of progression to CD. Studies have demonstrated that children with an earlier age of onset of ODD have a threefold increase in risk for the eventual development of CD, compared with children who meet criteria for ODD for the first time only later in the elementary school years or beginning in adolescence. About 30 percent of ODD children will eventually develop CD. Although the diagnosis of ODD is relatively stable over time, about two-thirds of children initially meeting diagnostic criteria will eventually exit from the diagnosis over a 3-year follow-up. Predictors of desistance from ODD remain unclear. Just as ODD confers risk for the eventual development of CD, CD confers risk for the development of antisocial personality disorder in adulthood. Longitudinal studies have shown that about 10 percent of ODD youngsters will grow up to meet antisocial personality disorder diagnostic criteria in adulthood. Preschool children who develop early-onset ODD are likely to exhibit additional psychiatric disorders later in childhood including ADHD, anxiety disorders, and mood disorders. Since longitudinal studies investigating the course and prognosis of ODD have been largely completed in male samples, it remains unclear if risk for progression to CDs is also true for females with early-onset ODD.

The course and prognosis of ODD also varies depending on which type of ODD symptoms are most predominant. The presence of argumentative, defiant, and vindictive symptoms carry most risk for the eventual development of CD. A preponderance of angry and irritable mood symptoms carries increased risk for the development of later emotional disorders such as anxiety and/or depression.

Treatment

Most experts consider primary and secondary prevention of at-risk children and families to be fundamental aspects of the treatment for ODD and other disruptive behavior disorders. Interventions are delivered in schools, in the community, and in the child's home. Key elements in prevention approaches to disruptive behavior disorders include treatment early in the child's life, preferably during preschool for at-risk youngsters, sustained treatment durations of longer than 2 consecutive years, intensive treatment occurring several times weekly, and simultaneously targeting multiple domains of the child's environment for therapeutic interventions including the child, parents, family, and school. Regular therapeutic home visitation to high-risk families as a preventive intervention has produced

positive results in preschool children at risk for ODD and disruptive behavior disorders.

Clinical approaches to the treatment of preschool and school-aged children with oppositional and defiant behavior problems in the family have typically been based on a psychosocial learning-based parent training model of behavioral intervention. Although many different types of parent management training (PMT) exist, the underlying rationale for all programs is based on the general view that child oppositional problem behaviors are inadvertently learned, developed, and sustained in the home by chronic and maladaptive parent–child interactions. During PMT, parents are trained to act as behavior change agents in the home. The child may or may not be directly involved in therapy. Therapy emphasizes the behavioral principles of a priori agreement on the most important oppositional behaviors to be targeted by therapy, developing a hierarchy of problem behaviors to be targeted for change, helping parents to learn not to inadvertently reinforce their child's maladaptive behaviors (for example, with attention), consistency of consequences for the child's defiant behavior across different caregivers and sustained across time, and consistent praise and reinforcers for the child when they demonstrate prosocial behavior. PMT can be implemented individually or in parenting groups. Older ODD children and adolescents may benefit from social problem-solving skills training. This type of therapy involves the child directly as a patient and teaches prosocial skills involved in social conflict resolution based on the principles of cognitive-behavioral therapy.

There exists little scientific evidence to suggest that ODD responds directly to medications. An exception is when ODD occurs in the context of ADHD. Psychopharmacological intervention studies with stimulants or noradrenergic agents, as monotherapy or in combination, have shown significant reductions in oppositional defiant symptoms when these occur in ADHD children.

CONDUCT DISORDER

Definition

The essential characteristic of CD is a repetitive and persistent pattern of behavior in which the basic rights of others or major age-appropriate societal norms or rules are repeatedly violated beginning in childhood or adolescence. These behaviors fall into four main groupings: aggression to people or animals, destruction of property, deceitfulness or theft, and serious rule violations. To meet criteria for diagnosis at least 3 of 15 criterion behaviors must be present during the past 12 months, with at least one behavior present in the past 6 months (Tables 46–1 and 46–2). The disturbance in behavior causes clinically significant impairment in social, academic or in occupational functioning. Severity is classified as mild,

moderate, or severe based on symptom frequency, severity, and harm to others. With the exception of requiring that the criteria for adult antisocial personality disorder are not present if the individual is aged 18 years or more, there are no exclusionary criteria. Youth with any diagnosable neuropsychiatric illness such as posttraumatic stress disorder (PTSD), depression, bipolar disorder, an organic condition such as a seizure disorder or head trauma, or schizophrenia can be additionally diagnosed with CD, if their behavior over the past year meets inclusion and exclusion criteria. As currently defined, CD is a very broad and heterogeneous diagnostic category that encompasses many diverse types of behaviors and vulnerabilities to different kinds of psychopathology.

Subtypes and Specifiers of Conduct Disorder

In hopes of reducing the heterogeneity inherent in the diagnostic criteria for CD, subtypes are recognized. DSM-5 recognizes three subtypes of CD: childhood-onset type, adolescent-onset type, and unspecified-onset type. A specifier identifies CD with or without limited prosocial emotions. Subtyping CD by age of onset in DSM-5 is retained from the DSM-IV-TR criteria.

Childhood-onset type refers to the presence of one criterion behavior prior to the age of 10 years. It has been known for some time that age of onset of antisocial behavior has important implications. Research finds that a relatively small group of children (generally boys) with onset of aggressive and antisocial behaviors in childhood (as contrasted with onset in adolescence) display many features suggestive of chronic psychopathology and neuropsychiatric disease. This early-onset CD subgroup has an especially poor prognosis over the lifespan. Compared to the later-onset group, children with early-onset CDs display more neuropsychological deficits, comorbid sustained attentional deficits, failure to inhibit impulsive responding, chronic learning failure and academic underachievement, more violent antisocial behaviors, aggressive and antisocial behaviors generally committed alone and not part of a larger social group such as a gang, a family history characterized by antisocial activities, and a higher risk for a more persistent and chronic course of antisocial activity across development. In epidemiological samples, this early-onset group accounts for a disproportionate amount of illegal activities, despite being only a tiny fraction of the total population of all youngsters with conduct-problem behaviors. For example, research has shown that the early-onset, persistent subtype of CD is characteristic of about 5 percent of males in the population.

In the adolescent-onset type, all the constituent behaviors for diagnosis begin after 10 years of age. The adolescent-onset group is generally comprised of girls as well as boys, generally expresses less violence in their antisocial activities, and may desist from conduct-disordered behaviors

when they achieve economic, psychological, and educational levels of adult independence in society. Although not all studies agree, research generally finds a steep decline in aggressive behavior (but not in nonaggressive antisocial behaviors) when CD begins at a later age of onset in adolescence. Youths with earlier ages of onset of conduct problems generally engage in more frequent and more variegated conduct problems, especially physical aggression, than youths with a later adolescent age of onset of conduct problems.

CD unspecified onset is used when criteria for a diagnosis of CD are satisfied but the age of onset of the first CD symptoms cannot be reliably determined.

DSM-5 includes a CD specifier assessing the presence of limited prosocial emotions. Characteristics include a lack of remorse or guilt when doing something wrong, a general lack of concern about the negative consequences of one's antisocial behaviors, a lack of empathy causing a general unconcern for the feelings of others even when they are harmed, little concern about poor performance at school, work, or in other important activities, a tendency to externalize blame for one's own poor performance onto others, and a shallow, insincere, or superficial affect. Researchers have identified these characteristics as callous–unemotional (CU) traits, a core dimension of psychopathic traits in youth. CU traits appear to be moderately heritable and help predict a subset of CD youth who tend to show more persistent CD symptoms, higher levels of instrumental and proactive aggression, deficits in the cognitive processing of facial emotional expressions of fear and distress in others, and more serious adult antisocial outcomes including elevated risk for adult antisocial personality disorder.

History

The clinical criteria for CD describe a type of individual with personality traits and behavior patterns that psychiatrists have long recognized and struggled to describe and to help. Indeed, descriptions of youths with conduct, delinquent, and antisocial symptoms antedate the very existence of the field of child and adolescent psychiatry. As early as 1837, Prichard used the term *moral insanity* to describe young adult patients with recurrent patterns of antisocial behavior who were not overtly psychotic. Benjamin Rush, the father of American psychiatry, described cases exhibiting "innate, preternatural moral depravity" and speculated that these patients had a defect in the "moral faculties of the mind." In the 19th century, scientific thought emphasized the inherent traits and physical defects (i.e., phrenology) that appeared to mark the antisocial individual.

Beginning in the early 20th century, a shift in thinking occurred as clinicians, social workers, pediatricians, welfare workers, and academics began to consider the impact of the environment and adverse individual or

social conditions on the young juvenile offender. Concern over keeping the youthful antisocial offender out of jail, combined with hope that advances in the new psychoanalytic and psychodynamic therapies that were just being introduced into America in the first two decades of the new century might undo the psychological damage that early childhood adverse experiences might cause, lead to new optimism in the treatment of youngsters with antisocial behaviors. This shift in thinking combined with hope for new treatments led to the beginning of the child guidance movement in the United States with the opening of the Juvenile Psychopathic Institute in Chicago in 1909, and the Judge Baker Clinic in Boston in 1917. The initial purpose of these clinics was to advise the courts on the psychology of juveniles under arrest. In 1923, Karl Menninger brought together a group of psychiatrists concerned with youthful offenders and started the American Orthopsychiatric Association. Thus, psychiatry's concerns for youths with conduct problems and antisocial behaviors have been intimately intertwined with shaping psychiatry's own development as a medical discipline over the past 100 years.

Today, the thinking about the etiology of CD has evolved into considerations about the interaction between vulnerability genes and adverse environmental rearing experiences in the shaping of the individual across development. This evolution in thinking is reflected in changes describing antisocial individuals in the DSM system. The diagnosis of sociopathic personality with antisocial reaction for adults was first codified in 1952 in DSM-I. In 1953, the American Academy of Child and Adolescent Psychiatry was founded. The new discipline was reflected in DSM-II published in 1968 that contained for the first time, a section on behavior disorders of childhood and adolescence. The diagnosis for children with conduct problems became unsocialized aggressive reaction of childhood (or adolescence). Descriptions of the new diagnosis were more pejorative than scientific, describing such youths as quarrelsome, vengeful, and disobedient. The diagnosis of CD first appeared in 1980 with the publication of DSM-III and contained four subtypes: aggressive, nonaggressive, socialized, and undersocialized. In DSM-III-R, published in 1987, three new subtypes of CD were introduced as solitary aggressive type, group type, and undifferentiated type. To meet the diagnosis of CD, 3 of 13 criteria present for the past 6 months were required. DSM-IV (1994) and DSM-IV-TR (2000) expanded the symptom criteria list to 15 items grouped into four categories including aggression to people and animals, destruction of property, deceitfulness or theft, and serious violation of rules, and required that three items be present over the past 12 months with at least one criterion present over the past 6 months. The subtypes were changed to a childhood-onset type, with onset of at least one criterion characteristic of CD prior to age 10 years, and an adolescent-onset type, with absence of any CD criteria prior to age 10 years. There also is an

unspecified-onset subtype for the diagnosis of CD when criteria are met but the age of onset cannot be determined. DSM-5 retained the age of onset subtypes and added a specifier identifying the presence of limited prosocial emotions as described above.

Comparative Nosology

Diagnostic criteria for CD in DSM-5 appear in Table 46–2 and for ICD-10 appear in Table 46–1. The two diagnostic systems have both similarities and differences. Although the criterion lists for DSM-5, ODD and CD contain similar items as the criterion lists for CD in ICD-10, the symptom lists are combined in ICD-10 and are separate in DSM-5. Furthermore ICD-10 lists 8 symptoms of CD as mild and 15 symptoms as severe. The differential weighting of symptoms influences diagnosis in ICD-10 where mild symptoms are more consistent with CD, ODD subtype (discussed above under ODD), and more severe symptoms are used to diagnose other subtypes of CD. This is consistent with the ICD-10 approach of combining the diagnoses of ODD and CD, while DSM-5 separates them into two distinct diagnoses. Another difference between the two diagnostic systems is the identification of CD subtypes. As mentioned above, DSM-5 identifies three subtypes of CD based on the age of onset and a limited prosocial emotions specifier. The current ICD system identifies four CD subtypes, including CD confined to the family context, unsocialized CD, socialized CD, and CD, ODD subtype. ICD-10 also identifies a CD other subtype and a CD unspecified category, similar to the other and unspecified disruptive, impulse control, and CD designations in DSM-5. As a consequence, the two diagnostic systems each identify a slightly different group of youngsters with CD. The clinical and research implications of these differences are presently somewhat unclear.

Epidemiology

The prevalence of CD as a categorical diagnosis is to be distinguished from the prevalence of delinquency, conduct problems, and or antisocial behaviors. The prevalence of CD varies with the type of diagnostic criteria used, sample characteristics, age, and gender. Past modifications between DSM-III and DSM-III-R made the diagnostic criteria more stringent and reduced the diagnostic prevalence of the disorder. Few changes in diagnostic criteria for CD occurred between DSM-III-R and DSM-5, resulting in similar diagnostic prevalence rates across these DSM editions. One-year DSM-5 prevalence rates of CD range between 2 percent and more than 10 percent with a median of 4 percent in the general population. Rates are higher in clinically referred youths and in juvenile detention populations. For adults older than 18 years, the estimated lifetime prevalence of CD in the United States is 9.5 percent, including 12.0 percent

for males and 7.1 percent for females. Studies assessing lifetime prevalence rates using retrospective recall methodologies of adults suggest that the median age of onset of CD in the United States is 11.6 years. Age of onset generally occurs between mid-childhood and mid-adolescence. Onset after adolescence is rare. The prevalence of CD is much greater in boys than girls. Lifetime prevalence of CD is associated with younger age, male gender, and low educational attainment, being separated or divorced as an adult, and residing in urban settings.

Etiology

In order to rationally guide prevention and treatment efforts for conduct-disordered youth, it is important to understand etiologic and causal mechanisms. Identification of causal mechanisms would facilitate understanding of why CD develops in some at-risk youth while in other at-risk youths it does not. However, causality in the development of CD and by extension antisocial behavior, aggression, and violence is very difficult to demonstrate. Most research in this area has focused on revealing correlates of antisocial behaviors, delinquency, conduct problems, and CD. Correlates have many different ways of fitting into causal models and knowing the correlation does not inform as to which causal explanation fits best. For example, correlations do not tell us what factors are specific for the development of CD and what factors are generalized risks for the development of global psychopathology, one aspect of which may be CD. Similarly, correlations do not inform as to what constitutes a direct risk factor for the development of CD and what constitutes a risk factor that is indirect and mediated through other mechanisms. Most correlational research has focused on single variables and sought to determine their significance in the development of CD. These are called univariate or main effects models. However, causal mechanisms for CD and other types of antisocial behaviors are multifaceted, complex, and transactional (i.e., multiple risk and protective factors that feed forward and backward to influence one another over the course of a child's development). The field is rapidly moving away from single variable, main effects perspectives in the etiology of CD and toward viewpoints that attempt to integrate person specific (genetic and developmental factors), family specific, and environmental factors (shared and nonshared) into more ecologically valid models of etiology.

Biological

HERITABLE FACTORS. Research has recognized that antisocial, aggressive, and conduct problems cluster in families to a greater extent than pure chance would suggest. Familial clustering can reflect shared environmental factors (i.e., factors that all siblings in a family share such as socioeconomic

status), genetic factors, or the interaction between genetic vulnerability factors and adverse environmental experiences (i.e., gene–environmental correlations and interactions). Shared environmental factors known to be associated with aggregation of conduct problems and antisocial behaviors in families include growing up in a family with antisocial parents, having a father with an externalizing behavior disorder, parental psychological distress including maternal depression, exposure to paternal alcoholism, residing in an urban environment, and low socioeconomic status.

The evidence for genetic influence on conduct problems utilizes twin and adoption methodologies. In adoption methodologies, biological children of antisocial parents who are adopted away at birth to nonantisocial adoptive parents are compared on rates of conduct problems in later childhood or adulthood to rates of antisocial behaviors in adopted away offspring of nonantisocial parents. These studies are consistent in finding a genetic influence for antisocial behavior, aggression, and adult crime. Other studies consistently document statistically significant associations between antisocial personality disorder and crime in biological parents and similar disorders in adopted away offspring. Identical twin studies demonstrate a substantial genetic component for both criminality and antisocial personality disorder in adults. Behavioral genetic research finds that genetic influences account for about 40 percent of the variation in antisocial behavior among individuals in the population and that the magnitude of genetic influences on CD are around 50 percent. Shared environmental factors account for about 11 percent of the variance and the remainder is accounted for by aspects of the environment unique to an individual (e.g., physical or sexual abuse). Significantly larger estimates of genetic effects are found for more severe conduct and antisocial problems in contrast to less severe behaviors and in antisocial behavior using clinic referred, as opposed to community, samples.

Examples of gene by environmental interactive effects in the genesis of CD, are studies investigating the gene for the enzyme monoamine oxidase type A (MAOA). The MAOA enzyme is involved in the metabolism of several central nervous system monoamine neurotransmitters important in the etiology of diverse psychiatric disorders. In boys who experienced sexual or physical abuse during development (a nonshared and individual unique environmental factor) polymorphisms in the MAOA gene explained variance in the eventual development of CD. Abused boys with a gene variant for low MAOA activity were twice as likely to develop CD as those with a gene variant coding for high MAOA activity. In boys without abuse, variations in MAOA were not related to the eventual development of CD. These studies demonstrate the importance of examining both environmental risk factors and genetic vulnerability factors and their interactions in the genesis of a heterogeneous condition such as CD.

PHYSIOLOGICAL FACTORS. Studies have shown that individuals with CD, antisocial behaviors, and aggression often demonstrate many signs of physiological underarousal and decreased sensitivity to stress. Arousal theory hypothesizes that low levels of arousal are related to conduct problems in two ways. First, reward processing theory suggests that low physiological arousal to environmental stimulation is a constant and unpleasant internal state for antisocial individuals. Thus, more sensory input is needed by such individuals for the maintenance of a euthymic affect. As such, risk-taking activity including aggression and conduct-problem behaviors are considered a mode of sensation seeking through which the individual seeks to normalize or optimize arousal levels and emotional state. Next, fearlessness theory postulates that low levels of physiological arousal are markers of decreased sensitivity to fear. Lack of fear can explain increased risk for conduct problems because such children may not generate anticipatory anxiety in response to inappropriate behaviors and/or may not appropriately respond with anxiety to environmental cues of punishment. Since socialization and learning to refrain from inappropriate behaviors are based on aversive conditioning (i.e., that inappropriate behaviors will be punished resulting in the child experiencing a state of internal negative affect; the child learns to avoid negative internal affect by refraining from inappropriate behaviors), lack of fear sensitivity may result in decreased individual responsivity to environmental cues of sanction and increased risk for conduct-problem behaviors. Research has shown low resting heart rates and heart rate reactivity to stressful situations in fearless individuals. A lack of fear and anxiety in childhood to cues of social punishment may contribute to disturbed fear conditioning, the preferential use of aggression to solve interpersonal conflicts, and a lack of moral and conscience development in antisocial individuals. Low resting heart rate has been shown to be a predictor of violence independent of other social risk factors in longitudinal studies. However, many individuals with a low resting heart rate do not become conduct disordered. When physiological factors such as low resting heart rate are combined with environmental risk factors such as having a teenage mother, being economically disadvantaged, or residing in a family where parents' divorce, the risk for antisocial behavior becomes much greater. Other methodologies to measure physiological arousal include the resting electroencephalogram and skin conductance activity. These studies also report a correlation between measures of low physiological arousal and increased risk for antisocial behavior.

NEUROENDOCRINOLOGIC FACTORS. The hypothalamic–pituitary–adrenal (HPA) axis is a major stress-regulating system in the body. The final product of the HPA axis is the release of the hormone cortisol into the bloodstream. Cortisol has many effects on biological arousal systems,

preparing the organism to respond to environmental threats. Consistent with arousal theory, studies have found low basal cortisol levels to be correlated with conduct problem and antisocial behaviors in clinically referred, at-risk and in nonreferred community samples of children and adolescents. Studies have also reported blunted cortisol reactivity in response to stress in antisocial youngsters. Longitudinal studies have assessed the effects of low cortisol levels at age 10 to 12 years on predicting aggression at age 15 to 17 years. Other investigations have found that children meeting diagnostic criteria for disruptive behavior disorders had lower cortisol levels than control children when exposed to frustrating or provoking events.

Since males are more physically aggressive than females in animal species as well as humans, attention has focused on testosterone, the most important male sex hormone. Although many preclinical studies in rodent and mammal species demonstrate that the presence of testosterone is a prerequisite for the expression of aggressive behaviors, human studies are equivocal. Human studies implicating testosterone in aggression are more robust when investigating postpubertal as compared with prepubertal youngsters.

NEUROTRANSMITTER FACTORS. There is support for a relationship between lowered catecholaminergic activity (DA and NE) in the CNS and increased risk for aggressive behavior, ODD, and CD. Catechol-*O*-methyltransferace (COMT) and MAOA are enzymes important in the metabolism of catecholamines. Lower levels of COMT and MAOA activity are associated with increased risk for disruptive behavior disorders. Genetic studies have reported that variations in the structure of the gene encoding the dopamine D4 receptor (DRD4) are associated with increased risk for aggressive behavior as well as attentional deficits and increased hyperactive–impulsive behavior. Altered CNS dopamine and norepinephrine activity suggest hyposensitivity to reward and diminished salience of environmental cues of punishment for inappropriate behaviors associated with deficits in reward and punishment processing associated with disruptive behavior disorders.

Serotonin is a ubiquitous central nervous system neurotransmitter that plays an important role in stabilizing information processing in neural systems, resulting in coherent behavioral, emotional, and cognitive outputs. Disturbed serotonin neurotransmission is associated with disinhibited, aggressive, and impulsive behavior in humans, perhaps by increasing sensitivity to cues that elicit irritation and aggression and by diminishing sensitivity to stimuli that signal punishment or consequence for one's actions. Many studies suggest that serotonin plays a role in aggression directed toward others and directed toward the self (e.g., suicide). In adults there is compelling evidence of an inverse relationship

between peripheral and central measures of serotonin and antisocial behaviors. In children with disruptive behavior disorders, several (but not all) studies provide evidence of a role for serotonin in the modulation of conduct-problem behaviors in children and adolescents. Age may be an important developmental factor in explaining differences between serotonin study results in adults and in children. Conduct-disordered behaviors may be associated with developmental abnormalities of the serotonin system. Decreased sensitivity of the serotonin 1A receptor (5-HT_{1A}) and antagonism of the 5-HT_{1B} receptor are associated with increased impulsive aggression in animal and human studies.

NEUROANATOMIC FACTORS. Brain imaging research has consistently implicated several central nervous system anatomic regions in the expression of impulsive aggression and antisocial behaviors. Techniques using positron emission tomography (PET), magnetic resonance imaging (MRI), and functional MRI (fMRI) in violent adult offender samples, including murderers, violent schizophrenics, drug-abusing sociopaths, and community subjects with antisocial personality disorder, have consistently found anatomic or functional deficits in anterior brain regions, particularly in the prefrontal cortex. These findings suggest that frontal lobe dysfunction may be associated with deficits in the top-down regulation of behavior and with increased risk for generalized antisocial and violent behavior. Findings from clinical case studies involving brain injury implicate the ventromedial and orbitofrontal subregions of the frontal cortex. Impaired functioning in the orbitofrontal cortex may be associated with compromised affective decision making in ODD and CD. Imaging studies of impulsively violent offenders with executive cognitive functioning deficits suggest involvement of the dorsolateral prefrontal cortex. Other studies have examined subcortical regions of interest. Emerging evidence implicates amygdala underfunctioning associated with psychopathic personality traits.

NEUROTOXIC FACTORS. Maternal prenatal smoking has been associated with adverse behavioral events in offspring. These include increased rates of antisocial behaviors including delinquency, impulsivity, CD, truancy, and attentional difficulties. Individuals with substantial prenatal exposure to alcohol have been found later to more frequently engage in impulsive aggression and antisocial behavior relative to comparison groups. There is evidence of a linear alcohol dose–response effect. The greater the amount of maternal alcohol consumed during fetal development, including even moderate drinking, the higher the risk for offspring conduct problems. Postnatal lead exposure may have a small effect on later risk for conduct problems. Birth complications such as fetal anoxia during labor are associated with risk for the subsequent development of conduct problems,

especially in disorganized families with few resources. These associations continue to retain their statistical significance despite controlling for multiple potentially confounding factors.

Psychological

COGNITIVE FACTORS. Cognitive control theory posits that the optimal and adaptive regulation of thought, emotion, and behavior to changing environmental demands occurs via intact prefrontal cortical functioning. Mental processes such as planning, sequencing appropriate actions, working memory, and inhibition of inappropriate emotional or behavioral responses allow for flexibility in adaptation to changing environmental demands and optimizes individual emotional and behavioral responses. These mental processes dependent on intact prefrontal cortical functioning are known as executive cognitive functions (ECFs). Because the prefrontal cortex matures with age, prefrontal cortex control over behavior increases across development from childhood to young adulthood when neuronal myelination is thought to be complete.

ECF deficits are associated with conduct-problem behavior independently of their correlation with ADHD. For example, boys with disruptive behavioral disorders show diminished response flexibility to changing parameters of reward testing. In the laboratory, they continue a previously rewarded response that is changed and now punished. In other words, ECF impairment in these individuals leads to response perseveration and diminished flexibility in responding to changing environmental circumstances. This is thought to reflect diminished top-down cognitive control over emotions and behaviors. Overall, in investigations of school-aged children, adolescents, and adults with a variety of antisocial and externalizing behaviors, the effect size of a variety of ECF measures for the groups with conduct-problem behaviors ranges between 0.39 and 0.62 (a moderate effect size).

Other problems in information processing are also correlated with CD. A consistent finding has been poor academic performance, especially delays in reading, in youngsters with CD. Many studies report a correlation between impaired verbal ability and conduct problems. On tests of intelligence, many conduct-disordered youth have a diminished verbal intelligence quotient (IQ) relative to performance IQ. Delays in speech and language development are not uncommon in youngsters with CD.

Youngsters with CD frequently fail to appropriately attend to and accurately encode social cues from others in the environment. For example, delinquent and aggressive boys demonstrate a bias to attribute hostile intentions to others, even when the expressed cues are neutral and nonthreatening. Boys with disruptive behavior disorders have problems encoding social cues and generating nonaggressive responses. These boys

often feel confident in their ability to carry out an aggressive response. Both boys and girls with CD demonstrate more affective empathy deficits toward others than those without CD. Since empathy involves feelings that are congruent with another's situation, deficits in empathy may increase the risk for aggressive responding. Research reports stronger findings for empathy deficits in conduct-disordered adolescents than in younger children.

PARENT–CHILD FACTORS. Many studies find that poor parenting practices are related to disruptive behaviors in offspring. Aspects of child rearing that have been consistently associated with children's disruptive behaviors include the degree of parental involvement with the child, poor monitoring of the child's whereabouts, not knowing what peers the child is associating with, coercive family process, and harsh and inconsistent discipline practices. Physically aggressive punishment of the child has been linked to child aggression. Low parental warmth and lack of involvement with the child has been linked to child oppositional and defiant behaviors. The effects of parenting practices on child behaviors are complex and reciprocal. Children influence parental responses to their own behaviors as much as parents influence behaviors in their offspring. Parents may interact with sons differently than daughters. The past decade has seen an increase in the complexity of psychological models of parent–child interactions and a growing recognition that contextual and genetic variables must be accounted for in any attempt to characterize the complicated relationships between parents and offspring behaviors.

TRAUMATIC FACTORS. Childhood physical abuse, sexual abuse, and a history of neglect are associated with an increased risk for the development of a wide variety of both internalizing symptoms, such as depression and anxiety, and externalizing behavior problems, such as aggression, delinquency, and conduct problems in children and adolescents. No specific psychiatric syndrome has been linked to childhood experiences of maltreatment. Rather, abuse appears to be a risk factor in the development of many different and varied psychological and behavioral problems in youth. It is also important to note that many childhood abuse victims do not later demonstrate many of these sequelae. Childhood physical abuse may be a particular risk factor for the later development of conduct problems and aggressive behavior. This association is found for both community and clinically referred youth. Investigations of the effects of different forms of early abuse on later development of crime and violence in nonreferred community samples found that physical abuse and neglect early in childhood are significantly associated with arrest for violent crime in adulthood. This association retains its statistical significance even after studies control for the confounding effects of age, gender, and race.

Childhood physical abuse, childhood neglect, or the combination of childhood physical abuse and neglect appear especially associated with increased arrest rates for violent offenses in adolescence and adulthood. Sexual abuse in childhood may also be associated with the development of aggressive behavior and conduct problems in childhood and adolescence. However, childhood sexual abuse is associated with a wide range of developmental outcomes, including children who are asymptomatic, and aggression is one of many symptom patterns that may occur in sexually maltreated youth. Characteristics of the abuse such as severity, duration, frequency, relationship between victim and perpetrator, and violence associated with sexual abuse have a bearing on outcome including risk for CD.

PARENTAL FACTORS. Children of parents who demonstrate psychopathology have higher rates of emotional and behavioral difficulties compared to children of parents who have no psychiatric difficulties. Early studies of children of alcoholics found an increase in the rates of externalizing behavior problems in offspring, including ADHD, CD, and ODD. Later studies either failed to replicate an association between parental alcoholism and child conduct problems or found an increased risk for generalized psychopathology in offspring that is not specific for aggression and conduct problems in particular. Children of opiate-dependent parents demonstrate increased rates of conduct problems in addition to increased rates of generalized psychopathology. Maternal depression has been linked to an increased risk of conduct problems in offspring in some studies. In studies of depression in multiple familial generations, a threefold elevated risk for conduct problems and disruptive behavior disorders was found for children of depressed parents compared to children of nondepressed parents. Parental antisocial personality disorder and criminality, especially in the father, appears to be a strong and more specific risk factor for the development of child antisocial behavior, aggression, and conduct problems. Children who have both parents criminally involved are at very high risk for the development of aggressive and antisocial behavior.

Sociological. Extrafamilial risk factors for aggression include those that occur in the neighborhood, community, or in association with a deviant peer group. Larger trends in society such as poverty, the easy availability of firearms, and the effects of media violence are also important.

PEER FACTORS. The association between peer factors and aggression encompasses two distinct yet interrelated phenomena: first, early rejection of the aggressive child by peers and then later association with a deviant peer group. In the early school years, aggression toward peers is highly

associated with peer social rejection and peer social group victimization of the aggressive child. The aggressive child is disliked and singled out by the social peer group and then excluded from participation in the peer group's activities. The antisocial child then begins to associate with a deviant peer group. Both rejection and victimization appear associated with increased risk for subsequent conduct problems, aggression, and antisocial behaviors in the aggressive child and adolescent. Indeed, the extent to which peer relationships are organized around deviance and antisocial behaviors is a strong predictor of continued antisocial behavior across adolescence and into young adulthood.

SOCIAL FACTORS. General social deprivation includes such factors as poverty, low socioeconomic class, unemployment, poor housing, residing in violent neighborhoods, and overcrowded living conditions. There exists a relationship between indices of general social deprivation and increased rates of aggression, crime, and antisocial behavior in youngsters. Low social class and poverty may be related to serious criminal offenses. On the level of the individual family and child, the effects of general environmental social deprivation on youth conduct problems may be mediated by individual parenting factors discussed above. As the number of stressors grows in an individual family and as economic resources become increasingly constrained, the ability of parents to supervise and monitor their offspring in a manner conducive to the promotion of prosocial behavior may become increasingly strained and limited. Ultimately, the effects of social deprivation on risk for youth CD may be mediated by the availability and skills of individual parents.

Cumulative Risk Factors. The importance of a cumulative risk model for onset and maintenance of conduct-problem behaviors in youth is widely supported. Risk factors do not occur in isolation from one another, are frequently interactive and reciprocal, and are often multiple and chronic in a child's life. Since most biological, psychological, and sociological risk factors are nonspecific and exert their effects on risk for antisocial behaviors indirectly, the specific type of risk factor appears less important for the development of antisocial behaviors than the total number of risk factors present, their chronicity, and their interactions across child development. Cumulative effects of multiple risks (i.e., susceptibility genes for antisocial behavior and violence, parental psychopathology, low socioeconomic status, adverse life events, poor parenting practices, heritable risk factors for neuropsychiatric illness, antisocial personality, or psychopathy) have been demonstrated to have a far more serious impact on developmental outcomes in children than any specific type of risk factor. Two models of cumulative and interactive effects of risk factors on antisocial propensity and on aggressive behavior are illustrated in Figures

46–1 and 46–2.

Protective Factors. Protective factors are variables that exert a buffering effect in youth at high risk for CD. Protective factors are more than the absence of risk factors. Protective factors confer some specific resiliency for prosocial behaviors in the face of risk. Protective factors can be considered under differing domains such as child factors, family factors, and extrafamilial factors. Protective factors in CD are outlined in Table 46–3. It should be noted that many of these protective factors are general and diminish risk for many different types of psychopathology, not specifically just for CD.

Risk and protective factors interact with one another in different ways to determine child behavioral outcomes. Multiplicative interaction occurs when the presence of one factor multiplies the effect of another factor. Potentiating interaction occurs when the presence of one factor potentates the effect of another. Catalytic transactional interactions occur when factors affect child behavioral outcomes only in the presence of other factors, but do not independently alter behavior. In the compensatory model, stressors, risks, and vulnerability factors combine additively. In the challenge model, competency and resilience are enhanced as long as stress does not exceed a threshold. Once the threshold is exceeded, competency is overwhelmed and breaks down. In the protective model, buffering factors modulate the impact of stressors, for example, by improving individual coping skills, adaptation, and the building of competence. Some have suggested that the interaction of risk and protective factors is a balance between the power of the person and the power of his or her social and physical environment, with the adaptational outcome depending on the relative balance at specific periods of development.

FIGURE 46–1. The interaction between selected risk and protective factors is illustrated across environmental and person variables as development proceeds. The resulting outcomes of complicated interactions between these different variables are individual differences in the expression of conduct problems and antisocial behaviors. IQ, intelligence quotient; ASB, antisocial behavior; SES, socioeconomic status. (From Connor DF. *Aggression and Antisocial Behavior in Children and Adolescents: Research and Treatment*. New York: Guilford; 2002, with permission.)

FIGURE 46–2. A descriptive interactive model of the relationship between four neuropsychological domains commonly found in children and adolescents with conduct and other psychiatric disorders and the probability of aggressive responding to environmental cues. Negative emotions such as hostility or irritability interact with impulsive disinhibition, exaggerated fears of threat, and/or information processing deficits to increase risk for aggression.

Diagnosis and Clinical Features

The diagnostic criteria for CD appears in Tables 46–1 and 46–2. The essential characteristics and associated features of CD have been discussed above. Assessment must involve multiple informants including parents and the youngster. Research has shown that self-report involving covert and overt conduct-disordered symptoms is reliable if done in a therapeutic manner, free of coercion or judgmental attitudes, and in a setting in which honesty is valued. The use of rating scales is encouraged and often used to document the severity and pervasiveness of CD symptoms. An important issue for clinicians in assessment is the comorbidity that frequently accompanies a diagnosis of CD. Assessment must evaluate the presence of comorbid psychiatric conditions such as ADHD, depression, bipolar disorder, substance-use disorders, developmental delay, learning

disabilities (e.g., reading, speech and language delays), or psychotic disorders that frequently accompany a diagnosis of CD.

Table 46–3.
Protective Factors

Child Factors	Family Factors	Extrafamilial Factors
Female gender	Good parent–child relations	External supports
Easy temperament	Highly educated parents	Prosocial friendships
Higher-intelligence quotient (IQ)	High-functioning parents	Availability of opportunities
Internal locus of control	Intact family structure	High socioeconomic status
High self-esteem		Safe neighborhoods
Academic competence		Safe schools
Social competence		
Competence in activities		
Absence of susceptibility genes		

Kyle is a 16 year old who was psychiatrically evaluated while he was serving a 3-year sentence in a juvenile correctional facility for property destruction and arson. He reported becoming angry with his father over a limit being set while he was mowing the family lawn. To retaliate against his father, he flipped a lit cigarette into his father's car that was parked in the driveway. Flammable objects placed on the seat quickly caught fire and destroyed the car. When asked about his judgment in doing this, Kyle replied, "How was I supposed to know there was stuff in the front seat that would burn?" This was his third arrest and second term in a correctional facility. His first arrest occurred at age 14 years for possession of drugs with intent to sell and his second arrest at age 16 for disorderly conduct. His family functioning was characterized by conflict between his parents and between his father and himself. His mother had a history of depression and his father a history of alcoholism and a poor work record with frequent periods of unemployment. Early-onset difficulties were noted when Kyle began to attend school and a diagnosis of ADHD was made when he was 6 years old. Several trials of stimulants were prescribed but discontinued because of parental fears that they would predispose him to later substance abuse. Problems with school performance, especially poor reading skills, were noted beginning in the third grade. By grade six, Kyle was frequently skipping school and he dropped out of school permanently in the ninth grade. He reported that he "liked prison" because "the other kids here are just like me."

Pathology and Laboratory Examination

No laboratory tests are useful or required for making the diagnosis of CD. All youngsters meeting diagnostic criteria for the disorder merit a complete physical examination to rule out any associated physical trauma associated with a high-risk lifestyle. Particular attention should be paid to the possibility of drug abuse and risk for sexually transmitted diseases. In females with CD, early-onset sexual activity may lead to the possibility of early pregnancy. Because of the association with learning disabilities, the presence of academic difficulties requires psychoeducational testing in youngsters with CD.

Differential Diagnosis and Comorbid Disorders

CD is a heterogeneous condition, and youngsters meeting diagnostic criteria for the disorder often meet criteria for other psychiatric diagnoses. Isolated instances of conduct-problem behaviors that do not cause substantial daily impairment need to be differentiated from a pattern of rule breaking and violations of the rights of others that may constitute a disorder. Early-onset CD needs to be differentiated from ADHD that can be marked by hyperactivity, impulsivity, risk taking, and problems with affect regulation. When ADHD and CD co-occur, the prognosis is generally worse than the prognosis for either disorder alone. Although some studies support the conceptualization of ADHD and CD as a single disorder in light of their common co-occurrence, other studies support the conclusion that they are separate but related disorders. There appears to be a reciprocal relationship between CD and substance-use disorders. The presence of one disorder is highly associated with the occurrence of the other disorder. In clinically referred adolescents, bipolar disorder and depression may be comorbid with CD. In youngsters with conduct problems and academic and school difficulties, the possibility of comorbid learning disabilities or developmental delay needs to be evaluated. The risk for development of psychiatric comorbidity in youngsters meeting criteria for CD appears highest in those with the early-onset CD subtype.

CD and ODD share with intermittent explosive disorder (IED) symptoms that bring the individual into conflict with adults and authority figures such as teachers and parents. However, IED does not include the nonaggressive features of CD and contains no element of premeditation in order to achieve some contingent goal such as money or social dominance. The individual meeting criteria for ODD generally exhibits behaviors that are less severe than the individual with conduct-disordered behaviors and ODD behaviors do not include overt aggression toward people or animals, destruction of property, or a pattern of theft and deceit. While ODD generally precedes CD in the course of development, many children with ODD do not go on to meet criteria for CD later in adolescence. In DSM-5, ODD and CD are conceptualized as separate disorders yet with many overlapping features. When diagnostic criteria are met for both ODD and CD, both diagnoses may be assigned.

Course and Prognosis

Longitudinal studies have shown that the risk for CD unfolds across development in an orderly fashion, with the onset of less severe behaviors generally preceding the onset of more serious aggressive and antisocial behaviors. This orderly progression is illustrated in Figure 46–3, demonstrating a normative and a deviant developmental pathway. In the normative pathway, there is a gradual decrease in oppositional, defiant, and aggressive behaviors during childhood, with a transient increase in delinquent behaviors in adolescence, eventually leading to a prosocial

outcome in young adulthood. In the deviant pathway, the gradual accumulation of risk factors leads to a steady worsening of aggressive and oppositional behaviors in childhood and increasingly serious acts of antisocial behavior leading to CD in adolescence.

Researchers have found support for other developmental pathways to serious CD in boys. The "overt pathway" progresses from minor acts of aggression to physical fighting and then violence. The "covert pathway" before age 15 progresses from minor covert behaviors to more serious acts of property damage such as fire setting and vandalism. The "authority conflict pathway" before age 12 progresses from stubborn behavior to defiance of authority such as truancy, running away, and staying out late at night. These pathways represent different developmental lines, and children may progress to CD along more than one pathway simultaneously. Comorbid psychiatric disorders begin to emerge with early-onset CD in childhood. These may first include anxiety or depression and then later progress to substance-use disorders. As noted above, comorbidity with ADHD portends a more serious course with risk for more severe symptoms and an early age of onset of antisocial behaviors. Once established, conduct problems and antisocial behaviors generally persist over time, with 50 to 90 percent of youngsters still meeting criteria for diagnosis after 4 years. Studies show that the severity of ODD in childhood is significantly associated with adolescent CD independent of childhood ADHD. Current research suggests that about 30 percent of boys with ODD will progress to CD, and about 40 percent of conduct-disordered adolescents will progress to eventual antisocial personality disorder. This implicates about 10 percent of ODD boys being at risk for antisocial personality disorder in adulthood. At present, it is unclear if a similar picture holds for girls meeting childhood criteria for ODD, and more research on risks for CD in girls is needed.

Treatment

Reviews of treatment research conducted in the 1960s, 1970s, and 1980s documented a lack of treatment efficacy for aggressive children with antisocial behaviors and conduct problems. Many clinicians wondered whether it was at all possible to intervene effectively for children and adolescents diagnosed with CD. Psychiatric interventions largely based on psychoanalytic principles and psychological treatments given singly and sequentially in isolation did not seem to work for these youngsters. Early research was yet to elucidate the importance of developmental psychopathology in the etiology of early-onset CD, nor did clinicians appreciate the need for multimodal interventions applied concurrently as opposed to single interventions applied in isolation in the treatment of aggressive and antisocial youngsters. Although most contemporary clinicians would still agree that effective treatments are still lacking for CD and other forms of aggressive and antisocial behaviors in youths, clinicians now view such behaviors as partly, but not robustly, modifiable.

Most clinicians regard primary prevention as the gold standard in CD intervention. Results of programs specifically designed to prevent the onset of childhood aggression and antisocial behaviors show that they generally are effective, with long-term benefits in reducing antisocial behaviors, delinquency, CD, and substance-use initiation in at-risk youngsters over follow-up periods lasting several years. However, not all secondary prevention programs for conduct and antisocial problems have proved successful. Successful programs typically include: (1) multimodal

interventions that simultaneously target the child and family, parent supports, teacher involvement, and early childhood education (interventions with only a single focus appear much less effective); (2) intensive interventions generally delivered on a daily to weekly basis; (3) sufficient duration of intervention, generally 2 to 5 years or longer; (4) use of specific interventions empirically shown to be effective in ameliorating known psychosocial mechanisms that increase risk for conduct problems (e.g., coercive family process, harsh and inconsistent parental discipline, failure of parents to monitor the whereabouts of older children); (5) child and parent interventions that emphasize skill building, problem solving, and coping skills; (6) interventions that begin early in a child's life (between 0 and 6 years old); (7) individual case management; and (8) intensive collaboration among community, juvenile justice, school, family, and mental health professionals. These programs are expensive and generally require governmental financial support. Primary prevention programs that have these characteristics appear to reduce aggression and conduct problems during child development. For children and adolescents who demonstrate aggressive and violent behavior in the school setting, another approach is to emphasize violence prevention in the school. Studies reveal moderate violence prevention effects of various school programs.

Three well-studied mediators of early-onset aggression and conduct problems include coercive family processes, problematic parent practices, and deficient social skills. The first mechanism describes how parents and children train each other through the mechanism of mutual negative reinforcement to become oppositional and aggressive as a way of escaping aversive interpersonal situations. This learning may then generalize out of the home as the child develops and facilitate a developmental trajectory toward oppositional or CD. Other parenting practices associated with the development of antisocial behaviors include lack of parental monitoring of the child's whereabouts and friendships, low nurturing and engagement in the child's daily life, and harsh and inconsistent discipline. Research has described specific skill deficits from which aggressive children misinterpret neutral environmental stimuli as threatening and then react aggressively. As a result of this research, psychosocial treatments emphasize PMT and individual skill-building approaches. PMT teaches consistent parenting, positive and less harsh discipline practices, monitoring of the child, and positive feedback for the child. A variety of programs have been developed and tested against control conditions. In general, these parent-training programs appear effective in decreasing young children's oppositional, defiant, noncompliant, and aggressive behaviors. Several family therapy programs have been found to be promising, such as functional family therapy. Skills training approaches focus on the individual child. These programs emphasize social skills, problem-solving techniques, and anger

management strategies in reducing child aggression and conduct problems, and individual therapy approaches based on the principles of cognitive-behavioral therapy. Multifocused psychosocial programs for child conduct problems combine PMT, structural family therapies, and child skill-building treatments. The overall effect size of multifocused psychosocial treatment programs on preventing the worsening of conduct problems and aggression in at-risk youngsters is medium to large. Many of these programs demonstrate lasting effects after treatment is completed. Enhanced social skill building and conflict resolution skills in aggressive families may function as a mediator of treatment.

Multi-Systemic Treatment (MST) and Multidimensional Treatment Foster Care (MTFC) are programs that have been developed to treat older children and adolescents with established antisocial and aggressive behavior patterns necessitating juvenile justice involvement. These programs are designed as alternative placements to incarceration or psychiatric hospitalization and encompass a variety of psychoeducational, community, and mental health services delivered simultaneously to the adolescent and their family. MST and MTFC have demonstrated effectiveness in the treatment of severely disturbed families and violent adolescents, reporting decreased arrest rates ranging from 25 to 70 percent over 1- to 4-year outcomes. As such, these programs appear promising in the treatment of severely aggressive adolescents with chronic juvenile justice histories.

Psychopharmacologic treatments of CD are adjunctive to comprehensive psychosocial, community, and psychoeducational interventions. Pharmacological treatments generally do not focus on CD per se but on associated impulsivity, affective lability, on negative emotions such as fear and irritability, and on explosive aggression that may drive CD symptom frequency and severity. Psychopharmacological interventions are generally palliative and not curative in CD. Given high rates of diagnostic comorbidity with ADHD and affective disorders, medications targeting associated disorders may improve symptom severity, reduce daily impairment, and thus improve overall functioning of the conduct-disordered youngster. Meta-analyses have supported typical and atypical antipsychotics, mood stabilizers, and lithium (Eskalith) as being moderately effective in the treatment of explosive aggression in youngsters with CD. When antisocial symptoms arise in the context of ongoing ADHD, studies support the effectiveness of stimulants, atypical antipsychotics, and alpha-2A agonists such as guanfacine extended release.

FUTURE DIRECTIONS

There is much heterogeneity inherent in the diagnosis of CD. Since a DSM-5 diagnosis of CD requires the presence of any 3 of 15 possible symptoms, a grand total of 32,647 distinct symptom profiles meet criteria for a diagnosis

of CD. If one purpose of medical and psychiatric diagnosis is to facilitate understanding of a disorder's etiology and pathophysiology and thus arrive at a rational and scientifically based treatment plan, then there exists ongoing professional concern that CD fails as a useful and informative clinical diagnosis. DSM-5 provides for subtypes based on the age of onset, and a specifier identifying the presence of limited prosocial emotions, and there is evidence supporting the clinical utility of these subtypes in predicting the longitudinal course of CD. However, identification of more precise CD subtypes would be helpful in making the diagnosis more useful for clinicians. Other classification schemes with research support include distinctions between overt and covert antisocial symptoms, reactive, affective, defensive, impulsive (RADI) aggression, and predatory, instrumental, proactive (PIP) aggression; socialized versus unsocialized types of conduct problems; and the severity of relational aggression especially among females. Indeed, empirical support for these distinctions suggests that a more multidimensional classification system is needed to help best characterize CD.

Feeding and Eating Disorders of Infancy and Early Childhood

IRENE CHATOOR, M.D., AND LOREDANA LUCARELLI, PSY.D.

INTRODUCTION

The term *feeding disorder* is commonly used to emphasize the dyadic nature of eating problems in infants and young children. The term describes a variety of conditions including food refusal, food selectivity, eating too little, food avoidance, fear of feeding, pica, and rumination. It is estimated that in the general population 25 to 45 percent of infants and young children have various feeding problems, and that severe feeding disorders associated with poor weight gain occur in 1 to 5 percent of pediatric hospital admissions and between 4 and 14 percent in ambulatory care. However, an exact evaluation of the prevalence or incidence rates of feeding disorders, and of particular types of feeding disorders, has not been published up to now because of the variability of definitions used and the lack of a diagnostic classification of feeding disorders shared by clinicians and researchers. Overall, several studies have found that early feeding problems not only cause distress to the young child but affect the whole family and often continue into later childhood and adolescence.

Definition

Criteria for Feeding Disorder of Infancy or Early Childhood in DSM-IV have been criticized for being too restrictive and not capturing many young children with feeding difficulties, and an alternative system in DC: 0–3R (2005) has often been used. This system includes six subtypes of feeding behavior disorder proposed by Chatoor (2002). Avoidant/Restrictive Food Intake Disorder (ARFID) in DSM-5 has replaced Feeding Disorder of Infancy or Early Childhood in DSM-IV. It has expanded the earlier more limited diagnostic criteria by introducing three main categories of feeding/eating problems, and in the text addresses the three remaining feeding disorders from DC: 0–3R. In addition, the ARFID criteria can be applied to individuals of all ages, consistent with the recognition of the continuity of psychopathology across the age range from early childhood to adulthood.

The new criteria of ARFID in DSM-5 describe three variants of an eating

or feeding disturbance that is characterized by, for example, apparent lack or interest in eating or food; avoidance based on the sensory characteristics of food; concern about aversive consequences of eating. These new DSM-5 criteria of ARFID with the accompanying text map on directly on three of the DC: 0–3R subtypes. The new subtype "apparent lack of interest in food or eating," has been described in DC: 0–3R as infantile anorexia (IA); the second variant "avoidance based on the sensory characteristics of food" describes children who select or avoid food in relation to the appearance, taste, texture, smell, or temperature of food and has been defined in DC: 0–3R as Sensory Food Aversions; the third variant "concern about aversive consequences of eating" is described in DC: 0–3R as Feeding Disorder Associated with Insults to the Gastrointestinal Tract and has been described by Chatoor as Posttraumatic Feeding Disorder (2002).

In addition, in the text there is allowance to diagnose ARFID in infants and children with the remaining three feeding disorders described in DC: 0–3R, those who have difficulty with state regulation, those who may not engage with the caretaker during feeding, or those whose feeding problems are associated with a medical condition when the disturbance of intake is beyond what can be explained by the physical condition.

To delineate feeding disorders from less severe feeding difficulties, DSM-5 has expanded the criteria of impairment to affect one or more of four areas of health or functioning:

- Significant weight loss (or failure to achieve expected weight gain or faltering growth in children)
- Significant nutritional deficiency
- Dependence on enteral feedings or oral nutritional supplements
- Marked interference with psychosocial functioning

History and Comparative Nosology

Prior to the inclusion of the diagnostic category of Feeding Disorder of Infancy or Early Childhood in the DSM-IV, there were no nationally defined criteria for the diagnosis of feeding disorders. In the absence of a recognized standard, different authors have used several labels for feeding problems: Picky eaters, choosy eaters, selective eaters, problem eaters, food refusal, feeding resistance, food phobia, food aversion, and dysphagia. However, none of these diagnostic labels has been operationalized. The field of feeding disorders has been further complicated by the fact that feeding disorder and failure to thrive (FTT) have been used interchangeably. The term *failure to thrive* refers to inadequate weight gain, based on standard growth charts. Historically, FTT has been dichotomized along organic and nonorganic axes. Whereas the former attributes growth failure to a medically diagnosable cause, the latter has commonly been thought to reflect maternal deprivation or neglect. A third

category was later added and represents a mixture of organic and environmental etiological factors of growth failure.

Concerns have been expressed about the usefulness of the label FTT as a "catch-all" diagnosis for all feeding disorders. First, the overlap between FTT and feeding disorders is confusing because not all infants with FTT have feeding disorders, and not all infants with feeding disorders have FTT. Second, Goldbloom pointed out that the term FTT is purely descriptive and does not address the process that caused the infant to grow inadequately. Although many authors agree that FTT should be viewed as a symptom rather than a diagnosis, FTT continues to be used as a diagnostic label particularly in the pediatric and psychological literature.

As described above, because of the limitations of the diagnostic criteria of Feeding Disorder of Infancy or Early Childhood in DSM-IV, an alternative classification of feeding disorders has been adopted by DC: 0–3R, which served as a template for the new diagnostic category of ARFID in DSM-5.

The original diagnostic criteria were published by Chatoor in 2002 and were modified with the help of the 2003 Task Force for Research Diagnostic Criteria for Infants and Preschool Children. They were further developed with the help of a work group that was supported by the American Psychiatric Association, and the revised criteria were published in 2007 in *Age and Gender Considerations in Psychiatric Diagnosis*. As explained above, the diagnostic criteria for these six feeding disorder subtypes were also included in the 2005 edition of the *Diagnostic Classification of Mental Health and Developmental Disorders of Infancy and Early Childhood: Revised Edition* (DC: 0–3R).

The six feeding disorder subtypes are as follows: (1) feeding disorder of state regulation, (2) feeding disorder of caregiver–infant reciprocity, (3) infantile anorexia, (4) sensory food aversions, (5) feeding disorder associated with a concurrent medical condition, and (6) feeding disorder associated with insults to the gastrointestinal tract. The first four feeding disorders tend to start during specific developmental periods and are arranged accordingly, whereas posttraumatic feeding disorder and feeding disorder associated with a concurrent medical condition can occur at various stages of the child's development.

Since recently published research on feeding disorders has frequently used the classification in DC: 0–3R, the authors will discuss the various feeding disorders as listed in DSM-5 and will use the descriptions of the feeding disorders in DC: 0–3R as subtitles.

SPECIFIC FEEDING DISORDER SUBTYPES

Avoidant/Restrictive Food Intake Disorder

Subtype: apparent lack of interest in eating or food (DSM-5)

Infantile Anorexia (DC: 0–3R)

Diagnosis and Clinical Features. IA is characterized by poor appetite, lack of interest in eating, and poor growth in an otherwise active and playful child. It was first described by Chatoor in the 80s and was adopted in DC: 0–3R (2005) as one of the subtypes of Feeding Behavior Disorder. It usually begins in the first 3 years of life, most commonly between 9 and 18 months of age, when infants learn to walk, begin to talk, and are transitioned to spoon and self-feeding. The children are active and playful and appear to be interested in everything else but food and eating. They resist going into the highchair; they refuse to open their mouth to be fed and throw the food and feeding utensils. The parents become increasingly worried because of the children's poor food intake and growth, and they often resort to distracting, coaxing, and bribing to get the children to eat. Some parents become so anxious that they try to feed the children whenever they are willing to open their mouth, and some become so desperate that they resort to force feeding their children. Consequently, there is increasing conflict between the children and their parents, and mealtimes become miserable for the whole family.

Differential Diagnosis. IA needs to be differentiated from other feeding disorders that are characterized by food refusal. ARFID subtype: "concern about aversive consequences," usually has a more sudden onset of the food refusal following a traumatic event to the oropharynx or gastroesophageal tract, such as choking, severe gagging, or vomiting, or the insertion of feeding or endotracheal tubes. The infant with this feeding disorder may refuse all food, or only solid food, or only the bottle, depending on what mode of feeding the infant associates with the traumatic experience(s). Infants with ARFID subtype: "avoidance based on the sensory characteristics of food" or sensory food aversions (DC: 0–3R) consistently refuse specific foods but eat well if offered preferred foods.

Etiology and Course. Toddlers with IA have been found to have a higher level of physiological arousal and more difficulty down regulating their arousal. This may explain why they have so little awareness of hunger because they seem very excited by their play and enjoy talking, but they have difficulty turning away from these pleasurable activities. Studies from different centers have found significant correlations among difficult child temperament, irregular feeding and sleeping patterns, negative and willful behaviors by the toddlers, and mother–child conflict during feeding. At the same time, mothers' insecure attachment to their parents and mothers' drive for thinness and bulimia, anxiety, and depression also correlated significantly with mother–child conflict during feeding. Finally, mother–child conflict during feeding correlated strongly with the child's weight: the

more conflict between mother and child, the lower was the child's weight. However, correlations need to be used with caution to explain etiology, although the feeding histories of children with IA suggest that the lack of appetite and food refusal by the toddlers evoke severe anxiety and feelings of helplessness in the parents, who then try to engage the children in distractions and do anything to get the children to eat. The more insecure the parents feel, the more they allow the child to control the feeding situation, and the more ineffective the parents become in setting appropriate limits to the child's demanding behaviors. Consequently, parents and children become trapped in maladaptive interactional patterns.

Research further revealed that toddlers with IA on average performed in the normal range of cognitive development. However, the Mental Developmental Index (MDI) score of a control group of healthy eaters was 11 points higher than that of the group of toddlers with IA. Further analyses showed that not weight but mother–toddler interactions during feeding and play seemed to contribute significantly to these differences. Mother–toddler conflict and struggle for control during feeding and maternal intrusiveness during play were associated with lower cognitive performance of the toddlers.

A longitudinal study from Italy by Lucarelli and colleagues of children with IA who received only minimal intervention at the time of diagnosis, revealed some interesting findings. About 70 percent of the children with IA seen at follow-up during school age, showed ongoing eating problems and higher scores in anxiety, moodiness, aggressive behaviors, and somatic complaints when compared to the controls. These longitudinal data also showed significant correlations between continuing maternal eating and psychopathology, especially depression and anxiety, and internalizing problems of the children. This study on the natural course of IA highlights the importance of early diagnosis and specific interventions for children diagnosed with IA.

A follow-up study of 20 children at 6 months to 2 years at the time of diagnosis, who had completed a specific treatment described later, demonstrated that 17 children had changed considerably. The conflict in the parent–child relationship over the child's food intake was resolved. The children had learned to recognize hunger and increased their food intake, which had led to weight gain and improved growth. However, the parents reported that many of the children continued to lose their appetite when they were excited, if they had houseguests, if they had a birthday party, or if they traveled. Once they calmed themselves, they would regain their appetite and usually make up for the lost meals. There were three children who continued to struggle with their parents over their poor eating. In two cases, day care seemed to be too stimulating to allow these children to relax enough for eating. In the third case, the home situation was very

overcrowded and disorganized.

Clinical experience suggests that older children who have been untreated and who present for the first time with the diagnosis of IA during school age are usually thin and short for their age. However, their head size and their intellectual development appear to be normal for their chronological age. This was confirmed in a follow-up study by Chatoor and colleagues of children who were treated as toddlers for IA. It demonstrated that two-thirds of the children had outgrown their feeding disorder whereas one-third did not. Regardless of their malnutrition at the time of diagnosis or at follow-up, there was no correlation between their weight and intellectual functioning. Indeed, one-third of the children functioned in the superior range.

Treatment. This subsection describes a treatment that is based on a transactional model for the development of IA. According to this model, the infant's difficult temperament characteristics of emotional intensity, stubbornness, lack of hunger cues, irregular feeding, and sleeping patterns evoke conflicts over issues of control, autonomy, and dependency in a vulnerable parent who is anxious and insecure in regard to limit setting. The treatment addresses the infant's temperament and the parents' anxiety in regard to limit setting to facilitate internal regulation of eating of the infant.

1. The infant's temperament is discussed with the parents to help them understand that the infant's curiosity and emotional intensity interfere with the infant's awareness of hunger. Because the infant is very strong-willed and has learned that food refusal is a powerful tool with which to control the parents' attention, efforts by the parents to distract or entertain the infant to get him or her to eat may help temporarily but only perpetuate the problem by getting the infant more excited.
2. The parents' source of anxiety in regard to limit setting is explored. Some parents have been sensitized by previous losses of pregnancies, by infertility problems, or by the harshness and/or emotional unavailability of their parents. Understanding the parents' sensitivity in regard to limit setting is critical to helping them to be more effective in this area with their infant.
3. After this ground work, the parents are trained in respect to changing their behavior so as to facilitate internal regulation of eating by their infant. To boost the infant's biological rhythms of hunger and satiety, the parents are encouraged to feed the infant only at regular 3- to 4-hour intervals and not to offer anything but water in between these regular feedings. They are helped to understand that it is important to encourage the infant's self-feeding by commenting on the infant's feeding skills ("you get the spoon in your mouth all by yourself"), but they are not to comment on how much or how little the infant eats. It is helpful to give

the infant only a few bites at a time and after a while change to another food to keep the infant interested in eating and engaged with the parent without the parent becoming intrusive or distracting the infant. In addition, this helps the infant to continue eating until full and to learn to regulate his or her food intake by his or her internal signals of hunger and satiety. Eating should not be a performance for the parents. There should be no distractions during feedings, and no television or games, so that the infant is kept focused on eating. If the infant engages in inappropriate behaviors during feeding (climbing out of the high chair, throwing food or feeding utensils), the parents need to learn to use the "time-out" procedure. The time-out is used to accomplish two goals: To help the infant to stop behaviors that interfere with eating and to learn self-calming when upset because he or she cannot have his or her way.

This three-step intervention with the parents is best accomplished in double sessions, lasting 2 hours each, with the first two sessions being held within a few weeks of each other. The intensity of this brief intervention facilitates a close therapeutic alliance between the therapist and the parents and enables many parents to make major shifts in their interactions with their infants. Many of these parents need only a few follow-up sessions to deal with some specific questions that may arise. Frequently, after the infant has changed his or her eating pattern, the parents ask for help concerning the sleeping problems that many of these children have as well. However, there are some families who are more deeply entrenched in maladaptive interactional patterns with their infants, and some infants are so severely malnourished that more intensive interventions or hospitalization may be required. In particular, considering the associations between the severity of IA and risk factors such as the high mother–child interactional conflict, difficult child temperament, emotional and eating dysregulation in both, the children and of their mothers, the therapeutic approach should have a dual focus on the child and on the parents.

Rachel was 18 months old when she was referred by her pediatrician because of food refusal and malnutrition. The mother looked exhausted as she described how Rachel had never been a big eater from birth but that she stayed on the 25th percentile for weight and height on the growth chart until she was about 10 months of age. Her refusal to be fed by spoon became so strong that her intake of solid food became less and less. She depended primarily on bottles with milk for her nutrition. In spite of all of the parents' efforts to distract Rachel during feeding, to offer different foods, and to feed her whenever she would accept anything (including at night) and their desperate efforts to force food into her mouth, Rachel's food refusal had gotten worse, and she had fallen below the 5th percentile on the growth chart for weight and height. The mother admitted that trying to feed Rachel had taken over her entire life and that she felt exhausted and envious when she watched her friends' children eating without any effort on the part of the parents.

The observation of mother and infant during feeding and play revealed that Rachel was a thin little girl who seemed "all eyes," observing everything in the room, including the pictures on the wall and her image in the mirror. However, she paid little attention to the food. She ate some finger food, but refused to open her mouth and arched her back when her mother tried to

feed her by spoon. After a few minutes she appeared bored sitting in the high chair, threw the food, and indicated by grunting that she wanted to be taken out of the chair. Once she had her freedom, she ran around the room entertaining herself by exploring the furniture while her mother sat in her chair looking anxious and defeated.

The treatment addressed Rachel's special temperament characteristics, her intense curiosity and emotional intensity, her strong will, and her poor awareness of hunger, which seemed to have led to her increasing food refusal. The parents were helped to understand that they had a child with special temperament characteristics that required special parenting with special emphasis on limit setting. Specific instructions were discussed on how to handle mealtime, how to deal with Rachel's food refusal, and how to use "time-out" with a young child.

Although the mother struggled initially with how to set limits to Rachel's inappropriate behaviors—for example, stopping her from throwing food and keeping her in the high chair—the parents supported each other in implementing the new feeding instructions and were pleased with the change in Rachel's behavior. Once Rachel realized that her screaming did not change the rules, she stayed in the high chair without protest and became interested in feeding herself with the spoon. Within a few weeks, she seemed more aware of hunger, and her food intake increased accordingly. When seen for follow-up 1 year later, there was no longer conflict over Rachel's eating. Rachel had gained weight and grown in length, which brought her back to the 10th percentile on the growth chart.

Avoidant/Restrictive Food Intake Disorder

Subtype: avoidance based on the sensory characteristics of food (DSM-5)

Sensory Food Aversions (DC: 0–3R)

Diagnosis and Clinical Features. Sensory food aversions are common. However, whereas some children refuse to eat only a few specific foods, others may refuse most foods and take in only a limited diet of a few foods. The diagnosis of a feeding disorder should only be made if the food selectivity results in dietary deficiencies, and/or has led to oral motor and speech delay, and/or in older children is associated with social anxiety around eating and has led to marked interference of psychosocial functioning.

Within this disorder, food refusal is related to the taste, texture, temperature, or smell of particular foods. When the infant is fed specific foods, the infant's aversive reactions range from grimacing, to spitting the food out and wiping the tongue or mouth, to gagging and vomiting. After an initial aversive reaction, the infants usually refuse to continue eating that specific food. In addition, infants tend to generalize and refuse to even try foods of similar color, appearance, or smell. Occasionally, sensory food aversions become apparent in the newborn period when the infant is switched from breast milk to formula or from one formula to another. However, most commonly, infants begin to show aversive reactions when introduced to baby foods with different flavors and different textures or in the second year of life, during the introduction of different table foods. After the initial aversive reactions described earlier, some infants show such intense food refusal that they become limited to eating only a small variety of foods. They may refuse to eat whole food categories, such as

vegetables, fruits, or meats. In extreme cases they even refuse to eat a preferred food if it touched a "feared" food on the plate or if the food is not prepared by a specific restaurant or company. Children who refuse to eat vegetables and fruits usually develop vitamin deficiencies, and children who refuse to drink milk or eat meats may develop protein, zinc, and/or iron deficiencies. In addition, children who refuse to eat foods that require more chewing, such as meats, hard vegetables, or fruits, present with delay in oral motor development, which may be associated with articulation difficulties.

In addition to their sensory food aversions, many of these children experience hypersensitivities in other sensory areas as well. Parents frequently report that these children do not like to get their hands "messy," become distressed when asked to walk on grass or sand, and do not like to wear socks or shoes, certain fabrics, or labels on clothing. Many of these children are also hypersensitive to smells, and some may have difficulty with loud sounds.

Differential Diagnosis. This feeding disorder needs to be differentiated from oppositional food refusal that is common during the toddler years. Toddlers who like to exercise control over their parents may state that they do not want to eat a certain food and demand something else to eat. However, the food choices of oppositional toddlers are inconsistent and vary according to the mood of the toddler, whereas toddlers with sensory food aversions are usually consistent in their food choices, and they become distressed when the parents insist that they eat a certain food to which they are averse. Sensory food aversions also need to be differentiated from ARFID subtype: concern about aversive consequences of eating (DSM-5) or described as posttraumatic feeding disorder by Chatoor, which is characterized by the child's refusal to eat all solid food or to drink from the bottle, depending on what mode of eating the child associates with the traumatic event(s). However, some children with sensory food aversions may develop a posttraumatic feeding disorder if they have a strong aversive reaction to a food resulting in gagging or vomiting and/or the parents continue to insist that the child eat a food to which the child is averse. These children may become fearful of eating altogether.

Etiology and Course. There are no empirical studies that have examined the etiology of sensory food aversions in infants and toddlers. However, research with preschool and older children and with adults has related taste sensitivities to the bitter substance propylthiouracil, to strong food preferences, and to the number of taste buds on the individual's tongue (those with strong taste sensitivities, the "supertasters," have significantly more taste buds than "nontasters"). A study by Cooke and colleagues that examined food neophobia (the fear to try new foods, which

is one of the characteristics of sensory food aversions) in a large sample of twins aged 8 to 11 years estimated that 78 percent was heritable and another 22 percent of the variance was explained by nonshared environmental factors. Some studies have documented that parents and their biological children can share taste sensitivities, and various models of heritability—for example, incomplete penetrance, a two-locus model, and multilocus and multiallele models—have been suggested. In 2003, Kim and colleagues reported that specific polymorphisms on the taste receptor protein gene family Tas2r on chromosome 7 differentiated supertasters from nontasters.

In addition, certain aspects of the eating environment have been linked to the development of food preferences. For example, parents with strong taste sensitivities may offer a restricted range of food to their children, and limited exposure to a variety of foods may enhance the toddlers' food selectivity. On the other hand, if parents try to coax children or become forceful to get their children to try new foods, the children become oppositional and increasingly anxious and scared to try new foods. This pattern of forcing children to eat certain foods without adequate support to manage their anxiety may be a risk factor in sensory food aversions outcome. In support of this, longitudinal research by Nicholls and colleagues has shown that selective eating is associated with anxiety and obsessive-compulsive symptoms, social limitations, and school difficulties.

A longitudinal study of children's food preferences by Skinner and colleagues, who followed children from 2 to 3 years to 8 years of age, found that the number of foods liked at 8 years was predicted by the number liked at 4 years of age. Children were more likely to accept newly tasted foods between 2 and 4 years of age than during school-age years. School-age children with sensory food aversions may experience social anxiety and try to avoid social activities (parties, sleepovers, summer camp) that involve eating. Parents of children with sensory food aversions often report that they were unable to eat a variety of foods as young children and that they learned to eat new foods primarily during their adolescent or young adult years, when they wanted to fit in with their peers.

Treatment. Research by Birch and colleagues indicated that repeated exposures to new foods enhance young infants' acceptance not only of that food but also of similar foods. However, toddlers required more than 10 exposures of the same new foods until acceptance was reached. In addition, it is very difficult to get toddlers to try new foods if they are reluctant to do so. Birch and colleagues demonstrated that coercive techniques, such as threatening children to have them remain seated at the table until they finished eating everything on their plate or depriving them of certain privileges unless they tried the new food, have a significant negative effect. On the other hand, toddlers are very responsive to modeling by their

parents. They are more willing to try a new food if they observe their parents eating the food but not offering it to them.

No empirical studies have systematically examined how best to treat infants and young children with sensory food aversions, but clinical experience suggests that if infants or toddlers show strong aversive reactions to a new food, such as by spitting the food out or gagging or vomiting, the parents are best advised to give up on having the child eat this food. On the other hand, if the infant just grimaces, the parents may expose the infant to the new food at another time and pair a small amount of the aversive food with a preferred food. A gradual increase of the aversive food over several meals may allow the infant to get used to the new food.

Modeling eating new foods by the parents and waiting until the toddler asks to try a new food generally is more effective than putting new foods on the toddler's plate and requesting that the toddler try them. If the parents stay neutral as to whether the toddler likes the requested food, the toddler remains neutral as well and does not appear to become afraid of trying new foods. Once children fear to try new foods, their diet becomes more and more limited, and, by 3 years of age, most young children are not swayed by what their parents eat. Occasionally, preschool children may be willing to try new foods in a preschool setting, but more often they become anxious in social situations and try to avoid eating with others. On the other hand, preschool children are rich in phantasies and feeding the baby dolls with playfood can help to explore her fears and encourage them to first feed the baby doll and then eat themselves new foods.

John was brought for an assessment by the multidisciplinary feeding disorders team because he refused to eat vegetables, fruits, and meats. His parents had started to give him a multivitamin daily, but they were worried that he was missing other essential nutrients in his limited diet, and they were concerned that his articulation was so poor that nobody outside of the family could understand what he was saying. At the age of 2½ years, his daily diet consisted of Cheerios or pancakes in the morning and peanut butter sandwiches, some cheese (which had to be "American"), pasta, cake, crackers, ice cream, and milk during the rest of the day. His feeding problems started when he was introduced to baby food. He accepted baby food sweetened with fruit but grimaced when given baby food with vegetables and spat it out. He gagged when introduced to baby food with lumps of meat, and he refused to accept any baby food after that. At 9 months of age, John was offered soft table foods, which he ate only if he could finger-feed himself. He had another episode of gagging when introduced to green beans at 15 months of age, and consequently he refused to touch any green vegetables and fruits. He never tried any meats, and he became very distressed when his parents put any food on his plate that he did not want. When his parents insisted that he should at least try one bite of a new food before he could leave the table, John cried throughout the whole meal and ate nothing, not even his preferred foods. The parents had strong disagreements about how to handle John's food refusal. The father had similar food dislikes as a child and wanted to leave him alone. The mother was very concerned about John's health because of his limited diet, and she tried everything—bribing, coaxing, distracting, and threatening—just to get John to try new foods. Both parents experienced mealtime as very stressful and felt that John was getting increasingly rigid about his food likes and dislikes.

The observation of feeding revealed intense conflict between John and his mother regarding

the various foods that he refused to eat. The nutritional assessment showed that although John was taking in adequate calories, he was not getting enough zinc and iron from his diet and, without the multivitamin, his diet was deficient in vitamins. The oral motor assessment revealed that John used an immature chewing pattern that was felt to be due to his lack of practice with chewing crunchy and chewy foods. This oral motor delay was felt to account for his articulation problems.

