EDITOR-IN-CHIEF BIOGRAPHY

Paul Ducheyne

Paul Ducheyne is currently Professor of Bioengineering and Professor of Orthopaedic Surgery Research at the University of Pennsylvania, Philadelphia, PA, USA, and Director of its Center for Bioactive Materials and Tissue Engineering. He is also Special Guest Professor at K.U. Leuven, Belgium.

Ducheyne graduated from K.U. Leuven in Materials Science and Engineering (M.Sc.: 1972; Ph.D.: 1976). With fellowships from the National Institutes of Health (International Postdoctoral Fellowship) and the Belgian American Educational Foundation (Honorary Fellowship), he performed postdoctoral research at the University of Florida.

Over a diverse research career, he has organized a number of significant symposia and meetings, including the Fourth European Conference on Biomaterials (1983), the Engineering Foundation Conference on Bioceramics (1986) and the 6th International Symposium on Ceramics in Medicine (1993). The 1986 meeting led directly to the New York Academy of Sciences publications *Bioceramics, material characteristics versus in vivo behavior* (1988). He has lectured around the world and currently serves, or has served on, the editorial board of more than ten scientific journals in the biomaterials, bioceramics, bioengineering, tissue engineering, orthopaedics and dental fields. He has been a member of the editorial board, and then an Associate Editor, of *Biomaterials* (Elsevier), the leading biomaterials journal, since its inception in the late 1970s. He has authored more than 300 papers and chapters in a variety of international journals and books, and he has edited ten books. He has also been granted more than 40 US patents with international counterparts. His papers have been cited about 7,000 times; his ten most visible papers have been cited more than 2000 times.

Ducheyne started his career in Europe. While at K.U. Leuven (1977–1983), he was one of the co-founders of the Post-Graduate Curriculum in Bioengineering. This program is now a full M.Sc. program in the School of Engineering and Applied Sciences. In those initial years, he was also chairman-founder of the chapter on Biomedical Engineering of the Belgian Engineering Society (Flemish section) and director of Meditek, the Flemish Government body created to promote Academia to Industry Technology Transfer in the area of Biomedical Engineering.

He founded Gentis, Inc., which focuses on breakthrough concepts for spinal disorders. Previously, he founded Orthovita (NASDAQ: VITA) in 1992 and served as Chairman of its Board of Directors until 1999. Orthovita focuses on bioceramic implant materials for orthopaedics.

Ducheyne has been Secretary of the European Society for Biomaterials, is Past President of the Society for Biomaterials (USA) and Past President of the International Society for Ceramics in Medicine. He has been recognized as a fellow of the American Association for the Advancement of Science (AAAS), fellow of the American Institute of Medical and Biological Engineering (AIMBE), and fellow of the International Association of Biomaterials Societies. He was the first Nanyang Visiting Professor at the Nanyang Institute of Technology, Singapore and he has received the C. William Hall Award from the Society for Biomaterials.

Many of Ducheyne's PhD students and postdoctoral fellows have become leaders of the next generation. Among his students are Professors at the University of California at Berkeley, the University of Michigan, Columbia University, Georgia Institute of Technology, Kyushu University and K.U. Leuven. Among the six U.S. Associate Editors of the *Journal for Biomedical Materials Research* (Wiley and Society for Biomaterials), three were his PhD students.

CO-EDITOR BIOGRAPHIES

Kevin E. Healy

Kevin E. Healy, Ph.D., is the Jan Fandrianto Distinguished Professor in Engineering at the University of California at Berkeley in the Departments of Bioengineering and Materials Science and Engineering. He received a BSc. in Chemical Engineering from the University of Rochester in 1983. He obtained graduate degrees in Bioengineering from the University of Pennsylvania (M.Sc.: 1985; Ph.D.: 1990).

His research interests include the design and synthesis of biomimetic materials that actively direct the fate of embryonic and adult stem cells, and facilitate regeneration of damaged tissues and organs. Major discoveries from his laboratory have centered on the control of cell fate and tissue formation in contract with materials that are tunable in both their biological content and mechanical properties. These materials find applications in medicine, dentistry, and biotechnology.

Healy has authored or coauthored more than 200 published articles, abstracts, or book chapters. He is a named inventor on numerous issued United States and international patents relating to biomaterials, and has founded several companies to develop materials for applications in biotechnology and regenerative medicine.

He is currently an Associate Editor of the Journal of Biomedical Materials Research. He has served on numerous panels and grant review study sections for N.I.H. He has given more than 200 invited lectures in the fields of Biomedical Engineering and Biomaterials. He has chaired the Gordon Research Conference on Biomaterials and Tissue Engineering.

He was elected a Fellow of the American Institute of Medical and Biological Engineering (AIMBE) and was recently honored with the Clemson award for outstanding contributions to basic biomaterials science.

Dietmar W. Hutmacher

Dietmar W. Hutmacher is currently Professor and Chair in Regenerative Medicine at the Institute of Health and Biomedical Innovation, Queensland University of Technology, Brisbane, Australia. He holds Adjunct Professorships at the Georgia Institute of Technology and the Humboldt University, Berlin, Germany. Before this, he was at the National University of Singapore, where he also obtained his Ph.D. (2001). His undergraduate degree is in Biomedical Engineering (1988) and he was awarded an MBA from the Henley Management College, United Kingdom.

With a strong research focus in the field of biomaterials, tissue engineering, and regenerative medicine, Hutmacher developed an accomplished international profile that exemplifies the main challenge in the field of biomedical sciences, namely crossing traditional boundaries to nurture and initiate research and educational programs across different disciplines, and especially the boundaries between engineering, biology, and medicine.

Outcomes from Hutmacher's research have resulted in high-profile scientific and academic contributions as well as patents and commercialization. He was ranked 45 in the list of the world's top 100 materials scientists compiled by Thomson Reuters in 2010. Dr. Hutmacher has published more than 180 journal articles and 30 book chapters and edited three books. His citation record includes more than 5700 citations, with an h-index of 40. Hutmacher serves on the editorial board of *Biomaterials*, *Tissue Engineering*, *Journal of Biomaterials Sci. – Polymer Edition*, *Artificial Organs* (Associate Editor) and *Polymers International* (Associate Editor). Over the last ten years, Hutmacher has presented more than 30 invited international lectures and has served on more than 20 organizing committees of international conferences. Most recently, he was Chair of *Tissue Engineering and Regenerative Medicine International Society – Asia Pacific (TERMIS-AP) 2010*, and Chair of the *Australasian Society of Biomaterials and Tissue Engineering (ASBTE) 2010* meeting.

David Grainger

David W. Grainger is the *George S. and Dolores Doré Eccles Presidential Endowed Chair in Pharmaceutics and Pharmaceutical Chemistry*, Chair of the Department of Pharmaceutics and Pharmaceutical Chemistry, and Professor of Bioengineering at the University of Utah.

Grainger received his Ph.D. in Pharmaceutical Chemistry from the University of Utah in 1987. With an Alexander von Humboldt Fellowship, he undertook postdoctoral research under Prof. Helmut Ringsdorf, University of Mainz, Germany.

Grainger's research focuses on improving implanted medical device performance, drug delivery of new therapeutic proteins, nucleic acids and live vaccines, nanomaterials interactions with human tissues, low-infection biomaterials, and innovating diagnostic devices based on DNA and protein biomarker capture. He also has expertise in perfluorinated biomaterials and applications of surface analytical methods to biomedical interfaces, including surface contamination, micropatterns, and nanomaterials.

Grainger has published over 130 research papers at the interface of materials innovation in medicine and biotechnology, and novel surface chemistry. He has organized many international scientific symposia and chaired the Gordon Research Conference in Biomaterials and Tissue Engineering. He frequently lectures worldwide, including delivering many named, keynote, and plenary presentations.

Grainger serves on the editorial boards of four major journals in the biomedical materials field. He is currently Chair of the *Emerging Bioanalytical and Imaging Technologies* scientific review group (SRG) at the NIH, and has served on many other national and international review panels, including the NIH's *Surgery and Bioengineering* SRG. He remains active on academic scientific advisory boards for many academic programs in the United States, Asia, and Europe, including major research centers at the Universities of Wisconsin-Madison and of

Washington, the AO Foundation and EMPA, Switzerland, several other competence centers in Europe, and Waseda University's ASMeW Research Center, Japan. Grainger also sits on the scientific advisory boards for four biomedical companies and actively consults internationally with industries in applications of materials in biotechnologies and medicine.

His scientific and technical accomplishments are widely recognized, both at his institution and worldwide. Among several citations, Grainger is fellow of *the American Association for the Advancement of Science* (AAAS), the *American Institute of Medical and Biological Engineering* (AIMBE), and the *International Union of the Societies of Biomaterials Science and Engineering*. He has also been honored with the *2007 Clemson Award for Basic Research*, Society for Biomaterials, and the 2005 American Pharmaceutical Research and Manufacturer's Association's award for '*Excellence in Pharmaceutics*'.

Charles James Kirkpatrick

C. James Kirkpatrick is Professor of Pathology and Chairman of the Institute of Pathology at the Johannes Gutenberg University of Mainz, Germany, having taken up this position in 1993. He is also honorary professor at the Peking Union Medical College, Beijing and the Sichuan University, Chengdu, both in China.

Kirkpatrick is a graduate of the Queen's University of Belfast and holds a triple doctorate in science and medicine (PhD: 1977; MD: 1982; DSc: 1992). Previous appointments were in pathology at the University of Ulm, where he did postdoctoral research in experimental pathology, Manchester University (Lecturer in Histopathology) and the RWTH Aachen (Professor of Pathology & Electron Microscopy).

On moving to Aachen in 1987, he established a cell culture laboratory which began using modern methods of cell and molecular biology to study how human cells react to biomaterials. Since then, his principal research interests continue to be in the field of biomaterials in tissue engineering and regenerative medicine, with special focus on the development of human cell culture techniques, including novel 3D coculture methodology for biomaterials and the application of modern molecular pathology techniques to the study of biofunctionality of biomaterials.

Kirkpatrick is author/coauthor of more than 380 publications in peer-reviewed journals and has made more than 1000 presentations to scientific meetings worldwide. He is a former president of both the German Society for Biomaterials (2001–2005) and the European Society for Biomaterials (2002–2007) and has served on its council since 1995. He is also a member of the Council of the European Chapter of the Tissue Engineering & Regenerative Medicine International Society (TERMIS-EU).

Kirkpatrick is a long-standing member of the editorial board of the premier journal *Biomaterials* and is currently associate editor (since 2002). He has also served as associate editor of the leading *Journal of Pathology* (2001–2006). In total, he serves or has served as an editorial board member of 18 international journals in pathology, biomaterials, and tissue engineering.

Kirkpatrick was the Scientific Programme Committee Chair for the 8th World Biomaterials Congress in Amsterdam in 2008.

Kirkpatrick is a member of the Scientific Advisory Board of a number of research institutes, centres of excellence and companies in biomaterials and regenerative medicine in Europe, as well as the Medical Technology Committee, Federal Ministry of Education & Research in Germany (BMBF) (since 2005) and the German Federal Institute for Drugs & Medical Devices (BfArM)(since 2007).

Kirkpatrick has been recognized for his contributions. He is a Fellow of the Royal College of Pathologists, London and a Fellow of Biomaterials Science & Engineering (FBSE) of the IUS-BSE (International Union of Societies for Biomaterials Science & Engineering). He received the Research Prize of the State of Rhineland-Palatinate for Research on Replacement and Alternative Methods for Animal Research. He was the recipient of the George Winter Award from the European Society for Biomaterials (2008), and in 2010, he received, as first medical graduate, the Chapman Medal from the Institute of Materials, Minerals & Mining in London for "distinguished research in the field of biomedical materials".

PREFACE

Biomaterials is a dynamic, changing field that influences modern medicine and therapeutics in diverse ways. In view of the major expansion of the field of Biomaterials over the last decade, it was considered most timely to publish the present work, *Comprehensive Biomaterials*, with the intent to bringing together the myriad facets of biomaterials in one, major series of six edited volumes that would cover the field of biomaterials in a major, extensive fashion.

Experts from around the world in hundreds of related biomaterials areas have contributed to this publication that addresses the current status of most biomaterials in the field. The contributions discuss their strengths and weaknesses, their appropriate analytical methods and testing, and their device applications and performance. The chapters treat the subjects not only from a retrospective lens but one that is truly prospective, with many articles examining forthcoming materials as disruptive future technologies.

From the outset, it was our goal to review materials in the context of medical devices and tissue properties, biocompatibility and surface analysis, tissue engineering and controlled release. It was also the intent both, to focus on material properties from the perspectives of therapeutic and diagnostic use, and to address questions relevant to state-of-the-art research endeavors. Thus, in this publication, conventional, clinically used biomaterials as well as current emerging prototypes, studies and new ideas, along with visionary predictions of future biomaterials compositions and capabilities have been extensively covered by many colleagues in the field. The editorial team is cognizant of the major efforts our contributors have made in this regard, and appreciates the many, very insightful chapters received.

It was the objective of the editorial team to compose the publication with chapters that would provide strategic insights for those working in diverse biomaterials applications, research and development, regulatory management, and industry. Furthermore, we solicited papers written for a broad, cross-disciplinary audience, such that the work would include up-to-date information in a scholarly, readable and critical style. We are truly grateful to all authors, each of them leading experts in their own right, who dedicated their time to pursuing this goal.

In the first chapter "Biomaterials", the genesis of the structure of this publication is described. Materials are reviewed from the basic building blocks across the formulations and chemistry of *Metals*, *Ceramics and Polymers* to *Biologically Inspired and Biomolecular Materials*, *and Materials of Biological Origin*. Properties are analyzed on the basis of advanced *Methods of Analysis*. Unique aspects of *Biocompatibility*, *Surface Engineering*, *and Delivery of Drugs*, *Genes and Other Molecules* are covered. Materials uses in tissue engineered constructs and devices and implants are treated in *Tissue and Organ Engineering* and *Biomaterials and Clinical Use*. This chapter does not contain any references, as all the 200 chapters in these volumes are unique references in their own right.

From concept to print, this publication was developed and implemented over a five year time span. Even though at times, the editors may have entertained the thought to add some more chapters, it would not have been fair to all our colleagues who submitted their contributions in a timely manner to extend the development time any further.

The publishing field is undergoing major changes at this time. By way of example, scientific society memberships oftentimes provide electronic subscription to their journals, and members more often than not subscribe to this electronic format of journals exclusively. In addition, libraries have shifted to ordering books, compendia, monographs and major reference works in electronic format, and frequently not in printed form. It cannot be denied, though, that the learning process is also one that takes place by leafing through printed publications. Thus, with the goal of achieving the highest possible impact on knowledge dissemination that could result from

this Major Reference Work in the field of biomaterials, a printed format was also deemed necessary. The editorial team and Elsevier have worked closely together to make this publication available in two formats:

- online via the Science Direct platform guaranteeing worldwide distribution via an established medium;
- a printed version with printing-on-demand runs determined by orders received.

This dual publication actually also lends itself very well to publishing updates and additions such as video clips. Elsevier and the editorial team have already discussed some of the concepts in this regard and will be moving on this in the near future.

Comprehensive Biomaterials started with a very innocuous email from a publishing consultant requesting input for a project under discussion at Elsevier. After some soul-searching and corporate restructurings at Elsevier (what's really new in the corporate world?), the project got on track, and it has been my and the editorial team's delight to work with outstanding publishing professionals. David Sleeman was our first publisher. Interestingly, he also moonlighted as a football reporter which reminded me that there was always life after science (yes America, the whole world calls this football). He was succeeded by Graham Nisbet who gave up the trappings of a Politics major for science publishing. Louisa Hutchins and Anne Collett managed most of the editorial flow, ably assisted by Joanne Williams and Marise Willis. With the time difference between the UK and the US, matters had mostly been handled before the day broke on this side of the pond. Once we moved to production, Justin Taylor took charge. There was not a single email that went unanswered. Closer to home, actually in my professional home, the Department of Bioengineering at the University of Pennsylvania, Tabitha Hymans first, and then Jennifer Leung managed my paper flow.

As editors, we want to express a special word of thanks to our colleague, Professor Teruo Okano, Tokyo, Japan, who suggested quite a few interesting topics and excellent contributors when we launched the project. We also relied on a number of referees, among whom we want to single out Ravi Radhakrishnan, Jeremy Gilbert and Christine Knabe.

Lastly, and very importantly, as Editor-in-Chief, it is my pleasure mentioning that it was my privilege to work with a team of colleagues as co-editors. Their enthusiasm was infectious and their insight masterful!

Paul Ducheyne
University of Pennsylvania
Philadelphia, PA, USA

FOREWORD

Almost from the beginning of recorded time, humans have attempted – and often failed – to deploy a wide variety of substances and materials to treat their diseases and traumas. But only within the past few decades, as technologies have matured and materials selection and use diversified, have scientists and therapists discovered the ability to create artificial compounds suitable for *in vivo* usage. The concept of *biomaterials* was introduced no more than fifty years ago, around the mid-1960s. During a conference in 1986 in Chester (UK), colleagues and I struggled mightily to elaborate a consensual definition of biomaterials under D. F. Williams' leadership. This now accepted definition states: "*a biomaterial is a non-viable substance used in a medical device, intended to interact with biological systems.*"

With this definition in mind, one might wonder whether there is a science dedicated to *biomaterials*? Two notions present in this definition are important: utility, and interaction with living systems. *Per se*, they are enough to claim that biomaterial science does not exist. Of course, that is not to say the field itself does not exist. Demonstrably, biomaterials research now straddles such fundamental disciplines as chemistry, physical chemistry, physics, materials science – with its numerous sub-divisions, biology – with its yet-more-numerous sub-divisions. Biomaterial studies include applications in surgery, dentistry, and, more recently, pharmacology with the development of medicated devices. The field extends to scaffolds to support tissue cultures, and degradable and bioresorbable systems to avoid storage after completion of the function. Diversifying the field yet further from these fundamental aspects of "biomaterials" is the necessary, and now extensively developed, set of bioengineering precepts that pushes the field forward.

Today "biomaterials" is a maturing research area. As scientists, our enterprise stretches well beyond the very purest of research characterizing the early "gold rush" days. Furthermore, we are well beyond the initial generations of prosthetic and therapeutic devices made of industrially derived materials. With materials developed for other purposes, rather remarkable therapeutic successes were achieved. This period is now over. Today the challenges are in designing novel therapeutic systems, or finding the means to minimize the few percent of failures observed in systems which have reached the clinic. Having a common vision of such an enormous domain that groups various sciences, methodologies and technologies is a necessity, but it is difficult to achieve by people active in the domain. Individually, there is no chance, for sure. The future depends on interdisciplinary approaches involving top specialists from the diverse specialties that are capable of sharing tasks and thus are capable of understanding each others disciplines and approaches. One can hardly find a textbook, however, to train them and at the same time, to provide initiation to novices. All that has been available to date have been books composed of a collection of some articles and reviews that capture a segment of this expansive, and sometimes confusing, literature.

Comprehensive Biomaterials seeks to provide just such a common vision for the presently vast, and mushrooming domain of biomaterials, embracing numerous perspectives in an expansive, inherently interdisciplinary major reference work to support effective current research in a sometimes bewilderingly complex environment. Significantly, it is written by a panorama of the world's experts in hundreds of related biomaterials areas. The result is a continuum of rich information appropriate for many audiences. The work addresses the current status of nearly all biomaterials in the field, their strengths and weaknesses, their future prospects, appropriate analytical methods and testing, device applications and performance, emerging candidate materials as competitors and disruptive technologies, and strategic insights for those entering and operational in diverse biomaterials applications, research and development, regulatory management, and commercial aspects.

The question may be asked: in such an information-rich environment, what is the interest of this huge collection of 200 contributions? It offers the authority – and the vision – of well-known specialists in the field.

What is the originality of the content? While I have not read all of the contributions, those that I have appear remarkable with contents that are far beyond what reviews usually provide, thanks to clear efforts in updating the knowledge and a didactic writing style. Reading these articles, I felt ignorant but learnt something from each. I see *Comprehensive Biomaterials* as an excellent tool for training those new to the different disciplines and for expanding our numerous specialists' knowledge. Professor Ducheyne and colleagues are to be commended for this extraordinary enterprise.

No one really knows when Adam and Eve left Earth's Paradise. But would it really be important? Millennia forward, no one really agrees when Biomaterials came into existence. But does it really matter? The fragmented historical record indicates that even centuries ago, this is before Lister established the principles of aseptic surgical technique, materials were occasionally used to help in the treatment of injured or lost tissues.

In the era of rebuilding that followed the Second World War, innovators in the treatment of painful arthritic joints were using corrosion-resistant metals to restore motion and function to the joint. Half a century ago, a key consideration for the use of materials in surgery was the minimal reactivity of the material when implanted in the body. It was the principle that when foreign materials and devices would be implanted, there should be no adverse response, either in the local tissues or systemically, and this could best be achieved with materials that would not or would only minimally react when inserted in biological milieus.

Almost all metals used in the body, with the exception of the noble metals, derive their benign tissue response from the formation of a tenacious oxide film that forms spontaneously on their surface and thereby shields the underlying metal from further oxidation; this is corrosion. Thermodynamically, metals such as stainless steels, cobalt chromium alloys, and titanium and its alloys are not in their lowest state of energy, but the initially formed oxide film forms a protective layer that renders the kinetics of further oxidation extremely slow. This holds true as long as the oxide film is present and not compromised. Obviously, achieving this under any circumstance is still a major issue, as can be evidenced by reviewing the performance of some orthopedic joint replacement device designs today.

The advances in technical ceramics prompted their pursuit for medical use. The thinking went that to achieve minimal reactivity in tissues, ceramics were inherently better suited than metals, which can still be reactive in conditions in the body. In contrast, ceramics are materials that are composed of ionic compounds, and as such are thermodynamically very stable. This formed the first impetus for their use. Technical ceramics also possessed excellent wear and friction properties that made them uniquely attractive as a material of choice for artificial joints. It was expected, in an at the time unbeknownst way, that less wear particulates would be produced and as such that there would be less of a possibly adverse tissue response. This work was very prescient, since as it stands today, the prognosis for successful functioning of a total hip replacement is set at some 15 years, and the key limiting factor for longer successful performance is the osteolytic tissue response to the accumulated wear debris produced in the artificial joint.

A new school of thought emerged in the 1970s. It was held that, since any material implanted into the body will elicit a response, materials should be designed for directing a favorable tissue response and to guide the healing. Thus, bioactive ceramics were first formulated. Even though these materials are also composed of ionic compounds, they are reactive, and their reactivity, as well as the control of their reactivity is at the basis of their unique *in vivo* properties. When bioactive ceramics such as hydroxyapatite and bioactive glass were first described, their *in vivo* tissue response was barely understood. Initially, studies relied on materials science methodologies to describe surface reactions, more often than not focusing on inorganic material reactions. It was not for long, though, until fundamental advances in cellular and molecular biology pushed along the quest for a better and more thorough understanding. These studies revealed that molecules known to play important roles in cell function and cell signaling adsorb onto - and into - the surface reaction layers that form *in vivo* on bioactive ceramics. These events, in tandem with dissolution from the inorganic material, then prompt the cellular activity and enhance tissue formation.

A conceptually opposite path, but one the field followed in parallel, was the engineering of materials surfaces. New materials were created with molecules in order to specifically drive cell function. Studies focused on the biomimetic modification of materials to alter a material's compatibility with a biological system. The insight emerged that controlling cell behavior in contact with biomaterials critically depended on the material providing the correct chemical and physical signals to the cells. Cell adhesion and proliferation were controlled by designing the material to incorporate biomimetic chemistry that regulated cell function. Molecules such as peptides and growth factors were covalently coupled to an inorganic material's surface so that the cells surrounding the material recognized it through a normal biomolecular pathway.

Today, the field of Biomaterials is replete with studies and discussions of treatments that make use of biological processes to interact with materials, and, in so doing, aid in tissue formation and regain of bodily functions. Actually, the concept of 'smart materials', this is, materials that elicit and stimulate tissue formation, has become a mainstay in the field, as can be witnessed from the myriad of studies involving all classes of materials, including metals, ceramics, polymers, and composites. Materials have a surface composition intended to interact with biological pathways and cellular functions. Biological functionality is also built into material structures or is grafted onto material surfaces. New materials are designed to mimic biological structures or functions, giving rise to the class of biomimetic materials. And lest we forget we cannot possibly improve on Mother Nature, we also use materials of biological origin such as collagens, fibrin, and hyaluronic acid polymers.

Not only does surface chemistry have an effect on biological response, surface structures can be engineered to guide and direct a desirable biological outcome. Patterned material surfaces have been developed with the goal, first, to pursuing a fundamental understanding of how surface geometries and physical properties on a micro- and nanoscale affect cellular

biology. A second, not less important goal, is to define interfacial properties that optimally achieve repair with implanted materials. To mention an example, data has been published demonstrating that the shapes of nuclei of primary cells on microfabricated substrata are controlled by confining attachment and spreading isolated cells on adhesive islands. Gene expression, protein synthesis, and cell differentiation on such substrates are then altered by changing the nuclear shape of cells present within the substrate features. Thus, biomaterials studies have led to the discovery that nuclear shape, and not cell shape, is a predominant component affecting cell fate decisions in contact with materials.

From here, it is only a small step to conceive of therapies purely based on material concepts to upregulate a cellular response, and this without relying on any drugs or growth factors. In this context, the word 'theramer' has been used in studies of polymers with this built-in capability. Furthermore, bioactive ceramics, which have the inherent ability to adsorb and potentiate cellular ligands and growth factors as a critical step toward tissue formation and repair, also represent a class of materials uniquely illustrating this very principle of biomaterials. Theramers are integrated into tissue structures; and, bioactive ceramics react, are being transformed and are resorbed along with the remodeling tissues.

Even though there is major interest in material responses by themselves, there is also widespread focus on materials that are combined with therapeutic molecules and with various cells. These interests have evolved alongside with the development of Controlled Release (of drugs and other therapeutic molecules) and Regenerative Medicine and Tissue Engineering.