The parents were instructed to obtain vitamins complete with zinc and iron to compensate for the nutrients missing in John's diet. They were also offered speech therapy for John to help with his articulation problems. In addition, the parents were given a few parent training sessions to help them to emotionally neutralize mealtime. After the mother's anxiety about John's health was alleviated, she was able to offer John his preferred foods without attempting to get him to eat new foods. The parents were instructed to eat their regular diet in front of John without offering him any of their food, and to give him only a small piece of their food if he were to ask for it. They were not to praise him if he liked the food nor become disappointed if he no longer wanted to have it. After she had stopped offering John any new food for about 2 months, John surprised his mother by asking her to have some of her peach. He liked it and asked for more on another day. Gradually, he began to eat soft fruits without the peel, and after several months, he tried chicken nuggets. His diet increased in variety very slowly, and when he entered preschool, he tried a number of foods at school that he had not touched at home. His diet became more complete. However, John was not able to eat the variety of foods the rest of his family enjoyed.

Avoidant/Restrictive Food Intake Disorder

Subtype: concern about aversive consequences of eating (DSM-5)
Feeding Disorder Associated with Insults to the Gastrointestinal Tract (DC: 0–3R)
Posttraumatic Feeding Disorder (Chatoor, 2007)

Clinical Features. This feeding disorder may present with total food refusal, refusal to swallow solid food, or refusal to drink from the bottle, depending on what mode of feeding the child associates with the traumatic event. The onset of the food refusal is frequently rather sudden and follows traumatic experiences that involve the oropharynx or gastrointestinal tract, such as severe gagging, choking, vomiting, insertion of feeding or endotracheal tubes, or force-feeding. It is estimated that posttraumatic feeding disorder may affect 4 percent of infants with gastroesophageal reflux who do not have a history of esophageal surgery and up to 40 percent of children who undergo esophageal surgery. Frequently, the parents are not aware that the event was so frightening to the child that it triggered the food refusal because other children who may undergo the same experience will not necessarily develop a posttraumatic feeding disorder. It appears that children who develop a posttraumatic feeding disorder are more prone to anxiety and/or are more sensitive to pain than the average child. Older children who refused to eat solid food after an incident of gagging or choking reported that they were afraid that the food would get stuck in their throat and choke them to death. Infants and young children express this fear through their behavior by crying in anticipation of being fed or when seeing the high chair, the bottle, or the spoon. Some

infants or children are brave enough to put the food in the mouth but cannot bring themselves to swallow it. They keep the food in their cheeks and/or spit it out. In severe cases, the infants refuse to feed all together. These infants are in acute danger of dehydration because the fear of eating appears to override any awareness of hunger or thirst.

Often the food refusal of these children is so intense that the parents react with severe anxiety to their child's food refusal. They worry about their child's nutrition. Frequently, they try to coax and distract the child, they offer various types of food, and they try to feed the child day and night without success. However, some very young infants who are afraid to drink from the bottle when they are awake may drink when they are asleep and not aware of what they are doing. However, if they wake up and see the bottle, they usually push it away and cry. In general, the food refusal of these infants poses an acute threat to their health, and they require acute intervention.

Differential Diagnosis. This feeding disorder needs to be differentiated from IA and from food refusal because of sensory food aversions. IA is characterized by an inconsistent pattern of food refusal, depending on the mood of the child. Anorectic children are not afraid to eat and can eat all types of food if they want to eat. Sensory food aversions usually involve foods with a certain taste, texture, temperature, and/or smell. Usually, the food refusal is more selective and not as global as seen in a posttraumatic feeding disorder. However, sometimes children with sensory food aversions develop a posttraumatic feeding disorder if they experience a strong aversive reaction or if they are force-fed aversive foods that trigger gagging and vomiting.

Etiology and Course. The observation of infants with a posttraumatic feeding disorder reveals that their food refusal seems to be caused by fear. However, no empirical studies have been done to explain why only some infants with distressing experiences to the oropharynx react with a posttraumatic feeding disorder. There are also no systematic longitudinal data on the course of this feeding disorder. However, individual case studies indicate that many infants and children get locked into their fears of eating. Some drink milk from the bottle and eat only pureed food until they reach school age, when the social embarrassment of their eating behavior causes the parents to seek help. In extreme cases, when the infants refuse all food, gastrostomy feedings have to be implemented. To survive, some of these children may depend on gastrostomy feedings for years.

A recent study by Lucarelli and colleagues showed that children with a posttraumatic feeding disorder were in the clinical range of the aggressive behavior dimension, which is mainly characterized by angry moods, temper

tantrums, stubbornness, child screams a lot, is easily frustrated, and wants a lot of attention. Taking into account the history of traumatic feeding experiences, the emotional dysregulation in these children may further contribute to their ongoing feeding problems. Moreover, this study found that their mothers had significantly higher scores in anxiety symptoms, and some of them received a diagnosis of anxiety disorder. These data suggest reciprocal influences between the dysregulation in emotional functioning of these children and the anxiety symptoms of their mothers. Actually, maternal anxiety may compromise their parenting capacity to moderate the impact of the child's traumatic experience and consequent emotional dysregulation.

Treatment. Because of the complexity of many of these cases, particularly those that result from trauma inflicted by unavoidable medical procedures (e.g., intubation, suctioning), a multidisciplinary team consisting of a pediatrician or gastroenterologist, nutritionist, occupational therapist, and a psychiatrist or psychologist is best equipped to meet the needs of these infants. In cases of total food refusal, the infant is in acute medical danger of dehydration and malnutrition, and intravenous fluids need to be given. It is important to assess whether the infant might be coaxed into accepting any form of food or whether nasogastric tube feedings need to be instituted. Unfortunately, the insertion of feeding tubes can intensify the fear of feeding, and, if this is the case, the infant is better served by a gastrostomy tube. In any case, the infant's nutritional requirements need to be addressed prior to the implementation of the psychiatric treatment.

The psychiatric treatment of patients who exhibit total or partial food refusal centers on the desensitization of the infant to the fear of eating. Outpatient treatment can only be carried out if the infant accepts bottle feedings or receives adequate nutrition through a nasogastric or gastrostomy tube. It is best if the child is given the tube feedings at night and that during the day there are scheduled oral feedings at 3- to 4-hour intervals with no feedings in between. If the child feeds from the bottle, the bottle feedings should follow the oral feedings in the high chair, and there should be no bottle feedings at other times, to make the child hungry at mealtimes. Behavioral techniques of positive reinforcement, praise and social interactions of food acceptance, and preferred toys or favorite videos for distraction are instituted in the initial management to overcome the child's fear of eating. Encouragement of self-feeding is frequently helpful for these infants to gain mastery over the anticipatory anxiety of eating. When the infant begins to accept food from the spoon, it is important to proceed slowly when advancing the texture of food to avoid any incident of gagging that may set back the infant. The behavioral manipulation of the infant's eating frequently leads to external regulation of eating in response

to the reinforcers. Once the infant has overcome the fear of eating, it is important to phase out the external reinforcers and to encourage eating according to internal signals of hunger and satiety. The same principles described with regard to facilitating internal regulation of eating in children with IA should also be applied in this final stage of the treatment.

Inpatient treatment becomes necessary if the child is unable to overcome the fear of eating and remains dependent on bottle or tube feedings. Inpatient treatment involves two major components: Appetite manipulation and contingency management. For children who have feeding tubes, manipulating calories and ensuring hydration through water or Pedialyte are used to allow the child to become hungry. Positive and negative reinforcements for food acceptance and food refusal are the behavioral interventions most commonly used. However, these techniques need to be adjusted to the individual child and require a skilled team to help the child to overcome the resistance to feeding and to learn to eat in response to hunger and fullness. Counseling and psychological intervention for parents is necessary to help them cope with the child's traumatic and stressful experiences and support their parenting capacities during the interventions for their child.

Robert was 7 months old when he was referred by a gastroenterologist for an urgent psychiatric evaluation because of severe crying when offered the bottle and refusal to drink unless he was almost fully asleep and seemed unaware of his feeding. The mother reported that Robert was an 8-lb, full-term baby who had a vigorous suck and was feeding well from birth. However, after a few weeks he started to spit up during and after feedings, and by 3 months he developed projectile vomiting. In spite of the vomiting, he gained weight until he was about 4 months of age, when he was referred to a gastroenterologist and diagnosed with gastroesophageal reflux. Several medications were tried, but the vomiting continued, and by 6 months of age Robert started to arch himself during feedings as if he were in pain. He would cry and refuse to continue with the feeding. Soon afterward, the mother noticed that he would start to cry at the sight of the bottle, and he refused to accept the bottle totally, as long as he was awake. To stave off starvation, the mother relied on feeding him during the night when he was asleep. His food intake greatly diminished, and he started to lose weight. The mother tried to introduce solid food, but Robert seemed to have difficulty moving the food back to his throat and spat most of it out. At the time Robert was referred, his mother was exhausted and frightened because of Robert's continued weight loss. A recent examination by the gastroenterologist had shown that the reflux was markedly improved and that Robert's ongoing feeding difficulties could not be explained by his medical condition.

The observation of mother and infant during feeding revealed that Robert became distressed the moment his mother positioned him for feeding, and he started to cry and arch himself as soon as he saw the bottle. His mother put the bottle away and tried to comfort him, but it took more than 10 minutes until he could settle in her arms. When the mother got the bottle and tried to feed him again, he cried even louder and would not be calmed until the bottle was out of his sight. Because it was obvious that Robert was too frightened to feed from the bottle, the mother tried to feed him in his infant seat with the spoon, but he batted the spoon away and did not want to have anything put in his mouth.

As the first step of treatment, the parents were made aware that infants as young as Robert can make associations between pain, vomiting, or other distress and feeding and consequently become frightened of feedings. The parents were instructed to get Robert on a schedule of regular naps and to feed him from the bottle only when he appeared almost asleep to prevent any further activation of his fears while looking at the bottle. After a successful attempt at the

hospital to feed Robert in the high chair with a spoon in his hand and lots of encouragement to put it in his mouth, the mother was able to use another spoon and put some food in Robert's mouth. Consequently, she was encouraged not to focus on the amount of food she was able to get into him, but to look at the feedings as practicing sessions to help Robert overcome his fear of feeding and to develop oral motor skills that would allow him to handle solid food.

In the first 2 weeks, Robert would cry and refuse to continue feeding if he woke up and saw the bottle. However, gradually he seemed to realize that it was safe to drink from the bottle. The mother reported that after 4 weeks, she could even start the bottle-feeding when Robert was still awake. Robert also progressed quickly from accepting very little food from the tip of the spoon to eating up to several spoonfuls. After 3 weeks, Robert was finishing a whole baby jar at one meal. When Robert was 9 months old, the mother called to report that Robert was feeding better and starting to gain weight. At 10 months of age, Robert was taking the bottle when awake, and he had learned to use the spoon and feed himself.

Avoidant/Restrictive Food Intake Disorder (DSM-5)

Subtype: Very young infants may present as being too sleepy, distressed, or agitated to feed

Feeding Disorder of State Regulation (DC: 0–3R)

Clinical Features. This feeding disorder begins in the postnatal period and is characterized by irregular, poor feedings and inadequate food intake by the infant. Infants with this feeding disorder exhibit difficulties in state regulation, which interfere with their ability to feed effectively. They have difficulty reaching and maintaining a state of calm alertness necessary for feeding. Some are too irritable and cry excessively and cannot calm themselves for feeding. Others are too sleepy and cannot wake up or stay awake long enough to feed adequately. The parent may be anxious or depressed or may present with more severe psychopathology. Mother–infant interactions during feeding are characterized by irritability and/or sleepiness of the infant, maternal tension, and poor engagement between mother and infant.

Feeding disorder of state regulation can be seen in infants without any organic problems, but it is frequently associated with prematurity or dysmaturity and gastrointestinal, cardiac, or pulmonary disease.

Differential Diagnosis. This feeding disorder needs to be differentiated from pure organic disorders that can interfere with the regulation of the state of the infant. As described earlier, organic problems can trigger the feeding disorder and should always be addressed first. The diagnosis of feeding disorder of state regulation should be considered if treatment of the organic problem—for example, cardiac or pulmonary disease—cannot resolve the infant's difficulty in state regulation.

Etiology and Course. There are no empirical studies that have explained why some infants have more difficulty in regulation of state than others. However, the foundation for the regulation of feedings, which is so closely linked to the regulation of state, is further developed in the first

months of life. Infants with feeding problems during the early months trigger anxiety in their mothers and frequently continue to have difficulty in self-regulation of their food intake during the transition to self-feeding in the second year of life. In a longitudinal study from Sweden, 70 percent of infants with feeding difficulties and food refusal in the first year of life were observed to have eating problems during childhood.

Treatment. Treatment needs to be individualized and can be directed toward the infant, toward the mother, and toward the mother–infant interaction. If the infant is too sleepy to feed and difficult to arouse, gentle infant massage to stimulate the baby may help to improve the infant's alertness and facilitate better feeding. If the infant is too irritable and fidgety to feed, reducing stimulation before and during feedings by taking the child to the quietest room in the house and swaddling the baby during feedings may help to settle the infant and facilitate better feedings. However, if the infant tires easily and is unable to take in adequate calories to grow in spite of all efforts to improve the feedings, nasogastric tube feedings may have to be considered to supplement oral feedings. On the other hand, if the mother is exhausted, overly anxious, or depressed, her difficulties have to be addressed to enable her to be more effective with her infant.

Videotaping the feedings and observing the tape together with the mother is frequently helpful to heighten the mother's awareness of the infant's cues and to explore alternative methods that she can use to facilitate the infant's regulation of state and ability to feed.

Thomas was 3 months old when he was referred for a psychiatric evaluation because of his feeding difficulties and poor weight gain since birth. His parents were college educated, and both had pursued their professional careers until Thomas was born. Although Thomas was full-term and weighed 7 lb at birth, he had difficulty drinking from the breast. When he was 4 weeks old, his mother had reluctantly switched him to bottle feedings because he was losing weight. Although his intake improved somewhat on bottle feedings, he gained weight very slowly and was still less than 8 lb at 3 months of age. His mother appeared tired and described how Thomas would drink only 1, 2, or 3 oz at a time, wiggle and cry, and refuse to continue with the feeding. After a few hours, however, he might cry again as if he were hungry. However, she could not settle him to feed, and he would continue to cry inconsolably. The mother described that she would attempt to feed him on an average of 10 to 15 times in a 24-hour period, that Thomas would cry a lot during the day and at night, and that everybody in the family was getting very little sleep.

The observation of mother–infant interactions during feeding and play revealed that Thomas was a very alert and wiggly baby who had difficulty settling in his mother's arms. While drinking from the bottle he would kick his feet and move around with his arms, and soon the nipple of the bottle would slip out of his mouth. This upset him, and he started crying. His mother appeared anxious and tried to restart him by changing his position in various ways, but this only agitated him more. After repeated unsuccessful attempts to continue the feeding, mother and baby appeared exhausted, and the mother gave up.

The assessment revealed that Thomas was a very active and excitable baby who had difficulty keeping calm during feedings. After reviewing the videotape with the mother, the therapist explored ways in which the mother could better facilitate calming during feedings.

Using a quiet corner in the house, swaddling Thomas in a blanket, and singing to him before starting the feeding were the most useful suggestions. Thomas stayed calm during feedings, was able to drink larger amounts of milk, and waited longer between feedings. This in turn relieved the mother's anxiety and helped both to have calmer interactions.

Avoidant/Restrictive Food Intake Disorder (DSM-5)

Subtype: Infants and young children may not engage with the primary caregiver during feeding

Feeding Disorder of Caregiver–Infant Reciprocity (DC: 0–3R)

Clinical Features. This feeding disorder is characterized by a lack of engagement between mother and infant, leading to inadequate food intake and growth failure of the infant. The onset of the growth failure is usually between 2 and 8 months of age. The infant shows lack of age-appropriate social responsivity—for example, lack of smiling response, lack of vocal reciprocity, lack of anticipatory reaching out when about to be picked up, and lack of molding and cuddling when held. The mother frequently presents with acute or chronic depression, drug or alcohol abuse, and/or high psychosocial stress, which appear to interfere with her care of the infant. Mother–infant interactions are characterized by a lack of mutual engagement and lack of pleasure in their relationship. The mother frequently appears detached and noncontingent in her responses to the infant's cues.

Differential Diagnosis. This feeding disorder needs to be differentiated from organic conditions that lead to a lack of weight gain and weakness of the infant. However, mother and infant usually show better mutual engagement, and the infant responds more readily to the examiner.

Etiology and Course. This feeding disorder has been referred to in the literature as "maternal deprivation" or "deprivation syndrome." It has been postulated that lack of emotional nurture and infrequent feedings lead to the growth failure and developmental delays of these infants. Characteristically, infants with this feeding disorder become engaging and gain weight when admitted to the hospital and are in the care of a nurturing nurse.

This feeding disorder has also been referred to as "nonorganic failure to thrive," and in the DSM-III, this disorder was defined as "Reactive Attachment Disorder of Infancy" associated with FTT. However, in the DSM-IV the same diagnosis was changed to encompass only problems in relatedness without growth failure. However, several studies of infants with the diagnosis of "nonorganic failure to thrive" have demonstrated very high rates of insecure attachment, ranging from 50 to 90 percent of the infants studied. However, not all infants with insecure attachment are failing to

thrive. It appears that only a severe degree of a disturbance in the attachment process of the infant to the caretaker, or what some authors describe as "nonattachment," results in the severe disturbances in relatedness and growth failure seen in infants with this feeding disorder.

Children with a feeding disorder of caregiver–infant reciprocity are at high risk for delayed cognitive and disturbed emotional development. When such children are followed up to school age, deficits in cognitive performance, behavioral organization, ego control, and ego resiliency and behavioral symptoms have been reported.

Treatment. Depending on the severity of the growth deficiency and the evidence of neglect, various interventions have been suggested. In cases of no evidence of deprivational behavior on the part of the mother, or if the parents have sought medical care in the past and have some support in the extended family or the community, an outpatient approach may be safe. However, if the growth deficiency is more severe, if there is serious hygiene neglect, if the mother is abusing drugs or alcohol, or if the mother lives a chaotic lifestyle, immediate hospitalization is indicated. During the hospitalization, it is critical to assign a warm and nurturing nurse to engage the infant during feedings. While the nutritional, emotional, and developmental rehabilitation of the infant takes place, a more in-depth evaluation of the mother and the mother–infant relationship needs to be addressed as well.

Many of the mothers have experienced unsatisfactory relationships with their caretakers when they were growing up, and consequently they are distrustful and avoidant of professionals. It is important to identify any positive behavior the infant shows toward the mother to see whether the mother has any potential to engage in a mutually satisfying relationship with her infant. In addition, the mother's support system and her ability to become engaged with a therapist need to be explored prior to returning the infant to her care. In some situations of severe neglect and associated abuse, Protective Services need to be involved, and the infant has to be placed in foster care.

Discharge from the hospital is a critical time when all services need to be in place to assure follow-through of the treatment plan. The treatment plan should be individualized and may range from home visits by a health care professional, to day care for the infant, to mother–infant psychotherapy, and to family therapy for the parents.

Anna was 8 months old when she was admitted to the hospital through the emergency room because of a respiratory tract infection and severe "failure to thrive." After she had recovered from the infection and a medical workup for her malnutrition was found to be negative, a psychiatric consultation was requested. After repeated unsuccessful attempts, the psychiatrist finally reached the parents and set up an appointment to obtain more history and to observe mother and infant during feeding. The parents explained that the father had difficulty

obtaining time off from his construction job and that the mother did not have any means of transportation to the hospital. The couple was not married because the father had not gotten his divorce from his first wife, but they lived together with Anna in one room in a house that they shared with nine other members of the father's extended family.

The mother, who became pregnant with Anna during her last year in high school, described Anna as a quiet baby and denied any feeding problems. However, when the mother temporarily left the room, the father turned to the therapist and complained that the mother did not give enough attention to Anna and that she would talk on the phone or read from a magazine while feeding the baby.

The observation of mother and infant during feeding revealed that the mother looked sad and preoccupied while she held the baby loosely on her lap. The infant lay in a "surrender position" with her arms raised besides her head, and she looked away while drinking from the bottle. However, when she looked at her mother, the mother looked away as if she could not stand to have eye contact with her infant.

Further evaluation of the mother revealed that she felt very lonely and depressed. She was unable to finish high school because of the pregnancy with Anna. Her family had abandoned her for becoming involved with a married man. She described the father's family as hostile toward her. The baby's father worked long hours and was hardly around. The telephone calls the mother made to her girlfriends from high school were the only relief in her unhappy life.

During the hospitalization, Anna gained weight, became more engaged, and rewarded her favorite nurse with frequent smiles. After the social worker had arranged for transportation for the mother, she came regularly for her appointments with the social worker and spent more time with Anna. While nurturing the mother and trying to help her work on her situation with her family and the father's family, the social worker also spent time with mother and infant during play. She would point out how the baby was making progress, how she was trying to get her mother's attention, and how she had that special smile for her mother.

After 4 weeks in the hospital, Anna seemed stronger, and her mother seemed committed to continue working with the social worker. The hospital staff felt comfortable about discharging Anna. After Anna had returned home with her mother, a visiting nurse came to the home twice a week to check on mother and infant, and the mother visited weekly with Anna at the hospital to see the social worker. After 6 months, the visiting nurse came less frequently, but the mother and Anna stayed in treatment with the social worker for another year, when both seemed engaged and comfortable with each other.

Avoidant/Restrictive Food Intake Disorder

ARFID can be diagnosed if the feeding disturbance may persist after being triggered by a medical condition and following resolution of the medical condition.

Feeding Disorder Associated with Concurrent Medical Condition (DC: 0–3R)

Clinical Features. Although respiratory problems or cardiac disease that may tire out the infant during feeding are easily recognized, some medical conditions are not readily diagnosed, and food refusal may be the leading symptom. For example, food allergies can be difficult to diagnose in infants, and "silent" gastroesophageal reflux without vomiting can be overlooked because vomiting is usually the leading symptom that alerts pediatricians to this condition. Typically, infants with reflux can drink 1 to 2 oz until the reflux becomes activated. However, once reflux occurs the infants experience distress and may arch, cry, and refuse to continue feeding. Some infants can be calmed and resume feeding, but others may become increasingly agitated while their caretakers continue to offer the

bottle or food. Infants with respiratory distress may feed for a while and take a few ounces until they tire and stop feeding. In general, the feeding difficulties of these infants lead to inadequate food intake, failure to gain weight, or loss of weight.

Differential Diagnosis. This feeding disorder needs to be differentiated from other feeding disorders characterized by food refusal, such as IA, sensory food aversions, and posttraumatic feeding disorder. What helps in understanding this feeding disorder is the observation of feeding, which reveals that the infant usually initiates feeding without difficulty and that mother and child engage in pleasant reciprocal interactions until the infant experiences distress and stops feeding.

Etiology and Course. FTT of infants and young children was initially believed to be caused by either organic or nonorganic causes (e.g., maternal deprivation). In 1981, Homer and Ludwig described a third category of FTT, which is caused by a combination of various organic and nonorganic problems. Since then, it has been accepted that organic conditions can be complicated by psychological difficulties and lead to severe feeding problems and growth failure. However, although many young infants suffer from gastroesophageal reflux, only less than one-third of them are reported to present with feeding difficulties and growth failure. Clinically, these infants appear particularly alert and sensitive. However, no empirical studies have been done to explore why some infants develop severe reactions to their reflux, whereas others hardly seem bothered by it.

Only a few studies have been reported on the follow-up of these infants. Fortunately, with therapy, up to 80 percent of children with gastroesophageal reflux improve within 12 months. For those with more serious feeding difficulties and inability to take in adequate amounts of food for growth, modern technology allows for gastric tube feedings over a long time to safeguard their survival. However, the regulation of oral feedings is often very difficult, and even after the medical condition has been successfully treated, it may take time until the child learns to eat independently.

Treatment. Because of the interaction of organic and psychological factors contributing to the severe feeding difficulties of these children, collaboration between the pediatrician or pediatric specialist and the psychiatrist is critical. Optimal medical treatment of the child's illness is necessary before psychological interventions can be successful. Direct observation of infants with their primary caregiver during feeding is most helpful to monitor how well the medical condition is responding to the treatment. In addition, the observations during feeding can guide the therapist in helping the parents to develop more appropriate strategies that

allow infants to calm instead of escalating their distress during feeding. However, in situations in which the medical illness cannot be adequately treated and the infant continues to experience distress during feedings, supplemental nutrition through nasogastric or gastrostomy tubes must be considered. Then the therapist must work with the parents to maintain the infant's oral feeding skills while most of the nutrition is given via tube feedings. The parents need to learn to feed the infant to the point of discomfort but not beyond it. Reviewing the videotape of the infant's feeding and discussing the infant's cues with the parents is usually helpful in sorting out how to best feed the infant. In general, these are very difficult cases that require individualized attention by an experienced multidisciplinary team.

Sarah was 6 months old when she was referred by her pediatrician to the Multidisciplinary Feeding Disorders Team because of severe food refusal and poor growth. The mother reported that since birth Sarah occasionally "spat up" a little during and after feedings but during the last 6 weeks she had become increasingly difficult to feed. Usually she took 1 or 2 oz of her formula and then started to arch and pushed the nipple out from her mouth. If her mother tried to continue feeding Sarah, she cried and became increasingly agitated until her mother picked her up and comforted her by holding her on the mother's shoulder and walking her. Sometimes after 10 to 20 minutes, her mother could resume feeding Sarah, but often, Sarah started to cry again after suckling from the bottle for a few minutes only. In spite of her mother's efforts to feed Sarah every 2 hours, Sarah drank only half of the formula that she was supposed to take in for her age, and in recent weeks, she had started to lose weight.

The observation of feeding revealed pleasant mother–infant interactions at the beginning of the feeding, but after a few minutes of suckling, Sarah pushed the nipple of the bottle out of her mouth, arched her back, and started to cry when her mother tried to get her back to feeding. The harder her mother tried, the more agitated Sarah became, and mother and baby looked very distressed and gave up feeding. These feeding interactions raised concerns that Sarah experienced gastroesophageal reflux that caused her pain and interfered with her feeding. Further medical testing confirmed the diagnosis of moderate gastroesophageal reflux, which was somewhat surprising to the pediatrician and the gastroenterologist because Sarah had not shown any vomiting, the most common symptom of reflux.

Sarah was treated with medications for reflux, and her food intake doubled quickly. However, if she drank more than 3 or 4 oz at a time, the symptoms recurred. However, once the mother understood the reason for Sarah's food refusal, she learned to ease Sarah's feeding difficulties by thickening the formula and feeding her smaller amounts at more frequent intervals. Gradually, Sarah tolerated larger amounts of formula at each feeding, and at 15 months of age, she was found to have outgrown the gastroesophageal reflux.

Rumination Disorder

Clinical Features. Rumination has been defined as repetitive regurgitation of gastric contents that are subsequently rechewed and then reswallowed or spit out. The regurgitation occurs very soon after a meal and tends to persist for 1 to 2 hours. The sequence of events leading to regurgitation has been documented by using combined multichannel intraluminal impedance and manometry. These events include an increase in intra-abdominal pressure identified in the stomach, which initiates the reflux, followed by peristaltic fore contractions, which clear the

intraesophageal content. Rumination has been described in infants, in individuals with development disabilities, and in children, adolescents, and adults with psychiatric or neurological disorders. The major proposed change for rumination disorder in the *Diagnostic and Statistical Manual for Mental Disorders,* Fifth Edition is its relocation from section, titled "Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence," to the newly proposed section, "Feeding and Eating Disorders." This change emphasizes that this disorder occurs across the age range, including adulthood. Minor changes have been introduced to the DSM-5 phrasing of diagnostic criteria for rumination disorder to improve clinical utility by ensuring applicability across the age range and removing some ambiguity inherent in the DSM-IV phrasing.

Some infants can be observed to put the thumb or the whole hand in the mouth, to suck the tongue rhythmically, or to arch the back to initiate regurgitation. However, some infants ruminate when left alone, after they have been placed in the crib to sleep. They are frequently found in a puddle of vomitus, which is then falsely attributed to some organic problem. The latter type of rumination is most commonly observed in infants who have received little emotional stimulation and who have learned to stimulate and soothe themselves through rumination. Although initially most of the regurgitated food is vomited, some infants gradually learn to hold more of the food in the mouth, to rechew and to reswallow it. "Experienced" ruminators are able to bring up the food through tongue movements and reswallow it without losing any of it. Their rumination can only be discovered by observing the movements of their cheeks and the foul oral odor. Social functioning may be significantly impaired due to the recognized social undesirability of this behavior.

Differential Diagnosis. The term *regurgitation* implies that the behavior is volitional, distinguishing it from vomiting or gastroesophageal reflux. The regurgitation is not associated with nausea and is not explained by an illness or medical condition. Individuals may cough, engage in tongue or abdominal muscle contractions or movements, or place fingers in the mouth to facilitate food being brought back up. Because in young children reflux and rumination frequently coexist, it is important to observe the infant in different situations to see the initiation and the rhythmic oral movements of the ruminatory activity. As in pica, the diagnosis of rumination disorder should be given in the context of another mental disorder only if the symptoms require additional clinical attention.

Epidemiology. Rumination is believed to be a rare disorder. It appears to occur more often in males than in females and also in individuals with mental retardation. There are a few reports of children, adolescents, and adults who were diagnosed with rumination disorder, and some had

associated eating disorders.

Etiology and Course. Various mechanisms of etiology have been proposed. Several authors have attributed rumination to separations or a disturbed mother–infant relationship—for example, lack of responsiveness or neglect by the mother secondary to stressful family relations or life events. Others have considered rumination as a symptom of gastroesophageal reflux. Several authors have postulated that rumination is a learned behavior that is maintained by special attention to the regurgitation. In more recent years, opiate receptor insensitivity or reduced endorphinergic transmission have been implicated in rumination.

A biopsychosocial model has been proposed by which rumination is seen along a continuum in which an infant may have gastrointestinal pathology and little psychopathology at one end of the spectrum, or the opposite, in which an infant may have no organic pathology and severe psychopathology in the mother–infant relationship at the other end of the spectrum. Frequently, vomiting secondary to gastroesophageal reflux or vomiting associated with an acute illness precedes the beginning of rumination. It appears that at some point the infant learns to initiate vomiting and to rechew the food to achieve relief of tension, to self-soothe, and/or to self-stimulate. It seems that in situations in which the infant fails to elicit or loses either caring attention or tension-relieving responses from the mother, rumination becomes a means of self-regulation. Once the infant has experienced rumination as a means of self-soothing or self-stimulation, the rumination develops into a habit that is difficult to break.

The onset of rumination is frequently in infancy, most commonly in the first year of life. However, rumination may start at any point in life. It is believed that in some individuals the disorder remits spontaneously. However, some infants suffer serious complications, such as electrolyte imbalance, dehydration, and weight loss, and in earlier reports mortality rates as high as 25 percent have been described.

Treatment. Depending on the theories of the etiology of rumination, different treatments have been suggested. These range from mechanical restraints as described in the early literature and surgical interventions (Nissen fundoplication) to prevent reflux, to behavioral and psychodynamic treatments.

Based on the assumption that rumination is a learned habit that is reinforced by the increased attention that is given to the regurgitation, unlearning by behavioral techniques has been suggested. These treatments include the use of aversive taste stimuli (lemon juice or hot sauce), oral hygiene, differential reinforcement of incompatible behaviors, and electric shock. Proponents of the assumption that rumination is based on an unsatisfactory mother–infant relationship have suggested a psychodynamic

approach. A mother substitute who feeds the infant while the mother is helped through psychotherapy has been proposed.

After a thorough evaluation that should include the assessment of the infant and the mother, the therapist needs to individualize the treatment. In severe situations, if the infant is malnourished and continues to lose most of the food through rumination, a jejunal tube may have to be inserted before any psychosocial treatment can begin. Frequently, a combination of psychodynamic and behavioral interventions to enhance the mother–infant relationship in general and to treat the symptom of rumination in particular is most effective.

Justin was 9 months old when he was referred by a gastroenterologist for a psychiatric evaluation because of concerns that he continued to vomit because of rumination. Justin was born full-term and had developed nicely until he was about 6 weeks old, when he began to vomit increasing amounts of milk during and after feedings. He was diagnosed with gastroesophageal reflux, which was treated with thickened feedings and medication. Justin responded well to the treatment; he stopped vomiting almost completely and gained weight adequately. Because Justin was doing so well, his mother decided to go back to work when Justin was 8 months old. She transitioned his care to a young woman who would come to the house during the mother's working hours. Justin started to vomit soon after his mother left the house. The vomiting seemed to increase from day to day in frequency and in intensity, and after 2 weeks of the mother's return to work, Justin vomited several times daily and was losing weight. He was seen by a gastroenterologist and, during the barium swallow, it was noticed that Justin put his hand in his mouth, which seemed to trigger vomiting. Justin was put back on medication for gastroesophageal reflux, but he continued to vomit with increasing frequency, which led to the psychiatric consultation.

Observation of mother and infant during feeding revealed that as soon as Justin finished feeding, he put his hand in his mouth and vomited. When his mother restricted his hand, Justin moved his tongue back and forth in a rhythmic manner until he vomited again. This happened repeatedly, and Justin continued the rhythmic tongue movements even when he could not bring up any more milk.

Because of his poor nutritional state and moderate dehydration, Justin was admitted to the hospital, and a nasojejunal tube was inserted for feedings. When Justin was awake, a special nurse or the parents played with him and tried to distract him whenever he attempted to put his hand in his mouth or thrust his tongue rhythmically. Justin became increasingly engaged, and his ruminatory activity decreased accordingly. After 1 week in the hospital, small feedings were started, but Justin tried to ruminate again, and the oral feedings had to be stopped. At this point, the mother decided to stop working and take Justin home to continue the treatment there. The mother started small feedings, played with Justin after feedings, and was able to keep him from ruminating. After 4 weeks of slow increments in his feedings, Justin was able to take all of his feedings by mouth without ruminating, and the nasojejunal tube could be removed.

Pica

Clinical Features. Young children with this disorder typically eat plaster, paper, paint, cloth, hair, insects, animal droppings, sand, pebbles, and dirt. Many of the children engage in other oral activities, such as thumb sucking or nail biting, which they seem to use for relief of tension and for self-soothing. In some younger patients, as well as those with neurodevelopmental or learning disorders, some clinicians regard pica as a

form of self-soothing behavior. The pica may lead to anemia, diarrhea/constipation, worm infestation, toxoplasmosis, lead poisoning, and malnutrition. In some cases it may lead to intestinal obstruction as the result of hairball tumors. In addition to heterogeneity of substances consumed, pica's associated behavioral features can differ considerably among individuals (e.g., its compulsive nature and relationship to emotional arousal or need for oral stimulation).

The major proposed change for pica disorder in the *Diagnostic and Statistical Manual for Mental Disorders*, Fifth Edition is its relocation from the section, titled "Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence," to the newly proposed section, "Feeding and Eating Disorders." This change emphasizes that this disorder occur across the age range, including adulthood. In particular, changes to phrasing of diagnostic criteria in DSM-5 are intended to guide clinicians in distinguishing eating behaviors that warrant a diagnosis of pica from behaviors that are developmentally normal, culturally supported or socially normative, or that support a diagnosis of a different mental disorder.

Differential Diagnosis. Before the age of 18 to 24 months, mouthing and sometimes eating of nonnutritive substances can be relatively common and should only be diagnosed as pica if it is persistent and inappropriate for the developmental level of the child. In DSM-5, 2 years is suggested as minimum age for a diagnosis of pica; at younger ages, mouthing different kinds of objects is considered developmentally normal. Consumption of substances consistent with local cultural practices or social norms would not warrant a pica diagnosis. Pica may be comorbid with a number of mental disorders, which are more likely to come to clinical attention than pica itself, e.g., intellectual development disorder, autism spectrum disorder, schizophrenia, and obsessive compulsive disorder. In addition, pica can co-occur with hair pulling disorder and skin picking disorder when hair or skin is ingested. When nonnutritive substances are ingested as a means to suppress appetite in anorexia nervosa, a pica diagnosis is not warranted. Some individuals with ARFID, particularly those whose selective or restricted intake is based on sensory aspects of food, may also present with comorbid pica.

Epidemiology. A survey of a large clinic population with a wide range of ethnic backgrounds revealed that 75 percent of 12-month-old infants and 15 percent of 2- to 3-year-old toddlers were reported by their parents to put nonnutritive substances in their mouth. However, the true incidence of pica is not known. Available data suggest that in the US pica is rare in healthy children older than 2 years. However, a study reported that 33.9 percent of children in Detroit who were in treatment for sickle cell anemia had pica eating. Pica has also been reported as prevalent in children elsewhere,

including in some school-age populations in Africa (as high as 77 percent). Among individuals with mental retardation, the prevalence of the disorder appears to increase with the severity of the retardation. The prevalence of pica among institutionalized individuals with mental retardation has been estimated to range from 10 to 33 percent.

Etiology and Course. Organic, psychodynamic, socioeconomic, and cultural factors have been implicated in the etiology of pica. Inadequate intake of iron and calcium has been shown in rats to induce pica and has been considered to lead to abnormal cravings and pica in humans. Low plasma levels of iron and zinc have been found to be associated with pica, and it has been suggested that hypozincemia with low iron levels may be a possible cause rather than a consequence of pica. Psychosocial factors—for example, poverty, maternal neglect and abuse, and disorganized family situations with inadequate nurturing and supervision of the children—have been implicated in the etiology of pica. The cultural acceptance of pica in certain population groups has also been considered to play a role in its etiology. Some authors have proposed a multifactorial model of etiology by which organic, familial, socioeconomic, and cultural factors interact with each other.

In most instances, the disorder is believed to last for several months and then remit. However, it may occasionally continue into adolescence or, less frequently, into adulthood. Several authors have pointed to the seriousness of the developmental effect of the disorder. The younger children showed delays in their speech and psychosocial development. Half of the adolescents were observed to suffer from depression and/or personality disorders, engaged in other forms of disturbed oral activities, such as thumb sucking and nail biting, and abused tobacco, alcohol, or drugs. More recently, some authors pointed to a strong relationship of pica during early childhood and bulimia nervosa during the adolescent years.

Treatment. A variety of treatments have been proposed. These include physical restraints, aversive and nonaversive behavior therapy, the teaching of children to exchange inedible items for edibles, environmental enrichment, and individual and group therapy for the children and their mothers. It is important to conduct a comprehensive evaluation of the child, the caretakers, and the child's environment to develop an individualized treatment plan. This should include helping the adults to become aware of the short- and long-term dangers of pica, providing a lead-free and childproof environment, facilitating a more satisfying parent–child relationship, and applying behavioral techniques to extinguish the maladaptive behavior of pica.

Susan was 3 years old when her mother took her to the pediatrician because of abdominal pain

and lack of appetite. The mother complained that Susan put everything in her mouth but did not want to eat regular food. The pediatrician observed that Susan looked pale, thin, and withdrawn. She sucked her thumb and quietly looked down while her mother reported that Susan liked to chew on newspapers and put plaster in her mouth.

The medical examination revealed that Susan was anemic and suffered from lead poisoning. She was admitted to the hospital for treatment, and a psychiatric consultation was obtained.

Further exploration of the history and the observation of mother and child during feeding and play revealed that the mother was overwhelmed with having to care for three young children and had little affection for Susan. The mother was unmarried and lived with her three children and five other family members in a three-bedroom apartment in an old housing project. Her 4-year-old son was hyperactive and demanded almost constant supervision. Her 18-month-old infant was an engaging and active little girl, whereas Susan would sit quietly, rock herself, suck her thumb, or chew on newspaper.

The treatment plan included the involvement of social services and protective services to remove any lead paint from the walls in the apartment and to look for better living arrangements for the family. The mother was helped to enroll Susan and her brother in a preschool program that provided them with more structure and stimulation and gave the mother a few hours of relief every day. In addition, Susan was seen with her mother and her younger sister in play therapy to help the mother understand the different temperaments of the two children and to make her more responsive to Susan's weak attempts to engage her. Once the mother felt more supported and less overwhelmed by her situation, she became more empathic and understanding of Susan. When Susan put something in her mouth, the mother was able to engage her in a play activity rather than scream at her and scold her for whatever she was doing. Over the period of 1 year, the relationship between Susan and her mother gradually improved, and Susan seemed less in need of putting her thumb or inedible things in her mouth.

Tic Disorders

RAHIL JUMMANI, M.D., AND BARBARA J. COFFEY, M.D.

INTRODUCTION

Perhaps the best known of the tic disorders is Tourette disorder (TD), also known as Tourette syndrome, named after the French neurologist Georges Gilles de la Tourette, who in 1885, was among the first to recognize and describe the disorder and its comorbid conditions. Since the descriptions of Gilles de la Tourette, a spectrum of tic disorders has come to be recognized and codified in psychiatric nomenclature. No longer is Tourette disorder viewed as a rare, bizarre psychological entity with primarily disturbing manifestations, such as the shouting of obscenities, screeching, or barking. The comorbid psychiatric disorders that frequently occur in individuals with TD have become more widely recognized in recent years; it is these disorders that often may warrant treatment more than the tics themselves. Although the underlying etiologies of these disorders continue to be elusive, substantial progress has been made in the last few decades through the use of innovative neuroimaging techniques, genomics studies, and clinical science. Tic disorders have emerged as complex, heterogeneous, neurodevelopmental disorders that are the manifestation of an intricate interplay of genes and environment. Understanding of the etiology, genetics, neuroanatomy, and epidemiology of tic disorders has been significantly enhanced. Novel treatment approaches have also emerged, providing alternatives to the established pharmacological management of tics. Specific behavioral interventions have recently been established as first-line treatments for tic disorders. Deep brain stimulation, botulinum toxin injection, targeted surgery, and stem cell transplantation are examples of promising new treatments. The future holds tremendous possibilities as new insights into the etiology, pathophysiology, and treatment of tic disorders are rapidly developing. This chapter provides a review and update of the history, comparative nosology, epidemiology, etiology, diagnosis and clinical features, pathology, differential diagnosis, course and prognosis, and clinical treatment of tic disorders, including Tourette disorder.

DEFINITIONS

Tics are rapid, recurring motor movements (motor tics) or vocalizations

(phonic or vocal tics) that are nonrhythmic, involuntary or semivoluntary, and sudden in onset. Tics typically involve one muscle or a group of muscles and may be characterized by their anatomical location, number, frequency, duration, and complexity (Table 48–1). They can be classified as *simple* (involving one muscle, muscle group, or sound) or *complex* (slower, more purposeful movements involving coordinated muscle groups or multiple sounds). Simple motor tics cause a brief, jerking movement (*clonic tic*); a briefly sustained abnormal posture (*dystonic tic*); or an isometric contraction (*tonic tic*). Examples of simple motor clonic tics are eye blinking, shoulder shrugging, and head turning. Dystonic tics include sustained eye closure (blepharospasm), ocular deviations, teeth grinding (bruxism), mouth opening, twisting and tilting of the neck (torticollis), and shoulder rotation. Tonic tics are typically manifested by tensing of abdominal or limb muscles. Complex motor tics may include touching objects, jumping, rotating, or imitating others' gestures (*echopraxia*). Examples of simple vocal tics are throat clearing, coughing, and sniffing; repeating syllables, words, or one's phrases (*palilalia*) or repeating others' words or phrases (*echolalia*) are examples of complex vocal tics. Less commonly occurring tics include the involuntary vocalization of obscenities (*coprolalia*) and the involuntary production of obscene gestures (*copropraxia*).

Tics are often emitted in bouts of one or several tics separated by variable periods of no tic activity. Tics change in frequency, anatomical location, number, complexity, and severity over minutes, hours, and days, as well as over longer periods of time. Tics may persist during sleep. Simple motor tics are the most common initial presentation of a tic disorder, and eye blinking is the most common initial tic.

Tics are experienced as irresistible but can be suppressed for varying periods of time. Some patients describe suppressing tics for several hours, for example, while at work or school, and then experiencing a bout of tics. There is usually a reduction in the frequency and severity of tics during concentration on mental or physical tasks such as reading. Stress, excitement, boredom, fatigue, and exposure to heat can exacerbate tics. Tic frequency may also increase during relaxation following a period of stress, or sometimes when an individual is actively attempting to suppress tics. Some children, and occasionally adults, are unaware of their tics.

Many individuals with TD characterize their tics as a voluntary response to an uncomfortable feeling that precedes them. These feelings, or premonitory sensations, have been described by the majority of individuals with Tourette disorder; they can be localized or general, and physical or mental, in nature. These premonitory sensations distinguish tic disorders from other movement disorders. An example is a burning feeling in the eye before an eye blink. However, there are often nonlocalizable and more generalized premonitory phenomena, such as urges, sensations, or anxiety.

Many individuals report a "just right phenomenon," that to relieve the uncomfortable urge they must repeat a particular movement or sound or pattern of movements or sounds, until "it feels good" or "it feels just right."

Table 48–1.
Examples of Tics

Motor		Vocal	
Simple	**Complex**	**Simple**	**Complex**
Eye blinking	Touching objects or self	Throat clearing	Syllables or words
Nose twitching	Hitting or kicking	Coughing	Phrases
Shoulder shrugging	Hand gestures	Sniffing	Swearing
Sustained eye closure	Throwing	Blowing	Repeating one's or others' words
Tensing of abdominal or limb muscles	Squatting or jumping	Barking	Changes in the rate, rhythm, and volume of speech

Complex tics may be difficult to distinguish from compulsive behaviors. This is further complicated by the frequent presentation of obsessive-compulsive disorder (OCD) symptoms with tics. The difference between some complex tics and compulsions is subtle. It is important to determine whether the behavior is being pursued as a strategy to prevent or relieve anxiety rather than simply to satisfy an urge. If anxiety relief or prevention is the case, a compulsion rather than a tic is likely. Studies by Miguel and coworkers demonstrated that more cognitions and autonomic anxiety and fewer sensory phenomena are reported with repetitive behaviors in individuals with OCD without concomitant tics, whereas more sensory phenomena, such as the "just right phenomenon," and fewer cognitions are associated with repetitive behaviors in individuals with TD.

The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) and the tenth revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) provide diagnostic criteria in common use for tic disorders. According to the DSM-5 (with the equivalent ICD-10 diagnoses in parentheses), the tic disorders include provisional tic disorder (transient tic disorder in ICD-10), persistent motor or vocal tic disorder (chronic motor or vocal tic disorder in ICD-10), Tourette disorder (combined vocal and multiple motor tic disorder [de la Tourette] in ICD-10), and other specified tic disorder and unspecified tic disorder (tic disorder not otherwise specified in ICD-10).

By DSM-5 criteria, a provisional tic disorder is characterized by the presence of single or multiple motor and/or vocal tics for less than 1 year. There has been a change in DSM-5 from the text revision of the fourth edition (DSM-IV-TR), the previous edition of the *Diagnostic and Statistical Manual of Mental Disorders*. The requirement of the presence of tics for more than a 4-week period is no longer stipulated in DSM-5.

A persistent motor or vocal tic disorder is diagnosed when either motor or vocal tics, but not both, are present for more than 1 year. For this category of tic disorders, DSM-5 provides specifiers to indicate whether motor or vocal tics are present: *With motor tics only* and *With vocal tics only*. There has been a significant change in DSM-5 from DSM-IV-TR here as well. The absence of a tic-free period of more than 3 consecutive months is no longer required. The DSM-5 criteria are now more consistent with ICD-10 criteria.

Tourette disorder (combined vocal and multiple motor tic disorder [de la Tourette] in ICD-10) is defined by the presence of both multiple motor and one or more vocal tics for more than 1 year. Again, the DSM-5, departing from DSM-IV-TR and more aligned with ICD-10, no longer mandates that there may not be a tic-free period of more than 3 consecutive months.

According to the DSM-5, other specified tic disorder is a tic disorder that does not meet criteria for any of the other tic disorders, and the clinician specifies the reason criteria are not met. An unspecified tic disorder, on the other hand, is a condition that also does not meet criteria for any of the other tic disorders, but for which the clinician does not elaborate a specific reason. Included are presentations for which information to make a more specific diagnosis is lacking.

In addition to the foregoing criteria that the DSM-5 and ICD-10 share for the diagnosis of a specific tic disorder, the DSM-5 specifies a few common criteria that must be met to diagnose provisional tic disorder, persistent motor or vocal tic disorder, or Tourette disorder. Onset of tics must be before age 18 years, and a substance or medical condition must not be causally implicated. Shifting from DSM-IV-TR, DSM-5 no longer states in its diagnostic criteria for the tic disorders that tics occur many times a day, nearly every day. Rather, DSM-5 notes that tics wax and wane in frequency. The changes in the latest edition reflect information about the tic disorders that has accumulated over the years from both research trials and clinical experience.

HISTORY

In 1825, the French physician Jean-Marc Gaspard Itard provided the first clinical description of Tourette syndrome in a French noblewoman, the Marquise de Dampierre, who displayed body tics, barking sounds, and uncontrollable utterances of obscenities. In his description, Itard also noted the presence of comorbid obsessive thoughts. In 1885, Georges Edouard Albert Brutus Gilles de la Tourette, a French neurologist, described eight patients, in addition to the patient originally reported by Itard, with childhood-onset tics and coexisting emotional symptoms and behavioral problems, such as inattention, hyperactivity, impulsivity, obsessions, and compulsions. Gilles de la Tourette coined the term

coprolalia for vocal tics that manifested as uncontrollable utterance of obscenities. Furthermore, he and his mentor, Jean-Martin Charcot, viewed the disease as progressive and believed they had identified a hereditary degenerative disorder.

Psychoanalytic views of Tourette disorder, introduced in the 1920s and 1930s, thrived in the early twentieth century, and interpreted tics as expressions of repressed childhood sexual conflict. In the 1940s, Margaret Mahler attributed tic symptoms to infantilization, parental overindulgence, and overprotection, as well as sexual conflict. Serge Lebovici, the leading French child psychoanalyst during the 1950s and 1960s, asserted that neurotic mothers were the cause of tics in their children.

As more biologically based theories of the etiology and pathophysiology of tic disorders emerged, sedatives, stimulants, carbon dioxide inhalants, and other agents came to be used in the treatment of tics, in conjunction with, or as alternatives to, psychoanalytic psychotherapy. In the 1960s and 1970s, as the scientific era of the understanding of Tourette syndrome began with the work of Arthur and Elaine Shapiro, the first randomized clinical trials using neuroleptic medications were published. The perception of Tourette and tic disorders as rare, bizarre, psychological conditions slowly began to change. Advances in the last 50 years have led to the use of the α-adrenergic agonists and second-generation neuroleptics as the primary psychopharmacological agents for the treatment of tics. Comorbid psychiatric disorders have come to be more widely recognized and treated. Over the last three decades, the Tourette Syndrome Association (TSA) has effectively promoted clinical awareness of the condition and supported research into its causes and treatment. Behavioral interventions have come to the forefront. The quest for a more comprehensive understanding of the underlying etiology and pathophysiology of the tic disorders continues.

COMPARATIVE NOSOLOGY

The nosology of the tic disorders has depended, since their recognition, on the presence and classification of their primary symptom—tics. The two predominant current classification systems of tic disorders, the DSM-5 and the ICD-10 criteria, are based primarily, as described earlier, on the type of tics present (motor, vocal, or both) and the duration of symptoms (greater or less than 1 year). As new information about the etiology and pathogenesis of tic disorders emerges, a new nosology based on an etiological or pathogenic understanding may replace the current symptom-based taxonomy. Over the years, with newer iterations of the DSM, individual criteria have changed slightly as advances in understanding of the prevalence and course of tic disorders has emerged. For example, age of onset of Tourette disorder has varied from before age 15 years to before age 21 years. The most recent version, DSM-5, has instituted changes to the

criteria that reflect the current understanding of the neurodevelopmental and temporal nature of tics, as tic disorders are now contained in the section on Neurodevelopmental Disorders. Tics are now recognized to wax and wane, and restrictions on the time frame of tic-free periods have been removed.

EPIDEMIOLOGY

Provisional tic disorder, which can encompass both motor and vocal symptoms, is the most common of the tic disorders; the prevalence is estimated as up to 20 percent of school-age children. A methodologically rigorous study of more than 800 schoolchildren ages 4 through 16 years in the Basque region, however, indicated a prevalence of approximately 6.5 percent for all tic disorders. The vast majority of tics were mild in severity and duration. The prevalence of persistent tic disorders is between 2 and 4 percent. Prevalence estimates for Tourette disorder also vary. As in all population-based studies, results may be influenced by a variety of factors, including criteria used for diagnosis, methods of sampling and inquiry, gender and age distributions in the study population, and size of the sample. Once considered an extremely rare disorder, current lifetime rate estimates vary from 1 to 10 per 1,000 children in European and Asian populations, and a common prevalence figure for individuals meeting criteria for Tourette disorder is 1 per 200 for the full spectrum of chronic tic disorders. A population-based, epidemiological study of lifetime prevalence of Tourette disorder in Israel estimated a point prevalence of 3.1 to 5.5 per 10,000 in 16- and 17-year-olds. Prevalence rates have been estimated to be as high as 4 percent in one community-based study, and 3 percent in a survey of middle school youth in the United Kingdom. In a school-based community survey, Kurlan and colleagues reported prevalence rates of tic disorders of 23 percent in special education classes and as high as 8 percent for TD, as compared to 19 percent for tic disorders and about 3 percent for Tourette disorder in regular classrooms. The 2007 US National Survey of Children's Health (NSCH) surveyed parents of children and adolescents aged 6 to 17 years. The estimated prevalence of a lifetime diagnosis of Tourette disorder by parent report was 3 per 1000. Most recently, in a meta-analysis of 13 studies of children Knight and colleagues reported a prevalence of Tourette disorder at 0.77 percent (95 percent confidence interval, 0.39 to 1.51 percent).

Typically beginning between ages 3 and 8 years in the vast majority of patients, Tourette disorder manifests by 11 years of age. The average age of onset is age 6 years. Thought to be lifelong, limited and somewhat contradictory information exists on the longitudinal course of the disorder. Recent studies suggest that whereas tics may often persist into adulthood, tic severity often declines significantly in adolescence. Only 20 percent or fewer of those with Tourette disorder continue to experience significant

functional impairment by age 20 years. In the majority of cases, tics in adults represent the persistence or recurrence of childhood-onset tics, but in rare instances, patients may have their first occurrence of tics or an exacerbation of tics during adulthood. Studies in both children and adults suggest that males are at least three to four times more likely than females to manifest Tourette disorder.

Comorbidity with psychiatric disorders, especially attention-deficit/hyperactivity disorder (ADHD) and OCD, is common in both clinically referred individuals and community samples. In addition, mood disorders and anxiety disorders, such as separation anxiety disorder and generalized anxiety disorder, are not uncommon. In 2007, the US National Survey of Children's Health (NSCH) surveyed parents of children and adolescents aged 6 to 17 years, 79 percent had at least one comorbid mental health or neurodevelopmental condition. ADHD was the most frequent co-occurring condition, and the prevalence of comorbid ADHD with Tourette disorder was reported to be as high as 60 to 70 percent. In addition, approximately 50 percent of patients with Tourette disorder have prominent obsessive-compulsive symptoms.

Jeffrey was a 5-year-old boy whose parents sought evaluation for recent onset of tics. Jeffrey developed onset of eye-blinking tics at age 4 years and subsequently began repeatedly to push out his hands and legs in front of him, kicking and stomping his feet. These symptoms persisted for about 3 months and remitted. The movements returned about 1 year later, somewhat abruptly, according to his parents. At that time, Jeffrey developed eye blinking and nose twitching. Sometimes, he hopped while walking. He also developed vocal tics around that time, including clicking, throat clearing, sniffing, and coughing. Approximately 1 month prior to evaluation, Jeffrey developed truncal tics that occasionally began to disrupt his gait.

Jeffrey's parents were also concerned about his problems paying attention in school in the last year. Hyperactive since preschool, he had a very short attention span and was often distracted. He could be impulsive, often unaware that he was doing things that could be dangerous. He often interrupted his parents when they were speaking. He was restless and fidgety in school, and his teachers were concerned that he might disrupt his classmates.

Jeffrey was the product of a pregnancy complicated by intrauterine growth retardation. When amniotic fluid was found to be at low volume at 36 weeks, delivery was induced. The delivery was uncomplicated, and birth weight was 5 pounds, 10 ounces. Except for a minor delay in the acquisition of speech, developmental milestones were within normal limits.

Currently in kindergarten, Jeffrey had attended a well-regarded public school since he was 2 years of age. He lived with his parents and 2-year-old sister, had many friends, and enjoyed play dates.

Jeffrey had frequent upper respiratory infections. There were no known allergies and no major medical problems. There was no known family history of Tourette disorder, tics, or OCD.

MENTAL STATUS EXAMINATION

Jeffrey was a healthy-looking 5-year-old boy, well-groomed and dressed. He was initially very shy, clinging to his mother. He appeared to be quite active and restless. Multiple tics were noted, including nose twitches, finger snapping, and a cough. Jeffrey was somewhat oppositional when asked to do a drawing.

IMPRESSION

In summary, Jeffrey was a 5-year-old boy with multiple motor and vocal tics for short episodes, including a bout lasting 3 months at age 4 years, and just over 2 months currently, consistent with provisional tic disorder. Tourette disorder could not be entirely ruled out, but there was

no diathesis on the basis of family history. Jeffrey also appeared to meet criteria for ADHD, combined presentation, which may have predisposed him to the development of tics. The ADHD symptoms were causing impairment in his academic functioning.

TREATMENT PLAN

Parent and teacher ratings of ADHD symptoms were recommended at initial evaluation, and at follow-up after treatment was initiated. Treatment of ADHD was recommended, starting with a cautious trial of a methylphenidate-based stimulant. The plan was to add a low dose of an α-adrenergic agonist such as guanfacine or clonidine if tics increased significantly. Consultation and psychoeducation were recommended for Jeffrey's teacher.

ETIOLOGY AND PATHOPHYSIOLOGY

The etiology and pathophysiology of Tourette disorder and other tic disorders remain unknown. Considerable data accumulated during the last decade from neuroanatomical and neurochemical studies of TD point to a diffuse process in the brain involving corticostriatothalamicortical (CSTC) pathways in the frontal lobes and basal ganglia, including the striatum (caudate nucleus and putamen). Several neurotransmitters and neuromodulators have been implicated, including dopamine, serotonin, and endogenous opioids. Although a specific animal model has not been identified, some parallels may exist with horses with crib biting, which display spontaneous motor tics accompanied by vocalizations, dogs with acral lick syndrome and mouse models with repetitive movements and stereotypies.

A host of biochemical, imaging, neurophysiologic, and genetic studies support the concept that TD is an inherited, neurodevelopmental disorder. Twin studies have reported 89 to 94 percent concordance for Tourette disorder. However, environmental factors have also been implicated. In one study of 16 pairs of monozygotic twins, low birth weight was a strong predictor of more severe tics. Several gestational and perinatal insults, including hypoxia–ischemia, exposure to androgens, heat, and infectious agents, have been implicated in the pathophysiology of tic disorders. The effect of prenatal ischemic events may be to alter dopamine signaling, heralding the development of tics. Delivery complications, especially forceps deliveries, and fetal exposure to high levels of coffee, cigarettes, or alcohol were associated with male gender and OCD in a sample of TD probands.

Androgen exposure is speculated to play a role in the development of tics, given the higher prevalence of Tourette disorder in males. Studies in both children and adults suggest that males are at least three to four times more likely than females to manifest Tourette disorder. X-linked genomic transmission has also been considered, but this appears less likely in the context of frequent male-to-male transmission within families. The role of stress, given the strong association of tics with anxiety, is also compelling. Tourette disorder patients have been found to have significantly higher levels of cerebrospinal fluid (CSF) corticotrophin-releasing factor (CRF)

than normal controls or patients with OCD who do not have a tic disorder, demonstrating a heightened reactivity of the hypothalamic–pituitary–adrenal axis. Increased reactivity of the noradrenergic sympathetic system has also been shown in patients with Tourette disorder. A dopamine-mediated pathway in the hypothalamus that modulates sweating in response to changes in temperature has also been linked with tic activity. Increases in ambient and core body temperatures have been shown to transiently increase tics in some individuals. A stress diathesis model modulated by the hypothalamic–pituitary–adrenal axis, the associated stress-related neurotransmitters and hormones, and their targets may represent the final common pathway that may explain the variable expression of the tic disorders.

Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcal Infection

A postinfectious mechanism for the development of tics and OCD has been postulated since the late 1800s. A post-streptococcal infection autoimmune etiology has long been well established for Sydenham's chorea, the movement disorder that has been the model for the development of Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcus (PANDAS) hypothesis. In addition to chorea, some Sydenham's patients display motor and phonic tics, as well as obsessions, compulsions, hyperactivity, impulsivity, and inattention. In 1998, Swedo and colleagues first described a putative subgroup of 50 children with PANDAS with OCD and/or tic disorders with acute symptom onset and/or exacerbation precipitated by infection with group A β-hemolytic Streptococcus (GABHS). Although GABHS is considered the initial autoimmune response-inciting event in children with PANDAS, viruses, other bacteria, and even noninfectious immunological responses are thought to be capable of precipitating later symptom exacerbations. Case reports have also implicated Lyme disease and Mycoplasma pneumonia in the development of infection-triggered tics. By molecular mimicry—the postulated autoimmune mechanism—antibodies are formed against the inciting agent and subsequently attack neurons because of some structural similarity.

Specific diagnostic criteria for PANDAS have been described, including the presence of OCD and/or tic symptoms, prepubertal onset, episodic course with sudden, explosive onset and/or exacerbations and remissions, and a temporal relationship of GABHS infection and neuropsychiatric symptoms. A case-control study of 144 children with OCD, Tourette disorder, or another tic disorder conducted by Mell and colleagues provided the strongest evidence for the involvement of GABHS in the onset of tic disorders and OCD. Patients with OCD, Tourette disorder, or another tic disorder were found to be more likely than controls to have had a

streptococcal infection in the 3 months prior to the onset of symptoms. Risk was greatest among those with multiple streptococcal infections in the preceding 12 months. Others have found no more than a chance association between GABHS infections and tic symptom exacerbations. A case-control study by Perrin and colleagues found little evidence of increased tics, obsessions, or compulsions after well-documented and treated GABHS infections.

Several groups have reported increased antistreptococcal antibody titers in individuals with OCD and tic disorders, but several other groups have not found this association. A double-blind, placebo-controlled, crossover study of prophylactic oral penicillin to attempt to reduce PANDAS recurrences failed to show differences between drug and placebo. More recently, in two prospective case-control studies of children with PANDAS Kurlan and colleagues reported that Group A B-hemolytic streptococcus infection was not the only antecedent associated with exacerbations of tics and OCD symptoms in the cases; similarly, Leckman and colleagues found there was no evidence for a temporal association between GABHS infections and tic/OC symptom exacerbations in children who met published PANDAS diagnostic criteria.

Treatments based on a postulated autoimmune mechanism have been nonspecific, and the results have been inconsistent. Immune therapies such as intravenous immunoglobulin (IVIG), plasmapheresis, corticosteroids, and plasma exchange have been explored with inconsistent results. Immunomodulatory treatments remain experimental, and current recommendations are for use only in research protocols.

The link between infectious etiology and tic disorders/OCD remains a work in progress. Building on previous work, most recent investigation has shifted its focus on acute, explosive onset OCD symptoms, which Swedo and colleagues have described as Pediatric Acute Onset Neuropsychiatric Syndrome (PANS). Anxiety, emotional lability, developmental and behavioral regression, deterioration in schoolwork and handwriting, and excessive urination are among the secondary characteristics.

Other new areas of research include investigation of proinflammatory cytokines elevation, as well as decreased numbers of regulatory T cells in some Tourette disorder patients. Clinical implications suggest vigilance in evaluation of tic or OCD patients with pharyngitis or streptococcus exposure, a low threshold for obtaining streptococcus throat culture, anti-streptolysin O [ASO] and anti-DNAse B titers, and vigorous treatment with antibiotics when streptococcal infection is confirmed. Antibiotic treatment has been shown to be remarkably effective in some unambiguous cases of sudden onset or exacerbation of tics with associated laboratory documented streptococcal infection.

Neuroimaging Studies

Structural MRI studies in Tourette disorder demonstrate volume changes in brain regions associated with CSTC circuits. Some studies have shown a loss of the normal basal ganglia asymmetry, as well as decreased basal ganglia volume in TD patients. In ten pairs of monozygotic twins, the right caudate was smaller in the more severely afflicted individuals, supporting evidence for the role of environmental components. The largest study of basal ganglia volume with 154 patients with Tourette disorder and 130 controls, conducted by Peterson and colleagues, found a significant decrease in the volume of the caudate nucleus in both children and adults. Larger dorsal prefrontal regions in children, but significantly smaller volumes in adults, were also reported by this group. Dorsal prefrontal volume was inversely related to tic severity, such that patients with greater prefrontal volumes exhibited decreased tic severity. Larger prefrontal volumes in children with TD may be a manifestation of synaptic plasticity associated with the constant need to suppress tics in social contexts. Adults with persistent tics may represent a subsection of the overall Tourette disorder population who do not generate a neuroplastic, compensatory response in the prefrontal cortex, leading to increased severity of the disorder and its continuity into adulthood.

Larger parieto-occipital region volumes and smaller inferior occipital volumes have also been observed in individuals with Tourette disorder when compared with controls. Bloch and colleagues found an inverse correlation between caudate volume in childhood and tic severity in late adolescence and early adulthood. Smaller caudate volumes were associated with more significant later tic activity, as well as with OCD symptoms. Another more recent study reported increased volume of the putamen bilaterally in boys with Tourette disorder.

Decrease in corpus callosum size in children and an increase in corpus callosum size in adults with Tourette disorder have also been noted. Corpus callosum size correlates inversely with prefrontal volume and is positively related to tic severity. These findings may indicate age-dependent changes in the white matter tracts in the disorder. Alternatively, decreased corpus callosum size, like increased dorsolateral prefrontal volume, may represent a compensatory mechanism children with Tourette disorder develop to facilitate suppression of tics. Adults with TD tend to show the opposite pattern, exhibiting relatively decreased dorsal prefrontal and increased corpus callosum volumes that may be associated with the persistence of symptoms into adulthood.

Several studies consistently implicate primary cortical dysfunction in Tourette disorder. Cortical thinning has been documented in frontal and parietal lobes, especially the sensorimotor cortex; the degree of thinning may correlate with tic severity. Increased sensorimotor cortical volume has been correlated with strength of premonitory sensations in a study of adults with TD. Evaluation of subgroups of Tourette disorder patients has

shown a relationship between symptoms and location of cortical thinning. While most have found thinner cortex or decreased volume in several different cortical areas, a few studies have reported overall brain volume decreases in Tourette disorder subjects.

Larger left thalamic volumes were found in 18 patients with Tourette disorder compared to 16 control subjects in one study. Increased gray-matter volumes bilaterally in the ventral putamen and decrease in gray matter in the left hippocampal gyrus have also been shown. Peterson and team demonstrated significantly increased overall hippocampus and amygdala volumes in TD patients, with a decline in volume with age in the TD group, but not in healthy controls. In children and adults with Tourette disorder, these volumes were inversely correlated with the severity of tics, OCD symptoms, and ADHD symptoms. An explanation for these findings is that the sub-region plays a compensatory and neuromodulatory role with tic, OCD, and ADHD symptoms. In addition, cerebral hyperintensities—bright patches in brain parenchyma on T_2-weighted MRI that are indicative of neuroinflammatory or neurodegenerative processes—have been detected at increased rates in children and adolescents with Tourette disorder, OCD, or ADHD in subcortical regions (primarily the basal ganglia and thalamus). Taken together, volumetric studies suggest that cortical and subcortical impairment, including striatal anomalies, and disruption of the temporolimbic pathways of the CSTC circuits are implicated in the pathophysiology of Tourette disorder.

Functional neuroimaging studies using state-dependent cerebral blood flow, oxygenation, and energy (glucose) metabolism parameters as a measure of brain activity (e.g., functional MRI [fMRI], positron emission tomography [PET], and single photon emission tomography [SPECT]) suggest altered activity (increased or decreased) in various areas of the brain (e.g., frontal and orbital cortex, striatum, putamen) in TD patients compared to controls, or across brain regions within TD patients. An fMRI study by Bohlhalter and colleagues that analyzed activity two seconds before and after tic onset indicated that paralimbic and sensory association areas are critical to tic generation. Other fMRI studies in individuals with TD indicate that greater ability of basal ganglia structures to suppress cortical activity may be related to decreased tic severity, supporting findings from PET and SPECT studies of the role of the basal ganglia in Tourette disorder. Functional neuroimaging studies suggest that voluntary tic suppression involves deactivation of the putamen and globus pallidus, coupled with partial activation of regions of the prefrontal cortex and caudate nucleus.

Event-related PET scanning has connected increased or decreased activity in many brain areas with the presence of tics, including the prefrontal cortex, premotor and primary motor cortex, anterior cingulate cortex, putamen, and caudate. fMRI scanning has demonstrated increased

neural activity in individuals with Tourette disorder compared to controls throughout various motor areas, including the sensorimotor cortex, putamen, pallidum, and substantia nigra; this increased activity correlates with symptom severity. On the other hand, weaker activity has been demonstrated in the TD patients' motor control pathways, including caudate and anterior cingulate cortex. More severe tics have been observed in those with progressively less activity in these regions, suggesting disruption in these areas results in failure to control tics or premonitory urges. Other fMRI studies have also shown age-related abnormalities in frontostriatal and frontoparietal connections, implicating abnormal maturational changes in Tourette disorder patients, strengthening the understanding that tics are the result of neurodevelopmental deficits.

Abnormal dopamine neurotransmission that contributes to the pathophysiology of Tourette disorder is supported by increased levels of dopaminergic innervation of the striatum of TD patients in SPECT studies. A study in monozygotic twins concordant for Tourette disorder but discordant for severity demonstrated abnormalities in D_2 receptors in the caudate area in the more severely afflicted twin. These neuroimaging findings are consistent with results of well-established tic suppression treatments with neuroleptic drugs that block dopamine receptors. Furthermore, TD patients have been shown to release more dopamine in response to amphetamine at dopaminergic synapses than healthy controls, and dopamine-releasing drugs may precipitate or exacerbate tics. Midbrain dopaminergic neurons play a central role in motor control and attentional processes through direct connections to the striatum and cortex, respectively. Glutamatergic, serotonergic, cholinergic, noradrenergic, and opioid systems may also be implicated, given that they are present in CSTC circuits and interact with the dopaminergic system.

Taken together, structural and functional neuroanatomical findings support the understanding that Tourette disorder results from abnormal activity in diverse cortical and subcortical brain regions. Active suppression of tics may require activation of dorsolateral prefrontal circuits that increase overall activity in the caudate nucleus, thereby inhibiting activity in the putamen.

Genetic Findings

Genetic data have been derived historically from family pedigree and twin studies. Tourette disorder, persistent tic disorders, and OCD cluster in families. Twin studies have shown a high concordance rate for tic disorders among monozygotic (MZ) pairs (ranging from about 50 to 90 percent), in contrast to a relatively low rate among dizygotic twins (often around 20 percent). Other studies have shown that first-degree relatives of TD patients have a higher risk of Tourette disorder, persistent tics, and OCD

than normal controls. Historically, genetic analyses were thought to be consistent with an autosomal dominant mode (with incomplete penetrance) of inheritance; some investigators argued that a semidominant, semirecessive pattern could also exist. However, older studies were confounded by relatively high rates of bilineal transmission with apparent genetic contributions from both paternal and maternal lines.

More recently, investigators have proposed multiple gene loci in combination with environmental factors. The precise type or severity of tic disorder may be different from one generation to another and may be modified by nongenetic factors. A systematic genome scan of 76 affected sibling pair families with 110 sib pairs conducted by the Tourette Syndrome Association International Consortium for Genetics (TSAICG) demonstrated that 4q, 8p, and four other regions on chromosomes 1, 10, 13, and 19 were regions of interest. Efforts to confirm and extend these findings, however, have led to the identification of new regions and a failure to replicate the original findings.

Specific TD populations have been studied in South Africa, Costa Rica, and French-speaking Canada. Regions near the centromere of chromosome 2, as well as on 6p, 8q, 11q, 14q, 20q, 21q, and X, have been implicated. A linkage analysis study of a large pedigree of multigenerational TD patients in the United Kingdom is suggestive of linkage at loci on chromosomes 5, 10, and 13 in at least one of the families. The largest genetic linkage study, undertaken by the Tourette Syndrome Association International Consortium for Genetics (TSAICG), consisting more than 2,000 individuals, using a whole-genome scan with 390 microsatellite markers demonstrated strong evidence of linkage for a region on chromosome 2p.