Controlled release was first pursued with the goal of achieving drug blood plasma concentrations that would vary much less than with intermittent bolus administration, even to the extent of staying constant. It was the hope that with continuous delivery, a concentration could be maintained that would not be less than the minimum therapeutic dose and also would not exceed the toxic threshold concentration. Today, Controlled Release as a field is much vaster in scope and pursues its goals in part by designing materials concepts for optimal delivery. Areas of interest include superior biological tolerance ('biocompatibility') of the materials in which molecules are embedded; local drug delivery with implanted materials for greater treatment efficacy by achieving much greater local drug concentrations than possible with systemic administration; targeted delivery of therapeutics with controlled release particles that hone in on cell membrane receptors uniquely expressed by cancer cells; release subsequent to site-specific enzymatic degradation of the delivery material; local delivery to eliminate risks of systemic toxicity associated with oral and parenteral therapies; delivery of water-insoluble drugs to increase bioavailability; protection of molecules with a short half life, such as growth factors; convenience (anticonceptive); avoidance of compliance issues in treating mental disorders; and tunable delivery to achieve space- and time-dependent delivery. A whole plethora of materials are used in this regard: polymers, ceramics, even metals. In fact, surface modifications of metals are designed in order to incorporate molecules that, upon release, produce a bactericidal effect.

The explosion of the biological sciences and the quest for using this wealth of new knowledge for better treatments also did not leave biomaterials untouched. As was indicated earlier, it advanced the understanding of the modes of action of bioactive ceramics and materials with engineered biomimetic surfaces. But, there is also the converse of this path. In the pursuit of treatments to regenerating tissues and organs, cell biology has been unraveling answers to questions such as how to deliver cells, in what state, from which source, and subject to what prior treatment. These studies include many aspects of stem cell biology and cell signaling. This field, oftentimes captured by the words 'Regenerative Medicine', has come to suggest the importance of cell carrier materials vis-à-vis excellent cellular preparation, proper cell signaling, and successful delivery of cell constructs into *in vivo* tissue beds. This represents the next frontier in biomaterials: rather than deciphering reactions to materials, the mechanistic understanding of cellular stimulation is now used to advance delivery of cells and pursue optimal cell and tissue engineering treatments.

At its core, tissue engineering integrates aspects of advanced cell biology, of delivery and release of various molecules that signal cellular function, and of materials that act both as optimal scaffolds for cellular functional expression and as vehicles for release of any biological molecule relevant in this process. This essence of tissue engineering reveals a critical aspect of modern biomaterials, namely the complex interplay among various components ('cells, signals, and scaffolds'), where solutions to the difficult problems the field addresses derive from information in a multiplicity of related fields. In tissue engineering studies, one can easily discern the core principle of materials science, which is the materials science triad. This principle reflects the interdependency among processing, composition and structure, and properties. Focusing on tissue engineering and, within it, the unique biomaterials aspect, the methodology of scaffold material synthesis critically determines composition and surface structures, which in their turn affect molecule release and cellular stimulation (to name but a few of the scaffold properties). All aspects are coupled, and modification of one of the parameters in this materials universe typically will affect many other parameters and outcomes.

Over the many years that the field of Biomaterials has evolved, there has been the overarching focus on contributing to better medical care. There has been an evolution from extraneous repair by replacing tissues to intrinsic repair by stimulating tissue formation and regeneration. A merger of these evolutions is underway, as devices continuously co-opt biological functionality. The example of drug-coated stents is the one that jumps most readily to mind. The field is also moving inexorably into nanoscience, and in this instance, it is again the result of a logical evolution. Even though nanotechnology at large is at the forefront of many engineering disciplines, it evolved in a gradual and natural way. In fact, nanotechnology, at large, involves using the typical engineering skills of analysis, quantification, synthesis, and design, but then at ever smaller levels of organization. The evolution came about with ever better tools and methods being developed. In Biomaterials, these tools enable probing at the smallest levels of organization of materials and tissues and make it possible to design and synthesize materials with ever smaller dimensions. In the context of biomaterials, it may be apparent that modifying surfaces with molecules and physical features having

nanodimensions in order to stimulate biological response is one but an outstanding illustration of this principle. Other, not less revealing examples are materials which by themselves have nanodimensions, such as quantum dots, nanoparticles for controlled and targeted delivery, and nanofibers that are incorporated in tissue engineering scaffolds.

Advances in methods, tools, and techniques have contributed critically to the progress in biomaterials. Obviously, there are the methods derived from Cellular and Molecular Biology alluded to earlier. There are also the advances in microscopic and spectroscopic techniques that enable probing materials and tissues, and very importantly, the interface between materials and tissues. New imaging techniques have evolved that enable the study of materials and devices *in vivo* with unprecedented richness of information. And there are the computational methods, both in mechanics and in chemistry that use sheer computational power to address fundamental questions of the effects of physical and chemical properties on any detail of material tissue interaction.

Understanding and guiding the biological response is at the core of the field of Biomaterials. In the mid-eighties, the field actually tried to capture this essence by defining biocompatibility this way. At the Consensus Conference "Definition in Biomaterials" of the European Society for Biomaterials in Chester, England, March 1986, one came to define biocompatibility as "the ability of a material to perform with an appropriate host response in a specific application". As a corollary today, can it then not be stated that biocompatibility is existential to modern Biomaterials Science?

The definition of biocompatibility also emphasized the application. This observation carries with it important consequences. First and foremost is the need to study materials in functional forms reflecting actual treatments *in vivo*. In so doing, medical aspects such as issues associated with trauma, pathology, patient variability, and patient compliance enter into the analysis. It is interesting to revisit the early evolution of Biomaterials in the post-Second World War era. At the time, the standard-of-care for treating painful, arthritic hip joints was arthrodesis, this is, a 'stiffening' of the joint. Today, one still uses this approach of removing motion, but then in the treatment of painful spines. Spinal fusion entails the removal of the intervertebral disk and the coalescence of bone tissue from the neighboring vertebrae. In so doing, motion and function of the 'spinal motion segment' are severely reduced. Notwithstanding the fact that arthrodesis is long past in the treatment of arthritic hip joints, but conversely is actively practiced in spinal surgery, it is interesting to note that the past advances in the joint replacement field are regularly invoked to rationalize developments in spinal care. At first sight, this is surprising, given that anatomical structures, tissue properties, and surgical details are all vastly different in the spine and the joints of the lower extremities. However, even though the same materials are used to advance spinal care as were used in joint replacement surgery, including various metals, polymers and ceramics, the materials properties are now studied in view of these significantly different uses.

Analysis of clinical performance is part of the field of Biomaterials. Today, it is well established that for new materials, new devices, or new material-based treatment concepts to be introduced clinically, a five-pronged evaluation scheme needs to be addressed: (i) *in vitro* evaluation of biocompatibility in simple, a-functional conditions; (ii) *in vitro* evaluation of acceptable performance in conditions mimicking functional *in vivo* conditions; (iii) *in vivo* evaluation of biocompatibility in simple, a-functional conditions; (iv) *in vivo* evaluation of satisfactory performance in functionally relevant conditions (typically appropriate animal models are then used); and (v) evaluation of materials and devices in well-conceived clinical trials. During these studies, one addresses questions not just related to material properties *per se*, but properties in view of surgery(or other procedure)-related characteristics, tissue properties, trauma or illness-related conditions, and patient factors. Today, with the advent of personalized medicine, we may be, perhaps, at the verge of having to include considerations of genomic variations.

Biomaterials is a field that bears testimony to the adage that paradigm-shifting fields are situated at the cross-section of various existing disciplines. In Biomaterials, advanced materials science with its chemical, mechanical, and physical components, crosses into biology and makes this knowledge all its own, and this with the intent on furthering medical care and contributing to medicine.

How does one structure such a vast, dynamic, and complex field? Materials technologies spanning the continuum from academic and industrial research to clinical applications in devices, drug delivery, tissue engineering, and regenerative medicine occupy an enormous intellectual and technological bandwidth. The field embraces fundamental linkages within device and regenerative medicine innovation. Contemporary biomaterials science encompasses molecular, computational, recombinant and biotechnological, nanotechnological, hybrid composite, microbial and cell- and tissue-based approaches.

The question begs repeating. How does one structure such a vast, dynamic, and complex field? In this 200-chapter publication, the modern aspects of biomaterials are described from basic science to clinical applications. Materials are reviewed from the basic building blocks across the formulations and chemistry of **Metals, Ceramics and Polymers** to **Biologically Inspired and Biomolecular Materials, and Materials of Biological Origin**. Properties are analyzed on the basis of advanced **Methods of Analysis**. The unique aspects of **Biocompatibility, Surface Engineering, and Delivery of Drugs, Genes and Other Molecules** are covered. Materials uses in tissue-engineered constructs and devices and implants are treated in **Tissue and Organ Engineering** and **Biomaterials and Clinical Use**.

By the very nature of the field of Biomaterials, these subjects are extensively interrelated, and as such, it may appear as though there is some overlap. However, this is only appearance, as typically, there are different vantage points from which one can review the information. Thus, overlap must not be confused with complementarity. As a case in point, there are chapters on "Fretting Corrosion of Orthopedic Implants" and "Electrochemical Behaviour of Metals in Biological Milieus". In the former, the emphasis is on the actual fretting corrosion/mechanically assisted corrosion that has been documented in orthopedic implants. In the latter, there is limited focus on actual implant construct behavior, but extensive focus on the fundamental mechanisms of corrosion. In the former, there is ample discussion of implant testing and metallic ion release

analysis. In the latter, the basic mechanisms of oxidation and reduction, and the shifts in electrical potential that occur during oxide abrasion are described.

Health care and the commitment to excellent care are typical characteristics of advanced countries. In *Comprehensive Biomaterials*, some major advances in medicine and health care that came about by studying and using materials in medicine are covered. The publication provides many examples from the main medical disciplines to which Biomaterials has contributed: cardiovascular care, orthopedics and dentistry, to name but a few. This publication, however, is not a comprehensive description of all matters 'Biomaterials'. It cannot be, by virtue of the field's enormous reach and ever-changing dynamics. Rather it is a current, broad-based review of the salient directions of the field.

Biomaterials Science is very much a part of the broader discipline of Biomedical Engineering. Whereas Engineering, and Materials Science by extension, used to derive their foundation from mathematics, physics, and chemistry, Biomedical Engineering and Biomaterials have also embraced biology as a basic science on which they build. Thereby, the scope of the parent disciplines is expanded in a way no other activity in engineering currently does or currently achieves with the thoroughness of the biomedical engineering or biomaterials community. The major advances in the biological sciences are followed in lockstep. With the twenty-first century turning into the age of biology, Biomedical Engineering and Biomaterials contribute to society by building on the advances in this critical science. Biomedical Engineering, and within it Biomaterials, is advancing as a discipline worldwide. Full-fledged Biomedical Engineering educational programs at the undergraduate level have been started worldwide and departments in biomedical engineering are continuously being created.

The foray of biomedical engineers and biomaterial scientists into areas, such as heart pacing, joint replacement, and imaging brain function, and so many more challenges seemed daunting beyond comprehension half a century ago. Many of these challenges have been conquered, all while progress continues. Other areas of great complexity are now related to the universe of genes and stem cells and are also being tackled by the biomedical engineering and the biomaterials community. This publication shows the strides made and the challenges that remain.

Glossary

Alloy A material composed of at least two chemical elements. At least one of these elements must be metallic and the alloy must have metallic characteristics.

ASTM International ASTM develops standards for a wide range of activities including materials and testing procedures used in the medical device field.

Crystal structure The arrangement of atoms in simple, repeated, three-dimensional arrays. Almost all metals are crystalline (as opposed to amorphous).

Dislocation(s) Dislocations are extended defects in the structure of a crystal (e.g., edge dislocations are represented by an extra partial row of atoms in the crystal). Dislocation behavior is critical to deformation of metals.

Fatigue Progressive localized damage due to repeated applications of load. This can lead to crack formation, crack growth, and component failure.

Fracture mechanics The study of the behavior of structures in terms of the stress conditions and defects (e.g., cracks or flaws) in the structure.

ISO The International Organization for Standardization develops standards in a variety of fields including materials and tests for the medical device industry.

Recrystallization Formation of new, ductile grains from previously worked metal grains by heating the metal to an elevated temperature. This increases ductility and decreases strength of the metal.

Abbreviations

BCC Body centered cubic
FCC Face centered cubic
FDA Food and drug administration
HCP Hexagonal close packed
MRI Magnetic resonance imaging
PSB Persistent slip bands
α Alpha, in titanium alpha phase refers to the hexagonal closed packed crystal structure
β Beta, in titanium beta phase refers to the body centered cubic crystal structure

1.102.1. Introduction

Implantable materials make critical contributions to modern medicine. Many of the treatments we now take for granted (joint replacement, pacemakers, heart valves, stents) would not have been possible without the advanced metals, polymers, and ceramics that are available to the medical device community.

The human body presents a very challenging environment for materials engineers because of the need for implants that are highly corrosion resistant and, in many applications, able to withstand millions of high stress load cycles. This chapter focuses on implantable metals, with the emphasis on their composition, mechanical properties, and the relationships between processing methods (i.e., the techniques used to produce the implant) and mechanical properties. As the field is so broad, this discussion primarily covers metals used in load bearing applications for structural components.

1.102.2. General Requirements for Long-Term Implantation

Any implantable metal must be well tolerated by the host tissue. Therefore, metals of interest must be nontoxic and biocompatible (various aspects of the biological response to implants are discussed in **Chapter 4.401, The Concept of Biocompatibility**; **Chapter 4.402, Biocompatibility and the Relationship to Standards: Meaning and Scope of Biomaterials Testing**; **Chapter 4.403, The Innate Response to Biomaterials**; **Chapter 4.404, Adaptive Immune Responses to Biomaterials**; **Chapter 4.405, Leukocyte–Biomaterial Interaction *In Vitro***; **Chapter 4.406, Protein Interactions with Biomaterials**; **Chapter 4.407, Bacterial Adhesion and Biomaterial Surfaces**; **Chapter 4.408, Integrin-Activated Reactions to Metallic Implant Surfaces**; **Chapter 4.409, Surfaces and Cell Behavior**; and **Chapter 3.319, Characterization of Nanoparticles in Biological Environments**). In this regard, composition and corrosion resistance are the key factors for metallic materials. With the exception of noble metals such as platinum and gold, implantable metals form very thin, passive oxide films that reduce their corrosion rates to extremely low levels.

Implantable materials must exhibit mechanical properties that are appropriate for specific applications. High fatigue strength is needed for devices such as femoral hip stems and pacemaker leads; metallic suture wires must be relatively soft and ductile.

Only a limited number of metals can be safely implanted for long periods of time; the metals made in the greatest commercial quantities (steels, aluminum alloys, copper alloys) are not suitable for use as implants.

In many cases a material is chosen for an implant application because of a unique property or combination of properties. For example, platinum or palladium alloys are used in a variety of applications where radiopacity is important (i.e., marker bands). Wear behavior is a critical aspect of devices that articulate, and the choice of material for these applications is often made on the basis of wear characteristics; cobalt base alloys, oxidized zirconium, and aluminum oxide ceramics are often used in these applications because of their wear behavior. **Table 1** provides a broad overview of implantable metals along with their important attributes and typical applications.

1.102.3. Key Metallurgy Concepts

The atoms in metals are arranged in simple, repetitive, long-range, three-dimensional crystal structures. For the metals of interest in this chapter, the relevant crystal structures are body centered cubic (BCC), face centered cubic (FCC), and hexagonal close packed (HCP). The nature of atomic bonding in metals is quite different from that found in other materials. Metallic bonding involves the sharing of valence electrons between closely packed atomic cores. The mobility of shared electrons is crucial to the electrical and thermal conductivity of metals. As the bonds are not localized, individual metal atoms or planes of atoms can move, or slip, relatively easily with respect to one another.

Permanent, or plastic, deformation of metal crystals occurs most frequently by dislocation motion. Dislocations are defects in the crystal; edge dislocations (an extra half plane of atoms) are a common type (**Figure 1**). If the applied loads are high enough, atomic bonds break in a sequential fashion and the dislocation moves through the crystal. Dislocations move most favorably on close packed planes within the crystal. Metals with the FCC structure have more close packed planes than BCC and HCP structures and therefore are generally more ductile. While dislocation theory is a complex subject beyond the scope of this chapter, it is important to note that the approaches used to alter the strength and ductility of metals

Table 1 Overview of some major groups of implantable metals and their applications

Alloy family	*Reason for medical use*	*Some typical uses*
Stainless steels	Fatigue strength, corrosion resistance	Fracture fixation, stents, hip stems, spinal implants, cables
Cobalt base alloys	Fatigue strength, corrosion resistance, wear resistance	Joint replacement, stents, pacemaker conductor wires, spinal disc replacements, dental bridgework
Titanium alloys	Fatigue strength, corrosion resistance, ability to bond to bone (osseointegration)	Joint replacement, dental implants, fracture fixation, spinal fusion implants, spinal disc replacements
Nitinol	Shape memory	Stents
Tantalum	Corrosion resistance, radiopacity	Porous structures for bone ingrowth, X-ray markers
Zirconium	Wear resistance of oxidized zirconium	Joint replacement
Platinum alloys	Radiopacity, electrical properties, corrosion resistance	Pacemaker electrodes, guide wire marker bands, aneurysm coils
Gold alloys	corrosion resistance, radiopacity	Crowns, inlays, guide wire marker bands

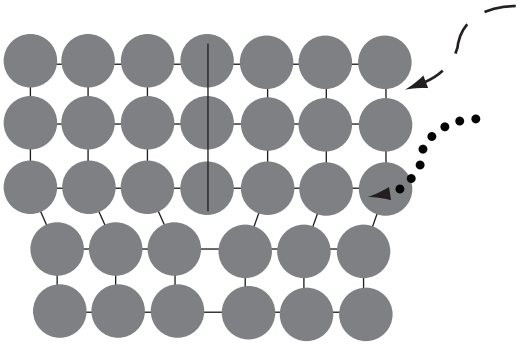

Figure 1 Dislocation motion is the most common mechanism for plastic deformation in metals. In this schematic, an edge dislocation (extra row of atoms) is shown by the solid line. It is easier to break bonds between atoms one at a time along the plane indicated by the dotted line than it is to break all the bonds at one time along the plane indicated by the dashed line. Illustration with permission from Haggard, W. O.; *et al*. In *Surgery of the Hip*; Berry, D. J., Leiberman, J. R. Eds.; Elsevier, (in press).

rely on mechanisms that alter the ability of dislocations to move through the crystal structure. Deformation by twinning is another deformation mode in some metals. The deformation behavior of Nitinol (the major shape memory alloy) is quite different from that of conventional metals; Nitinol deformation involves phase transformations and reversible twinning processes (Nitinol is discussed in **Chapter 1.104, Shape Memory Alloys for Use in Medicine**).

Most metal objects contain large numbers of individual grains. The orientation of the crystal within each grain is generally different from the orientation in adjacent grains. This mismatch between grains is accommodated by grain boundaries, which are thin disordered regions. Grain size is an important factor in the mechanical strength of metals. In general, finer grains lead to higher strength. A well-known equation describing this behavior is the Hall–Petch relationship, $\sigma_y = \sigma_o + kD^{-1/2,}$ where σ_Y is the yield stress of the metal, σ_o is a frictional stress required to move dislocations, k is the Hall–Petch slope, and D is the grain size.[1]

Pure metals are typically quite soft and ductile; extremely pure metals are also very expensive to produce as it is difficult to avoid contamination by small amounts of impurities. Therefore, the vast majority of metals are alloys with more than one ingredient. The major constituent may be thought of as the solvent and the minor constituents as solute atoms. Metallic alloying elements generally take the place of the solvent atoms at random locations in the crystal structure; they are referred to as substitutional alloying elements. (Nitinol is an exception to random alloying element locations. NiTi has an ordered structure with the Ni and Ti atoms alternating in the lattice.) As the substitutional alloying elements are not the same atomic size as solvent atoms, the crystal lattice is distorted by the addition of these elements. This makes dislocation motion more difficult and increases the strength of the metal. Small atoms such as nitrogen, oxygen, and carbon tend to be located in the regions (or interstices) between the solvent atoms; these are known as interstitial alloying elements. Interstitial alloying elements 'pin' dislocations very effectively, so small additions of these elements can have a large impact on mechanical properties. Chemical composition is also an important determinant of the crystal structure of the material. The crystal structure of a metal determines how many and which slip systems are available; this in turn affects deformation behavior and response to mechanical loading.

Another technique to improve the strength of metals is to increase the number, or density, of dislocations within the crystal. There are a number of mechanisms which produce additional dislocations within a metal crystal as the crystal is deformed. As dislocation density increases, the dislocations begin to interact, and further dislocation motion becomes more difficult. This behavior forms the basis for strengthening metals by work hardening (also known as cold working or strain hardening).

1.102.4. Chemical Composition and Structure

The metals most frequently used for implants include iron-based stainless steels, cobalt-based alloys, titanium-based alloys, and nickel–titanium (Nitinol) shape memory alloys. Shape memory materials are the subject of **Chapter 1.104, Shape Memory Alloys for Use in Medicine**. There is limited use of zirconium, tantalum, and a variety of noble metals (platinum, gold, etc.).

1.102.4.1. Stainless Steels

Implantable stainless steels are iron-based alloys. Although other types of stainless steels exhibit BCC or duplex (BCC+FCC) crystal structures, the implantable alloys exhibit a FCC crystal structure referred to as austenite. Austenite is nonmagnetic; given the widespread use of MRI techniques, this is a critical requirement for implantable materials today. Stainless steels with lower amounts of alloying ingredients (e.g., 302 and 304) can transform to the magnetic martensite phase during cold working operations. If part of a catheter or guide wire made from these materials breaks off in a patient, it could lead to serious consequences. A portion of the FDA warning about unretrieved device fragments is related to this (http://www.fda.gov/MedicalDevices/Safety/AlertsandNotices/PublicHealthNotifications/ucm062015.htm).

Typical stainless steel alloying ingredients include chromium (Cr), nickel (Ni), molybdenum (Mo), manganese (Mn), and nitrogen (N). Chromium is added primarily to enable the alloys to form a protective chromium oxide layer (passive film). Passive films in stainless steels and cobalt–chromium alloys are often thought of as being simply Cr_2O_3 layers, but they are more complex as they may contain small amounts of other oxide species and may interact with the human environment postimplantation. Additional information on the nature and behavior of passive layers may be found in Gilbert.[2] Ni and/or Mn additions are necessary to stabilize the nonmagnetic FCC crystal structure. Nitrogen additions also help stabilize austenite and improve strength and corrosion resistance while Mo improves corrosion resistance (particularly pitting corrosion). Although carbon is a key alloying ingredient in conventional steels, carbon is kept at low levels in these alloys to reduce the possibility of chromium carbide formation (a phenomenon known as sensitization) during slow cooling

Table 2 Chemical composition of common implantable stainless steels

Alloy designation	*Cr (wt%)*	*Ni (wt%)*	*Mn (wt%)*	*Mo (wt%)*	*N (wt%)*	*Minor elements*

from elevated temperatures. Formation of these carbides reduces the Cr content along grain boundaries making sensitized stainless steels more likely to experience intergranular corrosion.

The use of stainless steels for implants began in the mid 1920s[3] with the use of Fe–18% Cr–8% Ni screws. The 18-8 alloy was quickly replaced with an improved version that contains additions of Mo for better corrosion resistance. This type of alloy was used for a variety of fracture fixation devices as well as an early total hip replacement developed by Wiles.[4] Over time, 316L stainless steel emerged as the most commonly implanted stainless steel. Common applications for 316L include fracture fixation products and stents.

Stainless steels with improved mechanical properties and superior corrosion resistance to 316L appeared in the 1980s. These alloys contain higher levels of Cr, Mn, and N than 316L. An example of this alloy is Rex 734™ which is used for hip stems. The most recent implantable stainless steels contain very low Ni content; these alloys were created in response to concerns about patient sensitivity to nickel. These low nickel alloys contain high levels of Mn and N to stabilize the desired austenitic phase. Table 2 lists the chemical composition of some implantable stainless steels along with their ASTM and/or ISO standards.

1.102.4.2. Cobalt Base Alloys

Cobalt base alloys share many similarities with stainless steels. Under most conditions, they exhibit an FCC crystal structure and often contain the same alloying elements (Cr, Ni, Mo, N) used in stainless steels. As with stainless steels, the corrosion resistance of these alloys is due to the formation of a thin chromium oxide passive film. Low levels of nitrogen (0.25% max) increase strength. Nickel additions stabilize the FCC crystal structure.[11,12] Deformation of cobalt base alloys can cause some of the FCC structure to transform to the less ductile HCP phase; this is somewhat less prevalent if nickel is added to these alloys. The cobalt base alloys that are generally used in product forms that require extensive amounts of deformation (e.g., wire, tubing,

and thin strip) commonly contain nickel. The cobalt alloys used to produce orthopedic implants such as hip stems and knee replacements contain much lower nickel content than the other implantable cobalt base alloys. Table 3 lists the chemical composition of commonly implanted cobalt base alloys.

Unlike implantable stainless steels, some of these alloys contain significant levels of carbon (up to 0.35%) which results in the formation of carbide particles throughout the material. Carbides are intermetallic compounds with fixed ratios of metal and carbon atoms. In the cobalt base alloy used in orthopedics, the presence of carbon results in formation of primarily $M_{23}C_6$-type carbides. In this carbide, the metal atoms (M) are primarily Cr.[13] The size and the distribution of the carbides depend on the manufacturing process used to produce the alloy. Carbides in cast versions of this alloy are much coarser than those found in wrought material of the same composition.

The initial use of cobalt base alloys was in dental appliances; a paper by Venable published in 1937 demonstrated favorable response to a Co–Cr–Mo alloy when implanted in a canine model.[14] This alloy, which came to be known as Vitallium® among other trade names, found its initial implant use in hip 'molds' (a cup placed over the head of the femur to eliminate bone-to-bone contact).[15] As joint replacement procedures evolved, the use of this type of alloy became common in hip and knee replacements. Other cobalt base alloys are used to produce pacemaker leads, stents, heart valve cages, and a variety of other implants.

1.102.4.3. Titanium Base Alloys

Titanium alloys are often divided into categories based on the crystal structure of the alloy. The three categories that are used in medical devices are alpha (α), which has HCP crystal structure (e.g., CP titanium), alpha plus beta (α+β) which contains both HCP and BCC structures (e.g., Ti–6Al–4V and Ti–6Al–7Nb), and beta (β) alloys such as Ti–12Mo–6Zr–2Fe. The crystal structure of these alloys depends on the chemical composition of the alloy and processing conditions such as the cooling rate from elevated temperatures. Some alloying elements (e.g., Al, O) act to stabilize the α phase; such elements are referred to as α stabilizers. Other elements (e.g., Mo, V, and Nb) stabilize the β phase, so they are referred to as β stabilizers. These beta alloys are sometimes referred to as metastable as they rely on rapid cooling from elevated temperatures to retain the β crystal structure. If α+β alloys are cooled in this manner, they will transform to a martensitic structure with undesirable mechanical properties. Table 4 lists the chemical compositions of some of the most widely used titanium alloys.