Cytogenetic abnormalities in Tourette disorder families have also been studied. A study by the TSAICG reported disruption of the contactin a–associated protein 2 gene on chromosome 7, coding for a membrane protein important for signal conduction along myelinated neurons at the nodes of Ranvier, in TD patients. Affected individuals were found to have alterations in chromosomes 2 and 7. Other Tourette disorder patients have been described with de novo duplication of the long arm of chromosome 7, a balanced translocation between chromosomes 6 and 8 with a translocation breakpoint on chromosome 8q, and an 18q21.1–q22.2 inversion. Abelson and colleagues identified a candidate gene, SLITRK1, on chromosome 13q31.1 in some individuals with Tourette disorder, with expression of the gene product in the basal ganglia and deep layers of cortex, brain regions implicated in the pathophysiology of Tourette disorder. Most recently, Ercan-Sencicek and colleagues reported a rare functional mutation in the *HDC* gene encoding l-histidine decarboxylase, the rate-limiting enzyme in histamine biosynthesis, in linkage analysis in a two-generation Tourette disorder pedigree.

Overall, current understanding of Tourette disorder and tic disorders

implicates multiple vulnerability genes that likely determine the form and severity of tics in the wide variety of afflicted individuals and their families. Candidate genes have been identified in individuals with Tourette disorder, including the dopamine receptor genes, the dopamine transporter genes, several noradrenergic genes, and some serotonergic genes. However, the recently published TSAICG genome-wide association study (GWAS) reported that no genes reached threshold significance.

DIAGNOSIS AND CLINICAL FEATURES

A comprehensive, detailed history with observations derived from multiple sources is the cornerstone of clinical evaluation of tics and comorbid neurodevelopmental and psychiatric disorders. Neurological, laboratory, and imaging examinations in patients with tic disorders are usually normal. Because tic disorders are diagnosed on the basis of history, reliable sources of information are essential. This is particularly important because in many patients tics may be suppressed during the initial examination. It is critical to determine the degree to which tics interfere with emotional, social, family, and academic functioning, because treatment strategies are most effective when the severity and impact of tics are taken into consideration. Diagnostic evaluation is closely connected with the first steps of treatment.

Historical inquiry should include detailed medical and developmental information, medication history (including substances of abuse or recreation), educational and occupational data, social and interpersonal history, and a thorough family pedigree covering at least three generations. A careful, descriptive, longitudinal assessment of the tic disorder is important, including onset, course, current severity, presence of premonitory sensations and the capacity for tic suppression, overall burden, and treatments to date. The physical examination should include height, weight, presence or absence of dysmorphic features, posture, gait, reflexes, and a systematic rating of current abnormal movements. The Abnormal Involuntary Movement Scale (AIMS) is a systematic assessment procedure (and rating form) that can be adapted for use with children. Videotaped standardized interviews and evaluation procedures are used in some research studies; these could also be used in the clinical setting. However, the absence of observed tics on initial examination does not preclude the diagnosis of a tic disorder. Unusual histories, co-occurring mental status changes, or the presence of seizures always warrant referrals for thorough neurological evaluation.

Psychiatric evaluation should include a formal assessment of the behavioral and emotional problems known clinically to cluster with tic disorders, including ADHD, OCD, anxiety disorders, mood disorders, and manifestations of impaired or dysregulated affect (e.g., aggression). The use of structured or semistructured interviews, such as the Diagnostic Interview Schedule for Children (DISC) or the Children's Schedule for

Affective Disorders and Schizophrenia (K-SADS), can improve classification and evaluation of psychiatric comorbidity. Standardized rating scales developed specifically for the tic disorder population have improved diagnostic reliability in research studies and can also be helpful in clinical care. The Yale Global Tic Severity Scale (Y-GTSS) and the Tourette Syndrome Symptom List (TSSL) rate tics, compulsions, and other associated features. Specific rating scales for OCD (the Children's Yale-Brown Obsessive Compulsive Scale [C-YBOCS]) and ADHD (the Iowa Conners parent and teacher rating scales, or the Swanson, Nolan, and Pelham [SNAP] scale) can also be used. Because rating instruments can provide quantifiable baseline data, such as frequency and intensity of tics, these data can also be used to measure treatment response (Table 48–2).

Auxiliary data from outside sources is essential. Pediatric and medical records may document developmental and medical history, adequacy of medication trials, hospitalizations, and laboratory findings. Review of educational records is advised for children because many TD patients manifest tics or associated problems in school settings. Report cards can document academic performance. Direct phone contact with teachers may provide data about attentional functioning, social and emotional competencies, and any behavioral difficulties. Neuropsychological or speech and language testing may be indicated for patients with impairments in school or occupational functioning. Identified areas of strength and weakness are subsequently conveyed to appropriate personnel for inclusion into educational or vocational planning.

Table 48–2.
Rating Scales

Domain	Type	Reliability and Validity	Sensitive to Change
Tics			
Yale Global Tic Severity Scale (YGTSS)	Clinician	Excellent	Yes
Abnormal Involuntary Movement Scale (AIMS)	Clinician	Excellent	Yes
Tic Symptom Self-Report	Parent/self	Good	Yes
ADHD			
Swanson, Nolan, and Pelham-IV (SNAP-IV)	Parent/teacher	Excellent	Yes
Abbreviated Conners Questionnaire	Parent/teacher	Excellent	Yes
OCD			
Yale-Brown Obsessive Compulsive Scale (YBOCS) and Children's Yale-Brown Obsessive Compulsive Scale (CYBOCS)	Clinician	Excellent	Yes
National Institute of Mental Health Global	Clinician	Excellent	Yes
Mood and Anxiety Disorders			
Children's Depression Inventory (CDI)	Clinician	Good	Yes
Children's Depression Rating Scale (CDRS)	Self	Good	Yes
Multidimensional Anxiety Scale for Children (MASC)	Self	Good	Yes

General			
Achenbach Child Behavior Checklist (CBCL)	Parent/teacher	Excellent	No
Clinical Global Impressions Scale (CGI)	Clinician	Excellent	Yes

PATHOLOGY AND LABORATORY EXAMINATION

In general, laboratory tests are indicated only to rule out other disorders when such conditions are highly implicated in the differential diagnosis of a given patient. For example, specific tests are available for the definitive diagnosis of Huntington disease, Wilson disease, and neuroacanthocytosis.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis of tic disorders can be challenging (Table 48–3). Medical and family histories, physical and neurological examinations, and baseline laboratory testing enable clinicians to rule out potential causes of de novo tics such as infection, trauma, substance use, or toxin ingestion. Diagnostic hallmarks of tic disorders include the waxing-and-waning natural history, onset in childhood or adolescence, and repetitive, rapid, nonrhythmic phenomenology, and involuntary features. In the absence of at least some history of simple tics, the diagnosis of a tic disorder may be questioned. Furthermore, the presence of vocal tics is helpful in ruling out other disorders because phonic manifestations are rare in other neurological conditions. Tics must be distinguished from other types of abnormal movements: myoclonus, tremors, chorea, athetosis, dystonias, akathisia, and compulsive rituals.

Diagnostic considerations among the movement disorders include Sydenham's chorea, poststreptococcal neurological complications such as choreiform, writhing, and truncal movements; Huntington disease, an autosomal dominant disorder presenting with chorea and dementia and with an onset typically in the fourth or fifth decade; Parkinson disease, typically a late-life disorder, characterized by flattened facies, bradykinesia, rigidity, cogwheeling, and "pill-rolling" resting tremor; Wilson disease, an autosomal recessive disorder of copper metabolism that presents with liver abnormalities and neurological symptoms: early dementia, mood disorders or psychosis, asterixis (a flapping tremor of the hands); parkinsonism; structural diseases such as hemiballismus associated with sub-thalamic nucleus impairment; and neuroacanthocytosis, a rare movement disorder marked by progressive muscle weakness and atrophy, progressive cognitive loss, chorea, acanthocytosis (spiked red blood cells), and, sometimes, facial tics. In psychiatric settings, patients who have been exposed to neuroleptics are at risk for neuroleptic-related dyskinesias, including tardive and withdrawal dyskinesias. It is important to remember that dyskinesias may also be observed in tic disorder patients secondary to neuroleptic therapy but may be easily overlooked.

Table 48–3.
Differential Diagnosis of Abnormal Movements

Descriptive Terms	Observable Movement Pattern(s)
Akathisia	Motor restlessness (unpleasant need to move), usually in the lower extremities
Athetosis	Slow, irregular, writhing movements, usually in the hands and fingers but often involving the neck
Ballismus	Intermittent, coarse, large-amplitude, jerking, shaking, flinging movements
Chorea	Irregular, spasmodic movements, usually affecting the limbs or face
Compulsion	Repetitive behavior that is more goal directed and may be undertaken to prevent or reduce anxiety or distress
Dyskinesia	Choreiform or dystonic movement that is involuntary, stereotyped, and not suppressible
Dystonia	Sustained, tonic contraction that progresses to abnormal postures
Myoclonus	Sudden, brief, clonic, shock-like jerks, usually involving the limbs
Periodic movements of sleep	Periodic dorsiflexion of the foot and flexion of the knee, occurring during sleep
Spasm	Stereotypic, prolonged movement involving the same group of muscles
Stereotypy	Repetitive, usually meaningless, gestures, habits, or automatisms
Tic	Stereotyped, rapid, recurring motor movement (motor tic) or vocalization (phonic or vocal tic) that is nonrhythmic, involuntary or semivoluntary, and sudden in onset
Tremor	Unintentional, somewhat rhythmic, muscle movement involving oscillations of one or more parts of the body

COURSE AND PROGNOSIS

The typical course of Tourette disorder is characterized by onset of simple motor tics of the eyes, face, head, or neck at about age 6 or 7 years, followed by a rostral-caudal progression of motor tics over several years to involve the shoulders, trunk, and extremities. Eye blinking is the most common initial tic. Vocal tics typically start at ages 8 to 9 years; more-complex tics often begin later, as do obsessive-compulsive symptoms, at about ages 11 to 12 years. As many as half of clinically referred Tourette disorder patients may show signs of ADHD, such as hyperactivity, impulsivity, and distractibility, prior to the onset of tics. Tics range from mild to severe and tend to stabilize over time; most children evaluated even in specialty clinics have mild to moderate tics. Some patients have lengthy periods during which most or all manifestations attenuate or remit. Recent studies indicate that tic severity improves significantly in most patients by early to mid-adolescence.

Social functioning may be impaired because of rejection by peers or anxiety about having tics in social situations. Tics may impair academic functioning by their disruptive impact in class or interference with homework completion; occupational functioning may be impaired by inability to use a computer or complete work tasks. Persistent tic symptoms may cause considerable distress and can lead to social isolation and

personality changes. In severe cases, tics may directly interfere with daily activities. For example, violent head and neck tics may cause physical complications, such as compressive cervical myelopathy.

Comorbid Psychiatric Disorders

The relationship between Tourette disorder and frequently observed comorbid psychiatric disorders has not yet been disentangled. Obsessive-compulsive symptoms, developmentally inappropriate motoric hyperactivity and inattention, anxiety, and aggressive dyscontrol have often been described in patients with Tourette disorder. Motor, vocal, behavioral, cognitive, and emotional dysfunction may represent manifestations of an underlying central core disinhibition.

A majority of clinically referred individuals with Tourette disorder meet full or sub-threshold diagnostic criteria for ADHD, OCD, or both at some time during the course of their illness. Interestingly, these findings are also reported in community samples. ADHD and OCD are more likely to interfere with overall functioning and academic and work performance than the tics. A recent investigation of functional impairment in youth with Tourette disorder conducted by Storch and colleagues found that non–tic-related problems caused more dysfunction than the tics per se, most often either ADHD or OCD symptoms.

ADHD is diagnosed by history of an enduring pattern of developmentally inappropriate inattention and/or hyperactivity and impulsive behavior; there is a bidirectional relationship between tics and ADHD. Some investigators have reported that 50 to 75 percent of Tourette disorder patients also meet criteria for ADHD, whereas about 10 to 30 percent of ADHD patients also meet criteria for a tic disorder. Co-occurring Tourette disorder and ADHD are often associated with academic difficulties, peer rejection, family conflict, and disruptive behaviors such as explosive outbursts, overt aggression, low frustration tolerance, and poor treatment adherence. The nature of the relationship between ADHD and Tourette disorder is not firmly established, but it has been clearly demonstrated that ADHD predicts greater disability than that associated with tic disorders alone, including an earlier diagnosis of Tourette disorder, and a much higher rate of anger control problems and oppositional defiant disorder, sleep difficulties, learning disability, mood disorders, social skills deficits, sexually inappropriate behavior, and self-injurious behavior.

OCD is characterized by obsessions—recurrent, intense, intrusive ideas, thoughts, impulses, or images that cause anxiety or distress, or compulsions—repetitive behaviors or mental acts sought to prevent or ward off anxiety or distress caused by an obsession. Additionally, there appears to be a bidirectional relationship between Tourette disorder and OCD in most patient cohorts. From 20 to 40 percent of Tourette disorder patients meet full criteria for OCD, and up to 90 percent have been reported to have

sub-threshold symptoms such as repetitive counting, touching, or symmetry needs.

Family studies provide the most compelling evidence for the association of tic disorders with OCD. First-degree relatives of TD probands have higher frequencies of TD, as well as OCD, and first-degree relatives of OCD probands have higher frequencies of OCD and tic disorders than relatives of control subjects. Studies of OCD probands indicate that the earlier the onset of obsessions or compulsions in the proband, the higher the genetic loading in family members for both OCD and tics.

In addition to ADHD and OCD, mood and anxiety disorders have been described in clinically referred and community samples of Tourette disorder patients, including major depression, bipolar disorder, generalized anxiety disorder, separation anxiety disorder, panic disorder, and simple and social phobias. Coffey and colleagues reported that comorbid mood disorders were the most robust predictors of psychiatric hospitalization and illness severity in a cohort of Tourette disorder patients. Tic severity was only marginally significant as a predictor of psychiatric hospitalization. More recently, in a controlled study of older adolescents with TD, Gorman and colleagues found that, independent of comorbidity with ADHD, TD patients had significantly higher rates of depression and poorer overall outcome than healthy controls.

Whether mood symptoms are primary (i.e., related to the underlying pathophysiology of Tourette disorder) or secondary to the demoralization and/or impairment related to having a chronic illness remains to be clarified. Furthermore, a substantial minority of youth with Tourette disorder evaluated in clinical settings may meet criteria for intermittent explosive disorder manifested by rage attacks or oppositional defiant disorder. Budman and colleagues reported that children with TD plus ADHD and OCD are more likely to experience explosive outbursts, and the number of outbursts is positively correlated with the number of comorbid conditions. Tic type and severity are not linked to the presence of explosive outbursts.

Learning and academic problems are common in children with Tourette disorder; in a database of 5,450 patients with Tourette disorder, 1,235 (22.7 percent) had learning disabilities. Young patients with Tourette disorder may experience problems with executive functions, such as planning, persistence, organizational skills, and social problem solving. Patients with Tourette disorder have been consistently shown to have difficulties with procedural learning, fine motor control, motor inhibition, nonverbal memory, and visual motor integration. In addition, handwriting may be poor.

Many clinically referred children with Tourette disorder are reported to have difficulty with sensory-perceptual functioning, such as extreme sensitivity to touch or sound. Investigators have hypothesized that

dysregulation of central sensory integration and/or sensory gating problems may result in these sensitivities, but more research is needed.

Mark was a 13-year-old boy referred by his pediatrician for consultation for tics and anxiety. Mark developed the onset of chewing his collar at around age 4 or 5 years. Between ages 5 and 6 years, he began to make sniffing and snorting sounds, and at age 6 or 7 years, he developed eye blinking and head and neck movements. Mark was subsequently referred at age 8 years to a pediatric neurologist, who diagnosed Tourette disorder. No treatment was initiated at that time because Mark's tics were not causing any distress or impairment. His parents reported that since age 10 years, the severity of Mark's tics had diminished. He was currently repeating words and making guttural sounds and bird noises at times.

Parents reported that Mark had a long history of anxiety. As a very young child, he was anxious about separation for preschool. He was described as a child who was slow to warm up, with a cautious temperament, waiting until he was familiar with a situation to enter into a group. Over the years, teachers commented that they would like to see more class participation from him. Parents reported that Mark often preferred to stay at home rather than to go out or take initiative to see friends on play dates.

Mark reported that he did not like to speak in public because he was afraid that what he would say would "not be perfect." Mark described ruminating on "things he should have said or done differently." Mark always worried about performance, about his mother dying, and about bad things happening. Mark had slept with his parents until age 10 years because of a history of nightmares.

Mark had had concerns about contamination, and he used Purell® and washed his hands frequently. Mark hoarded objects, and preferred to do things a certain number of times; in his backpack he kept 20 books, 20 blue pencils, and 20 black pencils. In the past, he used to sharpen pencils excessively to get them to a "just right" point.

Mark was the product of a full-term, uncomplicated pregnancy; developmental milestones were described as entirely within normal limits. Currently in eighth grade, he had attended private school since kindergarten and was an A student. Mark enjoyed sports and spending time with friends.

There was no family history of Tourette disorder or OCD. Mark's father had been treated for anxiety. A paternal uncle had a long-standing history of eye blinking. Mark had no history of hospitalization, head injury, seizures, allergies, or other major medical problems.

MENTAL STATUS EXAMINATION

Mark was a slender, peripubertal boy in age-appropriate casual clothing. He was very restless. There were multiple motor and vocal tics, including eye blinking, shoulder shrugging, facial grimacing, mouth opening, coughing, and grunting. Mark showed a range of affect and was pleasant and cooperative. Mark reported that his tics did not really cause him any problems but he felt worried a lot.

IMPRESSION

In summary, Mark was a 13-year-old peripubertal boy with a long history of multiple motor and vocal tics consistent with Tourette disorder. Given the contamination concerns, obsessional worries and ruminations, and the tendency to count and arrange, Mark also met criteria for OCD. In addition, there were symptoms suggestive of social anxiety disorder, given his reluctance to speak up in class, his slow-to-warm behavior, and a history of shyness. The excessive worry about performance was suggestive of a generalized anxiety disorder.

TREATMENT PLAN

Treatment of Mark's anxiety was indicated because it appeared to be pervasive and was causing distress. The recommendation was to start cognitive-behavioral therapy to address both his social anxiety and obsessive-compulsive behaviors. Given that Mark was neither in distress nor impaired by his tics and was probably past his lifetime peak severity, simple monitoring of the tics was recommended. It was likely the tics would decrease once the anxiety was treated.

TREATMENT

Individuals with mild and even some moderate tics may not need treatment at all, if the tics are not causing significant distress or impairment. Simple, active monitoring may be all that is necessary for some individuals with mild tics. Indications for treatment of tics include physical pain or discomfort, interference with social interactions, and impairment in any aspect of educational or occupational functioning. The first step in treatment is proper education of the patient, family members, teachers, and others who interact with the patient. Parents, educators, and physicians must work as partners to advocate for the optimal school environment for children with tic disorders. National and local support groups, such as the Tourette Association of America (http://www.tourette.org), can provide additional information and can serve as a valuable resource for patients and their families.

Nonpharmacological treatments have been developed that are as successful as pharmacotherapy. In fact, the first-line treatment for mild to moderate tics is cognitive-behavioral intervention. Medications are usually considered only when symptoms are significant, unable to be addressed by psychotherapeutic interventions, and interfere with academic or job performance, peer relationships, social interactions, or activities of daily living. Pharmacotherapy for tic disorders is individualized and tailored specifically to the needs of the patient; the most distressing and/or impairing symptoms are targeted first. The goal of treatment is not to eliminate tics, but to relieve tic-related discomfort or embarrassment and to achieve a degree of control of tics that allows the patient to function as normally as possible.

General Guidelines

Behavioral intervention is the cornerstone of effective treatment for tic disorders. Treatment goals should be to reduce symptoms, support adaptive functioning and strengths, and enhance developmental progress. Self-esteem at all times should be supported, given that most patients with tic disorders will have at least some sense of personal and emotional vulnerability. Early on in the diagnostic process, education as to phenomenology and natural history of the tic disorders is essential.

Clarification that the patient's symptoms are not voluntary in most situations eases psychological burdens for both patients and families. This is especially important because families observe that tics, at times, can be suppressed. Struggles over whether the symptoms are tics or "negative behavior" are pointless and should be curtailed; a more practical goal involves personal management of, and responsibility for, symptoms and behavior, regardless of their origin.

Containment is another cornerstone of treatment. Even with the use of

effective medications, it is rare for tics to remit completely. Use of a "tic room" or a "time out" area provides an opportunity to contain problematic tics or compulsions and to "de-stimulate." Because emotional conflicts and stress frequently increase symptom intensity and frequency, time-limited withdrawal from stressful situations can be beneficial. A balanced, healthy diet and exercise regimen may contribute to stress reduction and overall well-being. Caffeine and excess amounts of sugar should be minimized because they might exacerbate tics in some patients.

Psychoeducational Approaches

Educating patients and their families is essential. Patients and their parents frequently experience relief at the time of diagnosis. There should be ongoing opportunities for discussion of patients' and families' questions and concerns. Referral to the Tourette Association of America and to its local chapters is recommended for all newly diagnosed patients and their families to maintain continuing education and support.

Behavioral Therapies

Behavioral treatment is a primary intervention for many tic disorder patients. Simple behavioral approaches can be used with the majority of Tourette disorder patients to "de-stimulate" and contain the symptoms. Specific paradigms are indicated for obsessions, compulsions, and, more recently, tics. Relaxation techniques, such as deep breathing, guided imagery, and use of relaxation tapes, can be useful for the anxious TD patient.

Habit-reversal therapy or training (HRT) forms the essence of therapeutic intervention in the cognitive behavioral treatment known as comprehensive behavioral intervention for tics (CBIT) in youth and adults. The superiority of CBIT over supportive therapy and psychoeducation alone is also well established; CBIT is now considered first-line treatment for mild to moderate tics when intervention is warranted. The primary components of CBIT include awareness training, competing response training, relaxation training, contingency management, social support, and relapse prevention. Awareness training teaches patients to identify the premonitory urges or sensations that typically precede tics, as well as to recognize the situations in which tics are likely to occur. The second component of CBIT, teaching the patient a competing response to the targeted tic, has been developed to prevent the emergence of the tic. Parents are taught to provide appropriate support and encouragement to the child in practicing the technique at home. Tic substitution (substituting a more socially tolerable tic for a less socially tolerable one) can be useful.

Behavioral interventions are also critical for the management of oppositional, defiant, or explosive outbursts, which are not uncommon in

clinically referred youth with tic disorders. Scahill and colleagues demonstrated that parent management training is helpful in improving disruptive and explosive behavior problems in children with tic disorders. In children and adolescents, cognitive-behavioral paradigms are also the cornerstone of treatment of mood and anxiety disorders, which often co-occur in clinically referred individuals with Tourette disorder.

Psychotherapy

Individual, group, and family therapies are supportive adjuncts to behavioral interventions and pharmacotherapy. Individual supportive therapy is indicated for patients having difficulty adjusting to the disorder, to their peers or family, or with school or occupational functioning. It is particularly useful when there is evidence of moderate stress or anxiety or another comorbid psychiatric disorder responsive to this form of psychotherapy (e.g., mild depression). It can help to restore or maintain self-esteem and promote mastery and coping. Furthermore, supportive psychotherapeutic interventions may facilitate the normal developmental tasks of friendship development, school adjustment, and day-to-day stress management.

Family therapy is extremely useful in dealing with the many complex interpersonal and family issues that arise for children with Tourette disorder. At a minimum, both parents should be involved in the initial evaluation. Ideally, family members can be sources of support and nurturance. Ongoing family therapy is indicated when family development (i.e., growth and maturation) has slowed or halted because of the focus on the patient with the tic disorder. It may also help with maladaptive reactions from or to siblings or with specific symptoms that are affecting the entire family.

Group therapy is another important adjunct treatment. Support and education for parents and family members of patients with Tourette disorder can be found through the Tourette Association, which has created a well-organized network of state and community support groups. Informal, unstructured activity can be arranged through local chapters of the Tourette Association. Formal, structured support is also possible through social skills groups.

School and Occupational Interventions

Learning problems and classroom difficulties occur commonly in tic disorder patients. Specific developmental disorders and ADHD- or OCD-related symptoms may interfere with academic performance.

Clinicians should be available to provide consultation, guidance, and education to teachers or employers of patients with tic disorders. Useful special educational interventions include creating moderate, task-oriented

structure in the classroom, preferential seating, one-to-one support, and individualized educational or work plans. Flexibility is a key element in educational and occupational intervention. To promote tic control, there may be a need for optional "time outs" from class or work settings. Time limits may have to be extended or eliminated for exams. Some patients may also benefit from writing aides, such as laptops. Laptop and tablet computers may allow patients with handwriting difficulties to take notes in class without disturbing others. Adaptive, as contrasted to regular, physical education can be particularly helpful for children with Tourette disorder. This form of physical education can be arranged through special education departments in local schools. Programs can be tailored to each child's needs, strengths, and weaknesses.

Specific workplace interventions include structured tasks, organization of tasks into smaller units, flexible time limits, and ample physical space.

Medications

The decision to treat tics and/or comorbid symptoms with medication should be based on a comprehensive evaluation. Patients with symptoms that significantly interfere with adaptation to family, school or work life, peer relationships, or developmental progress should be treated, especially if psychotherapeutic options are either unavailable or not optimally beneficial. Patients who suffer significant emotional distress or inadvertently cause significant distress to significant others in their lives may also be the candidates for treatment, even when symptoms are relatively mild. Most patients with very mild symptoms need only monitoring, education, guidance, and support. Moderate to severe symptoms usually should be treated aggressively.

The clinical workup before initiating pharmacological treatment should include a complete physical examination and neurological screening, psychiatric evaluation, vital signs including height, weight, and body mass index (BMI), an AIMS screening, basic laboratory screening (including a complete blood count with differential, urinalysis, and a blood chemistry screen including liver and thyroid tests, fasting blood glucose, and metabolic screen including cholesterol and triglycerides), and an electrocardiogram (ECG).

Medication should be initiated at the lowest possible dose, and dose titration should be gradual in general. Most maximum doses will be low (compared to doses needed for other indications of these same medications) in Tourette disorder patients. When possible, a single medication (monotherapy) should be used initially. At times more than one agent will need to be prescribed simultaneously (targeted combined pharmacotherapy) when monotherapy has not been effective or has resulted in limiting adverse effects or when target symptoms include more than one disorder.

Determining an adequate duration for a medication trial for patients with tics can be quite challenging because the natural history of Tourette disorder is characterized by waxing and waning of symptoms over time. A 1-month baseline observation period before treatment is initiated is recommended, if feasible. In general, it is best to wait at least several weeks after changing a dose before making any conclusions about therapeutic response. External stressors must be taken into account at all times as potential determinants of increased symptomatology during medication trials. Comorbid conditions, such as ADHD and OCD, which significantly affect the individual should be targeted aggressively because it is well established that these conditions are often more impairing than tics and that they respond to treatment.

α-Adrenergic Agonists. The α-adrenergic agents are recommended as first-line pharmacological treatment for most patients with mild to moderate Tourette disorder, especially in those with comorbid ADHD. Clonidine (Catapres), an α_2-adrenergic (presynaptic) agonist, has been used for more than 20 years for the treatment of Tourette disorder. When given in low doses, it is postulated that presynaptic noradrenergic effects mediate the observed clinical improvement in motor and vocal tics. Clonidine activates presynaptic autoreceptors in the locus coeruleus to reduce norepinephrine release and turnover in the cerebral cortex. In addition, clonidine also reduces the disinhibition, impulsivity, inattention, and hyperactivity often present in young Tourette disorder patients.

Clonidine should generally be started at 0.025 mg daily to twice daily for prepubertal children and increased by 0.025 mg every 5 to 14 days. Prepubertal patients will generally need dosing three or four times daily. Adolescents or adults can be started on 0.05 mg daily and increased by 0.05-mg increments to twice-daily dosing. The total daily dose typically is 0.05 mg to 0.45 mg (i.e., up to 8.0 μg/kg). Common side effects include sedation, headache, dry mouth, stomachache, mid-sleep awakening, and irritability. Sedation, the most common and sometimes limiting side effect, usually abates over several weeks; when it does not, dose reduction may be helpful. Hypotensive effects are minimal in this dose range, but blood pressure, pulse, and ECG should be monitored at baseline and follow-up visits. More concerning is the risk of rebound increases in blood pressure, anxiety, and tics if abrupt discontinuation of clonidine occurs. A transdermal form (Catapres TTS-1, TTS-2) is available and may be an alternative when patients require very frequent dosing and/or cannot tolerate the sedative effects. A long acting oral formulation is now also available (Kapvay) and designed to be administered twice daily.

Guanfacine (Tenex), an alternative α_2-adrenergic agonist, may also be efficacious for hyperactivity, impulsivity, and tics. Guanfacine activates postsynaptic prefrontal α-adrenergic cortical receptors. Prepubertal

patients are typically started on 0.25 mg daily and increased by 0.25-mg increments every 5 to 14 days given twice daily; older patients and adults are typically started on 0.5 mg daily and increased by 0.5-mg increments to about 3.0 mg daily. Adverse effects, generally less significant and more tolerable than with clonidine, include sedation, mid-sleep awakening, constipation, and hypotension. A long acting, once daily form (Intuniv) is now also available.

Neuroleptic Agents. Since the late 1960s when haloperidol was first introduced as a treatment for Tourette disorder patients, haloperidol (Haldol) and pimozide (Orap) have been the only Food and Drug Administration–labeled, formally approved agents for the treatment of Tourette disorder. These typical neuroleptic medications block postsynaptic D_2 (dopamine) receptors in the basal ganglia, decreasing dopaminergic input from the substantia nigra and ventral tegmentum and thus reducing tics. These medications are generally effective in tic reduction; however, considerable variation exists in clinicians' and patients' thresholds for neuroleptic use. The decision to use a neuroleptic may be guided by both symptom severity and quality-of-life concerns. Significant side effects, including acute dystonic reactions, oculogyric crises, torticollis, parkinsonism, akathisia, tardive dyskinesia, weight gain, sedation, dry mouth, blurred vision, galactorrhea, gynecomastia, constipation, urinary retention, social phobia, loss of drive/energy/personality, and electrocardiographic changes including tachycardia and QTc prolongation, limit their use to second- or third-line treatments. In general, neuroleptic agents are not recommended for mild tics. Of the typical neuroleptics, haloperidol and pimozide have been the most investigated, with double-blind, placebo-controlled studies supporting their use.

The newer, atypical neuroleptics, or second-generation antipsychotic agents, are recommended as first-line treatment when a neuroleptic is indicated for moderate to severe tics. These agents, which block both D_2 dopamine and 5-HT_2 serotonin receptors, have the potential advantage of fewer extrapyramidal side effects (EPSs) (acute dystonic reactions, oculogyric crises, torticollis, parkinsonism, akathisia, tardive dyskinesia). Their dual pharmacological activity appears to protect against the neurological adverse effects associated with typical neuroleptic agents. Among them, risperidone (Risperdal) has been found to be efficacious for tics. Multiple trials, including randomized, controlled trials, support risperidone use. It has been shown to be superior to placebo and equally effective as pimozide and clonidine for tic reduction. Doses are typically in the 1- to 3-mg range. Common side effects include appetite increase, weight gain, lipid and glucose metabolism abnormalities, and sedation. Sleep disturbance, social phobia, galactorrhea, gynecomastia, and erectile

dysfunction have also been reported.

Additional atypical options with some evidence base for efficacy in Tourette disorder include ziprasidone (Geodon) and olanzapine (Zyprexa). Results of one placebo-controlled trial of ziprasidone indicated that it was as efficacious as risperidone for tic reduction. Side effects, including weight gain, are similar. Ziprasidone carries the added risk of altered cardiac conduction, especially QTc prolongation. An ECG has been recommended before initiating treatment, during dose adjustments, on reaching the maintenance dose, and annually thereafter. Evidence for effectiveness of olanzapine is supported by open-label and case-report studies.

Aripiprazole (Abilify) is a novel atypical neuroleptic with partial agonist–antagonist effects on the dopamine and serotonin system. Several open-label trials as well as a placebo-controlled study have been published on its effectiveness and tolerability in Tourette disorder. The most common adverse effects include weight gain, akathisia, and sedation.

Fasting glucose and a lipid panel are recommended before initiating treatment, as well as on reaching the maintenance dose and at regular intervals thereafter, with all atypical neuroleptics. Weight, waist circumference, and BMI should also be monitored. An ECG may be helpful, especially when there is a known individual or family cardiac history.

Neuroleptics should be initiated at the lowest possible doses and increased very gradually. Risperidone is typically started at 0.125 to 0.25 mg daily to twice daily and titrated upward over weeks to about 1 to 2 mg daily in prepubertal children; adolescents are typically started on 0.25 mg daily to twice daily. For haloperidol, children are typically started at 0.125 to 0.25 mg daily to twice daily and increased by 0.125- to 0.25-mg increments weekly or biweekly. Adults are usually started on 0.5 mg with weekly or biweekly increases of 0.5 mg. Pimozide is an alternative D_2--blocking agent, which may cause fewer side effects than haloperidol. However, because pimozide also has calcium-channel–blocking properties, normal cardiac function (ascertained from cardiac assessment and an ECG) is a prerequisite to its use. Pimozide has been shown to prolong QTc intervals, and the risk for cardiac conduction abnormalities may increase when pimozide is combined with drugs that inhibit the cytochrome P450 3A4 isozyme. An ECG is also recommended during dose adjustments, on reaching the maintenance dose, and annually thereafter. Approximately half as potent as haloperidol, pimozide should be started at 0.5 mg to 1.0 mg for children and at about 1.0 mg for adolescents or adults. Most patients require less than 10 mg daily.

Common adverse effects of neuroleptics include weight gain, sedation, muscle cramps, and stiffness. Dose reduction or switch to an alternative drug is the best way to address these side effects. Fortunately, EPSs do not appear to be common sequelae from neuroleptic use at usual doses in tic disorder patients; nevertheless, clinicians should be alert to the possibility

of these reactions and consider appropriate interventions (e.g., dose reduction, anti-Parkinson agents,) on a case-by-case basis. EPSs may be less common with the atypical agents than with the typicals. Tardive dyskinesia, although probably not common, has been described in patients with Tourette disorder and may be difficult to differentiate from tics.

Weight gain is likely with both typical and atypical neuroleptics, but the risk appears to be greater with use of the atypical agents such as olanzapine and risperidone. The possibility of weight gain should be addressed proactively in all youth who are candidates for neuroleptics. Education regarding the need for a healthy diet and regular exercise at the outset of treatment is helpful; at times nutritional consultation may be indicated.

Tiapride and sulpiride are D_2-receptor–blocking neuroleptics used in tic treatment in Europe but not available in the United States. Tetrabenazine, a nonneuroleptic dopamine antagonist that acts by inhibiting central vesicular monoamine transporter type 2 (VMAT2), may be useful for the treatment of tics, but it is currently only approved as an investigational drug and more study is needed.

Selective Serotonin Reuptake Inhibitors. Serotonergic agents such as fluoxetine (Prozac), paroxetine (Paxil), fluvoxamine (Luvox), citalopram (Celexa), escitalopram (Lexapro), and sertraline (Zoloft) are first-line agents for pharmacological treatment of significant OCD, anxiety disorders, and mood symptoms. All of the selective serotonin reuptake inhibitors (SSRIs) except citalopram and escitalopram have been studied in placebo-controlled investigations in children with OCD. Although there is no evidence to support the use of the SSRIs for the suppression of tics, their use may nonetheless be warranted. Because many Tourette disorder patients have obsessions or compulsions and neuroleptics and the α_2-agonists do not effectively alter these specific symptoms, the SSRIs may be beneficial in some patients. In addition, complex motor tics such as repetitive squatting and touching may be very similar to compulsive rituals. Furthermore, stress and anxiety are known to exacerbate tics, and the use of the SSRIs to reduce anxiety may indirectly serve to reduce tics.

Fluoxetine has received the most study in Tourette disorder, but efficacy likely is relatively comparable among serotonergic agents. Choice typically rests with consideration of the side-effect profiles of the agents. Often, higher doses of the SSRIs are required for the treatment of OCD symptoms than for the treatment of anxiety disorders or depression, and many patients with OCD plus a tic disorder respond less well to SSRIs. The addition of small doses of a neuroleptic or an atypical neuroleptic, which increases the response to the SSRIs, may be required.

Mild OCD symptoms often respond to cognitive behavioral therapy alone, but when obsessions or compulsions are of moderate to severe intensity or impair adaptive functioning, SSRIs are potentially indicated.

Fluoxetine typically is started at 2.5 to 5.0 mg daily for children and at 5.0 to 10 mg for adolescents or adults. Dose ranges are not well established for children and adolescents with TD. It appears that most children will respond to 10 to 20 mg daily; adults may require 20 to 80 mg daily. Fluoxetine in combination with a neuroleptic can be useful for both tics and obsessive-compulsive symptoms; neuroleptic doses may require reduction or adjustment because of the cytochrome P450 enzyme–inhibiting properties of fluoxetine. Common side effects include activation, insomnia, headaches, anorexia, and weight loss.

Sertraline, fluvoxamine, citalopram, and escitalopram may also be beneficial, but experience with them is limited. There are more data available on the use of clomipramine (Anafranil) in OCD, but adverse effects may be more problematic. These medications may represent alternatives for patients who experience limiting side effects on fluoxetine. Current recommendations for the treatment of comorbid tics and OCD are to use the appropriate agent indicated for each symptom. For example, one may combine an α-agonist or atypical neuroleptic with an SSRI to target significant tics and OCD symptoms.

Tricyclic Antidepressants. Clomipramine should be started at 10 to 25 mg daily for children and 25 to 50 mg for adolescents or adults when used for the treatment of OCD. Total dose ranges are typically 100 to 300 mg daily; blood levels may be obtained, but no therapeutic range has been established. Common side effects are those seen typically with other tricyclic antidepressants, including sedation, dry mouth, constipation, blurring of vision, weight gain, tachycardia, and ECG changes.

Some studies of desipramine (Norpramin) have suggested potential efficacy for treatment of tics as well as ADHD symptoms in patients with comorbid ADHD. Doses are not established, but may parallel doses used in ADHD without tics. Careful cardiovascular monitoring must take place, including blood pressure, pulse, and baseline and follow-up ECGs (Table 48–4).

Benzodiazepines. Benzodiazepines have not been well investigated in tic treatment, but may hold some promise (e.g., clonazepam [Klonopin]). Some studies suggest a reduction in tics independent of anxiolytic effects. This effect may also result from a reduction in anxiety that, in turn, could reduce tic frequency. In addition, benzodiazepines can be used to treat comorbid anxiety symptomatology or panic attacks that can also occur in Tourette disorder patients. Doses are not established, but are often quite low (e.g., 0.125 mg daily to twice daily for clonazepam). Adverse effects of particular concern in the juvenile population are sedation, disinhibition, cognitive impairment, and dependence.

Stimulants. Stimulants are first-line agents for the treatment of ADHD. There was controversy in the last decade about the role of stimulants in Tourette disorder and whether their use causes or exacerbates tics; however, recent studies have demonstrated that TD patients with significant ADHD symptoms may be candidates for stimulants. In the first systematic investigation of methylphenidate use, by Gadow and colleagues, behavior improved and tics did not worsen at moderate doses of 0.1 to 0.5 mg/kg methylphenidate. When group data are analyzed, there is no significant increase in tics when stimulants are used in patients with tic disorders; however, individual patients may experience at least a transient increase in tics. In some studies, stimulant use is associated with a decrease in tics. Stimulants are equally effective in improving ADHD symptoms with or without comorbid tics. A randomized, controlled study conducted by the Tourette Syndrome Study Group of clonidine and methylphenidate in ADHD and chronic tics reported that the combination and each drug alone was more effective than placebo in reducing both tics and ADHD symptoms. Increase in tics did not occur in the methylphenidate group to any extent more significantly than in the placebo group. Finally, in a recent meta-analysis examining pharmacotherapy for youth with comorbid ADHD and tics, methylphenidate, α_2 agonists, desipramine, and atomoxetine (Strattera) were effective for ADHD symptoms. Supra-therapeutic doses of dextroamphetamine appeared to worsen tics. There was no short-term evidence that methylphenidate exacerbated tics. A judicious approach to the treatment of ADHD in the context of a tic disorder is to start with a methylphenidate-based stimulant, in low doses, and gradually increase, monitoring for any exacerbation of tics. Common adverse effects of stimulants include insomnia, appetite suppression, and weight loss.

Nonstimulant ADHD Treatment: Atomoxetine. Atomoxetine, a selective norepinephrine reuptake inhibitor, is approved for treatment of ADHD in children, adolescents, and adults. It has also been studied in youth with ADHD and chronic tics. One recent study reported that atomoxetine improved both ADHD symptoms and tics in children and adolescents with comorbid ADHD and Tourette disorder. It is dosed based on body weight and titrated from a daily starting dose of 0.5 mg/kg to 1 to 1.5 mg/kg. Therapeutic response, unlike stimulants, takes a few weeks. Common adverse effects include headache, nausea, fatigue, and stomach aches.

Table 48–4.
Pharmacotherapies for Tourette and Tic Disorders

Class/Medication	Typical Range (mg)	Starting Dose (mg)	Maximum Dose[a] (mg)	Common Side Effects

Neuroleptics				
Haloperidol	0.25–5.0	0.25–0.5	5.0	Sedation, weight gain, dysphoria, extrapyramidal effects, dry mouth, blurred vision, constipation, urinary retention
Pimozide	1.0–10	0.5–1.0	15–20	Sedation, weight gain, dysphoria, extrapyramidal effects, dry mouth, blurred vision, constipation, urinary retention, ECG changes (QTc prolongation)
Risperidone	1.0–3.0	0.25–0.5	4–6	Weight gain, sedation, lipid and glucose metabolism abnormalities, extrapyramidal effects
Ziprasidone	20–80	5–10	120–160	Weight gain, sedation, lipid and glucose metabolism abnormalities, extrapyramidal effects, ECG changes (QTc prolongation)
Aripiprazole	2.5–15	1.25–2.5	20	Akathisia, sedation, agitation, weight gain, lipid and glucose metabolism abnormalities, extrapyramidal effects
Partial α_2-adrenergic agonists				
Clonidine	0.05–0.45	0.025–0.05	0.45	Sedation, headaches, insomnia, stomachaches, hypotension, dry mouth, midsleep awakening, irritability
Guanfacine	1.0–3.0	0.25–0.5	3–4	Sedation, headaches, hypotension, midsleep awakening, constipation
Tricyclic antidepressants				
Desipramine	25–300	10–25	250–300	Sedation, dry mouth, weight gain, tachycardia, constipation, blurred vision, ECG changes
Clomipramine[b]	50–200	10–25	250–300	Sedation, dry mouth, weight gain, tachycardia, constipation, blurred vision, ECG changes
Selective serotonin reuptake inhibitors[b]				
Fluoxetine	5.0–40	2.5–10	60–80	Insomnia, activation, anxiety, anorexia, weight loss, headaches, gastrointestinal distress, sexual dysfunction; suicidality
Sertraline	25–200	12.5–25	200–300	Insomnia, activation, headaches, gastrointestinal distress, sexual dysfunction; suicidality
Paroxetine	10–40	5–10	50–60	Insomnia, activation, headaches, gastrointestinal distress, sexual dysfunction; suicidality
Fluvoxamine	50–300	12.5–25	300	Insomnia, activation, headaches, gastrointestinal distress, sexual dysfunction; suicidality
Citalopram	5–40	2.5–5	60	Insomnia, activation, headaches, gastrointestinal distress, sexual dysfunction; suicidality
Escitalopram	2.5–20	2.5	20	Insomnia, activation, headaches, gastrointestinal distress, sexual dysfunction; suicidality

ECG, electrocardiogram.

[a]These are usual maximum doses for adults.

[b]These medications have been found to be effective in patients with obsessive-compulsive disorder.

Other Alternatives. Many other medical treatments have been used in Tourette disorder patients. Immune therapies such as IVIG, plasmapheresis, and corticosteroids have been explored in patients with

PANDAS/PANS. These remain experimental treatments under study. Opioid antagonists (e.g., naltrexone) may be an alternative for patients with self-injurious behaviors. The dose range for naltrexone may be approximately 25 to 75 mg per day. Nicotine, both in gum and in the transdermal form, has also been studied in Tourette disorder. Results have been equivocal. In a double-blind, placebo-controlled trial of 61 patients with Tourette disorder at doses up to 7.5 mg daily, mecamylamine (Inversine), a nicotine antagonist, was found to be no more effective than placebo.

Baclofen, a GABAergic muscle relaxant, has been studied in one large open-label and one controlled trial. In the controlled trial, there was no difference between drug and placebo in total tic score, but baclofen was superior to placebo with regard to tic-related impairment on the Yale Global Tic Severity Scale. A placebo controlled study of omega-3 fatty acids derived from fish oil revealed no improvement in tic measures, but clinically meaningful improvement in tic-related impairment compared to placebo.

The use of botulinum toxin to suppress tics by injection into discrete muscles involved in tic generation has been examined in several studies. Botulinum toxin blocks acetylcholine release at the neuromuscular junction and produces a temporary, reversible diminution of muscle activity, which may last weeks to months for dystonic tics. Open-label and placebo-controlled trials have demonstrated efficacy for isolated tics. Botulinum toxin may be the most useful agent for the treatment of solitary, focal dystonias. There are reports of suppression of ear-wiggling tics and laryngeal tics. Adverse effects include soreness at the injection site and muscle weakness.

Targeted combined pharmacotherapy—the specific combination of two or more medications at one time—has evolved as a treatment option. Ideally, this approach should be used only after adequate trials of monotherapy have failed. However, many patients with Tourette disorder also have comorbid ADHD or OCD, and often both, and frequently monotherapy addresses one problem but not the remaining disorders. Judicious use of SSRIs and neuroleptics for Tourette disorder and comorbid OCD is one example of this approach; in some patients with OCD and tics, this approach may be more effective than monotherapy. Another example is the combination of methylphenidate and clonidine to target tics and ADHD symptoms. In general, for comorbid tic disorders and OCD or ADHD, each condition should be treated with its respective first-line option. A randomized, controlled trial of pramipexole, a mixed dopamine agonist with presynaptic autoreceptor effects, failed to show efficacy.

Surgical Treatment

Initial reports on surgical interventions for Tourette disorder appeared in

the 1960s. Stereotaxic neurosurgical techniques have since been used in a few cases of severely impaired adults. Bilateral capsulotomy was associated with at least 50 percent improvement in both motor and vocal tics in 12 patients who had Tourette disorder, with no severe adverse effects. In 1999, deep brain stimulation (DBS) was introduced for the treatment of intractable tics. Several patients have since undergone bilateral thalamic stimulation with promising results. However, given the significant medical risks for these procedures, there has been limited experience with use of these techniques in youth, and they have generally been reserved for severe and refractory tics that significantly interfere with function and persist into adulthood.

Transcranial magnetic stimulation involves generating a brief, powerful magnetic field by a small coil positioned over the skull, inducing an electrical current in the brain. This noninvasive approach has been demonstrated to effect long-term changes in cortical excitability, which may be abnormal in tic disorders. It is an exciting potential future treatment for tics. Neural stem cell transplantation is another proposed treatment for tics, and animal studies are underway.

Jack was a 14-year-old boy referred by his mother for management of his Tourette disorder. Jack developed the onset of skipping and clapping episodes when he was approximately age 7 years. This was followed by stretching movements of his mouth and nose accompanied by facial grimaces. His mother reported that Jack's tics remitted entirely until just before his 12th birthday when he began to "give the finger" for no apparent reason, and began to curse using the "F" word. Children often teased him, and he was in significant distress about this.

Jack was the product of a full-term, uncomplicated pregnancy; developmental milestones were described as within normal limits. Jack's parents divorced when he was 2 years of age. Jack attended private school from pre-kindergarten through, at the time of referral, the 9th grade. He had difficulty with mathematics. He had a group of friends, including a best friend, and enjoyed music and video games.

Jack's maternal grandmother had OCD, and maternal great uncles had eye-blinking tics. Jack had no history of head injury or seizures. Electroencephalographic and computed tomography scans were within normal limits. Past medication included adequate trials of clonidine, guanfacine, risperidone, and ziprasidone. Medications at the time of referral included haloperidol, 4 mg, which led to excessive sedation, including somnolence in school.

MENTAL STATUS EXAMINATION

Jack was a moderately overweight adolescent boy. Of note were multiple motor tics, including pelvic thrusting, hand movements, outward leg twisting, head and neck thrusting, eye blinking, abnormal inhalation, chin hitting, shoulder licking, and genitalia scratching. In addition, there was copropraxia in the form of "giving the finger." There was also a change in his vocal inflection intermittently and a tendency to yawn on occasion.

IMPRESSION

In summary, Jack was a 14-year-old adolescent referred for management of his Tourette disorder. His clinical picture was consistent with moderately severe Tourette disorder. He had been treated with a variety of tic medications that were ineffective or intolerable.

TREATMENT PLAN

The recommendation was for a trial of aripiprazole, which is not formally approved for treatment of Tourette disorder. In addition, a trial of comprehensive behavioral intervention for tics was recommended. Jack and his parents were also counseled that at age 14 it was

possible he was seeking treatment currently at his lifetime peak tic severity, and tic symptoms might begin to attenuate over the next few years.

FUTURE DIRECTIONS

The French neurologist Georges Gilles de la Tourette in 1885 was among the first to recognize and describe the neurodevelopmental disorder that now bears his name, as well as its psychiatric comorbid conditions. Since the first case descriptions of Gilles de la Tourette, a spectrum of tic disorders has come to be recognized and codified in psychiatric nomenclature. Tic disorders are complex neurodevelopmental disorders with heterogeneous phenotypes characterized by core disinhibition mediated by the CSTC tracts. Tic disorders are genetically determined in most cases. There is a growing appreciation and understanding of the role of psychiatric comorbidity in the diverse clinical presentation, and it is often the neurobehavioral, occupational, and psychosocial problems that co-occur in clinically referred individuals that warrant treatment rather than the tics per se. Treatment strategies should be multimodal in nature and include cognitive-behavioral, individual and family intervention, educational monitoring and, where indicated, pharmacotherapy. Future investigation is needed to better understand the phenomenology, developmental psychopathology, and novel approaches to the treatment of tics. Tremendous progress has been made in the last few decades through the use of innovative neuroimaging techniques, genetic studies, and clinical interventions. Understanding of the etiology, genetics, neuroanatomy, and epidemiology of tic disorders has been significantly enhanced. Novel treatment approaches have also emerged, providing alternatives to the pharmacological management of tics. Targeted behavioral intervention has been proven to be as effective as medication and is now first-line treatment. Deep brain stimulation, botulinum toxin, targeted surgery, and stem cell transplantation are examples of promising new treatments. The future holds tremendous promise as new insights into the etiology, pathophysiology, and treatment of tic disorders are rapidly developing.

Elimination Disorders

EDWIN JENS MIKKELSEN, M.D.

ENURESIS

The disorder of enuresis has been recognized for centuries. However, substantial progress in the understanding of the disorder did not begin to occur until there were effective treatments. The first effective treatment was the application of the bell-and-pad method of conditioning, which was subsequently followed by pharmacological treatment in the form of imipramine (Tofranil) and more recently desmopressin acetate (DDAVP). Each of these advances has led to etiological research that might explain the efficacy of the particular intervention. The amount of interest in the disorder, as assessed by the number of published articles, has been relatively constant over the last several years. At the beginning of this decade, a literature search using the key terms *enuresis and children* (0 to 18 years), with a time frame of the prior 10 years, yielded a total of 822 citations. A recent search performed with the same parameters produced 785 citations. This chapter reviews the accumulated clinical knowledge concerning enuresis, as well as the emerging research that may lead to a greater understanding of the disorder.

Definition

Enuresis is defined as the involuntary or intentional voiding of urine. The severity is determined by the frequency of urination; quantity is not a diagnostic consideration per se. Quantity can become a factor in treatment decisions if a child emits only small quantities of urine; in actual practice, quantity usually does not figure heavily into the treatment plan. Frequency, however, can be important in planning a hierarchy of treatment approaches. The major diagnostic qualifier relates to age of onset. Finally, the definition precludes a physical cause for the disorder.

The length of time before continence is considered established varies in the literature between 6 months and 1 year. The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) requires a chronological age of 5 years, or alternately, a developmental level equivalent to that age. In practical clinical terms, children who have never maintained continence for more than 1 year are referred to as having *primary enuresis*, whereas children who have achieved continence for 1

year or longer and then resume wetting are referred to as having *secondary enuresis*. The DSM-5 requires a frequency of at least 2 episodes a week for 3 consecutive months. However, it allows an exception for distress or impairment in functions. This means that an individual can receive the diagnosis if they are deemed to experience significant distress and do not meet the frequency criteria.

The disorder is also further defined according to the timing of the episodes throughout the day. Episodes occurring only at night are referred to as *nocturnal*; daytime wetting is labeled *diurnal*. The term "nocturnal and diurnal" refers to a combination of these two subtypes. Most children display only nocturnal enuresis, but some manifest diurnal or nocturnal and diurnal patterns.

History

A scholarly review of the history of enuresis found references dating back about 3,550 years to the Papyrus Ebers. The term derives from the Greek word *enourein*, which means "to void urine." In retrospect, many of the treatment approaches that were used in the past now appear almost sadistic in nature. Although some of these interventions may have been misguided but well-intentioned therapies (as in the use of leeching for other disorders), they may also reflect the commonly held view that the disorder is somehow under the (direct or indirect) control of the child and that punishment would lead to its cessation.

A confluence of somewhat disparate observations contributed to the evolution of the current understanding of enuresis. Although each of these is discussed in more detail in the following sections, a brief reference to them here will provide an overview of the various lines of research and their relative contributions to the present understanding of the disorder. The long-standing observation that enuresis tends to run in families evolved into the observation that a positive family history was a positive prognostic indicator for response to pharmacological interventions and, ultimately, to sophisticated research with large pedigrees pointing toward specific genetic loci and modes of transmission. The observation that imipramine was an effective treatment for enuresis ushered in the modern era of research because the efficacy of imipramine suggested biological contributions to the etiology of the disorder. Imipramine has now been largely supplanted by DDAVP as a pharmacological treatment modality, and related research into its mechanism of action has contributed interesting insights into the pathophysiology of the disorder. Juxtaposed with the research into pharmacological treatment and organic contributions to the disorder has been the impressive literature, which now dates back several decades, indicating that behavioral treatment in the form of the bell-and-pad method of conditioning is equally effective as the two leading pharmacological interventions for the disorder. The

observation that the wetting episodes usually occur at night also led to decades of research investigating the relation between sleep architecture and the occurrence of enuretic events. Although none of these lines of research has provided a parsimonious explanation, each has provided important contributions to the evolving understanding of the disorder. The accumulating literature with regard to enuresis increasingly suggests that a single unified theory of enuresis that applies to all children will not be identified.

Comparative Nosology

The variety of differing nosological and diagnostic schemas seen with many disorders does not exist for enuresis. The behavior is concrete and definite: The child wets or does not. That criterion makes it possible to integrate research data from different countries, cultures, and treatment centers with a greater reliability than is possible for many other disorders. The efficacy of a given treatment is reported in terms of its effect on the frequency of enuretic events. The primary differences with regard to diagnosis concern the frequency required to make a diagnosis of enuresis as a pathological state and the period of continence necessary to separate primary from secondary enuresis, with a duration of 6 months occasionally being used instead of 1 year. Only slight differences exist between the tenth revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) and the DSM-5. The ICD-10 states that enuresis "would not ordinarily be diagnosed in a child under the age of 5 years or with a mental age under 4 years." This is slightly different from the DSM-5 cutoff of 5 years for chronological and mental age. However, Tables 49–1 and 49–2 indicate the same 5-year cutoff for chronological and mental age as is described in the DSM-5. The ICD-10 also notes a change in required frequency of enuresis after 7 years of age (at least twice a month before and once a month after). Recent research has suggested there may be a meaningful clinical distinction between monosymptomatic and polysymptomatic enuresis. The latter term refers to those children who not only have nocturnal enuresis, but also have multiple episodes of wetting, daytime wetting, soiling, and signs of bladder hyperactivity.

Table 49–1.
ICD-10 Diagnostic Criteria for Nonorganic Enuresis

A. The child's chronological and mental age is at least 5 years.
B. Involuntary or intentional voiding of urine into bed or clothes occurs at least twice a month in children younger than 7 years of age and at least once a month in children 7 years of age or older.
C. The enuresis is not a consequence of epileptic attacks or of neurological incontinence and is not a direct consequence of structural abnormalities of the urinary tract or any other nonpsychiatric medical condition.
D. There is no evidence of any other psychiatric disorder that meets the criteria for other ICD-10

categories.

E. Duration of the disorder is at least 3 months.

Epidemiology

The first comprehensive data concerning the incidence of enuresis came from the Isle of Wight Study. They found that 15.2 percent of boys (7 years of age) were enuretic less than once a week, whereas 6.7 percent were wetting at least once a week or more. In 7-year-old girls, the frequency was 12.2 percent for those wetting less than once a week and 3.3 percent with a frequency of once a week or more. By 9 and 10 years of age, 6.1 percent of the boys were wetting less often than once a week, and 2.9 percent were wetting once a week or more. The corresponding figures for 9- and 10-year-old girls were 3.5 percent wetting less than once a week and 2.9 percent wetting once a week or more. The frequency for boys decreased considerably by 14 years of age, at which time 1.9 percent were wetting less than once a week, and 1.1 percent were wetting at a frequency of once a week or more. The rates also decreased for girls by 14 years of age, with 1.2 percent wetting less than once a week and only .5 percent wetting once a week or more.

Table 49–2.
ICD-10 Diagnostic Criteria for Nonorganic Encopresis

A. The child repeatedly passes feces in places that are inappropriate for the purpose (e.g., clothing or floor), involuntary or intentionally. (The disorder may involve overflow incontinence secondary to functional fecal retention.)
B. The child's chronological and mental age is at least 4 years of age.
C. There is at least one encopretic event per month.
D. Duration of the disorder is at least 6 months.
E. There is no organic condition that constitutes a sufficient cause for the encopretic events.

A New Zealand study involving 8-year-old children found the prevalence of nocturnal enuresis to be 7.4 percent, with 3.3 percent labeled primary and 4.1 percent labeled secondary. A similar large Scandinavian study involving 7-year-old children reported a prevalence of 9.8 percent, with the highest prevalence (6.4 percent) involving children with nocturnal enuresis, 1.8 percent with diurnal enuresis, and 1.6 percent with mixed nocturnal and diurnal enuresis. A report from Australia described an incidence of 5.1 percent for children in the range from 5 to 12 years of age. A review of the published epidemiological literature concerning enuresis

indicates remarkably consistent findings from different countries and cultures, even though the research methods are somewhat variable. A standard consensus format that defines uniform reporting parameters would greatly enhance the epidemiological literature base.

The epidemiological literature is consistent in confirming that enuresis is a self-limiting disorder that will eventually spontaneously resolve. Common point prevalence figures are in the range of 7 percent of boys and 3 percent of girls at 5 years of age, dropping to 3 percent of boys and 2 percent of girls by 10 years of age. Only 1 percent of boys still wet at age 18 years of age, and still fewer girls wet at this age. A spontaneous remission rate of between 5 and 10 percent per year after 5 years of age is usually cited. Secondary enuresis may occur at any time, but most commonly it begins between 5 and 8 years of age.

Etiology

Inclusion in the DSM-5 (as well as previous editions) definition of enuresis of children who wet intentionally with those whose enuresis is involuntary can be problematic. The vast majority of enuretic children do not wet intentionally or even on a subconsciously motivated basis. Increasingly, the research is pointing toward causal factors that may involve irregularities in physiological processes. Clearly, children who wet intentionally are in a different phenomenological grouping than those who do so on an involuntary basis, even if they do meet the other diagnostic requirements. The most likely explanations for voluntary intentional wetting are an oppositional defiant disorder (ODD) or a psychotic disorder. There are also a small number of children who originally have enuretic events involuntarily and subsequently manifest the behavior on a voluntary learned basis as well.

There is a correlation between enuresis and psychological disturbance that increases with age. This association is even more significant for enuresis, which persists into adolescence. Children living in socially disadvantaged situations and experiencing psychosocial stress have a greater frequency of enuresis than those who are not. The type and range of behavioral disturbance seen in children with enuresis are broad, and no marker can reliably differentiate between behaviorally disturbed and nondisturbed enuretic children. Thus, the associated behavioral disturbances are nonspecific and may represent a coincidental or secondary relationship rather than a causal correlation. Further supporting a secondary correlation are the repeated findings that children with enuresis have significantly more developmental delays and minor neurological dysfunction than nonenuretic children, compared to controls and other children attending a psychiatric clinic. Reports of delayed bone development in children with enuresis have also been linked to a possible general delay of maturation as a common underlying factor. However, new

studies refute this finding, and no clear conclusion can be drawn at this time. The most recent research into a general developmental delay contributing to enuresis has used evoked potentials and electromyographic recording of startle eye-blink performance. Separate investigations using these methods have pointed to delayed maturation of brainstem functions.

Another approach to this etiological question is represented by a large, longitudinal, population-based study in the United Kingdom, which compared the intelligence (as assessed by the Wechsler Intelligence Scale for Children–Third Edition [WISC-III]) of controls with children who still exhibited bedwetting in the age range of 7 years and 6 months to 9 years and 3 months. The authors reported that the bedwetting was associated with lower intelligence quotient (IQ) even after children with an IQ of less than 70 were excluded. However, this finding was primarily related to lower scores on the Performance section of the WISC-III. This observation led the authors to conclude that enuresis may be related to deficits in the maturation of the central nervous system.

One comprehensive effort reviewed the psychodynamic literature concerning enuresis and encopresis to define the concepts conveyed in that literature and then to determine empirically how often those concepts were verified and supported by the analysis of clinical material. The literature review yielded 24 generalizations that were consistently applied to enuretic and encopretic children. In subsequent statistical analysis of the clinical material, only 2 of the 24 generalizations reached statistical significance. Another recent study in this regard used a standardized behavioral rating scale, the Eyberg Child Behavior Inventory (ECBI), which was applied to children with primary nocturnal enuresis (PNE) (N = 92), a nonclinical control sample (N = 92), and a clinical sample (N = 92). The results indicated that the children with PNE had higher scores than the nonclinical control sample but significantly lower scores than the clinical sample. However, the mean score for the children with PNE was actually lower than the clinical cutoff score that had been determined for the ECBI.

Related to the association between behavioral disturbance and PNE are studies that address the frequency of diagnostic comorbidity. The most commonly reported comorbid diagnosis is attention-deficit/hyperactivity disorder (ADHD). In general, studies have reported that the co-occurrence of ADHD and PNE is approximately 30 percent greater than the frequency that would be expected from chance alone. A large contemporary study found that 32 percent of children diagnosed with ADHD also met diagnostic criteria for enuresis, whereas only 14 percent of a control group met the criteria. This finding was statistically significant at the $p < 0.001$ level. The rates of primary and secondary enuresis were not significantly different in the two groups. This study then investigated the degree of psychopathology and impairment in the ADHD children (with and without comorbid enuresis) and found no significant differences. Similar findings

were reported for the rates of psychopathology when the control children with enuresis were compared to those without the condition. Thus, the diagnosis of enuresis did not appear to increase the risk of psychopathology for the controls or the degree of impairment in the children who also had a diagnosis of ADHD. However, there was a higher incidence of learning disabilities and impaired academic performance in the control children with enuresis when compared to the control children without enuresis. This difference in the incidence of learning disabilities was not found when the ADHD children with enuresis were compared to those without the comorbid disorder. Thus, the co-occurrence of enuresis did not appear to increase the risk of learning disabilities in children with ADHD.

Another investigation used a family pedigree methodology to study the transmission of enuresis in the relatives of index family members who were diagnosed with PNE and in control probands who were diagnosed with ADHD as compared to those without this diagnosis. The results indicated that the two disorders were transmitted independent of one another.

Enuresis has been noted to occur statistically more frequently in the premorbid histories of children who develop early adolescent bipolar I disorder as compared to controls. An increased incidence of enuresis and other childhood psychiatric disorders has also been found in the history of adults with bipolar disorder and is associated with earlier onset of the disorder.

The association between behavioral disturbance and enuresis is stronger with secondary enuresis. This has been demonstrated by controlled studies and anecdotal reports of an association between the onset of enuresis and the loss of a parent through divorce or death. However, it should be noted that a large study from the Netherlands reported similar rates of psychopathology in children with primary enuresis as compared to those with secondary enuresis. The prevalence of psychodynamic factors in children with secondary enuresis would intuitively make sense because they have, by definition, demonstrated the physiological competence to maintain continence for a prolonged period of time before losing that ability. The most specific study of this association indicated that exposure to four or more stressful life events in a year and delayed acquisition of nocturnal continence were risk factors for the development of secondary enuresis. An association between the occurrence of traumatic events and the development of secondary enuresis has also been demonstrated.

There has been one innovative attempt to explore the possible relation between physiological and psychological factors. Specifically, it was postulated that children with enuresis who did not present with a concomitant behavioral disturbance would be those with dysfunctional or abnormal bladders, whereas those with a behavioral disturbance would be more apt to have normal bladders. The study found the converse to be true:

The group with behavioral disturbance had more dysfunctional bladders with lower volumes. The behaviorally disturbed group also had a greater number of developmental delays. A subsequent investigation reported no difference in bladder size among controls, children with PNE, and those who had been diagnosed with PNE but who were now continent. It also was demonstrated by two independent investigations that fluid loading can precipitate enuresis in children who have no prior history of enuretic events. The most recent investigations into this issue have used ultrasound techniques, which investigate both the volume capacity of the bladder and the thickness of the bladder wall in both controls and children with enuresis. This research suggested three subtypes: Large-capacity bladder with thick wall; normal-capacity bladder with normal wall thickness; and low-capacity bladder with thick wall. The children with enuresis were then assessed with regard to their response to a treatment with DDAVP. The results indicated that the children with the two abnormal bladder subtypes were less responsive to treatment than those with the normal bladder physiological characteristics.

The observation that enuresis tends to occur in family members has been known for decades. A large Scandinavian study involving more than 3,000 children found that a child's risk for developing enuresis was 5.2 times greater if the mother also had the disorder and 7.1 times greater if the father had the disorder, lending further support to a genetic influence. Within the last few years, there have been tremendous advances in the study of the genetic transmission of enuresis, which suggests that genetic contributions are likely to be significant in families with multigenerational histories of enuresis. A Scandinavian group identified 11 families that manifested PNE over three generations in a pattern that was suggestive of an autosomal-dominant inheritance, with penetrance greater than 90 percent. Genetic linkage studies with these families indicated markers on chromosome 13q. Similarly designed studies have also implicated chromosomes 4p, 8, 12q, and 22, suggesting genetic heterogeneity. A large multigenerational study that specifically investigated chromosome 22 found that only 39.3 percent of families had linkage to genetic markers on this chromosome. The genetic modes of transmission that have been discussed include sporadic, autosomal recessive, and autosomal dominant. Linkage studies have also suggested the possibility of mutation in the aquaporin-2 (AQP2) water channel locus in families with a dominant mode of transmission of primary enuresis, in that AQP2 appears to be essential for concentrating urine. Although genetic linkage studies continue to provide important information with regard to the etiology of enuresis, it increasingly appears that the genetic contributions are heterogeneous in nature and vary substantially among pedigrees that contain multiple generations of individuals with enuresis. Thus, it is likely that there is more than 1 mode of genetic transmission that contributes to the disorder; and

different mechanisms may be operating in different family pedigrees.

One particularly important etiological hypothesis was that urinary tract obstruction frequently caused enuresis. The significance of that belief revolves around the related implications for surgery to correct the obstruction. Extensive review of the relevant literature found no basis for concluding that bladder neck repair or urethral dilation was a reasonable or effective treatment for enuresis. That generalization does not apply to patients with specific anatomical or pathophysiological findings.

Research into the association between sleep physiology and enuretic events has evolved steadily since the 1970s. The research can be seen as evolving through the following four stages. During the first phase of the research, it was postulated that enuretic events were dream equivalents that occurred in deep sleep. The second major theory grew out of the observation that enuretic events originated in delta sleep and followed arousal signals. Thus, enuresis was seen as a disorder of arousal, which led to the hypothesis that enuretic children who were not psychologically disturbed did not produce arousal signals, whereas behaviorally disordered children did but failed to respond to them. The third phase of sleep research is represented by the two largest controlled studies, both of which found that, when the time of night is also considered, enuretic events occur in all sleep stages in proportion to the amount of time spent sleeping in each stage. A fourth phase of investigation has attempted to couple cystometry with sleep studies in an attempt to identify subtypes. These investigations have yet to produce any definitive results that can be replicated.

A long-debated issue has been whether children with nocturnal enuresis are more difficult to awaken from sleep than other children. Earlier literature had suggested that anecdotal reports from the parents of children with enuresis that they were difficult to arouse stemmed from their lack of experience in attempting to arouse their other children, who did not have enuresis, from a deep sleep. However, studies have suggested that children with enuresis may, in fact, be more difficult to arouse than control children. Recent reports have also found that obstructive sleep apnea may play a role in the development of PNE in some children.

The efficacy of DDAVP as a treatment for enuresis has led to the theory that some children lack the ability to concentrate urine produced during the night and thus cannot reduce urine volume, and manifest enuretic episodes as a result. That hypothesis has led to studies investigating the circadian variation of plasma atrial natriuretic peptide (ANP). Children with enuresis have not consistently been found to differ from controls with regard to ANP. In one study, 14 of 55 children with enuresis had lower ANP concentrations than controls, and 9 of the 14 children had an excellent response to treatment with DDAVP. An investigation into the concentration of vasopressin in plasma and urine in 18 children with PNE

and 20 matched controls found the concentration of vasopressin in plasma at 8:00 AM was significantly lower in the enuretic group. Total 24-hour urinary vasopressin excretion was also lower in the enuretic group but not significantly so.

Another hypothesis that has been investigated is that endogenous arginine vasopressin (AVP) levels would be different in children with enuresis who respond to DDAVP as opposed to those who do not. This would suggest the existence of a specific subgroup of children with enuresis based on their endogenous AVP levels and their positive response to DDAVP. A study involving a small number of subjects supported this hypothesis by indicating that AVP levels in the morning differentiated between controls and children with enuresis, as well as between DDAVP responders and nonresponders. However, a large study that also controlled for water intake over 72 hours and that sampled AVP more frequently found that only 14 of the 55 children with enuresis had a significant decrease in AVP when compared to controls. Of these, 9 had a significant positive response to DDAVP. Further complicating this line of research is the finding that AVP is not secreted in a continuous manner over 24 hours, but rather is secreted in a pulsatile pattern, suggesting that definitive studies of this variable require frequent sampling. Investigations that have adopted this methodology have yielded conflicting results, in that one reported no differences between DDAVP responders and nonresponders, whereas another study with a small number of subjects that used hourly measurements found that in the 11:00 PM to 4:00 AM time period, children with enuresis ($N = 9$) had significantly lower AVP levels than did controls ($N = 8$).

There have also been related studies into the role of urine osmolality. One hypothesis is that a decreased ability to concentrate urine could contribute to an increase in the volume of urine. In general, these studies indicated that children with enuresis do have lower urinary specific gravities (as compared to controls) but not to a level that reaches statistical significance. It has also been reported that the levels of AVP can be increased in controls and children with enuresis by fluid restriction and, furthermore, that plasma osmolality can effect AVP secretion. In this regard, a comparison of controls, DDAVP nonresponders, and DDAVP responders indicated that fluid deprivation produced an increase in AVP levels in all groups, but the response was less robust in the DDAVP responders than in the other groups.

Another variation on this line of research is that refractory enuresis persisting into adolescence and adulthood may be secondary to a relative insensitivity to AVP, which can be positively affected by DDAVP. These observations contribute to the hypothesis that the primary pathophysiology of enuresis may occur at the receptor level, and this may also explain why some children do not respond to DDAVP.

Further complicating the research into the mechanism of action of DDAVP are two independent investigations that suggested that there is a central nervous system mechanism that may account for its efficacy in some children with enuresis.

Thus, as the foregoing review suggests, what initially appeared to be an intuitive explanation for the mechanism of action of DDAVP has not been supported by a number of studies, and a precise mechanism that applies to all children who respond to DDAVP has not been identified.

There have also been investigations that have implicated tubular mechanisms with regard to the urinary excretion of potassium and sodium by children with enuresis. Although this research has primarily focused on the possible mechanism of action of DDAVP, it has also led to a reanalysis of imipramine's mechanism of action. Imipramine can produce a decrease in the excretion of sodium and potassium, which then produces a reduction in osmolal clearance and a decrease in urinary output. It has also been reported that imipramine can affect the secretion of nocturnal urinary antidiuretic hormone (ADH) and that this may account for its efficacy.