The internal microstructure of α+β and β titanium alloys can be altered over a very wide range by control of deformation parameters (amount of deformation, deformation temperature), cooling rates, and the use of heat treatment. This allows airframe and jet engine manufacturers to tailor alloys for specific mechanical demands such as high fracture toughness or resistance to high-stress-low-cycle fatigue. The ASTM and ISO standards for alloys such as Ti–6Al–4V require fine dispersions of equiaxed α and β phases because this condition offers excellent high-cycle fatigue performance.

A key aspect of microstructure control in Ti alloys involves the temperature at which the β phase transforms to a mixture of α+β (the β transis temperature). In α+β alloys, cooling from above the β transis leads to lamellar structures; faster cooling rates result in finer lamellae. The fine grain equiaxed α+β microstructure generally used in implants results from deformation below the β transis followed by recrystallization and annealing cycles(or a single 'mill anneal' cycle), also below the β transis. A complete review of the relationships between processing, structure, and properties can be found in Lütjering and Williams.[21] The microstructural changes associated with processing above the β transis mean that operations such as welding or other high-temperature processes (sintering to apply a porous coating) will lead to formation of lamellar microstructures. This may cause some reduction in high-cycle fatigue strength.

The corrosion resistance of these alloys is due to the formation of titanium dioxide (TiO_2) passive layers. Titanium is extremely reactive, so the passive film forms extremely rapidly. The high reactivity of titanium means that any melting or elevated temperature fabrication processes must be done

Table 4 Chemical composition of common implantable titanium Alloys

Alloy designation	*Crystal structure*	*Al (wt%)*	*V (wt%)*	*Nb (wt%)*	*Mo (wt%)*	*Zr (wt%)*	*Fe (wt%)*	*O (wt%)*
Commercially pure Ti (ASTM F 67[16], ISO 5832 Part 2[17])	Alpha						0.20 max Grade 1 0.50 max Grade 4	0.18 max Grade 1 0.40 max Grade 4
Ti–6Al–4V ELI (ASTM F 136)[a]	Alpha plus beta	5.50–6.50	3.5–4.5				0.25 max	0.13 max
Ti–6Al–4V (ASTM F 1472, ISO 5832 Part 3)	Alpha plus beta	5.50–6.75	3.5–4.5				0.30 max	0.20 max
Ti–6Al–7Nb (ASTM F 1295, ISO 5832 Part 11)	Alpha plus beta	5.50–6.50		6.50–7.50			0.25 max	0.20 max
Ti–15Mo (ASTM F 2066[18])	Metastable beta				14.0–16.0		0.10 max	0.20 max
Ti–12Mo–6Zr–2Fe (ASTM F 1813[19])	Metastable beta				10.0–13.0	5.0–7.0	1.50–2.50	0.008–0.28
Ti–15Mo–5Zr–3Al (ISO 5832 Part 14[20])	Metastable beta	2.50–3.50			14.0–16.0	4.5–5.5	0.35 max	0.20 max

[a]The composition of ELI Ti–6Al–4V falls within the ranges specified by ISO 5832 Part 3.

under strictly controlled conditions to avoid contamination and resultant reduction of mechanical properties.

As a viable production process for titanium and its alloys did not become available until after World War II, development and use of titanium implants lagged behind the use of stainless steels and cobalt alloys. Reports by Leventhal and Down cover some of the earliest uses of titanium and its alloys for implant applications.[22,23]

An active area of research in medical materials involves new titanium alloys. Most of this work involves β alloys. The interesting attributes of β alloys include low elastic modulus, ability to utilize large oxygen additions without brittle failure, lower notch sensitivity in fatigue, and the ability to work harden and cold form shapes.

Metallic joint replacements alter the stresses experienced by the surrounding bone; this can lead to loss of bone density. The difference between the stiffness of bone and the stiffness of an implant is an important factor in this bone loss.[24,25] The elastic modulus of femoral cortical bone is on the order of 17–20 GPa,[26,27] significantly lower than the values for stainless steels (~190 GPa), cobalt base alloys (~230 GPa), and α+β titanium alloys (~110 GPa). The Ti–35Nb–4SN β alloy has been processed to result in elastic modulus levels of 40–60 GPa[28]; it remains to be seen if low modulus Ti alloys will yield clinical benefits for human patients.

Current titanium alloys contain low levels of oxygen (0.13–0.28% max depending on the alloy) because of loss of ductility with further increases in oxygen content. Higher oxygen contents (up to 0.68%) have been studied in a Ti–35Nb–7Zr–5Ta alloy. Yield strength of this alloy at 0.68% oxygen is over 1050 MPa with a high level of ductility (over 20%).[29]

The fatigue strength of α+β alloys declines significantly if the material has surface discontinuities or notches; this behavior is known as notch sensitivity. In general, β titanium alloys are less sensitive to notches. For example, Murray *et al.* reported a 585 MPa 10^7 million cycle endurance limit for smooth Ti–6Al–4V samples in a rotating beam fatigue test. The endurance limit decreased to 280 MPa for specimens with a notch (stress concentration factor of 1.6). For the β alloy Ti–12Mo–6Zr–2Fe, the smooth and notched values were 585 and 410 MPa, respectively.[30]

As the BCC structure of the β alloys offers more slip systems than the HCP α phase, these alloys are easier to deform at low or room temperature. Thus, the β alloys offer more possibilities for strengthening by work hardening. Jablokov *et al.* have published tensile property data on cold worked, and cold worked and aged Ti–15Mo. In this study, a 40% reduction in area increased the ultimate tensile strength from 758 MPa (solution treated) to 1104 MPa. Further increases in strength were achieved by aging the alloy.[31]

The ability to deform β alloys at low temperatures has led to efforts to form parts at room temperature (as opposed to the more common hot forging process).[28] More information on the range of β titanium alloys that have been studied can be found in Niinomi.[32]

1.102.4.4. Other Implantable Metals

Some of the earliest attempts to use metals in surgery, dating back to around 150 AD, involved gold suture wire.[33] Gold was also reportedly used in the 1500s and 1600s.[34] Today, applications of noble metals such as gold, platinum, and palladium are limited; the high cost of noble metals tends to limit their applications to very small devices or components of devices. In addition to cost, many of these materials exhibit relatively low mechanical properties further limiting their range of applications.

In the past decade, porous tantalum (Ta) and an oxidized zirconium (Zr) alloy have been used in orthopedic applications. The porous Ta structure is used in applications where bony ingrowth is desired; it may be used as a free standing material or bonded to implants.[35,36] Ta is also used in some devices to provide radiopaque markers and it has been used to produce other types of implants. The oxidized Zr alloy is used in articulating applications (total knee replacements, femoral heads for hip stems) due to the wear resistance of its zirconium oxide (Zr_2O_3) surface layer.[37]

1.102.5. Mechanical Properties

Any implant must have mechanical properties that enable it to perform its function for the desired lifetime of the implant. The properties of interest are specific to each application and depend on design of the implant and the properties of the material used to produce the implant. The factors that control mechanical properties are the material composition and the processes used to fabricate the implant. Processing choices (e.g., using a cast part vs. a forged part) can have a dramatic effect on the final properties of the implant.

Mechanical properties can be divided into properties determined by a single load application such as a tensile test and fatigue properties determined by repeated application of loads. These categories are often referred to as static and dynamic properties. As many medical devices routinely see millions of loading cycles over their lifetimes, fatigue properties are especially important.

1.102.5.1. Static Properties

Static properties are generally measured using laboratory specimens that are loaded using specialized testing machines. The most common loading condition applies tensile loads, but testing in compression, shear, or torsion is also possible. Typical data reported from this testing are yield and ultimate stress, elongation, and modulus of elasticity. Yield stress is sometimes reported as proof stress or yield strength, and ultimate tensile stress may be referred to as tensile strength or ultimate tensile strength.

The materials standards published by groups such as ISO and ASTM include minimum standards for tensile properties of implantable metals. Table 5 shows the ASTM requirements for minimum tensile properties of selected metal alloys. The data in the table demonstrate the impact of some processing variables. For 316L and Rex 734™ stainless steels, it is clear that as a result of work hardening, the cold worked (or medium hard) condition exhibits higher strength and lower ductility as expected. Cobalt alloys such as MP35N exhibit similar behavior. The properties of wrought, warm worked Co–Cr–Mo are much higher than those of investment cast material because

Table 5 Tensile properties of some common implantable metal alloys

Alloy designation	*Yield strength (min.) (MPa)*	*Ultimate strength (min.) (MPa)*	*Elongation (min.) (%)*	*Reference*
316L stainless (annealed)	190	490	40	ASTM F 138
316L stainless (cold worked)	690	860	12	ASTM F 138
Nitrogen strengthened stainless steel (REX 734™); annealed	430	740	35	ASTM F 1586
Nitrogen strengthened stainless steel (REX 734™); medium hard	700	1000	20	ASTM F 1586
'Nickel free' stainless steel (BioDur 108®); annealed	517	827	35	ASTM F 2229
'Nickel free' stainless steel (BioDur 108®); cold worked	827	1034	20	ASTM F 2229
Investment cast Co–Cr–Mo	450	655	8	ASTM F 75
Co–Cr–Mo (wrought, warm worked)	827	1192	12	ASTM F1537
Commercially pure Ti	170 (grade 1) 483 (grade 4)	240 (grade 1) 550 (grade 4)	24 (grade 1) 15 (grade 4)	ASTM F 67
Ti–6Al–4V (ELI)	795	860	10	ASTM F 136
Ti–12Mo–6Zr–2Fe (solution annealed)	897	931	12	ASTM F 1813

of structure refinements (much smaller grain size, smaller carbides in the versions of this alloy, which contain carbon), and the development of a worked structure within the grains.

Under some conditions, the strength of work hardened cobalt alloys can be further increased by aging treatments. As per ASTM F562, the yield strength of cold worked MP35N is 1000 MPa (minimum) in the hard condition (ASTM specifications do not specify the amount of cold work or reduction of area). In the cold worked and aged condition, the minimum yield strength is 1596 MPa.

The static mechanical properties of titanium alloys depend on chemical composition and processing history. Oxygen content has a large impact on the strength of these alloys, which can be seen in the strength levels of the various grades of commercially pure titanium (**Table 5**). The amount of oxygen that can be added to current titanium alloys is limited because excessive amounts of oxygen result in low ductility. As was mentioned earlier, recent work with a Ti–35Nb–7Zr–5Ta alloy suggests that higher amounts of oxygen can be tolerated in Ti alloys that contain large amounts of other alloying ingredients. Although at least some of the titanium alloys respond to work hardening or heat treatment (aging), the effect of these treatments is not specified in either the ASTM or ISO specifications for these alloys.

1.102.5.2. Fatigue

The study of fatigue began in the mid-nineteenth century after failures of locomotive axles caused fatal accidents. The disastrous Comet airliner crashes in the 1950s are another example of historically significant fatigue failures. In the device industry, the most devastating fatigue failures involved the Björk Shiley 60° Convexo-Concave (BSCC) heart valve. There have been hundreds of deaths associated with the fracture of the outlet struts which were welded to the main body of the device: failure of the struts resulted in the carbon disc no longer functioning as a valve. Welding quality issues and higher than anticipated stresses have both been implicated in this tragic case.[38]

Modern medical implants are not free from fatigue failures. Implants used for fracture fixation or spinal fusion may fail if the location that is being stabilized does not heal. Fracture of segments of stents is also observed.[39] Forces at the hip joint can be as high as eight times body weight during running and three times body weight while walking.[40] These forces can lead to fatigue fractures of femoral hip stems. Hip stem fracture becomes more likely if the proximal region of the implant is not supported by bone. This lack of support increases the moment arm acting on the device leading to high stresses. Overall statistics on the rate of hip stem or other orthopedic implant fractures are not readily available, but the MAUDE (Manufacturer and User Facility Device Experience) database on the FDA website can be searched to find reports of fractures in specific devices (http://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfMAUDE/search.CFM).

A basic definition for fatigue is "... a degradation of mechanical properties, leading to failure of a material or component under *cyclic* loading."[1] The stresses needed to create damage by fatigue are typically lower than the overall yield strength of the material. The fatigue process involves three stages: crack initiation, crack growth, and final failure due to overload. As many implants experience millions of load cycles over their lifetime, it is not surprising that mechanical failures of metallic implants are almost always because of fatigue. The possibility of fatigue failure depends primarily on the design of the component, the fatigue strength of the material used to produce the component, and the nature of the surface of the device (e.g., surface roughness, residual stresses, stress concentration sites such as sudden transitions in section size and sharp radii, and surface flaws such as cracks and inclusions).

Wöhler, a German engineer working in the Prussian railway system, is generally credited with pioneering the systematic study of the relationships between applied stress and the number of loading cycles a component could withstand. In this method, a number of samples are tested at different loads and the applied stress (S) is plotted against the log of the number of loading cycles (N) to yield an S/N (or Wöhler) curve. Shütz has prepared an extensive review of the development of our understanding of metal fatigue.[41]

A feature of the metals discussed in this chapter is that they exhibit a fatigue or endurance limit. If the maximum stress level is below the endurance limit, the material can be cycled indefinitely without failure. Fatigue tests are generally run to 10^7 million loading cycles to establish an endurance limit (cardiovascular stents are often tested to 4×10^8 million cycles as a heart rate of 60 beats per minute translates to over 30 million cycles per year).

Table 6 Some published values for 10^7 million cycle fatigue strength of common implantable metals

Material	*Material condition*	*10^7 cycle endurance limit (MPA)*	*References*
Co–Cr–Mo (ASTM F 75[42], ISO 5832-4[43])	Investment cast	200 (min)–450	44–46
Co–Cr–Mo (ASTM F 1537[47], ISO 5832-12[48])	Forged or warm worked	656–930	34, 44, 49
Ti–6Al–4V (ASTM F 136[50], ISO 5832-3[51])	Wrought	500–800	34, 46, 49, 52
Ti–6Al–7Nb (ASTM F 1295, ISO 5832-11[53])	Wrought	540–750	52

It is important to realize that there is variation in S/N fatigue test outcomes; a large number of specimens are needed to obtain good statistics. Sources of variability include variation in the processes used to produce the test material and the test sample, and the random nature of flaws such as inclusions. Fatigue crack initiation generally begins at, or very close to, a surface of the sample as stresses are generally highest at the surfaces. This makes surface finish and the presence (or absence) of residual surface stresses factors which can affect the test results. The type of fatigue test used may also result in different results. As a result, different investigations may result in different estimates of the endurance limits of implantable metals; **Table 6** contains a few examples of published values for some common alloys. Implant designers should keep this variability in mind when deciding what material properties to use for implant strength calculations.

Starting in the 1960s, fracture mechanics methods began to be applied to studies of component life under fatigue loading conditions. This approach assumes that flaws are inherent in the material and seeks to predict the response of the flaw to the loading conditions. This approach is generally referred to as damage tolerant design; the US Air Force requires key airframe and engine components to be designed to damage-tolerance guidelines (the US Air Force Handbook for damage tolerant design is on-line at http://www.afgrow.net/applications/DTDHandbook/sections/page1_0.aspx).

Application of the fracture mechanics approach to airframes and jet turbine components was driven by unanticipated component failure. The fracture mechanics approach assumes all components have flaws and then characterizes the behavior of the flaws when loads are applied to the component. This analysis relies on understanding the crack growth behavior of the material and it demands accurate modeling of the high stress regions of the component. The original Paris relationship between crack growth rate and loading conditions is $da/dN = C(\Delta K)^m$, where da/dn is the crack growth rate, ΔK is the stress intensity factor at the crack tip, and C and m are empirical constants.[54,55] Since Paris published this work, it has been widely used even though there are several issues with it. Shütz summarizes the issues as follows: "... it contains neither the influence of mean stress on crack propagation, nor the static fracture on reaching the fracture toughness K_{1c}, nor the 'fracture mechanics fatigue limit' AK_0, that is the stress-intensity range below which no fatigue–crack propagation occurs."[41] If fatigue crack growth rates (da/dN) are known as a function of the stress intensity factor (ΔK), it is possible to calculate a threshold cyclic stress intensity factor (ΔK_{TH}) for cracks of various sizes. For medical devices this information may be used to calculate the size of a flaw that will not propagate under the highest stress conditions experienced by the part (this is referred to as the critical flaw size). As long as the component can be inspected to insure that any flaws are smaller than this critical size, flaws at or below the critical flaw size will not grow (or will require billions of load cycles to grow); thus the component should not fail.

The fracture mechanics approach has been used to model a heart valve and a stent but the method is not in general use for medical devices.[56,57] A complete description of this method is beyond the scope of this chapter; see Shütz for a review and list of references on this approach.

The vast majority of medical device fatigue evaluations continue to rely on the S/N approach. The fracture mechanics approach focuses on crack growth calculations and, in the case of aircraft components, utilizes periodic inspections to monitor crack length. Most medical device designs seek to avoid crack initiation as once a crack starts in a medical device, it is likely to propagate until the device fails; crack size inspection for implanted devices is not possible and the cost of implant failure is high. Another issue with the fracture mechanics method involves assessing the maximum stress conditions. For highly stressed components like femoral hip stems, patient variability (weight, activity level, bone size, and bone quality) makes it difficult to determine a true worst case stress situation. Conservative estimates for all of these factors might result in impractical designs (i.e., large components that would not be useful for many patients).

As the classic S/N approach is commonly reported in the medical device literature, it will be the focus of further discussion. S/N curves are usually generated with laboratory specimens as (opposed to testing complete devices). This testing is generally done in air as opposed to simulated body fluids such as Ringer's solution. Testing in air may result in higher observed fatigue strengths for stainless steels,[58] but there does not appear to be a difference when testing Ti alloys in air and in Ringers.[52,59] If the component of interest is large enough, it may be possible to machine test specimens from actual implants.[60] This can help capture the influences of the production processes on fatigue. It is more common to machine test specimens from more convenient product forms such as round or flat bars of the material of interest; care must be taken with this approach to ensure that the raw material used is as representative as possible of the material condition found in the device of interest.

Testing methods to measure fatigue strength include rotating bending (with either a constant bending moment or a cantilever loading situation), flat plate cantilever bending, and axial testing. An example of a rotating test with a constant bending moment is the R.R. Moore method; this creates a sinusoidal loading condition with equal maximum tensile and compressive loads. In this case, the mean stress is zero and the ratio of the minimum to maximum stress (the R value) is -1.0. As this type of test generally uses an hour glass shaped

specimen, the volume of the specimen exposed to the maximum load is very small. Another issue with rotating bending tests is that many implants do not experience reverse bending while in service. In spite of these issues, its relative ease and the simple, robust testing equipment involved make rotating bending a common screening method. Flat plate cantilever bending and axial loading tests make it possible to apply a mean stress. In these types of tests, a stress ratio of 0.1 is often used and the specimen is never loaded in compression. These tests have the advantage of testing a greater volume of material than a standard rotating sample with an hour glass cross-section; if there are flaws within the material, tests that involve additional material in high stress regions are more likely to result in failures initiated by the flaws. The differences between these testing methods, therefore, may lead to different fatigue strength outcomes depending on the test protocols that are used.

Another type of fatigue of interest for medical devices is fretting fatigue. Fretting involves low amplitude cyclic rubbing between two surfaces that are in contact. Surface damage can occur under these conditions making crack initiation easier. Modular joint replacements, fracture fixation devices, and spinal fusion products all have multiple parts that are assembled in the operating room. When these components undergo loading in the body, relative motion and fretting can occur at the junctions between the parts. Fretting corrosion may be observed under these conditions; this is discussed in **Chapter 6.607, Fretting Corrosion of Orthopedic Implants**. In general, the fatigue strength of metals under fretting conditions is expected to be lower than the strength levels obtained from smooth laboratory samples. A paper by Neu provides an excellent review of this topic for Ti–6Al–4V.[61] A decline in the fatigue strength of Ti–6Al–4V from ~550 to 175 MPa because of fretting has been observed.[62]

These results were generated using a flat cantilever bending test; for the fretting tests, two cylinders were clamped across the test specimen yielding a cylinder on flat contact situation. ASTM F 1875 describes two methods for evaluating fretting corrosion; one of these methods can also be used to determine fatigue strength of the junction between a femoral hip stem and a modular head.

While laboratory specimens provide useful information, testing of finished components provides more assurance that the product will meet its performance requirements. Final component testing takes into account design features, surface conditions, and processing effects that are difficult to mimic in a laboratory test specimen. Final component tests can also apply more complex loading conditions than those found in simple rotating beam or cantilever bending tests. For example, testing of completed stents ensures that postlaser cutting processes such as electropolishing have adequately removed any recast layer associated with laser cutting operations while testing hip stems in their final form ensures that any effects of the actual manufacturing processes are accounted for.

Typical fatigue tests of finished components seek to approximate the loading conditions experienced in clinical service. In the case of femoral hip stems, 'the validity of these methods has been empirically established through the reasonably good correlation of test results with historical clinical data.'[63] If there are implants with excellent clinical histories (in terms of mechanical failure rates), the performance of these implants in standard tests can be used to establish performance requirements for subsequent implants. Standards organizations such as ISO and ASTM have written test method standards for a variety of finished implants. Examples include ISO 7206 parts 4[64] and 6[65] and ASTM F 1612[66] for hip stems, and ASTM F 2477[67] for stents.

Finished component testing is generally performed to establish that the implant in question meets specified performance requirements. Determination of an endurance limit for specific devices is uncommon. In the case of orthopedic implants, a potential problem for this type of test is the reliance on historical clinical data. Thus, major changes in the patient population such as greater numbers of obese patients and increasing use of joint replacements in younger, more active patients may result in higher stresses than those observed in the historic joint replacement population.

In both laboratory testing and in the clinical setting, fatigue crack initiation is generally the critical stage. If a crack initiates on a medical implant, it is likely that the implant will experience enough additional loading cycles to lead to failure. Fatigue cracks generally initiate at or near the surface of implants. If there are flaws on the surface of a device in a highly stressed region, they may act as crack initiation sites. Examples of this include porosity, laps or cracks in the material, and inclusions (foreign materials, typically oxide particles, which were entrapped in the material in the early stages of production). **Figure 2** shows SEM micrographs of fatigue initiation in 177 μm MP35N wire; in one case, the fracture initiated near a small Al_2O_3 inclusion and in the other example, the failure initiated at a surface tool mark.

Design and manufacturing issues can also provide potential crack initiation sites; sudden changes in section size or sharp

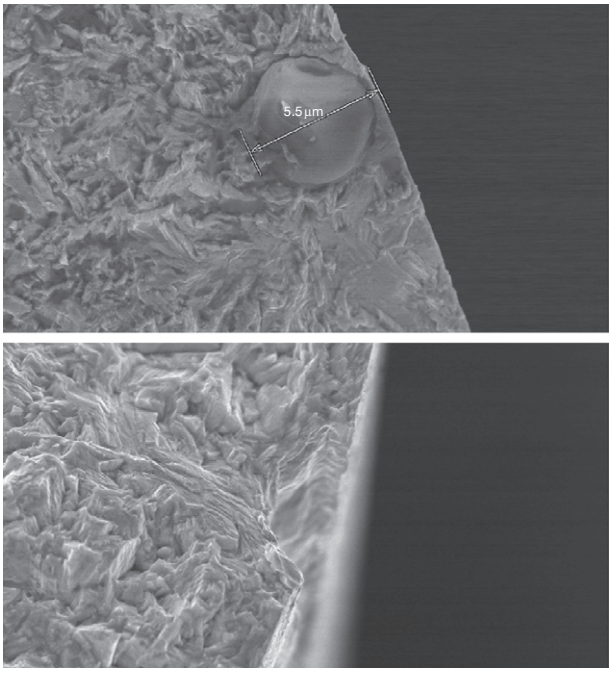

Figure 2 SEM micrographs showing fatigue initiation sites in 177-μm MP35N wire. The top image shows an alumina inclusion very near the initiation site while the bottom image shows initiation from a tool mark on the surface of the wire. Images provided by Mr. Jeremy Schaffer, Fort Wayne Metals, used with permission.

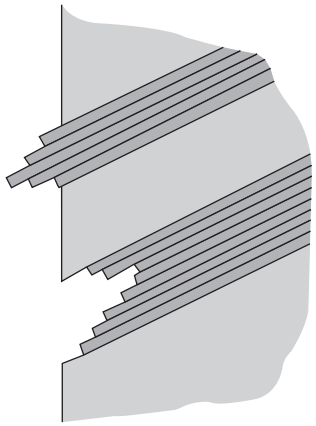

Figure 3 Intrusions and extrusions formed by slip on the surface of a metal. These surface features may act as stress concentrators and crack initiation sites.

radii are examples of design issues that result in stress concentrations and potential failure. Some machining operations (e.g., aggressive grinding) can result in microstructural change due to overheating or formation of small cracks on the surface; a reduction in the endurance limit for Ti–6Al–4V from 596 MPa (polished) to 310 MPa (abusively ground) has been reported.[68] In the absence of any of these discontinuities, localized slip processes can lead to formation of persistent slip bands (PSBs) followed by formation of intrusions and extrusions on the surface which may act as stress concentration sites (Figure 3); PSBs and intrusions/extrusions may also interact with other discontinuities to initiate cracks. Thoughtful implant design, stringent control over manufacturing processes, and careful inspection methods all help to minimize the risk of implant fatigue failure.

Figure 4 shows SEM micrographs of a failed 316L bone screw. This screw exhibited multiple initiation sites followed by a crack growth phase (as evidenced by the fatigue striations) and final overload once the cross-sectional dimensions of the screw were reduced to the point that it could no longer support the load.