Diagnosis and Clinical Features

The concreteness and simplicity of enuresis make the diagnosis relatively easy. The DSM-5 continues the same age criteria that were used in the DSM-IV and DSM-IV-TR by specifying that the diagnosis is not made in a child whose chronological or mental age is younger than 5 years of age. The stated rationale is that, by this age, continence can be expected to have occurred. As noted by the reference to a mental age of 5 years, children with developmental disabilities may have a greater chronological age. The wetting must occur at least twice per week for at least 3 consecutive months, or, if less frequent, it must produce significant distress or functional impairment. Physical causes, such as a bladder infection, must be excluded. Qualifiers to the diagnosis indicate whether it is primary or secondary enuresis. As previously noted, *primary enuresis* refers to those children who have never maintained continence for any length of time, whereas *secondary enuresis* refers to those who had achieved continence for at least 6 to 12 months and then resumed wetting. The other qualifiers refer to the timing of the enuretic event during the day. Although most children exhibit only nocturnal enuresis, some have daytime (diurnal) patterns or a combined nocturnal and diurnal pattern.

The inclusion of children who wet intentionally with those who wet involuntarily under the same diagnostic heading can be problematic because that distinction has significant clinical implications. Children who are wetting intentionally almost certainly are doing so as a manifestation of a psychological disturbance. Although there is an association between behavioral disturbance and involuntary enuresis, the nature of the correlation is relatively nonspecific. Thus, although the coexistence of other

behavioral problems is not a diagnostic issue per se, it is of clinical importance.

John was a 10-year-old boy who had consistently wet the bed throughout his life. He averaged three to four nocturnal episodes per week, and his longest period of continence was a few weeks. Thus, John warranted a diagnosis of primary enuresis. John's father had been enuretic until 12 years of age, as were his father and a paternal uncle. Accordingly, the family had always assumed that this was a genetic hereditary disorder that John could not control. In keeping with this perception, John's parents had never adopted a punitive approach to the bedwetting. The wetting was handled in a matter-of-fact manner, with John washing his sheets every morning and showering before going to school.

The family sought consultation at this time because John was increasingly being asked to sleep overnight at the homes of friends and also wanted to attend an overnight Boy Scout camp. These concerns led the family to meet with their pediatrician, who suggested a trial of the bell-and-pad method of conditioning. This approach was not effective, in part because the family lived in cramped quarters and the alarm that was meant to awaken John also woke his two brothers who shared the bedroom with him.

At this point, the family's pediatrician suggested that they meet with a child psychiatrist with whom she worked. The child psychiatrist described the clinical literature on DDAVP. However, when John's father indicated that his health insurance did not cover prescriptions and that the family was having difficulty covering their household expenses on his income, which was only moderately above minimum wage, the psychiatrist felt compelled to discuss the relative costs of DDAVP and imipramine, which was less expensive than DDAVP. However, the psychiatrist also indicated that John would require a baseline electrocardiogram (ECG) (which his insurance could cover).

Ultimately, the family decided that John would need medication only for brief, discrete periods (overnights at friends and 1 to 2 weeks of summer camp) because they had worked out an acceptable plan for responding to the wetting on a day-to-day basis. Furthermore, they reasoned that, within approximately 2 years, John would experience a spontaneous remission of his enuresis, given that this was the family pattern. Thus, they decided that, because DDAVP has a rapid onset of action, they would pay out of pocket for the relatively small amounts of DDAVP that would be needed for these discrete periods over the next 2 years. The pediatrician advised the family of the Federal Drug Administration (FDA) alert regarding the risk of hyponatremia and seizures. They decided to use the oral form of DDAVP because the FDA identified the nasal spray as being more likely to produce hyponatremia and indicated that this form of DDAVP was no longer indicated for childhood enuresis. They were also advised to (1) limit John's fluid intake on the nights when DDAVP was administered, (2) discontinue its use if John developed the flu or another illness that could affect his fluid balance, and (3) discontinue the medication and notify their physician if symptoms of nausea, vomiting, or headache developed.

Pathology and Laboratory Examination

Because urinary tract infections can produce enuresis, a urinalysis should be part of every evaluation. Using radiographic procedures with contrast media to detect an anatomical or physiological cause for the enuresis is more problematic because the procedures are invasive and painful and the diagnostic yield is low. A large study carried out in a pediatric primary care setting found a 3.7 percent incidence of obstructive lesions in children with enuresis. Others have reported similar findings. The literature cited earlier in the section on etiology concerning the use of noninvasive ultrasound techniques to establish bladder capacity and wall thickness have not been replicated to a degree that would warrant their use on a routine basis.

However, they may be of use for children who are refractory to standard treatment.

Differential Diagnosis

As suggested previously, the primary differential diagnosis is a urinary tract infection. This is especially true for girls, who are more prone than boys to develop urinary tract infections. A urinary tract infection should be the first consideration for a girl who has been continent for a considerable period of time and has recently begun wetting. Although the diagnostic yield is smaller with boys, a urinalysis should still be carried out.

Enuresis can result from anatomical malformations or obstructive lesions, but the percentages are relatively low. If the history and interviews with the child suggest that the enuresis is intentional, then it is almost certainly related to an underlying psychological disturbance. The relation between psychological disturbance and involuntary enuresis is less clear. The coexistence of another behavioral disturbance should be noted and attended to clinically. The most common comorbid psychiatric disorder is ADHD.

It has also been documented that enuresis has a negative effect on self-image and that enuretic children have more negative feelings about their disorder as compared to children who have other chronic illnesses.

There have also been case reports linking the onset of enuresis in children to the administration of both the selective serotonin reuptake inhibitor (SSRI) antidepressants and the atypical antipsychotic agent risperidone (Risperdal). Thus, the possibility of enuresis as a side effect to these medications should be considered if a chronological correlation exists.

Secondary enuresis has also been identified as an important symptom of the abrupt onset of Type 1 Diabetes in children and is related to the polydipsia and polyuria that accompany that disorder.

Course and Prognosis

The natural history of enuresis is significant because it is a self-limited disorder that can spontaneously remit. The fact that the diagnosis is not made until 5 years of age takes into account children who have delays in toilet training that are not outside the accepted range (between 2 and 5 years of age). The prevalence of enuresis is relatively high, between 5 and 7 years of age, and then drops off substantially. The vast majority of enuretic children experience a spontaneous resolution of the problem at some time, and only a few remain enuretic into adulthood. By 14 years of age, only 1.1 percent of boys wet once a week or more. The peak age for secondary enuresis is between 5 and 8 years of age.

Treatment

The methods for the treatment of enuresis that have been empirically proven to be effective are primarily behavioral and pharmacological. Psychotherapy may be useful for ameliorating some of the associated behavioral problems that can be seen with enuresis, especially secondary enuresis. A particularly common clinical scenario for secondary enuresis is the development of wetting after the loss of a parent through death or divorce. In these patients, psychotherapy is the primary treatment modality. A review of the efficacy of psychotherapy for primary enuresis found a 20 percent success rate, which is probably not significantly greater than would be expected by the rate of spontaneous remissions and random chance.

Behavior Therapy. A comprehensive review of several studies determined the success rate for behavioral interventions as 75 percent. Recent studies have yielded comparable response rates. The primary behavioral intervention is the bell-and-pad method of conditioning. A pad is placed on the bed, with a wire running to a bell. When the child wets, the moisture completes a circuit in the pad, ringing the bell and waking the child. With repeated use, the child learns to awaken before wetting occurs. Several studies have indicated that concomitant behavioral disturbance reduces the likelihood of success of behavioral interventions.

Recent behavioral studies have focused on embellishment of the standard method and comparisons with different methods. For example, no difference was found between an audio alarm and a vibratory alarm. A study that compared the basic bell-and-pad method with methods in which the bell and pad were coupled with more response contingencies for wetting versus not wetting found no statistical difference other than a slightly lower relapse rate with the adjunctive use of reward contingencies. One innovative strategy involved replacing the bell and pad with an alarm clock timed to go off after 2 to 3 hours of sleep, when maximum bladder capacity would be expected. The authors reported responses that were equal to results with the standard bell-and-pad method.

The relationship between bladder capacity and response to behavioral treatment has also been investigated. One study found that bladder capacity did not affect outcome with the bell-and-pad method of conditioning, whereas another found that children with smaller bladder capacities tended to do slightly better when retention-control training was linked to the bell-and-pad method. A meticulous investigation into which treatment variables might relate to the efficacy of the bell-and-pad method found that the inability to be awoken by the alarm correlated significantly with failure, as did low functional bladder capacity.

There is some evidence to support the use of biofeedback for children

who have small bladder capacities and unstable detrusors and who have been refractory to prior treatment. The newest advance in this behavioral methodology has been the use of an external ultrasonic monitor that is attached to a waistband. The monitor then signals the alarm when the bladder reaches maximal capacity. Clinical research with this device has yielded success rates similar to those with the basic bell and pad and has also reported increases in bladder capacity. The bell-and-pad approach has also been coupled with the use of DDAVP for children who have been refractory to prior treatment owing to family dysfunction or a concomitant behavioral disorder, or both. Although the bell and pad is the most intensively studied method of behavioral intervention, it is not the only type of behavioral treatment. A recent comprehensive review of this subject also noted other behavioral methods, such as evening fluid restriction, nighttime toileting, rewards, overlearning, and retention-control training.

Pharmacotherapy. The initial description of imipramine's efficacy for enuresis was followed by more than 40 double-blind studies that confirmed its therapeutic value. This marked the advent of the pharmacological era of the treatment of enuresis, with imipramine being the dominant pharmacological entity used for more than two decades. Although imipramine has now been largely replaced by DDAVP, there are still reasons to include a discussion of its use in a comprehensive review of enuresis. Imipramine is still a consideration for children who are refractory to other forms of treatment. There is also a significant cost differential between imipramine and DDAVP, so that imipramine may well be the first pharmacological choice for those families who do not have any form of insurance and who have limited financial resources.

Later studies with imipramine focused on the relation between response and concentration of imipramine in the blood. Although one study found no connection between positive response and imipramine concentration alone or in combination with its metabolite desipramine (Norpramin), three studies found a significant correlation between positive response and total concentration of imipramine and desipramine. More specifically, optimal response was found at combined concentrations (imipramine plus desipramine) of greater than 60 ng/mL in one study and of greater than 80 ng/mL in another. The most recent study also found that efficacy was related to increasing dose but noted tremendous variation in serum concentrations among individual children receiving the same dose. The adverse effect of dry mouth also correlated with concentration in blood, providing clinicians with a crude index of blood concentration in children who are extremely reluctant to have their blood drawn.

Clinically, when one encounters a history of a lack of response to imipramine, one must ascertain the specific dose used because nonresponse is frequently related to dose: Primary care physicians often

prescribe only 25 to 50 mg per day. However, low-dose responders do exist, and it is reasonable to start treatment at a daily dose of 25 mg, titrating up by 25 mg every 4 to 7 days. This enables identification of the low-dose responders because the response to imipramine usually occurs within 1 to 2 days. The majority of children exhibit a positive response in the range from 75 to 125 mg. The standard maximal limit for dose is 5 mg/kg body weight, and ECG monitoring is recommended at doses greater than 3.5 mg/kg. A pretreatment baseline ECG is also recommended. Blood concentration values may also be clinically useful if higher doses fail to elicit a response.

There is also a possible risk of overdose by the child with enuresis. Children can engage in magical thinking, and there have been reports of children who believed that, if taking a few pills would stop the wetting for a night, then consuming the whole bottle would make it disappear forever. Thus, parents should be advised to control the medication carefully and to store it in a secure place. Severe overdoses may require treatment with physostigmine (Antilirium), whereas more moderate overdoses may be treated by the symptomatic management of arrhythmias and seizures.

Because almost all children at some point experience spontaneous remission of the enuresis, it does not make sense to prescribe medication for years without checking for a spontaneous remission. One solution to that problem is to taper the imipramine dose at 3-month intervals. Should enuresis reappear as imipramine dose is tapered, it can simply be returned to the optimal level for another 3-month period. Clinically, one often finds that more children remain dry after 3 to 6 months of treatment than can be expected from spontaneous remission alone. In general, treatment with imipramine should be viewed as necessary until spontaneous remission occurs.

Three clinical subtypes of enuretic response to imipramine exist: True nonresponders, true responders who maintain a response over time, and transient responders who respond for a few weeks and then resume wetting. Increasing the dose for transient responders usually recaptures the response but only for another few weeks, and ultimately one reaches a point at which the dose cannot be increased further. However, the initial transient response can be replicated after a medication-free interval; thus, one can use the medication for especially important, time-limited social events, such as summer camp.

As indicated previously, DDAVP has now surpassed imipramine as the first-line pharmacological approach for enuresis. A thorough review done as early as 1993 revealed 18 randomized, controlled trials, including a total of 689 subjects. Many subjects had been refractory to previous treatment for enuresis. DDAVP reduced enuretic frequency by 10 to 91 percent in these studies. Positive prognostic factors were age (older than 9 years of age) and lower pretreatment frequency of enuretic events. In most studies, wetting resumed after the medication was discontinued. Follow-up studies

indicated that 5.7 percent of children remained dry after cessation of medication, but many of those cases could have been due to spontaneous remission. The most common reported adverse effects were mild abdominal pain, epistaxis, headache, and nasal stuffiness. Several subsequent studies attempted to find factors that might predict or relate to an increased likelihood of a positive response to DDAVP. No one factor appears to predict a positive response, but larger functional bladder capacity and a positive family history of enuresis appear to be positively correlated with treatment success. Factors that are not reliably related to treatment outcome are urine osmolality, plasma osmolality, ADH secretion, urine production, and nocturnal AVP concentration. However, individual studies can be found that link these factors with a positive outcome.

A large multicenter follow-up treatment study of DDAVP from Sweden (N = 399) used a 4-week baseline observation phase, a 6-week dose titration period (range from 20 to 40 μg), and a 1-year follow-up period. The study design also included an assessment for the rate of spontaneous remission by means of a 1-week medication-free period every 3 months. Sixty-one percent (N = 245) of the children met the requirement of at least a 50 percent reduction in frequency during the dose titration period that was required to enter the 1-year follow-up phase of the study. The average frequency of enuretic events in the baseline observation period was 5.3 events per week, and this declined to 0.8 nights by the end of the year-long follow-up period. As with other studies, older age was a positive prognostic sign. Of interest was the observation that 77 children experienced a complete remission of their enuresis within the first 6 months of the active treatment phase. There has been one report of an attempt to increase the rate of spontaneous remission by aggressively titrating the dose until cessation of wetting is obtained and then maintaining this dose for 4 to 6 weeks before beginning to decrease the dose by 10 μg per month until it is discontinued. The authors reported that, by using this strategy, complete remission was achieved for 71 percent of the children. The median length of follow-up was 18 months, and the mean dose of DDAVP was 20 μg.

Studies have also specifically investigated the efficacy of DDAVP for children who were refractory to conditioning treatment and imipramine. One of these involving 52 children (dose range from 20 to 40 μg intranasally) found complete cessation of wetting in 53 percent, a partial response in 19 percent, and minimal or no response in 28 percent. A long-term, follow-up study (mean length of follow-up of 13 months) of children treated with DDAVP found no hematological or hormonal adverse effects.

Treatment with DDAVP has been compared to the bell-and-pad method of conditioning. The difference in response rate was not statistically significant; 86 percent improved with the bell and pad, and 70 percent improved with DDAVP. Another investigation comparing the combined use of the bell-and-pad method and DDAVP with placebo indicated that the

combination achieved significantly more dry nights. Similar results were found in a study comparing alarm monotherapy to alarm treatment coupled with DDAVP. The combination proved superior, especially for children with severe, almost nightly, wetting.

The development of oral tablets greatly simplified the administration of DDAVP. The nasal spray was difficult for some children to use, and this could (in some cases) contribute to variable administration. A controlled multicenter study found no difference in response between oral DDAVP and the traditional nasal spray. A dose of 400 μg produced more dry nights than did a 200-μg dose.

A significant dose–effect correlation was found in a placebo-controlled study that used 200-, 400-, and 600-μg oral doses. In a separate follow-up study (7 years), the rate of spontaneous remission at 2 and 7 years was reported as greater than would be expected solely on the natural history of the disorder. As with other treatment modalities, consistent findings in the clinical literature concerning positive responses to DDAVP are older age, larger bladder capacity, and lower pretreatment frequency of enuresis. The newest innovation in the use of DDAVP has been the development of a sublingual desmopressin oral lyophilisate (MELT). A recent randomized, controlled study that compared this formulation to the oral tablets found it to be equally effective. The children also expressed a greater preference for the MELT. This increase in preference was especially pronounced in the younger age group (5 to 11 years of age).

As the use of the DDAVP nasal preparation became more common, there were an increasing number of case reports of hyponatremic seizures with prolonged use. A review of 14 articles that reported data on serum sodium concentration in DDAVP-treated patients and 11 articles that reported individuals who developed altered consciousness or a seizure while taking DDAVP for enuresis concluded that hyponatremia is a potential adverse effect of DDAVP treatment. The authors also noted that excess fluid intake was a contributing factor in 6 of the 11 case reports. They concluded that patients receiving DDAVP for nocturnal enuresis should be advised not to consume more than 8 oz of fluid on nights when DDAVP is administered. The data on hyponatremia also suggest that periodic monitoring of serum sodium concentration would be prudent. The number of reported cases of hyponatremia and seizures, including two deaths, prompted the FDA to issue an alert concerning DDAVP in December 2007. The alert identified 61 postmarketing incidents of hyponatremia-related seizures that were related to the use of DDAVP. Sodium levels obtained at the time of the seizure ranged from 104 to 130 mEq/L. A particular concern was that two of the individuals who experienced seizures with hyponatremia died. The intranasal formulation of DDAVP was implicated in 36 of the cases, and 25 of these were individuals younger than the age of 17 years, most of whom were receiving DDAVP for treatment of nocturnal

enuresis. The FDA alert concluded that the intranasal formulation of DDAVP was no longer indicated for the treatment of PNE. The alert also suggested that treatment with the tablet form should be halted during illnesses that could produce disturbances in fluid dynamics and/or produce electrolyte imbalance. The alert also recommended that fluids should be restricted from 1 hour before to 8 hours after the administration of the tablets. The latter recommendation is consistent with earlier published reports that linked the amount of fluid intake to the risk of acute hyponatremia.

Although imipramine and DDAVP have been the dominant pharmacological treatment modalities over the last several years, there continue to be reports of success with anticholinergic agents. The majority of these reports relate to oxybutynin, both as a first-line intervention and for individuals who are refractory to other interventions.

General Treatment Considerations. The results of the studies reviewed, in conjunction with the natural history of enuresis, can help the clinician to develop a decision tree tailored to a given child. The first decision, naturally, is whether to treat at all. That decision is affected by the frequency of the wetting, the age of the child, and the amount of psychological distress that the wetting causes to the child. Enuresis has a negative effect on the self-esteem of these children, and self-esteem improves after successful treatment. One may choose not to treat a child who is wetting infrequently and who is at an age at which a spontaneous remission may be expected.

If one does elect to treat, it makes sense first to try the bell-and-pad method of conditioning because its efficacy has been repeatedly demonstrated and behavioral intervention is considered less invasive than pharmacological approaches. A large follow-up study that compared observation only with imipramine, DDAVP, and the bell and pad indicated that, although all of the active treatments were significantly superior to observation alone, the positive response was much more likely to be sustained after treatment cessation with the bell and pad than with either pharmacological treatment. Despite these apparent advantages, one large population-based investigation revealed that only a relatively small number of enuretic children (38 percent) saw a physician, and, of that number, only 3 percent were treated with the bell-and-pad method of conditioning, whereas more than one third received pharmacological treatment. A more geographically restricted survey of primary care physicians yielded significantly different responses, in that 80 percent of physicians indicated that they recommended the bell-and-pad method of conditioning. The most recent comparative study of the long-term efficacy of DDAVP versus the enuretic alarm involved 142 children who were randomized to either form of treatment for 6 months, with determination of success rates at 6 and 12

months. Interestingly, only 5.2 percent of the DDAVP group withdrew after randomization, as compared to 30.7 percent of those assigned to the enuretic alarm group. The results for those who completed 6 months of treatment (defined as at least 90 percent in wet nights) indicated that 76.8 percent of the DDAVP group was deemed to be successful, as compared to 61.8 percent of the alarm group. The success rates at 12 months were comparable with 77.8 percent of the DDAVP group meeting success criteria, as compared to 75 percent of the alarm group. However, when the large drop-out rate after the assignment to the alarm group was taken into account, the success rates were adjusted to 68.8 percent for the DDAVP group, and 46.2 percent for the alarm group. Thus, this study essentially confirmed the results of numerous prior studies, in that the two treatment modalities were found to be equally effective, but the ability to implement the bell-and-pad alarm system was too difficult for many families to successfully implement.

When the bell-and-pad method of treatment is unsuccessful or not feasible, it makes sense to proceed to pharmacological treatment, assuming that the enuresis is severe enough to warrant pharmacological intervention. For decades, imipramine was the first choice for pharmacological treatment. Although precise figures are not available for its relative use in the treatment of PNE, DDAVP appears to have surpassed imipramine as the most popular pharmacological treatment.

Only recently, with the effect of managed care, have articles appeared that address the financial cost of the various treatments for enuresis. The bell-and-pad method of conditioning appears to be the most cost-effective treatment. It is as effective as the pharmacological approaches, is more likely to lead to sustained improvement after the cessation of active treatment, and requires only the initial expense of the apparatus and replacement pads. Recent suggested retail prices for the basic apparatus ranged from $6.00 to $196.00, depending on the brand chosen. Other expenses to be considered are the time of the professional who counsels the parents on its use and the parental time involved. Imipramine is available generically, so its actual cost is quite modest. Related costs are the physician's time and the cost of a baseline ECG, periodic monitoring of ECG, and periodic blood concentration determinations.

The nasal preparation of DDAVP has been available in a generic form for some time. However, as noted earlier, the recent alert by the FDA indicates that the nasal preparation of DDAVP is no longer indicated for PNE. The oral preparation is now available generically but is still more expensive than imipramine. This cost differential has narrowed with the availability of generic DDAVP. A recent comparison of the retail price for 30 of the 0.2 mg DDAVP tablets ranged from $28.00 to $113.00, with the average being in the $30.00 to $100.00 range. The cost for 60 of the 50 mg imipramine tablets ranged from $17.00 to $33.00, with the average falling

in the mid $20.00 range. Thus, for some families without insurance, that covered DDAVP cost would still be a differential. The newer sublingual formulation has been in Phase III clinical trials for several years and has not yet been approved by the FDA. However, it is available in Canada and the United Kingdom.

ENCOPRESIS

Encopresis does not receive as much research attention as does enuresis. A literature search at the beginning of this decade using the key words *encopresis and children* yielded 165 citations. A recent search using the same parameters yielded 118 citations. Thus, although this disorder does not generate as much research interest as enuresis, the rate of new publications has been relatively steady over the last two decades.

Definition

The DSM-5 criteria are virtually unchanged from those of the DSM-IV and DSM-IV-TR and define *encopresis* with four related criteria: (1) the repeated inappropriate passage of feces, usually involuntary, (2) occurrence at least once a month for at least 3 months, (3) a chronological or mental age of 4 years of age, and (4) exclusion of a substance or medical condition as a cause.

For several years, the clinical and research literature concerning encopresis has distinguished between retentive and nonretentive encopresis. The DSM-5 recognizes this distinction and lists two subtypes: With constipation and overflow incontinence, and without constipation and overflow incontinence. The subtype with constipation and overflow incontinence corresponds to retentive encopresis. The subtype without constipation and overflow incontinence corresponds to nonretentive encopresis.

Some clinicians refer to a *primary type* in which the person has never established fecal continence and a *secondary type* in which the disturbance develops after a period of established fecal continence.

History

The history of encopresis is not as richly detailed as is that of enuresis, possibly because encopresis affects fewer children, and the events are less frequent. Unless the feces are particularly fluid, it may also be easier for children to hide the symptoms. A high frequency of encopresis and enuresis was found in children who were separated from their parents in World War II, thus documenting the effect of environmental factors.

The more contemporary history of encopresis is noteworthy for the establishment of a treatment methodology that involves cathartics to re-establish bowel dynamics (coupled with education), which has proven to be

quite successful. An innovative use of biofeedback technology showed much initial promise after its introduction in the 1980s, but it now appears that it is not more effective than the older method. Constipation is a common precursor to encopresis, and recent research has also focused on effective treatment for this disorder.

Comparative Nosology

As noted above, the DSM-5 has adopted the widely held clinical distinction between retentive and nonretentive encopresis, although the terminology differs slightly. The current DSM-5 definition includes voluntary and intentional encopresis that is obviously a distinction of major clinical importance. This statement appears to minimize the importance of a rather substantial subgroup of children with nonretentive encopresis who are encopretic because they cannot adequately control the anal sphincter or do not recognize the need to defecate in time.

The most comprehensive categorization of encopresis distinguishes three types of patients: (1) intentional—children who do have bowel control but intentionally deposit feces in inappropriate places for psychological reasons; (2) involuntary—those who cannot adequately control the sphincter or lack an awareness of the process, or both; and (3) involuntary—those whose soiling is related to excessive fluid from retentive overflow (75 percent of this category), diarrhea, or anxiety. Thus, this classification schema incorporates the retentive and nonretentive dichotomy and the distinction between voluntary and involuntary incontinence.

The ICD-10 diagnostic classification for encopresis essentially follows this schema and allows notation of the three subtypes. The primary differences with the DSM-5 criteria are the ability to code for three subtypes rather than two and a duration of 6 months at a frequency of at least once a month, as opposed to the DSM-5 duration of 3 months at a frequency of at least once a month. The ICD-10 also states that if encopresis coexists with enuresis, then "the coding of the encopresis should have precedence." This statement is problematic in terms of using diagnostic databases for research, given that it is important to know how many children are polysymptomatic.

Epidemiology

Two large epidemiological studies have yielded consistent results. The Isle of Wight Study reported a prevalence of 1.3 percent for boys and .3 percent for girls (10 to 12 years of age) soiling at least once a month. A large study involving 8,863 children found a 1.5 percent prevalence rate for boys (7 and 8 years of age). In that study, the ratio of boys to girls was more than 3:1. A significant correlation between encopresis and enuresis has also been found.

Etiology

The dramatic nature of fecal soiling has contributed to psychodynamic speculation. The term *chronic neurotic encopresis* has been used to describe the small number of children whose encopresis is predominantly psychological. The clinical characteristics described in these children are (1) a distant father and neurotic mother, (2) early and often harsh bowel training, and (3) a history of neurological delay. The one systematic study that attempted to verify the clinical features usually attributed to enuretic and encopretic children in the literature by analyzing actual case material could not substantiate the existence of 20 of the 22 factors developed through the literature review. As with enuresis, the distinction between primary and secondary encopresis relates to the issue of associated psychopathology. A study involving 63 boys with encopresis found that boys with primary encopresis were more likely to have developmental delays and associated enuresis, whereas those with secondary encopresis were more likely to have experienced higher levels of psychosocial stressors and to be diagnosed with conduct disorder. Another large study examined several psychological and physiological variables in children with chronic constipation as compared to children with encopresis unrelated to constipation. The group with constipation had significantly longer colonic transit times, whereas both groups had relatively high frequencies of abnormal defecation dynamics. A subsequent independent investigation of colonic transit time (CTT) in children with chronic constipation found that a CTT greater than 100 hours was related to a poor outcome at 1-year follow-up.

A large population-based study in the United Kingdom involving 8,242 children (7 to 8 years of age) investigated the association of soiling with a variety of psychological disturbances. The children with encopresis were divided into those who soiled frequently (at least once a week) or occasionally (defined as less than once a week). There was also a large control group. Both of the symptomatic groups had significantly higher rates of behavioral and psychological disturbance than the controls. The rates of disturbance were also higher in the group that soiled frequently than in the occasional-soiling group. However, there was no particular behavioral profile that correlated with encopresis. The authors noted higher rates of attentional, obsessive-compulsive, and oppositional presentations in the symptomatic children than in the controls.

A premorbid history of encopresis has been found to occur more frequently in individuals with prepubertal and early adolescent bipolar disorder phenotype (PEA-BP) than in controls. A recent large, retrospective study (in a military health-system database) involved 32,773 children who were identified as having ADHD. The results indicated that 4.1 percent of those children had constipation, as opposed to 1.5 percent of control

children without ADHD. The corresponding rates for fecal incontinence were 0.9 percent in the children with ADHD, as compared to 0.15 percent of the controls. Both of these results were statistically significant with high levels of confidence, leading the authors to conclude that ADHD was a risk factor for fecal incontinence.

A recent large birth cohort study involving 358 children also found higher rates of both enuresis and encopresis among children with ADHD.

No correlation between encopresis and social class was reported in two independent studies. The issue of neurological competence as a contribution to encopresis has been investigated. One study found no abnormalities of anal-rectal motor or sensory function but did find that a significant number of encopretic boys had abnormal anal-rectal expulsion dynamics. A sophisticated physiological study using a triple-lumen catheter attached to a hydraulic manometry infusion system found that age of onset, frequency, and duration of encopresis were all highly correlated with the amount of anal sphincter spasm that occurred when defecation was attempted. The amount of pain reported with bowel movements correlated positively with frequency of encopresis and inversely with maximum squeeze pressure. An investigation involving the concentrations of gastrointestinal (GI) hormones in controls and children with retentive encopresis indicated that the latter had higher concentrations of pancreatic polypeptide after a meal and less of a motilin response. However, the authors noted that these abnormalities could be the result of, or the cause of, the chronic constipation.

An extensive series of studies concerning physiological factors and the interplay of physiological and psychological factors has been carried out. The principal physiological findings were (1) 56 percent of children with retentive encopresis could not defecate rectal balloons (research technique used to assess sphincter competency), and most had abnormal anal sphincter contractions; (2) only 14 percent of those who could not defecate the balloons were found to have responded to treatment at 1-year follow-up, compared to a 64 percent success rate for those who could; (3) at 1-year follow-up, 70 percent of children who could relax the anal sphincter at the time of initial evaluation were improved, as opposed to 13 percent of those who could not; and (4) none of the children who initially presented with an abdominal fecal mass was improved at 1-year follow-up, regardless of other factors.

One subset of these studies physiologically compared constipated children to controls during the act of bearing down. All of the control children displayed decreased anal sphincter activity when bearing down, compared to 58 percent of the constipated children who could defecate a balloon and 7 percent of constipated children who could not defecate the balloon. The constipated children who could not defecate the balloon were also significantly less likely to respond to laxative treatment. Nonrelaxation

of the anal sphincter was found in 75 percent of encopretic children, as opposed to 13 percent of a control group in a study, which used anal electromyography. This study also reported lower pressures for the encopretic children, at rest and on squeezing; this observation has also been described by other investigators.

An attempt was also made to assess the relative effect of physiological and psychological factors. Specifically, anal-rectal manometric and electromyographic assessments were correlated with behavioral and social competence profiles as related to treatment outcome. Psychological variables were not found to be predictive of outcome, but physiological variables were.

Diagnosis and Clinical Features

The rather objective and concrete nature of the encopretic event makes diagnosis relatively easy and uncomplicated from a phenomenological perspective if the child meets the frequency, duration, and age requirements set forth in the DSM-5. The involuntary versus intentional dichotomy is not a requirement or reason for subclassification according to the DSM-5, but it has important clinical implications. Similarly, the retentive versus nonretentive schema has clinical usefulness. Differentiating between primary and secondary encopresis is important, given that one might expect medical or psychological factors to play a greater role in secondary encopresis.

Henry was an 11-year-old boy with almost-daily encopresis and a number of associated behaviors, including hiding the feces around the house. He resided in a specialized foster care setting, having been removed from his biological parents at 7 years of age because of physical and sexual abuse. Both parents were involved with substance abuse, and his early history was not well documented. However, the parents did indicate that he had never exhibited sustained bowel continence for several months. Henry had also been enuretic until 6 years of age, but this had resolved to an occasional nocturnal episode every 4 to 6 months.

Henry also qualified for a diagnosis of ODD. Although he had experienced physical and sexual abuse, he did not have flashbacks or other symptoms that would meet the criteria for posttraumatic stress disorder (PTSD). Henry also had ADHD and was being effectively treated with 10 mg of methylphenidate (Ritalin) twice a day.

The foster family resided in an urban area that had access to a nationally recognized children's hospital. The ambulatory care department had a specialized behavioral encopresis program that coupled the bowel training method with a psychoeducational component and psychotherapy. The psychiatric consultant to the specialized foster care program doubted that this program would be successful for Henry because he had so much associated psychopathology and the feces were often deposited around the house in a symbolic manner. In addition, the encopresis was not of the retentive-overflow type, and the feces were always well formed. However, because no apparent harm could come from the referral, the consulting child psychiatrist agreed to it. Much to the surprise of the consultant, the several-week outpatient bowel training course coupled with the psychoeducational component and psychotherapy resulted in a complete cessation of the encopresis. On one of her visits to the home, Henry proudly showed his case manager a diagram of the functioning of the digestive system that was part of the psychoeducational program. In retrospect, it appeared that, although there were symbolic aspects to Henry's encopretic behavior, the soiling was ego-dystonic, and he was highly motivated to change the behavior, although this motivation could

not be prospectively detected by the treatment team because of his oppositional defiant manner of responding to adults.

Pathology and Laboratory Examination

The extensive, detailed physiological studies cited previously suggest that physiological factors are important in many children with encopresis, given that they correlate with treatment outcome at 6-month and 1-year follow-up. However, that does not imply that a physiological workup that is this thorough is required for every child who presents clinically. The clinician needs to rule out definite physiological illnesses, such as Hirschsprung disease. Beyond that, clinicians might consider more detailed physiological investigations, such as those used in the experiments described previously, for children who prove refractory to conventional treatment. That type of specialized testing could also be difficult to obtain outside of an academic research center. A simple plain abdominal roentgenogram may aid in the diagnosis and confirmation of retentive encopresis. In one study, 78 percent of children who met the diagnostic criteria for encopresis also met roentgenographic criteria, whereas 22 percent did not.

Children with a condition referred to as *slow transit constipation* may present with intractable encopresis. Although the etiology of this disorder is not fully understood, some of these children appear to have abnormal innervation of the colon. Clinical signs of this disorder include severe constipation within the first year of life and refractory encopresis at an early age. Colonic transit studies are necessary to confirm the diagnosis.

Psychological testing can be useful for those children who exhibit concomitant behavioral problems, or for those who are intentionally encopretic. Finally, clinicians should not overlook the importance of a detailed history obtained from the parents and the child that documents the time course, frequency, and circumstances surrounding the encopresis.

Differential Diagnosis

Encopresis can be a symptom of other processes or can be a syndrome in itself, as described previously. The medical illnesses that need to be ruled out include stenosis of the rectum or anus, endocrine abnormalities, smooth muscle disease, and Hirschsprung's disease.

The child's psychological profile should be considered because children with intellectual deficits or pervasive developmental delay may have episodes of soiling related to those processes. Children with impulse-control disorders or attention-deficit disorder may at times have episodes of soiling related to lack of attention. Encopresis has been reported as one of a number of symptoms that can be seen following sexual abuse. A large retrospective study investigated the hypothesis that the association between encopresis and sexual abuse was of sufficient significance that

encopresis could be classified as an indicator of sexual abuse. The three study groups (4 to 12 years of age) included 466 children with documented sexual abuse, 429 children with externalizing psychiatric disorders, and 641 controls. A history of sexual abuse had been ruled out in the latter two groups. The rates of fecal soiling were similar in both the abuse (10.3 percent) and psychiatric groups (10.5 percent). The soiling rate in the control group was much smaller (2 percent). Thus, the authors concluded that the symptom of fecal soiling could not, in and of itself, be used as a predictive indicator of sexual abuse. A thorough history and psychiatric assessment should make it possible to identify those children, as well as those children who soil on an intentional-oppositional basis. Extreme stress may also provoke encopretic episodes in children who are otherwise functioning well.

Course and Prognosis

As with enuresis, continued maturation provides increasing numbers of spontaneous remissions over time. However, the rate of spontaneous remission is not as clearly defined as that for enuresis. That trend should be factored into the assessment of the efficacy of any long-term intervention. The results from relatively simple behavioral interventions involving educational, behavioral, and physiological components are striking (78 percent), suggesting that the disorder responds to treatment in most cases.

Treatment

The first clinical approach to encopresis is primarily behavioral, with educational and physiological components. That method entails initial educational interventions with the child and family around bowel function. The process is meant to correct misconceptions that the family may have and to dissipate anxiety that may develop around the soiling. The physiological component is instituted next with an initial bowel catharsis, followed by daily doses of laxatives or mineral oil. The behavioral element of the program entails daily timed intervals on the toilet, with success being rewarded. Follow-up studies have reported a 78 percent success rate for this method. The physiological research findings concerning abnormal defecation dynamics in children with encopresis led to interest in biofeedback training as an adjunctive treatment. Although this treatment received positive reports from uncontrolled studies, a review of controlled studies indicated that biofeedback training did not provide additional benefit over conventional treatment. A large, long-term, controlled outcome study that compared conventional treatment with biofeedback training plus conventional treatment indicated that the positive results for both groups were high and quite similar. Specifically, the conventional method yielded an 86 percent improvement rate, as compared to 87

percent for the combined group. This suggests that the combination treatment was no better than the conventional treatment alone. However, it was also found that length of time at follow-up was a powerful factor because it significantly correlated with improvement for the group as a whole at the $p < 0.01$ level. This indicates that the passage of time is an important variable to consider in any investigation of treatment approaches.

A recent systematic meta-analysis of the literature with regard to behavioral and/or cognitive treatments for fecal incontinence concluded that treatment with biofeedback did not improve the results obtained from the traditional treatment.

One element of the aforementioned physiological studies, namely, the ability to defecate a rectal balloon, has been shown to correlate with treatment outcome. A study involving 139 children with constipation and encopresis and 20 controls found that all of the controls were able to defecate the balloon, as compared to 47 percent of the encopretic group.

One year after beginning treatment, 51 percent of the children who could defecate the balloon at baseline were considered to be recovered, but only 34 percent of those who could not defecate the balloon were improved. Although the group comparisons were considered significant, the balloon test alone could not predict response to treatment on an individual basis.

Psychotherapy may be of use for children who have concomitant behavioral problems and those with psychodynamic factors that appear to be especially strong and are contributing to the disorder. This would also be true for those who began soiling after a stressful or traumatic event. Naturally, psychotherapeutic approaches are of primary importance for children who are intentionally soiling or depositing feces in inappropriate places.

Pharmacological treatment for encopresis has not been extensively studied or reported. There are six case reports (encompassing 15 individual patients) that have described imipramine as effective for encopresis. Twelve of the 15 patients were boys. The therapeutic effect had relatively rapid onset (as it does with enuresis), occurring within a few days to 2 weeks, usually at doses of 25 to 75 mg. Although the subtype of encopresis is not clearly delineated in all of the case reports, one would anticipate that, if imipramine were to be helpful, it would be in those with nonretentive encopresis. There is one well-controlled study that substantiated the efficacy of the prokinetic-propulsive agent cisapride (Propulsid). This agent is no longer commercially available in the United States, having been removed from the market owing to concerns about side effects.

The relatively high success rate of the combined educational, physiological, and psychological approach described makes it a reasonable first approach once other diagnoses have been ruled out. Psychotherapeutic and pharmacological approaches could be considered for children who

prove refractory to that form of treatment.

50

Other Disorders of Infancy, Childhood, and Adolescence

▲ 50.1 Reactive Attachment Disorder and Disinhibited Social Engagement Disorder

MARGARET J. HAUCK, PH.D., MARY MARGARET GLEASON, M.D., AND CHARLES H. ZEANAH, M.D.

Reactive attachment disorder (RAD) of infancy and early childhood first appeared in the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III). The DSM-IV-TR delineated two subtypes—an emotionally withdrawn/inhibited pattern and an indiscriminately social/disinhibited pattern. Research, conducted primarily in the past 10 years, has demonstrated that both subtypes emerged only after an infant or very young child had experienced a significantly inadequate caregiving environment and yielded evidence that the subtypes are distinctive, with different presentations, neurobiology, and course of development. Based on a growing body of literature, DSM-5 describes two disorders—reactive attachment disorder (RAD), which is evident when children show the emotionally withdrawn/inhibited pattern of behavior, and the disinhibited social engagement disorder (DSED), which describes children who demonstrate the indiscriminately social/disinhibited pattern. Together, these disorders are often designated "disorders of attachment," though controversy remains about whether DSED should be considered an attachment disorder.

The normal development of the infant and young child's attachment system, first described by John Bowlby, is the trajectory to which behavior indicating disordered attachment is compared (Table 50.1–1). In the context of a grossly inadequate caregiving environment, the child's attachment does not develop normally. Descriptions of the phenotypes associated with attachment disorders emerged in case reports and descriptive studies in the mid-20th century, but systematic research appeared only in the past two decades. Recent studies of disturbances of attachment in institutionalized and maltreated infants and young children

have provided broad support for the phenotypic patterns of the two disorders, begun to characterize the disorders in later childhood and adolescence, and started to uncover neurobiological correlates of each disorder.

DEFINITIONS AND CONTEXT

RAD, as defined in DSM-5, describes young children who show no consistent evidence of selective attachment behaviors towards an adult caregiver. Instead of approaching adults for comfort, support, nurturance, and support, they fail to approach, show distress without seeking or responding to comfort, and display emotion regulation difficulties, especially absence or minimal positive emotional displays and sometimes unexplained outbursts of irritability, fear, or sadness. They rarely engage in socially reciprocal interactions with adults. DSED describes young children who exhibit lack of expected reticence about approaching and engaging with unfamiliar people. They also display physically or verbally intrusive behavior and violation of social boundaries. Both diagnoses (RAD and DSED) also require that the children's clinical problems are preceded by and presumably explained by grossly insufficient care that limits opportunities to form stable attachments, such as that which occurs in social neglect/deprivation, repeated changes of primary caregivers, or rearing in institutions.

Attachment

Attachment, as described by Bowlby in his influential theory, refers to a biobehavioral system which coordinates the balance between the need for seeking safety in proximity to a caregiver or set of caregivers and the tendency to explore and seek novelty and mastery in infancy and early childhood. Bowlby argued that human infants were motivated by an attachment behavior control system to seek proximity to a small number of identified caregivers. He inferred that the reason for seeking proximity in order to attain an internal feeling of security. This internal sense of security is reinforced by repeated experiences of the caregiver's emotional and physical availability in times of need.

Beginning around 7 to 9 months of age, infants are thought to develop internal representations of their relationships with important caregivers. These representations, or internal working models, form the basis for the intense emotional bond between infants and their primary caregivers and behavior in later relationships. The normal developmental progression of attachment, captured in attachment-related behaviors, is summarized in Table 50.1–1. The commonly accepted method for classifying patterns of attachment is the Strange Situation Procedure, which involves an examination of the balance between the child's tendency to explore and

tendency to seek comfort while interacting with an attachment figure and an unfamiliar adult (the "stranger"). Individual differences in the balance between attachment and exploratory behavior and how those are expressed are used to classify the infant's attachment to this caregiver into one of four types of attachment: secure, in which children express distress directly, seek comfort actively, and obtain soothing readily from attachment figures; avoidant, in which children minimize signs of distress and show no comfort seeking efforts despite physiological arousal; resistant, in which children show significant distress to separation but fail to obtain comfort from their attachment figure and cannot be soothed; or disorganized, in which children show some mixture of the secure, avoidant or resistant, or anomalous behaviors that preclude classification as another pattern. These patterns of attachment represent risk or protective factors rather than diagnoses.

Table 50.1–1.
Developmental Features of Attachment in Early Childhood

	Birth–2 Months	2–7 Months	7–12 Months	12–18 Months	Older than 18 Months
Phase of attachment	Limited discrimination	Discrimination with limited preference	Preferred attachment	Secure base	Goal-oriented partnership
Characteristics	Physical attributes of babyishness attract caregivers, but infant expressions of preference are limited to olfactory and auditory realms and require experimental conditions to be demonstrated	Infant differentiates among different interactive partners; infant may seem more comfortable with primary caregiver but is willing to interact readily with other social partners	Clearly expressed preference for a small number of caregiving adults; separation protest and stranger wariness are normative	Use of the attachment figures as a secure base from which to venture out confidently and to explore the world and a safe haven to return to in times of danger; proximity to caregiver promotes feeling of security in infant	Cooperation with caregiver despite frequent conflicts; goal is to balance autonomous functioning with reliance on caregiver for help when needed; verbal relatedness is important, including attention to emotional integration and fluency of discourse

Early Environment

RAD and DSED derive from adversity in the early caregiving environment, involving extremes of social and emotional deprivation (although the child's basic physical survival needs may well have been met). The importance of early experience on infant development was recognized as far back as the 13th century when the Holy Roman Emperor Frederick II reportedly ordered that a group of infants be chosen who would be given simple physical care but with whom no one would be allowed to speak. The experiment was intended to see what language the children would eventually use. According to the Franciscan monk whose chronicle recounted the events, the experiment ended with the premature death of the children, who "could not live without clappings of the hands, and gestures, and gladness of countenance, and blandishments."

The relatively common practice of institutionalizing infants in the United States in the first half of the 13th century unwittingly provided more evidence of the detrimental effects of what has been called "maternal deprivation." Pediatricians had long argued against the practice of institutionalization, particularly because of the high mortality rates related to failure to thrive, but other health care providers did not take notice of the effects of institutionalization on social and emotional development until René Spitz in the 1940s and James and Joyce Robertson in the 1950s conducted more rigorous studies (including control groups). These studies also led Spitz to propose a diagnostic entity that he called *anaclitic depression*, which foreshadowed the DSM-III criteria for RAD. Anaclitic depression, which included mood and social symptoms as well as immunological and growth problems, seemed to follow prolonged separation of infants from their caregivers and was most severe if the infants were old enough to have developed a preference for that caregiver.

A study by Barbara Tizard identified the two sets of behaviors that inform the current DSM-5 diagnoses as well as the *International Statistical Classification of Diseases and Related Health Problems, 10th revision* (ICD-10) classifications of attachment disorders. The children in the study were in institutions, but with a relatively low caregiver-to-child ratio, mixed age groups, and toys and books to enrich the environment. However, the caregivers were explicitly instructed not to form attachments to the children. Although 8 of the 26 children followed in the study managed to form secure attachments despite the constraints of the environment, 8 were found to be emotionally withdrawn and socially unresponsive (similar to children with RAD), and 10 were indiscriminately social with unfamiliar adults (as seen in children with DSED).

The eventual recognition of the clinically detrimental consequences of institutional rearing led to a marked decrease in state-run orphanages in the United States and the United Kingdom. Nevertheless, institutional care remains widely used as an intervention for orphaned, abandoned, and maltreated young children in Asia, Central and South America, and Europe,

particularly Eastern Europe.

Recognition of the scope and consequences of the problem of child maltreatment in the United States did not begin until the latter part of the 20th century, spurred initially by C. Henry Kempe's classic 1962 article on the *battered child syndrome*. Since the early 1960s, there has been a great deal of research on the developmental effects of maltreatment on children. This body of work includes substantial consequences of serious neglect, including serious disturbances of attachment.

COMPARATIVE NOSOLOGY

The criteria for RAD have evolved markedly since the diagnosis was first introduced in the DSM-III. This early version of the disorder description included growth failure and lack of social responsivity as central features. The diagnosis had to start by 8 months of age (the age at which preferred attachment to a restricted set of caregivers is usually just beginning to be evident) and could not result from a diagnosable medical condition. Gross neglect of the infant's physical and emotional needs had to be evident, and, as with later criteria, the presence of autism or mental retardation precluded the diagnosis. Pertinent behaviors cited in the criteria included poor tone, weak cry, excessive sleep, lack of interest in the environment, and weak rooting and grasping when feeding.

Although failure to thrive is a potentially important problem in infant mental health, it is not equivalent to an attachment disorder. The restrictive age range criterion and the requirement for growth failure made the DSM-III definition difficult to apply in most cases. Furthermore, it is rarely possible to rule out autistic disorder or mental retardation in severely malnourished infants younger than 1 year of age. The link between failure to thrive and RAD was dropped in the revised third edition of the DSM (DSM-III-R), and the age of onset was changed to the first 5 years of life. The two subtypes of the disorder—inhibited and disinhibited—were introduced with the DSM-III-R and persisted in the DSM-IV-TR. The criteria continued to include an emphasis on the etiological link between the disorder and evidence of "pathogenic care" at the hands of the young child's primary caregivers and the exclusion of children whose symptoms might be accounted for by cognitive delay or one of the pervasive developmental disorders.

With the publication of the DSM-5, the two subtypes of RAD have been separated into two different diagnoses: RAD and DSED. This separation brings the DSM nosology more in parallel with the ICD-10. The ICD-10 includes the Reactive Attachment Disorder of Childhood (RAD), which is similar to RAD in DSM-5 and Disinhibited Attachment Disorder of Childhood (DAD), which is similar to DSED in DSM-5. Although differences among these approaches can be identified, common features include aberrant social behavior that is cross-contextual, insufficient care

(neglect) as a necessary etiological factor, and the two clinical pictures of RAD (emotionally withdrawn/inhibited behavior) and DSED (indiscriminately social/disinhibited).

Recent research examining the criteria has affirmed that RAD and DSED may be reliably identified in high-risk children. Studies have also demonstrated that these diagnoses are rare in clinical samples, unless children have histories of severe neglect. Children with RAD also seem to be quite responsive to improvements in the caregiving environment. For example, in a randomized, controlled trial of foster care as an alternative to institutional care in Bucharest, Romania, children with diagnoses of RAD responded within months to placement in families with decreases in signs of RAD to levels comparable to never-institutionalized children in the community. However, children with DSED continue to show behaviors consistent with the diagnosis after family placement, typically showing a reduction but not an elimination of their signs of DSED. In addition, studies of children who have been internationally adopted from institutions show that these children do not manifest RAD but do demonstrate persistent signs of DSED. Signs of RAD, which reflects a lack of attachment, diminish when children are placed in families and have the opportunity to form an attachment to foster or adoptive parents. However, signs of DSED persist in a minority of children even after they form attachments to foster or adoptive parents, suggesting that the core deficit in this disorder is not the lack of an attachment relationship.

EPIDEMIOLOGY

Very little data exist on the prevalence of either RAD or DSED. RAD is rarely seen in adequate caregiving environments and always following a history of severe deprivation. DSED appears to be more prevalent, though it is seen in a minority of children even if they live in inadequate caregiving environments. Preliminary estimates are that for children who are known to have been neglected or raised in institutional settings in the first few years of life, prevalence is roughly 10 to 20 percent.

ETIOLOGY

Research has established that the risk of RAD and DSED increases in the context of grossly neglectful care. Less clear is what degree of neglect is necessary for the disorders to occur. Still, even in environments characterized by severe deprivation, most children do not develop signs of RAD or DSED. Thus, more research on vulnerability factors and the critical elements of neglectful care responsible for these disorders is needed.

The longer children live in conditions of deprivation, the more likely they are to develop an attachment disorder. A critical age may exist, as research has found attachment disorders to be very rare in children adopted before 6 months of age, and signs of DSED have not been reported

in children whose deprivation begins only after 2 years of age. Children with lower IQs and stunted growth may also have attachment disorders because deprivation compromises both growth and IQ; it is difficult to know whether these problems precede or are merely additional consequences of deprivation. Studies are also beginning to identify possible genetic polymorphisms as risk factors for attachment disorders.

Preliminary research suggests that children who have experienced serious deprivation may show differences in brain structure and functioning compared to nondeprived children, and many of these children may also show signs of attachment disorders. For example, researchers have found reductions in gray and white matter volumes and reduced electrical activity in higher frequencies and increased electrical activities in lower frequencies in children who have experienced institutional deprivation. Importantly, reduced white matter volume mediated the effect of institutional rearing on EEG alpha power, meaning that reductions in myelinated circuitry likely account for the reduced EEG power. If children were placed with families before 24 months of age, the differences in electrical activity between deprived and nondeprived children were no longer seen at 8 years of age. These findings have been demonstrated in children with histories of institutional deprivation and are not specific to those with attachment disorders, however.

Difficulties with inhibitory control also have been shown in children with indiscriminant social behaviors, implicating ventral frontostriatal circuitry, though findings are not consistent across studies. Children adopted from institutions also showed reduced amygdala discrimination between mothers and strangers on fMRI, and these reductions were moderately associated with the children showing indiscriminant behaviors. Thus, preliminary research is demonstrating that early deprivation has an impact on brain development, although this relationship has been shown primarily in children with the behaviors consistent with a diagnosis of DSED and does need replication.

Although research on what causes caregivers to be neglectful is limited, caregiver characteristics, from severe personality disturbance to psychopathology, appear to be important. Parental mental retardation and poor basic parenting skills, particularly in the context of little social support, may also increase risk of neglect, though neglect sufficiently severe to contribute to RAD and DSED is rare in parents even with these challenges. Infants who are cared for by multiple caregivers in succession, as sometimes happens in the foster care system in the United States, are also at increased risk of attachment disorders. The traumatic experience of prolonged separation from a caregiver in early childhood, as documented by Spitz, the Robertsons, and Bowlby, is enough to cause attachment disturbance. Repeated, prolonged separations typically cause more severe symptoms, and, when these separations are accompanied by neglect,

attachment disorders appear to be even more likely to occur.

DIAGNOSIS AND CLINICAL FEATURES

RAD as described in DSM-5 is characterized not only by an inhibition of positive emotional and social engagement but also by the lack of selective or discriminating attachment behaviors directed at an adult caregiver. At times when young children should be motivated to seek closeness or comfort for distress or protection from danger, children with RAD do not seek or even readily respond to adults' efforts to comfort, reassure or protect them. Instead, they may appear withdrawn and unresponsive or they may show distress with no anticipation of comforting. Emotion regulation abnormalities include reduced or absent expressions of positive emotions and unexplained displays of irritability, sadness, or anxiety. Children have histories of severe neglect, and the signs typically remit within weeks of being placed in adequate caregiving environments. Occasionally, children may be seen with RAD that has persisted following placement into foster care. This is often because de facto neglect continues in the foster home because the child's withdrawn and negative behavior is off putting for adult caregivers who fail to override the children's miscues and avoid interacting with them. The diagnosis also requires the child to have experienced, a pattern of extremes of insufficient care, operationalized as social neglect/deprivation, repeated changes of primary caregivers that limit opportunities to form stable attachments (e.g., frequent changes in foster care), and/or rearing in group settings that severely limit opportunities to form selective attachments (e.g., institutions with high child-to-caregiver ratios).

The disturbed attachment behaviors must be present before the chronological age of 5 years and the child must have a developmental age of at least 9 months. This final criterion ensures that children have reached the point where they are cognitively able to form attachments; children in whom RAD is being considered must have a cognitive age of at least 9 months. Finally, the child must not meet criteria for autism spectrum disorder (ASD).

DSED, as described in DSM-5, is characterized by lack of stranger wariness which ordinarily becomes apparent between 7 and 9 months of age. The disinhibition in DSED is social, leading to behaviors in which a child actively approaches and interacts with unfamiliar adults. Though sometimes referred to as indiscriminate friendliness, the behavior is usually experienced as intrusive and may include overly familiar verbal or physical behavior that goes beyond culturally sanctioned and with age-appropriate social boundaries. Children with DSED often fail to track their caregivers whereabouts, even in unfamiliar settings and may even be willing to go off with an unfamiliar adult without hesitation. As in RAD, the child with DSED must have experienced a level of insufficient care such as

occurs in social neglect or repeated changes in placement. DSED criteria also stipulate that the disordered behaviors are not limited to the kinds of behavioral impulsivity that occurs in attention-deficit/hyperactivity disorder (ADHD), but rather is socially disinhibited behavior. Again, as in RAD, the care is presumed to be responsible for the behavior and the child must have a developmental age of at least 9 months.

Diagnosis of RAD or DSED requires a multisession evaluation, particularly when the caregiver's behavior is not known to be abusive or when the child's history does not include multiple placements. Ascertaining whether the child has less deviant behavior in the presence of the clinician or another trusted adult is important and may take time. This comparison may be especially helpful in distinguishing highly social children, for example, from those with DSED or somewhat behaviorally inhibited children from those with RAD. The child's relationship with the primary caregiver can be adequately assessed with a combination of careful history, and observations of interaction during free play, structured tasks that stress the dyad, and a brief separation and reunion. Videotaping the assessment is a useful way to document social responses, and the introduction of a clinically trained person whom neither partner has met is often informative. Children who meet criteria for this disorder may look quite different, depending on their developmental stage.

An 11-month-old girl recently placed in foster care was referred by state child protective services along with her biological and foster families to assist with long-term case management. Her parents both had chronic and serious substance abuse histories that included violence in their relationship and grossly inadequate care of the 11-month-old and her older siblings. Foster care placement occurred when police were called to the home during an episode of violence, found squalid conditions, including narcotic pain pills strewn on the floor.

The foster mother reported that when the child first arrived, she looked frightened much of the time, cried sporadically and was not soothed by her and was unresponsive to social overtures. It was weeks before she smiled. Her appetite increased over the first few days and she began to stuff herself to the point that the foster mother, with directions from her pediatrician, to limit what she offered the child at meals and snacks. For the initial couple of weeks after placement, the child exhibited little interest in exploring and mostly rocked quietly by herself. This pattern was suggestive of RAD.

The clinicians encouraged the foster mother to interact with the child despite the girl's lack of interest and to respond to distress as if the girl had requested it in order to teach her that she could be comforted when distressed. Gradually, the girl seemed to relax more, to smile—at first fleetingly but then more frequently—and to accept comfort for distress and then gradually to seek comfort for distress. By 1 month following placement, the foster mother reported that the girl seemed to be showing attachment behaviors towards her. She also reported feeling closer to the girl herself, who had first been hard for foster mom to connect to. The stuffing behavior slowly dissipated after this point. The girl became somewhat clingy to her foster mother and was quick to show distress to even minor changes in routine, but she began to seem much affectively brighter and to have much better emotion regulation.

A 45-month-old boy was referred by his adoptive parents because of hyperactivity and disruptive behavior at school. He had been placed with the family at 30 months and adopted at 36 months of age, after living most of his life in a Romanian orphanage, in which he received care from a rotating shift of caregivers. Although he had been below the 5th percentile for

height and weight on arrival, he quickly approached the 10th percentile in his new home. However, both of his adoptive parents were frustrated by their inability to "reach him." They had initially worried about a hearing disturbance, although testing and his capacity to engage many adults and children verbally suggested otherwise. He approached and engaged socially with complete strangers and more than once had followed strangers willingly. Teachers liked him, although they found him to be attention seeking and sometimes disruptive. At times, they thought he was appealing and even charming, but at other times they felt that his feelings were shallow. He was frequently injured because of seemingly reckless behavior, although he had an extremely high tolerance for pain. He was diagnosed with disinhibited social engagement disorder. Intensive intervention focused on decreasing his self-endangering behavior, enhancing his ability to read emotional expressions, and describe social situations and rewarding him for socially appropriate reticence. Target behaviors improved over several months, though tendencies to engage with unfamiliar adults persisted at a somewhat reduced and more manageable level.

DIFFERENTIAL DIAGNOSIS

Since RAD and DSED differ significantly in their clinical presentations, each have different diagnoses that need to be examined when differential diagnoses are made. For RAD: ASD, and depressive disorders; for DSED: ADHD. Also, developmental delay and intellectual disability should be distinguished from both diagnoses.

Depressive Disorders

Children with RAD and with depression both show reduced or absent positive affect and social withdrawal. In a longitudinal study of institutionalized or previously institutionalized young children, there was a moderate-to-high association between RAD and signs of depression in young children, but the majority of children who were diagnosed with a depressive disorder did not meet criteria for RAD. In general, children with depression ought to turn to caregivers for comfort and show behaviors that are indicative of an attachment. The neurovegetative signs of depression and the excessive guilt associated with depression are not characteristic of RAD. Only if these children had a history of social neglect and did not seek comfort would the diagnosis of RAD be warranted.

Autism Spectrum Disorder

Children with both ASD and RAD show impaired social behaviors, especially social withdrawal and minimal reciprocity. However, children with ASD typically also show atypical language development, while language skills in RAD may be delayed but are not stereotyped or otherwise deviant. Additionally, children with ASD show restricted and repetitive behaviors which are not found in children with RAD. Finally, children with ASD do show attachment behaviors with a limited number of caregivers some of the time and very rarely have the history of social neglect or maltreatment that is seen in children with RAD. The differential diagnosis of RAD and ASD may be challenging because quasi-autistic behaviors have

been described in formerly institutionalized, adopted children. However, the course of quasi-autism seems to be different from ASD in that at least partial remission may occur after several years of familial placement.

Attention-Deficit/Hyperactivity Disorder

Young children who are hyperactive and impulsive may also appear socially disinhibited. Furthermore, deprivation is known to increase the risk of both inattention or hyperactivity and DSED. The social disinhibition of DSED, however, is not necessarily accompanied by inattention or hyperactivity. However, children with DSED can also meet criteria for ADHD, requiring careful assessment of the potential differential diagnosis as well as comorbid conditions.

Intellectual Disability (Intellectual Developmental Disorder)

The adverse caregiving environment necessary for the manifestation of RAD or DSED also may include environmental deprivation that can lead to developmental delays. However, in longitudinal studies of children from institutions, RAD and DSED were only moderately associated with cognitive delays. In terms of differential diagnosis, children with intellectual disability typically show social and emotional skill levels that are relatively consistent with their cognitive levels. These children are also capable of forming stable attachments, as long as their developmental ages are greater than 9 months, the age at which attachments to caregivers should start to form.

COURSE AND PROGNOSIS

There is limited research addressing the natural course of RAD. Among children in institutions, the diagnosis appears relatively stable; young children who met criteria for RAD at one point in time continued to show the behaviors at other times. However, children who are placed into families typically do not show signs of RAD on follow-up (i.e., 1 year later). This would suggest a relatively good prognosis for amelioration of signs of RAD once they are in a stable caregiving environment, though whether they are at increased risk of insecure or atypical attachments, or other psychiatric disorders seems less clear.

More longitudinal research following children who meet the criteria for DSED is available. These studies suggest that the diagnosis is moderately stable from year to year in young children. Studies that have followed children into later childhood find that those with over-friendly and attention seeking behaviors at the age of 4 tend to continue to show these behaviors at the age of 8. Moreover, at the age of 16, these children demonstrated superficial and conflicted relationships with peers. Thus, the behaviors consistent with a diagnosis of DSED appear somewhat resistant

to change once established.

TREATMENT

The first consideration in the assessment of children exposed to grossly inadequate care is the child's safety. Child maltreatment is associated with significant morbidity, and mortality is not uncommon, particularly in children younger than 48 months of age. Early involvement of child protective services is often warranted, and assessment of parental fitness may be a necessary part of the evaluation. In some cases, placement of the child may be necessary, and reunification of parent and child may not be warranted. Children in this situation often have not had appropriate medical care, and medical referral is almost always indicated. Unfortunately, the foster care system and the family court system sometimes lead to multiple placements in the first years of life and thus increase the likelihood of an attachment disorder. The clinician may play a crucial role in staying involved with the child who is placed in foster care, providing expert testimony in court and individual or family treatment.

Once the child is in a safe placement, full attention can be paid to psychosocial intervention, which must often be tailored to the individual. For children who exhibit RAD, providing a primary attachment figure is the goal. Caregivers who foster secure attachments in infants and young children are those who are sensitively responsive, value the child as an individual, and place the needs of the child ahead of their own. These also are the characteristics needed for assisting the child with RAD. For children who are establishing attachments in adoptive or foster families and who exhibit the high levels of indiscriminate behavior seen in DSED, the clinical consensus is to advise parents to limit their unnecessary contact with adults outside the family for several months if possible. The rationale is that children may need time to consolidate attachment relationships within their family before they experience other relationships. Although this approach has face validity, it has not been evaluated formally.

Additional interventions should be those that reduce child or adult (caregiver) barriers to attachment. Child barriers include various miscues about their needs, including aggressive and oppositional behavior, emotional dysregulation, and withdrawn behavior. Adult barriers include distractions from the newly developing relationship, such as here-and-now crises, problematic relationship histories—including unresolved losses and trauma—and lack of psychological commitment to the child. Some attachment-specific treatments are available, such as Circle of Security, which weaves together psychoeducation with psychotherapy, or Attachment and Biobehavioral Catch-Up that is also manualized and more prescriptive about which behaviors are coached. Both treatments rely heavily on review of videotaped parent–child interaction. Other interventions that involve some form of caregiver–child dyadic therapy are

attachment informed rather than attachment derived, such as child–parent psychotherapy. These approaches typically weave together developmental training and guidance with an active attempt to address pressing instrumental issues (e.g., poor housing and inadequate medical care). The complexity of these approaches reflects the complexity of the clinical problem. Long-term interventions are necessary in these cases, and psychiatric treatment should be bolstered by early intervention programs and ongoing medical care for the child.

In general, research following children with RAD suggests that the symptoms of the disorder disappear with placement in a family that can provide a positive caregiving environment. This research additionally does find that these children can continue to show insecure or disorganized attachments, indicating that treatment to improve attachments with the foster or adoptive caregivers is important. However, research finds that some children with a diagnosis of DSED continue to show indiscriminant behavior, even after being placed in enhanced caregiving environments. Children with DSED may even form secure attachments, indicating that more than enhanced caregiving may be necessary to significantly reduce the signs of DSED. It has been suggested that intervention to target social cognitive abnormalities that may underlie the indiscriminate social behaviors shown in DSED would be a possible way to improve these behaviors, but research is needed in this area.

▲ 50.2 Stereotypic Movement Disorders in Children

ROBERT LLOYD DOYLE, M.D., D.D.S.

INTRODUCTION

A stereotypy is defined as a frequent, almost mechanical repetition of the same posture, movement, or form of speech (as in schizophrenia). This rather broad definition encompasses a range of motor phenomena from statuesque catalepsy as occurs in schizophrenia to dizzying degrees of spinning seen in autism. A stereotypy can be as benign as eye blinking or can be quite dangerous, as in the case of intense head banging resulting in traumatic brain injury. Although the term "stereotypy" may be applied to many types of behaviors, including normal repetitive behaviors of infancy, abnormal repetitive behaviors in autistic individuals, dyskinesias caused by psychotropic medications, and symbolic gestures associated with schizophrenia, to name a few, this section focuses on stereotypic movement disorders of childhood as described in the text revision of the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) and the tenth edition of the *International Classification of Diseases and Related Health Problems* (ICD-10).

HISTORY

The first mention of purposeless, repetitive behaviors in the clinical literature dates back 300 years to Nehemiah Grew, who wrote, "We see also Mad people . . . run upon some one action . . . without variation." Possibly the first description of a dopamine-driven stereotypy should be attributed

to Samuel Gee, who conducted an experiment in which he injected a large dose of apomorphine into a dog. A few minutes after the animal vomited, it began to pace around the room in a "curiously persistent methodical manner." In the early 1900s, Emil Kraepelin linked stereotypic behaviors to dementia praecox. Of note, Kraepelin's careful observations of stereotypic behaviors were made before the development of antipsychotic medications, and so the behaviors were likely related to a pathological brain state rather than to medication-induced dyskinesia. Several seminal papers published in the 1940s set the stage for the following 50 years of research on the subject.

Landmark research on stereotypic behaviors began with Lauretta Bender and Paul Schilder in the early 1940s. Their contribution differentiated impulsions from obsessions and compulsions based on the premise that impulsions were associated with positive affect, whereas obsessions were notably negative. They also speculated that impulsions could have connections to the primitive motor stereotypic behaviors of infancy, and that impulsions might become obsessions and compulsions in adolescence. In 1949, Reginald S. Lourie theorized that the feedback from infantile rhythmic behaviors fostered normal motor development. For instance, infants will assume the four-point crawling position on hands and knees, then rock front to back as if rehearsing the more complex coordinated movement in which only the arm and leg on one side of the body moves forward to provide locomotion. This simple repetitive rocking in place could serve as the basis for a repertoire of more-coordinated movements needed to crawl. Thus, according to this theory, repetitive behaviors occur in a normally developing child, but these recede as the child masters more-complex, functional behaviors. These behaviors become stereotyped if they persist beyond the developmental purpose they served, as seen in persons who are blind or have autism or mental retardation.

ETIOLOGY

Several theories have been proposed to explain the emergence and maintenance of stereotypic behaviors. As just described, stereotypic movements may be the precursor to mastery of more-sophisticated motor tasks. This path toward more complex motor behaviors may veer in a pathological direction based on the interplay among abnormal development, behavioral reinforcement, and psychological conflict. In Down syndrome, for instance, stereotypic behaviors are similar to those seen in children without a diagnosis of mental retardation but differ in that in Down syndrome they appear at a later-than-expected chronological age and do not disappear. Therefore, developmental factors could contribute to the manifestation of stereotypic behaviors.

Behavioral factors might maintain the stereotypic behavior through

positive or negative reinforcement. Careful behavioral analysis can identify social reinforcers and then aim to eliminate them. From a psychodynamic standpoint, stereotypies are considered instinctual, autoerotic, and self-soothing or gratifying behaviors. The psychodynamic factor implies that a stereotypic behavior, such as nail biting, might be a reaction to intense feelings about one or more conflicts. Biologically based theories have replaced most psychodynamic formulations explaining stereotypic behaviors.

Early observations in animals and humans indicated that environmental factors might modify the expression of stereotypic behaviors. For example, R. J. Gallagher and Gershon Berkson showed that even short periods of normal social interaction reduced the expression of stereotypic behaviors in institutionalized infants with profound retardation. Most studies show that substituting alternative activities for stereotypic behaviors effectively reduces their expression.

Even though enriched environments usually diminish stereotypic behaviors, they do not eliminate them. The predictable persistence of stereotyped behaviors in childhood autism and other conditions, despite environmental enhancement, indicates that organic factors might play a role. One organic theory proposes that endogenous opioid compounds are released in persons with autism as they engage in stereotypic behaviors. The pleasurable effect of the endorphin release could reinforce the repetitive maladaptive behaviors. Although studies using the opioid antagonists naloxone (Narcan) and naltrexone (Trexan) resulted in modest improvements in stereotypic behaviors, these have not been a definitive cure for stereotypic behaviors in individuals with autism. Therefore, an organic-based explanation is not entirely satisfactory either. Perhaps an interplay between experiential effects on the brain and physiological processes within the brain might best account for stereotypic behaviors. Bender and Schilder theorized that a common connection must tie all sorts of stereotypy together; however, studies fail to support the existence of an encompassing stereotypic factor.

Nevertheless, research has pointed to several factors that might act independently or in concert to bring about the expression of a stereotypic movement. These include genetic factors, as seen in nail biting and Lesch–Nyhan syndrome, and neurobiological factors, as evidenced by the many compounds that can precipitate stereotypic or self-injurious behaviors (SIBs). For example, dopamine D_1 supersensitivity due to chronically low levels of dopamine has been described in animal models of SIBs. Of interest, postmortem tissue from patients with Lesch–Nyhan syndrome appears to be dopamine deficient as well. Furthermore, dopamine antagonists have successfully treated nonsyndromal SIBs and at least one case of Lesch–Nyhan syndrome. Dopamine has also been implicated in the emergence or exacerbation of certain repetitive behaviors related to

stimulant use. Psychostimulants work by blocking the reuptake of dopamine, thereby causing a relative increase in the availability of dopamine in the synaptic cleft. Stimulant-induced repetitive behaviors include bruxism, skin picking, lip biting, compulsions, nail biting, perseveration, tics, and various stereotypies. Other neurotransmitters, such as serotonin, opioids, and γ-aminobutyric acid, may be involved as well.

EPIDEMIOLOGY

Many stereotypic behaviors emerge in early childhood and are considered part of normal development. These rhythmic, repetitive behaviors appear and progress in a cephalocaudal direction and can be correlated with chronological age. An estimated 80 percent of normal children display rhythmic activities that disappear by age 4 years. Although determining the prevalence rate in the general population is difficult, studies estimate that some 3 to 15 percent of children without disabilities engage in head banging. About 20 percent of children exhibit repetitive body rocking. If these behaviors continue beyond the normal developmental age range for such behaviors, they might evolve into a stereotypic movement disorder. Consider thumb sucking. Endearing in infants, thumb sucking easily becomes a reason for teasing in the school-age child. In an extreme case, an adolescent boy with profoundly severe mentally retardation sucked his thumb until a large portion of soft tissue eroded away and exposed the underlying bone. Finger and thumb sucking occurs more often in girls than boys, and more in whites than in African Americans.

Bruxism—the habitual grinding of teeth—occurs in approximately 56 percent of normally developing infants. Even if chronic bruxism wears down enamel, this rarely results in long-term problems in young children because deciduous teeth will be replaced by the permanent dentition. Bruxism in adolescents and adults can cause major dental pathology ranging from periodontal disease to temporomandibular joint dysfunction.

Sean was a burly but affable dental student with severe bruxism. He had no personal or family history of psychiatric illness. He was the eldest child of a large, upper–socioeconomic status family. Sean had always maintained a respectable grade point average, and he continued to do so in dental school. By age 23 years, Sean had worn the cusps of his posterior teeth completely away due to his chronic bruxism, which began in childhood. Although bruxism is often caused by malocclusion between maxillary and mandibular dentitions, this could not explain his persistent problem. Sean's posterior teeth had been worn down to flat occlusal surfaces without any cusps to cause interferences in his bite. His case was so impressive that his professors requested permission to take photographs and make models of his teeth to teach future generations of dental students. Ironically, his bruxism worsened as the stress of dental school caused him to chronically clench his teeth together. His dental health was compromised by broad areas of exposed dentin in places once covered by enamel. Sean was at risk of losing his molar teeth, as well as for developing painful temporomandibular joint dysfunction.