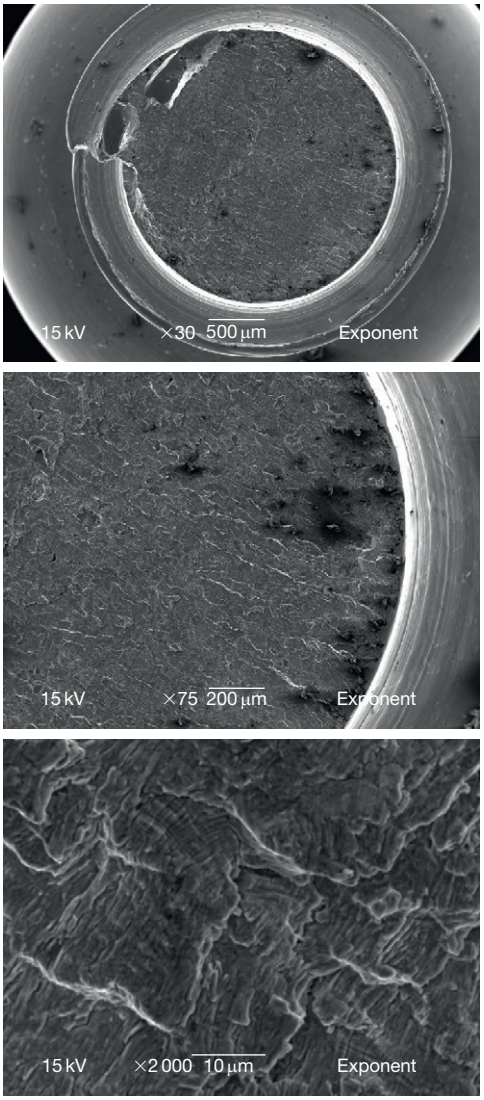

Figure 4 SEM micrographs of a 316L bone screw that failed because of fatigue. The top view shows the overall screw surface; multiple initiation sites are evident in the middle image; the crack then grew by fatigue as indicated by the striations in the lower image. Images supplied courtesy of Brad James PhD Exponent, used with permission.

1.102.6. Processing Effects

For a given chemical composition, the choice of process routes has an enormous effect on mechanical properties. Processing choices influence factors such as grain size, hardness, extent of cold work within grains, and the presence of texture (i.e., preferred orientation of the crystal structure, leading to mechanical properties that are anisotropic). Processes also influence properties by altering the nature of the surface of the device in question. Internal structure alterations influence dislocation motion. Surface modifications, such as shot peening and application of porous surface layers, affect the ease of initiating cracks. Processing can also introduce flaws into an implant. Examples include inclusions that are introduced in melting operations, porosity in castings, cracks in forgings or extruded tubing, surface damage due to laser marking, etc. Figure 5 shows examples of processing related flaws.

1.102.6.1. Metal Processing Overview

Nearly all metals, including those used to fabricate implants, require a melting operation as part of their production. In some applications, components are made to near net dimensions by pouring molten metal into a shaped cavity, or mold, which mimics the shape of the desired object. A version of the casting process known as investment casting is in wide use for production of orthopedic implants such as femoral knees. Other metal products begin with the casting of large (~500–5000 kg for specialized implantable alloys) ingots. The main constituent and the desired alloying ingredients are melted together to achieve the desired overall chemical composition. As-cast ingots have very large grains; some alloys may also exhibit segregation of the alloying elements at this stage. Control of the melting process is crucial to minimize

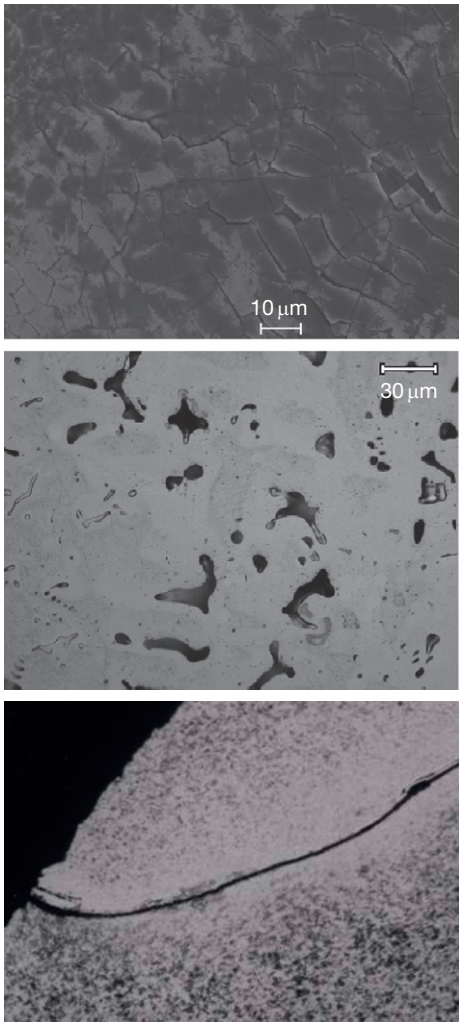

Figure 5 Processing of metals may result in flaws which can impact the mechanical properties of the device. The top image shows the development of surface cracks in a laser etched part number on a titanium implant. The middle image shows porosity observed in an investment cast stainless steel hip implant (with permission from Griza). The lower image shows a surface crack found in a Ti–6Al–4V forging during routine inspection.

entrapment of oxide particles or other undesirable inclusions and reduce alloy segregation. The alloys of interest for medical devices are generally melted under protective atmospheres (i.e., vacuum or inert atmospheres) to eliminate formation of oxide particles and they are routinely melted several times to improve chemical homogeneity. Excessive inclusion content may harm corrosion resistance and mechanical properties; ASTM and ISO specifications for implantable stainless steels and some cobalt base alloys include 'microcleanliness' requirements that limit the number of large, nonmetallic inclusions that may be present in these alloys. The impact of inclusions on mechanical properties depends on the location of the inclusion and, to some extent, the size of the implant. A 5–10 μm inclusion in a 15-mm-diameter hip stem may not impact mechanical properties, but a similar inclusion in a device with very small dimensions (e.g., wires in pacing leads, stents) may have large effects on fatigue strength. The benefits due to reducing inclusion size in small devices have been demonstrated in MP35N wire. Here, the Ti content in the alloy was reduced from 1.0% to 0.01%, which reduced the size and number of titanium nitride (TiN) inclusions in the material. Rotary beam fatigue testing was done on work hardened 177 μm MP35N wire. At a stress of 758 MPa, the average fatigue life of the conventional high Ti content wire was 1 154 000 cycles; for the low Ti content wire, the average fatigue life was 33 470 000 cycles.[69]

A recent report of Ti–6Al–4V bar stock containing unalloyed or incompletely alloyed regions underscores the need to achieve a high level of chemical homogeneity prior to subsequent working operations.[70] In this case, supplies of this material reached a number of medical device producers before the problem was discovered.

After casting, large ingots must be reduced to useable sizes. Dislocation motion is necessary for the deformation process and additional dislocations are generated during deformation; if the initial breakdown of the ingot were to take place at room temperature, the metal would fracture before a significant amount of reduction took place. Thus, the bulk of the size reduction steps (i.e., press forging, rotary forging, and rolling) are done at elevated temperatures. The forces required to deform metals are much lower at high temperatures and the metals are more ductile. During deformation processes above a critical temperature range, dislocations are annihilated as new grains form. These new grains contain low dislocation densities, so they can be readily deformed. This cycle of deformation and formation of new stress-free, deformable grains is common to the materials of interest in this chapter. The deformation steps may occur in sequence (i.e., deformation operations followed by separate annealing cycles) or in a continuous operation. The temperature at which new, stress-free grains will develop from heavily worked, high dislocation density grains is known as the recrystallization temperature. This is not a fixed temperature and it is different for different metal alloys. Besides the alloy composition, factors influencing recrystallization behavior include the extent of deformation, the time at temperature, and the presence of second phase particles. Metals that have been processed through this series of deformation and recrystallization steps are referred to as wrought materials. For some product forms, the final deformation steps may occur at relatively low temperatures or even at room temperature to produce work hardened material. Overall, these processes reduce the grain size of the material and improve chemical homogeneity.

1.102.6.2. Process Effect Examples

1.102.6.2.1. Work hardening and annealing

The key factor in work hardening are the interactions between dislocations and the generation of additional dislocations during plastic deformation. As the number of dislocations in a metal increases, the dislocations begin to interact and tangle. As more and more dislocations are produced during deformation, these interactions become increasingly complex, and resistance to further deformation increases. If this deformation continues beyond a critical level, voids will begin to form in the metal followed by cracking and failure. The details of these

processes are quite complex; material science textbooks can be consulted for more information.[1,71] Since dislocations are defects, they have stresses and strains associated with them. As the number of dislocations increases, the total energy in the crystal increases. This increased energy provides the driving force to recrystallize the metal by heating (or annealing) it. Thus, in broad terms, grain size, hardness, and resultant mechanical properties of metals can be altered by controlling the amounts of deformation and the thermal cycles used, if any, to recrystallize the material.

Implantable austenitic stainless steels are strengthened by alloying effects and work hardening. While 316L is still the most common implantable stainless steel, more recently developed alloys such as Rex 734™ and BioDur 108® contain higher amounts of key alloying elements, which improve both mechanical behavior and corrosion resistance. In the annealed condition, these alloys are all relatively soft and ductile. Deformation of these alloys at temperatures below the recrystallization temperature causes increased levels of hardness, tensile and fatigue strength, and decreased ductility. The amount of deformation is routinely described in terms of percent reduction in area: $(A_I - A_f/A_I)100$ where A_I is the initial cross-sectional area and A_f is the final cross-sectional area. Table 5 shows the impact of cold working on mechanical properties of some representative stainless steel and cobalt base alloys.

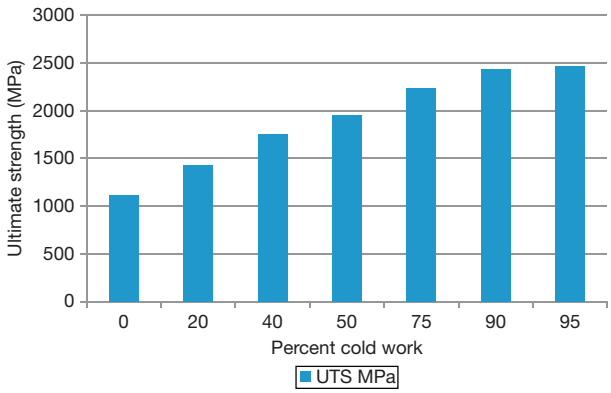

Figure 6 Response of MP35N wire to cold work. Note the wide range of strength depending on the amount of cold work. The initial wire diameter was 5.1 mm. Data provided by Fort Wayne Metals; used with permission. MP 35N® is a registered trademark of SPS Technologies.

The data in Table 5 show the normal trade off between strength and ductility in cold worked metals. As strength is increased by cold work the ductility decreases. It should be noted that it is very difficult to achieve uniform amounts of cold work through the entire cross section of large components. In the case of large cross sections, it is likely that the material at or near the surface will be more heavily worked than the material at the core. Annealed stainless steels are used where a high level of ductility may be required (e.g., balloon expandable stents, suture wire); various levels of work hardening can be specified for devices that require higher strength.

Figure 7 shows the microstructure of 316L in both the annealed and cold worked conditions. Indications of deformation (slip) within the grains of the cold worked specimen are evident. These images were obtained by polishing the samples to provide smooth, flat surfaces. The samples are then chemically etched using various acids or other solutions which preferentially attack grain boundaries or second phases within the sample. After the samples are prepared, they are examined at high magnification using light or scanning electron microscopy. The resultant images reveal features such as grain size, distribution of different phases (e.g., α and β in titanium alloys), cleanliness of the material (i.e., inclusion content), flaws (porosity, cracking), and the extent of deformation within grains.

Cobalt alloys such as L-605 and MP35N respond in a similar manner as stainless steels to work hardening. Figure 6 shows the relationship between ultimate tensile stress and the percent reduction of area for MP35N wire. Heavily cold worked MP35N is routinely used for pacemaker leads.

Closed die forging is a common technique to produce orthopedic implants. This process uses a sequence of shaped dies mounted in a press. The shape of the final die is close to the shape of the desired part and the press supplies the force needed to deform the metal into the shape of the cavity. This is generally done at elevated temperatures to reduce the forces required and maximize the ductility of the metal being deformed. The use of elevated temperatures suggests that forgings should exhibit annealed structures and properties but this is often not the case. Published data on forged Rex 734™ hip stems[60] show tensile properties well above annealed levels

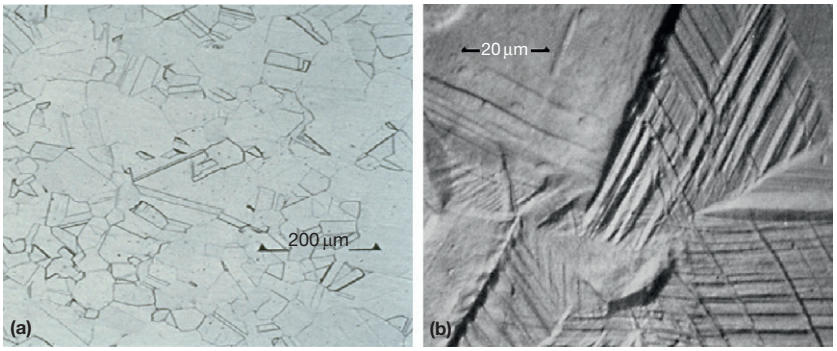

Figure 7 Microstructures of annealed (a) and cold worked (b) 316L stainless steel. Note evidence of slip within the grains of the cold worked material. (b) Reproduced from Brunski, J. B. In *Biomaterials Science*; Ratner, B. D., Hoffman, A. S., Schoen, F. J., Lemons, J. E., Eds.; Elsevier: Amsterdam, 2004; p 142, with permission from Elsevier.

indicating that these forgings are work hardened. Cobalt alloy forgings also have higher properties than these alloys in the annealed condition; minimum ultimate tensile strength for forged Co–28Cr–6Mo alloy is 897 MPa in the annealed condition and 1172 MPa in the warm worked condition per ASTM F 1537. ASTM F 799 (Cobalt–28 Chromium–6 Molybdenum Alloy Forgings for Surgical Implants) does not describe forging parameters, but the mechanical property, grain size, and hardness requirements ensure that the forging process results in a work hardened metal. Details of the structure changes that occur in Co–C–Mo alloys during hot deformation can be found in Immarigeon *et al.*[72] and Yamanaka *et al.*[73]

Production of bar stock, tubing, and wire used in implant applications utilizes a series of deformation and annealing operations. The annealing processes can be tailored to produce either fine or coarse grain structures. Fine grain materials result from annealing at lower temperatures and/or shorter times while grain growth will occur with increases in temperature or time. In general, finer grain materials are preferred for typical medical products. For example, balloon expandable cardiovascular stents are often made by laser cutting thin walled tubing. Desirable attributes of the tubing include uniform, equiaxed small grain size, and high ductility. These attributes can be obtained by a series of low temperature tube drawing steps followed by controlled annealing cycles (i.e., short cycles at temperatures that do not cause rapid grain growth). Details of the response of L-605 stent tubing to different amounts of cold work and different annealing temperatures can be found in Poncin *et al.*[74]

It is important to remember that heating a work hardened material above the recrystallization temperature will result in the formation of new, soft, ductile grains. This causes strength levels to decrease while ductility increases. Common high temperature processes such as welding or sintering a porous coating on a work hardened device will cause dramatic reductions in both static and fatigue strength.

1.102.6.2.2. Wrought versus cast alloys

Cast cobalt alloys are common in orthopedic and dental applications. Investment cast stainless steel hips, although once fairly common, are rarely used today because of their relatively low strength (a recent report discusses fatigue failure of a cast 316L hip stem).[75] Figure 8 compares the microstructure of an investment cast Co–Cr–Mo alloy with the microstructure of a wrought alloy of similar composition. The cast material contains very large carbides and the grain size is much larger than that of the wrought material. The wrought material has a much smaller grain size, a very fine carbide distribution, and a higher dislocation density because of the deformation involved in forming the part. These structural differences lead to the large differences in tensile and fatigue strength shown in Tables 5 and 6.

1.102.6.2.3. Precipitation hardening

A process known as precipitation hardening, or aging, can be used in some cobalt and titanium base alloys. The aging process involves heating the metal to a temperature at which a second phase can precipitate out of the matrix. If the precipitates are small enough they will interact with dislocations and increase strength. The specific response of an alloy to this type of treatment depends on the alloy system and the details of both the heat treatment and prior conditions such as the deformation history of the material. Implantable austenitic stainless steels do not respond to heat treatment (although stainless steels used to make surgical instruments are hardened by heat treatment). Cobalt base alloys can be heat treated to alter properties. Formation of small HCP precipitates within the FCC matrix is an important feature in these alloys.[76,77] ASTM specifications F 562 and F 1058 include mechanical property information for MP35N and Elgiloy™ in the cold worked and aged condition. The ultimate tensile strength of thin (0.110–0.469 mm) Elgiloy™ strip increases from 1725 to 2170 MPa. Beta titanium alloys can be strengthened by aging treatments that result in formation of a fine dispersion of α within the β matrix. Ti–15Mo has shown an increase in ultimate tensile stress from 770 MPa in the solution annealed condition to 1280 MPa in the solution annealed plus aged condition; for Ti–15Mo–5Zr–3Al, the ultimate tensile stress increases from ~950 to ~1500 MPa because of aging.[78,79]

1.102.6.2.4. Surface condition effects

Altering the surface of an implant can have either negative or positive effects. Negative effects are often due to the presence of features that act to concentrate stresses in a critical region of a

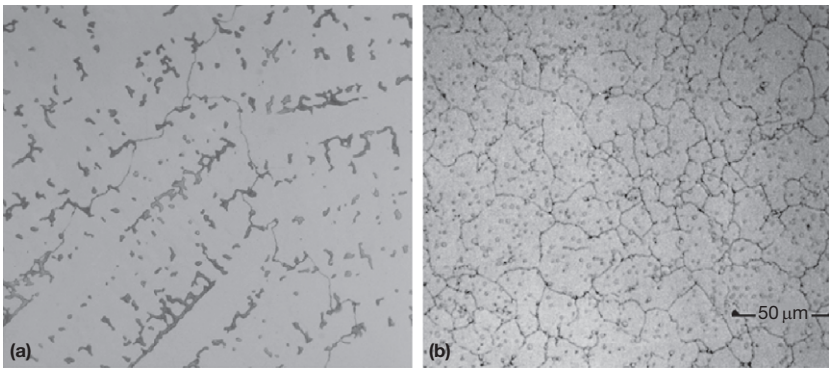

Figure 8 Microstructures of as-cast (a) and forged Co–Cr–Mo (b); ASTM F 75 and ASTM F 1537, respectively. The cast material contains large carbides (the dark phase) which form in the interdentdritic regions and along the grain boundaries. The grains are very large in the cast material. The forged microstructure contains very fine carbides and much smaller grains. (b) Reproduced from Brunski, J. B. In *Biomaterials Science*; Ratner, B. D., Hoffman, A. S., Schoen, F. J., Lemons, J. E., Eds.; Elsevier: Amsterdam, 2004; p 142, with permission from Elsevier.

device. This includes design features as well as surface conditions that result from the processes used to make the implant. Undesirable design features include sudden transitions in the dimensions of the component and sharp radii at corners. Processing issues include undetected flaws in the material such as surface cracks or porosity. Laser cutting and marking operations can also create surface damage. The fatigue strength of wrought cobalt and titanium alloys can be reduced by 60–70% by using lasers to apply part numbers if the laser marked surface is loaded in tension.[44,80] Several authors have reported hip implant failures associated with laser marking.[81,82] Marking lasers can create a fine network of surface cracks as seen in **Figure 5**; if these small cracks are located in high stress regions, they may grow and lead to fatigue failure. ASTM F 86 'Standard Practice for Surface Preparation and Marking of Metallic Surgical Implants' advises that part markings be located in low stress areas.[83]

When laser cutting is used to machine stents from thin wall tubing, a thin recast layer is formed on the cut edges. This layer may be brittle and somewhat rough, so it is removed by electropolishing or mechanical operations such as light grit blasting or tumbling.

Surface damage can also occur in the operating room. Simulated contouring of Ti spinal rods has been shown to form cracks.[84] Care must also be taken in the operating room to avoid striking implant surfaces with sharp surgical instruments as this could create notches on the implant surface.

Porous layers are routinely applied to orthopedic implants to allow for fixation by bony ingrowth; this topic is covered in detail in **Chapter 6.605, Porous Coatings in Orthopedics**. It should be noted that most coating application methods have substantial impact on mechanical properties of devices. High temperature sintering results in structural changes in the implant that reduce strength. The bond sites between the porous layer and the implant can act as stress raisers. Designers of these devices must incorporate these effects when analyzing the strength of porous coated implants.

Residual surface stresses can have either positive or negative effects depending on the nature of the stress and the loading conditions that the part experiences in service. Most orthopedic implants experience tensile loading in their high stress regions, so creating residual compressive stresses in these regions can improve fatigue resistance. This can be achieved by operations such as shot peening, laser shock peening, and low plasticity burnishing.[85]

1.102.7. Future Developments

The metals currently used for medical implants are highly successful and the costs associated with developing and commercializing new alloys are quite high. This combination tends to limit development of new metal alloys for implants. Most of the alloys used by the device community were developed for other purposes and then applied to implants. However, trends toward less invasive surgery (which can require smaller, easier to insert devices) and the application of implants in younger, more active patients increase the likelihood that future devices will have to withstand higher stresses and survive for longer times. This may lead to efforts to develop higher strength materials.

Trends in implantable stainless steels over the past several decades have been toward more corrosion resistant alloys that can be processed to higher strengths than 316L. These alloys rely on additions of nitrogen and, in recent days, contain minimal amounts of Ni because of concerns about nickel sensitivity. It is possible that additional stainless steels will be developed along these lines.

As mentioned previously, there is a significant amount of research aimed at developing new β titanium alloys. These alloys appear to offer opportunities for higher strength or lower elastic modulus than current Ti alloys.

Another area with potential for improving mechanical properties involves creating materials with extremely small grain sizes. The techniques to achieve this involve extensive amounts of deformation under carefully controlled conditions. Yamanaka has reported grain sizes below 1 μm for a heavily deformed Co–Cr–Mo alloy.[73] Titanium grain sizes less than 500 nm have been reported by Valiev and a β titanium alloy with grain size in the 50 nm range has been reported by Hao;[86,87] if these methods can be commercialized, they could result in higher strength alloys.

1.102.8. Summary

Successful long-term metallic implants must be able to withstand both mechanical and environmental stresses. There are a limited number of metal alloys with the appropriate combination of corrosion resistance and mechanical properties necessary to survive in the body. The major alloy systems in use in load bearing applications are austenitic stainless steels, cobalt–chromium alloys, and titanium alloys.

The corrosion resistance of the major implantable alloys depends on formation of thin oxide films. Corrosion behavior is primarily controlled by the composition of the alloy; secondary factors such as inclusion content can influence corrosion.

Mechanical properties of devices depend on the product design, the properties of the material used to make the product, and the details of the processes used to fabricate the device. A wide range of properties can result from a given chemical composition because of these processing effects.

Fatigue is the most common cause of mechanical failure of medical devices. Variation in fatigue strength is inherent in materials. Rigorous control of raw materials and production processes can reduce but not totally eliminate this variability.

Abbreviations

Ag/AgCl	Silver–silver chloride reference electrode
Co–Cr–Mo	Cobalt–chromium–molybdenum alloys
$CoO–Cr_2O_3$	Cobalt oxide, chromium oxide
cp-Ti	Commercially pure titanium
EMF	Electromotive force
FCC	Face-centered cubic
NHE	Normal hydrogen electrode
NiTi	Nickel titanium alloy (typically in the range of 50:50 wt%)
OCP	Open circuit potential
PBS	Phosphate-buffered saline
SBF	Simulated biological fluid
SCE	Saturated calomel electrode
Ti–6Al–4V	Titanium, 6 wt% aluminum, 4 wt% vanadium
Ti–6Al–7Nb	Titanium 6 wt% aluminum, 7 wt% niobium
TiO_{2-x}	Titanium dioxide with anion deficit
TMFZ	Titanium, molybdenum, zirconium, iron alloy
zcp	Zero current potential

Symbols

A^*	Complex admittance
A'	Real admittance
A''	Imaginary admittance
b	Constant related to charge of moving ion and jump distance in high-field oxide growth
C	Oxide capacitance
C_i	Concentration of ith species
D_i	Diffusivity of ith species
$\mathrm{d}V/\mathrm{d}x$	Gradient of potential (electric field)
e^-	Charge of an electron 1.6e −19C
E_{corr}	Corrosion potential
E_f^M	Fermi energy level in the metal
E_f^{ox}	Fermi energy level in oxide
E_{fb}	Flat-band potential
E^{eq}	Equilibrium potential
E^o	Standard potential
E_{pp}	Passivating potential
F	Faraday's constant (96 500 coul mol^{-1})
i	Current density
i	Imaginary number ($\sqrt{-1}$)
i_{corr}	Corrosion current density
i_{diss}	Dissolution current density
i_{diss}^o	Exchange current density for dissolution reaction
i_{film}	Current density associated with oxide film formation
i_o	Exchange current density
J_i	Flux of ith specie
k	Boltzmann's constant
L	Laplace operator
M_w	Molecular weight of oxide film
n	Valence
N_D	Number of charge carrier per volume in oxide
[Ox]	Oxidized species activity
Q	CPE impedance
R	Ideal gas constant 8.314 J $mol^{-1}K^{-1}$
[Red]	Reduced species activity
R_s	Solution resistance
R_p	Polarization resistance
Tanδ	Tangent of the phase angle, δ
w	Activation energy for atom jumping in an oxide film
Z^*	Complex impedance
Z'	Real impedance
Z''	Imaginary impedance
Z_{CPE}	Impedance of the constant phase element
α	CPE exponent
β	Tafel slope
β_M^a	Anodic Tafel slope for metal half-cell reaction
β_o^c	Cathodic Tafel slope for oxygen half-cell reaction
ΔG_{ox}	Gibbs free energy of oxidation
ΔG_{red}	Gibbs free energy of reduction
ε	Dielectric constant
ε_o	Permittivity of free space
η	Overpotential
Φ_M	Work function of a metal, M
κ^{-1}	Debye thickness
μ	Chemical potential
θ	Area fraction covered by oxide
ρ	Density of oxide film, or charge density
ω	Frequency
v	Volume of oxide

1.103.1. Introduction

Metallic biomaterials have been, and will continue to be, used in implants spanning all areas of use in the human body. Whether one considers orthopedic, spinal, dental, cardiovascular, neural, urological, or other implant applications, metals are central to the success of these devices. Metallic biomaterials will remain central to these applications because of their unique properties compared to those of other classes of materials. Electrical behavior and mechanical properties are the main reasons for this uniqueness. Whether we are interested in delivering electrical energy (e.g., pacemaker leads), or providing structural support (e.g., hip replacements), metals will continue to be used for the foreseeable future. However, a major concern with metals is their susceptibility to corrosion and the associated problems corrosion processes cause in the biological system.