Treatment took a multimodal approach. Sean was advised to monitor himself for clenching and grinding during the day. Whenever he became aware of these behaviors, he was instructed to simply separate his upper and lower teeth. To prevent neuromuscular programming, his dentist recommended that he stop chewing gum. These interventions helped during the day;

however, nocturnal bruxing continued. Sean was not aware of grinding his teeth in his sleep, but he did notice tenderness around his jaw in the morning. On exam his dentist noted crepitus —the sound of bone rubbing against bone—with mandibular movement. Because crepitus is a sentinel sign of temporomandibular joint dysfunction, the dentist fitted Sean with a custom night guard that served two purposes: It prevented further eroding of enamel and it curtailed the chronic temporomandibular joint inflammation. Sean also took ibuprofen to relieve inflammation and pain. His dentist offered a prescription for clonazepam (Klonopin) to help him deal with the pressures of his professional education. Sean, however, did not want to become addicted to a benzodiazepine, so he chose to try other measures first. Buspirone (BuSpar) was also offered as an option because of its reduced abuse potential. Fortunately, his dental condition stabilized fairly quickly, and he set his sights on having his lost tooth structure restored with ceramic crowns.

Nail biting occurs quite commonly in childhood and frequently continues into adulthood. Occasionally, nail biting progresses to the point of causing dermatological or even dental problems. It does not seem to be associated with the child's age, level of intelligence, or socioeconomic status, but nail biting seems to have a familial basis. Toenail biting, however, does appear to be much more prevalent in girls. An estimated 50 percent of children exhibit nail biting. It can be seen as early as 4 years of age, with peak prevalence between age 10 and 18 years. According to one study, 4.5 percent of adults continue to bite their nails. Adults with onychophagia may not have comorbid psychiatric illness, and children with nail biting do not appear to be more anxious than peers who do not bite their nails. In most adult cases, nail biting seems to cause distress rather than result from stress.

As mentioned earlier, genetics seems to play a factor in the expression of some stereotypic behaviors. In twin studies, children born to parents who were nail biters were nearly three times as likely to be nail biters as control subjects. The concordance rate for monozygotic twins was 66 percent versus 34 percent in dizygotic twins. Onychophagia is the most severe type of nail biting. Monozygotic twins with onychophagia had a 75 percent concordance rate, whereas dizygotic twins only had an 18 percent concordance.

Of interest, stereotyped behaviors often occur in blind children. Elisa Fazzi and others studied a group of congenitally blind children. In their group of 11 boys and 15 girls with and without neurodevelopmental disabilities, 73 percent showed stereotypic behaviors. The most frequently encountered stereotypic behaviors were body rocking (30.7 percent), repetitive handling of objects (30.7 percent), and eye pressing along with eye poking (30.7 percent). These researchers also found that the stereotypic behaviors could be decreased by encouraging appropriate adaptive behaviors and increased by restricting the environment, reducing sensory stimulation, and limiting mobility.

Stereotypic behaviors are more common among children with a history of parental neglect, but they may be present in children who do not have emotional problems. An estimated 20 percent of individuals with severe

mental retardation exhibit stereotypic behaviors. Alfred A. Baumeister and Rex L. Forehand found that two-thirds of a population institutionalized with mental retardation exhibited stereotyped behaviors, and J. R. Dura and colleagues later reported that 34 percent of nonambulatory individuals with profound retardation who were institutionalized exhibited at least one stereotypic behavior. Despite the need for longitudinal studies, evidence from cross-sectional studies suggests that developmental age and experiential history, rather than chronological age, are the relevant mediating variables for stereotypic movements. Stereotypic movements frequently peak in adolescence and then diminish thereafter.

The prevalence of SIBs varies from between 2 and 3 percent for children and adolescents in the community to about 10 to 15 percent for adults with severe or profound retardation living in residential facilities. In individuals with severely retardation living in institutions, stereotyped movements increase with chronological age; however, the opposite is true of children without disabilities. In individuals with mental retardation, the most common stereotypic movements are body rocking, head rolling, and repetitive hand movements, and self-hitting, head banging, and self-biting are among the most common forms of SIBs. The prevalence of head banging ranges between 3 and 15 percent in normally developing children. Approximately three times as many boys as girls exhibit the behavior. Head banging usually emerges between 5 and 11 months of age, but only 5 percent of these cases persist beyond 3 years of age.

Per the DSM-5, stereotypic movements may occur with or without SIBs. A study by Gal and colleagues monitored SIB and stereotypy in typically developing children as well as those who were intellectually impaired, visually impaired, hearing-impaired, or autistic. In this sample of 90 subjects with at least one SIB, only three did not exhibit a co-occurring stereotypy. Interestingly, the rank order of prevalence of SIB and stereotypy was same across all five groups.

Given that the strongest predictor for the presence and severity of SIB was other repetitive behavior, an earlier model proposed by Guess and Carr in which SIB was thought to evolve from stereotyped movements makes some sense. SIBs, such as head banging, and stereotypy occur in typically developing children, but the SIB emerges later in development than stereotypy. In individuals with intellectual disabilities, SIB and repetitive behaviors appear temporally related; however, stereotypic behaviors still precede SIB.

Of note, Cornelia de Lange syndrome (mutations including the NIPBL gene in region 5p13, SMC1L1 in the Xp11.2 region, SMC3 gene in region 10q25), Fragile X syndrome (mutation at Xq27.3), Smith–Magenis (3.7 Mb interstitial deletion in chromosome 17p11.2), Cri-du-Chat syndrome (deletion in chromosome 5p15), and Rett syndrome (mutation in the methyl CpG–binding protein 2) are genetic disorders that present with

various forms of stereotypic movements and SIB. Since these genetic defects are quite diverse, yet each gives rise to stereotypies with and without self-injury in the same individual, finding treatments for stereotypic behaviors remains a challenge.

Nevertheless, theories for stereotypic movements abound, and research continues to reveal new information regarding the etiology of these behaviors. An array of new research techniques will allow genetic information to be linked with neuroimaging results and facilitate understanding of the phenotypic expression of stereotypic behaviors.

NOSOLOGY

In many cases, the origin of stereotypic movements seems contextual to certain psychiatric illnesses or medical conditions in which they occur. The evolution of the DSM has tried to reflect such insights in its various iterations. Recent versions of the DSM had reserved the diagnosis of stereotypic movement disorder for cases in which the stereotypic behavior is not a core symptom of another psychiatric disorder or the expected manifestation of a medical condition. Therefore, the repetitive facial movements due to either prolonged neuroleptic use or rapid discontinuation of this class of medication would be described as stereotypic movements, but these would not have met DSM-IV-TR criteria for stereotypic movement disorder. Although this continues to be the case in DSM-5, the current criteria requires the clinician to specify whether stereotypic movement is associated with a known medical or genetic condition, neurodevelopmental disorder, or environmental factor. For instance, a person with Down syndrome and stereotypic movements would be coded as (307.3) stereotypic movement disorder associated with Down syndrome. In the case of autism spectrum disorder, a comorbid diagnosis of stereotypic movement disorder should be made whenever the stereotypic behaviors cause injury or appear sufficiently severe to become a focus of treatment.

Also, the DSM-5 has placed more emphasis on culture-related issues. Although stereotypic movements, with or without self-injury, manifest in all races and cultures, the attitudes of a particular culture may delay diagnosis. Clinicians need to be aware of cultural context and remain sensitive as they explain the diagnosis to patients and their families who come from a different country or culture. This will help patients accept and maintain appropriate treatment for the condition.

At first, the DSM criteria were somewhat broad. The DSM-III provided criteria for a diagnosis of atypical stereotypic movement disorder for conditions such as rocking, head banging, and repetitive hand movements characterized by quick, rhythmic hand rotations or tentative voluntary movements that usually involved the arms or fingers. The DSM-III stipulated that such movements differed from tics in that they were

voluntary but not spasmodic or distressing. In the DSM-III, atypical stereotypic behaviors were considered often to occur in patients with extreme psychosocial deprivation, mental retardation, and pervasive developmental disorders; however, another mental disorder did not have to be present.

In the revised version of the DSM-III (DSM-III-R), atypical stereotypic movement disorder was renamed stereotypy/habit disorder. The criteria for stereotypy/habit disorder became broader, so that intentional, repetitive, nonfunctional behaviors such as nail biting, nose picking, skin picking, and object mouthing were included. The DSM-III-R also specified a severity criterion, which required the behavior to cause injury or markedly interfere with normal activities to be considered a clinically significant "disorder." The severity criterion allowed clinicians to determine whether the stereotypic movement was part of normal development, as is often seen with transient nose picking, or a more pathological picture, in which chronic nose picking causes significant tissue trauma or social stigmatization. A stereotypy or habit described by DSM-III-R criteria could include more intense forms of normal motor patterns seen in childhood, or they might be associated with some type of psychiatric or organic pathology. An additional criterion, however, excluded the diagnosis if the patient met criteria for pervasive developmental disorder or tic disorder. This exclusion criterion recognized and eliminated the redundancy of making the diagnosis of stereotypy/habit disorder in these disorders, which have repetitive behaviors as core symptoms.

Another name change occurred with the publication of the DSM-IV. In an effort to be compatible with the ICD-10, the DSM-IV renamed the disorder stereotypic movement disorder. Because the intentional nature of a stereotypic movement might be impossible to determine in certain cases —for example, individuals with severe mental retardation with limited ability to communicate, the clinician is no longer obligated to prove that the movement was intentional. The DSM-IV also drew boundaries between stereotypic movement disorders and several other disorders, including pervasive developmental disorder, tic disorder, obsessive-compulsive disorder (OCD), trichotillomania, and mental retardation. As in the DSM-III-R, the diagnosis is not made if the stereotypic behavior is attributable to pervasive developmental disorder or tic disorder. Given the similarity between tics and compulsions, the DSM-IV excluded stereotypic behaviors that were compulsions related to OCD. The DSM-IV also stipulated that the stereotypic behavior could not be due to the physiological effects of a substance or a general medical condition. A diagnosis of stereotypic movement disorder would not be made for repetitive hair pulling if DSM-IV criteria for trichotillomania were met. In addition, a diagnosis of stereotypic movement disorder with SIB could be made in persons with mental retardation if the SIB was significant enough to become a focus of

therapy. Subsequent versions of the DSM—the DSM-IV-R and the DSM-IV-TR—used those criteria established by the DSM-IV.

In general, the DSM-IV-TR and DSM-5 as well as ICD-10 criteria for stereotypic movement disorder describe the diverse and unrelated stereotyped movements that are not part of any other recognized neurological or psychiatric condition. According to the DSM-5, a stereotypic movement disorder is a repetitive, seemingly driven, and nonfunctional motor behavior. It lists hand shaking or waving, body rocking, head banging, mouthing of objects, self-biting, picking at skin or body orifices, and hitting one's body as examples. The DSM-5 definitions excludes behaviors with a clear purpose or adaptive function, but, as acknowledged in the DSM-IV-TR, the driving force behind a stereotyped movement may be difficult to determine in cases in which the person has limited ability to communicate internal states. What is more, a stereotypic behavior may provide a signal that an undiagnosed neurodevelopmental disorder exists, especially in children younger than 3 years of age.

The DSM-5 specifies that for a repetitive motor behavior to be considered a stereotypic movement disorder, it must interfere with social, academic, or other activities and may result in self-injury. In severe cases, the behavior can cause death, but even less severe cases might result in disabling or disfiguring impairments.

Consider the case of Ruth, a middle-aged woman, was admitted to the inpatient unit at a university-based teaching hospital due to unrelenting head scratching. Her outpatient psychiatrist had tried the full array of pharmacological interventions, including combinations of anxiolytic, antidepressant, and antipsychotic medications, but the stereotypic scratching progressed to the point that she required surgical intervention. Ruth had scratched through her scalp and penetrated the skull, exposing the dura mater.

In Ruth's case, a complete DSM-5 diagnosis would be Stereotypic Movement Disorder with Self-Injurious Behavior, Severe. Per the DSM-5, the diagnosis is specified as with or without SIB. Note, however, that the disorder should be specified as "with self-injurious behaviors," if injury would occur in cases that protective measures were not present to prevent injury. Ruth obviously displayed severe symptoms, given that continuous monitoring and protective measures were required to prevent serious injury. Moderate symptoms require protective measures and behavioral modification; whereas, mild symptoms can be easily suppressed with sensory stimulus or distraction. Clinicians should also specify whether the stereotypic movement is associated with a known medical or genetic condition, neurodevelopmental disorder, or environmental factor. An additional code identifying the associated medical/genetic condition or neurodevelopmental disorder aides aids in billing and communicating with third party payers.

The ICD-10 diagnostic criteria for Stereotypic Movement Disorders

appear more succinct. Per the ICD-10, the stereotyped movements must either cause physical injury or markedly interfere with normal activities. The duration of symptoms lasts at least 1 month. In contrast to DSM-5, no other mental or behavioral disorder can be present, except for mental retardation.

DIFFERENTIAL DIAGNOSIS

The outward appearance of a complex tic or a compulsion may closely resemble stereotypic movements, and this may lead to diagnostic difficulties. James W. Bodfish, T. W. Crawford, and colleagues found high rates of stereotyped behavior in adults with comorbid mental retardation and compulsion disorder. Compared with a noncompulsive matched control group, their sample showed an increased prevalence of stereotypy (32 percent), an increased prevalence of self-injury (40 percent), and an increased prevalence of stereotypy plus self-injury (37 percent) in those with compulsive disorder. A review by J. L. Rappoport reported that 20 percent of patients with OCD also exhibit motor tics, which complicates the diagnosis further. Nevertheless, some simple caveats can help to sort out stereotypic movements from other repetitive movements.

Generally speaking, a stereotypic movement is a rhythmic, repetitive motor behavior. It usually is simpler than other forms of perseverative behaviors. Although a stereotypic behavior appears to be purposeless, it can also serve to alleviate anxiety or another aversive state. Tics ordinarily have an involuntary quality even though tics may be suppressed for limited periods of time and they are not rhythmic. Compulsions appear more complex and ritualized. A stereotypic movement differs from a complex tic and a repeating compulsion in that it is not performed as a preventative measure, nor is it motivated by a sense of incompletion. In addition, complex tics and compulsive behaviors typically are not rhythmic.

With regard to autism, a recent study by Fiona Zandt and colleagues suggested that compulsions coexist with stereotypic behaviors in children with autism spectrum disorder. They found that children with OCD had more obsessions and compulsions than children with autism spectrum disorder; however, both the OCD group and the group with autistic stereotyped behaviors exhibited more obsessions and compulsions than a comparison group with a typical developmental trajectory. Similarly, J. M. Ringman and J. Jankovic reported on a series of 12 patients with autism spectrum disorders and stereotypic movements. These patients were referred to a specialized movement disorder clinic for the evaluation of tics. Tics were clearly present in seven of the patients, and six of these patients met criteria for both Asperger syndrome and Tourette syndrome. Even though the diagnosis of stereotypic movement disorder excludes repetitive movements that may be core symptoms of other DSM-5 disorders, the literature suggests and this author observes that stereotypic behaviors in

autistic spectrum disorders may be comorbid with OCD or tic disorder.

The DSM-IV-TR specifies that the stereotypic behavior not be due to the direct physiological effects of a substance or a general medical condition. This criterion would exclude tardive dyskinesias as in chronic neuroleptic exposure or skin picking secondary to stimulant use. Although tremors associated with Parkinson syndrome and Parkinson disease are abnormal and stereotypic, neither would fit the current criteria for stereotypic movement disorder because they are due to the physiological effects of neuroleptic medication in Parkinson syndrome and a medical condition in the case of Parkinson disease.

Mental retardation is a common feature of a number of genetic disorders. If the stereotypic or SIB occurs in the context of intellectual disability, the behavior no longer must be severe enough to become a focus of the treatment to meet diagnostic criteria for DSM-5. Repetitive motor behaviors noted in a person with intellectual disabilities would be correctly recorded per the DSM-5 as stereotypic movement disorder associated with intellectual developmental disability. In Lesch–Nyhan syndrome, the degree of mental retardation does not seem to predict the magnitude of self-mutilation. Some patients with mild mental retardation may display extreme forms of self-injury. Notably, stereotypic movements occur in approximately two-thirds of individuals with intellectual disabilities living in residential facilities.

In addition, the DSM-5 criteria no longer require that the repetitive movement must be present for 4 weeks or more. Typically, stereotypic movements peak in adolescence, but they have no typical age of onset. Stereotypic movements in persons with severe or profound mental retardation may last for years; however, an abrupt onset of stereotypic behaviors may signal the presence of an underlying acute medical condition in nonverbal individuals with severe mental retardation. Clinicians should be mindful of clues that such individuals may be experiencing pain, distress, anxiety, or mood shifts and then promptly treat any identified problems. Stressful events also may precipitate stereotypic behaviors. However, stereotypic movements may emerge and become a focus of treatment in individuals with mental retardation who are institutionalized in nonstimulating environments.

ICD-10

The ICD-10 defines stereotypic movements in childhood in a fashion similar to the DSM-5, since one of the goals of DSM-5 aimed at providing compatibility between the two diagnostic systems. As in the DSM, physical injury or marked impairment in normal activities must be present for the diagnosis. This criterion attempts to sort out stereotypic movement disorder from stereotypic movements that are benign or are typical of normal development. The duration criterion provides another dimension to

the impairment and ensures that the stereotypic movement is more than a passing novelty. In addition, history of another psychiatric or behavioral disorder should not be present and account for the stereotypic movement.

DIAGNOSIS

No clinical tests are available to make the diagnosis of stereotypic movement disorder. Nevertheless, the history and physical exam may be revealing. Dental and physical exams may provide evidence of tissue trauma that would raise suspicions for stereotypic behaviors, especially the self-injurious type. Anemia may be a sign of self-induced rectal bleeding. The delicate architecture of the eye is particularly vulnerable to repetitive trauma from behaviors such as head banging and eye poking. Sometimes a subtle physical sign clues the clinician to stereotypic behaviors and movements that go unobserved by others.

Rating scales assist in diagnosing and tracking response to treatment in many psychiatric conditions; however, rating scales for stereotypic behaviors have not been so helpful. A number of rating scales have been developed, but none provides optimal psychometric properties across the spectrum of stereotypic behaviors. Even commonly used instruments for tracking drug-induced stereotypic behaviors, such as the Angus Involuntary Movement Scale (AIMS) and the Barnes Scale, focus on involuntary movements rather than the wide range seen with stereotypic movements. Berkson and Davenport developed a stereotypy checklist to track stereotyped behaviors mainly due to social deprivation. Unfortunately, experiments intended to test the reliability and validity of the Berkson and Davenport Stereotypy Checklist have shown variable results.

Recently, video and computer-assisted technologies have been used to study tardive dyskinesia. These technologies may elucidate the characteristics of other stereotypic behaviors such as that developed for use in monitoring attention-deficit/hyperactivity disorder (ADHD). These motion-detecting devices connected to sophisticated computer programs can give detailed descriptions of the randomness, as well as the range of movements on a second-by-second basis. This type of technology might prove valuable in research or for clinical applications related to stereotypic behaviors.

Eventually, research may lead to feasible diagnostic tests using genetic and/or neuroimaging techniques to assist in the diagnosis and treatment of stereotypic behaviors. In the meantime, a comprehensive clinical exam remains the standard for making an accurate diagnosis.

INJURIOUS BEHAVIORS

Stereotypic movements can manifest in a variety of injurious behaviors that put patients and caregivers at risk. The ramifications of head banging range

from hematomas and head injuries to retinal detachment and blindness. However, even seemingly benign stereotypic behaviors could cause cumulative damage over time. For example, hair loss could be a consequence of chronic head rolling. In addition, parents and caregivers are at risk of accidental bites and bruises as they attempt to protect children and many adults who engage in stereotyped self-injury. Even children who typically do not exhibit self-injury can be hazardous to others. A child being held may surprise a parent or caregiver with spontaneous swift head bobbing that results in a broken nose or blackened eye. Stereotypic movements, with or without potential for self-injury, may cause major management problems, which hamper habilitation and stifle social adaptation.

Onychotillomania refers to compulsive picking or tearing at the nails. It can produce ridges and a central depression on the nail from chronic rubbing by the nail of another finger. Most commonly, the thumbnail of the dominant hand produces the trauma to the nail plate of the second or third finger. Onylysis refers to separation of the nail from the nail bed. Onychotillomania and onycholysis may be manifestations of rare conditions involving self-mutilation like Lesch–Nyhan syndrome and congenital insensitivity to pain.

Appropriate attention to the patient's history will help to sort out other stereotypic or SIBs. For example, a stereotypic behavior may have been present in a patient with schizophrenia prior to any neuroleptic medication exposure. A careful history of symptom onset can prevent a misdiagnosis of medication-induced stereotypy. Secondary gain in factitious disorders might be the driving force in some instances. In other cases, the inability to control anger or anxiety may lead to repetitive cutting as seen with patients with borderline personality disorder.

TREATMENT

A variety of treatment options from psychotherapy to pharmacotherapy have been used to treat stereotypic and SIBs. Even surgery and electroconvulsive treatments have been used in refractory cases. Behavioral treatments have been used with some success, and these include positive reward techniques such as differential reinforcement of behaviors other than the targeted maladaptive behavior (DRO) and differential reinforcement of behavior incompatible with the targeted maladaptive behavior (DRI). Rewards may be immediate or delayed, as in token economies, but they must be individualized so that they produce the maximum motivation. Rewards also may lose their novelty over time; therefore, changing rewards may provide a fresh incentive for motivation. Punishment can range from misting water into the face to applying mild electric shocks to the patient. Although these techniques might seem mean-spirited, they should be employed if self-injurious or stereotypic behaviors

have high potential for severe harm. Of course, the clinician should document a thoughtful risk versus benefits analysis and discuss this with the guardian or family before using such methods. Other forms of punishment include positive practice, removal of reinforcement, and restitution. A study by Jonathan M. Miller and others used behavioral modification techniques of habit reversal and differential reinforcement of other behaviors in an effort to suppress stereotypic behaviors in 12 nonautistic children between the ages of 6 and 14 years. After a mean follow-up time of 12.1 months, motor stereotypies were significantly reduced on the Stereotypy Linear Analog Scale and the Stereotypy Severity Scale. These results correlated with the subject's motivation and the number of sessions attended. The Child Global Assessment Scale also improved, but no correlations were seen with level of motivation or number of sessions.

Pharmacological approaches have been a mainstay treatment of stereotypic behaviors. An estimated 50 percent of persons with mental retardation living in residential or institutional settings are prescribed high doses of antipsychotic medication, but this statistic does not give an accurate account of the percentage of these patients who have a known psychotic illness. About 75 percent of patients receiving psychotropic medications develop some form of motor dysfunction. In the early days of treatment, movement disorders occurred at even higher rates due to the misconception that motor dysfunction was the definitive sign that a patient had achieved an adequate dose of medication to treat psychosis. Even though antipsychotic agents are used to treat stereotypic movements, they also can cause repetitive, purposeless movements. For instance, akathisia secondary to neuroleptic medication may appear clinically as a shifting from foot to foot, crossing and uncrossing of legs, pacing, hand wringing, or rocking, among other manifestations.

The newer generation of atypical antipsychotic medications does not pose the typical risk for motor dysfunction seen in older drugs. To date, risperidone (Risperdal) and aripiprazole (Abilify) have been approved by the U.S. Food and Drug Administration (FDA) for self-injurious and disruptive behaviors in children with autism. For the double-blinded, placebo-controlled clinical trial, the dose ranged from 0.5 to 3.5 mg per day in the 101 children studied. In a placebo-controlled study of chlorpromazine (Thorazine) used in doses ranging from 2 to 3 mg/kg per day, four adolescents and young adults with profound retardation exhibited a 35 percent reduction in stereotypic behaviors. Unfortunately, the improvement in stereotypic behaviors was offset by a cognitive decline. Several double-blinded, placebo-controlled studies used haloperidol (Haldol) in daily doses of between 0.5 and 4 mg to treat stereotypic behaviors in youth with autism. In these studies, haloperidol significantly reduced stereotypic behaviors without causing notable cognitive

impairment.

A variety of other agents have been tried, but these have fallen short due to limitations of study size or design. Although lithium carbonate (Eskalith) has been studied for SIBs in patients with mental retardation, the results of the few studies are inconsistent. Fenfluramine (Ponderax, Pondimin) reportedly reduced stereotypic behaviors and other problem behaviors in individuals with autism; however, the results also varied across studies. In addition, fenfluramine has been associated with cardiovascular and pulmonary problems. Several other serotonergic agents have been tried, including fluoxetine (Prozac), sertraline (Zoloft), citalopram (Celexa), trazodone (Desyrel), and buspirone (Buspar), but methodological issues related to the size or design of each study limited their usefulness.

Clomipramine (Anafranil) and desipramine (Norpramin) have been studied for their effect on stereotypic behaviors in autism and onychophagia. Gordon and coworkers showed that clomipramine was superior to desipramine, but both were better than placebo in reducing stereotypic behaviors associated with autism. Clomipramine was better than desipramine in treating severe onychophagia, but the dropout rate was greater than that seen in other studies of its use in OCD and trichotillomania. Henrietta L. Leonard and colleagues concluded that clomipramine was not the optimal treatment for severe onychophagia.

An endogenous opioid theory for SIBs has prompted the use of opioid antagonists. The original study of naloxone (Narcan) successfully reduced SIBs in two young adults with profound retardation. SIBs with low frequency of occurrence responded best to the intervention at low doses. Subsequently, several other studies showed that individuals responded variably to naloxone or naltrexone. However, these two agents may substantially decrease stereotypic, self-injurious, and hyperactive behaviors in some patients.

Clearly, more controlled studies are needed to evaluate these and other therapies based on behavioral and pharmacological interventions. Recent technological advances in genetic analysis, neuroimaging, and movement monitoring will promote this goal.

Although stereotypic behaviors manifest in many ways, diagnostic criteria for a stereotypic movement disorder in the DSM-5 and the ICD-10 describe repetitive, rhythmic movements that are not due to another psychiatric disorder, medical condition, or medication effect. Criteria for impairment help to clarify whether a stereotypic movement is an inconsequential habit or part of normal development. The careful clinician should use a thorough history and exam to identify the presence and possible causes of stereotypic behaviors. Once the clinician accurately characterizes the stereotypic movement, behavioral therapy with or without medication intervention may be applied. Although the literature on the treatment of stereotypic behaviors is limited, it does provide a starting

point for developing treatment plans that will likely be subject to change as warranted.

Mood Disorders in Children and Adolescents

▲ 51.1 Depressive Disorders and Suicide

KAREN DINEEN WAGNER, M.D., PH.D., AND DAVID A. BRENT, M.D.

DEPRESSIVE DISORDERS

Introduction

Depressive disorders in children and adolescents have a significant adverse effect on a youth's emotional, social, and cognitive development. Early onset of major depression is associated with more lifetime depressive episodes and suicide attempts, greater psychiatric and medical comorbidity, and poorer quality of life than later age onset of depression. Recognition of these disorders is essential so that children and adolescents may receive effective evidence-based treatments.

Definition

The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) includes in the category of depressive disorders the following: disruptive mood dysregulation disorder, major depressive disorder, persistent depressive disorder, premenstrual dysphoric disorder, substance/medication-induced depressive disorder, depressive disorder due to another medical condition, other specified depressive disorder, and unspecified depressive disorder. To be in the category of depressive disorders, there cannot be a history of ever having had a manic or hypomanic episode. There are coded specifiers for the depressive episode for severity (mild, moderate, severe, with psychotic features) and course (in partial remission, in full remission). The uncoded specifiers for the current episode include with anxious distress, with mixed features, with melancholic features, with atypical features, with mood-congruent psychotic features, with catatonia, with peripartum onset, and with seasonal pattern.

Disruptive mood dysregulation disorder in children is characterized by recurrent verbal or behavioral temporal outbursts (>3 or more times per

week) that are excessive and age inappropriate. In between these episodes, mood is irritable or angry most of the day nearly every day. These symptoms occur in at least two settings (school, home, or with peers). The duration of symptoms must be more than 12 months, without a 3 months symptom-free period in this time frame. Age of onset of the symptoms must be before 10 years old, and the diagnosis should not be made before age 6 years or after age 18 years.

Criteria for major depressive disorder in children and adolescents are at least one major depressive episode in which there has been at least a 2-week period of either depressed or irritable mood or a loss of interest or pleasure. In addition, at least four of the following symptoms are required: weight loss, weight gain, failure to make expected weight gain, or an increase or decrease in appetite; insomnia or hypersomnia; psychomotor agitation or retardation; fatigue or loss of energy; feelings of worthlessness or excessive or inappropriate guilt; diminished ability to think or concentrate or indecisiveness; and recurrent thoughts of death, recurrent suicidal ideation, suicide attempt, or suicide plan. The symptoms must cause impairment in functioning or cause clinically significant distress.

Persistent depressive disorder in children and adolescents is a chronically depressed or irritable mood for at least 1 year. In addition, there must be at least two of the following symptoms: poor appetite or overeating; insomnia or hypersomnia; low energy or fatigue; low self-esteem; poor concentration or difficulty making decisions; and feelings of hopelessness. During the 1-year period, the youth also has not been without depressive symptoms for more than 2 months at a time.

Premenstrual dysphoric disorder requires at least five symptoms in the final week before the onset of menses which start to improve a few days after the onset of menses and are either minimal or absent in the week following menses. One or more of the following symptoms must be present: affective lability, irritability/anger/interpersonal conflict, depressed mood/hopelessness/self-deprecating thoughts, or anxiety/tension/keyed up or on edge. In addition at least one of the following symptoms must be present: decreased interest, concentration difficulties, fatigue/low energy, appetite changes, hypersomnia/insomnia, feeling overwhelmed/out-of-control, and physical symptoms. The symptoms must be severe enough to interfere with functioning or cause clinically significant distress.

A diagnosis of other specified depressive disorder is used when full criteria for a depressive disorder are not met but the symptoms cause significant distress or impairment. The specific reason for not meeting full criteria is identified. The diagnosis of unspecified depressive disorder is used when the reasons for not meeting full criteria are not identified.

History

Although depression in children and adolescents is now recognized as a

common and serious illness, it was not until the 1980s that studies demonstrated that children do develop depressive disorders that can be diagnosed in a standardized manner. It was originally thought that children and adolescents developed a "masked" form of depression with predominantly behavioral symptoms, but subsequent studies have shown that children and adolescents have symptoms similar to those of adults with depression.

Comparative Nosology

The DSM-5 and DSM-IV-TR require five symptoms, one of which must be depressed or irritable mood or a loss of interest or pleasure over a 2-week period, for a diagnosis of major depressive disorder in children and adolescents. For a diagnosis of depressive episode, the tenth revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) requires at least four symptoms, of which at least two of the following must be present: depressed mood, loss of interest or pleasure, and decreased energy or increased fatigability. Unlike DSM-5 and DSM-IV-TR, which allow specific depressive criteria for children and adolescents (irritable mood, failure to make expected weight gain), the ICD-10 has no specific criteria for depression in youth compared to adults. Similarly, DSM-5 persistent depressive disorder and DSM-IV-TR dysthymic disorder criteria allow a 1-year period of symptom duration for children and adolescents, compared to 2 years for adults. However, there are no differences in the minimum 2-year duration criterion for dysthymia in ICD-10.

The major differences between DSM-5 and DSM-IV-TR criteria for major depressive disorder and ICD-10 criteria for depressive episode are number of symptoms required, type and number of core symptoms, and allowing for mood to be irritable in children and adolescents. A study was conducted to determine whether there would be differences between the two diagnostic classification systems in diagnosing children with a depressive disorder. It was found that more children met DSM-IV-TR criteria for major depressive disorder than ICD-10 Diagnostic Criteria for Research (ICD-10-DCR) criteria for a depressive episode. Of the 33 children who had a diagnosis of major depressive disorder according to DSM-IV-TR criteria, 8 (24 percent) did not have a depressive episode according to ICD-10-DCR criteria because these children did not meet the criterion of at least two core symptoms. Using DSM-IV-TR criteria as the gold standard, the sensitivity for major depressive disorder with the ICD-10-DCR was 76 percent and the specificity was 99 percent. Therefore, use of the ICD-10 may miss the diagnosis of children who meet criteria for major depressive disorder.

Disruptive mood dysregulation disorder is a new diagnosis in DSM-5 depressive disorders to address issues related to potential overdiagnosis of

bipolar disorder in children. This diagnosis is not included in ICD-10. Premenstrual dysphoric disorder is a diagnosis in DSM-5 but had been in the DSM-IV-TR appendix for further study. Premenstrual dysphoric disorder diagnosis is not contained in the ICD-10.

Epidemiology

The prevalence of major depressive disorder in children is approximately 2 percent. In adolescence, there is a substantial increase in the prevalence of major depression, with prevalence rates of 4 to 8 percent. In children, the gender ratio is 1:1, whereas with puberty, adolescent girls are two to three times more likely to have an episode of major depression than adolescent boys. By age 18 years, the cumulative incidence of major depression is 20 percent. Children with a family history of affective disorders are about three times more likely to develop a major depressive disorder than children with a first-degree relative without a lifetime affective disorder.

The prevalence rate for persistent depressive disorder in children ranges from 0.6 to 4.6 percent, and in adolescents it ranges from 1.6 to 8.0 percent. Estimates of the prevalence rate of disruptive mood dysregulation disorder are up to 3 percent. It is more commonly diagnosed in boys compared to girls.

Etiology

Genetic. The most predictive factor for a child or adolescent to develop major depressive disorder is a high family loading for major depressive disorder. There is an increased risk of depression in relatives of depressed children (odds ratio = 3.98 compared to healthy controls) and among offspring of depressed adults (odds ratio = 2.12 compared with healthy controls). Younger age of onset of depression in parents increases the risk of depression in children. Parental major depression is associated with greater severity of illness, longer episode duration, more impairment, and more recurrences in depressed offspring. Twin studies have demonstrated that depression is moderately heritable, with rates about 31 to 42 percent.

Neurobiology. Neuroendocrine studies have evaluated the hypothalamic–pituitary–adrenal (HPA), hypothalamic growth hormone (HGH), hypothalamic–pituitary–thyroid (HPT), and hypothalamic–pituitary–gonadal (HPG) axes in youth to determine whether there are abnormalities related to depression. HPA-axis abnormalities have been detected in depressed children and adolescents with some evidence of nonsuppression in stimulation studies. Growth hormone–axis abnormalities have been found in prepubertal depressed children who have a blunted growth hormone response to stimulation with growth hormone-

releasing hormone. There have been inconsistent findings with regard to abnormalities in the HPT axis in children and adolescents with depression. The majority of studies of corticotropin-releasing hormone have found no abnormalities in depressed youth.

Abnormalities in the serotonergic system have been examined in depressed youth. Serotonin challenge agents that cause the release of prolactin have shown greater prolactin release in depressed children compared to controls.

Neuroimaging studies of depressed youth have found smaller left subgenual prefrontal cortex in adolescent girls, smaller frontal white matter volumes, larger frontal gray matter volumes, and larger lateral ventricular volumes. Amygdala functioning has been shown to be disrupted in depressed children. Disconnectivity in frontolimbic circuitry has been associated with depression in adolescents. Larger pituitary- and amygdala-to-hippocampal volume ratios have been found in depressed youth compared to healthy controls. Depressed children and adolescents have been found to have smaller left and right amygdala volume than healthy controls. Increased pituitary gland volume has been found in treatment-naive youth with major depressive disorder, particularly in males with nonfamilial major depressive disorder. Magnetic resonance spectroscopic imaging has found an increase in choline in the left dorsolateral prefrontal cortex and orbitofrontal cortex and increased choline/creatinine and choline/*N*-acetylaspartate ratios in the left anterior medial frontal lobe in depressed youth.

Sleep abnormalities have been examined in depressed youth, and the findings from polysomnography have been mixed. Some studies found no differences between children with major depressive disorder and controls; whereas other studies have found shorter rapid eye movement (REM) latencies, longer sleep latency, higher number of REM periods, and increased REM time for depressed children. In studies of depressed adolescents, shorter REM latency, more REM sleep, more REM density, and longer sleep latency have been reported. Subjective reports by youth of sleep disturbance (sleep quality, waking in the middle of night, morning tiredness) were not confirmed by electroencephalogram (EEG). Of interest, the depressed children who rated their sleep most poorly had better sleep by EEG measures than those who rated their sleep more positively. In a study using polysomnography as a measure of recurrence of depression in youth, those youth who had a later recurrence had decreased sleep efficiency and delayed sleep onset at baseline sleep polysomnography.

Environmental. Adoption studies have supported the role of environment more than genetic factors in the development of pediatric depression. Family factors, including parental substance abuse, poor marital adjustment, parent–child conflict, and lack of family cohesion, are

risk factors for depression in children and adolescents. Life stressors, such as abuse, neglect, death of a parent, and psychosocial adversities, may contribute to depression in youth. Cigarette smoking, physical illness, and functional impairment have been associated with youth depression. Recurrence of major depression may also be affected by environmental stressors.

There may be gene–environment interactions with regard to pediatric depression. Twin studies of life events have shown that the effect of life events on depression is greater in youth with higher genetic liability. Family conflict and family adversity have also been demonstrated to interact with genetic liability and contribute to depression in youth.

Cognition. Depressed children and adolescents may have a negative view of themselves, the world, and the future. They may possess a negative attributional style in which they view themselves as the cause of negative outcomes and view positive outcomes as externally derived. Low self-esteem, feelings of worthlessness, and perceived incompetence are some outcomes of these cognitive distortions. Cognitions about self-worth and self-efficacy have been found to be mediators of stressful life events in the development of depression. The combination of stressful life events and negative self-concept has been shown to be predictive of depression in youth.

Diagnosis and Clinical Features

It is important for the clinician to conduct a comprehensive evaluation of a child to ensure the accuracy of the primary diagnosis, as well as of comorbid diagnoses. The clinician should interview the child and parent separately so that each can express their concerns. Teenagers are often reluctant to disclose their feelings or issues related to peers in the presence of their parents. Similarly, parents may be reticent to discuss sensitive topics with their children present. Other sources of information may be obtained from discussion with school personnel, from school records, or from medical records.

Children with the diagnosis of disruptive mood dysregulation disorder are persistently irritable or angry most of the day nearly every day and have severe recurrent (>3 times per week) temper outbursts, either verbal or behavioral. These temper outbursts are developmentally inappropriate and are out of proportion to the situation. For example, a child who is chronically irritable at school may throw a chair at a peer during one of these temper outbursts. To make this diagnosis, the symptoms must be present for at least 12 months (no period >3 months without symptoms in this time frame) and be present at least two settings (school, home, or with peers). The diagnosis cannot be given to children under the age of 6 years, and the onset of symptoms must be before age 10 years. Disruptive mood

dysregulation disorder cannot co-occur with oppositional defiant disorder, bipolar disorder, or intermittent explosive disorder. If a child has symptoms that meet criteria for both disruptive mood dysregulation disorder and oppositional defiant disorder, then the diagnosis of disruptive mood dysregulation disorder should be given. If the child has ever had a manic or hypomanic episode, then the diagnosis of disruptive mood dysregulation disorder should not be given.

Major depression in children and adolescents is defined using DSM-5 criteria of at least 2-week duration of depressed or irritable mood and/or loss of interest or pleasure, along with at least four of the following symptoms: Weight or appetite change, sleep disturbance, psychomotor retardation or agitation, fatigue or loss of energy, feelings of worthlessness or guilt, diminished concentration, and suicidal ideation, intent, or plan. The symptoms must cause impairment in the child's functioning with regard to, for example, social or school performance or peer relationships, which is critical to the diagnosis in youth. Impairment helps to distinguish these symptoms from a passing phase of childhood or adolescence.

Youth with major depressive disorder often display irritable mood rather than dysphoria. Typically they are not aware of the extent of their irritability or its effects on their interaction with other people. Teenagers who have some insight into their irritability might say that everything makes them angry whether it is important or not. Loss of pleasure or interest may be noted by the youth's withdrawal from school or sports activities and from friends. Sleep disturbance is common in depressed youth, particularly difficulty falling asleep. Weight loss or failure to gain weight is more common than significant weight gain. Youth with depression are often fatigued and may nap after school. Diminished concentration may be manifested by declining school grades. A child often describes a feeling of worthlessness as no one liking him or her, including peers, teachers, and family members. Suicide attempts and psychotic features are more common in depressed adolescents than in depressed children.

Depressed youth typically do not view themselves as having depression, because their mood is usually irritable rather than depressed. Parents often do not recognize individual symptoms of an adolescent's depression, but they recognize the burden on the family in dealing with an extremely irritable adolescent. Children and adolescents with depression are more likely to be brought for evaluation because of declining school grades, substance abuse, suicide attempt, or a change in behavior.

For a diagnosis of persistent depressive disorder, a child or adolescent must have depressed or irritable mood for at least 1 year. In addition, the youth must have two of the following symptoms: poor appetite or overeating, insomnia or hypersomnia, low energy or fatigue, low self-esteem, poor concentration or difficulty making decisions, and feeling of

hopelessness. Youth with persistent depressive disorder have fewer melancholic and neurovegetative symptoms than youth with major depressive disorder. Although the depressive symptoms are milder in persistent depressive disorder than in major depressive disorder, the chronicity of persistent depressive disorder results in significant psychosocial impairment (e.g., relationships with friends and family).

Depressive disorders in youth are often comorbid with other psychiatric conditions. Rates of comorbidity range from 40 to 90 percent of children and adolescents with a depressive disorder, with up to 50 percent of depressed youths having two or more comorbid disorders. Anxiety disorders often precede the onset of depression and are a very common comorbid disorder. Major depression and persistent depressive disorder also frequently co-occur in youth. Other common comorbidities are attention-deficit/hyperactivity disorder, oppositional defiant disorder, conduct disorder, and substance use disorder. It is important for clinicians to identify comorbid disorders that are associated with depressive disorders in youth, since these comorbidities may adversely affect the course and treatment outcomes of depressive disorders.

Laboratory Examinations/Assessment Instrument

No laboratory findings are diagnostic of depressive disorders in youth. If a child presents with symptoms of depression and hypothyroidism (e.g., dry skin, feeling cold, and memory difficulties), then thyroid function tests should be obtained. If hypothyroidism was found, the diagnosis would be depressive disorder due to another medical condition.

The Children's Depression Rating Scale-Revised (CDRS-R) is a 17-item, clinician-administered instrument that assesses symptoms of depression in children and adolescents. The scale assesses cognitive, somatic, affective, and psychomotor symptoms. The items are rated for severity on a scale of 1 to 7 for some items and 1 to 5 for other items for a total score of 113. Typically a score of 45 or greater is considered a marker of clinically significant depression. The CDRS-R is useful for obtaining baseline symptomatology prior to treatment and for monitoring treatment outcome.

Given that youth with bipolar disorder may present with a depressive episode, it is important to ask about symptoms of mania or hypomania. Some diagnostic checklists for mania have been shown to discriminate bipolar from nonbipolar disorder in youth of ages 5 to 18 years old, including the Mood Disorder Questionnaire-Adolescent (MDQ-A), the Parent General Behavior Inventory 10-item short form (PGBI-SF10), and the Parent Young Mania Rating Scale (P-YMRS). These checklists are completed by the parents about their child's behavior. Adolescent self-report measures about symptoms of mania have demonstrated low validity in identifying bipolar disorder.

Differential Diagnosis

Depressive symptoms may be related to stressors and fulfill criteria for an adjustment disorder with depressed mood. A child may have experienced the death of a significant person in his or her life, and the depressive symptoms may be related to bereavement. Depression or irritability may be attributable to substance use or withdrawal, which would be considered a substance-induced depressive disorder.

When a child presents with depressive symptoms, it is important for the clinician to consider bipolar disorder within the differential diagnosis. The clinician should ask about a past or present history of manic or hypomanic symptoms.

There is substantial symptom overlap among various psychiatric disorders, which might complicate the differential diagnosis. Irritability and sleep disturbance may be found in depression, persistent depressive disorder, bipolar disorder, posttraumatic stress disorder, and generalized anxiety disorder. Appetite changes may be associated with eating disorders. Children with attention-deficit/hyperactivity disorder who are failing in school and having difficulty with peer relationships may exhibit symptoms such as depressed mood and low self-esteem. Anxiety disorders and oppositional defiant disorders may have some symptom features of depression. Children with pervasive developmental disorder may present with depressive symptoms but not fulfill diagnostic criteria for major depression.

Medical conditions may manifest with symptoms of a depressive episode and should be diagnosed as depressive disorder due to a general medical condition if the mood disorder is attributable to the consequences of the medical condition. Neurological disorders (e.g., seizure disorder and multiple sclerosis), endocrinological abnormalities (hypothyroidism, hypopituitarism, Cushing disease), infections (e.g., pneumonia, AIDS, and mononucleosis), autoimmune diseases, and cancer are some medical conditions to consider within the differential diagnosis. Medications such as anti-inflammatory agents, antibiotics, steroids, stimulants, and oral contraceptives may lead to depressive symptoms.

Course and Prognosis

Disruptive mood dysregulation disorder onset must be before age 10 years old. The symptoms are predominantly limited to childhood. Of children who were diagnosed with disruptive mood dysregulation disorder, only 19 percent continued to meet criteria for the disorder at 12 and 24 months follow-up. Children with disruptive mood dysregulation disorder are at risk to develop depression and anxiety disorders in adulthood.

The mean length of an episode of major depression in children and adolescents is 8 months. Recovery rates from an index episode of

depression are high in youth, even independent of treatment. More than 90 percent of depressed children and adolescents typically recover from an episode of major depression within 1 to 2 years.

Relapse rates, with relapse being defined as a return of symptoms in the index episode, are between 34 and 50 percent, with the greatest likelihood of relapse in the first 6 months to 1 year after treatment discontinuation. Recurrence rates (onset of a new episode of depression) are high, with rates ranging from 20 to 60 percent after 2 years of remission and up to 70 percent at 5-year follow-up.

Risk factors for relapse or recurrence include severity of illness, suicidality, comorbid disorders, residual symptoms, psychosocial stressors, family conflict, family history of recurrent depression, negative cognitive style, low socioeconomic status, early onset of parental mood disorder, baseline social difficulties, and history of sexual abuse.

Youth who present with an episode of major depression are at risk of the development of bipolar disorder. Overall estimates are that 20 to 40 percent of youth with a major depressive episode are at risk of subsequent development of bipolar disorder. In a longitudinal study of prepubertal children diagnosed with major depression, the rate of bipolar I disorder was 33 percent and that of bipolar spectrum disorders (I, II, not otherwise specified [NOS]) was 48 percent by young adulthood. Risk factors for switch to bipolar disorder are prepubertal onset of major depression, loaded or multigenerational family history for mood disorders, psychotic features, and hypomania when treated with antidepressant medications.

There is increased recognition of the continuity between depression in youth and depression in adulthood. In a follow-up study of depressed school-aged children in community and clinic samples, 18 percent continued to have major depression into adulthood. In a clinic sample, adolescent-onset major depressive disorder increased the risk twofold of major depressive disorder in adulthood. In a community sample, 53 percent of adolescents with a history of major depressive disorder developed a new major depressive disorder in young adulthood.

Early age of onset of depression increases the risk of anxiety disorders, substance abuse, psychiatric comorbidity, suicide attempts, psychiatric and medical hospitalization, impairment in relationships with parents, siblings, and friends, more lifetime depressive episodes, nicotine dependence, increased adulthood body mass index, educational underachievement, unemployment, early parenthood, and worse overall quality of life.

The duration of persistent depressive disorder ranges from 2 to 3 years in clinically referred and community-based youth. After recovery after an episode of persistent depressive disorder, the estimated relapse rate is 45 percent. Youth with persistent depressive disorder are at increased risk of psychosocial difficulties, substance use disorder, episodes of major depression, and suicidality. The risk of suicide attempts in youths with

persistent depressive disorder increases with comorbid conduct disorder or substance use disorder.

Children and adolescents with both major depressive disorder and persistent depressive disorder have a worse course of illness than those with either disorder alone. These youth have more-severe depression, longer depressive episodes, more comorbid disorders, more suicidality, and greater psychosocial impairment.

Pharmacological Treatment

There are no FDA-approved medications to treat disruptive mood dysregulation disorder. Since this is a new childhood diagnosis, there are no studies of medication treatments for this disorder. Pharmacological treatment recommendations range from stimulants to treat aggression, mood stabilizers such as atypical antipsychotics and valproate to treat mood dysregulation, or selective serotonin uptake inhibitors to treat depressive symptoms.

Selective serotonin reuptake inhibitors (SSRIs) are the only antidepressants that have demonstrated efficacy in double-blind placebo-controlled trials for children and adolescents with major depression. Two SSRIs have FDA approval for acute and maintenance treatment of major depression in children and adolescents: fluoxetine (>8 years old) and escitalopram (>12 years old).

SSRIs that have also demonstrated efficacy in controlled studies of depressed youth are citalopram and sertraline. Other studies of SSRIs failed to demonstrate superiority of medication to placebo on the primary outcome measure, including citalopram, paroxetine, and escitalopram. A meta-analysis of SSRI trials in youth showed superiority of SSRIs to placebo, with an average response rate of 60 percent for antidepressants and 49 percent for placebo.

Other classes of antidepressants have not shown statistically significant improvement with antidepressant medication compared to placebo, including venlafaxine, nefazodone, and mirtazapine and selegiline transdermal system. In a failed study, duloxetine and fluoxetine were not superior to placebo. Tricyclic antidepressants have not been shown to be effective for the treatment of depressed children and adolescents. There is some speculation that the early maturation of the serotonergic system compared to the noradrenergic system may account for the lack of efficacy in noradrenergic antidepressants compared to serotonergic agents in youth. There are no controlled trials of bupropion in the treatment of major depression in children and adolescents.

There has been much discussion about why controlled studies of antidepressants in children and adolescents with major depression have not shown efficacy, that is, statistically significant separation from placebo. One explanation is the high rate of placebo response in these studies—up to

59 percent. Other explanations are methodological issues in the antidepressant trials, including number of sites, experience of site personnel, patient recruitment source, inclusion and exclusion criteria, duration of treatment trial, dosing, and outcome measures.

Adverse Events. Common side effects of SSRIs are nausea, abdominal pain, headaches, dry mouth, insomnia, somnolence, and sexual dysfunction. Impulsivity, agitation, irritability, and behavioral activation may occur, particularly with young children. Potential serious side effects include serotonin syndrome, increased bleeding, and amotivational syndrome. Common side effects of venlafaxine are anorexia, abdominal pain, insomnia, somnolence, dizziness, and elevated blood pressure. Common side effects of mirtazapine are increased appetite, weight gain, and somnolence. Common side effects of duloxetine are nausea, headache, abdominal pain, and somnolence.

FDA Warning and Suicidality. In a combined analysis conducted by the FDA of 24 short-term, placebo-controlled trials of antidepressant medications in child and adolescent major depressive disorder, obsessive-compulsive disorder, or other psychiatric disorders, the risk of suicidality (suicidal thinking and behavior) was 4 percent—twice the placebo rate of 2 percent. There were no suicides in any of the clinical trials. The FDA directed manufacturers to add a black box warning to the health professional label of antidepressant medications to describe the increased risk of suicidal thoughts and behavior in children and adolescents being treated with antidepressants, as well as to recommend the need for close monitoring of patients on antidepressant medications.

In a later meta-analysis of 27 trials of pediatric major depression, the risk of suicidality (suicidal ideation and attempts) was 3 percent in the antidepressant group and 2 percent in youth who received placebo. The pooled absolute rate of antidepressant response was 61 percent, and the placebo response was 50 percent. The number needed to treat (NNT) (number needed to treat to get one positive response to medication) was 10, and the number needed to harm (NNH) (number needed to get one event of suicidality) was 112. Based on this finding, the investigators concluded that the benefits of antidepressants in youths outweigh the potential risk from suicidal ideation or attempts.

There have been recent reports of an increase in suicide rate in youth following the black box warning on antidepressants and a significant decrease in the rates of diagnosis and treatment of pediatric depression.

A medication guide that addresses antidepressant medications, depression, and suicidality has been approved by the FDA. The guide states that depression and other serious mental illnesses are the most important causes of suicidal thoughts and actions and that antidepressant medication

may increase suicidal thoughts or actions in some children and teenagers when medication is first started. The patient or family member is encouraged to contact the health care provider if there is a change in mood or thoughts.

Informed Consent. Prior to prescribing antidepressant medication to a child or adolescent, an informed consent process should occur with the youth and the parent. Elements of informed consent are the purpose of treatment, description of the treatment process, benefits and risks of the proposed treatment, and alternative treatments. Because there is minimal information about the long-term effects of antidepressant medication in children, parents should be informed that there may be unknown risks of these medications.

Medication Treatment Algorithm. An evidence-based consensus algorithm for the treatment of major depression in children and adolescents was reported in which four stages of medication treatment were identified. It was recommended that if a child failed to respond to treatment in one stage, then the clinician should move to treatment in the next stage. The first stage of treatment is with an SSRI. The second stage of treatment is with an alternative SSRI. The third stage of treatment is selection of a different class of antidepressant medication (venlafaxine, bupropion, mirtazapine, duloxetine). If a child fails to respond to these agents, then it was recommended that there be reassessment of the diagnosis and treatment consultation.

In the Treatment of Adolescents with SSRI-Resistant Depression (TORDIA) study, it was found that there was no difference in response rates for those adolescents switched to venlafaxine or another SSRI (48 vs. 47 percent) after treatment failure with an SSRI. Therefore, if an adolescent does not respond to the initial antidepressant, there is approximately a 50 percent chance of responding to the second antidepressant.

Table 51.1–1.
Dosing of Antidepressants in Children and Adolescents

	Typical Starting Dose (mg)		
Medication	**Child**	**Adolescent**	**Target Dose (mg)**
Citalopram	5–10	10	20–40
Escitalopram[a]	5	10	10–20
Fluoxetine[b]	5–10	10	20–40
Paroxetine	5–10	10	20–40
Sertraline	25	50	100–200
Bupropion	50 twice daily	50 twice daily	100–200
Duloxetine	20	20	60–120
Mirtazapine	15	15	30–45

Venlafaxine	37.5	37.5	150–225

[a]Approved by the U.S. Food and Drug Administration for the treatment of major depression for children ages 12 years and above.

[b]Approved by the U.S. Food and Drug Administration for the treatment of major depression for children ages 7 years and above.

Lower initial starting doses of antidepressants are typically used in children and adolescents than in adults. However, the dose range tends to be similar to that used with adults. Antidepressant doses in children and adolescents are shown in Table 51.1–1. Doses are usually increased by 3 weeks if there is no symptom improvement. If there is no improvement with additional dose adjustment after 8 to 10 weeks, then switching to another treatment is recommended. Antidepressants should be continued for 6 to 12 months after symptom remission. At the time of discontinuation of an antidepressant, the dose should be tapered slowly, usually over a 2- to 3-month period.

Psychotherapy

The two most-studied treatment modalities for depression in adolescents are cognitive-behavior therapy (CBT) and interpersonal psychotherapy (IPT). There are no published controlled trials of these treatments in children with major depression.

Cognitive-Behavior Therapy. CBT focuses on cognitive distortions and behavioral deficits associated with depression in youth. Components of CBT for children and adolescents include psychoeducation and mood monitoring, pleasant activity scheduling and behavioral activation, and cognitive restructuring. Relaxation training and improvement in social and problem solving skills may be included.

The efficacy of CBT was assessed in adolescents with major depression or dysthymia. The youth were randomly assigned to adolescent group CBT, adolescent group CBT with a separate parent group, or wait-list control. The CBT groups showed higher depression recovery rates (67 percent) than the wait-list group (48 percent) and greater reduction in self-reported depression. The addition of a parent group did not affect outcome.

CBT (12 to 16 sessions) was compared to nondirective supportive psychotherapy and systemic behavior therapy in a randomized trial. CBT was significantly superior to the other treatments, with greater reduction in depression, more rapid symptom relief, and a higher remission rate—65 percent, compared to 39 percent for nondirective supportive therapy and 38 percent for systemic behavior family therapy. However, in a 2-year follow-up study, there were no significant differences in outcome among the psychotherapies. Eighty percent of the adolescents had recovered from depression, but 30 percent had a recurrence of depression.

Computerized CBT in the form of an interactive fantasy game (SPARX) has been developed for adolescent depression. A study comparing SPARX to treatment as usual for adolescents with depressive symptoms showed similar treatment response rates.

The Treatment for Adolescents with Depression Study (TADS) was the largest randomized, controlled trial to compare the efficacy of CBT, fluoxetine, CBT plus fluoxetine, and placebo in adolescent outpatients with a diagnosis of major depression. Response rates (much or very much improved) for CBT (43 percent) were not statistically significant compared to those for placebo (35 percent). Response rates to fluoxetine plus CBT (71 percent) and fluoxetine alone (61 percent) were significantly superior to those to CBT alone and to placebo. Fluoxetine with CBT showed the greatest reduction in suicidal thinking. Although remission rates at the end of 12 weeks of treatment were highest in the combination group (37 percent) compared to the other treatment groups (fluoxetine, 23 percent; CBT, 16 percent; placebo, 17 percent), these overall remission rates were low. The long-term effectiveness of these treatments was assessed over 36 weeks. It was found that for adolescents with moderate to severe depression, treatment with fluoxetine alone or the combination of fluoxetine with CBT accelerated the improvement of depression compared to CBT alone. The addition of CBT to fluoxetine decreased persistent suicidal ideation and treatment-emergent suicidal events.

Although the TADS study showed some benefit to the combination of CBT plus fluoxetine, other trials failed to show a significant advantage of adding CBT to medication for depressed adolescents. In one study, for adolescents with moderate to severe major depression, there was no difference in outcome at 28 weeks between youth who received combination CBT plus an SSRI and youth who received an SSRI with routine clinical care. In addition, there was no evidence of a protective effect of CBT on suicidal thinking or action. In another study, it was found that adding CBT to SSRI treatment in a pediatric primary care setting showed no significant improvement in depression compared to primarily SSRI medication.

In the TORDIA study, adolescents who did not respond to initial treatment with an SSRI had a 55 percent response to CBT added to an alternate medication compared to 41 percent for those treated with an alternate medication only.

Interpersonal Psychotherapy. IPT focuses on the relationship between depressed symptoms and interpersonal relationships. Four areas of focus are loss, interpersonal disputes, role transition, and interpersonal deficits. IPT has been modified for depressed adolescents (IPT-A) and has added a focus on developmental issues such as separation from parents, authority figures, peer pressures, and dyadic relationships. The adolescent and

parents are educated about the association between depressive symptoms and events in interpersonal relationships. The adolescent learns skills to improve interpersonal relationships that may help to relieve depression.

The efficacy of IPT-A was assessed in a 12-week study of 48 adolescents with major depression who were randomly assigned to IPT-A or clinical monitoring. IPT-A led to greater decrease in depressive symptoms, improvement in social functioning, and improved problem solving compared to clinical monitoring.

The effectiveness of IPT-A in school based health clinics was evaluated in depressed adolescents who were randomly assigned to IPT-A or treatment as usual for 16 weeks. The IPT-A training was done with existing staff at the health care clinics in high school. The adolescents who received IPT-A had greater symptom reduction and improvement in overall functioning. The greatest treatment effects occurred in older and more severely depressed adolescents.

There is also a group format (IPT-AG) that allows for peer support for depressed adolescents who have similar interpersonal problems. Adolescents can receive feedback from their peers about their interpersonal interactions and strategies to improve them. The efficacy of IPT-AG was compared to individual IPT-A, and there was similar improvement in depression for both formats of IPT.

Psychotherapies. In a meta-analysis of psychotherapy for depression in children and adolescents, the overall effect size was small (0.34). CBT was not superior to other psychotherapy treatments. It was also found that the treatment effect diminished over time to the point of no effect at 1-year follow-up. Another meta-analysis of randomized, controlled trials found that psychotherapy, particularly CBT and IPT, was more effective than no-treatment, waiting-list, or attention-placebo approaches at posttreatment for youth with depression. However, the effectiveness of psychotherapy was no longer significant at 6-month or later follow-up. The investigators concluded that psychotherapy appears to be helpful for treating depressed youth in the short term but that more long-term effective treatment strategies are needed.

Other Treatment Components

Treatment of depressed children and adolescents should also include psychoeducation, supportive management, family involvement, and school involvement.

Psychoeducation involves educating the patient and parents about depression, including causes, symptoms, course, and treatment options, including benefits and risks of treatment. Depression should be explained as an illness not a character flaw of the child or parent. The parent and child should be informed about the importance of adhering to treatment to

ensure an optimal outcome.

Supportive management includes assisting the child with problem solving, improving coping skills, and fostering involvement in treatment.

It is important to involve parents in the treatment process. Parents can provide important information about the child's symptoms over the course of treatment. Parents may also need guidance in managing their depressed child at home.

With regard to school involvement, children with depression may have academic difficulties that require school remediation or accommodation in the child's school schedule or program.

Clinical Issues Affecting Treatment Response

When a depressed child fails to respond to evidence-based treatment, there may be clinical issues that are affecting treatment outcome. The diagnosis should be reassessed because there might be symptom overlap among disorders that could lead to misdiagnosis. Comorbid disorders might have been unrecognized and the depression treatment response adversely affected by lack of treatment for the comorbid disorder. Psychosocial issues such as abuse, family conflict, parental psychopathology, peer difficulties, and family discord might be exacerbating the symptoms of depression. Lack of compliance with treatment will affect treatment outcome. Some youth do not take medication as prescribed and are reluctant to inform the clinician. Similarly, some youth do not perform behavioral exercises or assignments that might be a component of psychotherapy treatment. With regard to medication management, it is important for parents to participate in monitoring their child's medication compliance.

Treatment Recommendations

The American Academy of Child and Adolescent Psychiatry published treatment recommendations for children and adolescents with depressive disorders. For children with uncomplicated or brief depression or with mild psychosocial impairment, psychoeducation, supportive treatment, and case management are generally adequate initial treatment. For children who do not response to supportive psychotherapy after 4 to 6 weeks, a trial of specific psychotherapy and/or antidepressants is indicated. Similarly, for children with moderate to severe depression, chronic or recurrent depression, significant psychosocial impairment, suicidality, agitation, or psychosis, it is recommended that psychopharmacological treatment or specific types of therapy be initiated. CBT or IPT alone may be effective for moderate depression. However, more severe depression typically requires treatment with antidepressants. For children who do not respond to either form of treatment alone, combination with psychotherapy or antidepressants may be required.

SUICIDAL BEHAVIOR IN CHILDREN AND ADOLESCENTS

Introduction

It is appropriate to discuss child and adolescent suicidal behavior together with depression because depression is the most significant psychiatric risk factor for suicidal behavior, and because suicidal behavior is a symptom of depression. Nevertheless, the vast majority of depressed individuals neither complete nor attempt suicide, and many children and adolescents who engage in suicidal behavior do not have a mood disorder. Moreover, even in those depressed individuals who also manifest suicidal behavior, it is still an open question as to whether the treatment of depression is sufficient to reduce suicidal risk.

Definitions

Suicidal phenomena occur on a spectrum ranging from suicidal thoughts to suicide. The category of *suicidal thoughts* or *suicidal ideation* can vary from passive thoughts of death (e.g., maybe I would be better off dead), to active suicidal ideation (e.g., I would like to kill myself), to suicidal ideation with a *plan and intent* (e.g., I plan to kill myself with my hunting rifle when my parents go out tonight). *Suicidal threats* are the verbalization of suicidal ideation. A *suicide attempt* can be defined as "self-destructive behavior with inferred or explicit intent to die." This definition differentiates suicidal behavior from "*non-suicidal self-injurious behavior (NSSI)*," which involves intentional self-injury such as cutting for motivations other than to die, most commonly, to relieve negative affect. *Suicide* is a suicide attempt that results in death. *Autoerotic asphyxia* can superficially resemble suicide by hanging. In autoerotic asphyxia, the individual partially cuts off carotid circulation using a neck ligature simultaneous with masturbation to heighten the intensity of sexual climax. The presence of a ligature, sexual paraphernalia, and evidence of sexual activity support the latter condition over suicide.

Epidemiology

The Youth Risk Behavior Survey for 2014, which gathered data on risk behaviors using self-report, found that, in the past year, 13.6 percent of youth had a suicidal plan, 8.0 percent made a suicide attempt, and 2.7 percent made an attempt requiring medical attention. Lifetime rates of suicidal behavior using data obtained by interview rather than self-report yield lower estimates of lifetime suicidal ideation with plan and attempts, both around 4 percent. Deaths by suicide are much more rare, occurring in 8.26/100,000 of adolescents 15 to 19 and 1.87/100,000 of adolescents aged 10 to 14. The rates of suicidal ideation, attempts, and deaths by suicide increase with age across childhood and adolescence. The increase in

ideation is explained by an increased incidence of depression that occurs during adolescence. The increased rate of attempts and suicide deaths in adolescence relative to childhood are explained by higher rates of depression and alcohol and substance abuse, as well as by a greater ability to plan and execute a potentially lethal suicide attempt.

FIGURE 51.1–1. US suicide rate in 15 to 19 year olds (per 100,000) by sex and race (2013). (Accessed Injury Prevention & Control: Data & Statistics (WISQARS) http://www.cdc.gov/injury/wisqars/index.html. Updated July 13, 2015.)

Suicidal ideation and attempts are more common in female than male adolescents after puberty, following a similar pattern to depression. However, suicide deaths are over twice as common in males than females aged 10 to 14, and over three times as common in males than females aged 15 to 19. The higher rate of suicide in late adolescent males relative to females may be due to higher rates of substance abuse and conduct disorder and a tendency to use more lethal, and therefore more irreversible, means of suicide.

The rate of suicide is particularly high in the United States among Native Americans, who show a suicide rate about twice that of the overall rate, 15.2/100,000 for 15 to 19 year-olds in 2013 (see Fig. 51.1–1). This pattern of high suicidal risk among indigenous peoples is found worldwide and may be related to erosion of traditional cultural values, increased alcoholism, legal difficulties, and unemployment. Whites have a higher rate of suicide than African-American youth, although the rate of suicide among African-American boys has climbed over the years to around 75 percent of the rate in white males.

After peaking in the 1990s, the suicide rate in adolescents declined until 2004, when it increased for the first time in a decade. Since 2007, there has been a gradual increase in the suicide rate both in males and females (see Fig. 51.1–2). The decline in the rate during the 1990s has been attributed to

more restrictive gun control laws and to increased prescription of SSRIs through correlative studies, although it is difficult to identify causal factors. The use of SSRIs among adolescents has declined since 2004, which corresponds in time with the FDA's black box warning on antidepressants. Some pharmacoepidemiological studies have shown a relationship between the decline in use of antidepressants and an increase in the rate of suicide and suicide attempts, but none of these studies are definitive.

The most common method for adolescent suicide attempts is overdose, with the second-most-common method being wrist cutting. Although suicide attempts in adolescents are frequently of relatively low intent, ingestion of acetaminophen is associated with a significant risk of liver toxicity and fatality without prompt medical attempt. Much more rarely, adolescents engage in highly lethal suicide attempts, using methods more commonly found in completed suicide. The most common method in the United States for suicide fatality is by firearms, followed in frequency by hanging, jumping, carbon monoxide poisoning, and taking an overdose.

Risk Factors, Assessment, and Etiology

Because completed suicide is so rare and most of the risk factors for completed suicide overlap with those for suicidal ideation and attempt, accurate prediction of suicide completion is not possible. However, the identification of individuals at risk of suicidal behavior is still worthwhile because most of the risk factors are associated with significant functional impairment and therefore require treatment.

FIGURE 51.1–2. US rates of suicide (per 100,000) in youth 15 to 19: overall by sex. (Accessed Injury Prevention & Control: Data & Statistics (WISQARS) http://www.cdc.gov/injury/wisqars/index.html. Updated July 13, 2015.)

The best predictor of future suicidal behavior is current and recent past suicidal behavior. The more serious the previous episode of suicidal

ideation (e.g., with a plan) or behavior (high suicidal intent), the greater is the likelihood of a suicide attempt. Suicidal behavior and ideation are assessed across five domains: intensity and intent, lethality, precipitant, motivation, and availability of lethal agents.

Intensity and Intent. Suicide ideation is assessed both with respect to *intensity* (i.e., how frequent and how compelling) and *severity* (from passive ideation to ideation with intent and a plan). *Suicidal intent* refers to the degree to which the individual with suicidal ideation intends to carry out a suicidal act; when the individual has made an attempt, intent refers to the degree to which the individual wished to die. The worst-ever level of suicidal ideation is also predictive of future attempts and suicide deaths. Suicidal ideation is a strong predictor of future suicidal behavior. In one study, 33.4 percent of those with suicidal ideation developed a plan within a year, and 60.8 percent of those with a suicidal plan made a suicide attempt within a year. The risk of attempt is lower in those with ideation without a plan, about 20 percent in 1 year.

An adolescent who has made a suicide attempt has a 15 to 30 percent chance of a reattempt within 1 year, with the highest risk of reattempt in the first 3 months after the attempt. Suicide attempters are at a 10- to 60-fold increased risk of completed suicide, with those who make attempts of high lethality and intent at highest risk. Suicidal intent is assessed not only based on the suicidal individual's self-report, but also based upon his or her actual suicidal behavior, such as the degree of preparatory behavior and timing of the event to minimize discovery, which often belie the suicidal individual's self-report. Those who die by suicide are also much more likely than attempters to have confided to a friend about their suicidal intent. This is reflective of a more stable and intense ideation in those who die by suicide versus attempters, but it also reflects a simultaneous wish to live and wish to die on the part of even the most suicidal individuals. NSSI has emerged as a potent predictor of suicidal behavior, in some studies showing a stronger association with future suicide attempts than a previous history of a suicide attempt. Finally, adolescents who express regret for having survived a suicide attempt are at increased risk of recurrent and fatal suicidal behavior.

Motivation. Motivation refers to the reason why the individual engaged in suicidal behavior. An understanding of motivation is key to the development of an effective treatment plan. About one-third of adolescents who attempt suicide do so with a wish to die. The remainder of adolescent suicide attempters report that they wanted to escape an intolerable situation, could not tolerate their psychological pain and distress, wanted to express hostility, or to get attention and support.

Precipitant. Parent–child conflict, difficulties in peer and romantic relationships, and disciplinary problems are the most common precipitants for suicidal behavior, and to the extent that these precipitants are likely to recur, the suicidal individual continues to be at increased risk of a reattempt. In younger children and adolescents, precipitants are most commonly parent–child conflict, whereas older adolescents are more likely to report romantic or peer difficulties as precipitants. Part of therapeutic intervention should be to help the patient cope differently, without engaging in suicidal behavior, when faced with a similar precipitant in the future.

Lethality. Lethality refers to the medical dangerousness of the suicide attempt. Intent and lethality are not always highly correlated, especially in children and young adolescents. Therefore, an attempt of low lethality should not be dismissed as a "gesture," because this attempt could still convey high suicidal intent. Conversely, impulsive attempts without clear high intent can sometimes result in highly lethal or even fatal attempts, such as in overdose of acetaminophen, or in younger adolescents without clear psychopathology, for whom the availability of a loaded gun is by far the most significant risk factor for suicide. However, those individuals whose attempts resemble suicide fatalities with regard to method—for example, with the use of hanging or firearms—are much more likely to eventually die by suicide.

Availability of Lethal Agents. In the United States, approximately 60 percent of youth suicides involve firearms, although hanging is the leading cause of death in many other countries and has been increasing as a method of choice in American youth as well. Case–control studies, cross-country comparisons, and quasi-experimental studies consistently show an association between the availability of guns, particularly handguns, and risk of suicide. Guns are two to ten times more likely to be found in the homes of suicide victims than in those of demographically, and even psychiatrically, matched controls. The only risk factor that differentiated between youth who died by suicide and living control youth, all of whom had no clear evidence of psychiatric disorder, is the availability of a loaded gun in the homes of the suicides. Restriction of access to guns has been associated with regional and national declines in firearm-related and overall suicide rates. Restricting the availability of acetaminophen in the United Kingdom and in France by requiring a prescription and dispensing a limited number wrapped in bubble pack to prevent easy ingestion of large quantities have been shown to favorably affect the rate of overdose and the case fatality per overdose. Other studies have suggested that the addition of barriers to a bridge that is commonly used for suicide might have reduced the suicide rate from that site. However, not all studies of method

restriction show a consistent effect, and in some studies there is evidence for partial or complete method substitution.

Other salient risk factors and correlates of adolescent suicidal behavior include mental disorder, health risk behaviors, chronic medical conditions, psychological characteristics, familial–environmental factors, exposure to suicidal behavior, and biological risk factors.

Mental Disorder. The rate of psychiatric disorder in suicide and attempted suicide is 90 and 80 percent, respectively. Greater chronicity, severity, and complexity (e.g., comorbidity) are all characterizations of psychiatric illness in those individuals with suicidal ideation, attempts, and completions. Because the majority of psychiatrically ill individuals never engage in suicidal behavior or die by suicide, the treatment of psychiatric disorder is likely to be necessary but may not be sufficient to prevent suicidal behavior.

Mood disorders are strongly associated with suicidal ideation, attempts, and suicides. Approximately 60 percent of adolescent suicide victims had a mood disorder at the time of death. Bipolar disorder conveys a particularly high risk of suicidal attempts and completions, especially when the patient is experiencing rapid cycling or a mixed state. About one-third of clinically referred youth with bipolar disorder report having made at least one suicide attempt. Among the symptoms of depression most closely associated with suicidal ideation and behavior are insomnia, agitation, and irritability. Longitudinal follow-up of one study of adolescent-onset depression found a 10-year rate of suicide of 7.7 percent versus no suicides among the controls.

Anxiety disorders—specifically social anxiety, panic disorder, and post-traumatic stress disorder—have all been reported to be associated with suicidal ideation and attempts, although most studies find that anxiety most strongly contributes to suicidal risk when comorbid with mood disorder. Suicide and attempted suicide are also commonly associated with alcohol and substance abuse disorders, especially when these conditions are comorbid with mood disorders. Alcohol abuse differentiates ideators and attempters, possibly by reducing restraint against engaging in suicidal behavior in an individual already contemplating suicide. In one large study, the prototypical older adolescent male who died by suicide was triply comorbid with mood disorder, conduct disorder, and substance abuse. The risk of suicide and suicidal behavior among incarcerated youth is very high.

Other conditions, such as schizophrenia and eating disorders, also have a high lifetime risk of suicide attempt and suicide fatality, but in adolescence is usually associated with suicide attempts, with the increased mortality risk emerging during young adulthood.

Health Risk Behaviors. Suicidal behavior most commonly occurs as

part of a constellation of other health risk behaviors, such as NSSI, binge drinking, abnormal eating behavior (either restricting or bingeing), weapon carrying, and having unprotected sex. Therefore, it is important to assess for the range of health risk behaviors when assessing suicidal risk. Those who engage in self-poisoning not only have an increased risk from dying by suicide but also have a 10-fold increased risk of accidental death as well. Studies have shown that common risk factors for these health risk behaviors include impulsivity and poor problem-solving skills, a weak connection between parent and child and/or a conflictual parent–child relationship, low degree of parental supervision and monitoring, poor connection between child and school, and association with deviant peers.

Medical Conditions. Some specific chronic illnesses show higher rates of depression and suicidal behavior, particularly in illnesses that involve the central nervous system (e.g., migraine and epilepsy), or inflammation (e.g., inflammatory bowel disorders and asthma). There appear to be three components explaining the increased risk of depression and suicidal behavior in chronic medical disorder. First, there is a general effect of chronic illness that results in pain, disability, and disrupts the ability to enjoy oneself and achieve mastery. Second, there are specific pathophysiological aspects of the diseases that increase the risk of depression and suicidal ideation and behavior, as noted above. Third, there may be aspects of treatment that increase the risk of depression and suicidal ideation, such as the use of some antiepileptic drugs, interferon, and steroids.

Psychological Factors. Psychological characteristics that differentiate adolescent suicide attempters from psychiatrically disorder comparison groups include impulsivity, impulsive aggression (the tendency to respond to frustration or provocation with hostility or aggression), and cognitive bias and attraction to suicide.

Most adolescent suicide attempts are impulsive, so it is not surprising that impulsivity is a strong correlate of suicidal behavior. Neurocognitive testing has demonstrated that adolescent suicide attempters make impulsive decisions and show a failure to learn from consequences. In addition, impulsive aggression, as measured by self-report, assessment of Cluster B traits, and neurocognitive testing, is associated with suicidal behavior. Impulsive aggression also predicts the onset of mood disorder, which in turn predicts the familial transmission of suicidal behavior. Disordered emotion regulation, characterized as having a lower threshold for dysregulation, is showing more extreme and a more prolonged response to provocation. Emotion dysregulation has been demonstrated with self-report, neurocognitive, and fMRI studies as a key contributor to suicidal risk.

There also is evidence that suicide attempters are more likely to show a self-identification with death and suicidal behavior that is detectable on an Implicit Association Test, and that this increased self-identification with suicide is a robust predictor of future suicidal behavior.

Same-sex attraction has been consistently shown to be a risk factor for suicidal behavior in youth, in part mediated by family and peer rejection, and an increased rate of past maltreatment and sexual exploitation, which in turn accounts for the increased rates of mood, substance abuse, and suicidal behavior.

Familial and Environmental Factors. The parents of adolescent suicide attempters and completers show much higher rates of depression, substance abuse, and assaultive behavior than do the parents of psychiatric and normal controls. Adoption, twin, and family studies also show that the suicidal behavior is transmitted within families independent of the transmission of psychiatric disorder. For example, monozygotic twins show a higher concordance for suicidal behavior than do dizygotic twins, even after controlling for the concordance of psychiatric disorder. The first-degree relatives of adolescent attempters and completers show a two- to sixfold increase in the risk of suicidal behavior, even after controlling for the increased risk of familial psychopathology. Studies show that the offspring of depressed suicide attempters are at much higher risk of making an attempt than are the offspring of depressed, nonattempting parents. In addition, greater family loading is related to a greater risk and an earlier age of onset of suicidal behavior. The familial transmission of suicidal behavior is mediated by the familial transmission of impulsive aggressive traits.

However, in addition to evidence that suicidal behavior is heritable, there is also substantial evidence for a role for familial–environmental factors. Parent–child discord, perceived lack of support, and high levels of criticism and hostility are associated with child suicide attempt. Conversely, expressing high parent–child warmth, having high levels of parental supervision, and spending time together (e.g., eating dinner together and engaging in leisure time together) are protective against suicidal behavior. Some studies indicate that having a moral objection to suicide is also protective against suicidal behavior.

Parental psychiatric hospitalization and parental loss, the latter especially true in youth who lose their parent prior to the age of 12, are both associated with an increased risk of suicide in offspring. Suicide among either family or peers does not seem to increase the risk of imitation, but a suicide attempt in a friend is prospectively associated with an increased risk of an adolescent attempt. Although it is difficult to differentiate the effects of assortative friendships from imitation, assortative friendships alone would not explain the *timing* of the relationship between peer

attempts.

The most clinically significant familial–environmental risk factor for suicidal behavior is maltreatment, namely physical and sexual abuse, and emotional and physical neglect, with the strongest associations being reported between sexual abuse and suicidal behavior. The population-attributable risk of sexual abuse for suicidal behavior has been estimated as slightly less than 20 percent, meaning that, in theory, one in five cases of suicide attempt could be eliminated with the elimination of sexual abuse. In reality, the relationship between abuse and suicidal behavior is more complicated because abuse occurs within the social context of socioeconomic strain, family disruption, parental history of abuse, parental depression, substance abuse, suicidal behavior, and low parental monitoring and supervision. The likelihood of suicidal behavior is greater with greater severity of abuse—for example, with vaginal or anal penetration, as compared to molestation, the latter of which is not associated with an increased risk of suicidal behavior.

Youth at risk of suicidal behavior are not well connected to school, work, or family. Youth who are engaged in bullying, are victimized by other peers, or both are at increased risk of suicidal ideation and behavior. Students at risk of dropping out of school, as characterized by poor academic performance and attendance, are also at high suicidal risk. Youth disconnected from all major support systems are at very high risk of completed suicide, although it is likely that other factors such as depression and substance abuse that contribute to suicidal risk also contribute to the disruption of these connections. Conversely, youth who have a strong connection to school, even in the face of other risk factors, experience some protection from suicidal risk. A deviant peer group is associated with increased risk of suicidal behavior, in part because such a group encourages behavior that may lead to precipitants for suicidal behavior, such as a disciplinary or legal crisis. Conversely, youth otherwise at high risk, namely those with a history of abuse, are protected against suicidal risk by having a prosocial peer group.

Exposure to Suicidal Behavior. Approximately 5 to 10 percent of all youth suicides occur in time-space structures, implying at least the possibility that one suicide increases the risk of suicidal behavior in those who are exposed. Studies of the effect of media publicity about suicide have consistently shown that such publicity is followed by an increase in suicide and suicidal behavior, most markedly in the young. The increase is proportional to the amount of publicity, the notoriety of the individual who committed suicide, and the extent to which the report romanticized the suicide as compared to presenting information that describes the relationship between suicide and psychiatric illness. In some instances, specificity of method choice in imitation has also been demonstrated.

Biological Factors. On neurocognitive tasks, adolescent suicide attempters show a bias toward suicidal preoccupation, impaired reward learning, and a tendency toward more risky decision making. Neuroimaging studies of adolescent depressed suicide attempters, compared to depressed nonattempters, and healthy controls show alterations of attention and salience networks that are not evinced during "cold" cognitive tasks, but only emerge with emotional stimuli (e.g., exposure to angry faces). Overall, these findings are consistent with a profile of impulsive aggression, a tendency to risk taking, and poor emotion regulation that are known clinical characteristics of adolescent suicide attempters. Alteration in HPA axis and in levels of inflammatory cytokines may also be related to risk of suicidal behavior. Postmortem studies in adolescents who died by suicide have demonstrated the greatest degree of alteration in the prefrontal cortex and hippocampus, areas associated with known deficits for suicidal individuals, namely emotion regulation and problem solving. These brain studies have shown alteration in 5-HT_{2A} binding, decreased activity of protein kinase A and C, downregulation in cAMP response element-binding (CREB) protein, and decreased activity of brain-derived neurotrophic factor (BDNF), the latter two of which are involved in signaling and protection from the neurotoxic effects of stress.

Course and Prognosis

Suicidal behavior is highly recurrent. Around 15 to 30 percent of adolescents reattempt suicide with 1 year of the initial attempt, and the risk of a completed suicide is around 0.5 to 1 percent per year. Factors that discriminate between those who die by suicide and those hospitalized for suicidal ideation or an attempt include male sex, availability of a gun, mood disorder comorbid with substance abuse or conduct disorder, diagnosis of bipolar disorder, and high suicidal intent. Among those adolescents who engage in self-poisoning, prospective studies show that the hazard of death by suicide and accidents is elevated more than 40-fold, with a mean time a suicidal death was 1.6 years after presentation in the emergency department. Predictors of suicide in this sample of youth who took overdoses included male sex, older age, history of multiple overdoses, depression, and previous psychiatric care.

Assessment of Imminent Suicidal Risk

Often, the clinician is called upon to assess a patient for imminent suicidal risk, meaning whether the person is likely to engage in suicidal behavior in the next 24 to 48 hours. Suicide occurs because of an imbalance between distress and restraint. Factors that increase distress and that decrease restraint increase imminent suicidal risk. High distress is found in patients with very high anxiety, hopelessness a mixed bipolar state, agitation,

psychosis, or emotional dysregulation. Insomnia is a particularly lethal contributor, because it tends to both increase distress and decrease restraint. Factors that decrease restraint include availability of a lethal means of suicide, impulsivity, alcohol and substance abuse, or feeling that people will not care or will be relieved by the person's suicide. Acute crisis intervention to decrease suicidal risk aims to decrease distress and augment restraint.

Treatment

Although the treatment of depression is an important component of reducing suicidal risk, at least in depressed patients, adolescent depressed patients who are also suicidal probably require additional targeted interventions. Suicidal ideation is highly correlated with the severity of depression, and clinical trials of child and adolescent depression have shown a concomitant decrease in suicidal ideation along with reduction in depression. In comparing clinical trials of fluoxetine in those under and over the age of 24, those depressed individuals over the age of 24 showed improvement in both depression and suicidal ideation, whereas in those under the age of 24, depression improved just as much as it did in older subjects, but suicidal ideation did not improve to the same degree. This may be due to the fact that, although depression is salient to suicidal behavior across the life span, it accounts for less of the variance in suicidal ideation and behavior in younger people compared to mid-life and elderly adults. There is some evidence that use of antidepressants is associated with a slight increase in the risk of suicidal events (defined as either new onset or increase in ideation, or an attempt). These events are almost all increases in suicidal ideation, with relatively few attempts and no suicide completions, so that the clinical significance of these events is unclear. Predictors of the development of these events include high levels of baseline suicidal ideation and irritability. In one meta-analysis of the benefits and risks of antidepressants in child and adolescent depression found an increased rate of spontaneous events of 7 for every 1,000 patients treated and that 11 times more individuals benefited from the medication than developed a suicidal event, which, in the view of many but not all clinicians and families constitutes an acceptable risk–benefit ratio.

In contrast, pharmacoepidemiological studies consistently show that increases in sales or prescriptions of antidepressants are related to a lower suicide rate both in cross-sectional and longitudinal studies. The apparent discrepancy between the higher rate of suicidal events in clinical trials and the protective effect of antidepressants in pharmacoepidemiological trials may be attributed to the following differences between randomized clinical trials and pharmacoepidemiological studies: outcome (suicidal events in trials vs. suicide in pharmacoepidemiological studies), patient selection (those with high suicidal risk excluded from clinical trials), sample size

(much larger in pharmacoepidemiological studies), and time frame (much shorter in clinical trials). Therefore, pharmacoepidemiological studies may be more representative of the "real world," and much better able to detect effects on suicide and suicidal behavior, even though clinical trials are conducted with more rigorous experimental control, albeit in high selected patient samples studied over relative brief periods of time.

There are no definitive psychosocial or pharmacological treatments for suicidal behavior. In clinical trials of the treatment for depression, suicidal ideation declines with the treatment of depression, and in some, but not all studies, the combination of antidepressant and CBT produces the most rapid decline in suicidal ideation. While there are no definitive studies for the treatment of suicidal behavior, there are four promising treatment approaches. Attachment-based family therapy, which increases supportive interaction between parent and adolescent, has been shown to reduce depression and suicidal ideation in one clinical trial. An integrated CBT with a strong substance abuse and family treatment component was shown to reduce suicide attempts more so than treatment as usual. Mentalization, which teaches youth to conceptualize actions in the forms of thoughts and feelings, has been shown to reduce self-harm (which includes both suicide attempts and NSSI) more so than treatment as usual. A program to promote more positive parent–child interactions, when added to treatment as usual, has been shown to reduce suicidal risk related to usual care alone. Finally, an adaptation of Dialectic Behavior Therapy (DBT), which teaches emotion regulation and interpersonal effectiveness skills, was shown to reduce self-harm behaviors to a much greater extent than the usual treatment. All of these treatment approaches await replication with larger samples by groups not associated with the development of the treatment before they can be considered "evidence-based." There have been no studies of pharmacological treatments for youth with suicidal behavior, although meta-analyses in adults suggest that lithium may be efficacious in preventing suicide in individuals with bipolar, and even unipolar, depression.

Clinical guidelines for the management of suicidal youth support treating the related psychiatric disorder and addressing psychosocial risk factors for suicidal behavior, such as family discord, emotional dysregulation, and dysfunctional problem solving. Best practice recommends the development of a safety plan, that is, *a plan shared by the family, patient, and clinician that can be utilized to avoid precipitants for recurrent suicidal behavior and to cope with suicidal ideation if it reoccurs*. The development of a safety plan involves a review of the sequence of emotions, behaviors, thoughts, and events leading up to the attempt and identification of the approaches that are simplest and most likely to be successful for coping with ideation and suicidal urges in the short term, such as relaxation, avoidance (leaving the room if an argument

appears to be imminent), seeking support at home or from a friend, and calling the clinician or his or her designatee. Written and verbal no-suicide contracts have been shown not to reduce the risk of subsequent suicidal behavior and are not recommended. Current guidelines recommend that the restrictiveness of the care of the suicidal individual be proportional to the assessed suicidal risk, including high suicidal ideation with inability to formulate and/or adhere to a safety plan. However, there has never been an empirical evaluation of the therapeutic benefit of psychiatric hospitalization. Post-discharge from psychiatric hospital is a very high risk period for suicide and suicidal behavior, and some evidence suggests that better post-discharge assertive follow-up, availability of 24-hour crisis services, multidisciplinary reviews of patient suicides, and availability of dual-diagnosis services all can contribute to reductions in regional post-discharge patient suicides.

There have been relatively few evaluations of programs intended to prevent suicidal behavior in adolescents. The Signs of Suicide (SOS), which combines screening and identification of at-risk students with education about depression and suicide, was shown, in a randomized clinical trial, result in greater knowledge and more adaptive attitudes toward depression and suicide, and a lower rate of attempts among youth exposed to the program. In a very large, multicountry cluster-randomized clinical trial based conducted in Europe, a program similar to SOS was compared to gatekeeper training, screening and referral, and a psychoeducational control intervention. Only the youth mental health awareness intervention showed a decrement in both severe suicidal ideation and suicide attempts. One universal preventive intervention delivered to first-graders in poor, urban neighborhoods, "The Good Behavior Game," has been shown in one sample, to be associated with a reduction in suicidal ideation and behavior two decades later.

In light of the paucity of empirical studies, it is clear that treatment studies of suicidal individuals are greatly needed, and in addition, it is important to include suicidal individuals in clinical trials that focus on depression. Current guidelines recommend that care for the suicidal adolescent include an assessment of the proper level of care to safely deliver the treatment, the development and continual updating of a safety plan, securing or removing lethal agents from the home, treating the underlying psychiatric disorders, and addressing the psychosocial issues, such as family discord and poor emotional regulation skills that have been found to be salient to suicidal risk.

▲ 51.2 Early-Onset Bipolar Disorder

GABRIELLE A. CARLSON, M.D., STEPHANIE E. MEYER, PH.D., AND CAROLY SUE PATAKI, M.D.

INTRODUCTION

The frequency with which early-onset bipolar I disorder (BP) occurs in children is controversial compared to onsets after puberty which more

closely resemble classic adult BP. It is especially challenging to identify a manic episode in a prepubertal child, partly due to the frequent absence of distinct mood episodes, as well as the difficulty distinguishing it from severe attention-deficit/hyperactivity disorder (ADHD), which is may be comorbid with mania in children. Relying purely on symptoms of mania rather than discrete episodes has caused a significant increase in the diagnosis of bipolar spectrum disorders in children. There have been concerns over the last 15 to 20 years about whether children who appear to meet symptom criteria for mania grow up to be adults with bipolar disorder.

The confusion between severe ADHD and mania evolved from a series of diagnostic criteria changes in earlier versions of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM), in which *emotion dysregulation* was removed as a core feature of ADHD, and the demarcation of an *episode* of mania became less well defined. DSM-5 now mandates that in mania, both "an abnormal and persistently elevated, expansive or irritable mood" *and* "persistently increased goal-directed activity or energy" are present. DSM-5 further clarifies an episode by specifying that changes in mood and behavior must vary to a *significant degree* and represent an *observable change* from usual behavior. In an effort to provide a diagnosis for youth who are chronically (vs. episodically) irritable, explosive, and equally disabled, but without other symptoms of mania, a new diagnosis "disruptive mood dysregulation disorder" was added to DSM-5 to identify children whose mood is ". . . persistently irritable or angry most of the day, nearly every day, and is observable to others" (DSM-5).

Definition

The episodic nature of mania and depression has been the classic hallmark of bipolar disorder. The DSM-5 defines an episode as a "distinct period" different from the person's "usual self" during which specific symptoms co-occur. For mania, these include an "abnormally and persistently elevated, expansive, or irritable mood" *and* "persistently increased goal-directed activity or energy," accompanied by at least three additional symptoms (four if mood is irritable), including inflated self-esteem or grandiosity, decreased need for sleep, pressured speech, flight of ideas, distractibility, increased activity in work or socially, or psychomotor agitation, and excessive involvement in activities with a high potential for painful consequences. To meet full criteria for mania, symptoms must last at least 1 week, or 4 days for hypomania. The mood disturbance is "sufficiently severe to cause marked social or occupational functioning" or hospitalization and represents a change from prior functioning.

Episodes of depression, which must last a minimum of 2 weeks, are characterized in children by a sad, empty, or irritable mood along with

other symptoms of feeling worthless, preoccupation with death or suicide, agitation/feeling slowed down, and changes in appetite, sleep, and energy level. The diagnosis of dysthymic disorder, now called persistent depressive disorder, which is required to last 2 years in adults, has only a 1-year requirement in children.

In DSM-5, the coexistence of "three manic symptoms" within a depressive episode is enough to meet criteria for the specifier "with mixed features." Likewise, within a full manic episode, the presence of three depressive symptoms also merits the specifier "with mixed features." In fact, when a full manic episode and a full major depressive episode coexist, according to DSM-5, a diagnosis of manic episode with the specifier "with mixed features" should be made, due to the severity and impairment associated with mania.

HISTORY

Recognition of manic depression in child and adolescent psychiatry began with the dissemination of Kraepelin's monograph *Manic Depressive Insanity and Paranoia* after 1921. Child psychiatrists searched for the same condition in their patients but found mostly adolescent depression, which was highly familial. Mania was very rare, even in teens. Brief attempts to broaden the concept of manic depression for younger children were discouraged by a literature review conducted by Anthony and Scott in 1960 that used very stringent criteria to identify manic depression in youth. They found only 3 of 60 cases reported prior to puberty. However, the tension between restricting the diagnosis to classical presentations versus altering the criteria to fit children continues to the present.

In the 1960s, evidence of lithium's efficacy for treating adults with manic depression led to interest in identifying lithium-responsive clinical profiles in children. Early studies suggested that lithium response was most promising in early-onset cases resembling classic manic depression, whereas there was no support for the use of lithium in treating children with broader behavioral dysregulation. When standard symptom criteria became available in the 1970s for describing mania more precisely in adults, Weinberg and Brumback, two pediatric neurologists, adapted these criteria for use with children. The concept of a "manic-depressive variant syndrome of childhood" was subsequently introduced in 1979 and characterized children between 6 and 16 years of age who were hyperreactive to seemingly minor events and were also hyperactive, had disruptions in interpersonal relationships, and often had a family history of manic depression.

By the 1980s, there was increasing acceptance of the diagnosis of manic depression, or bipolar disorder as it became known to the field, in youth. Research efforts initially focused on describing the phenomenology of pediatric bipolar disorder and established standard assessment techniques.

In more recent years, there has been a surge of genetic, high-risk, and treatment studies, as well as investigations of neurobiological, behavioral, and physiological markers. However, decades later, there continues to be disagreement regarding the definition and application of specific criteria for bipolar disorder in children, thus significantly slowing these efforts and complicating the interpretation of findings.

Epidemiology

Prevalence rates of bipolar disorder vary depending on the whether bipolar I, II, or spectrum conditions are included, the age studied, the definitions and methods used to make the diagnosis, and the type of sample interviewed. Furthermore, rates of BP can vary depending on whether shared symptoms of ADHD and BP are counted toward each condition, or if shared symptoms must have exacerbated in order to be counted toward a manic episode. Rates of reported lifetime mania in youth have varied from 0.1 percent by Stringaris and colleagues, to 1.7 percent in adolescents, and 2.5 percent for bipolar I and II lifetime disorders among adolescents, by Merikangas and colleagues. In a meta-analysis of studies worldwide, Van Meter and colleagues reported an overall rate of 1.2 percent for bipolar I disorder. The sample most reliably addressed adolescents as the information on children was scanty. Prevalence rates of subthreshold symptoms of bipolar disorder range from 5.7 percent among adolescents in the Oregon Adolescent Depression Study to at least 10 percent in the mid-Missouri sample, and between 2.4 and 6 percent in adult samples. Bipolar spectrum disorder rates from the recent VanMeter meta-analysis were as high as percent. While tightly defined bipolar spectrum disorder appears to have an up to 40 percent rate of conversion to BP I or II, manic symptoms alone are less often associated with such a conversion as seen in both the Longitudinal Assessment of Manic Symptom Study (LAMS), where mania rarely developed, and the Oregon Adolescent Depression Study, where it never developed.

The diagnosis (vs. the actual condition) of bipolar disorder among youth in the community has increased dramatically over the last decade. A study of outpatient physician visits in the United States found that juvenile-onset cases of bipolar disorder comprised 42 percent of outpatient mental health-related visits in 2003, an increase from 6.67 percent of cases in the early 1990s. Another study, using data from the National Hospital Discharge Survey, revealed increases in the rate of bipolar disorder diagnoses among psychiatrically hospitalized children from 10 percent in 1996 to 34.11 percent in 2004, and from 10.24 percent to 25.86 percent among psychiatrically hospitalized adolescents during that same period. The increased rate of bipolar disorder appeared to reflect a shift in diagnostic practices such that childhood mood lability and aggression, which previously might have been attributed to conduct problems, ADHD or

impaired family relationships, has increasingly being considered by some clinicians as indicative of bipolar disorder. The psychopharmacology clinic at Massachusetts General Hospital (MGH), however, using the same assessments for the last 15 years, reported a stable rate of youth bipolar disorder in their clinic of 16 percent, over this time period. Although one cannot generalize from one clinic to the next, the consistency of the MGH rate over time suggests that the actual number of children with bipolar disorder has probably not increased.

ETIOLOGY, MECHANISMS, AND RISK FACTORS

Estimates from adult twin studies suggest that genetic influences explain approximately 60 to 93 percent of the variance in bipolar disorder, whereas shared and unique environmental factors account for 30 to 40 percent and 10 to 21 percent, respectively. There are no "narrow phenotype" twin studies of early-onset bipolar disorder. However, two large-scale twin studies using the *Child Behavior Checklist-Juvenile Bipolar Disorder/Dysregulation Profile* (CBCL-JBD) as a proxy measure of broad phenotype BP suggested that genetic influences account for considerable variance in scores, although shared environmental factors may play a significant role in the specific presentation course of this phenotype. Other data from these studies also suggested that most children evaluated with the CBCL-JBD do not have traditionally defined BP I or II. Environmental risk factors including sexual, physical abuse, or neglect, harsh parenting, poor social support, and prenatal exposure to substances may interact with genetic factors resulting in earlier onset of BP disorder. In turn, earlier onset of first BP episode and exposure to abuse have been found in the Course and Outcome of Bipolar Youth (COBY) study follow-up to be prevalent in the group with the worst outcome.

Elevated rates of bipolar disorder have been found among relatives of children with narrow phenotype bipolar disorder as compared to adult-onset cases. However, there does not appear to be an increased risk of narrow phenotype bipolar disorder within families of children with broad phenotype bipolar disorder/severe mood dysregulation (SMD), suggesting that broad and narrow BP may be etiologically distinct. Moreover, symptoms of affective dysregulation and attention problems appear to segregate together in certain families. Whether this symptom profile represents a particularly virulent form of early-onset bipolar disorder or a marker of severe but nonspecific psychopathology has yet to be determined.

Rates of depression, anxiety, and behavioral disorders (especially ADHD) are consistently elevated in offspring of parents with BP and are considerably higher than rates of bipolar I disorder. Rates of bipolar disorder I among high-risk youth, however (4 to 6 percent in most studies), are significantly higher than in offspring of well parents, for whom rates of

BP are negligible. Bipolar spectrum conditions occur in up to 38 percent of offspring of bipolar parents. Rates of childhood BP disorders depend on how broadly the bipolar spectrum is defined, and also the clinical setting in which parents and children are evaluated. Parents in tertiary care clinics appear to have offspring with more psychopathology than parents in community samples, suggesting gene–environment interactions.

BRAIN STRUCTURE AND FUNCTION

Youth with bipolar disorder exhibit impairments in global social functioning, and display particular difficulties with the identification of emotional faces. Whitney and colleagues have documented that even youth at risk of BP, such as offspring of bipolar parents, demonstrate impaired social reciprocity. Significant brain networks that process facial expressions include the amygdala and the prefrontal cortex. Garrett and colleagues have shown that a combination of deficient prefrontal cortex regulation and heightened amygdala response to emotional stimuli occurs in youth with bipolar disorder.

Early-onset BP may reflect earlier evidence of neurocognitive deficits, but with a potential for improvement with treatment, however, this remains to be documented.

Similar to studies of adults, results from both structural and functional magnetic resonance imaging (MRI) studies indicate that early-onset bipolar disorder is associated with abnormalities in cortical and subcortical brain regions involved in the regulation of emotion. Two replicated morphological findings are the presence of white matter hyperintensities and decreased amygdala volume. In functional MRI (fMRI) studies, it appears that heightened activation of the amygdala during emotional challenges may interfere with attentional capacities in children with BP, increasing the probability that they will misinterpret the incoming stimuli (facial expression) and respond in an inappropriate manner.

Findings from studies using magnetic resonance spectroscopy, although preliminary, provide further support for the presence of cortical and subcortical abnormalities in pediatric bipolar disorder. Studies of youth meeting criteria for early-onset bipolar disorder have preliminary evidence of decreased *N*-acetylaspartate (a marker of neuronal density) in the prefrontal cortex and elevated myo-inositol levels (an indicator of decreased neuronal homeostasis) in the anterior cingulate cortex. Moreover, there is evidence to suggest that abnormal findings normalize with the introduction of medication treatment.

Assessment

The American Academy of Child and Adolescent Psychiatry (AACAP) Practice Parameter advocates (1) screening patients for mania and bipolar

depression, both current and past; (2) applying DSM criteria (currently DSM-5); (3) using the designation “bipolar NOS” for children with manic symptoms with durations of less than 4 days (called “other specified bipolar disorder in DSM-5); (4) examining for comorbidities; and (5) using caution when diagnosing preschool children.

Making an accurate diagnosis of bipolar disorder in children requires systematic and thoughtful evaluation procedures that go well beyond the simple application of DSM-5 criteria for mania and depression. Screening measures, completed by multiple informants (i.e., parent, teacher, child), are useful in alerting the clinician to current symptoms of mania, depression, and other possible comorbidities. Interviews with caregiver(s) and child and review of other diagnostic information are required. It is most useful to interview caregivers first because they are likely to provide the most reliable information, and this material can be presented within the child interview to address any discrepant responses. Caregiver interviews should include an overview of current symptoms, developmental history, and longitudinal course.

Although the most pertinent information regarding symptoms of mania and depression may come from the parent interview, the child interview is critical for eliciting important information regarding environmental factors contributing to mood variability, as well as features of other conditions that may be confused, or co-occur, with mania, including autism spectrum disorder, language or thought disorder, psychosis, anxiety, suicidal behavior, physical/sexual abuse, and substance use.

Structured and semistructured diagnostic interviews are used in research settings to elicit symptoms of bipolar disorder and other childhood conditions, and they may also be useful in clinical settings to confirm a diagnosis. The Schedule for Affective Disorders and Schizophrenia in Children (K-SADS) is the most commonly used interview and has a number of versions, including the K-SADS-PL (present and lifetime version) and a version developed at Washington University, the WASH-U-K-SADS. Clinical judgment is required to determine whether a respondent is under- or over-reporting symptoms, misinterpreting developmentally appropriate behaviors, or misunderstanding questions about clinical behaviors. To this end, it is critical that clinicians probe beyond affirmative responses to elicit examples of specific behaviors, as well as the context in which behaviors are occurring.

Several rating scales have been developed to measure the severity of mania. These include an interview measure, the Young Mania Rating Scale (Y-MRS), which is used in both adult and youth medication trials, and parent rating forms for the child, including the Child Mania Rating Scale, the General Behavior Inventory, and Parent Young Mania Rating Scale.

Collateral information, such as teacher input, is helpful in determining whether manic-like symptoms are occurring across settings. Although there

are discrepancies between parent and teacher reports, home and school observation can be useful. Outside assessments, including neuropsychological, occupational therapy, psychoeducational, speech and language assessments, and medical records, can also be extremely helpful in identifying developmental, cognitive, and medical factors that may contribute to emotional dysregulation and complicate episodes of mania and depression. It may also be useful, in certain cases, to obtain a sleep-deprived encephalogram (EEG), a sleep EEG for sleep apnea, a thorough neurological assessment, or laboratory tests. Family history of mood disorder, bipolar and unipolar, and comorbid psychiatric disorders including oppositional defiant disorder, ADHD, learning disorders, and autism spectrum disorders should be assessed as part of the parent interview. If there is a positive family history for bipolar disorder, it is important to probe for details regarding clinical presentation, comorbid conditions, and response to treatment.

Diagnostic Issues Relevant to Children

Defining a mood episode in children, especially younger children, is complicated by the fact that a "usual self," developmentally, is a moving target. Thus, a previously docile infant who enters the "terrible two's" may be developmentally normative, and yet approximate criteria for mania, if this is defined as a persistent mood state different from the child's usual self. Children stressed by school may have observable persistent mood "episodes" which subside over the summer. Geller and colleagues proposed a definitional framework in which the term "episode" describes the length of time that an individual exhibits all criteria for mania/hypomania or depression. The term "cycle," then, refers to shifts in mood that occur throughout each day of the episode, which many consider mood lability occurring within the context of a single episode. Studies that used this framework reported that between 78 and 99 percent of children diagnosed with bipolar disorder experienced daily cycling within an episode duration ranging from 1 to 4 years. Indeed, the boundaries of an episode are blurred both in their onset and offset. In adult studies, in which a typical manic episode lasts for 4 to 8 months, a euthymic period of 8 weeks constitutes remission. Using the above framework, it is unclear how long to construe a remission if most of an individual's childhood has been considered an episode.

Efforts have been made to adapt adult definitions of the cardinal symptoms of mania for young children, taking into account developmental differences. However, children may have difficulties with the concept of elation, or increased self-esteem, which requires an ability to self-assess, a skill absent in young children. Finally, silliness and bravado, which some clinicians construe as childhood manifestations of euphoria and grandiosity, may also be seen in children with ADHD, autism spectrum

disorders, or social skills deficits.

What has emerged in attempts to apply DSM symptom criteria to children are descriptions of young people whose course does not resemble the episodic nature of bipolar disorder in late adolescents or adults. According to McClellan and colleagues, "outbursts of mood lability, irritability, reckless behavior, and aggression," which have come to represent the modal presentation of very early-onset bipolar disorder in the community, may represent a subtype of bipolar disorder or may characterize mood dysregulation that has no particular diagnostic specificity.

Leibenluft and colleagues at the National Institute of Mental Health (NIMH) have been exploring bipolar subtypes in an effort to distinguish between *narrow phenotype bipolar disorder* and a possible broad bipolar phenotype that they termed SMD. The narrow phenotype BP calls for direct application of the former DSM-IV-TR (and the current DSM-5) criteria for BP without modification, including the presence of clear manic/hypomanic episodes characterized by euphoric mood and/or grandiosity. SMD describes children exhibiting chronic irritability with extreme reactivity to negative stimuli and symptoms of hyperarousal. Up to 80 percent of children with SMD met DSM-IV-TR criteria for both ADHD and oppositional defiant disorder. Longitudinal follow-up of youth with chronic, but nonepisodic irritability and mood dysregulation, from community samples and clinical samples suggests that these youth are not destined for bipolar disorders, rather they are at risk of new-onset unipolar depressive disorders and anxiety disorders. The conceptualization of SMD has evolved into the new DSM-5 *Disruptive Mood Dysregulation Disorder* (DMDD); however, in contrast to SMD, DMDD does not include symptoms of hyperarousal, and it cannot coexist with oppositional defiant disorder, intermittent explosive disorder, or bipolar disorder. Other investigators have focused on symptoms rather than episodes. Geller and colleagues define *pediatric and early adolescent bipolar disorder* (PEABD) as requiring two of three cardinal symptoms of mania (euphoria, grandiosity, and/or irritability) but with reinterpretations of euphoria and grandiosity which is described in the Washington University version of the K-SADS. A third early-onset bipolar phenotype, used by Biederman, Wozniak, and colleagues at MGH, characterizes children who manifest severe, explosive irritability and other symptoms of mania, with or without accompanying grandiosity and euphoric mood.

Even where there is agreement regarding definitional parameters, there may be varying ways in which the criteria are applied or interpreted. In a study comparing diagnostic practices regarding pediatric mania in the United Kingdom and the United States, 73 psychiatrists from England and 85 psychiatrists in the United States were enlisted to formulate provisional diagnoses in five case vignettes, each describing a child with "possible

bipolar disorder." Only one case was considered to be a "classic" case of mania in a young adolescent, whereas four were chosen to capture the complexities of diagnosing bipolar disorder in children. In the first instance, a young woman developed a depression at age 10 years after the loss of her grandmother, which remitted with treatment. She later developed an acute, severe mania, which was clearly different from her otherwise unremarkable personality. In the second case, an 11-year-old girl with a long history of ADHD symptoms gradually became increasingly defiant and irritable, disregarding schoolwork, believing it was unnecessary, and became interested in pornographic Web sites. Her parents, however, not her teachers, complained of the more manic-like features. In the first case, there was good agreement on a diagnosis of mania. In the second, US clinicians diagnosed mania and ADHD; UK clinicians diagnosed ADHD and behavior disorder. In other vignettes as well, US psychiatrists were significantly more likely to diagnose mania in children than were UK psychiatrists, whereas UK psychiatrists were more likely to view these children as exhibiting attention-deficit disorder, autism spectrum disorders, and adjustment disorders. The authors concluded that "results illustrate the current confusion that exists surrounding the diagnosis of prepubertal mania, where similar symptoms may be interpreted to have different diagnostic meanings."

Comorbidities

Children and adolescents meeting criteria for BP nearly always present with co-occurring conditions. Symptoms of mania may overlap with those of concurrent ADHD and oppositional defiant/conduct disorder, depression, and anxiety, precisely the conditions with which co-occurrence is highest. ADHD is the most common comorbid diagnosis among children with BP, with published rates of 70 to 95 percent among preadolescent youth, and 50 percent among adolescents. The frequency of comorbid diagnoses is influenced by how different interviews manage symptom overlap between mania and the comorbid disorder. If the interview or investigator deems that a given symptom counts toward all disorders (as does the WASH-U-KSADS) or interviews from Biederman and colleagues, rates of comorbid ADHD and ODD will be higher than if symptoms counted toward mania are only those presenting an intensity significantly beyond a usual baseline. Thus, counting any overlapping symptoms toward all diagnoses, the Treatment of Early Mania Study found that 92.8 percent of the youth with BP had comorbid ADHD in their index episode.

The LAMS study identified ADHD, bipolar spectrum disorders, and comorbidity in a multisite sample of 707 children who were rated by their parents as having elevated symptoms of mania. The LAMS study found that 76.2 percent of their sample met criteria for ADHD, 22.9 percent met criteria for bipolar spectrum disorders, 16.5 percent had both disorders,

and 17.5 percent of the sample had neither disorder. The majority of children who met criteria for BP I disorder (69 percent) also had ADHD. The high rate of comorbid ADHD in the entire sample was best explained by independent rates of these disorders in youth, rather than a hypothesis that ADHD is a risk factor for bipolar disorder in youth.

Rates of conduct disorder and oppositional defiant disorder are reported to be as high as 79 percent in youth with BP. The combination of externalizing disorders and bipolar disorder appears to run in families and is associated with significant functional morbidity. Comorbid anxiety disorders have been reported in up to 77 percent of children with narrow phenotype bipolar disorder, with particularly high rates of generalized anxiety disorder, separation anxiety, and specific phobia. There is some evidence that, in a number of cases, anxiety symptoms may intensify during episodes of depression and mania, resolving when mood symptoms are effectively treated. Finally, features of autism spectrum disorders appear to be quite common among youth with narrow phenotype bipolar disorder, with one study reporting that approximately 20 percent of their sample met full criteria for a comorbid autism spectrum condition.

As with adults, substance and alcohol abuse are common comorbidities in adolescents with BP. ADHD and conduct disorder are both risk factors for the development of substance use problems. In an epidemiological sample, young bipolar patients with substance use problems had conduct disorder rates three times higher (52 percent) than those without substance abuse (14.8 percent; $p < 0.01$). By comparison, young subjects without either mania or substance problems had conduct disorder rates of only 7.75 percent. Substance abuse in bipolar adults may be more related to childhood conduct disorder than uncomplicated bipolar disorder. Nevertheless, substance abuse and bipolar disorder clearly exacerbate each other, and youth with bipolar disorder are at high risk of substance abuse.

For externalizing disorders comorbid with BP there appears to be a developmental shift over time. Rates are highest in children (greater than 75 percent), lower in adolescence (approximately 50 percent, especially if both depression and mania have onset after puberty), and lowest, but still present, in adults, in whom rate of lifetime ADHD has been reported to be approximately 20 percent. Similarly, conduct disorder/antisocial personality co-occur in adults at double the rates in those with bipolar onset before age 30 years (33 percent) versus after age 30 years (16 percent).

Differential Diagnosis

The five most common clinical conditions to be distinguished from bipolar disorder are ones with which it is most often comorbid. Severe ADHD and oppositional defiant disorder in young children are the ones most often confused with mania. The reason for emphasis on episodes, euphoria, and

grandiosity in making the diagnosis of mania emerges because ADHD is, by contrast, a chronic (rather than episodic) disorder for which elation and grandiosity are not considered symptoms. The clearer these symptoms and behaviors are, the easier the differential diagnosis. If severe irritability and explosiveness become the hallmark of early-onset mania, the distinction from severe ADHD with oppositional defiant disorder is extremely difficult. The new "disruptive mood dysregulation disorder" which identifies youth with temper outbursts and chronic, severe irritability, cannot be diagnosed in the presence of manic symptoms lasting more than a day. This exclusion was included in order to help separate children with non-episodic irritability from those with mania. Another difficult diagnostic issue is the development of conduct disorder in older children with ADHD. Children with conduct disorder often are very irritable and oppositional, stay out late in defiance of their parents, and thus, may appear to need less sleep, engage in early sexual behavior and drug use (pleasure-seeking without regard for consequences), and are hedonistic in their self-interest, caring little for the rights of others.

A third difficult diagnostic distinction is between an agitated, anxious depression and a mixed episode of mania. This complicated differential diagnosis is not unique to children and adolescents. In adult psychiatry, the trend has been to err on the side of making a diagnosis of bipolar disorder and avoiding medications to treat the depression and anxiety in order to diminish the potential risk of exacerbating mania. It is necessary to keep an open mind about this issue, and if treatments for mania are not helpful, a diagnosis of depression and anxiety alone should be reconsidered.

Substance abuse not only may render a teen depressed, irritable, emotionally labile, and euphoric, it may also precipitate a psychosis that may be indistinguishable from mania. In the short term, it is often impossible to determine whether the psychopathology is primary or substance induced.

Finally, especially in adolescence, first-episode schizophrenia poses an important differential diagnosis. For many years, schizophrenia was considered to be the only psychosis that occurred in adolescents. It is now understood that depression with psychosis (often a harbinger of bipolar disorder) and mania with psychosis are equally likely to occur. In the clearest cases, teens developing schizophrenia will have an insidious onset to psychosis, long-standing cognitive difficulties, and prominent and bizarre delusions. However, that may not be the case, and only careful follow-up over several years will allow the true diagnosis to emerge.

Jake is a 14-year-old male, 9th grader who was brought to the emergency room due to confusion, agitation, and bizarre behavior. Jake has had behavioral and academic problems since kindergarten. In the first grade, Jake began to have problems paying attention, he was aggressive with his peers, and seemed unable to learn letters and numbers at the same rate as his classmates. An individualized Educational Plan was developed for Jake and he was

provided a resource room in which he received individualized help each day with reading, writing skills, and math. He progressed slowly and by the time he had reached the 5th grade he was only scoring at <25 percentile on academic achievement tests, and had begun to express a dislike for school. During the emergency room interview, Jake disclosed that he had been sexually abused from ages 7 to 13 years by his mother's boyfriend, and that his mother never knew. By the time Jake entered middle school, he had developed moderate anxiety and depression, intermittently expressing suicidal ideation especially when he was frustrated about his school work and felt rejected by his peers. According to his parents, Jake started to become more irritable and erratic about a month prior to the emergency room visit. Over the course of the month, Jake became excessively religious, reading books all night, with increased activity and talking, praying in school, and threatening his teacher on several occasions. He was belligerent with the police when they were called by his school, and he was brought to the hospital in hand cuffs. When Jake arrived at the emergency room, he was confused, incoherent and posturing, expressed his believe that he was God, and also heard the voice of God, was getting messages from the TV, and exhibited paranoid thoughts that creatures from space would kill him.

During his hospitalization he was agitated, hyperverbal, paranoid, and continued to feel that he had special powers. He was started on olanzapine, and was titrated up to a dose of 20 mg/day. At the end of his month-long hospitalization, he was calmer and less paranoid, was no longer hearing voices and was willing to go home with his parents. His discharge diagnosis was bipolar I disorder, manic with psychotic features. After discharge, Jake returned home, he remained on his medication, and attempted to go back to school. He was placed on home instruction because he could not function. Even with a one-to-one tutor, he could concentrate for only brief periods of time. Jake said he felt emotionally flat, almost numb. It was concluded that he was depressed.

When Jake was evaluated psychiatrically 6 months after his hospital discharge, he was found to be sad, and lonely, socially isolated, introverted, suspicious, and he was experiencing illusions. He thought that he could read minds, had restricted emotions; and expressed depersonalization. He was not having auditory hallucinations, and no formal thought disorder was present. He was being treated with lithium, 1,500 mg per day along with olanzapine. At his 6 months evaluation, he was assessed to be in partial remission. Over the next year, Jake seemed to get back to "normal," and he went on to finish the 10th and 11th grades. By 24 months, after his initial hospitalization, however, Jake had another manic episode. He believed he was a saint from God and he had to stop crime; he felt powerful, slept less than 3 hours per night, talked a lot, could not concentrate, and had racing thoughts. Jake became hostile, irritable, and was suspicious of his mother, believing that she might be trying to poison him. Jake's olanzapine was increased to 30 mg/day, and his lithium increased to 1,800 mg/day. Over the next 2 months his mania resolved, but he became even less social, had trouble concentrating, and spent much of his time alone. He reported that he had problems with his memory.

By 48 months, after his initial hospitalization, Jake remained on lithium but experienced another manic episode with referential delusions and paranoia about his mother. After this episode of mania, Jake, now 18 years of age, was demoralized and no longer in school. He had managed to get his GED in between his manic episodes but he spent all day at home. He had very limited psychosocial functioning (watched TV and went shopping with his mother for food), and was not working. Jake's mood was flat, his affect blunted, he had concise speech but mild poverty of content. He was well groomed and had, mild deficits in face and body expression; marked poverty of speech, and long latency of response.

Jake's sister reported that he took medications reliably but noted that he had become more aggressive with each episode, and she was worried that he would never be able to hold a job or live on his own.

Course

There have been four areas of investigation into the outcome of bipolar disorder: (1) the duration and relapse rate of manic and depressive

episodes, (2) percent time symptomatic over longitudinal follow-up, (3) functional outcome, and (4) diagnostic stability (i.e., how likely is a youth to retain the diagnosis of bipolar disorder).

The median duration of an episode of mania in adults is 3 to 6 months. Mixed episodes, which last longer, have durations of about a year. In young people, where episodes are often "mixed," the duration is measured in years. However, in comparing episodes reported in research studies, it is important to pay attention to whether studies describe the index episode as mania, depression or do not specify the polarity of the episode. Depressive episodes are almost always longer than manic episodes.

Duration of episode (or time to remission), when remission is defined as 8 weeks of either no symptoms or subthreshold symptoms, varies widely in young people. In Geller's sample of children with a mean age at intake of 11 years, the index episode lasted 3.6 (±2.5) years.

The Course and Outcome of Bipolar Illness in Youth study (Birmaher et al., 2008, 2014) in which bipolar youth ages 7 to 17 years were combined from 3 different sites reported a median episode duration of 78 weeks. Purely adolescent-onset samples fare somewhat better. The median duration of index episode from one hospitalized sample (mean age 16 years) was 11 weeks; the mean in another was 29 ± 31 weeks. In older adolescents (mean age 17 years), median episode duration was 30 weeks. Outpatient teens with mania (average age 14 years) from India had a median episode duration of only 8.7 weeks. The reasons for these differences in duration are not clear.

Among those children and adolescents who achieve remission, rates of relapse range from 27 percent among community-based adolescents at 2-year follow-up to 70 percent among child and adolescent outpatients at 4-year follow-up.

General risk factors for longer episode duration include nonadherence with pharmacological treatment, rapid cycling, psychotic symptoms, earlier age of onset, low socioeconomic status, comorbid anxiety, ADHD, and/or disruptive behavior disorders. Alcohol use disorders and exposure to antidepressants have been associated with increased risk of recurrence; involvement in psychotherapy appears to have a protective effect. Notably, males diagnosed with pediatric bipolar disorder appear to have a less severe course with greater chance of recovery from the initial episode than females. Moreover, compared to children with bipolar I or II disorder, those with *unspecified* bipolar disorder endured a more chronic course of illness with persistent subthreshold symptoms and delayed treatment response.

Of 367 outpatient youths participating in the COBY study who were interviewed approximately every 6 months over an average period of 8 years, there were four distinct outcome groups based on a latent class growth analysis of percent time euthymic who were (I) "predominantly

euthymic" (24 percent of sample), (II) "moderately euthymic" (34.6 percent/ of sample), (III) "ill with improving course" (19.1 percent of sample), and (IV) "predominantly ill" (22.3 percent of the sample). Group I was found to be euthymic, on average for 84 percent of the 8 years; group II was euthymic for 47.3 percent of the 8 years study period; group III was euthymic for 42.8 percent of the 8 year period, and group IV was euthymic for 11.5 percent of the 8-year follow-up period. Factors related to a better course, with longer periods of euthymia included (1) older age at onset of symptoms and first episode, (2) less severe depression, (3) less severe manic or hypomanic symptoms, (4) less frequent subsyndromal episodes, (5) fewer suicide attempts, (6) lower rates of sexual abuse, and (7) less family history of bipolar disorder or substance use disorders. The youth in the groups with greater periods of euthymia had a less complicated course overall, with lower rates of comorbid ADHD and anxiety disorders, and lower rates of all psychiatric disorders in family members. In fact, almost half of the group with the most time euthymic did not experience another episode during the 8-year follow-up. However, although the other half of group I was also euthymic for about 84 percent of the 8-year study period, they did continue to have new mood episodes during the follow-up period.

Comprehensive investigation of the stability of diagnosis of bipolar disorder in adults is uncommon and has yet to be addressed in any large scale studies of children and adolescents. The questions regarding BP in youth are for whom will the cycles be mainly depressive, or manic, how often will they reoccur, and for whom will BP completely and forever remit? This is important to keep in mind to determine how long a medication (mood stabilizer or antipsychotic) should be administered during and after resolution of an episode, and whether there are observable predictors of longitudinal course. In a 10-year follow-up of early episode 15 to 50 years old patients ever diagnosed with bipolar disorder by Carlson and colleagues, diagnostic consistency occurred in only half the sample. Much of the diagnostic instability was predicated on change in course of illness. BPI became clearer over time in 17 percent (as people with psychotic depression developed mania for example), but in the rest, even though BPI seemed obvious early, other conditions emerged. The most powerful predictors of diagnostic instability (i.e., not maintaining a BPI diagnosis) were having any childhood psychopathology (OR 2.8, CI 1.4 to 5.6), and specifically having a childhood externalizing disorder (OR 4.7, CI 2.5 to 8.9). The more acute and uncomplicated the diagnosis at onset, the more stable the diagnosis; however, poor premorbid adjustment in terms of childhood psychopathology and nonacute onset predicted diagnosis change. Prognostic implications were substantial as the consistently diagnosed bipolar group had significantly better functioning on Global Assessment Functioning (GAF) (p <0.001), spent less time symptomatic over their first 48 months of illness (26 percent vs. 47 percent) (p <0.001)

and much less time psychotic (7 percent vs. 31 percent) (p <0.001). Jake, the case previously described, represents either a youth with poor-outcome bipolar disorder, or one who has developed negative symptoms and is better considered schizoaffective.

Functional outcome outside of symptom status has not yet been addressed in longer-term longitudinal studies. The Child Global Assessment Scale score in Geller and colleagues' 8-year follow-up of early-onset mania was 33.5 (SD 10.6) for those with the disorder at age 18 or older. Another 1-year follow-up study reported functional recovery in only 39 percent of the sample. ADHD comorbidity and poor medication adherence was associated with poor function. However, it appeared that functional outcome was also associated with syndromal status.

TREATMENT

Current evidence-base addresses both medication and psychosocial intervention with considerably more data for the former in the treatment of mania. Industry-sponsored clinical trials have addressed the relative efficacy of atypical antipsychotics with less robust data for anticonvulsants and some data supporting lithium. Trials of medication for bipolar depression are much smaller and to date, only one regimen has been shown to be more effective than placebo. Psychosocial interventions are beneficial in addition to medication not replacements for it. If a child has SMD or if rages are the behaviors being targeted, their frequency, intensity, number, and duration need to be monitored. Medication management also requires obtaining baseline laboratory tests relevant to the medication used and monitoring side effects.

Practice parameters and clinical guidelines, such as the AACAP Practice Parameters are consistent in advocating the importance of medication.

Pharmacotherapy

As part of the *Best Pharmaceutical Act for Children,* newly developed medications to be used in children or adolescents must be tested for safety and effectiveness in that sample. U.S. Food and Drug Administration (FDA) labeling requirements allow fewer studies to be done if the condition —in this case mania—is the same condition that exists in adults, such that similar measures to test safety and efficacy are valid in that age group. A consensus conference convened in 2002 established that youth between ages 10 and 17 years can experience the same condition. The same BP disorder in younger children was less well established, hence the cutoff at age 10 years. This is important because it means that the medications and doses used for adults are being studied in older children and adolescents.

As of 2015, lithium, chlorpromazine, olanzapine, quetiapine, risperidone, aripiprazole, and asenapine have FDA approval in adolescents.

Risperidone, aripiprazole, quetiapine and asenapine have approval for children aged 10 to 17 years of age. There has been a positive randomized clinical trial in youth for ziprasidone but no FDA approval yet as of this writing. Although medication treatment for mania is the same, youth and adult treatment responses are not identical. Until recently, although lithium had been approved for adolescent mania, there were no decent-sized, placebo-controlled trials to support this "grandfathered" approval, although open trials of lithium suggested response rates of 50 to 60 percent. Four of the atypical antipsychotic medication trials completed for pediatric bipolar disorder, were in response to an FDA written request. Olanzapine was tested in adolescents, flexibly dosed, because the written request had been issued before the FDA decision to include children down to age 10 years. With doses ranging between 10 and 20 mg, 44.8 percent of youth on olanzapine showed at least a 50 percent reduction in symptoms compared to a placebo response rate of 18.5 percent. This was significant ($p < 0.001$). The mean decrease from the baseline Y-MRS entry score of 33 was 17.7 points and the effect size was 0.84.

Other atypical antipsychotic trials for risperidone, aripiprazole, and quetiapine were required to use low- and high-dose alternatives. Both high and low doses of risperidone and aripiprazole were significantly effective as measured by a 50 percent reduction in Y-MRS entry scores and a decrease of Y-MRS scores of between 14 and 18 points compared to placebo responses of 8 to 10 points. In general, 45 to 65 percent of subjects improved on active medication versus 18 to 37 percent on placebo. The absolute treatment benefit (percentage of drug responders minus placebo responders) averaged 19 to 38 percent, and the number needed to treat (NNT) in successful trials in which drug was better than placebo varied from about 2.6 (high-dose aripiprazole and high-dose risperidone) to around 5 (low-dose aripiprazole and high-dose quetiapine). Side effects were usually greater for the high-dose condition without a correspondingly higher improvement.

Several anticonvulsants and lithium have FDA treatment indication for mania in adults. Data for bipolar youth is less robust. An industry-sponsored trial with divalproex ER requested by the FDA, which was only 4 weeks in duration (the duration of adult trials), was negative; drug and placebo responses 24 and 23 percent, respectively. Published trials of two other anticonvulsants in youth, topiramate and oxcarbazepine, have not been found to be significantly better than placebo.

Atypical antipsychotics outperform divalproex in clinical trials. Additionally, where it was measured, the time to response for atypicals was shorter than for divalproex. Blood levels were adequate in both the industry-sponsored trial and in the ("Treatment of Early Age Mania" study [TEAM]. In the latter study, poor response likely had due to the >90 percent rate of comorbid ADHD.) As noted below, comorbid ADHD is a

predictor of poor treatment response.

There have been small trials of lithium in children for many years but none addressing acute mania with a placebo control until recently. The TEAM study, which randomized children to risperidone, lithium or divalproex reported a lithium response rate of 35.6 percent. There was no placebo arm but placebo responses in industry sponsored trials are about 25 to 30 percent. Thus, lithium would not have beaten placebo in that study. However, the Collaborative Lithium Trials (COLT) found a 4.5 point difference on the Y-MRS scale at week 8 between lithium and placebo-treated participants (p = 0.031). Even so, rates of response (≥50 percent drop in Y-MRS) did not differ significantly between lithium and placebo groups, respectively (37.7 percent vs. 28.6 percent, Robb et al., 2014).

Correll and colleagues provide a meta-analysis with relative effect sizes of different classes of medication. Atypical antipsychotics for mania/mixed mania show a larger effect size than mood stabilizers (effect size [ES] 0.65, confidence interval [CI] 0.53 to 0.78 compared to ES 0.20 CI 0.02 to 0.39) and a 50 percent reduction in Y-MRS entry score is seen in 50 to 70 percent of subjects compared to 20 to 37 percent on placebo. The NNT in successful trials where drug was better than placebo varied from 3.8 to 5.3.

The presence of ADHD complicates and attenuates treatment response for youth with BP. Attempts to treat both conditions include one study in which mixed amphetamine salts was added to divalproex decreasing ADHD symptoms in that group. In another study, children with bipolar disorder stabilized on a thymoleptic received varying doses of methylphenidate (MPH) and placebo. ADHD rating scale scores were significantly improved compared to placebo in the MPH-treated youth. MPH added to aripiprazole did not destabilize youth in a cross-over study (though ADHD was not significantly improved, either). Finally, a small open label study of atomoxetine added to a mood-stabilized regimen for BP and ADHD and found atomoxetine was effective in treating the ADHD, although 2 subjects out of 12 reported worsening mood at some point during the 8 week study.

Given the level of severity and impairment with which most children and teens begin a bipolar treatment study, the improvement, when it occurs, is noteworthy, but it often is not sufficient. Few data are available to predict treatment response. Use of more than one medication has increasingly become acceptable for treating mania/bipolar disorder in both adults and young people. In youth, there are three types of studies: (1) comparing two medications to one—for example, combined divalproex and quetiapine versus quetiapine alone; (2) adding one to another if the first drug does not work—for example, adding risperidone to lithium or divalproex; and (3) starting two together—for example, lithium and divalproex—and discontinuing one.

Although the types of adverse effects of medication are similar in children and adolescents, the frequency and severity may differ. For

instance, weight gain with metabolic syndrome especially in medication-naive patients and cases of polycystic ovaries may be of particular concern in young people. Similarly, disinhibited behavioral responses to many types of central nervous system medications seem to occur more often in children and perhaps slightly less so in teens.

Prevention of Relapse

Children and adolescents with bipolar disorder appear to have higher relapse rates and more episodes over the course of a year than adults. Regarding relapse prevention for mania, there is some suggestion that aripiprazole in one study and lamotrigine in another by Findling increase the time to relapse for mania. Beyond these trials, it is prudent to assume that medications that stabilized a child with BP should be continued for at least an entire school year, while a child is in school. The AACAP Practice Parameter suggested 12 to 14 months. In cases in which it has taken a long time to stabilize the child and in which there is clear evidence from symptom monitoring that treatment has been effective, it may be wise to continue the treatment until the child has improved function, academically, socially, and within the family. The decision to continue medication treatment or not should be assessed annually. In cases in which treatment response is more tenuous and side effects more troublesome, longer maintenance is more difficult to support.

Treatment of Bipolar Depression

Treatment of bipolar depression in young people has received relatively little attention. Even in adults, only three medications (olanzapine/fluoxetine combined [OFC], quetiapine, and lurasidone) have FDA-approved indications for bipolar depression. In youths, there have been two open trials—one of lithium monotherapy in hospitalized adolescents with bipolar depression and one using lamotrigine alone or with other medications in outpatient adolescents. Symptoms declined in both studies. In the absence of placebo-controlled studies, and given the high placebo response in depression studies in youth in general, the treatment utility of these medications in youth remains to be demonstrated. Moreover, the adolescent samples studied had considerably more subthreshold manic symptoms (Y-MRS scores were 12 or fewer) than in the adults, whose Y-MRS scores were 2 or fewer. Thus, it is not even possible to extrapolate intelligently from adult data.

The one positive study of bipolar depression used the OFC. This regimen was superior to placebo (effect size of 0.46) and has been approved by the FDA for the acute treatment of bipolar I depression in patients 10 to 17 years of age.

There is a modest, if anecdotal, literature on the efficacy of

electroconvulsive therapy (ECT) in mood disorders in teens. The reader is referred to the AACAP's ECT Practice Parameter on its indications and contraindications.

Treatment of "Broad Phenotype" Bipolar Disorder or Explosive Outbursts

Treatment of youth diagnosed with the "broad phenotype bipolar disorder"/SMD by some clinicians, unspecified bipolar disorder by others, and mania with comorbid ADHD by still others, is currently dependent on consensus recommendations. Most clinicians recommend stabilizing the mood disorder first and then addressing the comorbid disorder. ADHD is the only condition that has been systematically studied in children with mania or unspecified bipolar disorder. A recent meta-analysis found that comorbid ADHD with BP in youth, lowered treatment responsiveness to the bipolar disorder treatment, which suggests that the ADHD may need to be addressed first. Although there have been concerns among some clinicians that using stimulant medications for ADHD in children with definite or possible mania may exacerbate or precipitate mania, an increasing number of studies are substantiating the utility of treating comorbid ADHD either before or after mood stabilization. It is important to note that treating ADHD with therapeutic doses of stimulants is quite different from the effects of abusing cocaine and other stimulant drugs which may truly precipitate mania and psychosis.

Psychosocial Treatment

Psychosocial interventions (1) target the recognition of future episodes before they progress too far, (2) enhance treatment adherence, and (3) address environmental stressors that act as possible precipitants to further episodes. There are four models of psychosocial treatment studied in children and adolescents with early-onset bipolar disorder. These include multifamily and individual family psychoeducation, family-focused therapy for adolescents, child and family-focused CBT for younger children, and collaborative problem solving. Each emphasizes the importance of psychoeducation and destigmatization, as well as increasing parental collaboration by reducing parent self-blame for "causing the disorder." Other components include helping parents to distinguish between normative developmental behavior and bipolar symptoms, taking proactive steps to decrease the risk of relapse, developing tools for effectively managing emotional arousal, improving family communication skills, and teaching adaptive problem solving strategies.

FUTURE DIRECTIONS

Developments in neurosciences, neurobiology, genetics, and neuroimaging, as well as longer-term follow-up studies, will undoubtedly help to advance

the understanding of this complex and disabling disorder, in particular its relationship to other psychiatric disorders such as ADHD, conduct disorder, developmental disorders, and psychotic disorders. It is hoped that such advances can shed light on the etiology and underlying pathophysiology, including the identification of dysfunctional brain circuits that may underlie pediatric mania.

Anxiety Disorders in Children

▲ 52.1 Obsessive-Compulsive Disorder in Childhood

ADAM B. LEWIN, PH.D., AND JOHN PIACENTINI, PH.D.

Pediatric obsessive-compulsive disorder (OCD) is a chronic neuropsychiatric condition associated with broad impairments in functioning. Over the past two decades, increased attention has been focused on OCD in childhood, given heightened public and professional awareness of substantial upward revision of the prevalence of this disorder in youth. Advances in functional neuroimaging, genetics, neurosurgery, neuropsychological, and psychoneuroimmunology have contributed to a better understanding of etiological factors contributing to the pathogenesis of OCD in childhood. Concurrently, treatment-outcome research has produced multiple controlled trials of first-line treatments of OCD in childhood, cognitive-behavioral therapy (CBT) with exposure and response prevention (E/RP), and serotonin reuptake inhibitors (SRIs). More recently, studies have extended support for family-based E/RP to very young children with OCD. Nevertheless, despite promising interventions OCD remains a chronic and disabling disease affecting children and families; marked social, academic, and familial dysfunction are common sequelae. For individuals who do not benefit from available treatment, further refinement of treatment approaches remains paramount in order to diminish suffering and impairment while increasing the likelihood that youth with OCD can maintain relatively normal lives. Because many youth do not receive treatment due to lack of access to child psychiatrists and psychologists trained in evidence-based intervention, improving availability of care is another key goal.

DEFINITIONS

OCD is characterized by the presence of recurrent obsessions or compulsions that are distressing, time consuming, or debilitating. Obsessions are defined as recurrent, persistent, and intrusive thoughts, ideas, impulses, or mental images that are experienced by the individual as

distressing and as a product of one's own mind (to differentiate them from thought insertion). These thoughts or ideas are usually described as generating (or associated with) feelings of anxiety, tension, disgust, or aversion. Common obsessional fears are listed in Table 52.1–1. Compulsions are purposeful, repetitive behaviors, or mental acts that typically function to neutralize, prevent, or reduce anxiety. Common compulsive behaviors are also listed in Table 52.1–1. Often, compulsions are performed in response to an obsessive thought or according to some other rigidly applied rules. Although compulsions function to mitigate distress or anxiety or prevent some dreaded event, they are clearly excessive or are not realistically connected with the triggering stimulus (e.g., tapping three times to prevent illness after someone in the room coughs). Although obsessions and compulsions are frequently ego dystonic and are often recognized by children as senseless or exaggerated, such insight is not required for the diagnosis of OCD in childhood. Otherwise, symptoms to OCD in childhood resemble those seen in adults.

HISTORY

Early examples of childhood onset OCD, consisting of case descriptions, date back to the late 19th century. In 1895, Sigmund Freud described an 11-year-old child with obsessions. Subsequently, the French physician Pierre Janet provided the first description consistent with OCD in childhood in his 1903 report on a 5-year-old boy. In the first half of the 20th century, descriptions of clinical samples and generalizations emerged. In 1942, L. Berman extracted clinical information on 62 children with possible obsessive-compulsive neurosis out of a case registry of 3,050 cases. In 1955, Louise Despert described more than 60 cases of children with "obsessive-compulsive neurosis," noting a male preponderance, children's recognition that their symptoms are abnormal and unwanted, and the tendency to attempt to conceal their symptoms from treatment professionals and others. Leo Kanner's 1962 textbook of child psychiatry contained descriptions of childhood OCD and the consequences of social isolation and family accommodation.

In 1965, Lewis Judd provided descriptive criteria for the diagnosis of OCD in children that closely resembles the current diagnostic criteria, including the requirement of significant impairment in functioning. Reports as recent as 1973 implicated parental withdrawal of attention as a critical causal factor in childhood OCD. However, by the 1980s, the notion that OCD was a neurobiological disorder with possible childhood onset became more commonplace. Further, findings from the Epidemiologic Catchment Area (ECA) study that indicate that most adults with OCD report an onset of the disorder during adolescence prompted increased awareness of the disorder in childhood as well as research in this area. Programmatic work in the 1980s under the direction of Judith Rapoport

and her group at the National Institute of Mental Health provided the basis for the first systematic studies of epidemiology, phenomenology, and treatment of childhood- and adolescent-onset OCD as well as fundamentally dismissing any notion that the emergence of OCD in youth was unusual or unexpected.

Table 52.1–1.
Common Symptoms of Pediatric Obsessive-Compulsive Disorder Obsessions

Obsessions
Concerns with dirt, germ exposure, fears of illness
Fears of harm befalling self or others
Need for symmetry, order, exactness
Need to save or hoard
Excessive moral, religious, or sexual concerns
Compulsions
Cleaning rituals
Checking
Repeating behaviors
Ordering or arranging
Confessing, reassurance seeking

COMPARATIVE NOSOLOGY

Diagnostic criteria for OCD have remained relatively constant over the past three editions of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM). The DSM-5 published in 2013 defines the following features of OCD: (1) recurrent obsessions or compulsions; (2) obsessions or compulsions cause marked distress, are time consuming (take more than 1 hour per day) or cause significant impairment in functioning; and (3) obsessions and compulsions not due to the presence of another mental disorder, substance, or other medical condition. The DSM-5 also includes specifiers to code degree of insight and to indicate whether the individual has a history of tic disorder. The tenth revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) provides a description of OCD that is consistent with DSM-5.

EPIDEMIOLOGY

Although estimates vary, studies suggest lifetime prevalence for OCD in children between 1 and 3 percent indicating that OCD is more common than previously thought and as common in youth as in adults. Sample age may explain some of the variability in these estimates. Older adolescents yield prevalence rates between 0.53 and 4.0 percent, whereas estimates for school-aged children remain lower. In fact, a large prevalence study from the United Kingdom showed an exponential rise in rates across age groups

(5 to 7, 8 to 10, 11, 12, and 13 years). Another recent community sample found a prevalence rate of 3 percent for "clinical" OCD, defined as symptoms severe enough to cause distress and interference in functioning. The most commonly accepted 6-month prevalence rate is between .5 and 1 percent of the general pediatric population. Of note, rates of OCD in late adolescence make it more common than panic disorder, schizophrenia, and bipolar disorder.

Mean age of onset is between ages 6 and 11. Onset age appears bimodal and varies by gender with a male preponderance in cases of prepubertal onset with an initial peak of incidence around puberty and subsequently in young adulthood. The gender distribution becomes roughly equivalent during adolescence. It is currently believed that up to 80 percent of adult OCD cases have an initial onset during childhood. Children with an early onset of OCD (below age 7) have also been shown more likely to be male and to have a family history of OCD in comparison to children with later onsets, suggesting that genetic factors may be more likely to play a role in the development of early onset cases. Referral bias may account for the underrepresentation of minorities and youngsters from lower socioeconomic strata in clinical samples of OCD youth, as this pattern has not been replicated in epidemiological studies with adult samples.

The occurrence of OCD in childhood may be somewhat higher than reported given secrecy that children often display in reporting embarrassing thoughts and behaviors. Additionally, limited insight into the abnormality of their symptoms (and linking OCD symptoms to potential impairment), parent inability to recognize OCD symptoms, and the lack of awareness about the availability of efficacious treatments may contribute to underdiagnosis. Therefore, it is reasonable to assume that many childhood cases of OCD remain undetected.

Table 52.1–2.
Comorbid Diagnoses in Pediatric Obsessive-Compulsive Disorder

Diagnosis	Frequency (%)
Anxiety disorders	26–70
Mood disorders	11–62
Tic disorders	11–26
Attention-deficit/hyperactivity disorder	16–20
Disruptive behavior disorders	9–19
Autism spectrum disorders	3–7

Comorbidity

In childhood, psychiatric disorders co-occurring with OCD are the norm rather than the exception. For example, in an analysis of 70 clinical cases of youth with OCD, 84 percent carried at least one additional Axis I

psychiatric diagnosis. It has been estimated that as many as 50 percent of pediatric patients with OCD have two or more co-occurring diagnoses (Table 52.1–2). The most common comorbid disorders include other anxiety disorders, depressive disorders, tic disorders including Tourette disorder, attention-deficit/hyperactivity disorder (ADHD), and disruptive behavior disorders.

ETIOLOGY

Neurobiological Factors

Although the cause of OCD remains unknown, multiple neurochemical, neuroanatomical, and immunological etiologic theories have been proposed. Clinical descriptions of OCD associated with Sydenham chorea (SC), tic disorders, traumatic brain injury, encephalitis, and Huntington chorea have helped to solidify the broad concept of the disorder as brain based and presumably reflecting impaired striatal functioning. Although the neurocircuitry and neurochemistry involved in OCD symptomology have been better clarified through the use of in vivo brain techniques and evaluation of responses to psychoactive medications, there continues to be a need to further refine etiological models of the condition.

Neurochemical. Dysfunction of the central serotoninergic neurotransmitter system continues to be suspected in OCD symptomology. Primary support for this premise is observed efficacy of selective serotonin reuptake inhibitors (SSRIs) and altered sensitivity to acute administration of 5-hydroxytryptamine (5-HT) agonists, as well as from results of preliminary studies of 5-HT synthesis. Platelet [3H]imipramine binding has been observed to be reduced in young patients with OCD; conversely, those OCD patients with higher [3H]imipramine binding at baseline differentiated responders versus nonresponders to SSRI treatment.

Involvement of the dopaminergic neurotransmitter system has also been suggested. This may be especially relevant to childhood OCD given the increased rate of comorbid tic disorders. Clinically, administration of psychostimulants appears to worsen obsessions and compulsions. Conversely, the coadministration of dopamine antagonists with SSRIs may augment the beneficial effects of these agents. However, direct assessment of the dopamine system remains unstudied in children, including a lack of controlled administration of dopamine antagonists. Further, animal studies suggest that excessive glutamatergic output from the cortex to the striatum is associated with repetitive movements. Human studies in children with OCD have reported correlations between striatal glutamate with OCD symptoms and the drop in striatal glutamate with SSRI treatment. In sum, available neurochemical models suggest the possibility of several neurotransmitter abnormalities associated with OCD.