This chapter provides a current state-of-knowledge assessment of the nature of metallic biomaterial surfaces in the biological milieu. This includes descriptions of the electrochemical nature of surfaces, the basic concepts of electrochemistry, the effects of the presence of metal–oxide thin films, the electrical semiconducting nature of the surface, adsorption of proteins, interactions of cells and surfaces, and the complex interplay between surface mechanical processes (e.g., fretting and wear) and electrochemical processes.

The *central paradigm* of metallic biocompatibility has been: "The more corrosion resistant, the more biocompatible." That is, the primary concerns of metal corrosion in the biological milieu have been the release of ions and particles and the effect of these ions and particles on the biological system. While this view still has merit and is discussed in this chapter, it is not a complete and inclusive view of the electrochemical interaction of metals in the body. Other factors, including the interaction of surface mechanics and corrosion, and the role of reduction reactions, are important to understand. In this chapter, we expand on this central paradigm and include the effects of mechanical processes (fretting and wear), and the role of reduction reactions on metallic corrosion and biocompatibility. As shown subsequently, biological behavior at metallic implant surfaces is dramatically affected by reduction reactions that occur at metallic biomaterial surfaces which have not been previously appreciated.

Therefore, the goals of this chapter are to discuss the metallic biomaterials in use today. Observations of corrosion from retrieval studies and the consequences of corrosion are discussed. The basic materials science of metallic biomaterial surfaces is described including the presence of metal–oxide

thin films and includes their structure, voltage-dependent growth, and their electrical double layer as well as protein adsorption. Next, the concepts of the biological milieu are presented to discuss the complex and variable environment to which devices are exposed. This includes discussion of variations in the environment because of wounding, location, protein adsorption, and the presence of inflammatory species including reactive oxygen species (ROS). This chapter then moves on to describe some basic electrochemistry including passive oxide film electrochemical character and electrochemical impedance spectroscopy (EIS), and then presents current concepts of mechanically assisted corrosion. Finally, this chapter discusses the biological consequences of electrochemical processes and the electrochemical consequences of biological processes. This chapter is not intended to comprehensively review the literature compiled over 40 years on the corrosion of metallic biomaterials, but rather to describe the nature of the electrochemical interface in the biological milieu based on the experience and understanding of the author.

1.103.2. Metals Currently Used in Medical Devices

There are several metals and alloys used in the human body. The three major alloy systems in use today are based on titanium (Ti), cobalt–chromium–molybdenum (Co–Cr–Mo), and stainless steel (316L SS). Other metals that are seeing increased use include zirconium (Zr), tantalum (Ta), platinum (Pt), gold (Au), and others.[1] Recently, some newer alloys are being investigated for use as degradable metals including those based on magnesium (Mg) where corrosion is purposeful and planned for. Most of these metals have complex surfaces in terms of structure and chemistry. In particular, metal–oxide thin films (also known as passive films) are present on the surface of most of these alloys, and it is these oxide thin films that are the key to understanding corrosion. These so-called passive films are not in the strict sense 'passive.' They are dynamic structures that can change in chemistry, thickness, defect density, and resistance to corrosion and are susceptible to change in response to the biological environment and the overall voltage drop across them. Furthermore, metal–oxide thin films experience mechanical perturbations including fretting, wear, and fatigue which require understanding of the mechanical behavior of these films and corrosion consequences of disruption.

By far, the first three listed alloy systems make up the largest fraction of alloys used in medical devices. Therefore, most of this chapter focuses on the behavior of these materials. However, other metal alloys are gaining in interest and others are used in smaller amounts but in circumstances where electrochemical behavior is an important element in their use.

1.103.2.1. Titanium Alloys

Titanium, universally viewed as the 'most biocompatible metal,' has several alloys that are in use today in medical devices including cp-Ti (commercially pure titanium), Ti–6Al–4V, TMZF (Ti–Mo–Zr–Fe), Ti–6Al–7Nb, NiTi (shape memory alloy), and others. Each of these alloys has specific chemical and structural features that make them similar and some that separate them from each other. For example, most alloys of Ti owe their corrosion resistance to the presence of the passive oxide film TiO_{2-x} (an anion-deficit, n-type semiconducting oxide) that spontaneously forms on their surface. The substrate alloy has two typical crystal structures: alpha, which is a hexagonal close packed (HCP) crystal, and beta, which is a body-centered cubic structure. Elements such as Mo, Nb, and V are beta stabilizers while Al is an alpha stabilizer. The oxides that form on these surfaces are impacted by the substrate in terms of their structure.

Ti surfaces have been studied more than any other metal surface and we know much about the oxides that form[2–5] For the most part, Ti-oxides are TiO_2 at the surface and change to more reduced forms toward the metal. Native oxides of Ti are of 2–10 nm thickness and are mostly thought to be nanocrystalline or amorphous. As the anion deficit character results in excess electrons in donor energy levels of the energy band gap, they are good electron conductors but do not transport positive charge easily.

1.103.2.2. Co–Cr–Mo Alloys

The alloys based on Co–Cr–Mo are more complex metallurgically (composition, grain size and structure, carbide chemistry and structure). The alloys of Co–Cr–Mo can be cast (large grained with large carbides at grain boundaries), forged, wrought, or powder consolidation products, where the microstructure is small grained with discrete blocky carbides.[2] The crystal structures possible with Co–Cr–Mo alloys include face-centered cubic (FCC), HCP, and other nonequilibrium and carbide phases.[6] Much less is known about the oxides on Co–Cr–Mo in terms of their chemistry, structure, and electrochemical properties or how these change with time and exposure. The basic oxide is thought to be comprised primarily of $Cr_{2-x}O_3$ (a cation-deficit, p-type semiconducting oxide); however, there is evidence that during immersion, the oxide takes on n-type semiconducting behavior. There is some evidence that the chemistry of these oxides can change over time with immersion and with the electrochemical potential established at its surface. There is also some evidence that the oxide film on these alloys may be mixed oxides such as $CoO–Cr_2O_3$ (a spinel oxide) or a heterogeneous amorphous oxide with varying chemistry with depth into the surface as well as variability over the surface.[2] For example, long-term immersion tends to result in increased Cr in the oxide. There is also uncertainty related to the nature of the surface oxide on the carbide surfaces present in these alloys.

1.103.2.3. Stainless Steel

Alloys of stainless steel include 316L stainless, as well as low Ni high nitrogen stainless steel.[2] Stainless steels are primarily austenitic (FCC) structures and derive their corrosion resistance as a result of the formation of Cr_2O_3 oxides that can be mixed with Fe_2O_3 oxides and others. These oxides are complex and susceptible to chemical variations due to immersion, time, and voltage.

1.103.3. Metallic Biocompatibility

While this chapter is not meant to be focused specifically on metallic biocompatibility, it is worthwhile to mention some elements of biocompatibility here and to acknowledge the relationship between corrosion behavior and biocompatibility.

The biocompatibility of any material is defined as the ability of the biomaterial to perform its intended function with an appropriate host response. For metals, the following is the main paradigm for metallic biocompatibility: *The more corrosion resistant, the more biocompatible*. That is, for well over 50 years, metal alloys successfully used in the body have been those materials that have a high resistance to the release of metal ions and metal oxidation products (oxides, chlorides, etc.). Indeed, virtually all of the studies in orthopedics (where the literature of metallic biocompatibility is most extensive) have focused on the toxicological effects of metal ions and the local and systemic effects of metal and metal oxide particulates released into the peri-implant space.[7]

It is known, for example, that metallic ion and particle release associated with modular taper connections in orthopedic devices results in osteolysis.[8] Modular tapers are metal–metal connections in orthopedic implants such as hip and knee replacements where a conical male tapered component is fitted tightly into a female counterpart to assemble the device *in situ*. These modular implants provide great flexibility in materials and design selection to result in the optimal device for a specific patient. However, as is discussed in greater detail below, these tapers can induce particularly severe corrosion reactions when they are mechanically loaded. The corrosion products and local environment resulting from these reactions can then affect the tissue adjacent to the implant and impact the success or failure of the device.

Metallic biocompatibility, as with other biomaterials, is dependent on the specific medical device application. In blood-contacting devices, the requirements of the surface (and its corrosion behavior) can be very different than what is required in, say, a dental implant. In the former, blood clotting and neointimal hyperplasia (high rates of tissue growth at the intimal lining of the vessel) may be most important, whereas the dental implant may require good bone-cell attachment and mineralization capabilities.

1.103.3.1. Immune Response and Haptens

In the paradigm of 'the more corrosion resistant, the more biocompatible,' the concern relates specifically to how metallic ions (e.g., Co^{2+}, Cr^{3+}, Cr^{6+}, Ni^{2+}, Fe^{2+}, Mo^{2+}, Ti^{4+}, Al^{3+}, etc.) interact with the biological system. We know, for example, that Cr ions can complex with many biological molecules forming haptens,[9] which can induce an immune response in some patients with highly wear-prone CoCr joint replacements. There have also been recent reports of elevated metal-ion levels in blood, serum, and urine in patients with highly wear-prone and corroding hip resurfacing implants or total joint replacements and that there is an established correlation between the extent of wear and corrosion, and the measured ion levels.[10]

1.103.3.2. Wound Healing and Biocompatibility

For most implant alloys, the biocompatibility reactions are associated with the wound healing processes taking place after implantation. Surgical intervention to place a medical device results in damage to the surrounding soft and hard tissues of the body (depending on the site). Therefore, wound healing, comprised of the processes of blood clotting (hemostasis), acute inflammatory response, and chronic inflammatory responses, critically impacts on the ultimate metal–tissue interface that gets established. For most metallic devices, some form of fibrous capsule is ultimately developed to encase the metallic biomaterial. This is the typical end state of the wound healing response when an implant material is present. However, when significant ions and/or particles are released, then more aggressive chronic inflammatory reactions can and do take place. Under these conditions, the local solution constituents may be dramatically altered from the normal extracellular solution and may, as a result, alter the electrochemical reactions associated with the metal surface. That is, corrosion *in vivo* can be altered by the inflammatory state of the local solution. These changes include the presence of oxidizing proteins, enzymes, and molecules such as superoxide anions (i.e., ROS). These latter molecules can include byproducts such as hydrogen peroxide, hypochlorous acid, and peroxynitrite, all of which can act as oxidizing agents for the implant metals.

Another element of the biocompatibility of metals relates to the size. Small particles (on the scale of the cell or smaller) will induce a biological response far different from that induced by large size metals. The type and severity of the response will depend on the size, shape, and chemistry of the particles.

1.103.3.3. The Reduction Half-Cell in Biomaterials Corrosion

Recently, work by the author, Ehrensberger and Gilbert,[11] and that by others, Kalbacova *et al.*,[12] have shown that cellular biocompatibility *in vitro* is affected by the reduction processes that are present on metallic biomaterial surfaces. Indeed, these recent observations (to be described in greater detail below) have opened up a whole host of questions related to metallic biocompatibility which have yet to be recognized or addressed in the biomaterials community. When cells are cultured on metallic surfaces (either Ti or CoCr, for example), and the voltage of these surfaces is held slightly cathodic of the open circuit potential (OCP), the cells die within several hours of the onset of this condition. This observation is important because metallic medical devices which are subject to wear or surface oxide abrasion can experience large sustained cathodic voltage shifts that can result in reduction reactions taking place on a majority of the implant surface. Thus, reduction reactions appear to play a significant role in the viability and behavior of cells adjacent to these surfaces.

1.103.4. The Biological Milieu

Primarily, the biological milieu is one of a 0.9% NaCl solution. That is, we are bags of salt water. Many early corrosion studies,

therefore, utilized 0.9% NaCl (isotonic saline) as the corrosion environment. Of course the biological milieu is highly complex and highly variable. The complexity comes from the range of ions, the presence of biomolecules (proteins, enzymes, ROS), location in the body (vascular, brain, orthopedic, dental, etc.), severity of the wound used to introduce the device, the potential for bacterial infection, and a whole range of other factors.

1.103.4.1. The *In Vitro* Approximation to the Biological Milieu

Most corrosion studies of metallic biomaterials have utilized pH 7.4, aerated or deaerated saline solutions. Mostly inorganic salts in the absence of organic species are used in these studies. The range of inorganic salt solutions utilized to study biomaterial corrosion include 0.9% NaCl, Ringer's solution, Hanks balanced salt solution, phosphate-buffered saline (PBS), and other simulated biological fluids (SBFs) – see Table 1 for compositions of these solutions.

In some experiments, additions of single proteins or serum to ionic electrolytes have been used, and pH adjustments using HCl to as low as pH 2 have been explored as specific modifications of the biological environment. There has been much less focus on the role of other organic and inorganic species on the corrosion behavior of metallic biomaterials; however, these could be important to explore the effects of wound healing environments and infection. For example, additions of hydrogen peroxide as the electrolyte in corrosion tests may help to explore highly inflammatory conditions and may bring to light differences in surface oxides and corrosion rates.

Serum and other protein additions have been investigated in terms of their effects on corrosion reaction and in terms of wear–corrosion behavior. The literature in this regard is somewhat conflicting. In some cases serum additions appear to increase corrosion rates while in others, particularly where wear and fretting are present, proteins seem to inhibit the corrosion.[13] There is consistent evidence that OCPs of titanium tend to become more negative in the presence of serum proteins compared to measurements made in PBS.[14]

Very little work has been done to systematically explore the effects of inflammatory species on the corrosion behavior of medical alloys. Messer *et al.*[15] recently looked at the effects of IL-1b on the corrosion of Ti and found increased susceptibility of a Ti alloy to this cytokine. Others have investigated the effects of hydrogen peroxide (a ROS generated during inflammation) and its role in cell-alloy surface interactions. Some work has appeared looking at corrosion in the presence of hydrogen peroxide where increased corrosion rates were observed for all tested alloy surfaces.[16]

Clearly, simulation of the biological milieu is complex and challenging. It depends on the site to be approximated and the nature of the peri-implant tissue activity. Significantly more work is needed to understand the role of local factors and the range of local chemical and biological conditions present on the corrosion processes of these alloys.

Table 1 Summary of physiological solutions typically used in corrosion testing of biomaterials

Solution	*0.9% NaCl*	*HBSS*	*RS*	*PBS*
DI H_2O (ml)	1000	400	1000	800
NaCl (g)	9.000	4.000	6.300	8.000

1.103.5. Basic Electrochemistry Concepts

The basis for understanding the corrosion of metallic biomaterials comes from several disciplines including electrochemistry, materials science of surfaces, physics of semiconducting thin film oxides (passive oxides), biological phenomena at surfaces, and electrical phenomena at interfaces. These disciplines, each having arisen somewhat independently, combine to provide insight into the electrochemistry in the biological milieu. Each part of this interdisciplinary subject provides important theoretical underpinnings and therefore each needs to be presented to give a good picture of what transpires at the metallic biomaterial interface. This section will provide some of the basic principles and equations required to understand corrosion. This will include the development of electrified interfaces, the driving force for corrosion including both oxidation and reduction. We will discuss the mixed-potential theory of corrosion and explore the Butler–Volmer equation for corrosion of active metal surfaces. Then, the structure, chemistry, and physics associated with semiconducting passive oxide thin films on metal surfaces and adjacent to an aqueous electrolyte solution will be described. The electrified nature of this interfacial region, with its high electric fields, electronic and ionic transport mechanisms across the metal–oxide–solution interface, and growth and reductive dissolution mechanisms will be described including the role of voltage on the properties of the interfaces. Next, the techniques to measure the electrochemical character of metal surfaces will be discussed including polarization testing methods (potentiodynamic polarization, linear polarization, and cyclic polarization). Then, EIS methods will be presented to show how the metal–oxide–solution interface can be analyzed on the basis of its frequency response to small scale voltage excursions.

1.103.5.1. Active Corrosion Theory: Oxidation and Reduction

During corrosion, two basic sets of reactions must be present. These are oxidation and reduction. Each is one half of the overall process of corrosion, and thus, is referred to as a half-cell reaction. It is important to understand that one cannot have corrosion (oxidation) without the corresponding reduction half-cell reactions accounted for as well. Each has influence over the other as the overall process requires both to

take place. Indeed, a central tenet of corrosion, in the absence of any externally applied potentials, is that the sum of all currents generated by oxidation reactions must balance with the sum of all currents generated by reduction reactions on a metal surface. This governing rule, called the 'Mixed-Potential Theory,'[17] is central to our understanding of corrosion in general and in corrosion of metallic biomaterials, in particular. It holds for all cases, even when oxide films are present and has consequences for how the voltage of a metal surface varies with changes in the rates of either oxidation or reduction reactions. Before we explore the mixed-potential theory, let us discuss the basic concepts of oxidation and reduction.

The basic concepts of corrosion have to do with the susceptibility of metals to increase their valence state from atomic element to ion. This process is called oxidation and the metal atoms increase their valence state to become metal ions (or cations). Two typical types of oxidation reaction for elemental metal to its cationic form are shown in eqn [I] below.

$$\mathrm{M} \rightarrow \mathrm{M}^{+} + ne^{-} \qquad \text{(ionic dissolution)}$$

$$n\mathrm{M} + m\mathrm{H_2O} \rightarrow \mathrm{M}_n\mathrm{O}_m + 2m\mathrm{H}^{+} + ne^{-} \quad \text{(oxide formation)} \qquad [\mathrm{I}]$$

These are only meant to be representative of oxidation reactions and not exhaustive of all the types of oxidation processes possible. In the first, metal atoms transit the interface from the metal to the solution to become ions in solution while the electrons liberated remain behind in the metal (see **Figure 1**). In the second, metal atoms transit the interface and react with water to become metal oxides (or hydrated metal oxides), and liberate both hydrogen ions into the solution and electrons into the metal.

In all oxidation reactions, the characteristic increase in the valence state of the metal to become a cation is associated with electrons remaining behind in the metal. Thus, oxidation reactions result in a buildup of positive charge in the solution and negative charge left behind in the metal. The oxide formation reaction may result in oxides in solution or the development of an oxide film on the surface.

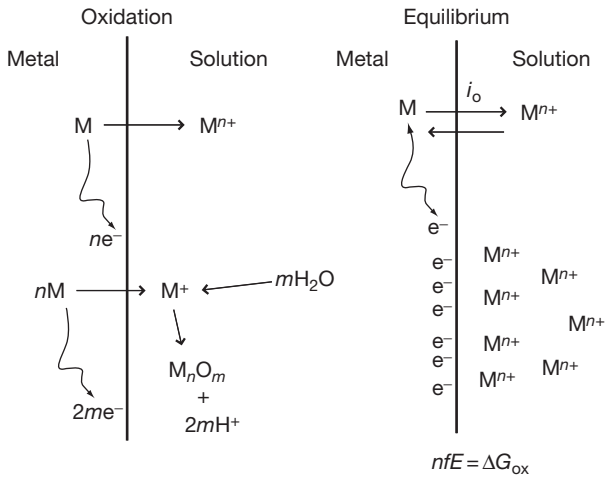

Figure 1 Simplified representation of a half-cell reaction across a metal–solution interface. Metal atoms get oxidized to ions in solution and leave electrons behind in the metal. Also metals can react with water to form oxides (either in solution or as films). A build-up of charge occurs across the interface whose electrical energy balances the oxidation energy driving the reaction at equilibrium.

There are two main thermodynamic forces at play that will balance each other when the oxidation reaction reaches equilibrium (i.e., equal forward and reverse reactions) and there are no other reactions at play. These two forces are the Gibbs free energy driving the oxidation reaction (ΔG_{ox}), or the negative of the Gibbs free energy change for the opposite reaction (reduction), that is, $\Delta G_{red} = -\Delta G_{ox}$. The second force arises from the separation of charge that is established across the interface – much like the charging of a capacitor – which gives rise to an electrical energy (nFE, where n is the valence of the ion, E is the potential across the interface, and F is Faraday's constant, 96 500 coul mol^{-1} of electrons). At equilibrium, these two terms are equal and the so-called Nernst equation results:

$$nFE = -\Delta G_{red} \quad \text{or} \quad E^{eq} = E^{o} + \frac{RT}{nF} \ln\left[\frac{[\mathrm{Ox}]}{[\mathrm{Red}]}\right] \qquad [1]$$

where R is the ideal gas constant, T is temperature, and [Ox] and [Red] are the activities of the oxidized and reduced forms of the half-cell reaction, respectively. E^{eq} is the equilibrium potential for the half-cell reaction and E^{o} is the potential of the half-cell when the activities of the oxidized and reduced forms are equal to 1 or equal to each other (i.e., where the natural log term equals 1).

The Nernst equation shows that there is a voltage that gets established across a metal–solution interface as a result of the accumulation of charge separation across the interface that depends on the free energy driving the oxidation. The greater the chemical driving force for oxidation, the more negative this potential (i.e., greater build-up of charge) is. This scale, called the electromotive force (EMF), or electrochemical series, provides a relative scale of the thermodynamics driving oxidation. On the most positive side of this scale are metals such as gold and platinum while on the most negative side are metals such as Na, Mg, Ti, Cr, Fe, Co. It is important to note that many of the metals used in medical alloys today have high negative EMFs including titanium (−1.6 V vs. the normal hydrogen electrode (NHE, which is arbitrarily defined as 0.0 V)). That is, metals used as biomaterials typically have high driving forces for corrosion and given the opportunity they will oxidize very rapidly. As we will discuss, the presence on the surface of a very thin layer of oxide – called the passive oxide film – prevents this rapid oxidation from taking place. The passive film is a kinetic barrier preventing the high driving forces of oxidation from oxidizing the metal. This is important to understand when we discuss mechanical disruption of oxides and their repassivation.

When a half-cell reaction (such as metal ion release in **Figure 1**) is at its equilibrium Nernst potential, there is still a current per unit area (referred to as an exchange current density (i_o)) which reflects the reaction rate constant for the oxidation and reduction reactions of metal changing to cation and cation changing back to metal across the interface. The exchange currents are equal and opposite at equilibrium, but they are NOT zero. In fact, the exchange current density is important to

consider when the voltage of the interface deviates away from the Nernst potential as it will when a second half-cell reaction is introduced.

For a single half-cell reaction (e.g., metal oxidation), one can derive, using the activated complex theory (see Bard and Faulkner[18] for a good description), a relationship between the current density, i, the exchange current density, i_o, and the potential deviation away from the Nernst potential for that half-cell reaction, η (the over potential). This equation, when diffusion and mass transport rates are assumed to be high relative to the rate of the interfacial reactions (i.e., the reactions are 'activation limited') is called the Butler–Volmer equation:

$$i = i_o\left(10^{\eta/\beta_a} - 10^{-\eta/\beta_c}\right) \qquad [2]$$

where η is $(E-E_M^{eq})$ the overpotential, or deviation away from the Nernst potential for the half-cell reaction, and β_a and β_c are the anodic and cathodic Tafel slopes for the half-cell reaction. These slopes can be visualized on a so-called Evans diagram which plots the potential versus Log base 10 of the current density (see Figure 2). In this figure, each term in the Butler–Volmer equation is plotted as voltage versus Log_{10} (current density), with the equilibrium Nernst potential at −500 mV and the exchange current density at 0.1 μA cm^{-2}.

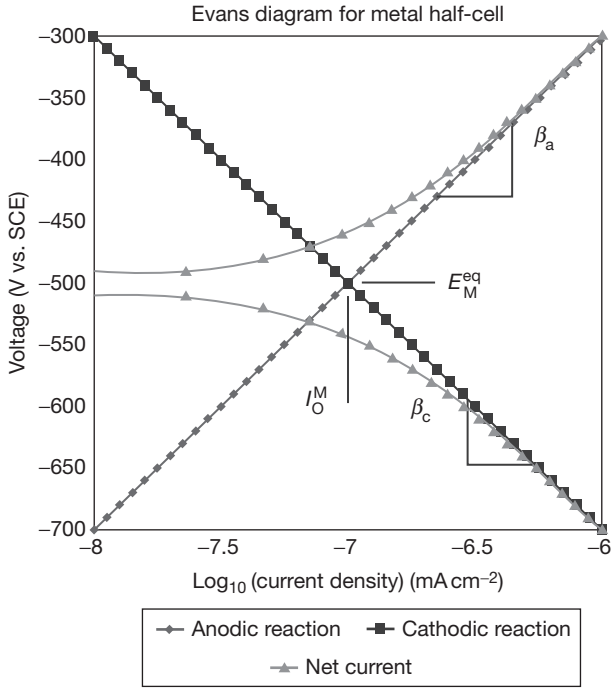

Figure 2 Evan's diagram for the metal half-cell reaction. This is a plot of V versus Log(i) and represent the Butler–Volmer equation. The two straight lines represent the current densities that arise when the voltage of the electrode is moved away from the equilibrium (Nernst) voltage (the overpotential). Increases in either anodic (oxidation) or cathodic (reduction) current densities arise. The net current at any voltage is just the sum of the anodic and cathodic currents. The intersection represents the exchange current density which is a measure of the inherent rate of the reaction. The slopes of the lines are the Tafel constants for oxidation and reduction.

The Tafel slopes are assumed to be 200 mV per decade of current. The net current density, i, when one deviates away from the equilibrium potential, E_M^{eq}, is the sum of the anodic and cathodic current densities at the potential of interest. One can see that as the potential approaches the equilibrium (where η goes to 0), the net current density approaches zero and the $Log_{10}(i)$ goes to negative infinity.

The Evans diagram's graphical representation of one half-cell reaction is helpful in identifying the important features of the Butler–Volmer equation. However, in virtually all corrosion conditions, there are usually at least one oxidation half-cell and one reduction half-cell present on the surface. When multiple half-cell reactions are taking place, then one must write a Butler–Volmer equation for each half-cell and the mixed-potential theory states that the total interfacial anodic and cathodic currents must balance for the sum of all anodic and cathodic processes. The Evans diagram for two half-cell reactions and the associated interfacial reaction schematics are shown in Figure 3 where a second reaction has been added to the half-cell reaction in Figure 2. Also shown is a schematic of the metal surface where both reactions are present, as is an oxide film.