Neurostructural. The pathogenesis of pediatric OCD has been characterized by abnormalities in the prefrontal–basal ganglia circuits, specifically frontal–striatal–thalamic–cortical (FSTC) circuit disruption. This premise is supported by imaging studies of OCD, co-occurrence with other disorders with presumed basal ganglia disruption, as well as neuropsychological studies. Volumetric analyses using both magnetic resonance imaging (MRI) and computed tomography (CT) approaches have revealed that treatment-naive children and adults with OCD have smaller basal ganglia segments than adults. For example, a recent study found reduced globus pallidus volume and gray matter volumetric abnormalities in the anterior cingulated gyrus in pediatric patients with OCD compared to healthy controls. More recently, abnormalities in white matter coherence have been found in child OCD, with greater white matter irregularities linked to increased OCD severity differences compared to healthy controls.

Treatment-naive children appear to also have large thalamic volumes. Thus, it has been hypothesized that children with OCD display abnormalities in normal developmental remodeling of neuronal structures affecting integration, response inhibition, gating/cognitive control, and processing. Positron emission tomography (PET) suggests dysfunction in FSTC circuitry, with studies showing increased glucose metabolism in orbitofrontal cortex, ventral striatum, right caudate nucleus, and anterior cingulate gyrus, at rest and in response to symptom provocation. Orbitofrontal and caudate metabolic rates are highly correlated, suggesting that interconnecting loops are freed from usual inhibitory influences and reverberate. Disruption of affective/reward processing loops and cognitive control loops have been linked to OCD, and differential development of these systems may be expressed in OCD course and presentation. Recent studies in child OCD suggest that differential development of FSTC circuits and various interconnectivity (e.g., between behavioral inhibition) may explain differential symptom expression, for example, a finding suggested hypoconnectivity of cognitive control circuity in early-onset cases.

The observations that both medication and behavioral therapies reduce orbitofrontal and caudate blood flow seem to validate the importance of these brain regions in OCD pathogenesis. Paradoxically, lower baseline orbitofrontal glucose metabolism predicts better response to pharmacotherapy. Imaging also suggests the frontal–limbic–basal ganglia system may mediate OCD symptom expression, demonstrating a wider interaction of cognitive and emotional circuits. Specifically, symptom provocation appears to activate paralimbic regions as well as insular, anterior temporal, and amygdalar regions.

Neuroimmunology. Significant attention has been focused on the triggering of OCD-like symptoms following group A beta-hemolytic

streptococcal infections (GABHS), similar to OCD symptoms observed in SC. These infection-triggered cases of OCD have been coined pediatric autoimmune neuropsychiatric disorders associated with streptococcus (PANDAS) and are believed to represent an autoimmune process related, if not identical to, that associated with rheumatic fever (RF) and SC. (It is noteworthy that patients with RF and SC both display higher frequencies of obsessions and compulsions versus comparison groups, and up to one third of patients with SC meet research criteria for the diagnosis of OCD.) Immune activation leads to the inflammation of the basal ganglia and disruption of the cortical–striatal–thalamo–cortical (CSTC) function. This acquired basal ganglic dysfunction may result in choreiform movements, tics, obsessions, compulsions, and hyperactivity. PANDAS are characterized by abrupt childhood onset and episodic or sawtoothed course. Relationships between the size of the basal ganglia nuclei and OCD symptom severity have been observed using MRI. Similarly, small sample studies of immune-modulating treatments (intravenous immunoglobulin G [IgG] and plasmapheresis) have been associated with improvements in OCD patients with suspected PANDAS. However, there is a lack of well-controlled studies; these interventions remain experimental, and efforts to establish markers of PANDAS have been inconclusive. In addition, the proportion of child OCD cases potentially attributable to streptococcal infection remains unknown. Although additional research into PANDAS appears warranted, the association between GABHS infection and OCD remains debated. In light of the current literature, evidence-based psychopharmacological and behavioral (e.g., CBT with E/RP) approaches remain first-line options for treating OCD symptoms of suspected immunological origin. Experimental, high-risk interventions should be used cautiously given safety concerns and lack of clear evidence in support of their efficacy.

More recently, the term PANS (pediatric acute-onset neuropsychiatric syndrome) was coined to characterize cases with similar clinical presentations as PANDAS but without link or presumed cause with GAS infection. Similar to PANDAS, PANS requires abrupt/dramatic/overnight onset of OCD symptoms, and severe and acute onset of at least two of the following: anxiety, emotional lability, irritability/aggression, developmental regression, academic deterioration, sensory sensitivity, somatic symptoms (including sleep disturbance, enuresis or urinary frequency). Similar to PANDAS, diagnosis is not straightforward and even putative PANS casesness does prohibit potential benefits of CBT or SSRIs nor does it necessitate the need for experimental interventions. Given the lack of definitive tests for PANS/PANDAS, evaluation requires careful multifaceted assessment of medical and psychiatric histories. Parents should be cautioned regarding pursuit of PANS/PANDAS diagnosis/treatment without first exhausting evidence-based OCD

treatments.

Neuroendocrine. Observations of OCD onset during puberty, pregnancy, and during the postpartum period have led to speculation that hormones may influence the emergence or severity of OCD symptoms. Although transitory, antiandrogen treatment has appeared to show benefits in some refractory individuals. The effects of adrenarche and menarche on relevant brain circuits that underlie OCD symptoms need further study.

Family Genetic, Behavioral, and Cognitive Factors

Family Genetic. OCD is a heritable disorder—the familial nature in most cases of OCD is well recognized. Monozygotic twins have a higher OCD concordance rate (0.52) compared to dizygotic (0.21). A meta-analysis of studies exploring familial patterns of psychopathology in relatives of subjects with OCD has documented a fourfold increased frequency of OCD in first-degree relatives of OCD probands (8.2 vs. 2.0 from control families). Rates of OCD among parents of youngsters with OCD range from 17 to 19 percent. A 2005 review of twin studies suggests 27 to 65 percent heritability rates for OCD (including nonpediatric onset). In addition, subclinical features of OCD (usually defined as typical symptom constellations without the level of interference required for formal diagnosis) are higher among family members with OCD (e.g., reported in 52 percent of parents). In fact, relatives of probands with early onset OCD exhibit even higher rates of OCD and tic symptoms. Analysis of family patterns of OCD finds support for subclinical OCD as an intermediate phenotype that shares similar genetic risk factors.

The relationship between OCD and tic disorders, including Tourette syndrome, has emerged from family studies. Tic disorders and some cases of OCD appear to share some susceptibility factors, leading to arguments that OCD may be an alternative expression of the risk factors underlying tic disorders. Some suggest an autosomal dominant model of inheritance with incomplete penetrance. In other words, the phenotypic expression varies in expression from OCD symptoms to tic disorders.

Data from twin and family studies suggest that OCD may be transmitted in families, but specific genes for the disorder have not been identified. Findings from the multisite Obsessive Compulsive Genetic Association Study (OCGAS), the largest such study to date (1,065 families and 1,406 patients with OCD), failed to identify single nucleotide polymorphisms at genome-wide significance. Investigators posit larger samples that are needed to identify genes associated with OCD. Preliminary findings suggest OCD is polygenetic and likely arises from a large number of diverse genes. Candidate gene studies have yet to produce replicable, significant genes culpable in OCD. The neuronal glutamate transporter gene (SLC1A1) has the strongest support, with some findings implicating the serotonin

promoter variant (5-HTTLPR). Definitive copy number variants associated with OCD have not been identified. To date, OCD-specific genetic markers remain to be found.

Behavioral Factors. Hobart Mower's two-factor conditioning theory provides a behavioral explanation for OCD symptoms. Via classical conditioning, a neutral stimulus (or event) becomes conditioned to elicit distress because of its association with an unrelated aversive (or feared) stimulus. Fear can be conditioned to both mental events (e.g., blasphemous thoughts) and physical stimuli or behaviors (e.g., a "contaminated" object, items perceived as dangerous, driving, eating). Subsequent to the acquisition of the conditioned fear, rituals develop to reduce or avoid distress. These rituals (or compulsive behaviors) persist and become excessive because they temporarily ameliorate the distress associated with obsessive thoughts via operant conditioning (specifically, a negative reinforcement paradigm). In other words, the escape-from/reduction-of anxiety associated with performing a compulsive behavior or ritual results in an increase likelihood of the ritual being used in future instances of anxiety.

However, specific traumatic events responsible for the conditioned response are rarely identified. Additionally, behavioral theories do not adequately explain the acquisition of obsessive fears. Regardless, these behavioral theories are useful for understanding the maintenance of many OCD symptoms and provide the foundation for behavioral intervention.

Cognitive Factors. The cognitive perspective of the etiology of OCD posits that OCD results from the interpretation of intrusive thoughts rather than the frequency or content of these cognitions. If intrusive thoughts are interpreted in such a way that an individual perceives responsibility for causing or failing to prevent harm, obsessional patterns develop. Attempts to neutralize intrusive thoughts (or obsessions) via motor or cognitive rituals, avoidance, and reassurance-seeking behavior prevent the disconfirmation of the patient's fears and facilitate the proliferation of anxiety. The most common cognitive misinterpretations include thought-action fusion or the tendency to equate thought with action (e.g., thinking something bad is the same as doing it), and exaggerated responsibility for potential untoward consequences of inaction (e.g., "If I don't wash my hands and someone gets sick as a result, then it's my fault.").

Similar to behavioral theory, cognitive theory does not adequately explain the etiology of symptoms. It is likely that cognitive misinterpretations and reinforcement theory (see above) maintain and expand OCD symptoms in individuals with biological propensity for OCD development.

DIAGNOSIS AND CLINICAL FEATURES

Presenting problems among children and adolescents with OCD generally resemble the adult presentation. However, compared to adults, children are more likely to deny impairment due to obsessions and compulsions. Children may also be somewhat less likely to consider their OCD symptoms excessive, perhaps due to lower levels of cognitive awareness. Children do not need to recognize their symptoms as senseless or unrealistic for diagnosis to be assigned; the level of insight varies considerably likely related to a child's developmental level. Unlike most adults, children might not report symptoms to be ego dystonic. However, children are typically willing to discuss distress from family conflict arising from their rituals (e.g., chronically running late, excessive need for reassurance, time burden on parents, disruption of siblings functioning) or interference in schoolwork resulting in dropping grades. Overall, most children are quite open in describing their symptoms and seek assistance in better managing the illness.

Although comorbidity is the rule rather than the exception in childhood OCD, the content of the obsessions and compulsions cannot be better explained by a co-occurring Axis I disorder. Examples include self-deprecating ruminations associated with depression, obsessive concern with appearance in body dysmorphic disorder, hair pulling in trichotillomania, and fears of harm befalling a loved one in separation anxiety disorder. Similarly, the symptoms also are required not to be substance induced or due to the influence of a medical condition. The range of obsessions and compulsions experienced in childhood is similar to that of adults with OCD, although children are more likely to engage in compulsive reassurance seeking and involve family members in their rituals. Most children with OCD have both obsessions and compulsions; pure obsessional illness is rare in this age group. In fact, most childhood cases of OCD involve multiple obsessions and compulsions (mean number of four current compulsions and four current obsessions in one report). Compulsions in the absence of anxiety-related or otherwise distress--inducing obsessions may occur in (mostly younger) children, who often describe their rituals as being performed in response to an irresistible urge or an otherwise vague sensation (the "just-right" phenomena). The absence of reported obsessions in these cases may be due to underdeveloped awareness or ability to articulate these thoughts or result of a misdiagnosed tic disorder. Specific types of symptoms (e.g., touching/tapping/rubbing) may change with age, but the number of symptoms generally remains constant.

The most common obsessions in childhood include fears of contamination (e.g., dirt, exposure to germs, toxins, contracting an illness), fears of harm befalling self or others (e.g., becoming aggressive, failing to prevent harm), need for symmetry or exactness, hoarding or saving

concerns, and excessive moralization or religiosity. Obsessions also may manifest as excessive guilt, self-doubt, or other forbidden thoughts. Common compulsions involve cleaning/washing rituals, checking, repeating behaviors (touching, tapping, rubbing), counting, ordering/arranging, avoidance, doubt/indecision, confessing, seeking reassurance, and slowness. The content and type of obsessive and compulsive symptoms may change over time. OCD is also stress sensitive, and many children experience acute symptom exacerbations during times of psychosocial stress or change (e.g., attending a new school, moving to a new home, death or a family member).

Similar to adult OCD, family members are commonly drawn into the child's OCD symptoms through provision of reassurance to the child, modification of family routines as a result of the child's symptoms, or even actual participation in the child's compulsive rituals. Such accommodation can negatively impact the family environment and lead to increased levels of family conflict and negative emotional reactions toward the affected child. Accommodation has also been associated with increased feelings of depression and anxiety on the part of the accommodating family member (typically mothers).

Given the typically strange and senseless nature of many OCD symptoms, many children and adolescents will attempt to camouflage their rituals. It is not uncommon for children with OCD to be able to inhibit their rituals for short periods of time to avoid detection (e.g., in class). Not infrequently, teachers, peers, and even parents remain unaware of the child's OCD for months or years, only becoming aware of the problem after the child can no longer control the symptoms or becomes too overwhelmed to cope.

DIFFERENTIAL DIAGNOSIS

Developmentally Normative Rituals and Superstitions

Benign habits, transitory superstitions, or mildly excessive thoughts are not uncommon during childhood. In certain phases of early childhood, rituals or superstitions may be utilized by a child to manage new or stressful situations (first day of preschool, separating from a parent) or achieving a sense of mastery. For example, a child may require a particular bedtime ritual or demand to wear a particular item of clothing. These normative rituals usually fade by the time of entry into formal schooling and are rarely associated with distress, significant interference with activities, or overlap in content with typical obsessions or compulsions. The absence of functional impairment differentiates mild, age-appropriate superstitions and habits from obsessive-compulsive symptoms.

Other Anxiety Disorders

Despite the presence of preoccupation and worry about issues related to their fears, children with other anxiety disorders typically do not engage in compulsive behaviors to reduce their anxiety. The content of the worry can also be useful in differentiating syndromes. Pediatric patients with generalized anxiety disorder (GAD) present with heightened anxiety relating to their health and safety, safety of others, and their future. The content of these symptoms, although exaggerated, is grounded in everyday matters (finances, health, grades, safety) as opposed to the unusual or even bizarre content of obsessive worries. Behavioral analogs to compulsions are rare besides the requests for reassurance from others to reduce anxiety. Patients with social anxiety have fears of negative evaluation and extreme scrutiny by others. Again, fears are by definition excessive, but typically not bizarre. Rituals are rare, although avoidance of feared situations is common. Similarly, the content of fears expressed by children with separation anxiety disorder are, by definition, confined to themes of separation or fears of harm to self or loved ones. Besides avoidance of separation, other behavioral features or rituals are absent from presentation.

Tic Disorders and Tourette Syndrome

Children and adolescents with tic disorders typically display phonic or motor tics that occur frequently and may appear behaviorally similar to compulsive actions, particularly more complex tics. Tics are differentiated from compulsions is usually being avolitional and are not preceded by precipitating obsessional thoughts. The content of tics is unlikely to be as purposeful as common compulsions (e.g., washing and arranging). It is noteworthy that there is substantial overlap between tic disorders and OCD in childhood, symptoms of each are not uncommon and both diagnoses may be warranted.

Autism Spectrum Disorders

The term autism spectrum disorder (ASD) comprises of children from a wide range of intellectual (and adaptive) functioning. Pervasive and stereotypic behaviors (including pragmatic language) are characteristic of ASD. In contrast with OCD, perseverations lack an association with anxiety; indeed, ASD perseverations or stereotyped behaviors may contain sought-after or pleasurable topics. Similarly, the stereotyped behavior may be elicited by excitement or frustration or may serve to manage stimulation and are generally not associated with preceding intrusive thought or impulse. Obsessions may be described but they are generally better characterized as idiosyncratic interests accompanied by marked perseveration and no awareness of the disinterest of others (or the excessiveness of their focus). Examples include ordering, arranging,

sequencing, and preservative speech. It is not uncommon for parents to report a child appearing "driven" to engage in his or her "compulsions," especially younger children. Although OCD can overlap with ASD (6 to 20 percent of patients with OCD are estimated to have ASD traits), distinction can usually be made by establishing the developmental context of the behaviors.

Psychotic Disorders

The differential diagnosis of OCD from incipient psychosis in youth can be challenging. The fixed nature of bizarre or unusual obsessions can have delusional qualities and resemble schizophrenic symptomology. Although OCD-related obsessions and compulsions may appear bizarre, insight is usually preserved and common themes are often evident. Children with OCD are typically aware that symptoms are products of their own mind (i.e., not thought insertion). OCD can usually be distinguished from schizophrenia by the absence of other symptoms, including formal thought disorder and hallucinations, and by the ability to engage in reality testing. In severe cases of OCD, reality testing may be challenged, and the boundary between obsession and delusion may be difficult to distinguish. OCD and psychotic disorders, though rarely, do co-occur.

Hypochondriasis

If the distressing thoughts are exclusively related to fears of having a serious medical condition, based on misinterpretation of bodily symptoms, hypochondriasis should be considered instead of OCD. Behaviorally, persistent need for medical evaluation and reassurance is not uncommon. However, if the preoccupation with illness is accompanied by rituals (e.g., washing, avoidance, checking based on the concern about contracting, exacerbating, or spreading illness to others), then a diagnosis of OCD may be appropriate.

COURSE AND PROGNOSIS

OCD with onset in childhood is a chronic condition characterized by substantial morbidity. Follow-up studies suggest that 43 to 68 percent of youth diagnoses with OCD continue to meet diagnostic criteria for the disorder up to 14 years after identification. Worse outcomes at follow-up were predicted by poor initial treatment response, a lifetime history of tic disorder, and a parental Axis I psychiatric disorder. The literature lacks long-term controlled treatment studies, and most follow-up data are from extant treatment trials following only a few months post-treatment. Further, this literature is complicated by multiple confounding variables, including treatment type, comorbidity, age or age of onset, and access to follow-up care.

The largest long-term follow-up study to date was based on 142 youth initially treated for OCD at the Maudsley Hospital and recontacted a mean of 9 years after intake. At follow-up, 41 percent of subjects still met diagnostic criteria for OCD with 4 percent reporting subclinical OCD symptoms. Although many reported functioning reasonably well, 50 percent were currently receiving treatment and 70 percent were diagnosed with any psychiatric disorder (following OCD, GAD, major depressive disorder [MDD], and tic disorders were most common). One other long-term retrospective follow-up study reported similar findings. Overall, despite reasonable success with acute treatments of pediatric OCD, the limited available long-term data suggest considerable room for improvement with regard to the durability of these interventions.

Even with remission following treatment, children with a history of OCD or subclinical OCD symptoms should continue to be monitored for relapse in symptoms. Likewise, relatives (siblings) of patients with OCD should be monitored closely and considered for treatment with the emergence of subclinical symptoms, even in the absence of more severe or impairing symptoms.

TREATMENT

Currently, there are two approaches supported in the research literature for pediatric OCD: CBT based on E/RP and pharmacotherapy with SRIs. A meta-analysis of randomized controlled trials (RCTs) for pediatric OCD yielded effect sizes of 1.45 (95 percent CI = 0.68 to 2.22) for CBT and 0.48 for pharmacotherapy (95 percent CI = 0.36 to 0.61), although methodological issues complicate direct comparison of efficacy for these two treatment approaches. Combined intervention with both CBT and SSRI might yield benefits beyond use of either of these treatments alone. As a result, the American Academy of Child and Adolescent Psychiatry treatment guidelines consider CBT or CBT + SSRI medication the first-line treatment of pediatric OCD. It is important to note, however, that behavioral approaches are overwhelmingly preferential to parents (75 percent prefer CBT only compared to CBT + SSRI with the disparity increasing among parents of children under age 9). Notably, a large multisite controlled study found that for youth who did not respond to an initial course of CBT with E/RP, extending E/RP was as effective as SSRI augmentation. This suggests that extending E/RP may be an alternative to SSRI augmentation in some cases. A recent Cochrane meta-analysis suggested CBT generally out performs SSRIs for pediatric OCD; Combined SSRI + CBT is favorable to SSRI alone. For those who had failed an SSRI, adding CBT was superior to continuing the SSRI. However, those who failed CBT did as well with continued CBT as with switching to an SSRI.

Cognitive-Behavioral Therapy with Exposure and Response Prevention

The efficacy of CBT in children has been demonstrated in numerous open trials and at least six controlled trials. Indeed, treatment response rates in the extant CBT trials are quite high, ranging from 57 to 90 percent. Unlike pharmacotherapies (for which relapse is not uncommon when medication is discontinued), treatment gains from CBT commonly endure more favorably after therapy is completed in contrast to medication discontinuation. In contrast, CBT with E/RP for OCD is distinguished from other "talk therapies" with no supported efficacy in the extant literature, including role-play–based, supportive, insight-oriented, relaxation, psychoanalytic, and psychodynamic therapies. Several treatment manuals outlining CBT with E/RP for children and adolescents are available. They consist of exposure (placing the patient in situations that elicit anxiety related to their obsessions), response prevention (deterring the compulsive or ritualistic behaviors that may serve to reduce or avoid anxiety from occurring), and cognitive therapy (training the patient to identify and reframe anxiety-provoking cognitions). The first step of treatment is psychoeducation about OCD and E/RP. It is important for the child and parents to understand the rationale for exposure to fear and restraint from anxiety-reducing compensatory behaviors. Next, a "fear hierarchy" is developed rank ordering symptoms. Following this, patients are systematically exposed to the feared situations (least feared first) while being instructed not to engage in their ritualistic behavior. Over repeated exposures, the associated anxiety dissipates through the process of autonomic habituation. In addition, when the feared consequences of not ritualizing fail to occur, the patient's heightened expectations of harm disappear, reducing anxiety even further.

Format and intensity of CBT with E/RP are variable. Studies suggest that weekly outpatient CBT for child OCD is equivalent in efficacy to intensive CBT. It is recommended that treatment of child OCD be conducted in vivo and in the context of the family in order to promote generalization. There is preliminary support for telehealth-based E/RP approaches but more studies are needed.

In addition to E/RP, adjunctive cognitive strategies are utilized with pediatric patients. However, younger children and those with impaired cognitive functioning receive fewer and less sophisticated cognitive components to treatment due to developmental and cognitive limitations. A child's age, cognitive functioning, and insight into the nature of his or her OCD is paramount in determining the direction of treatment, as introduction of cognitive components of therapy depends on the child's developmental level and insight.

Additionally, children's rituals frequently involve parental and family participation, and more severe family dysfunction has been shown to predict worse child treatment outcome. Moreover, E/RP requires significant out-of-session practice for mastery and extinction of OCD

symptoms. Many children are unwilling or unable to complete the necessary "homework" from therapy on their own (perhaps due to anxiety, lack of motivation, distraction). Thus, substantial parental involvement appears warranted, especially for younger children. Family treatment should include significant psychoeducation about OCD as well as mechanisms of E/RP. Parents may benefit from observing techniques presented by a skilled therapist so that they can assist their child with exercises in a supportive, noncoercive approach. Additionally, this can help parents to correctly extinguish ritualistic behavior and disengage from OCD rather than scold/react/blame. Teaching family members experiencing significant OCD-related conflict or discord skills to enhance affect modulation and problem-solving has been shown to enhance child treatment outcomes. Studies suggest family based CBT is effective for youth with OCD symptoms as young as age 3.

Pharmacotherapy

The efficacy of pharmacotherapy for OCD in pediatric populations has been demonstrated in several controlled trials with SRIs and SSRIs. At present, the U.S. Food and Drug Administration (FDA) approval has been granted for four medications for pediatric OCD use: clomipramine, fluoxetine, sertraline, and fluvoxamine, although the minimum approved age varies by compound. Table 52.1–3 lists medications and dose ranges for pediatric OCD.

Table 52.1–3.
Medications and Dose Ranges for Pediatric Obsessive-Compulsive Disorder

Medication	Typical Dosage (mg/day)
Fluoxetine (Prozac)	10–80[a]
Sertraline (Zoloft)	50–200[a]
Fluvoxamine (Luvox)	50–300[a]
Paroxetine (Paxil)[b]	
Citalopram (Celexa)	10–60[a]
Escitalopram (Lexapro)	5–20
Clomipramine (Anafranil)	50–200[a]

[a]Mean doses as per the American Academy of Clinical Child and Adolescent Psychiatry 2012 Practice Parameters, based on randomized controlled trials.

[b]Paroxetine is not recommended for use in children/adolescents.

Clomipramine, a tricyclic antidepressant, is the most researched SRI in the treatment of pediatric OCD. In a double-blind, 8-week, placebo-controlled study, 60 percent of pediatric patients showed significant improvement. Patients treated with clomipramine reported a 37 percent

mean reduction in OCD symptoms compared to 8 percent for the placebo group (with an effect size approaching 1.0). In another 10-week controlled trial, a significant difference was found between clomipramine and placebo, with 75 percent of pediatric patients showing at least moderate improvement. Other research found that clomipramine was superior to the noradrenergic reuptake inhibiting tricyclic antidepressant desipramine. This crossover trial found that 64 percent of patients who initially received clomipramine during their first treatment showed relapse of OCD symptoms during desipramine treatment. Overall, a 2003 meta-analysis of pharmacotherapy trials in children identified clomipramine to be significantly superior over SSRIs, which did not differ among one another, in reducing OCD symptoms. Nevertheless, the risk profile, adverse effects, and required electrocardiogram and blood-level monitoring associated with tricyclic antidepressants (e.g., antiadrenergic, anticholinergic, and antihistaminergic adverse effects) are of concern with clomipramine. Thus, clomipramine is relegated to a second- or third-line treatment choice for children and adolescents and should not be used until sufficient trials of CBT with E/RP, two or more SSRIs, and combination CBT with SSRI therapy have been attempted.

Selective Serotonin Reuptake Inhibitors

In a 20-week, double-blind, placebo-controlled trial of the SSRI fluoxetine in children and adolescents with OCD, 44 percent reductions in OCD symptoms were reported. A 13-week controlled trial also demonstrated the efficacy of fluoxetine, with 55 percent of patients treated with fluoxetine rated as much or very much improved. Another 16-week, placebo-controlled trial of fluoxetine in children reported that 57 percent of patients demonstrated significant improvement. Several open trials also present favorable findings for the use of fluoxetine for pediatric OCD.

Data also support the use of the SSRI sertraline for the treatment of pediatric OCD. A 12-week, multicenter, randomized, placebo-controlled trial of children and adolescents with OCD found that 42 percent of patients receiving sertraline were rated as much or very much improved. Further, in a 52-week, open-label extension of the previous study, 71 percent of children (aged 6 to 12) and 61 percent of adolescents (aged 13 to 18) demonstrated 25 percent decreases in OCD symptoms and were rated as much or very much improved. Another multisite, randomized controlled trial found that 21.4 percent of pediatric patients entered clinical remission following a 12-week course of sertraline.

A 10-week, multicenter, placebo-controlled trial of fluvoxamine also yielded a 42 percent response rate along with evidence for the safety and 1-year durability of this treatment. Citalopram and escitalopram are also used for pediatric OCD, with a putative mechanism of action similar to sertraline and fluoxetine, but RCT data is scant. One pilot randomized

study of only 29 youth found no group differences in efficacy or safety between fixed dose (20 mg) citalopram and fluoxetine at 6 weeks. Although paroxetine has also been studied for use in pediatric OCD, an FDA advisory recommending that paroxetine not be used in the treatment of MDD, due to increased risk of suicidal ideation, has largely curtailed the use of this treatment in children and adolescents.

Overall, clinically significant reductions in OCD symptomology have been documented in children and adolescents using SSRIs with a relatively minimal side-effect profile (as compared to clomipramine). The most frequent SSRI side effects include nausea, insomnia, headache, and asthenia. During clinical trials, the inability to tolerate treatment due to side effects was reported in 15 percent or less of cases. Based on these findings, SSRIs are the consensus first-line medication for pediatric OCD. Although there are very limited controlled comparisons between these medications in children, research suggests that the SSRIs are equally efficacious in children and the specific choice should be based on the patient's medical history, concomitant medications, and the adverse events. Sertraline and fluoxetine have been studied more extensively in youth, suggesting possible initial options. Poor clinical response to one SSRI is not necessarily predictive of failure with other SSRIs, suggesting adequate trials of multiple SSRIs may be indicated before augmentation. Additionally, significant clinical response is unlikely within the first few weeks of taking an SSRI; generally, 10 to 12 weeks at adequate dosage is necessary to fully evaluate the efficacy of the medication.

In 2005, the FDA issued a black box warning for antidepressant medications to alert health care providers to an increased risk of suicidality (suicidal thinking and behavior) in children and adolescents being treated with these agents. In light of this warning, increased attention to symptoms of depression among pediatric patients being treated with antidepressant medications appears warranted. This should include formal assessment of suicidal ideation prior to and throughout the course of pharmacological treatment. An implication of this warning, combined with strong research support for CBT with E/RP, suggests attempting an adequate trial of the CBT prior to pharmacological intervention. Notably, a recent large-scale Scandinavian study suggested that for CBT nonresponders continued CBT was as effective in comparison to SSRI augmentation.

Other Treatments

In pediatric cases that are unresponsive to CBT and trials with multiple SSRIs, pharmacological augmentation may be considered. There is growing support for SSRI augmentation with atypical antipsychotics for refractory OCD in adult patients. For example, an 8-week, double-blind, placebo-controlled trial was performed to determine the efficacy of risperidone augmentation in adults with treatment-resistant OCD found a 40 percent

response rate. A preliminary open label study of aripiprazole (mean dose 4.75 mg/day) 16 children (non-responders to CBT and at least two SSRIs) with OCD (80% with comorbidity) suggested benefit after 12 weeks. However, replication is needed in a larger, randomized-controlled design. Other data suggest aripiprazole augmentation of SSRIs may be beneficial for treatment resistant youth (failed multiple SSRIs and CBT). Additionally, two recent meta-analyses of off-label use of neuroleptics (including haloperidol, risperidone, olanzapine, and quetiapine) in adults with OCD suggest that initial findings from open trials, controlled trials, and case series are promising despite a need for substantial further research, especially in youth. Lithium carbonate and buspirone augmentation have generally not been efficacious augmentation strategies for treatment-refractory OCD in adults but may ameliorate depressive symptoms. Thus, augmentation may also be the case in children with comorbid conditions, for example, a tic disorder may require the addition of an α_2-agonist or neuroleptics.

In sum, unlike the adult literature, there is a paucity of empirical data supporting augmentation strategies for pediatric OCD. Additionally, significant undesirable side effects should be considered prior to prescribing neuroleptics and benzodiazepines in children.

Ace is a 15-year-old male of European ancestry from a southeastern suburban community. He lives with his parents and two younger sisters. Ace originally presented to his primary care physician in the fall following an exacerbation in obsessive-compulsive symptoms. Parents described their son as a worrier, even as a young child. He would worry about his own performance, health, and safety. He was always questioning adults to ascertain, “Am I doing this right?” or “You’re not angry at me?” In addition to questioning, Ace would always check over his homework, chores, and personal details (e.g., appearance) very carefully. However, approximately 6 months ago, more unusual and atypical behaviors developed. Ace would rewrite homework assignments six or seven times, shredding papers if he had to erase the slightest mistake. He would change his clothes several times per day, stating that items “got dirty,” when there was no evidence for any need of cleaning. His parents noticed a pile of his previously favorite, sports jerseys and expensive athletic shoes stashed in the attic. When questioned, Ace claimed they were “contaminated” and could not be worn again, despite any indication of soiling. He became late for school and activities, locking himself in his room for long periods before leaving the house. He was evasive when questioned about this behavior, but stated, “There are things I need to do to make sure things will be okay.” He latter clarified that he would repeat a sequence of prayers and sayings in his head until “they felt just right” and he could subsequently go out of the house. Whereas Ace’s ninth grade teacher had tolerated tardies and late assignments given his history of being a stellar student, his high school teachers did not accept late work and reprimanded him for being late. Consequently, his grades were plummeting. At the same time, his extracurricular interests appeared to be diminished, and rituals replaced the time he had spent on age-appropriate activities. Fights were erupting between Ace and his parents because Ace’s rituals made his mother late for work, and both parents grew tired of their son’s increased need for reassurance.

There was no history of OCD in Ace’s family. However, his father had a history of untreated “anxiety” and Ace’s 7-year-old brother had been diagnosed with Tourette syndrome. Ace’s problems had never been mentioned to a health care professional before. His parents felt they were just idiosyncratic aspects of his personality. Moreover, he had been functioning at a high level and there was no evidence of distress, except when his parents were not available to provide reassurance. They presented for treatment given Ace’s increased distress and

impairment. It was recommended by his pediatrician that Ace begin 20 mg of fluoxetine. Ace's parents met with a child and adolescent psychiatrist for additional guidance. At that visit, Ace's parents discussed reluctance to start medication, especially given the warnings that they had heard that "these drugs can make my son suicidal," and had read that many children can show remission with E/RP alone. Consequently, the psychiatrist referred the family to a colleague in his practice—a board certified child and adolescent psychologist with expertise in child OCD. Ace and his family presented for initial consolation with the clinical psychologist who agreed CBT with E/RP was indicated and she reviewed the treatment model with the family. Ace and his family participated in weekly sessions for about 12 weeks, focusing on exposure of his feared thoughts and prevention of ritualistic behavior in a systematic method. Therapy was family-based, emphasizing family-based in vivo practice of E/RP, generalization of exercises outside of session, and minimizing disruption to school. A hierarchy of feared symptoms was developed at visit two, and in vivo E/RP commenced at visit three.

After about 3 months of CBT with E/RP, Ace reported an improved ability to manage his obsessive thoughts and to resist rituals. He reported decreased anxiety as well as urges to ritualize. His parents reported an improved understanding of OCD as well as how to react to his reassurance seeking (and other compulsive behaviors) in order to facilitate his recovery. The family understood the algorithm for intervening with future obsessions or compulsions as well as the potential need to resume CBT if symptoms resurged. The family chose to remain with the psychologist for a few additional sessions to address family conflict that had developed surrounding the OCD behaviors.

▲ 52.2 Posttraumatic Stress Disorder in Children and Adolescents

JUDITH A. COHEN, M.D.

Two-thirds of American youth America experience at least one potentially traumatic event (PTE, e.g., child abuse, domestic or community violence, disaster, accidents, medical trauma, war, or multiple/complex trauma). A third experience multiple traumas, increasing risk of serious mental, and medical health problems. Up to 10 percent develop full-blown posttraumatic stress disorder (PTSD); many more suffer from subsyndrome PTSD symptoms with equivalent functional impairments. New criteria for PTSD in DSM-5 increase attention to developmental and cultural manifestations of trauma symptoms. Genetic and psychobiological factors also influence the development of PTSD. Recognition of the frequency with which children develop PTSD symptoms has led to improved strategies for assessing and treating traumatized children.

DEFINITION

PTSD is defined by developing characteristic features after exposure to trauma, that is, events involving threat to life, safety or physical integrity, experienced or witnessed directly by the child, or affecting someone close to the child (criterion A). The clinical presentation varies and not all children manifest emotional fear, helplessness, or horror as previously required. Children ages 7 years or older must have one intrusion symptom such as recurrent trauma-related memories or dreams, or intense psychological of physiological response to trauma reminders (criterion B); one symptom of persistent avoidance of trauma-related stimuli (criterion C); two symptoms of negative alterations in cognitions such as persistent negative trauma-related beliefs or persistent posttrauma negative emotional state (criterion D); and two arousal symptoms (criterion E). The revised criteria include developmentally sensitive diagnostic criteria for children 6 years and younger. These children must have one intrusion symptom (criterion B); one symptom of avoidance or negative alteration in

cognitions (criterion C); and two arousal symptoms (criterion D). The duration of symptoms must be more than 1 month, and the disturbance must cause clinically significant distress or functional impairment.

HISTORY

Descriptive accounts of children traumatized by the London blitz during World War II, of the kidnapping and subsequent burial of children in their school bus, and of children exposed to a fatal schoolyard sniper attack were published by early child trauma pioneers. Subsequent empirical studies of children exposed to sexual abuse, peer suicide, cancer, burns, and terrorist attacks confirmed that increased levels of trauma exposure and lack of adequate social support strongly predict the emergence of PTSD and other psychological symptoms. The September 11, 2001 terrorist attacks, the Asian tsunami of 2004, and Hurricane Katrina have documented that peritraumatic panic, delayed evacuation, and perceived life threat to self or family members are significant risk factors for later PTSD development. In the past 20 years, a number of empirically rigorous randomized controlled trials (RCTs) have documented the superiority of trauma-focused psychosocial treatments over usual care for pediatric PTSD. Few pharmacological RCTs have examined the treatment of pediatric PTSD.

COMPARATIVE NOSOLOGY

PTSD was first officially recognized in 1980, in DSM-III. DSM-III-R was the first version to include representative items for childhood PTSD. Importantly for children, this version increased the number of avoidance or numbing symptoms needed to meet diagnostic criteria from one to three. DSM-IV further elucidated childhood variants of symptomatology. The development of an alternative algorithm for diagnosing PTSD in preschool children and growing research led to the new diagnostic criteria in DSM-5 for children younger than 7 years old. Research documenting that many do not respond with horror, fear, or helplessness supported the removal of this criterion in DSM-5. Other research led to including a new cluster for alterations of mood and cognitions in DSM-5.

EPIDEMIOLOGY

Surveys document PTSD prevalence rates in the general youth population of 8 to 9 percent with another 14.1 percent reaching subclinical levels. More relevant are prevalence rates among trauma-exposed children, as by definition PTSD is only possible in this population. Nonreferred samples of adolescents exposed to various forms of trauma have documented that 25 to over 90 percent develop PTSD, depending on the trauma experienced, time since exposure, and assessment method used. Chronic traumas, such as ongoing child abuse, or traumas that result in disruption of family and

the broader social support network, such as war or refugee experiences, tend to result in greater risk of PTSD than acute traumas, such as natural disasters. Exposure to multiple traumatic events is associated with an increase in PTSD. Female gender also tends to predict greater risk of developing PTSD as well as other mood and anxiety disorders. Furthermore, the above rates only include children meeting full diagnostic criteria; several studies have indicated that the majority of trauma-exposed children develop PTSD symptoms severe enough to interfere with functioning, even in the absence of a PTSD diagnosis.

ETIOLOGY

PTSD is one of the few DSM disorders that require the presence of an etiological agent (a serious traumatic event). Exposure factors also predict outcome with severity and frequency of trauma exposure, exposure to interpersonal violence, greater perceived life threat, death of a family member, greater peritraumatic panic, and delayed evacuation (if during a mass trauma experience) all predicting higher risk of developing PTSD. Nevertheless, not all children exposed to such events develop PTSD, so other etiological factors must also be considered.

Biological Factors

Female gender is a risk factor for developing PTSD. Children with pre-existing anxiety disorders are at increased risk to develop PTSD following trauma exposure, and a history of depression in first-degree relatives also predicts increased vulnerability to developing PTSD. Prior trauma exposure is a risk factor for developing PTSD upon exposure to a new trauma, with greater number of traumas predicting greater risk of disorder. Recent studies have demonstrated that genetic risk factors interact with other risk and protective factors, such as social support, in determining whether trauma-exposed children will develop PTSD, or will be resilient despite traumatic experiences. Numerous psychobiological abnormalities have been found in children with PTSD, including complex alterations in hypothalamic–pituitary–adrenal (HPA) axis functioning, increased excretion of adrenergic and dopaminergic metabolites, smaller intracranial volume and corpus callosum area, as well as lower intelligence quotient (IQ) and memory deficits. In addition to these alterations, adults with PTSD have evidence of amygdala hyperactivity, medial prefrontal cortex underactivity, and decreased hippocampal volume. However, because of the paucity of prospective studies, it is unclear whether these findings are indicative of etiological (causal) factors in the development of PTSD or the effects of PTSD on children's developing brains.

Psychological Factors

Classical and operant conditioning are involved in the development of PTSD. Extreme stressors typically produce negative emotions (terror, anger, sadness) as well as physiological arousal from the activation of the sympathetic nervous system (the "fight, flight, or freeze" response). Classical conditioning occurs when neutral cues that were present at the time of the trauma become associated or "paired" with the trauma to the extent that they too elicit these intense psychological and physiological reactions. Operant conditioning occurs when the child learns to avoid trauma-related cues in order to reduce the likelihood of experiencing these distressing reactions. As avoidance behaviors are repeatedly reinforced, they may also generalize. New responses can be acquired through pairing of exposure and inhibitory learning.

Children's maladaptive cognitions are also relevant to PTSD development. Shame, self-blame, believing that one is undeserving of being loved, protected or being treated well, or believing that others cannot be trusted are common maladaptive cognitions among children who experience interpersonal trauma. Such children may have difficulty differentiating between what was done to them (the traumatic experiences) and who they are (their identity). This has important implications for how such children's trauma symptoms are manifested (i.e., in assessing complex PTSD symptoms as described below).

Social Factors

Many pretraumatic social factors including lower socioeconomic status, economic deprivation, family dysfunction, parental separation or death, lower intelligence, minority racial or ethnic status, and family psychiatric history have been found to predict higher risk of developing PTSD. Absence of a strong social support network has been found to increase the risk of developing PTSD. Parental psychopathology has also been implicated as a risk factor in children developing PTSD following exposure to a variety of traumatic events. Thus, there is growing evidence that social factors may have a role in the etiology of this disorder. However, a recent study demonstrated that twins who had been sexually abused were at significantly greater risk of developing a variety of adverse outcomes than their nonabused twins, despite shared genetics and family environment. Social etiological factors should therefore not be overestimated.

DIAGNOSIS AND CLINICAL FEATURES

Exposure to a Traumatic Event

To qualify for a diagnosis of PTSD, the child must have been exposed to a traumatic event that consisted of direct personal experience; witnessing an event in person; learning about the trauma of a close family member or close friend (in the case of death, the event must have been violent or

accidental); or experiencing repeated or extreme exposure to aversive details of the traumatic events (but not only through media descriptions). A number of qualifying traumatic events are listed in DSM-5, which specifies that in the case of child abuse, there does not have to be threat physical violence or injury (e.g., genital fondling without penetration would qualify).

Re-Experiencing

The child must have at least one persistent intrusion symptoms related to the traumatic event. Children may have recurrent, involuntary, and intrusive thoughts, memories, images, or body sensations reminiscent of the traumatic event. In young children, this may take the form of repetitive play in which traumatic themes are present (e.g., sexually abused children may repeatedly re-enact inappropriate touching in their play). Children may have recurrent distressing dreams about the event, or in the case of younger children, there may be frequent frightening dreams without any recognizable content. Children may have dissociative reactions; these may include periods when they act or feel as if the event were reoccurring in the present moment (a flashback). In young children, trauma-specific re-enactment may occur (e.g., sexually abused children may insert objects into their own or other children's private parts or otherwise recreate abusive acts perpetrated against them). Children may experience intense psychological distress or physiological reactivity when exposed to triggering events, people, or situations that remind them of the original traumatic event (e.g., children who witnessed a drive-by shooting may become agitated or have difficulty breathing when they hear thunder or a backfiring car). These reminders may be highly idiosyncratic to individual children.

The above criteria also apply to diagnose PTSD for children 6 years or younger, but in these children, spontaneous and intrusive memories might not appear distressing. It may not be possible to ascertain that the frightening content of dreams is related to the traumatic event.

Avoidance and Numbing

The child must experience persistent avoidance of stimuli associated with the traumatic event and numbing of general responsiveness, as indicated by at one of the following symptoms. Children may avoid or make active efforts to avoid memories, thoughts or feelings about or closely associated with the traumatic event. They may avoid or make efforts to avoid external reminders (e.g., discussions about the traumatic event or people, places, situations, or activities that remind them of the trauma). For example, after the sudden death of a loved one, children may refuse to say the name of the deceased or insist that others not do so.

In order to diagnose PTSD for children 6 years and younger, one or

more symptom representing *either* persistent avoidance of trauma-related stimuli *or* negative alterations in cognitions and mood associated with the traumatic event must be present.

Negative Alterations in Cognition and Mood

Children may be unable to recall one or more important aspect of the traumatic event (dissociative amnesia). Children may have persistent overly negative beliefs about themselves (e.g., "No one loves me"); others (e.g., "I can't trust anyone") or the world (e.g., "Nothing is safe"); or maladaptive cognitions about why the trauma happened (e.g., "I should have known he would hurt me") leading to distorted self- or other-blame. Children may develop negative emotional states such as shame, guilt, anger, sadness, or fear that persist after the traumatic event. Children may have diminished interest or participation in their normal activities, for example, not wanting to play with friends (social withdrawal) or participating less in the classroom. They may feel detached or estranged from others (e.g., feel that no one understands them; affiliate with deviant peers) or may experience diminished capacity to feel emotions, especially warm interpersonal emotions (e.g., children may say, "I don't feel like I love anyone anymore.").

In order to diagnose PTSD for children 6 years and younger, one or more symptom representing *either* persistent avoidance of trauma-related stimuli *or* negative alterations in cognitions and mood associated with the traumatic event must be present.

Arousal and Reactivity

The child must also experience persistent symptoms of arousal and reactivity that were not present prior to the traumatic event, as evidenced by at least two of the following. Children may have increased irritability and angry outbursts, with little or no provocation; these may be expressed as aggression toward others (and are often misdiagnosed in children as externalizing behavior disorders). The may have reckless or self-destructive behaviors (e.g., self-injury, substance abuse, reckless driving, or unprotected sexual activity). They may exhibit hypervigilance (e.g., children may ask their parents to check several times every night to be sure that all the doors are locked) or exaggerated startle reaction (e.g., jumping whenever the telephone rings or a pencil drops in the classroom). Children may have difficulty concentrating or completing tasks, which may impair academic performance. Children may have trouble falling or staying asleep, or may have restless sleep, whether or not they are having trauma-related dreams.

The above criteria also apply for children 6 years and younger except that these children do not typically exhibit reckless or self-destructive

behaviors.

Duration, Types, and Clinical Features

These symptoms must be present for at least 1 month and must be accompanied by significant distress or impairment in an important area of functioning. PTSD with dissociative symptoms should be specified if the child meets the above criteria and experiences persistent or recurrent depersonalization or derealization symptoms that are not attributable to substance abuse. If the onset of symptoms does not occur until more than 6 months after the traumatic event, the diagnosis is PTSD with delayed expression. "Complex PTSD," "complex trauma," and developmental trauma disorder have been suggested to represent the complexity of symptoms existing in children experiencing repeated, interpersonal traumas involving attachment disruption. Such children have severe dysregulation of affect, behavior, cognitive, attachment, perceptual, and biological domains that result in marked functional impairment. It is not clear whether the new DSM-5 PTSD criteria will more adequately describe these complex problems or whether a new diagnosis will be required.

PATHOLOGY AND LABORATORY EXAMINATION

Although several alterations in laboratory, neuropsychological, and neuroimaging tests have been reported in children with PTSD, there is currently no laboratory or other test that can reliably distinguish children with PTSD from other children on an individual basis.

DIFFERENTIAL DIAGNOSIS

Assessment of pediatric PTSD is complex and beyond the scope of this article. PTSD symptoms overlap and co-occur with several other psychiatric conditions. Acute stress disorder (ASD) occurs and is resolved within the first month after traumatic exposure. Children with less significant trauma-related adjustment symptoms may be diagnosed with an adjustment disorder. Several diagnostic criteria of PTSD overlap with those of anxiety disorders and major depressive disorder. For example, recurrent intrusive thoughts are a hallmark of obsessive–compulsive disorder, while avoidance of social situations, social withdrawal, and tantrums is characteristic of social phobia. The specific content of these thoughts or fears may clarify that they are not trauma focused. However, because children frequently do not disclose traumatic experiences unless specifically asked, it is important for the assessing clinician to inquire directly about traumatic exposure whenever children present with anxiety-related symptoms.

In a similar manner, irritability, feelings of emptiness, decreased interest in normal activities, sleep disturbance, psychomotor agitation, inappropriate guilt, and decreased concentration are all symptoms shared

by PTSD and major depressive episode. Distinguishing between these two disorders may be particularly difficult in children with avoidance symptoms that prevent them from discussing the traumatic event. Careful history taking is essential in determining whether the child's symptoms are trauma related and to what extent the child meets criteria for either or both diagnoses. Children with traumatic bereavement are particularly likely to meet partial or full criteria for both disorders.

Children and adolescents presenting with substance use disorder may have a past history of trauma that is either covert (never disclosed) or minimized by the child or assessing clinician. Accurately identifying PTSD in such children may be critical to their optimal treatment, as standard substance use interventions do not contain important elements of trauma-focused treatment. If such children are using drugs or alcohol to self-medicate trauma-related symptoms, it is unlikely that their substance use will improve without adequately addressing these symptoms.

Additionally, PTSD may coexist with or be misdiagnosed as behavioral disorders such as attention-deficit/hyperactivity disorder (ADHD) or conduct disorder. Particularly in younger children who are less able to verbalize their anxiety, PTSD-related irritability, sleep difficulties, and difficulty concentrating may present as classic ADHD. Eliciting a history of trauma exposure and evaluating the timing of these symptoms may be important in distinguishing these disorders.

PTSD can mimic medical conditions such as hyperthyroidism, seizure disorder, caffeinism, migraine, asthma, or side effects from prescription or nonprescription medications.

Symptoms of complex PTSD (severe affective, behavioral, relationship, and cognitive dysregulation) may resemble those of bipolar disorder. Particularly if such children are avoidant of disclosing a trauma history, they will likely be diagnosed with bipolar disorder rather than PTSD. Since first-line treatments of these disorders are very different (medications for the former; psychotherapy for the latter), it is crucial to always inquire about children's trauma histories and to assess their symptoms from a trauma-informed neurodevelopmental perspective.

Psychotic symptoms may occur in up to 20 percent of children with PTSD; flashbacks or other intrusive phenomena must be distinguished from true hallucinations or substance-induced disorders.

COURSE AND PROGNOSIS

The natural course of childhood PTSD has not been adequately determined. Based on the available studies, it appears that while PTSD symptoms spontaneously remit in some children, they persist for years or even decades in many others. There is also growing evidence that trauma-focused treatment significantly alters the natural course of pediatric PTSD. Studies have documented continued remission of PTSD 2 years

posttreatment in children who received trauma-focused cognitive-behavioral therapy (TF-CBT).

The prognosis for children with untreated PTSD has become a matter of increasing concern since research has documented the numerous psychobiological abnormalities associated with this disorder, and the severity of some of these (decreased intracranial volume, decreased corpus callosum area, and lowered IQ) is directly correlated with the duration of symptoms. Growing evidence that childhood sexual abuse is predictive of adult suicidality as well as depression and suicidality in the offspring of such victims also suggests a poor prognosis for unresolved PTSD in childhood. This emphasizes the importance of identifying symptomatic children and providing effective interventions early in the course of this disorder.

Treatment

Children with PTSD receive many treatments, but the effectiveness of most of these interventions has not been evaluated. To date trauma-focused psychotherapies have the most empirical evidence of efficacy for treating pediatric PTSD. Although several selective serotonin reuptake inhibitors (SSRIs) have been shown to effectively treat adult PTSD symptoms, two RCTs have failed to show superiority to placebo in traumatized children. Similarly, although open trials of adrenergic agents have had promising results, two RCTs have failed to show superiority of propranolol to placebo in treating pediatric PTSD.

Psychotherapeutic Treatments

Cognitive-Behavioral Therapies. Currently TF-CBTs have the strongest evidence for resolving child PTSD and associated problems. TF-CBT has been found in 15 RCT to be superior to other active treatments or comparison conditions in decreasing PTSD as well as depressive, anxiety, cognitive, behavioral symptoms, and functional impairment in traumatized children. TF-CBT has been tested in youth who have experienced sexual trauma, domestic violence, terrorism, disaster, war, multiple and complex trauma, in multicultural cohorts in the United States, Europe, Africa, and Australia. TF-CBT is typically provided over 12 to 25 treatment sessions. Its core components are summarized by the acronym PRACTICE: *Psychoeducation* about the child's traumatic experiences and responses; *Parental or caregiver inclusion* in treatment, including a parenting skills component; *Relaxation skills,* which are individualized for each child and parent; *Affective* modulation skills; *Cognitive* coping techniques (connections between thoughts, feelings, and behaviors are taught and practiced); *Trauma narrative* and cognitive processing, consisting of carefully calibrated efforts to encourage the child to describe increasing

details about the traumatic event and to identify and process inaccurate or unhelpful thoughts related to the traumatic event; In vivo mastery of trauma reminders; *Conjoint* child–parents sessions in which optimal communication is emphasized and practiced; and *Enhancing safety* and future developmental trajectory, in which the child develops and practices effective strategies for maintaining personal safety. A group CBT model for school settings, Cognitive Behavioral Intervention for Trauma in Schools, has been tested in schools and found to be effective in reducing PTSD and depressive symptoms. Other CBT-based treatments such as the UCLA Trauma/Grief Program for Adolescents and a child adaptation of Narrative Exposure Therapy have also been tested with positive results among refugee or war-exposed children.

Eye movement desensitization and reprocessing (EMDR) utilizes exposure and cognitive reprocessing interventions with bilateral eye movements. EMDR has been adapted for children and tested in two well-designed studies. A recent study comparing EMDR to TF-CBT found that both treatments were equally effective and efficient at improving children's PTSD symptoms, with TF-CBT being superior for improving comorbid psychiatric symptoms.

Psychodynamic and Attachment-Based Therapies. Child–parent psychotherapy (CPP) is an attachment-based treatment of trauma-exposed infants and preschool children and their primary caretakers. CPP has been tested in one RCT for preschoolers exposed to marital violence and found to be superior to case management in improving these young children's PTSD symptoms and in their mothers' PTSD symptoms. CPP includes the following components: Providers begin by providing developmental guidance or psychoeducation about the child's behavior and how it may be understood in light of normal development and changed through simple behavioral interventions. If needed, additional interventions are added to help the parent to understand the child's behaviors and enhance child–parent attunement. These may include behavior management, cognitive reframing and processing, developing a joint narrative of the child and parent's traumatic experiences, and interpreting child or parent behaviors, emotions, and past experiences.

Psychopharmacological Treatments

RCTs of sertraline (Zoloft), D-cycloserine, and propranolol (Inderol) have failed to show significant differences from placebo in improving pediatric PTSD. While open treatment trials have demonstrated clinical improvement in child PTSD symptoms following use of adrenergic blocking agents (guanfacine [Tenex], clonidine [Catapres]), a dopamine antagonist (risperidone [Risperdal]), or an opiate (morphine [Roxanol]), none of these medications have been tested in well-designed double-blind, randomized

trials. Pharmacological treatments thus lack evidence for treating pediatric PTSD. Children who have comorbid psychiatric conditions for which effective pharmacotherapy is established should receive the appropriate psychopharmacological treatment of those disorders; it is not yet known whether such treatment will also impact favorably on coexisting PTSD symptoms.

Biological Treatments

Since dysregulation of the HPA axis is generally found in both children and adults with PTSD, use of a corticotropin-releasing factor (CRF) antagonist has been suggested as a potential intervention for preventing this disorder from developing or in reversing PTSD symptoms once they are present. This intervention has not yet been tested in children or adults.

C was a 15-year-old girl referred to treatment following hospitalization for a suicide attempt. From 6 to 12 years old, C had been sexually abused by paternal grandfather. C disclosed the abuse to her parents at 12 years old, who were supportive; however, a week later grandfather committed suicide. The following year C came out to her parents and close friends who were supportive. Parents thought C was doing well until the suicide attempt. In the hospital C disclosed the following: Since coming out, C experienced worsening physical, sexual, and verbal abuse in school related to her gay identity, but kept this from parents. During the current school year, C was repeatedly sexually assaulted by three male peers who threatened to kill her younger brother if she disclosed the abuse. Guilt (she "froze" during these episodes and did not say "no" or fight back) and negative self-cognitions led to the suicide attempt.

During the initial evaluation, C reported intrusive thoughts and nightmares about sexual abuse and grandfather's gory suicide. C tried unsuccessfully to push these images out of her mind. She acknowledged maladaptive cognitions including that she "deserved to be raped for killing my grandfather" and that she was "a terrible person." She endorsed sleep disturbance, increased startle, irritability, and sadness. She scored 58 on the UCLA PTSD Reaction Index (RI), consistent with very severe PTSD, and 20 on the Beck Depression Inventory (BDI), consistent with major depressive episode.

C and her parents attended 23 sessions of TF-CBT. Twenty of these were individual sessions (half of the session was spent with C and half with parents); three sessions were conjoint child–parent sessions in which the family met together. During the stabilization phase (11 sessions), C and parents learned about trauma reminders (e.g., the threat of sexual assault would serve as a trauma reminder for C in light of her history of sexual abuse), trauma impact (e.g., fight, flight, freeze, and trauma impact on affect, behavior, biology, cognitions, relationships and perceptions), as well as a variety of coping skills for trauma reminders. C and her parents reported that this helped them to make sense of C's response to the rapists as a trauma response and was "a huge relief" for C. C preferred using visualization and the cognitive triangle (changing thoughts in order to change feelings and behaviors). She carried a notebook with her and practiced changing her thoughts whenever she had a negative feeling. She found that this was very helpful and when paired with visualization, enabled her to reduce her distress level significantly in most situations. C's parents were very upset at the school for failing to protect C from harassment and physical assaults at school, and with C's agreement, investigated other schools that C could attend.

During the trauma narrative phase (7 sessions), C developed a detailed description and cognitively processed her personal trauma experiences. Through this process her understanding and cognitions about these experiences changed substantially. She identified how her grandfather manipulated her into worrying about her parents' response if she disclosed, and contributed to her self-blame for his suicide. Her new cognitions were that only the perpetrators were responsible for the abuse; grandfather chose to kill himself rather than face up to prison and that she did not deserve to be hurt for any reason. During this process, C

also made the decision that she wanted to go to a different school because "they didn't protect me and other gay kids the way they should have."

During the integration and consolidation phase (5 sessions), C shared her narrative with parents and engaged in safety planning with them. This included how C could protect herself from bullying going forward, and how parents could also advocate for her. C made the transition to her new school successfully and found this to be a more supportive environment. C and parents addressed healthy sexuality together and in individual sessions and C reflected on her future hopes and plans. At the end of treatment, C's RI score was 15 and BDI was 10 (both normal).

FUTURE DIRECTIONS

1. Evaluating DSM-5 diagnostic criteria for children ages 7 to 17 years, particularly those with complex trauma to determine whether the new criteria adequately describe the complex difficulties of these youth, or an additional diagnosis is needed.
2. Developing and testing effective treatments for children who have PTSD in the presence of comorbid psychiatric disorders.
3. Evaluating the relative efficacy of pharmacological treatments for pediatric PTSD, alone and in combination with psychotherapy.
4. Developing a biomarker for pediatric PTSD and other effective neurobiological tools for assessing pediatric PTSD.
5. Developing effective dissemination strategies for training community therapists in evidence-supported treatments for children with PTSD, including making these treatments usual care by embedding evidence-based treatments into routine graduate school training for counseling and social work students.
6. Developing and testing the use of social media applications for screening and treating pediatric PTSD. Given the large number of children who have PTSD, some will never reach mental health providers but most have access to electronic media.

▲ 52.3 Separation Anxiety, Generalized Anxiety, and Social Anxiety

COURTNEY P. KEETON, PH.D., JESSICA LEE SCHLEIDER, M.A., AND JOHN T. WALKUP, M.D.

Fear and worries are very common throughout childhood. Developmentally normal anxiety is short lived and nonimpairing and includes fears about the dark, monsters, or strangers for younger children and worries about friends, school, or decision making for older children and adolescents. Despite the common occurrence of transient fears and worries, a number of children experience persistent and impairing levels of anxiety that warrant a diagnosis of an anxiety disorder and clinical attention.

The three most common pediatric anxiety disorders—separation anxiety, generalized anxiety, and social anxiety—share the same underlying construct of anxiety, have significant symptom overlap, are highly comorbid with one another, and show similar familial relationships and continuity with adult anxiety and depressive disorders. For these reasons, the three disorders are often grouped together as they are in this section. The three anxiety disorders are described separately here; however, the reader should note that each etiology and treatment section is informative with regard to separation anxiety, generalized anxiety, and social anxiety.

Anxiety disorders comprise the most prevalent class of mental health problems among youth, affecting up to 1 in 5 individuals by the time they reach adulthood. Children with anxiety disorders have an early onset and a persistent or recurring course with high levels of short- and long-term impairment. In addition to being comorbid with one another, anxiety disorders are often comorbid with nonanxiety disorders. Fortunately, there are highly effective psychosocial and pharmacological treatments for these disorders. Current challenges include identification of treatment methods to optimize outcomes and address co-occurring emotional and behavioral problems, and dissemination and utilization of evidence-based treatment.

SEPARATION ANXIETY DISORDER

Definition

Separation anxiety disorder is characterized by excessive and developmentally inappropriate fear of being away from an attachment figure, avoidance of such separations, and irrational beliefs about the consequences of being apart from a caregiver. Attachment figures are usually parents, but may also be siblings, grandparents, or other caregivers

or, for adults, children or spouses. Whereas developmentally appropriate separation anxiety typically presents around age 6 months and declines between ages 2 and 3 years, children with separation anxiety disorder have either persistent and worsening or new onset separation anxiety in the school-age years (i.e., ages 6 to 12 years). This section differentiates between developmentally normal separation anxiety in infancy and toddlerhood and separation anxiety disorder in school-age children.

Comparative Nosology

Separation anxiety disorder appeared initially in the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) and was classified as an anxiety disorder of childhood or adolescence. Although it was subsequently categorized in the DSM-IV as a "disorder usually first diagnosed in infancy, childhood, or adolescence," separation anxiety is currently classified in the DSM-5 as an anxiety disorder. Since first introduced the diagnostic criteria for separation anxiety disorder have been modified in four ways, along with modified wording in DSM-5 to capture symptom presentation in adulthood. Unlike earlier versions, the DSM-5 does not require onset prior to age 18 and recognizes that some adults report onset after age 18 years. The minimum duration was increased from 2 weeks in DSM-III to 4 weeks in DSM-IV and subsequent versions, and DSM-5 specifies at least 6 months in adults to avoid overdiagnosis of transient fears. Also, evidence of serious distress or impairment was added for diagnosis starting in DSM-IV. Finally, recurrent excessive distress about (1) anticipated or (2) actual separation was collapsed into one symptom in DSM-IV, and thus the symptomatic threshold for separation anxiety disorder was reduced from three of nine symptoms in DSM-III-R to three of eight symptoms in DSM-IV and currently in DSM-5.

Epidemiology

Epidemiological studies show the lifetime prevalence rate of childhood and adolescent separation anxiety disorder is at least 4 percent, with peak onset between 7 and 9 years of age. Separation anxiety disorder is more common in childhood than in the preschool years or adolescence and is the most common anxiety disorder in children under the age of 12. Although the peak age of onset is in middle childhood, preschool children can be diagnosed with separation anxiety disorder (range from 0.5 to 10.5 percent) and can be distinguished from children with developmentally normal separation anxiety. Children with separation anxiety symptoms who do not meet diagnostic criteria are very common, with reported rates as high as 50 percent. Community studies suggest that girls are more likely than boys to meet criteria even in the preschool years, but clinical studies find the disorder to be equally common in girls and boys.

Etiology

Although the exact cause of separation anxiety is unknown, genetic, early temperamental, and family or environmental variables have all been associated with early-onset anxiety disorders. Although genetic factors likely play a significant role, early experiences, many of which are family-based, may play an important role in the onset of childhood anxiety disorders. Methods to sort the various contributions of genetics, temperamental, and biological vulnerabilities and family or environment are often confounded. However, it is likely that genetically based, temperamental, or biological vulnerabilities predispose affected children and their parents to interact in ways that either protect children from or predispose children to developing an anxiety disorder. For example, an 8-year-old child with separation anxiety born to a mother with an anxiety disorder may have a very different outcome if the mother was symptomatic or successfully treated during the child's early years. Although in both situations the child and the mother share genetic and temperamental and biological vulnerabilities, the effect of the child's anxiety on the affected (and treated) parent and the affected (and treated) parent's impact on the child may account for significant difference in both short- and long-term outcomes.

Twin studies provide perhaps the greatest evidence for the role of biological and environmental factors (shared and nonshared) in the etiology of childhood anxiety disorders. Although historically both genetic and environmental factors have been implicated in the etiology of childhood anxiety disorders, a large well-designed study of 6-year-old twins suggests significant genetic influence for the separation anxiety phenotype. The heritability estimate for separation anxiety was high, 73 percent, with the remaining variance attributed to nonshared environment, suggesting genetic effects on separation anxiety are substantial and more significant than environmental effects. Another investigation of the role of genetic and shared environment effects in a sample of twins and siblings over time reported that the influence of genetic effects increased and shared environmental effects decreased with age. Finally, newly emerging data suggest that the psychobiological trait of CO_2 hypersensitivity may increase risk for separation anxiety (and supports a proposed genetic association between separation anxiety and later-onset panic disorder).

Behavioral inhibition (BI) to the unfamiliar, characterized by fear, withdrawal, and avoidance of unfamiliar situations or things, is considered a temperament vulnerability in infants and toddlers that predicts anxiety disorder outcomes in later childhood. BI is usually assessed using observational methods in laboratory settings for children aged 9 months through 6 years. Approximately 10 to 15 percent of children are thought to display BI and longitudinal outcomes, suggesting young children with BI

are more likely than noninhibited children to exhibit clinical levels of multiple anxiety disorders including separation anxiety upon long-term follow-up. In cross-sectional studies, BI is associated with a range of anxiety symptoms and disorders in youth, and it has traditionally been considered a vulnerability that lacks specificity for any childhood anxiety disorder. However, longitudinal data found BI to predict *social anxiety disorder* in middle childhood, but not other anxiety disorders.

Parental psychopathology is also highly associated with childhood anxiety disorders. A variety of mechanisms are possible; parents and children can share the same genetic or temperamental vulnerability or parent–child interactive effects could further shape or elaborate both parental and child anxiety. Regardless of the mechanism, children of parents with an anxiety disorder are up to five times more likely to be diagnosed with an anxiety disorder. More specifically, parental panic disorder and major depression are associated with an increased risk for separation anxiety disorder in children.

Longitudinal studies examining the role of infant–mother attachment in the development of childhood anxiety often used the Ainsworth Strange Situation to assess attachment and then follow children overtime. In multiple studies children with an anxious or resistant attachment during infancy were more likely than securely attached infants to develop anxiety disorders, including separation anxiety and related behaviors (e.g., school avoidance). Although infant temperament or maternal psychopathology may affect attachment behavior, cross-sectional assessment of attachment status appears to be the more important factor in determining the presence of anxiety disorders at longer-term outcome.

Specific parenting behaviors such as high levels of parental intrusiveness, overprotection, and psychologically controlling behavior in the child's daily activities may also contribute to a child's risk for developing anxiety. Such anxiety-enhancing parenting approaches are thought to promote dependency and reduce the development of autonomy. Controlling and overprotective parenting may contribute to the development of anxiety by preventing the child from having a range of experiences that foster broad and complex coping skills. Furthermore, parental overprotection may communicate to the child that the world is a dangerous place, introducing a chronic and pervasive response bias. Parents may also support anxious behavior by encouraging anxious cognitions and avoidance in their children or children may mimic anxious cognitions and behaviors modeled by their parents.

Diagnosis and Clinical Features

The defining feature of separation anxiety is excessive and persistent worry about harm befalling an attachment figure (e.g., parent getting into car accident, spouse becoming ill or dying) or oneself (e.g., getting lost, being

kidnapped, having an accident) upon separation. Symptoms may include avoidant behaviors such as refusal to go to school or work, sleep alone, or be without the attachment figure, in order to minimize separation and to reduce distress. Other common symptoms include nightmares with references to separation, and physical symptoms such as stomachaches or nausea in response to possible or actual separation. DSM-5 requires three of eight symptoms, a duration of 4 weeks in children and adolescents, and corresponding functional impairment. The diagnosis can be made in adults who are typically excessively concerned about their spouses or children and symptomatic for at least 6 months.

At home, children with separation anxiety display clingy behavior and shadow their caregiver. They often are reluctant to be in any room alone and may not want to sleep alone in their bedroom. These children often request a parent to fall asleep with them or find their way to their parent's bed at night. Also, they are uncomfortable staying with babysitters and may request to call parents frequently. In public, children with separation anxiety stay close to their caregiver and prefer to sit on their lap or be in physical contact. They are reluctant or refuse to attend birthday parties, sleepovers, camps, and extracurricular activities if the attachment figure is not present. Somatic complaints especially gastrointestinal (e.g., stomachaches, nausea) and cardiovascular (e.g., pounding heartbeat, light-headedness) are commonly reported, particularly before other anxiety-provoking separations. Children may show their separation anxiety distress by tantruming or becoming panicky or oppositional when anticipating separation.

At school, the child may make repeated requests to call their parents to check in or visit the school nurse with physical complaints. When children experience anxiety at school they may become restless and fidgety and be so preoccupied that they are unable to attend to classroom work. Separation anxiety disorder is also a common cause of school refusal and may result in frequent tardiness or high numbers of school absences.

Younger children with separation anxiety disorder tend to report a greater number of symptoms and more nightmares with separation themes than adolescents. Some older children and adolescents with separation anxiety may not present obvious impairment or distress, as their parents and school find ways to accommodate the child's fears to decrease their distress.

As separation anxiety not only affects the child, disruption of family life or parent stress may result from accommodating and managing the child's anxious and avoidant behavior. It can be helpful in the assessment to attempt to quantify the amount of accommodation and to ascertain what the anxiety severity would be if the parents did not offer ongoing accommodation around the child's anxiety.

Anna is a 7-year-old referred for outpatient treatment by her pediatrician. She exhibited a pattern of clingy behavior with her mother and expressed worry about something bad happening to her mother. She expressed worry that her mother would die or that she would be kidnapped. Anna had a history of shyness and difficulty separating from her mother. There is a family history of maternal panic disorder and paternal depression.

Anna often becomes irritable on school mornings or complains of feeling like she needs to vomit. When it is time to leave, Anna hides in her closet or under her bed. She refuses to ride the school bus and insists that her mother drive her to school. Her mother escorts Anna into school, and many times Anna cries and begs her not to leave. Anna does well academically and gets along with peers; however, she occasionally asks to call home or visits with the nurse with stomach aches, hoping to be sent home.

At home Anna will not be in any room alone and requires that her mother is in sight or sound. Anna refuses to shower, brush her teeth, or fall asleep without her mother present. As a result, Anna routinely sleeps with her parents in their bed. She often complains of nightmares of being kidnapped or seeing the "boogie man" near her mom.

Anna will not participate in activities or social events without a parent present. She has attended birthday parties or dance class only when accompanied by her mother. When Anna's parents make arrangements to leave her with a sitter or relative, she cries in distress and begs them not to go. Her parents call home frequently to check in with her. In public, Anna stays close to her mom and frequently sits on her lap when at restaurants or appointments.

Differential Diagnosis

Separation anxiety disorder can be distinguished from developmentally normal separation anxiety based on its onset or increasing severity in the school-age years, the duration of symptoms, and the degree of impairment or distress or need for parental accommodation.

Separation anxiety also should be differentiated from other emotional and behavioral disorders. Children with separation anxiety, generalized anxiety, and obsessive-compulsive disorder (OCD) all have concerns about harm. Children with separation anxiety worry about events that lead to being apart from an attachment figure. Children with generalized anxiety are more fearful of the actual event such as a dog bite, lightning striking, or getting sick than the impact on separation. Children with OCD have repetitive intrusive and senseless thoughts of harm befalling them or their loved ones if they do not complete a ritual. For example, a child with OCD might fear they will die if they do not ritualistically wash their hand four times. Similarly, children with separation anxiety may have social avoidance (e.g., parties or school) similar to children with social anxiety disorder, generalized anxiety disorder, OCD, or even posttraumatic stress disorder (PTSD), but the rationale for the avoidance will differ for each of the disorders. Children with separation anxiety may be described as panicking upon separation or anticipation of separation, but the panic is distinguished from spontaneous panic attacks that characterize panic disorder.

Finally, children with separation anxiety may exhibit defiance, irritable or labile mood, and explosive behavior when presented with a situation that involves separation. These behaviors or moods should be distinguished from oppositional defiant disorder, which involves more general patterns of

argumentativeness and misbehavior, and from bipolar disorder, which has prominent elevation in mood, decreased need for sleep, grandiosity, and increased goal-directed activities.

Course and Prognosis

The course of separation anxiety is not consistent for all children. Some children with separation anxiety appear to spontaneously remit; some remain anxious but are no longer prominently avoidant of separation triggers, and some truly evolve from separation anxiety into other anxiety disorders or depression. Multiple well-done prospective studies document that the majority of children with separation anxiety appear to improve with time. Some indeed appear to spontaneously remit, while others as they get older make avoidant choices consistent with the separation anxiety and may not appear distressed or obviously avoidant. For others with separation anxiety their symptoms evolve into more adult patterns of anxiety or depression. Prospective, longitudinal studies including both community samples and children at familial risk found that those meeting DSM-IV criteria for separation anxiety disorder were at an increased risk of developing subsequent panic disorder with agoraphobia, specific phobia, generalized anxiety disorder, OCD, pain disorder, and alcohol dependence, even after controlling for the risk of parental psychopathology. On the contrary, a recent meta-analysis reported consistent evidence that separation anxiety disorder poses increased risk for all anxiety disorders, but evidence was weak regarding risk for depression and substance use.

Treatment of Separation Anxiety Disorder and Other Anxiety Disorders

Both cognitive-behavioral therapy (CBT) and antidepressant medications appear to be effective for the short- and longer-term management of youth with separation anxiety and other anxiety disorders (e.g., generalized anxiety disorder, social anxiety disorder). Immediately following treatment with CBT or a selective serotonin reuptake inhibitor (SSRI), over 60 percent of anxious youth show clinically significant improvement. In the longer-term (between 2 and 19 years posttreatment), at least half of treated youth maintain initial gains (ranging from 48 to 93 percent). Recent research advances, including completion of the largest double-blind, placebo-controlled trial for childhood anxiety disorders (the "Child/Adolescent Anxiety Multimodal Study [CAMS]") have begun to address questions about the relative efficacy of CBT and SSRI treatment, predictors and moderators of treatment response, the utility of specific CBT components, and efficacy of CBT for very young children.

The CAMS compared the relative efficacy of CBT, sertraline, combination therapy (CBT plus sertraline), and placebo for youth with generalized anxiety disorder, separation anxiety disorder, and/or social

anxiety disorder. All active treatments were superior to placebo, and combination therapy led to significantly higher response rates than did CBT or sertraline (81 percent vs. 60 percent vs. 55 percent, respectively), supporting additive benefits of these two treatment modalities. Remission rates (loss of principal diagnosis, loss of all anxiety diagnoses) were lower than response rates, ranging from 20 to 68 percent, and followed the same patterns as response rates based on treatment condition. Factors associated with higher response and remission rates in the CAMS included absence of comorbid internalizing disorders, absence of social anxiety disorder at baseline, lower baseline anxiety severity, lower caregiver strain, nonminority status, and younger age. Additional variables with a pattern on inconsistent findings related to outcome in prior (and perhaps less well-powered) studies, including parental psychopathology, youth gender, and socioeconomic status, were examined with the CAMS data and found not to predict remission status.

New research also has emerged on effective treatments for anxiety in very young children. Specifically, controlled trials using developmentally sensitive downward extensions of CBT treatments with preschoolers diagnosed with anxiety disorders suggest that anxiety disorders are treatable very early in life. CBT for preschool-age youth is differentiated from CBT for school-age youth and adolescents by its greater emphasis on parent anxiety management and modification of parenting practices believed to maintain child anxiety. In addition to psychosocial approaches, an algorithm proposed by the Preschool Psychopharmacology Working Group suggests prescribing fluoxetine to preschool-age children (as low as 5 to 8 mg/day) if symptoms persist after CBT treatment.

Psychotherapy. Of the existing psychosocial treatments for youth anxiety, CBT has the greatest empirical support and is considered the treatment of choice. Manualized CBT programs for child anxiety such as Coping Cat, Coping Koala, SET-C, and FRIENDS, generally consist of 10 to 16 1-hour sessions delivered in child-focused individual, family, or group formats. CBT is based on principles of classical, operant, and social learning and generally include the following components: (1) psychoeducation: Corrective information about the nature of anxiety and feared stimuli; (2) somatic management techniques: Feelings identification, diaphragmatic breathing, and progressive muscle relaxation to target autonomic arousal and related physiological responses; (3) cognitive restructuring: Identification of maladaptive thoughts and teaching realistic, coping-focused thinking; (4) exposure techniques: Graduated, systematic, and controlled exposure to feared situations and stimuli; and (5) relapse prevention: Methods to consolidate and generalize treatment gains over time. Cognitive restructuring and exposure have been validated as essential components by empirical data showing accelerated

improvement in symptom severity and overall functioning following their introduction in treatment.

Over 30 randomized trials have demonstrated the efficacy of CBT for youth with separation anxiety disorder, generalized anxiety disorder, and social anxiety disorder. Meta-analytic data show that CBT is equally effective for children and adolescents, when delivered in individual or group formats, and when compared to passive (no treatment control) or active control groups. CBT for anxiety yields a mean effect size of $d = 0.66$, and acute gains are sustained for follow-up periods of 2 years or longer. This moderate-to-large effect size finding and durability of treatment effects over time supports the conclusion that CBT is an effective treatment for anxiety disorders with children and adolescents.

Family involvement in CBT is always recommended, but studies of family-focused treatments have yielded equivocal results. Some studies suggest additional benefit and some report no additional benefit above and beyond that of individual CBT. One study comparing standard Coping Cat treatment to a separation anxiety-specific CBT protocol with a parent intervention component yielded no statistically significant differences in outcomes. However, as family-focused treatment studies vary greatly and target different aspects of treatment (e.g., psychoeducation about anxiety, support for the child's participation in CBT, addressing parental anxiety directly, addressing "anxiety enhancing" parenting behaviors, or basic contingency management for child avoidance behavior), it is difficult to draw conclusions about the effectiveness of family treatment for child anxiety.

In recent years, a handful of research groups have successfully adapted and modified parent–child interaction therapy (PCIT), originally developed to treat externalizing problems in young children, to treat various early anxiety problems. These adapted PCIT protocols target child symptoms by reshaping parent–child interaction patterns associated with the maintenance of child anxiety symptoms. This goal is achieved through the use of live, unobtrusive parent coaching, delivered through a bug-in-the-ear receiver from a therapist situated behind a one-way mirror. Recently, the first randomized controlled trial (RCT) was conducted to test the efficacy of a 9-week, PCIT treatment for separation anxiety in children ages 4 through 8. At posttreatment, 73 percent of children assigned to PCIT no longer met criteria for a diagnosis of SAD, and results were largely maintained at a 3-month follow-up visit. Preliminary efficacy studies of another PCIT adaptation, the Coaching Approach behavior and Leading by Modeling (CALM) Program, designed to target the full range of anxiety disorders affecting young children (generalized anxiety disorder and social anxiety disorder, in addition to separation anxiety disorder) suggest the promise and feasibility of this approach.

Although evidence strongly supports CBT as an efficacious treatment

for childhood anxiety disorders, disseminating this specialized form of psychotherapy is an ongoing challenge. Also, service utilization data show that far fewer treatment sessions are completed in practice as compared to protocol-based treatment trials for anxiety. Thus, recent years have spawned the development of computer-assisted treatments such as BRAVE-ONLINE and Camp-Cope-A-Lot, which combine computer-based sessions with online and phone contact with a CBT clinician. Preliminary trials of these programs, including one RCT, suggest that computer-assisted and in-person CBT produce statistically similar clinical improvements. Given the initial promising findings, and the capacity of computer-based CBT to increase treatment accessibility, these programs merit continued investigation.

Another newly emerging computer-based treatment for child anxiety disorders is Attention Bias Modification (ABM; also called Cognitive Bias Modification). This approach draws from cognitive theories of anxiety, specifically relating to attentional biases. Evidence indicates that individuals who experience anxiety disorders attend more to threat-related stimuli, leading them to grow hyper-vigilant to perceived threats. Over time, experiencing this hypervigilance exacerbates anxiety levels, which in turn increases attention to threat and produces a maladaptive feedback loop. ABM aims to intercept this cycle by using a dot-probe paradigm to implicitly modify biases toward threat in anxious individuals. A recent meta-review of ABM trials for pediatric anxiety found that, in eight of ten existing efficacy trials (including three RCTs), participants experienced significant improvements in anxiety postintervention. While these findings are promising, further research is needed to clarify the optimal frequency and duration of ABM, the most effective intervention setting, and whether ABM is a useful adjunct to traditional CBT.

Pharmacology. SSRIs are considered first-line medications for this population due to the favorable treatment response (effect sizes greater than 0.8) and low side-effect profile identified in a number of single-site and multisite randomized, controlled trials. Agents that have demonstrated efficacy include fluvoxamine (Luvox), fluoxetine (Prozac), sertraline (Zoloft), paroxetine (Paxil), duloxetine (Cymbalta), and the tricyclic antidepressant imipramine (Tofranil). Despite demonstrated efficacy of SSRIs for anxiety in RCTs, no SSRIs are approved by the U.S. Food and Drug Administration (FDA) for use with children and adolescents. However, the serotonin-norepinephrine reuptake inhibitor duloxetine received an FDA indication for generalized anxiety disorder in children and adolescents ages 7 to 17 years.

Open-label follow-up studies of SSRIs suggest that youth who benefit acutely continue on a positive trajectory for up to 6 months. Further, since anxiety disorders tend to run a chronic course with associated impairment,

longer treatment with medication may be justified to support consolidation of initial gains and prevent return of anxiety symptoms.

How long to treat children with medication to maximally reduce the chance for return of symptoms upon medication discontinuation is not known. Therefore, making the decision when to discontinue medication is often determined pragmatically. Treatment for 6 to 12 months after remission in symptoms may provide extended benefit without undue burden and may offer an opportunity to reduce the chance for a return of symptoms after medication discontinuation. However, longer-term treatment may be necessary if children experience a return of symptoms when medication doses are missed or during known trigger points such as the start of school in the fall or after the winter holidays (separation anxiety), grade reports or final examinations (generalized anxiety), or group activities at school or camp (social). Such tenuous symptom control suggests that continued treatment, dose increases, or more intensive psychosocial treatments be provided to stabilize the patient before considering medication discontinuation. In addition, the timing of the discontinuation trial is critical to prevent the child from being exposed to a return of symptoms at a time when anxiety triggers are present or when family or medical support are not available (i.e., start of school for separation anxiety or participation in performance activities for generalized or social anxiety).

Benzodiazepines have not been extensively studied for the acute or chronic management of anxiety in children, and while potentially useful, they may lead to both psychological and physical dependence and thus complicate treatment longer term. Given the efficacy of SSRIs and other antidepressants for childhood anxiety, benzodiazepines should not be considered as first-line treatment. If used at all, benzodiazepines may be considered for short-term augmentation of antidepressants early in the course of treatment for some highly anxious children.

There is little evidence supporting the use of other medications such as antihistamines, α-adrenergic agonists, or antipsychotics for the treatment of childhood anxiety disorders; however, it is not uncommon to see patients clinically who are treated with such agents to address problems with insomnia related to anxiety. Combining other medications with SSRIs to address anxiety-related insomnia should only occur when antidepressants have been maximally adjusted upward and anxiety and insomnia persist. Then the use of sedating antidepressants is preferred to the use of antihistamines, α-adrenergic agonists, or antipsychotics.

GENERALIZED ANXIETY DISORDER

Definition

In contrast to separation and social anxiety, which generally have one

anxiety triggering experience (i.e., separation and social humiliation, respectively), generalized anxiety disorder is characterized by excessive and uncontrollable worry about a number of anxiety-provoking events. The most common symptoms among affected youth are poor concentration, restlessness, and irritability, but other symptoms include fatigue, sleep disturbance, or muscle tension. As with other anxiety disorders, generalized anxiety must cause marked distress, interfere with social, emotional, and educational functioning, and is not simply a reaction to recent stressors.

Comparative Nosology

Prior to DSM-IV, a diagnosis of generalized anxiety was reserved for individuals 18 years or older, and children with multiple fears and worries could be diagnosed with overanxious disorder. Overanxious disorder was characterized by excessive or unrealistic worry for a period of at least 6 months. Due to the poor reliability and validity of this diagnostic category and symptomatic overlap and continuity with adult generalized anxiety, overanxious disorder was incorporated into the DSM-IV generalized anxiety disorder diagnosis. Research comparing cases diagnosed by DSM-III-R and DSM-IV criteria found that the change in terminology did not affect the characteristics of cases. Criteria remained unchanged for DSM-5.

Epidemiology

Generalized anxiety disorder is a common diagnosis in children, with a reported lifetime prevalence of 9.0 percent. Community samples of preschool children report a prevalence range of 0.5 to 6.5 percent for overanxious disorder or generalized anxiety disorder. Based on data from two community epidemiology studies, the 3-month prevalence rate for generalized anxiety disorder among children aged 9 to 12 is 1.4 percent. The prevalence for adolescents aged 13 to 18 ranges between 2.3 and 5.0 percent. Whereas rates of separation anxiety decline with age, rates of generalized anxiety increase with age, with a mean age of onset of 8 to 9 years, and median age of onset of 12 years. Girls are twice as likely as boys to meet diagnostic criteria.

Pediatric generalized anxiety disorder is commonly associated with other anxiety disorders and mood disorders. Data from the NCS-A and GSMS found that up to 2/3 of affected youth met criteria for another anxiety disorder, and about ½ met criteria for a mood disorder. Preschoolers with generalized anxiety have the highest rates of comorbidity compared to preschoolers with other anxiety disorders. Few significant differences in rates and patterns of comorbidity across age and gender have been identified; younger children are more likely than adolescents to have separation anxiety as a comorbid diagnosis, and males are more likely than

females to have an externalizing disorder as a co-occurring diagnosis.

Etiology

Similar to separation anxiety disorder, both genetic and environment factors contribute to the development of generalized anxiety disorder. However, heritability estimates are lower for generalized disorder (approximately 30 percent), suggesting that environmental factors, both shared (e.g., uterine environment in the case of twins, exposure to common parenting in the case of siblings) and nonshared (e.g., personal traumatic experience, peer relationships), may have a more prominent etiological role. Twin studies show that generalized anxiety may be better explained by additive genetic factors and nonshared environmental factors compared to shared environment factors. Low heritability estimates in twin studies and high familial rates of generalized anxiety suggest that increased rates in families may be more related to environmental factors. For example, parental anxiety, parenting approaches, or exposure to stressful life events may negatively affect childhood anxiety outcomes. Similarly, childhood anxiety may also impact parental or sibling anxiety as the child's anxiety may change the larger home environment.

Anxiety sensitivity is a temperamental or trait-like factor under genetic influence that is considered a risk factor for anxiety in general. It is characterized by a tendency to interpret physiological symptoms as a sign that something harmful will result. Such factors, while not specific to anxiety, may predispose children in certain environments to become symptomatically more anxious and impaired. Similarly, an attentional bias toward threatening cues and a tendency to interpret ambiguous situations as threatening are associated with children with current anxiety disorder. Although such relationships cannot be considered causal, it is possible that such attentional biases coupled with environmental variables such as parenting influences (e.g., hearing information from a parent about the potential dangers of a situation) may ultimately shape anxiety-related beliefs and behaviors. Anxiety sensitivity has been related specifically to panic in adolescents and otherwise has been linked to anxiety in general.

Diagnosis and Clinical Features

The hallmark feature of generalized anxiety disorder is excessive worry that is difficult to control (Table 52.3–1). The threshold for diagnosis differs slightly for adults and children; adults are required to experience three of six associated symptoms, whereas children are required to have only one associated symptom. A diagnosis also requires the child to experience excessive worry more days than not for 6 months, the worry and associated symptoms must interfere with daily functioning, and the anxiety is not triggered by recent stressful events.

Table 52.3–1.
DSM-5 Diagnostic Criteria for Generalized Anxiety Disorder

A. Excessive anxiety and worry (apprehensive expectation), occurring more days than not for at least 6 months, about a number of events or activities (such as work or school performance).
B. The individual finds it difficult to control the worry.
C. The anxiety and worry are associated with three (or more) of the following six symptoms (with at least some symptoms having been present for more days than not for the past 6 months):
Note: Only one item is required in children.
   1. Restlessness or feeling keyed up or on edge
   2. Being easily fatigued
   3. Difficulty concentrating or mind going blank
   4. Irritability
   5. Muscle tension
D. Sleep disturbance (difficulty falling or staying asleep, or restless, unsatisfying sleep)
E. The anxiety, worry, or physical symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
F. The disturbance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition (e.g., hyperthyroidism).
G. The disturbance is not better explained by another mental disorder (e.g., anxiety or worry about having panic attacks in panic disorder, negative evaluation in social anxiety disorder [social phobia], contamination or other obsessions in obsessive-compulsive disorder, separation from attachment figures in separation anxiety disorder, reminders of traumatic events in posttraumatic stress disorder, gaining weight in anorexia nervosa, physical complaints in somatic symptom disorder, perceived appearance flaws in body dysmorphic disorder, having a serious illness in illness anxiety disorder, or the content of delusional beliefs in schizophrenia or delusional disorder).

The vast majority of pediatric patients with generalized anxiety (75 to 80 percent) endorse physical symptoms. Common physical symptoms include headaches, tension, restlessness, gastrointestinal distress, and heart palpitations. Cognitive characteristics of generalized anxiety include negative thinking errors such as catastrophizing (i.e., expecting the worse possible outcome) or overestimation of the likelihood that something undesirable will occur. Generalized worries cover a range of everyday issues, such as being on time, upcoming activities, failure of loved ones or friends to meet basic expectations, or whether unexpected events (e.g., inclement weather) will change daily plans or schedules. Children and adolescents with generalized anxiety are often described as perfectionistic and overly sensitive. They are plagued by negative self-image, need for reassurance, and insecurities about competence, performance, and expectations about the future.

Andrew is a 13-year-old referred for outpatient treatment by his pediatrician for frequent headaches thought to be associated with anxiety. Andrew was born via cesarean section with no reported perinatal or postnatal complications. As an infant he was difficult to soothe.

Medical history was unremarkable. Andrew was reported to be sociable and well-liked by his peers. Academically, he was an honor roll student enrolled in advanced classes. He had no psychiatric treatment history. Family history was significant for paternal social anxiety and maternal depression. Andrew's two siblings, one older and one younger, were reported to be high functioning with no psychiatric history. Clinical interview revealed no concerns regarding externalizing behavior. Worries were reported about a range of situations including school, the future, athletic performance, family matters, and health and safety.

During the interview, Andrew was engaged and cooperative. He described himself as "stressed out" because of school. He was an A student, but endorsed worries related to examinations, grades, and whether his upcoming high school courses would prepare him adequately for college. He also played point guard on the school basketball team and acknowledged worries about his speed and height compared to other players and questioned whether he was good enough to make the high school team. In addition, he expressed concern about family-related issues such as finances, parental conflict, and the potential for his parents to get divorced. Andrew acknowledged having headaches and stomach upset at least 4 days per week. Upon questioning, he reported that he cannot stop worrying and that worries keep him awake at night about 5 days per week. When given rating scales to complete, Andrew asked several questions about the directions and was concerned about completing the forms correctly.

Andrew's parents described him as a "worry wart," saying he has always been anxious. They reported that he often has health concerns. Most recently, he stopped using an over-the-counter face wash containing salicylic acid and expressed concern about accidentally swallowing the product and being poisoned. Also, his recent trip to the pediatrician was prompted by Andrew's questioning about whether he needed a computed tomography (CT) scan due to his headaches. His parents report that he is frequently irritated and says that he is "stressed out" when questioned about school or basketball. He often seeks reassurance from his parents, but they find their attempts at doing so are unhelpful over the long term.

Differential Diagnosis

Worry associated with generalized anxiety has multiple targets that include worries regarding everyday life experience. Therefore, it may be more difficult to differentiate generalized anxiety from normative anxiety experienced by all individuals. However, the overall amount of anxiety, poor anxiety control, the lack of amelioration with appropriate reassurance and support and longer-term impairment associated with generalized anxiety differentiate it from normal worry.

Generalized anxiety can be differentiated from emotional disorders based on the greater number of anxiety triggers and the specific nature of the worries. Children with generalized anxiety are concerned with past and future experiences, physical health, weather, environmental changes, and unexpected events. They may appear to have similar concerns to children with separation and social anxiety but differ in important ways. For example, children with generalized anxiety may avoid going to school, not because of separation or social concerns but because of academic performance worries. That said, it is not uncommon for younger children with generalized anxiety disorder to also be diagnosed with co-occurring separation anxiety and older children with co-occurring social anxiety disorder. Individuals with generalized anxiety and perfectionism may superficially resemble those with OCD. For example, a child with generalized anxiety and concern about academic performance may

routinely check over homework for accuracy or study material repeatedly for the purpose of improving the work product or getting it "perfect." In contrast children with OCD know the work product is good or perfect, but experience doubt that their perception is accurate and then recheck for the purpose of rechecking. Also, individuals with generalized anxiety may have recurrent uncontrollable worries that could be mistaken for obsessions; however, worries of generalized anxiety disorder do not appear senseless, intrusive, or unwanted, rather they are described as powerful bona fide concerns and are usually tied to events or situations that would stimulate normal concerns. For example, normal children may worry about bad weather as it happens, generalized anxiety disorder children will worry that bad weather may happen on a cloudless day, and children with OCD may worry that if they do not count to three in sets of three then a loved one may die in a weather-related incident.

Ruminations (i.e., recurrent depressive cognitions) are characteristic of depression and tend to regard experiences negatively and hopelessly. For example, repetitive thoughts such as "No one will like me no matter what I do" can be readily distinguished from "I need to be perfect for my teachers and parents" by identifying the depressive (ruminative) quality of the former and the perfectionistic (generalized anxiety) quality of the latter.

Course and Prognosis

Prospective and cross-sectional studies of youth suggest that GAD is an episodic or recurrent disorder, and that prognosis is dependent on comorbidity and severity. Individuals with a comorbid diagnosis tend to have higher ratings of severity and functional impairment. Those with greater severity and psychosocial impairment at baseline are more likely to retain a diagnosis over time.

Like other anxiety disorders, generalized anxiety disorder is considered a risk factor for the development of additional psychiatric problems over time. Specifically, generalized anxiety may lead to the subsequent development of anxiety disorders, substance use, depression, or behavior problems. The New York Child Longitudinal Study investigated the associations between anxiety disorders and later psychiatric disorders in 9- to 18-year-old children and adolescents. DSM-III overanxious disorder was related to subsequent major depression, social anxiety disorder, and generalized anxiety. Whereas children with separation anxiety symptoms were less likely than other children to begin drinking alcohol were and did so later than others, those with generalized anxiety symptoms were more likely than other children to begin drinking were and did so earlier. Results from the GSMS found that DSM-IV generalized anxiety was associated only with later conduct disorder, but did not predict anxiety or other psychiatric problems.

Treatment of Generalized Anxiety Disorder and Other Anxiety Disorders

Similar to the previous section on separation anxiety, both CBT and SSRI treatment have demonstrated efficacy for pediatric generalized anxiety disorder. Preliminary trials also support PCIT adaptations as potentially effective treatments for very young children.

Psychotherapy. Although there are no randomized controlled CBT trials specifically for generalized anxiety, the basic concepts of CBT as introduced in the section on separation anxiety disorder apply to generalized anxiety disorder, but may require modifications to address the unique symptom presentation. For example, perfectionism is often a highly valued trait. Making perfectionism a negative symptom and using exposure exercises to tolerate the discomfort and distress associated with making mistakes may be more challenging than addressing more clearly impairing symptoms. It is also important to elicit physiological signs (i.e., heart pounding, sweating) in the controlled context of the exposure so that, in the process of achieving effective coping, the child learns there is a component of self-control in reducing somatic symptoms. In addition, the exposure must elicit relevant anxious cognitions (i.e., "If this isn't done just right, then I won't get the best grade.") so that the child learns to effectively challenge and reframe thoughts about specific anxiety-provoking situations.

Children with generalized anxiety disorder often have specific worries that are difficult or unsafe to challenge in reality and require greater use of imaginal exposures. Unrealistic worries, for example, about health, safety, death, or dying, may be difficult or impossible to enact through an in vivo exposure. A child with excessive worries about contracting a disease, for example, would be treated via imaginal exposure whereby detailed events and feelings are identified first. Next, problem solving, relaxation exercises, and cognitive restructuring are used to help the child interrupt the cycle of worrying, learn to tolerate discomfort associated with the anxiety, and develop realistic thought patterns. Parental involvement in treatment is essential to modify ineffective reassurance statements ("Don't worry. You won't get sick.") with realistic notions of uncertainty ("Chances are low that you will get sick, but there is no way to know for sure.") and by encouraging children's awareness of their self-coping ("What do you think would happen if you did get sick? But what else could happen?") rather than offering reassuring solutions ("If you did get sick, we would get you medicine to make you better.").

Pharmacology. Published trials specifically targeting generalized anxiety included one effectiveness trial with sertraline and two trials—one positive and one negative—with venlafaxine (Effexor), which were combined and published together. More recently duloxetine was found to

be effective in a large, industry-sponsored, randomized, placebo-controlled trial of children and adolescents 7 to 17 years old with generalized anxiety disorder leading to the first FDA indication of any medication for a non-OC, non-PTSD anxiety disorder in children and adolescents.

Although adults with generalized anxiety disorder may be treated acutely with benzodiazepines, there are few data to support the efficacy of this class of medications for youth. For example, a small double-blind, placebo-controlled randomized trial of alprazolam (Xanax) for the treatment of pediatric overanxious and avoidant disorders, demonstrated no benefit of medication over placebo. As noted previously in the section on separation anxiety, the efficacy of antidepressant medication combined with the lack of efficacy for benzodiazepines and the risk for physical and psychological dependence make it difficult to consider benzodiazepines as an important treatment option for childhood anxiety disorders.

Buspirone (BuSpar), a nonbenzodiazepine, nonantidepressant anxiolytic, is effective in studies of adults with generalized anxiety disorder and was evaluated in a large, multisite, industry-sponsored, RCT. Although the trial was not published, a report of the negative outcome of the study is available on the FDA website.

SOCIAL ANXIETY DISORDER

Definition

Social anxiety disorder, also called social phobia, is characterized by excessive, persistent, and impairing anxiety about potential scrutiny or embarrassment in social or performance situations. The worry may be restricted to a specific performance situation such as fear of being negatively evaluated during an athletic or musical performance. However, social anxiety disorder is more commonly generalized such that worry about being scrutinized or embarrassed occurs across a range of activities and situations.

Comparative Nosology

Social anxiety disorder (social phobia) first appeared in DSM-III, with minimal alterations in subsequent editions. One impactful change from DSM-III to DSM-IV was the removal of the diagnosis of avoidant disorder. Avoidant disorder was classified as an anxiety disorder of childhood or adolescence, and characterized by fear and avoidance of strangers resulting in significant impairment in peer relationships. Concern about the overlap between the two disorders and continuity between childhood avoidant disorder and adult social anxiety disorder resulted in the removal of avoidant disorder as a diagnostic category in DSM-IV. In DSM-5, there is no longer a requirement that individuals over age 18 must recognize their fear as excessive and unreasonable; instead, the anxiety must be out of

proportion to the actual threat posed by the event after taking into account sociocultural factors. Whereas the 6-month duration was limited in DSM-IV to individuals under age 18, this criterion now applies to all ages. Finally, unlike DSM-IV, there is no longer a specifier of "generalized" but there is a specifier for "performance only" in DSM-5.

Epidemiology

Social anxiety is a common anxiety disorder, with a cumulative incidence of 11 percent. Prevalence rates have increased over time, likely because of the removal of the avoidant disorder diagnostic category from DSM-III to DSM-IV; that is, youth who were once characterized with avoidant disorder are now diagnosed with social anxiety disorder, resulting in increased prevalence rates. According to data from the National Comorbidity Survey Replication Adolescent Supplement and the Early Developmental Stages of Psychopathology Study (EDSP), the 12-month prevalence for adolescents is 5.2 to 8.2 percent. The lifetime prevalence of social anxiety is 9.5 percent for females and 4.9 percent for males. Like generalized anxiety, the prevalence of social anxiety disorder increases with age, possibly reflecting changes in cognitive and emotional development (i.e., the capacity for self-evaluation and self-consciousness).

Age of onset for social anxiety disorder is during adolescence. The average age of onset in epidemiological studies is between 10 and 16.6 years and varies depending on the sample studied and the strategy for determining retrospective reports for age of onset. According to the EDSP which involved a community sample of 3,021 individuals aged 14 to 24, the incidence of DSM-IV social anxiety was greatest among those aged 10 to 19 years.

Etiology

Similar to both separation anxiety disorder and generalized anxiety disorder, factors that contribute to the development of social anxiety disorder include genetics, temperament, and family variables. Twin studies are useful in distinguishing between environmental and genetic influences. There are many discrepancies in the literature regarding the contributions of genetic and environmental influences because of differences in measurement (i.e., rating scale vs. psychodiagnostic interviews), informants (i.e., self vs. parent reports), and criterion (i.e., symptoms vs. severity vs. clinical diagnosis). However, the literature is consistent in showing that anxiety disorders are heritable and that both shared and nonshared environmental factors also play a role. Concordance rates for anxiety disorders including social anxiety disorder are higher for monozygotic twin than dizygotic twins (34 vs. 17 percent). Familial transmission is also evident by studies showing a high concordance rate of

social anxiety among first-degree relatives. Overall, studies investigating genetic transmission find evidence for an inherited propensity toward anxiety in general rather than for a specific type of anxiety.

As previously mentioned, BI is a temperamental construct characterized by increased physiological reactivity and avoidant behavior in the face of novel or challenging situations. Inhibited children have greater sympathetic activation than uninhibited children, evidenced by higher and more stable heart rates and greater heart-rate acceleration under stressful and novel conditions. Many studies support the existence of a specific link between BI and social anxiety. Both longitudinal and retrospective studies show that toddlers with BI assessed by observational or questionnaire methods are more likely than uninhibited children to exhibit social anxiety as adolescents. In a recent prospective longitudinal study, 215 children assessed for BI were assessed for psychiatric outcomes in a 5-year follow-up at a mean age of 9.6 years. Structured diagnostic interviews revealed that BI present at age 4 or 6, but not at age 21 months, predicted social anxiety. BI was not associated with other specific anxiety, mood, or behavior disorders. In another study, adults from a clinical sample provided retrospective reports of childhood inhibition, and those with the highest levels of inhibition also had the highest levels of clinical social anxiety disorder. It is important to note that less than 50 percent of toddlers and young children characterized as behaviorally inhibited go on to develop social anxiety disorder. Similarly, children who are considered shy or have shy temperaments most likely do not develop social anxiety disorder. Thus, BI is considered a manifestation of a biological predisposition that serves as a risk factor for anxiety.

Environmental variables such as parent–infant attachment and parenting behaviors also are associated with the expression of social anxiety disorder. As stated in previous sections, retrospective and observational research shows links between insecure infant attachment and the development of anxiety disorders. One study examined 172 adolescents 16 years after participating in the Ainsworth Strange Situation test at age 12 months and confirmed that infants with insecure attachments were more likely to meet criteria for anxiety, including social anxiety disorder. Adult parents with social anxiety disorder may sponsor social isolation by discouraging opportunities for social engagement. They also provide information that has the potential to heighten anxious arousal.

Diagnosis and Clinical Features

The defining feature of social anxiety is excessive fear about being scrutinized in social or performance situations (Table 52.3–2). Although the same criteria apply to children and adults, some provisions are indicated for children. First, social anxiety cannot be limited to adult settings and must occur in peer contexts. Second, in children, the anxiety

evoked by the social situation may involve crying, tantrums, freezing, or shrinking from social situations with unfamiliar people. Common fears related to social anxiety include public speaking, participating in class, initiating or participating in conversations, attending social events, and eating or writing in front of others. Fear of public speaking is considered the most commonly feared social situation; however, test anxiety is commonly feared among adolescents.

Some differences have been noted with respect to the presentation of social anxiety among different age groups. Adolescents endorse anxiety across a broader range of situations and more avoidance compared to children; however, both groups experience similar levels of distress. In addition, adolescents endorse more cognitive symptoms of social anxiety that likely reflect their greater cognitive maturity compared to children. Poor social skills, however, are evident across all youth with social anxiety disorder.

Table 52.3–2.
DSM-5 Diagnostic Criteria for Social Anxiety Disorder (Social Phobia)

A. Marked fear or anxiety about one or more social situations in which the individual is exposed to possible scrutiny by others. Examples include social interactions (e.g., having a conversation, meeting unfamiliar people), being observed (e.g., eating or drinking), and performing in front of others (e.g., giving a speech).
   Note: In children, the anxiety must occur in peer settings and not just during interactions with adults.
B. The individual fears that he or she will act in a way or show anxiety symptoms that will be negatively evaluated (i.e., will be humiliating or embarrassing; will lead to rejection or offend others).
C. The social situations almost always provoke fear or anxiety.
   Note: In children, the fear or anxiety may be expressed by crying, tantrums, freezing, clinging, shrinking, or failing to speak in social situations.
D. The social situations are avoided or endured with intense fear or anxiety.
E. The fear or anxiety is out of proportion to the actual threat posed by the social situation and to the sociocultural context.
F. The fear, anxiety, or avoidance is persistent, typically lasting for 6 months or more.
G. The fear, anxiety, or avoidance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
H. The fear, anxiety, or avoidance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.
I. The fear, anxiety, or avoidance is not better explained by the symptoms of another mental disorder, such as panic disorder, body dysmorphic disorder, or autism spectrum disorder.
J. If another medical condition (e.g., Parkinson disease, obesity, disfigurement from burns or injury) is present, the fear, anxiety, or avoidance is clearly unrelated or is excessive.

Specify if:
Performance only: If the fear is restricted to speaking or performing in public.

Infants and toddlers cannot meet DSM-5 anxiety diagnoses guidelines primarily due to developmental issues; however, many very young children exhibit higher than normal levels of social fear and associated distress. For example, some children have difficulties playing with new children, refuse to participate in playgroups and classes, play alone at parties or on the playground, and refuse to eat in restaurants or attend public events because of severe distress. Some pilot data reveal that children aged 18 months to 5 years can be diagnosed with a modified version of social anxiety disorder and are more likely than their nonanxious counterparts to display high levels of shyness, inhibition, and to have anxious parents. Many preschool-age children meet DSM-5 criteria for selective mutism which involves restricted speech in social situations due to high levels of fear and anxiety.

Jessica is an 11-year-old in the sixth grade at a public elementary school. She was referred for outpatient treatment by her school counselor for anxiety. Jessica was accompanied by her mother, who is a single parent.

During the assessment, Jessica was compliant but timid. She gave succinct responses to interviewer questions and frequently turned to her mother who often answered on Jessica's behalf. Her medication history was significant for irritable bowel syndrome. Psychiatric history was unremarkable. There is a history of maternal shyness and social anxiety, and Jessica's mother is presently prescribed an SSRI. Jessica was described as "painfully shy" as a very young child.

Jessica endorsed feelings of loneliness and reported having few friends. She reported that, in school, she does not answer questions or do other things that could draw attention to herself (e.g., leave class to use the bathroom). Recently, she refused to go to school on a day she was scheduled to give a presentation in one of her classes. In addition, she admitted to purposefully leaving her gym shoes at home on several occasions because she does not like to change in front of her peers in the locker room at school. Jessica is a Girl Scout but said she does not like the meetings or events and feels that the other girls do not like her. She also endorsed worries that other girls will make fun of her clothes. Jessica does not talk during the meetings and often asks her mother if she can skip. Jessica has attended a couple of birthday parties but typically does not initiate conversations and has been reluctant to fully engage in some of the birthday activities (e.g., bowling, hitting a piñata).

According to her mother, Jessica is shy in public social situations. She rarely orders her own food in restaurants and does not respond when asked a question by a store clerk. At home, Jessica does not answer the phone unless she recognizes the incoming call number identifies a familiar relative.

Differential Diagnosis

Social anxiety disorder can be distinguished from other disorders based on the predominant feature that fears center around the potential for embarrassment or receiving negative criticism. Although social anxiety and separation anxiety may both involve avoidance of social situations, the fear with separation anxiety is associated with concern about being apart from a caregiver and is not associated with potential humiliation or embarrassment. The generalized type of social anxiety is differentiated from generalized anxiety disorder on the basis of the individual feeling humiliated or embarrassed in public rather than a more global worry. Also,

children with generalized anxiety disorder may worry about a host of social issues (e.g., friendships, performance, how others view them), but worries are not limited to social or performance situations. Although individuals with social anxiety disorder may experience panic in the face of challenging situations, the fear and associated somatic and cognitive symptoms occur in response to specific situations and are not unexpected or uncued as they are in panic disorder.

Social anxiety is also distinguished from selective mutism, which is characterized explicitly by a failure to speak in situations where speech is expected and has a much younger age of onset relative to social anxiety disorder. Selective mutism is considered by some professionals to be a developmental variant of social anxiety.

Finally, it is important to distinguish social anxiety disorder from developmentally normal fears. For example, it is not uncommon for children to be anxious about speaking in front of the class. However, normative anxiety does not result in significant impairment in functioning or clinically significant distress as with social anxiety disorder.

Course and Prognosis

Social anxiety disorder that emerges by the early teen years is associated with progressive worsening or persistence of symptoms through early adulthood. Late adolescence is characterized by a waxing and waning course during which symptoms are exacerbated with social stressors. Factors associated with persistence of symptoms include early onset, more anxiety cognitions, severe avoidance and impairment, co-occurring panic, parental social anxiety and depression, BI, and harm avoidance.

Few individuals experience spontaneous remission; data from the prospective-longitudinal Early Developmental Stages of Psychopathology study suggest a natural remission rate of 15.1 percent. Individuals with social anxiety disorder withdraw from or avoid situations, limiting opportunities for optimal social, academic, and emotional development. Research shows that children with social anxiety disorder are less socially skilled than nondisordered counterparts, limiting their capacity to form intimate relationships with friends, family members, or partners. Symptoms and impairment at school may result in academic underachievement, including failure to graduate high school or pursue college. Disabilities in educational and social functioning may lead to demoralization and other emotional problems. Longitudinal studies show, for example, that social anxiety disorder is consistently linked with increased risk for subsequent depression. Further, individuals with comorbid social anxiety and depression are at increased risk for suicidal ideation and suicide attempts.

Several longitudinal studies find that social anxiety disorder is associated with the development of substance use problems. For example,

one prospective study based on a subsample of 816 individuals from the Oregon Adolescent Depression Project found that social anxiety disorder is a unique risk factor for the subsequent onset of alcohol and cannabis dependence. Specifically, a lifetime history of social anxiety disorder at age 17 was associated with 4.5 times greater odds of alcohol dependence and 6.5 times greater odds of cannabis dependence by age 30. Also, results from a different prospective study showed that youth with social anxiety disorder were significantly more likely 4 years later to smoke cigarettes and have a higher rate of nicotine dependence than a control group.

Treatment of Social Anxiety Disorder

As noted in previous sections on separation anxiety disorder and generalized anxiety disorder, effective treatments for social anxiety disorder include CBT and SSRIs. There is one comparative treatment trial specifically focused on youth with primary social anxiety disorder. Children and adolescents aged 7 to 17 were randomly assigned to Social Effectiveness Therapy for Children (SET-C, a behavioral approach), fluoxetine, or placebo and results revealed both active treatments to be superior to placebo in reducing social distress and behavioral avoidance and increasing general functioning. SET-C, however, was superior to fluoxetine on these outcomes and was the only treatment superior to placebo in terms of improving social skills, decreasing anxiety in specific social interactions, and enhancing ratings of social competence. Although both treatments are considered effective, SET-C provided added benefit by enhancing social skills.

Across psychosocial and medication trials for separation anxiety, generalized anxiety, and social anxiety, one-third to one-half of children continue to have clinically significant anxiety problems. Although most studies have not been adequately powered to detect factors that influence treatment outcomes, results of the CAMS suggested that a principal diagnosis of social anxiety disorder was associated with less favorable outcomes. Whereas Coping Cat CBT + sertraline yielded superior outcomes across all diagnoses and treatment conditions, stand-alone sertraline produced slightly better outcomes for individuals with social anxiety compared to stand-alone CBT. These findings paired with investigations of SET-C suggest that cognitive-behavioral treatments for social anxiety may need to include social skills training and exposure tasks with age-matched peers in order to produce optimal gains.

Psychotherapy. In addition to the SET-C comparative trial, several wait-list controlled trials of individual CBT with or without family therapy and group-based CBT have been conducted with youths with primary social phobia and show favorable results. Treatment is based on skill development, such as increasing coping self-talk, adopting relaxation

exercises, and using problem-solving approaches. In vivo exposures for social phobia focus on increasing comfort in situations involving unfamiliar people and peers.

Technological advances are also being used to develop innovative, more accessible treatment modalities for social anxiety disorder. One such modality uses virtual reality technology to facilitate graded, in vivo exposures. Within this approach, youth are immersed in virtual environments where they interact with clinician-operated avatars to practice socially challenging tasks (e.g., greeting peers, answering questions, assertiveness skills). The preliminary acceptability and feasibility of this approach has been demonstrated, and further research will assess its efficacy as a stand-alone treatment and adjunct to traditional CBT.

Pharmacology. There have been three studies that have assessed the efficacy of antidepressants in social anxiety disorder—two industry sponsored trials and one federally funded study. Venlafaxine extended-release preparation was found to be more effective than placebo in a large sample of children and adolescents (n = 293) ages 8 to 17 years old. Paroxetine was found to be more effective than placebo in a large sample (n = 322) of children and adolescents ages 8 to 17. Finally the only federally funded study that assessed an SSRI, fluoxetine, and found it to be more effective than placebo was the SET-C study described above.

Overall, the best evidence supports the use of SSRIs in the treatment of childhood anxiety disorders. The value of the SSRIs probably extends across the class so that medication choice can be based on a number of factors including evidence of efficacy in high-quality clinical trials, half-life, risk for drug–drug interactions, any subtle differences in side-effect profiles, and patient, family, and provider preference. The recent FDA indication for duloxetine may soon make it the medication of choice for generalized anxiety and given the high comorbidity of generalized anxiety with separation and social anxiety disorders it may become the first-line treatment for the triad of pediatric anxiety disorders. The TCAs, which can be effective, have not been consistently able to separate from placebo in larger clinical trials, so should be considered only as an alternative for those who have not responded to SSRIs or NSRIs. The value of TCAs in ADHD may make them a second-line choice for children with anxiety disorders and ADHD.

SAFETY. The SSRIs as a class share a number of important side effects that include physical symptoms such as stomachache and headache, and can also be associated with changes in behavior such as activation/disinhibition, insomnia, apathy, manic reactions and the potential for suicidal behavior. Activation/disinhibition (and similar or

related symptoms such as akathisia) are quite common in the pediatric population with 10 to 15 percent difference between SSRI and placebo groups. Activation often occurs early in the course of treatment—days after the initial dose or first meaningful dose increase (e.g., sertraline 25 or 50 mg; fluoxetine 10 or 20 mg), and goes away with medication discontinuation. It appears to be more common in younger children and those whose anxiety co-occurs with symptoms of ADHD, autism spectrum disorders or other early developmental psychopathology. The SSRIs impact sleep in two ways: (1) activation can make it more difficult to fall asleep and (2) SSRIs disrupt sleep architecture, hence users may recover from anxiety, may experience restful sleep, but may sleep more lightly and experience middle of the night awakenings. At higher doses of the SSRIs apathy may occur, leaving patients relatively free of anxiety but unmotivated or feeling disconnected from living.

Perhaps of greatest concern to prescribers of SSRIs in anxious children is the induction of a manic reaction that may herald a new and more severe course of illness. The concern regarding a manic switch is probably greatest when the anxiety disorder is complicated by problems with impulse control or aggressive behavior suggestive of bipolar disorder. Thankfully, manic reactions in the acute phase, large scale, randomized, controlled trials of the SSRIs are exceedingly rare (<1 percent). And even in longer-term follow-up studies the rates are low. Differentiating a manic reaction from the activation side effect can be challenging but an important distinction. Misdiagnosing an activation side effect as a manic reaction may shift the prescriber away from the antidepressants to the use of antipsychotics and mood stabilizer, neither of which are particularly effective for the anxiety disorders. Manic reactions can be differentiated by their presentation, time course of onset, and response to medication discontinuation. Manic symptoms include elevated and expansive mood, grandiosity, decreased need for sleep, and increased goal-directed activities, and symptoms are distinct from the irritability and impulsivity that is commonly seen with activation. Activation occurs early in the course of treatment; manic reactions occur later. With medication discontinuation activation symptoms decrease in relationship to blood level whereas manic symptoms may persist and require medication treatment to reduce symptoms.

Finally, the risk for suicidal behavior emerging or worsening during antidepressant treatment is probably the public's greatest concern. Recent meta-analysis suggests that the suicidal behavior risk difference between the antidepressant and placebo in high-quality clinical trial is <1 percent with numbers needed to harm of >100 and the number needed to treat in high-quality RCTs in depression (NNT = 3–4 in NIMH funded trials), OCD (NNT = 5) and the triad of anxiety disorders (NNT = 3). These data, the observed reduction in antidepressant use with the advent of a black box warning, and the subsequent spike in youth suicide gave rise to concerns

that the black box warning may have had unintended negative consequences. While the black box warning on antidepressant has not been changed, prescribers, but perhaps not the general public, are regaining comfort in the use of the antidepressants.

The side-effect profile of the NSRIs are similar to the SSRIs but now include symptoms consistent with norepinephrine reuptake including nausea, and the potential for initial worsening of anxiety (not activation per se), and for heart rate and blood pressure increases. The side-effect profile of the tricyclic antidepressants are well known and include prominent anticholinergic effects, dry mouth, constipation and urinary retention, and noradrenergic effects on cardiac function, elevated heart rate and orthostatic blood pressure changes, and the potential for prolongation of important cardiac intervals including the QTc.

FUTURE DIRECTIONS

Issues that warrant further clarification pertaining to treatment of youth with separation anxiety, generalized anxiety, or social anxiety include identification of moderators of treatment outcome, identification of critical elements of psychotherapy that contribute to outcome, questions of treatment sequencing and whether youth who fail to respond to either medication or CBT as their first treatment will respond to the other treatment, strategies for enhancing outcomes and addressing treatment resistance, and elucidating long-term outcomes particularly following medication treatment. A follow-up study of the CAMS sample, now underway, should provide information about long-term diagnostic and functional outcomes following receipt of evidence-based treatment, as well as patterns of posttreatment service utilization.

▲ 52.4 Selective Mutism

R. LINDSEY BERGMAN, PH.D., AND ARACELI GONZALEZ, PH.D.

INTRODUCTION

Selective mutism (SM) is a childhood behavioral disorder characterized by a persistent failure to speak in one or more specific social situations despite speaking in other situations. Although the syndrome was recognized as long ago as 1877, the disorder (earlier called elective mutism) did not appear in the *Diagnostic and Statistical Manual of Mental Disorders* until its third edition (DSM-III) in 1980. Current conceptualizations of SM emphasize the relationship between considerable social anxiety and the failure or extreme reluctance to speak. In addition, researchers continue to investigate the presence of speech or language anomalies as well as oppositional symptoms among children with SM. Although there has been increased interest related to SM recently, in comparison with many other childhood emotional or behavioral disorders, there is a relative lack of consensus on many issues related to the epidemiology, phenomenology, and treatment of the disorder.

DEFINITION

The DSM-5 defines SM as a consistent failure to speak in specific social situations where speaking is expected (e.g., to peers at school), despite speaking regularly in other situations. DSM-5 also specifies that in order

for the diagnosis to be assigned, the lack of speech must interfere with achievement or communication, must last at least 1 month (beyond the first month of school), and must not be due to a lack of knowledge or comfort with the language required in a given situation. Finally, DSM-5 specifies that the lack of speech cannot be better accounted for by a communication, developmental, or psychotic disorder.

HISTORY

In the 19th century, the term *aphasia voluntaria* was first noted in the psychiatric literature and was used to describe children who voluntarily chose not to speak in certain situations. Many other terms including voluntary mutism, speech phobia, suppressed speech, functional mutism, and speech avoidance have also been used to describe children who meet the current criteria for SM. The term *elective mutism* was first used in 1934 and appeared in DSM-III in 1980. Some believed that descriptors such as "voluntary" and "elective" that appeared in these early terms suggested a volitional choice to refrain from speaking, and possibly, an oppositional attitude. This attitude was also reflected in the DSM-III definition of elective mutism, which contained a reference to a "refusal" to speak in the definition of SM. In DSM-III-R, elective mutism was renamed SM, perhaps reflecting shifting conceptualizations of the disorder such that attention was more focused on social anxiety as opposed to oppositional or volitional aspects of the nonspeaking behavior.

COMPARATIVE NOSOLOGY

Consistent with the shifting conceptualization described above, SM was reclassified as an anxiety disorder in the current edition of the DSM (DSM-5). In the DSM-IV, SM was included in the section Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence. In the DSM-5, disorders within that category were reorganized into different categories and SM is now included as an Anxiety Disorder. This reclassification of SM in the Anxiety Disorders section of the DSM-5 is a logical fit given growing evidence for the phenomenological similarities between SM and social anxiety (see Etiology section). However, the nature of relationship between SM and social anxiety is complex and requires further research as discussed below. Other than the relocation of the SM diagnosis from Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence to the Anxiety Disorders section, the diagnostic criteria for SM are virtually identical in the DSM-IV and -5. Interestingly, a diagnosis of SM does not require the presence of fear or anxiety.

The disorder was not renamed in the tenth edition of the *International Statistical Classifications of Diseases and Related Health Problems* (ICD-10), and the current version describes *elective mutism* as a disorder characterized by a "marked, emotionally determined selectivity in

speaking," such that the child demonstrates a language competence in some situations but fails to speak in other situations. The disorder is also described as associated with social anxiety, withdrawal, sensitivity, or resistance.

EPIDEMIOLOGY

SM is often assumed to be rare. However, until recently, estimates of the occurrence of SM were based on scant evidence that was often inaccurate. Only a handful of community-based prevalence studies have been published. These studies, all but one conducted in Europe, have yielded widely disparate findings due to different sampling strategies and definitions of SM. A United Kingdom study identified 0.69 percent of 4- to 5-year-olds as completely mute (i.e., not speaking at all) at school. However, this rate dropped to 0.08 percent after approximately 8 months of school. Another survey, also in the United Kingdom, identified only 2 of 3,300 (0.06 percent) 7-year-olds as selectively mute at 36 months of age. More recent investigations have focused on the school environment to investigate the prevalence of SM. Two Scandinavian surveys found teacher-reported rates of DSM-IV-TR SM of 0.18 and 1.9 percent, respectively, and another study with Irish primary school children ages 4 to 12 years also found a prevalence rate of 0.18.

One US community prevalence study surveyed kindergarten, first-, and second-grade classrooms in an urban public school district and reported a DSM-IV-TR SM prevalence rate of 0.71 percent (16 of 2,256). A study in Israel yielded comparable results. These recent studies provide evidence that SM may be more common than is frequently recognized. In fact, it is likely that the point prevalence rate for SM is comparable to rates of other childhood psychiatric disorders, including obsessive–compulsive disorder (0.5 to 1 percent), and major depressive disorder (0.4 to 3 percent). It has also been reported that immigrant and bilingual or language minority children are at higher risk of SM, and prevalence of the disorder may be three times higher in these populations.

Overall prevalence does not seem to vary markedly by sex or race/ethnicity; however, there is evidence that slightly more girls than boys seem to be affected by SM, with an average reported female to male ratio of 1.2 to 1. There is some evidence to suggest that this gender difference may become more pronounced among older children. Although it is commonly reported that children with SM show significant symptoms from the age at which they spoke fluently, with the age of onset typically reported from 2 to 5 years old, SM is often not noticed until the time of entry into school.

ETIOLOGY

The conceptualization of SM has undergone a considerable shift over the past several years. At this point in time, evidence suggests that SM results

from multiple developmental pathways involving the complex interplay of genetic, neurobiological, temperament, and behavioral (e.g., avoidance) variables. Previously, it was often suggested that SM was related to a variety of conditions including oppositionality, trauma, or family neuroses. However, current conceptualizations view the disorder as closely related to, or even a developmental variant of, social phobia. Strong support for this position is derived from studies reporting that over 95 percent of children with SM also met DSM-III-R criteria for social phobia. Additional evidence comes from the finding that pharmacological agents used to treat adult social phobia are similarly effective in the treatment for SM. Last, family history data reveal an elevated rate of social phobia among parents of children with SM, and severity of children's SM symptoms may predict parents' diagnosis of generalized social phobia. These findings suggest a familial relationship between SM and generalized social phobia and provide further support that SM may be a developmental precursor to social phobia. Research regarding genetic risk of SM is in its infancy. One recent study examining genetic susceptibility factors for SM in families with social anxiety-related traits found evidence of increased risk of SM in individuals with a genetic variation in CNTNAP2, a gene implicated in various forms of language impairment.

Researchers and clinicians have also noted the resemblance between SM children and children described as "behaviorally inhibited." In fact, reluctance to speak is often considered to be a sensitive index of behavioral inhibition. Consistent with this is the finding that parents of children with SM rate their children as not responding well to new situations or handling transitions well, both widely considered to be fundamental elements of behavioral inhibition. Since there is evidence that the presence of behaviorally inhibited temperament is associated with increased risk of future anxiety disorders, it is possible that behavioral inhibition is an etiological factor in the development of SM. By contrast, a small proportion of children with SM do not exhibit social phobia with regard to nonverbal communication and will engage in social interaction using gestures, facial expressions, body language, and other socially engaged behavior. Such cases raise questions about the nature of the relationship between SM and social phobia, suggesting that some individuals may experience anxiety specifically related to expressive language and not to social situations more generally. Some researchers have investigated the notion that the "nonspeaking behavior" of children with SM essentially should be seen as an emotion regulation strategy aimed to reduce anxiety around social interaction.

As mentioned previously, oppositionality and recent trauma are often cited as etiological factors related to SM; however, studies utilizing systematic diagnostic procedures do not provide support for these relationships. In comparing children who met criteria for only social

phobia to those with both SM and social phobia and those with no disorder, researchers found no significant differences on parental reports of oppositionality. Furthermore, mean scores for ratings of oppositionality were in the normal range for children with SM. Thus, findings suggest that the majority of children with SM do not present with clinically significant oppositional behaviors. However, 29 percent of children with SM were rated as meeting criteria for oppositional defiant disorder (ODD) by clinicians. Thus, a subset of children with SM may exhibit comorbid ODD.

Somewhat more confusing are conflicting findings related to the prevalence of communication disorders among children with SM and the association between developmental delay and SM. Several studies have examined possible deficits in auditory or speech and language processing in children with SM. In one study, children with SM were compared to children with an anxiety disorder and normal controls on measures of language, nonverbal working memory, and social anxiety. When compared to children with other anxiety disorders and normal controls, children with SM had lower scores on language measures and deficits on tasks requiring them to remember verbal information. In another study, researchers found that children with SM did not exhibit deficits in visual memory, but they did show significantly poorer verbal memory than controls. Thus, children with SM may exhibit meaningful deficits in speech and language processing.

Although some children with SM may experience language delay or dysfunction and deficits in speech and language processing, it is noteworthy that among researchers it is not suggested that these problems supersede social anxiety as a major contributing factor toward nonspeaking. Furthermore, although language delay or speech disorder may be more common among children with SM, these problems could be a result, rather than a cause, of the disorder. Finally, speech and language problems associated with SM are likely to be subtle and are exclusionary criteria for the diagnosis of SM when they cannot be ruled out as the cause of the lack of speech. Ultimately, however, it is important to note that many in the field believe that neurodevelopmental and language anomalies occur more frequently among children with SM than among children with other anxiety related disorders.

DIAGNOSIS AND CLINICAL FEATURES

The primary symptom exhibited by children with SM is the failure to speak in some situations where speaking is expected despite speaking in other situations. The situation in which the child has no difficulty speaking is almost always in the home environment. In fact, families of children with SM often report that the child seems to be “overly” talkative at home. However, in severe cases, there may be some members of the household to which the child with SM does not speak. If a child who is presumed to have

SM does not speak at all at home, there is reason to seriously question the diagnosis of SM.

Several studies indicate that the situation in which speaking is most commonly avoided is at school. Within this common pattern (speech at home, failure to speak at school), there is large individual variation in terms of speaking patterns among children with SM. In the school environment, children with SM more commonly fail to speak to adults (e.g., teachers) than to peers, although a lack of speech with peers is not uncommon. However, many children with SM have individually distinct and stable patterns regarding to whom they do, and do not, speak. For instance, there are often particular extended family members with which the child does not speak and others to whom they consistently speak. Some children with SM have little or no difficulty speaking with strangers, whereas others place strangers at the top of their hierarchy of people with whom it is difficult to speak.

The label of SM can be used somewhat broadly to describe children who are consistently reluctant to speak or display low frequency of speech. Although some argue that children who speak inconsistently, reluctantly, or with low volume do not, in fact, have SM, these speaking behaviors are relevant for the diagnosis of SM because children who completely fail to speak in some situations often speak inconsistently, with low-frequency or volume, or reluctantly in others. For example, some children with SM may fail to speak at all in some situations, while in others they do not speak in a "normal" voice but whisper fairly readily. Also fairly common is the child who does not speak at all in some situations, but in other situations speaks in a "disguised" or odd voice that is mechanical, gruff, or babyish.

Given that SM appears to be so closely related to social phobia, it is not surprising that children with SM also have difficulty with nonverbal but socially relevant tasks such as eating in front of others, having their picture taken, and communicating nonverbally. When social anxiety symptoms not related to speech are present and meet criteria for social anxiety disorder, the additional diagnosis should be given. Even among those who are not also diagnosed with social anxiety disorder, children with SM are typically described as shy and self-conscious. However, it is important to note that not all children with SM are shy; although not typical, there are children with SM who present as outgoing, friendly and eager to interact but only interact nonverbally. This presentation has led some researchers to view SM as a type of specific phobia of speaking.

The following case exemplifies a common presentation of a child with SM.

James is a 5-year-old Chinese American boy who lives with his biological mother, father, and older sister. James's parents reported that he speaks normally at home but that he started to have difficulty speaking to adults and children at school upon entry to preschool. He continued to have difficulty speaking throughout his preschool year and has ongoing difficulty in

kindergarten. At home, his parents report that he is extremely talkative and outgoing when he is around immediate family members and extended family members close to his age. At school, James does not speak to any of the adults but answers classmates with one-word answers and speaks only in a whisper. By his parents' report, James also exhibits extreme social anxiety, to the point of "freezing" in certain situations when attention was focused on him. He often watches other children playing from a distance, does not join in group activities, and does not participate in circle time at school. James's parents also report that he hides behind them when strangers are around and that he dislikes having his picture taken. At the time of his evaluation, James had not received prior treatment for SM or any other emotional or behavioral disorders. James was born in the United States and speaks fluent English and limited Mandarin. His parents speak to him in both English and Mandarin and he mostly responds to them in English. According to his parents, he developed normally with no delays and appears to have above-average intelligence. They also reported that James enjoys riding on his bicycle, singing, and art activities.

During initial evaluation, James hid behind his parents and failed to respond in any way to the intake clinician. James's parents reported that this behavior is typical of him when in a novel situation with new people, but that he might answer with one-word answers softly, communicate nonverbally, and make eye contact with people once he gets more comfortable with them. James's parents reported that he speaks spontaneously and fluently when he is at home with his family. They also reported that he can be quite animated, is a lot of fun, and is very talkative at home. James received diagnoses of SM (moderately severe) and social phobia (moderately severe). Behavioral treatment was recommended.

Behavioral treatment was initiated following the intake evaluation. Initially, the therapist played nonverbal games and engaged in nonverbal activities with James to help him feel comfortable in the session (e.g., coloring, blowing bubbles, hiding pennies, and giving nonverbal clues). Next, James and his mother were asked to create a list of easy, medium, and hard speaking situations and a list of small, medium, and large rewards. These lists then became the basis for assignments (and reinforcement) for speaking tasks that gradually increased in difficulty. In general, sessions included time with James and his mother together to review past and future assignments as well as time with James and the therapist alone.

When treatment began, James did not communicate at all verbally with the therapist. The therapist gradually increased rapport (via unstructured play) while having James try increasingly difficult tasks, such as first whispering to his mother with the therapist in the corner, then nodding yes or no in response to the therapist's questions, pointing, using a puppet to "talk for him," whispering to his mother while facing the therapist, and then subsequently responding verbally to the therapist. A successful technique in working with James was having him whisper to his mother while playing games with the therapist and then having his mother move a few inches away each time he was asked to respond to the therapist. As the whisper became more audible, the therapist was able to hear his speech and responded directly to the whisper (without waiting for his mother to tell the therapist what James said). James became more comfortable with the therapist hearing his voice, and he was slowly able to direct his speech toward the therapist. After three sessions, James consistently and spontaneously talked to the therapist. James received stickers for completing each speaking assignment, and after filling up "sticker charts," he received rewards (i.e., small toy, special activity with parent, or treat from the reward list).

James was also given assignments that involved both his teacher and classmates. These were implemented in a gradual fashion and included waving to the teacher, playing a game with his parent first in an empty classroom then while his teacher was in the classroom, leaving a phone message for the teacher, playing an audiotape of him saying "hello" to the teacher, whispering to his parent loudly enough for his teacher to hear, whispering "hello" to the teacher, and speaking "hello" to the teacher in a regular voice. Assignments also involved classmates and included playing games with his parent and one classmate, asking classmates questions about their favorite things (e.g., color, animal, and food), playing games with classmates without his parent, and play dates at home. After approximately 12 sessions, James spoke a complete sentence to a group of three classmates, spoke to his teacher directly, and answered a question aloud in front of the entire class.

During the last few sessions, which were tapered over several weeks, James's mother took an increasingly primary role in assigning and following up on speaking assignments. James's

mother had him continue practicing talking assignments with extended family members and unfamiliar adults and children. James entered the first grade, and after only a few days, began regularly speaking to his teacher (both privately and in front of peers) and to most peers in class. Following completion of therapy, James's mother continued to monitor his speaking behaviors and to promote speaking in new situations by encouraging (and rewarding) James's gradual successes with novel people and situations.

DIFFERENTIAL DIAGNOSIS

Although children with SM can be misdiagnosed as having autism due to their lack of speech in the clinic setting, this is a readily avoided diagnostic error. The language deficits of a child with autism are not dependent on the situation, whereas the lack of speech associated with SM is by definition limited to certain situations. Similarly, the diagnostic criteria requiring that the child speak normally in some situations can often rule out a severe communication disorder.

Although many perceive the child with SM to be oppositional, distinguishing SM from primary ODD is fairly straightforward. Most importantly, the child with SM is unlikely to engage in significant oppositional behaviors outside of the context of verbal communication. If a child who appears to have SM (failure to speak in certain situations despite speaking in other situations) also exhibits oppositional behaviors in a variety of situations, both diagnoses are given. For children whose failure to speak does not appear to follow a consistent pattern with regard to situation and targeted individuals, appears primarily motivated by instrumental gains, and occurs in the absence of any other anxiety symptoms, it is possible that ODD rather than SM is the correct diagnosis.

As discussed above, current understanding of SM emphasizes that social anxiety underlies most selectively mute behavior. The resulting conceptual and diagnostic overlap between SM and social phobia complicates the clinician's determination of whether a child with SM also meets criteria for the presence of comorbid social phobia. One of the most successful strategies for the clinician attempting to make this determination is to direct queries toward the presence of social phobia symptoms that do not involve speaking. For example, the presence of fear and avoidance of eating in public, having pictures taken, using public restrooms, or writing in front of others provide strong evidence for an additional diagnosis of social phobia in a child who meets criteria for SM.

The DSM-5 criteria state that a child should not be diagnosed with SM if the failure to speak is due to a lack of knowledge of, or comfort with, the spoken language required. Researchers in the area of bilingual children with SM report that immigrant children and those learning a second language in their new country may be overlooked or misdiagnosed. Thus, the diagnosis of immigrant and language minority children can be difficult, and it is important to understand normal bilingual child development to diagnose SM properly. Many children learning a second language may go

through a nonverbal or "silent period" due to the realization that their native language is not understood by classmates and teachers and that their skills in the new language are not sufficient. To diagnose SM in bilingual children and children who are acquiring a second language, it is important to know that bilingual children with SM exhibit a failure to speak in both their native and newly acquired languages, in several unfamiliar settings, and for an extended period of time (>6 months). Although a child learning a new language may not feel completely comfortable speaking a new language for several months most children show no progression of speech as they gain mastery over their new second language, whereas a child with SM typically does not.

COURSE AND PROGNOSIS

SM appears to have an insidious onset, with most parents reporting failure to speak as a problem that was evident from the time their child began talking. However, commonly, the lack of speech outside of the home is not considered to be a problem until school entry. Although SM is generally considered to be a disorder that is difficult to successfully treat, at the same time it is believed to spontaneously remit over time in a large majority of cases. Based in part on one study that found a large reduction in SM over a 6-month period (from beginning to end of the school year), it was believed that the disorder spontaneously remitted over time in a large number of cases and that in these cases, and that SM should be described as transient rather than persistent. This distinction has been refined somewhat based on a school-based study that revealed that although close to 30 percent of children with SM showed some improvement from the beginning to the end of a school year, as a group, the SM children remained significantly more symptomatic than matched unaffected peers.

In a controlled long-term outcome study (mean follow-up period of 13 years), young adults with SM in childhood were compared to young adults with anxiety disorders in childhood and young adults with no psychiatric diagnosis in childhood. Researchers found that 18 percent of patients with SM in childhood showed only slight improvement in young adulthood, while the rest of the patients with childhood SM were found to be either markedly improved or totally improved in young adulthood. They reported a complete remission rate of 58 percent. Unfortunately, these data did not include comparisons related to variation in course with or without treatment. In the only controlled treatment study that assessed youngsters 1 year following successful behavioral treatment reported that children maintained or improved upon initial gains when reassessed.

Although it seems intuitively useful to discriminate between transient and persistent SM and to assume that persistent mutism may be related to more severe impairment, this distinction requires further investigation. Similarly, there is no information related to ongoing difficulties that might

result from even relatively short-term or transient SM. Given that that there is little information regarding lasting consequences related to early disturbance in verbal communication and that nonspeaking behavior is often conceptualized as a learned behavior that is reinforced considerably over time, it makes sense to target treatment toward younger, recent onset youngsters. Additional support for the importance of early intervention (vs. delaying treatment to establish if SM will resolve spontaneously) comes from recent findings that age of onset, duration of SM, and age at treatment all predict treatment effect size. Specifically, young age and shorter duration of SM were associated with larger treatment effects.

TREATMENT

Unfortunately, much of the published data on the treatment of SM consists of single case studies and case series of markedly varying quality and studies based on retrospective reports or records. Indeed, several additional studies reporting SM treatment outcome rely on small samples or single cases and do not identify diagnostic procedures, assessment or outcome methods, number of treatment sessions, or details of the treatment method. In spite of these limitations, the conviction that behavioral techniques are an essential component of treatment for SM is widespread. Recently, two small randomized controlled trials of behavioral treatment for SM were completed and support the efficacy of such interventions compared to waitlist control. Generally, these and other published reports in the literature describing treatment efforts provide a solid basis for the development of behavioral treatments that include parent and school involvement in treatment. In addition to behavioral strategies, a small but growing literature provides support for the efficacy of pharmacotherapeutic intervention (primarily the selective serotonin reuptake inhibitors [SSRIs]). In addition to a growing effort aimed at empirical validation of treatment for SM, recent efforts have also resulted in better instruments for the assessment of specific symptoms of SM. Instruments such as the Selective Mutism Questionnaire, a parent self-report measure of the affected child's lack of speech, and the School Speech Questionnaire, the companion teacher measure are commonly used in assessment of symptoms in both research and clinical settings.

Behavioral Treatment

Multiple published reports describe the successful utilization of relatively standard behavioral techniques such as contingency management, stimulus fading, systematic desensitization, negative reinforcement, and shaping for the treatment of SM. A combination of behavioral techniques is probably the most common and successful treatment approach. Behavioral approaches typically utilize a hierarchy or rank-ordered list of situations in

which the child has difficulty speaking. Then, the child is guided to systematically engage in speaking-related behaviors (e.g., mouthing speech, making sounds, and whispering) in increasingly more difficult situations. Over repeated successful attempts, the associated anxiety dissipates through the process of autonomic habituation. In addition, when the feared consequences of speaking fail to occur, patients' heightened expectations of harm disappear, reducing anxiety even further. Typically, the child receives positive reinforcement (rewards) following attempts to engage in speaking-related behaviors in order to shape the child's behavior. There are also several reports of treatments utilizing somewhat unique self-modeling behavioral interventions including audio and video editing techniques. Using these techniques, audio or videotapes are edited to show the child speaking in settings where the child usually does not speak. Then, these tapes are repeatedly played for the child so that the child habituates hearing him- or herself speak in these settings and no longer feels uncomfortable.

A number of considerations serve to complicate the behavioral treatment of SM and to distinguish it from treatment for social phobia, a disorder to which it is closely related. These factors include the child's failure to speak (even to the therapist), the young age of most SM patients, and the need for significant school involvement in almost all cases. The young age of children with SM necessitates considerably more parental involvement in treatment than is typically recommended for other anxiety disorders.

Although not without exception, most children with SM do not initially speak to the treating clinician. Obviously, a treatment approach for SM needs to consider the initial communication difficulties that are likely to be present and to include strategies for facilitating verbal communication with the therapist. The initial lack of verbal communication with the therapist is assumed to reflect the general anxiety underlying failure to talk in situations outside the home and is addressed accordingly. To decrease this anxiety and promote speaking in the treatment setting, traditional anxiety-reducing behavioral techniques (shaping, gradual exposure, reinforcement) are first introduced within the session.

The SM child's failure to speak represents a somewhat unique challenge for others in the child's life, particularly parents and school personnel. Although difficulty in differentiating oppositional behavior from anxiety-related avoidance characterizes many child anxiety disorders, when failure to speak is involved, parents and others are particularly likely to attribute avoidance to oppositional motivations and to get frustrated and angry. In contrast, other reactions to nonspeaking include the tendency to accommodate the child's lack of speech and speak "for" the SM child, thus decreasing the necessity of independent communication. This tendency, along with other ways that nonspeaking may be reinforced, also needs to be

addressed in the treatment of the disorder.

Nearly all forms of youth anxiety involve school-related impairment to some extent. However, unlike SM, they do not typically revolve as extensively around the school environment. For this reason, treatment that integrates school participation as a central component of the intervention is necessary for the effective treatment of SM. Most importantly, close rapport with school personnel that includes regular communication and support must be established to ensure the success of behavioral interventions in the school setting. Furthermore, treatment programs should include teacher education and training in the behavioral methods utilized for treatment. The utilization of teachers in the treatment of SM has been highlighted as a particularly cost-effective treatment approach.

Other Psychosocial Therapies

Although the most common accounts of successful psychosocial treatment for SM involve behavior therapy, there are descriptions in the literature of successful treatment for SM with play therapy, family therapy, psychodynamic therapy, and group therapy. Although most of these descriptions are flawed by their small sample sizes and failure to adequately describe the diagnostic or treatment intervention processes, it is noteworthy that descriptions of play, family, and group therapy all contain considerable emphasis on the use of behavioral interventions. In general, traditional psychotherapy aimed at addressing underlying intrapsychic conflicts or other interventions (including play therapy, art therapy, supportive therapy, and family therapy) not containing the behavioral elements described above have not been found to be effective for SM.

Speech and Language Therapy

As noted by the DSM-5, the criteria for SM include a caveat that the symptoms cannot be primarily due to a speech or language disorder. However, it is not uncommon for children with SM to also have some degree of speech or language difficulty that may exacerbate speech-related anxiety or self-consciousness. Although there is a lack of research on the efficacy of multimodal approaches, the combination of cognitive-behavioral techniques and speech or language therapy can be quite effective for the treatment of children with comorbid SM and speech or language difficulties. In addition, even in cases without significant contribution of speech or language dysfunction, the small supportive group setting of auxiliary speech services found in many schools may provide a beneficial environment in which to implement the graded behavioral intervention approach described earlier.

Psychopharmacological Treatments

Currently, there are no approved U.S. Food and Drug Administration (FDA) medications for the treatment of SM. However, several small studies suggest that SSRIs may be effective treatments for SM in children. This is not surprising given the central role of anxiety in the phenomenology of the disorder. Results from a single double-blind, placebo-controlled trial of fluoxetine in children with SM indicated significant improvement on parent ratings of mutism and anxiety. Results from open trials and case studies have also supported the efficacy of various SSRI treatments. In addition, a large multisite study of fluvoxamine for the treatment of separation anxiety disorder, social phobia, and generalized anxiety disorder in children included several children with SM who appeared to benefit from this treatment. These results, along with the mounting evidence that SM is closely related to social phobia, have begun to establish SSRIs as an important treatment option for children with SM. However, given concerns about medication use in young children, medication is not a first option for many families. In practice, behavioral therapy, when practical and available, should be considered as the first-line intervention strategy. In treatment resistant cases, combination treatment (behavioral therapy plus medication) appears to be the strategy of choice.

Early-Onset Psychotic Disorders

LINMARIE SIKICH, M.D., AND TARA CHANDRASEKHAR, M.D.

Positive psychotic symptoms such as hallucinations and delusions may be present in a number of child psychiatric disorders including the primary psychotic disorders, schizophrenia, and schizoaffective disorders, as well as more common disorders such as depression, bipolar affective disorder, severe anxiety, and posttraumatic stress disorder (PTSD). In addition, transient psychotic-like experiences including sleep-related hallucinations and imaginary friends may occur in young children with a mental age of less than 8 years who have no mental health problems. The diagnostic distinctions between these disorders are primarily related to the duration and context of the hallucinations and the presence of specific co-occurring symptoms.