If we assume in this example that the anodic reaction is metal oxidation and the reduction reaction is an oxygen reaction

$$\frac{1}{2}O_2 + H_2O + 2e^- \rightarrow 2OH^- \qquad [II]$$

for example, then the Evans diagram for both reactions results in Figure 3. In this case, the two half-cell reactions must be in balance if there is no external flow of current (i.e., equal oxidation and reduction currents), the electrons 'liberated' during the metal oxidation reaction (eqn [I]) must be consumed at an equal rate in the reduction reaction (eqn [II]). This condition requires that the two currents be equal (or the two current densities should be equal if the entire surface can participate in both reactions). Note that if the areas upon which the anodic reactions and the cathodic reactions occur are different, then it is the total anodic (oxidation) current that must balance the total cathodic (reduction) current. Therefore, the point of intersection of the metal oxidation curve with the oxygen reduction curve is where the two currents are equal and this is the corrosion current (or corrosion current density) of the two combined reactions. Note that as long as there is oxygen (or some other species) available to consume the electrons liberated in the oxidation reaction, the oxidation will continue; however, if the reduction reaction cannot continue, then the net oxidation will cease. This shows the importance of having reducible species available to depolarize the metal surface (sweep up the electrons) to force a continuation of the corrosion process. The voltage of the point of intersection is referred to as the OCP (or corrosion potential, E_{corr}) of the surface and the current density is the corrosion current density, i_{corr}.

It is important to emphasize that the OCP of a surface that can engage in redox reactions is dictated by the condition where the net anodic and cathodic currents passing an electrochemical interface are equal as can be seen in the Evans diagram of Figure 3. That is, when Faradaic (redox) reactions are present, the surface voltage is determined by the balance of all

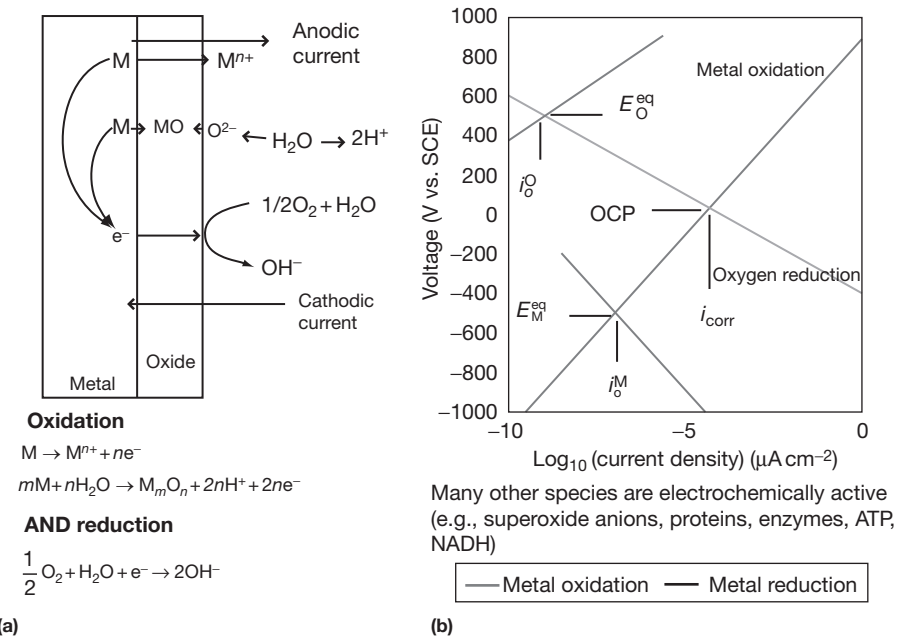

Figure 3 Schematic of a metallic biomaterial electrode (with oxide present) that presents oxidation and reduction reactions to show the overall process required for corrosion. Both oxidation and reduction are required. (a) Schematic of the half-cell reactions, the movement of ions, and electrons and the corresponding currents. (b) Evan's diagram for two ideal (Butler–Volmer based) reactions, both an oxidation half-cell and a reduction half-cell, showing that they intersect at the open circuit potential (OCP) and result in a corrosion current i_{corr}. The reduction half-cell consumes the electrons liberated in the oxidation reactions and continues to drive the corrosion of the metal.

of the anodic and cathodic currents and there is a resistance that one can measure called the charge transfer resistance, R_{ct}, which is sometimes referred to as the polarization resistance, R_P, described below (but is strictly not the same). This is a fundamental aspect of the mixed-potential theory[17] and the activated complex theory.[18] This condition on OCP is true regardless of whether the surface is an active metal, a metal with a passive film, or a semiconducting metal–oxide–solution interface. The OCP of an electrode surface is determined by the voltage required to balance the flow of anodic and cathodic currents across the interface. We will revisit this concept when we discuss mechanically assisted corrosion where mechanical disruption of the surface oxide can dramatically increase the oxidation reactions and result in a large negative excursion in the voltage as a consequence. If no electrochemical currents (no Faradaic processes) are present, the electrode is said to be a 'polarizable' electrode and the voltage of the surface is dictated by the charge at the surface, not the current. When both charge transfer across the interface (Faradaic process) and charge accumulation (non-Faradaic process) can occur, then the interface takes on characteristics of both a charging interface (e.g., a capacitor) and a charge transfer interface (e.g., a resistor). However, the OCP in this case is still defined by the sum of currents. This combined interfacial electrical character will be discussed in the section on impedance.

The Evans diagram can now help understand how and why OCP and corrosion rates can vary with changes in the electrochemical system. For example, if the exchange current density for the oxygen reaction is increased (moves to the right in Figure 3), then the reduction currents that arise when the voltage moves away from the equilibrium voltage for the oxygen half-cell also increase. This will cause the metal oxidation curve to intersect the reduction curve at a higher voltage (more positive OCP), and will result in a higher corrosion rate. Similarly, the equilibrium potential for the reduction reaction can shift due to changes in the concentration of oxygen in solution. For instance, if the oxygen level decreases, the equilibrium potential for oxygen will decrease (on the basis of the Nernst equation) and the reduction currents will be reduced as well. This will cause the OCP to become more negative and the corrosion rate to decrease. Similar thought experiments can be done with the metal parameters (exchange current density and equilibrium potential); however, some different outcomes will occur. For example, if the exchange current density of the metal increases, then the Evans diagram plot for the metal will shift to the right and the point of intersection between the metal oxidation curve and the oxygen reduction curve will shift to higher currents and lower voltages. Thus, the OCP will shift more positive or more negative depending on the changes that are taking place for either the oxidation half-cell or the reduction half-cell.

Some other important observations from the Evans diagram include the fact that voltages more negative than OCP do NOT stop corrosion processes from occurring. They may be decreased, but the corrosion will continue, albeit at a lower rate, until the voltage drops below the equilibrium potential for the metal, which can be very negative. Also, the curves plotted in Figure 3 represent only cases where the metal surfaces are active and no film or oxide layer is present to introduce other kinetic barriers to the process. This is, of course, not

representative of most metallic biomaterials used today where oxide thin films cover the surfaces and interfere with the activation-limited processes giving rise to the Butler–Volmer behavior.

The role of the reduction reaction in corrosion needs to be emphasized. The example used above only considered oxygen reduction as the cathodic half-cell; however, there are many other reducing species (also known as oxidizing agents) potentially available in the body to help increase the rate of corrosion. ROS, in particular, needs to be mentioned. Inflammatory cells can release ROS molecules that can react to form a variety of strong oxidizing agents (species available for reduction). These include hydrogen peroxide (a very strong oxidizing agent), hypochlorous acid, and peroxynitrite.[19] Local concentrations of these species near metallic biomaterial surface may become very large and may be influenced by other factors (e.g., infection, autoimmune disease, presence and severity of the chronic inflammatory reaction). Very little is known about the range and specific concentrations of these oxidizing agents or their effect on corrosion. We do know that hydrogen peroxide increases the rate of corrosion of most metallic biomaterials (see below).

Active metal corrosion behavior is not seen in many medical alloy systems. Those that may exhibit close to active corrosion condition include the noble metals (Au, Pt), or alloys such as those of Mg. However, the noble metal equilibrium potentials are so positive that there are few reduction reactions available to induce corrosion. That is, there is very low free energy available to drive oxidation of these alloys. Most metallic biomaterials are passive oxide film coated and therefore, the concepts outlined above, while useful, need to be modified to account for this important difference.

1.103.5.2. Passivating Metal Surface Behavior

When the surface of a metal becomes covered with a highly adherent compact thin oxide film, it is said to become passivated. These passive films result in several changes to the Evans diagrams shown above (see Figure 4). In this schematic (Figure 4(a)), the active region is at the bottom of the plot and in this potential range no oxide film will grow if the oxide is removed from the metal surface. (We should note that passive films may reductively dissolve if the surfaces are maintained at or below these potentials for sufficient periods of time.) If the potential is raised from its equilibrium level, active corrosion will occur up to the passivating potential (E_{pp}) where the first onset of oxidation reactions results in oxide film formation. As oxides cover the metal surface, they result in a physical barrier that kinetically limits continued ion release and the currents drop significantly. Superimposing a reduction reaction results in Figure 4(b) which is what is typically measured in polarization tests. Note that the active region of the metal may be hidden by the overlaid reduction reaction but it is still present and can lead to adverse (and poorly understood) mechanisms of attack.

An example of this behavior is seen with Co–Cr–Mo alloy (see Figure 5). Once the oxide film forms on the surface, the surface is said to be passivated; however, this does not mean that there are no ongoing reactions taking place. The oxide film will continue to grow with increasing potential, the chemistry of the oxide may change, ions may continue to be released into solution, the valence states of the ions may change, and the defect structure may be altered too. Polarization tests provide only incomplete information about the nature of the oxide surface, and the methods often adopted in performing polarization tests will not reveal the active region or the active-to-passive transition. This is because the potential range where these reactions occur is often more negative than the range of OCP which is typically used to determine the starting potential for anodic polarization testing (e.g., typically scans will start 200 mV cathodic of OCP and scan forward); however, the active-to-passive transition for CoCr surfaces is from −800 to −500 mV, and its OCP is typically in the −200 to +100 mV range (vs. Ag/AgCl).

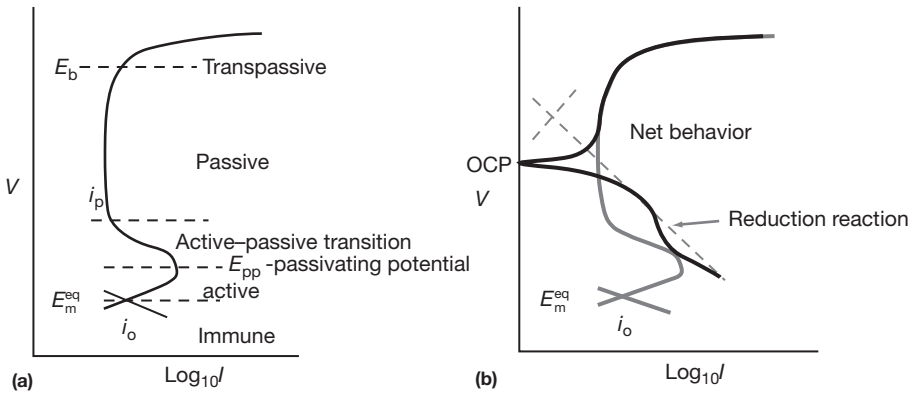

Figure 4 (a) Modified Evans diagram for a metal that undergoes both active corrosion and passivation to form an oxide on its surface. Note that the metal initially (at negative voltages, but above E^{eq}) engages in active corrosion, but when the voltage reaches the passivating potential, oxide film begins to form on the surface which kinetically limits the corrosion and decreases the current density. The active–passive region is where the oxide partially covers the surface and the passive region is where the oxide completely covers the surface. At the transpassive potential (sometimes referred to as the breakdown potential when pitting is involved), the oxide film loses its protective ability and the surface corrodes much more rapidly. Note that no reduction half-cell is present. (b) The same active–passive behavior with a reduction reaction overlaid to show the total behavior typical for such electrodes. Note that sometimes the active–passive region is hidden or masked by the dominating reduction reaction.

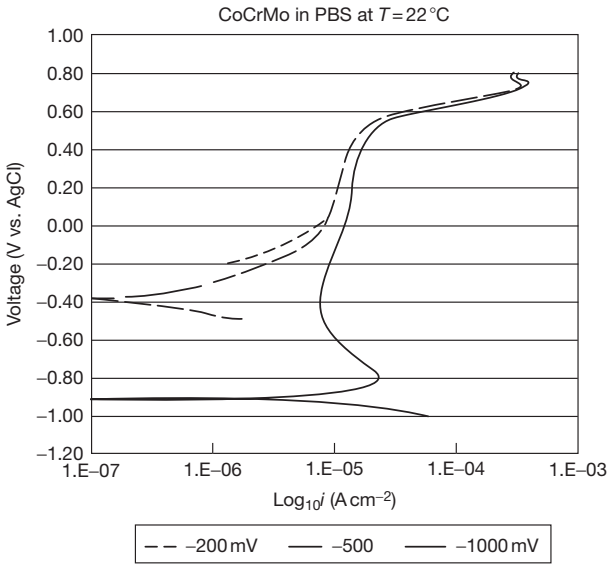

Figure 5 Anodic polarization test results for Co–Cr–Mo (ASTM F-1537) in PBS at room temperature. Note that three tests are shown, starting at three different potentials: −200, −500, and −1000 mV and scanned to +800 mV at 1 mV s^{-1}. The behavior changes slightly with starting potential, where the crossing potential (zero current potentials) shifts more negative with starting potential, and the active–passive transition from −800 to −500 mV arises when starting at −1000 mV.

The surface is fully passive between −500 and +200 mV. As the potential of the surface continues to increase beyond 200 mV, the oxide film can begin to enter into the transpassive region (see Figure 4 or 5).[20] Here, one or more of several events can occur depending on the metal and the condition of the oxide. Either the surface can begin to undergo pitting attack (typically seen in stainless steel) in which case the transpassive potential is known as the breakdown potential, or the oxide film can begin to react to the voltage by changing the valence state of the cations in the oxide (e.g., Cr(III) to Cr (VI)) and lose its passivity. In this case, the surface is said to go transpassive. It is clear that the polarization behavior of oxide film covered surfaces is significantly different from that of active surfaces; however, the Evans diagram can help understand how passive oxide surfaces behave in the presence of other redox species. Interestingly, it is very unlikely that the potential of metallic biomaterials will rise up to the levels needed to induce transpassive or breakdown behavior *in vivo*. Indeed, these surfaces are more likely to have a voltage established that is more negative than their resting OCP because of ongoing mechanical abrasion processes likely being present, especially in orthopedic and spinal devices (as well as others where metal–metal contact and relative motion can occur – see Section 1.103.9). In these cases, the OCP may shift into more active corrosion potentials especially for Cr-based oxides.

1.103.5.3. Polarization Testing

At this point, it is useful to introduce the concepts of potentiodynamic polarization testing including linear polarization and the concept of the polarization resistance. In potentiodynamic polarization testing, the working electrode (the sample) is connected to a potentiostat, which is an electrical device that can control the voltage of the working electrode and measure the current required to maintain that voltage with respect to a reference electrode. Typical polarization testing requires the use of a three electrode system where the first electrode is the working electrode, the second is a reference electrode, and the third is the counter electrode. The reference and counter electrodes are present to provide a stable datum or reference voltage from which to base the voltages of the working electrode, and the counter is present to provide an electrode surface through which the currents coming from the working electrode can be transported back into the electrolyte to complete the circuit. In some experiments, the reference electrode serves both purposes; however, if the currents get large enough, then the voltage of the reference will deviate due to the currents passing over its surface and it will no longer be stable. Thus, the potentiostat provides an electronic circuit that can isolate the reference electrode from any of the currents in the system, and complete the current path through the counter electrode while maintaining a high fidelity reference voltage.

Typically, reference electrodes are made from saturated calomel electrodes (SCE, a mercury–mercury chloride electrode), or a saturated silver–silver chloride (Ag/AgCl) electrode. Both have the characteristic of being nearly ideal nonpolarizable electrodes (their voltage remains relatively fixed even when small currents are passing through their interfaces). On the other hand, counter electrodes typically need to have relatively large surface areas compared to the working electrode and to be able to pass charge (either by capacitive charging or by Faradiac reactions) into the solution without degrading to complete the electrochemical circuit. Typical counter electrodes include platinum and carbon. Both materials are polarizable electrodes (their voltage changes rapidly with small currents) and the potentiostatic circuit will drive these electrodes to whatever potential is required to deliver the current necessary to maintain the working electrode at its set potential (i.e., to complete the circuit).

The solution in which these electrodes sit, besides influencing the chemical state or the surface and the reactions at the working electrode, provides the medium through which ionic charges can complete the electrical circuit for the test. There is a small amount of resistance associated with all ionic solutions (known as the solution resistance (R_s)) which depends on their ionic strength. Most solutions used in biomaterials corrosion testing have relatively low resistances (in the range of 20–70 Ω cm^{-2}). This solution resistance may affect the actual potential across the working electrode depending on the magnitude of the currents in the solution ($V = IR$). So, for example, if 10 μA of current is flowing through a solution with a 50 Ω resistance, then 5e-4 volts (or half of a millivolt) will be present across the solution and the remaining voltage drop will take place across the working electrode. Thus, for most experiments, the solution resistance plays a very minor role (if at all) in the polarization tests of metallic biomaterials. However, if high resistivity solutions (DI water) are used, then large voltage drops in the solution will be present and will affect the voltage at the interface.

In a typical potentiodynamic polarization test, the working electrode is placed in the SBF and its OCP is monitored for up

to 1 h to allow any short-time transient effects to settle out. It should be noted that OCP will continue to vary for days or even weeks after immersion as the interface continues to change upon immersion. After 1 h, the working electrode is brought to a fixed potential, which is suggested by typical corrosion test standards to be a few hundred millivolts cathodic to the OCP, but in reality can be any voltage desired as the starting potential. Then, after a conditioning time, the potential is typically scanned anodically (positively) at some fixed rate (0.167 up to 1 mV s^{-1} is typical). Differences in the starting potential, the scan rate, and the peak positive potential are on the basis of the type of test to be performed. For a linear polarization test, the voltage is typically moved only about 10 mV cathodic to OCP and scanned very slowly through OCP to about 10 mV above. Cyclic polarization and anodic polarization tests typically start at the potential 200–700 mV cathodic to OCP and scan either to a fixed positive potential (e.g., 1000 mV) or until the current density reaches a critical level (e.g., 2 mA cm^{-2}); then the voltage scan is either reversed (for cyclic polarization) or the test is terminated (anodic polarization).

1.103.5.3.1. Linear polarization and R_p

Linear polarization testing is used to try to determine the polarization resistance of the working electrode interface. In linear polarization, the assumption is made that the Butler–Volmer equation holds for the interface. Then, this equation is simplified to a linear equation by taking the Taylor series expansion of the current density and assuming that only the first (linear) term of the expansion is required. Then, a linear relationship between the current density and the voltage is obtained that is called the polarization resistance.

Starting with the Butler–Volmer equation for the case in Figure 3 (where two half-cell reactions are in equilibrium), we can rewrite this equation with the starting potential at the OCP and the overpotential defined as the deviation of the voltage away from OCP. In this case, two things change in the equation. The Tafel slopes for the equation are the anodic slope for the metal oxidation and the cathodic slope for the oxygen reduction, and the exchange current density is replaced by the corrosion current density, i_{corr}.

$$i = i_{corr}\left(10^{(E-OCP)/\beta_a^M} - 10^{-(E-OCP)/\beta_c^O}\right) \quad [3]$$

Now, converting to the natural exponent and taking the Taylor series expansion of this function yields

$$i = i_{corr}\left(1 + 2.3026\frac{(E-OCP)}{\beta_a^M} - \left(1 - 2.3026\frac{(E-OCP)}{\beta_c^O}\right)\right) \quad [4]$$

Taking the derivative of i with respect to E

$$\frac{di}{dE} = \frac{1}{R_p} = 2.3026 i_{corr}\left[\frac{1}{\beta_a^M} + \frac{1}{\beta_c^O}\right] \quad [5]$$

or

$$R_p = \frac{1}{2.3026 i_{corr}}\left[\frac{\beta_a^M \beta_c^O}{\beta_a^M + \beta_c^O}\right] \quad [6]$$

Thus, linear polarization, by measuring the Tafel slopes away from OCP and the slope of the I versus E curve through the OCP, allows one to relate the corrosion current density (i_{corr}) to the polarization resistance (R_p). This method, of course, presumes an active metal interface (not a passive film covered surface) and thus it is questionable whether one can use this method to directly link R_p with i_{corr}. However, even for passive film covered surfaces, there is likely to be an inverse relationship between the corrosion rate and the polarization resistance of the interface. The rate at which one scans to obtain the I versus E plot is important and with passive oxide film surfaces, this is particularly true.

1.103.5.3.2. Cyclic and anodic polarization testing

Cyclic polarization testing and anodic polarization testing are methods where the sample is swept through a range of potentials and the current is measured. These plots are developed to provide information about the passive and transpassive behavior of the surface. In cyclic polarization, reverse scanning is done after a sample has reached a vertex potential (usually around 800–1000 mV vs. SCE) to measure current response on reversal of scanning. If there had been any deleterious pitting attack of the surface, the reverse potential scan will remain at high current levels and will not retrace the forward scan currents. This indicates that unstable pitting attack is taking place and the current is said to develop a hysteresis (see Figure 6 for typical polarization plots). The extent of this hysteresis behavior indicates the susceptibility of the surface to sustained pitting attack. Indeed the voltage difference between the breakdown potential and the repassivating potential is a measure of the susceptibility to pitting. Most metallic biomaterials in use today do not suffer from pitting corrosion in cyclic polarization tests. The exceptions to this are 316L stainless steel and NiTi shape memory alloys. Even these surfaces can sometimes be prepared to resist pitting in

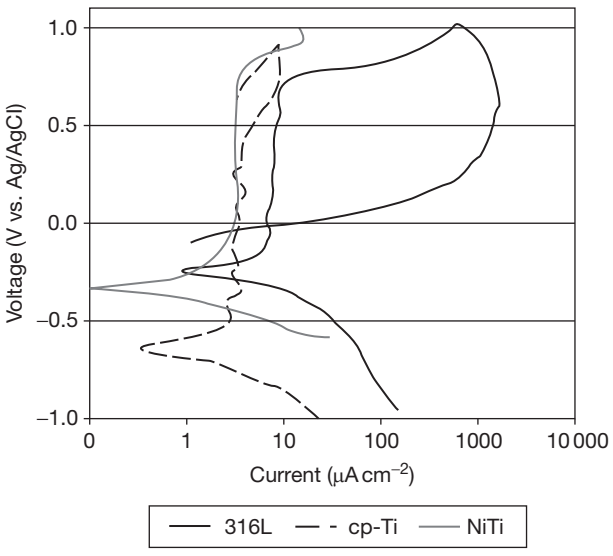

Figure 6 Polarization plots for 316L stainless steel, NiTi shape memory alloy, and commercially pure Ti. Note the hysteresis in the 316L SS plot showing the onset of pitting corrosion attack above about 700 mV.

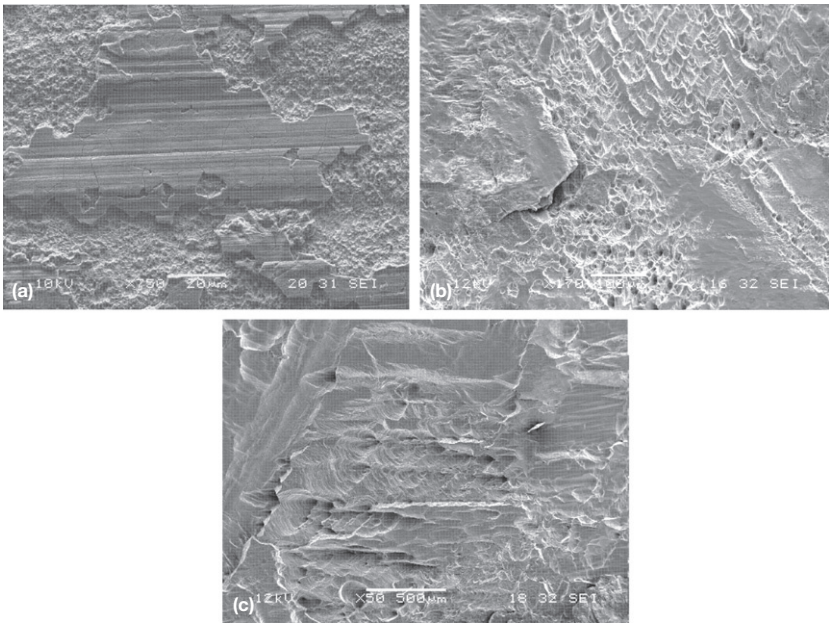

Figure 7 Scanning electron micrographs of retrieved Ti-6Al-4V alloy hip replacements in the modular taper interface showing severe corrosion attack of the Ti-alloy surface. (a), (b), and (c) represent different retrieved devices and both the male and female taper surfaces. The opposing taper alloy was also Ti-6Al-4V indicating that these corrosion processes are not galvanic in nature but result from the combination of fretting and crevice corrosion. Severe pitting is also observed.

these tests (by, e.g., increasing the nitrogen content in the steel, or pulsed anodization of the NiTi to drive the Ni ions out of the film and leave only TiO_2 on the surface). However, it is important to note that ALL metallic biomaterials have been shown to pit inside the human body under certain circumstances. Recent work by Rodrigues *et al.*[21] has shown that even Ti–6Al–4V can be induced to pit in modular taper interfaces of Ti–Ti modular body total hip stems *in vivo* (see Figure 7). Co–Cr–Mo alloys have been documented to undergo pitting, intergranular corrosion, selective dissolution and, corrosion fatigue failure *in vivo*.[22] This will be discussed in more detail below.

Typical polarization results for 316L SS, cp-Ti, Co–Cr–Mo, and NiTi are shown in Figures 5 and 6. These tests were performed in PBS at room temperature at a scan rate of $1\,mV\,s^{-1}$. These curves and their details will depend on the specifics of the solution, prior electrochemical history (voltage, solution, time path), and the starting voltage of the experiment. For example, the OCP for Ti is shifted to more negative potentials when proteins are added to the electrolyte; however, when hydrogen peroxide is added, the OCP shifts to more positive potentials. As the surfaces of these medical alloys have a semiconducting thin film on them that has a significant capacitance, the rate of scanning will affect the measured currents. The starting potential will affect the current response as well. If one starts a polarization test at more negative voltages (e.g., −1000 mV, held for 10 min), the voltage at which the current passes from cathodic to anodic state will shift to more negative potentials (see Figure 5). This point of zero current (zcp, zero current potential) can shift to as low as −800 mV for CoCrMo in PBS but no lower. Thus, the zcp appears to depend on starting potential up to a certain range and starting from a more negative value than that potential does not further alter the zcp. The shape of the curve may also change as well because of alterations in the surface oxide by way of voltages that may drive reductive dissolution or other changes in the oxide film (e.g., modifications in defect density).

1.103.6. Passive Oxide Films and Semiconducting Electrochemistry

1.103.6.1. Introduction to Passive Oxide Films

Oxide films are extremely thin (in the range of 2–10 nm) and are compact and tightly adhered to the metal substrates. We call these oxide thin films 'passive' films as they act to 'passivate' the surface and reduce the rate of corrosion. As we will see, these films are not 'passive' but are rather dynamic in terms of thickness, chemistry, and properties, and responsive to their environment. The thickness, resistivity, and chemistry are all affected by solution chemistry, voltage, and prior electrochemical history. The presence of the oxide thin films alters the polarization behavior of active metals as shown above, but also develops several other important differences that impact on the interaction with the biological system.

Oxides that result from the reaction of metallic titanium or chromium with water (i.e., TiO_{2-x}, $Cr_{2-x}O_3$) release extremely large amounts of energy during their oxidation. For example, the equilibrium voltage for titanium E_{Ti}^{eq} is about −1.6 V (vs. NHE), and gives off four electrons per cation. The energy released in the oxidation of a mole of Ti ($47.9\,g\,mol^{-1}$) is $\Delta G_{ox} = nFE\ (4 \times 96500 \times -1.6) = -620\,kJ\,mol^{-1}$. This is a very high amount of energy associated with this reaction.

It implies that if the reaction were allowed to proceed without any barrier effect of the oxide, the rate of the reaction would be extremely high. It has been reported that the oxide free Ti surface can generate current densities between 0.3 and 150 A cm^{-2}.[23–25]

The barrier concept is critical in understanding the behavior of these surfaces and their response to effects such as mechanical abrasion. To date, there is no simple theory that can describe the electrochemistry of metallic biomaterials with passive thin films. This is due to the complexity and multiplicity of physical and chemical processes that transpire at these interfaces. To begin to understand oxide thin films and their barrier effects on corrosion in the biological milieu, we must introduce several different concepts. These include high-electric field oxide thin film growth, semiconductor electrochemical behavior, ionic and electronic transport mechanisms in oxides, defects, internal stress distribution, adhesion theory, impedance behavior, electrical double layer, surface chemistry (adsorption/desorption), etc. Even areas of quantum mechanics (e.g., tunneling, molecular orbital theory, Fermi energies, energy band theory of semiconductors, band bending, etc.) play a role.

The following sections will provide background in many of the subjects listed above to serve as the foundation upon which a more complete understanding of metal–oxide thin films and their effects on electrochemistry in the biological milieu can be obtained. First, a simplified view of this surface is required. Figure 8 shows a schematic representation of the atomistic view of an oxide film. These films arise from the high-energy

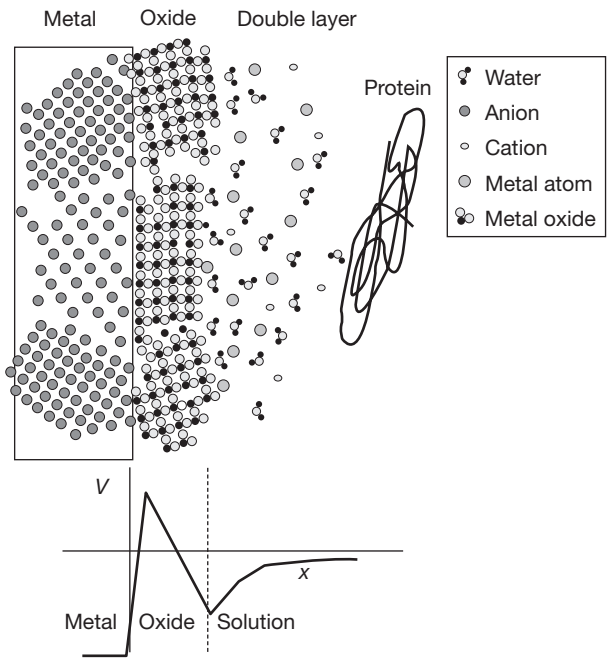

Figure 8 Atomistic view of the metallic biomaterial metal–oxide–solution interface. Crystalline metal grains intersect the surface and convert to oxide that is only a few atom layers thick. The surfaces of these oxides interact with water, ions, proteins, and other species. There is a voltage variation across this interface that promotes the oxidation of the metal.

reactions that take place between fresh metal atoms and virtually any oxygen that is available including that from water. In air, oxygen molecules will react in as little as a few milliseconds to convert the surface metal atoms to a metal oxide. Cabrera and Mott[26] were the first to propose a mechanism by which this occurs that depends on the development of a very high electric field which drives electromigration of the cations and anions through the film to react to grow the oxide.

1.103.6.2. High Electric Field Oxide Growth

The basic premise of Cabrera and Mott's theory is that high electric fields are developed across the oxide. Electrons from the metal tunnel through the surface and are captured by (and capture) oxygen at the surface. Oxygen serves as an electron trap providing a low-energy site for the electron. The deficit of electrons at the metal–oxide interface (i.e., the oxidation of the metal to metal ions) and accumulation of electrons in the oxygen ions at the solution–oxide surface result in very high electric fields across the interface (about 10 MV cm^{-1}). This field drives metal cations through the forming oxide by means of cation vacancy motion or cation motion as interstitial atoms in the oxide. The process of field driven motion is known as electromigration and is characterized by the Nernst–Plank equation[27] This equation comes from definition of activity, C_i, in terms of electrochemical potential, the flux equation (j_i) for ionic species, and the continuity equation in the absence of generation or elimination of species.

$$C_i = e^{(\mu_i - \mu_i^o - n_i FV)/RT}$$

Nernst–Plank equation:

$$j_i = -D\nabla C_i = -\frac{D}{RT}C_i\nabla\mu_i - \frac{n_i FD_i}{RT}C_i\nabla V$$

Nernst–Plank–Fick equation:

$$\frac{\partial C_i}{\partial t} = -\nabla\cdot j = \nabla\cdot D_i\nabla C_i + \frac{n_i FD_i}{RT}\nabla\cdot C_i\nabla V \qquad [7]$$

And the current density is

$$i = \sum n_i F j_i = -F\sum n_i D_i\nabla C_i - F^2\nabla V\sum\frac{D_i}{RT}C_i n_i^2 \qquad [8]$$

where C_i is the activity (concentration) of the ith species, D_i is the diffusivity (Note, $D = uRT$, where u is known as the mobility – the Nernst–Einstein equation), n_i is the charge per ion, F is Faraday's constant, μ_i is the chemical potential of the ith species, and V is the voltage. This equation provides insight into the forces driving ions through either oxides or solutions and may be helpful in understanding the high-field growth behavior of oxides.

Similarly, anion vacancies (and therefore anions) can also migrate from the solution–oxide interface inward, because of the electric field developed, by anion vacancy motion. When cations and anions combine, the result is growth in the oxide. The overall model and the variation of the voltage with position from metal through the oxide to the solution are schematically represented in Figure 9. In Figure 9, metal atoms at the

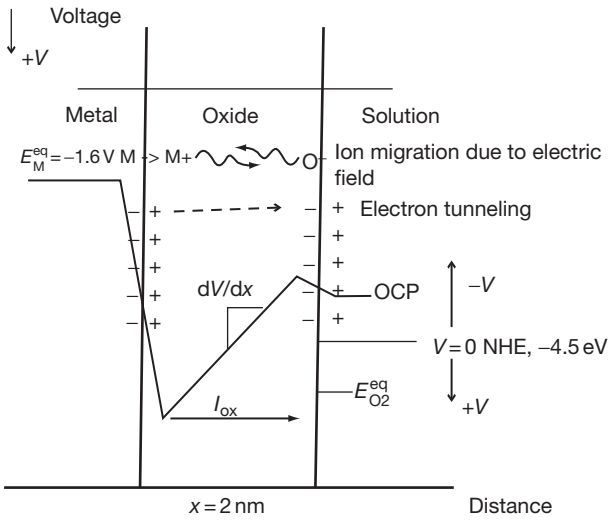

Figure 9 Schematic of the voltage variation across the metal–oxide–solution interface driving oxide thin film growth. High electric fields are developed because of the energy of oxidation and the tunneling of electrons from the metal to the oxide–solution interface. This leads to the high-field growth models of Cabrera and Mott.

metal–oxide surface tend to get oxidized because of the large free energy change associated with oxidation (−1.6 V for Ti); this creates cations at the metal–oxide interface and a separation of charge with some electrons remaining in the metal and some tunneling to the solution interface to be captured by oxygen. The resulting electric field through the oxide, dV/dx (see Figure 9), with positive charge at the oxide–metal interface, and negative charge at the oxide–solution interface then causes cations to migrate from the metal into the oxide and anions to migrate from the solution into the oxide because of the Nernst–Plank equation. Thus, the metal potential, dictated by its free energy of oxidation, changes across the metal–oxide interface, which is acting like a capacitor and becomes very positive just inside the oxide. Cations and anions will feel a high field in the oxide which itself is now acting like a leaky capacitor with charge distributed across the oxide from metal to solution, and ions will migrate toward one another and react to grow new oxide. The voltage at the oxide–solution interface (i.e., the measured OCP) is determined by the condition where the sum of all anodic and cathodic currents is balanced and therefore depends on the transport of both positive and negative charges (as cations and anions, and electrons and holes). There is an additional charged layer and capacitance, referred to as the electrical double later that forms on the basis of the net charge at the oxide–solution interface (see below). There is also a net flow of charge (i.e., an oxidation current) associated with ion transport through the oxide.

The rates of ion transport depend on the extent of ionic defects and the intrinsic mobility of the ions in the oxides. Indeed, Wagner[28] was an early contributor to the concept of electromigration, and anion and cation mobilities to provide a theory for oxide film growth. As the film thickens, the field decreases and lowers the driving force for continued oxidation until a limiting oxide thickness where the transport rates drop to very low levels. This thickness turns out to be only a few nanometers. It has been reported, for instance, that Ti-oxide films will grow at a rate of about 2 nm V^{-1} (the so-called anodization rate). This implies that the limiting field strength is about 5×10^6 V cm^{-1} below which the oxide's growth becomes limited. Similar anodization rates are seen for the other major alloys as well (CoCr and SS).

In Cabrera and Mott's theory, they proposed the following equation:

$$i_{film} = \frac{nF\rho A}{M_w}\frac{dx}{dt} = Ae^{-\left(w - b\frac{dV}{dx}\right)/kT} \quad [9]$$

where x is the oxide thickness, w is the activation energy for diffusion, dV/dx is the electric field, k is Boltzmann's constant, and T is the absolute temperature. A is related to the frequency of attempted ion jumps, the number of ions available to jump, while b relates to the charge of the ion and the jump distance (qa). Integration of this equation results in the so-called inverse-logarithmic growth law ($1/x$ = B-Alnt).[29]

Other models were proposed by Eley and Wilkinson,[30] and Gunterschulze and Betz.[31] These models, also referred to as high-field growth models, appear to have similar concepts related to their development and are reasonable estimates of the high field behavior seen. Eley and Wilkinson proposed a different term in the exponent of Cabrera and Mott ($w + ux$) where the activation energy for ionic jumping is proposed to increase as the thickness, x, of the oxide increases. This results in the logarithmic growth law ($x = A\ln(1 + Bt)$. Gunterschulze and Betz proposed an empirically derived equation, $I = ae^{-bx}$ similar to Cabrera and Mott equation.

1.103.6.3. Redox Electrochemistry at Oxide–Solution and Oxide–Metal Interfaces

This high-field view of oxide film growth is generally accepted as the process by which metal–oxide thin films form and grow on alloy surfaces. However, when one thinks about semiconductor electrochemistry theory in the absence of these growth processes or the underlying reactive metal, there are some different concepts that arise to explain how semiconductors allow electron transport so that solution-based redox reactions can occur.

Semiconducting electrochemistry theory is on the basis of electron energy band theory and typically presumes that the semiconductor is a bulk material whose only contribution to electrochemical processes is to provide a source or sink of electrons and holes (positive charge carriers in the valence band). Thus, knowledge of electron and hole movement in the semiconductor in response to voltage changes is central when considering semiconducting electrochemistry. This section lays out basic semiconducting electrochemistry theory and ignores changes in the oxide film because of growth effects. Overall synthesis of both field-assisted growth and semiconducting electrochemistry needs to occur for a more general theory to emerge.

Redox electrochemistry at bulk semiconductor surfaces can occur when a solution-bound redox half-cell is present. To understand these processes, the band theory of electrons is needed (see Figure 10). Here, the oxide is positioned between a metal phase and a solution phase. The band theory of

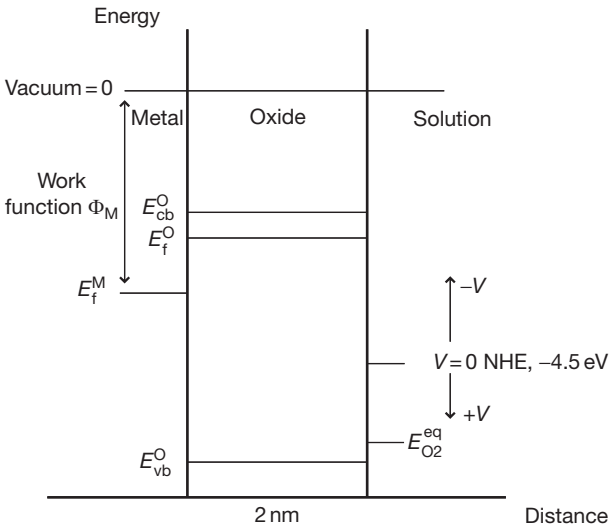

Figure 10 Electron energy diagram for the metal, oxide, and solution when they are not in contact or at equilibrium. Shown is the vacuum energy (= 0), the Fermi energy levels, E_f for each phase, and the conduction and valence bands for the oxide semiconductor. Also shown is the sense of electrochemical voltage in the solution and the energy equivalent for the normal hydrogen electrode (NHE).

electrons in a phase is used here. Electrons occupy discrete electron energy levels from the lowest up to the highest occupied energy level – known as the Fermi energy level. The energy of electrons in a material like a metal fill up to the Fermi energy of the metal, E_f^M. Thus, to remove an electron from this metal, additional energy is needed to raise the electron to the vacuum energy. This is known as the work function (Φ_M,) (see Figure 10). Each phase has a different Fermi energy level (as shown, Figure 10). In the case of the oxide, E_f^{ox} sits between the filled valence band and the unoccupied conduction band of the oxide. Its location within the band gap depends on the defect density giving rise to acceptor (for p-type), or donor levels (n-type) in the oxide. Electron energy is denoted by the vertical axis, where the top is the energy of vacuum (i.e., the energy needed to pull an electron out of the surface – the work function, Φ_M). In the oxide, the Fermi level sits between the filled valence band and the conduction band in the band-gap region and depends on the presence of donor or acceptor sites in the oxide as well as dopants and surface energy states.[32]

In the solution, the Fermi energy level is replaced by the concept of an equilibrium potential for the solution-based redox reaction of interest. Half-cell potentials and electron energies have been related to one another and it has been shown that the normal hydrogen electrode potential sits at about −4.5 eV on the electron energy axis (see Figure 10). Thus, one can relate electron energies in the oxide to the redox potentials of solution-based redox systems. Above and below the solution redox potential sit energy states for the oxidized and reduced forms of the redox system, respectively. As the redox voltage shifts negatively (upwards in Figure 10) more oxidized states convert to reduced states (i.e., more reduced form is present).

In general, the Fermi energy levels (or equilibrium potentials, i.e., $E_f^M \neq E_F^O$) for the different phases are not equal when the phases are not in contact, as shown in Figure 10. When the bulk (not thin film) oxide phase is brought into contact with the metal phase (see Figure 11(a)), or the solution phase (see Figure 11(b)), electron equilibrium (no net electron flow) requires that the Fermi levels become equal. This occurs by movement of electrons across the phase boundary until the E_f's are equal across the interface. In the metal case as shown in Figure 11(a), which is typical for implant alloy–oxide interfaces, as the Fermi level of the oxide is higher than that of the metal, electrons move from oxide to metal and the metal surface has a net negative charge while the oxide at the metal surface is depleted in electrons. This condition is known as a Schottky barrier.[33] The conduction and valence bands of the oxide have two conditions to which that they must hold. First, the energies of these bands must remain fixed at the oxide surfaces, and second, inside the oxide the relationship between the Fermi energy level and the band energies must remain constant. These two conditions result in what is known as band bending (see Figure 11). For the metal–oxide case (with no solution phase nearby), the oxide develops a space-charge region which is the depth into the oxide where the band bending is taking place. The thickness of this space-charge region, known as the Garrett-Brittain space-charge layer, is determined by the Poisson–Boltzmann equation just like in the case of the solution double layer.[34] It is important to note that the metal–oxide semiconductor discussion has not included any sort of redox processes of the metal to form oxide, and as the oxide is considered to be 'thick' the energy levels flatten out into the bulk. Neither of these is the case with the thin oxide films we are discussing.

For the case of a bulk oxide coming into contact with the solution phase, similar arguments hold (see Figure 11(b)). Here we have drawn the redox potential of the solution-based species to be more positive (lower electron energy) than the oxide Fermi Level. This is typical for TiO_2 in an oxygen-containing saline (E_{O2}^{eq} ~0.4 V NHE, E_{fb} Ti ~−0.4 V). Again, electron equilibrium (redox equilibrium) between the phases requires that the Fermi levels become equal and the oxide bands again bend to develop a depletion of electrons at the surface. Of course, if the redox potential is more negative than the oxide Fermi level, then the oxide bands will bend upward moving away from the surface, and an accumulation of electrons will occur at the surface. If the two levels are equal, then the oxide bands do not bend and this potential is known as the flat-band potential (E_{fb}).

The thickness of the space-charge layer in the oxide can be calculated; the approach is similar to the solution electrical double layer (see Appendix) and is known to depend on the number of charge carriers present per volume, N_D,

$$\kappa^{-1} = \left[\frac{\varepsilon\varepsilon_o kT}{N_D e^2}\right]^{1/2} \quad [10]$$

The typical value for the density of donor states is between 10^{17} and 10^{22} cm^{-3}. Using typical values for TiO_2 semiconductors, the space-charge layer is between 0.5 and 15 nm. From direct capacitance measurements, TiO_2 film thickness on cp-Ti

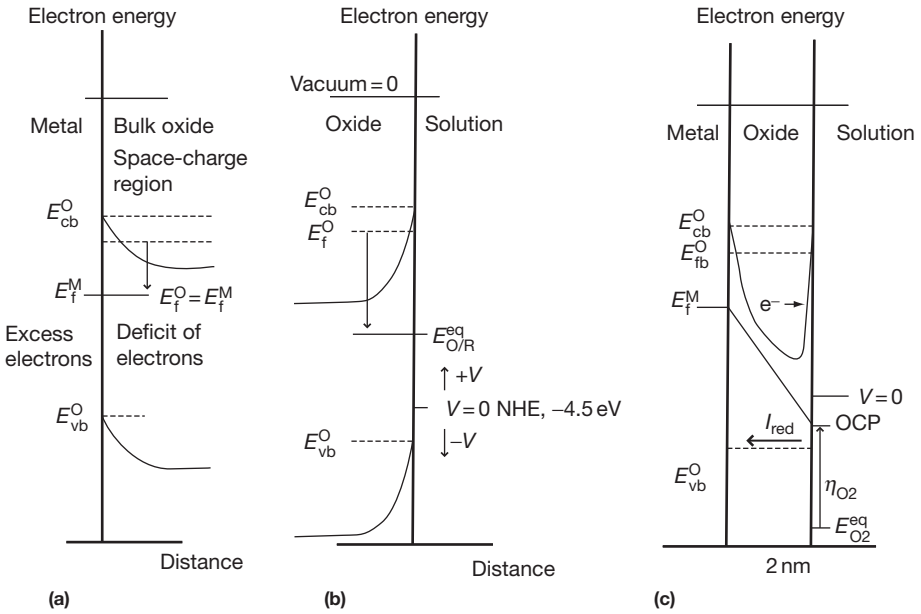

Figure 11 (a) Electron energy diagram for a metal–oxide junction demonstrating the electron energy band bending that gives rise to a Schottky barrier and a depleted space-charge region in the oxide. Electron equilibrium (no current) requires that the Fermi energy levels of the metal and oxide must be equal which requires that the valence and conduction bands bend at the oxide surface. (b) Electron energy diagram for bulk oxide–solution interface. The Fermi energy for the solution-based redox reaction is replaced by the Nernst potential. Again, equilibrium between the oxide and the solution-based species requires band bending and an electron-depleted zone in the oxide. The thickness of this space-charge region can be calculated (eqn [12]). (c) When the metal–oxide–solution construct is developed, where the oxide thickness is only a few nanometers, the combined electron energy diagram is shown. In this figure, the Fermi levels of the metal and solution are different thereby giving rise to a gradient in electron energy through the oxide. This will give rise to a current providing electrons to the redox reaction and causing reduction.

is about 4 nm at 0 mV versus Ag/AgCl. Thus, the space charge thickness is on the order of the thin film oxide thickness.

The space-charge region we have discussed so far gives rise to a capacitance of the oxide known as the space-charge capacitance, or oxide capacitance. The relationship between the oxide capacitance, the charge carrier density, the voltage of the interface, and the flat-band potential is known as the Mott–Schottky equation and is derived from the Poisson–Boltzmann equation (see Appendix Gelderman *et al.*[35]).

$$\frac{1}{C^2} = \left[\frac{2}{\varepsilon\varepsilon_o N_D e}\right]\left(V - V_{fb} - \frac{kT}{e}\right) \qquad [11]$$

where C is the oxide capacitance, ε is the dielectric constant, ε_o is the permittivity of free space, e is the electron charge, k Boltzmann's constant, T temperature, N_D is the number of donor levels (or charge carriers) per volume, V is the voltage of the interface, and V_{fb} is the flat-band potential. This equation is very useful in electrochemical impedance analysis of oxide film covered metallic biomaterials and has been used by a number of investigators to describe the character of the oxide film. The capacitance of the oxide is measured (see EIS discussion below) over a range of voltages and plotted as C^{-2} versus V to find N_D and V_{fb}. It is important to note that the above discussion assumed equilibrium. If a voltage is enforced on the oxide–solution interface and equilibrium is not attained, then the Fermi energy will slope through the oxide and charge will flow until equilibrium is reestablished.

1.103.6.4. Oxide Semiconductor Theory for Thin Oxide Films Between Metals and Solutions

The picture of semiconducting electrochemistry becomes more complicated when both a metal phase and a solution phase sandwich a very thin oxide phase (see **Figure 11(c)**). Here, we are not considering any oxidation effects of the metal, but simply assuming that the Fermi energy levels of the metal and solution are at different levels. When the oxide comes into contact with metal and solution under these circumstances, the Fermi energy level of the oxide must equal the metal Fermi level on the one hand, and the oxide–solution energy levels must be equal, but will likely be at a different level. The Fermi energy in the thin oxide will, therefore, be sloped such that electrons will move from metal through oxide to solution to reduce the solution-based redox system. This will be the case until the solution redox potential shifts to higher energies to bring all of the Fermi energy levels into equilibrium. As can be seen, the valence and conduction bands will be bent on both sides of the interface and indeed the two space-charge regions may overlap significantly depending on the thickness of these layers. With the conditions shown, one can see depletion of electrons on both sides of this oxide and under these conditions the oxide will not easily transport electrons across to participate in the reaction. This is what is seen under anodic conditions ($V > V_{fb}$) for, for example, titanium oxide thin films. The anodic currents are typically very low and the oxide acts much like an insulator.

It is clear from this discussion that the theory of semiconducting electrochemistry is not completely reconciled with the theory of oxide thin film growth discussed earlier. In the absence of oxide film growth and metal oxidation effects, the voltage (energy) distributions through the oxides are not the same as required for film growth. The differences arise because of the thin film character where electron tunneling can take place, and in the oxidation energy associated with taking metal atoms and converting them to cations. The high-field growth models require high electric fields which are positive at the metal–oxide interface and negative at the oxide–solution interface whereas the semiconductor theory only requires the conditions of equilibrium of Fermi energy levels and band bending. The former causes oxide growth, the latter allows only electronic charge to be transported to engage in a redox reaction in the solution. These views of the surface electrochemical processes need to be reconciled to have a more holistic understanding of thin-film oxide corrosion behavior for metallic biomaterials.

1.103.7. Electrical Double Layer

The net-charge distribution in the oxide established because of these processes also results in a distribution of charge in the solution adjacent to the oxide and is known as the electrical double layer which will have a capacitive character and the distribution of charge and voltage through this double layer is determined by the Poisson–Boltzman equation[34]

$$\nabla^2 V = \frac{1}{\varepsilon\varepsilon_o}\sum n_i F e^{-}\mathrm{e}^{-[nFV/RT]} \qquad [12]$$

where n_i is the valence of the ith species; the solution of this equation under conditions of a 'small' voltage results in the Debye–Huckel equation and the Debye thickness for the double layer.

$$V = V_o \mathrm{e}^{[-\kappa x]} \qquad [13]$$

$$\kappa^{-1} = \left[\frac{\varepsilon\varepsilon_o kT}{Ne^2}\right]^{1/2} \qquad [14]$$

where N is the number density of charged species (number per volume). It is important to note that the establishment of the electrical double layer on metallic biomaterial surfaces is determined by the voltage required to balance the anodic and cathodic currents and is not, as the theory lays out, on the basis of the static charge. Thus, zeta potentials of bulk oxides in no way represent the zeta potential of oxide thin films with underlying metals present. The electrical double layer could have a local solution layer with excess positive charge or negative charge. As V_{fb} is the potential with no net charge, if OCP is greater than V_{fb}, the solution at the surface will have a net negative charge (to balance the net oxide positive charge), and a double-layer capacitance will be present. In general, the metal–oxide–solution interface will have three different capacitances: the metal–oxide capacitance (Schottky barrier), the oxide capacitance, and the double-layer capacitance. The overall interface capacitance will, therefore, be a series combination of these three capacitances. In this case, as capacitances sum as the reciprocal, the total interfacial capacitance will be dominated by the smallest of these three capacitances. In most cases (i.e., at most potentials), the oxide capacitance will be the smallest of the three. However, the double-layer capacitance will become the smallest of these at negative voltages below about −700 mV (vs. Ag/AgCl).

1.103.8. Electrochemical Impedance Spectroscopy (EIS) of Metallic Biomaterials

The study of metallic biomaterials in the biological milieu has increasingly used the techniques associated with EIS to explore the behavior of these interfaces. Therefore, this section will briefly summarize the theory and methods of EIS and present some of the relevant findings related to biomaterials.

1.103.8.1. The Methods of EIS

EIS is a technique used to determine the impedance characteristics of an electrochemical interface. It has been used increasingly in biomaterials studies to understand the interactions between the surface and the biological environment. As discussed above, electrodes, either with or without an oxide thin film, can either accumulate charge at the interfaces, and/or can transport charge across the interface. Thus, all electrochemical interfaces can be thought of as being comprised of resistive and capacitive elements connected in series and/or parallel. EIS directly measures the frequency-based impedance of the interface and then typically attempts to relate the response to some resistive–capacitive circuit model to infer behavior. The technique typically applies a small (10 mV) sinusoidal voltage overtop of a static voltage using a range of frequencies typically from 10^5 to 10^{-3} Hz. The current response is then monitored and the current amplitude and phase (δ) are used to obtain the impedance of the interface. The impedance of any electric circuit is defined by its transfer function:

$$Z^*(\omega) = Z'(\omega) + \mathrm{i}Z''(\omega) = \frac{L(V(t))}{L(I(t))} \qquad [15]$$

$$\tan\delta = \frac{Z''}{Z'} \qquad [16]$$

where $Z^*(\omega)$ is the complex impedance and L represents the Laplace operator. One can see that the impedance of a circuit is comprised of a real (or resistive) term, and an imaginary (capacitive and/or inductive) term. The phase angle, δ, is a measure of the shift in time (the phase lag) between the input and the output and can be determined by the ratio of imaginary to real impedance.

The electrode interface can have one of several electrical analog models associated with it, depending on the complexity of the surface. These can range from a simple capacitive response, indicating an ideally polarizable electrode where no Faradaic currents are passed across the interface (see **Figure 12(a)**), to a parallel combination of a resistive and capacitive elements representing the charging and charge transfer processes possible at typical electrode surfaces (see **Figure 12(b)**, Randle's circuit), to more complex circuits that may be used to represent more complex interfaces with

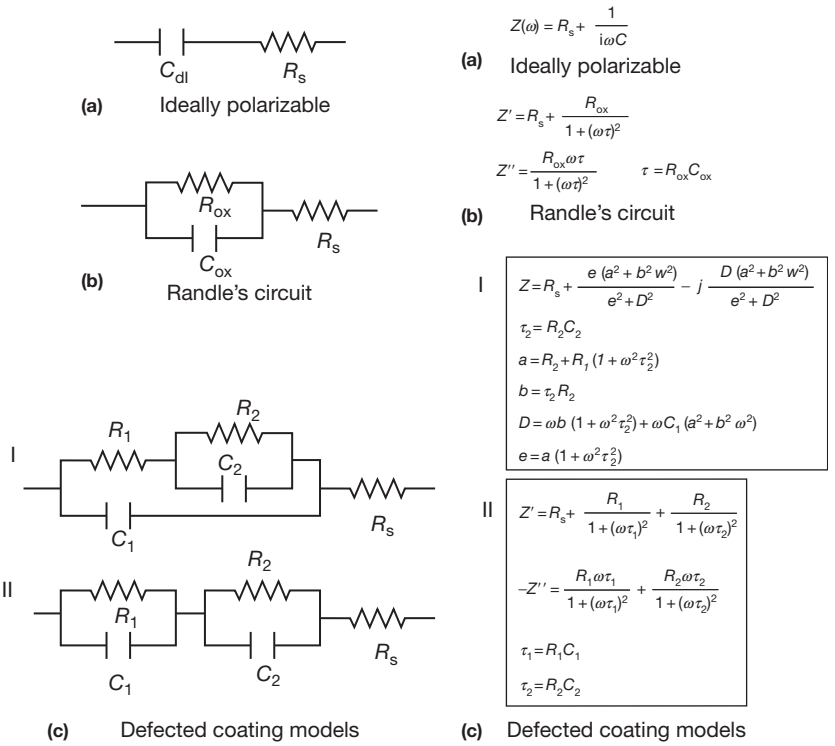

Figure 12 Circuit models used to analyze metallic biomaterial surface electrochemical impedance properties. (a) Ideally polarizable electrodes where no currents transit the interface. (b) Randle's circuit – typically used to describe oxide thin film surfaces. (c) Defected coating models used to analyze thicker coatings on metal surfaces. The impedance equations used to decrease each of these models are to the right of the figure.

defective coatings (see Figure 12(c)). The impedance of these electrical equivalent circuits can be found by defining $Z_R = R$ and $Z_c = 1/i\omega C$ (where $i = \sqrt{-1}$) and remembering that series impedances add, while parallel impedances sum as the reciprocal. Figure 13 shows the Bode and Nyquist representations for the two defect coating models assuming ideal circuit elements.

Real metallic biomaterial interfaces are often not adequately represented by ideal circuit elements. Real electrode interfaces have a distribution of behaviors and heterogeneity over the area of the electrode. This results in a distribution of capacitive and resistive character. To account for this heterogeneity, the concept of a constant phase element (CPE) has been introduced. Here, the capacitive elements of the electrode model are replaced with an impedance of the form[27]

$$Z_{CPE} = \frac{1}{((i\omega)^{\alpha}Q)} \qquad [17]$$

where α is the constant phase exponent which can vary from 1 to 0 and Q is the capacitive-like value of the CPE. When α is 1, the CPE acts like an ideal capacitor, while at values less than 1, the CPE takes on more and more of a resistive character.

The CPE substitutes for the capacitors in the ideal circuits discussed above and can be mathematically dealt with by knowing that

$$i^{\alpha} = \left[e^{\left(i\frac{\pi}{2}\right)}\right]^{\alpha} = e^{\left(i\alpha\frac{\pi}{2}\right)} = \cos\left(\alpha\frac{\pi}{2}\right) + i\sin\left(\alpha\frac{\pi}{2}\right) \qquad [18]$$

For a Randle's circuit with a CPE the impedance equations are

$$Z' = R_s + \frac{R_p\left(1+R_pQ\omega^{\alpha}\cos\left(\alpha\frac{\pi}{2}\right)\right)}{\left(1+R_pQ\omega^{\alpha}\cos\left(\alpha\frac{\pi}{2}\right)\right)^2 + \left(R_pQ\omega^{\alpha}\sin\left(\alpha\frac{\pi}{2}\right)\right)^2} \qquad [19]$$

$$Z'' = \frac{R_pQ\omega^{\alpha}\sin\left(\alpha\frac{\pi}{2}\right)}{\left(1+R_pQ\omega^{\alpha}\cos\left(\alpha\frac{\pi}{2}\right)\right)^2 + \left(R_pQ\omega^{\alpha}\sin\left(\alpha\frac{\pi}{2}\right)\right)^2} \qquad [20]$$

where Q is the magnitude of the CPE, thought to be related to the oxide capacitance (or space-charge capacitance), and α is the CPE exponent which is a measure of the deviation from ideality. R_p and R_s, for oxide thin film surfaces, are typically thought to be related to the oxide resistance (or polarization resistance) and solution resistance, respectively. These equations are used to fit the impedance response data generated in an EIS experiment and a nonlinear least squares regression method is typically used to fit these functions to the data.

The modified Randle's circuit (Figure 14(a)–14(c)) is the most commonly used circuit in modeling the metallic biomaterial interface impedance where the CPE replaces the capacitor in the model. A typical plot of the impedance and phase angle versus log of the frequency (known as Bode plots), and the plot of $-Z''$ versus Z' (the Nyquist plot) are shown in Figure 14(c) for typical values of the parameters. The Bode plot for impedance becomes more spread over frequency as α decreases from 1, while the Nyquist plot becomes a more-depressed semicircle as α decreases.

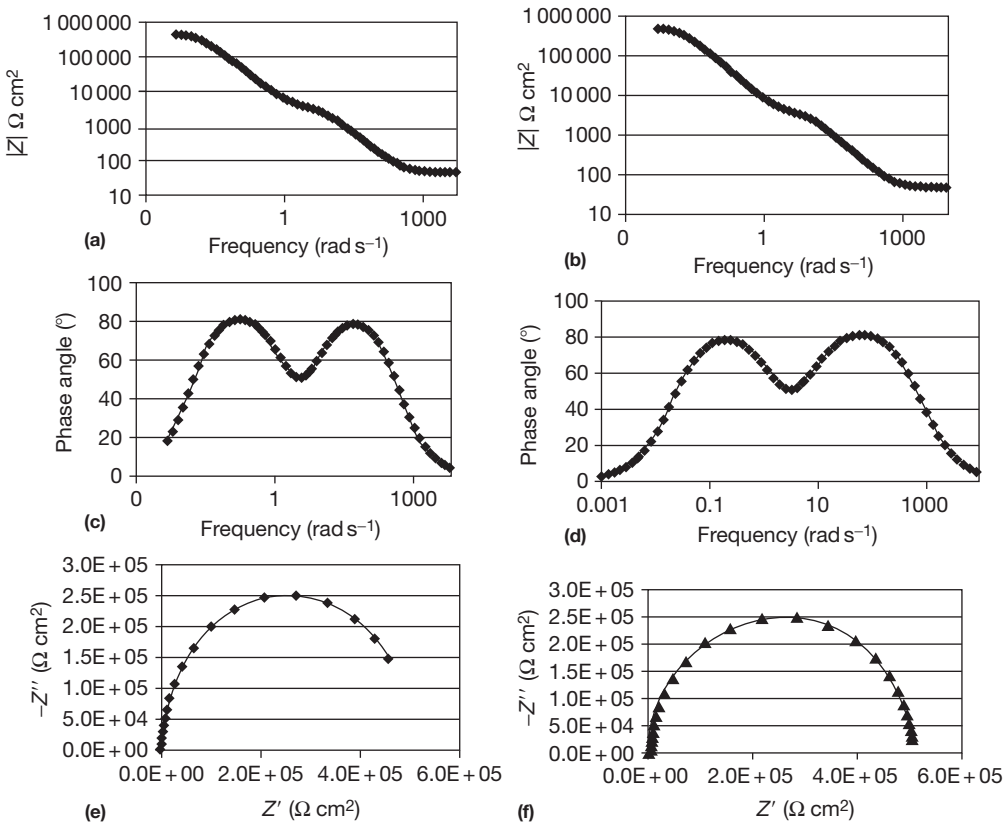

Figure 13 Bode plots (a,b,d,e) and Nyquist diagrams (c and f) for the defected coating models in **Figure 12**. (a) Model I, (b) Model II (both with $R_s = 50$, R1 = 5000, R2 = 5e5, C1 = 3e-5, C2 = 1e-4). The Bode plots are impedance and phase plotted as a function of log of the frequency, while the Nyquist plots show the imaginary versus the real impedance. These two models, with the appropriate values for the elements can model the same impedance behavior (compare with **Figure 15**).

1.103.8.2. Time-Based Methods

Impedance analysis can also be performed by obtaining the time-dependent response of the electrode interface and performing a time–frequency transform on the time-domain response. Here, potential step current-transient methods have been developed[36,37] for these studies. A benefit of using time-transient methods is that it allows one to explore a range of static voltage conditions by sequentially stepping through a range while capturing the current transient at each step. This so-called step-polarization impedance spectroscopy (SPIS) method can help provide information related to the voltage-dependent impedance behavior of these surfaces. Here, the reciprocal of the impedance, known as admittance ($A^*(\omega) = 1/Z^*(\omega)$), is found from the current transient that results from a small (25–50 mV) step from some initial potential.

$$A^*(\omega) = \frac{1}{\Delta V}\left(\int_0^\infty \frac{di(t)}{dt} e^{i\omega t} dt + i(t=0)\right) \qquad [21]$$

where $i(t)$ is the time-dependent current density response to the voltage step, ΔV.

The current is captured over several intervals of time (from 10^{-5} to 10^{2} s) and is analyzed with a numerical transform to obtain the admittance, while the late currents can be used to obtain the polarization plots for the surface. The earliest current response is a measure of the solution resistance (e.g., $I(t=0^+) = I(0) + \Delta V/R_s$), while the latest time currents relate to the sum of solution resistance and polarization resistance, R_p (e.g., $I(t\to\infty) = I(0) + \Delta V/(R_s + R_p)$).

Other time-based methods have also recently been published (see Haeri *et al.*[38] for example). Gettens and Gilbert[39,40] used the time-based solution of the Randle's circuit to a step in potential, and modified the exponential terms to be stretched exponentials of the form of the KWW function.[41] The stretched exponential raises the exponential terms of the time-domain solution to the differential equation, to a power, n (where n is between 0 and 1), that stretches the time response. The exponent, n, has similar characteristics to those of α in the CPE elements described above, and allows for a better fit of the data with the function.

The stretched exponential model proposed by Gettens and Gilbert[42] is

$$I(t) = I(0) + \frac{\Delta V}{R_s} e^{-(t/\tau)^n} + \frac{\Delta V}{R_p + R_s}\left(1 - e^{-(t/\tau)^n}\right) \qquad [22]$$

where this function is the solution to the differential equation of Randle's model (when $n = 1$), τ is the time constant and is related to the capacitance and the resistances of the model,

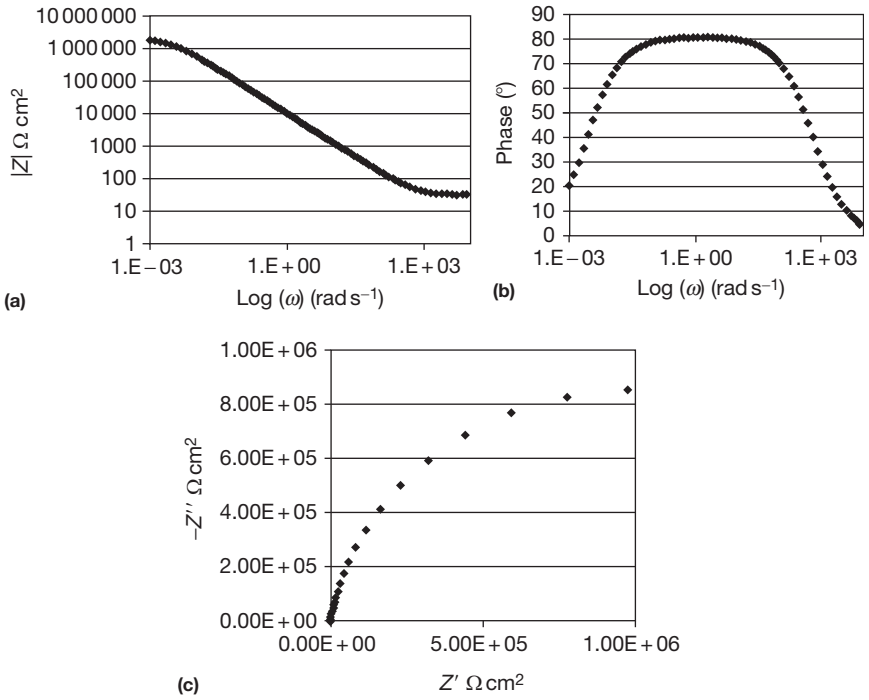

Figure 14 Bode (a and b) and Nyquist (c) plot for a Randle's circuit with a constant phase element. The values of the elements used ($Q = 1e\text{-}4$, $R_p = 2e6$, $R_s = 30$, $\alpha = 0.8$) are similar to that seen for typical oxide thin film covered metallic biomaterials.

and n is the stretch exponent. This method has been used to explore the impedance and polarization response of 316L SS immersed in PBS and PBS with fibrinogen[40] over a range of potentials from −1000 to 800 mV versus (Ag/AgCl). It was shown that the presence of fibrinogen did not significantly affect the overall impedance response except at very negative potentials, while the stretch exponential, n, was affected by the presence of fibrinogen at several potentials.

Other methods include a hybrid time–frequency method proposed by Ehrensberger and Gilbert[43] where the time-based transients are used to find the resistances and the time constant for the decay response, and the frequency-transformed behavior is used to determine the CPE exponent, α.

One benefit of these time-based methods is the ability to capture a range of voltages (by potential steps). From these voltage-dependent measurements, equations such as the Mott–Schottky equation (eqn [13]) can be used to determine the flat-band potential and the density of charge carriers in the oxide.

1.103.8.3. Impedance Behavior of Ti, CoCr, and 316L SS: Effects of Solution, Voltage, and Time

Typical examples of the EIS response for Ti–6Al–4V and Co–Cr–Mo can be seen in Figure 15(a)–15(c) which shows the Bode and Nyquist plots for Ti–6Al–4V and Co–Cr–Mo alloys in PBS after 24 h immersion at OCP and 37 °C. Impedance behavior of Ti-alloy, CoCr, and 316L SS interfaces all exhibit some degree of CPE behavior that varies with voltage, and each has a range of frequencies where it is acting very much like an ideal capacitor (where the phase angle is close to 90°).

It is also important to recognize that the impedance of an interface will be affected by factors including time of immersion, voltage experienced, and solution conditions (e.g., pH, temperature, proteins, inflammatory species, superoxide anions, etc.). It has been shown, for example, that the polarization resistance (oxide resistance) varies with time of immersion and can either increase or decrease with time depending on the voltage of the interface. For example, Ehrensberger and Gilbert[14] have shown that cp-Ti impedance in PBS at 24 h immersion is highly voltage dependent (see Figure 16). At potentials above about 0 mV versus Ag/AgCl, Rp remains high, well above 1 MΩcm^2. However, as the potential of the interface is held at more cathodic potentials, R_p of the surface decreases exponentially and drops to about 10 kΩcm^2 for potentials of −700 mV or more negative. These results show that the oxide film impedance characteristics are highly voltage and time dependent. CoCrMo and 316L SS both have voltage-dependent impedances.

The semiconducting character of the oxides of Ti and CoCr alloys can be obtained from their impedance behavior as a function of voltage (see Figure 17(a) for Co–Cr–Mo, and Figure 17(b) for cp-Ti). The oxide resistances of CoCrMo and cp-Ti are measured versus voltage and show significant variations over the range. Ehrensberger and Gilbert,[43] and others, have shown that the flat-band potential for Ti alloys is between −300 and −500 mV versus Ag/AgCl; for CoCr it is around −450 mV and for 316L SS it is around −100 mV.[39,40] The charge carrier density typically determined from Mott–Schottky analyses ranges from 10^{17} to 10^{22} cm^{-3}. A typical Mott–Schottky analysis of cp-Ti from Ehrensberger and Gilbert[43] can be seen in Figure 18.

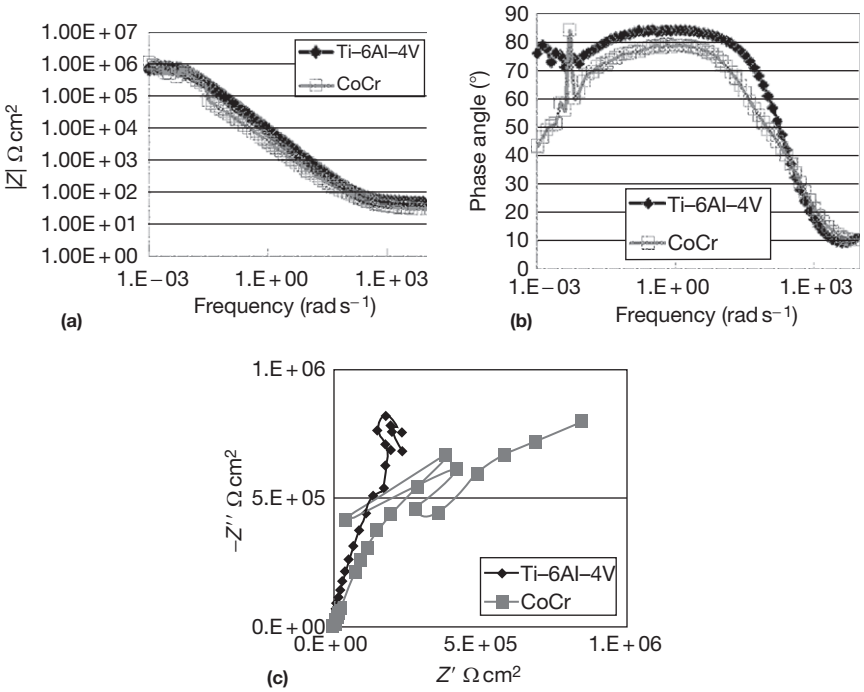

Figure 15 Impedance results (Bode: a,b; Nyquist: c) for Co–Cr–Mo and Ti–6Al–4V. Each of them has similar behavior that is mostly capacitive and the low frequency resistance (the oxide resistance) approaches 1 MWcm^2. Note the similarity between these actual data and the modified Randle's circuit in **Figure 14**.

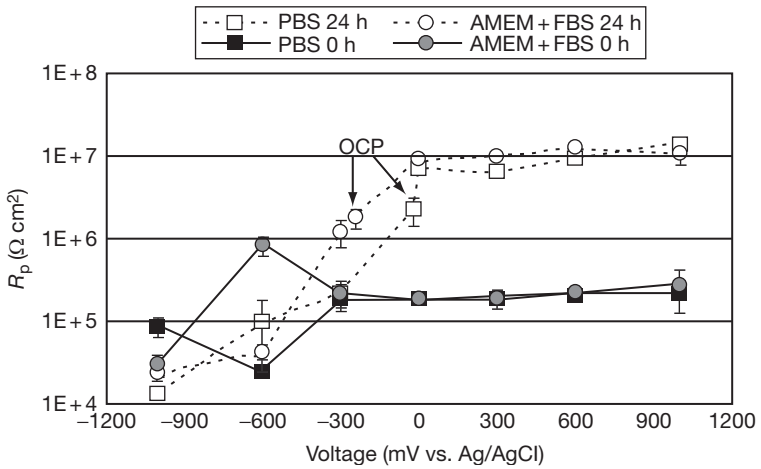

Figure 16 Plots of the polarization resistance of cp-Ti at 0 and 24 h held at fixed voltages. Both PBS and AMEM + FBS solutions were studied. Note the differences between 0 and 24 h. There is a significant increase in R_p for 24 h for both solutions above −300 mV. Also note that the R_p at 24 h shows an approximate log-linear decrease with decreasing voltage and drops almost three orders of magnitude over 1 V change. Reproduced from Ehrensberger, M. T.; Gilbert, J. L. *J. Biomed. Mater. Res. B* **2009**, with permission from J. Wiley and Sons.

It is important to note that the flat-band potential (as discussed above) represents the voltage where the oxide electron energy bands are not bent upward or downward. The voltage of the interface, however, is dictated by the balance of the redox reactions (net Faradaic currents sum to zero) and the potential can range from above the flat band (typical when the interface is not mechanically abraded) to below the flat-band potential (when abrasion processes are ongoing). When the potential drops below the flat band, the oxides become very capable of transporting negative charge via electrons and the oxide significantly decreases its resistance. However, it is likely that ionic transport through the oxides is also altered under reducing conditions.[44] In fact, studies of oxides have shown that they may undergo reductive dissolution with negative voltage, reducing the thickness of the oxide.[45]

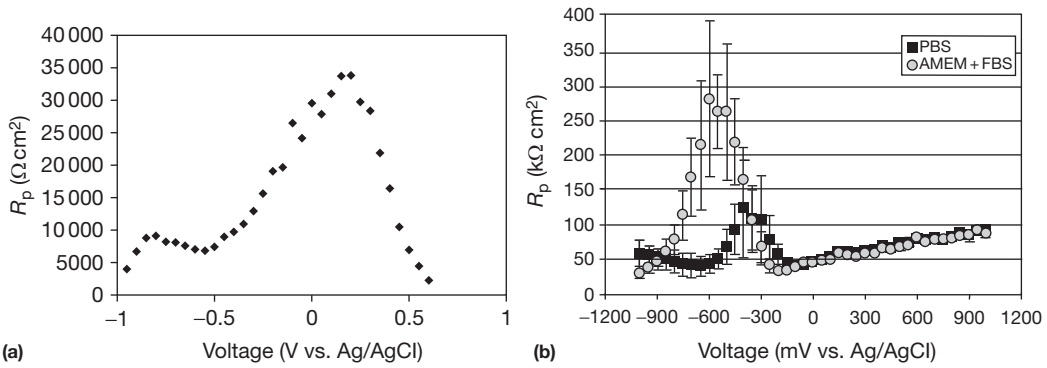

Figure 17 Polarization resistances measured for (a) CoCrMo in PBS and (b) cp-Ti in AMEM and FBS + AMEM using the step-polaization impedance spectroscopy method. Note the different scales for each. Each was tested starting at −1 V and scanning anodically. The impedance values are lower than is typical because of the scanning nature of the experiment but are consistently observed. The variation with voltage shows how the oxide films on each alloy is changing its electrical character with voltage. The peak in R_p for CoCr shows the oxide transitioning from a well coated surface oxide to a more defected oxide that ultimately breaks down above +200 mV. The Ti variations show changes in oxide behavior around the flat-band potential. (b) Reproduced from Ehrensberger, M. T.; Gilbert, J. L. JBMR-A **2010**, with permission from J. Wiley and Sons.

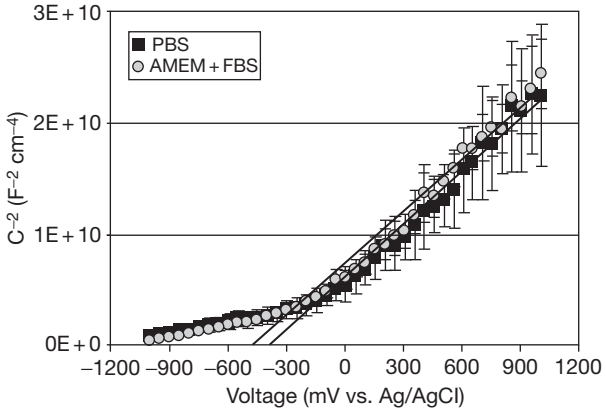

Figure 18 Mott–Schottky plot of cp-Ti in PBS and AMEM with 10% fetal bovine serum. Note that the extrapolation of C^{-2} versus V to the voltage axis yields a flat-band potential of about −400 mV. The slope of this line yields a charge carrier density of about 2.5e + 21 cm^{-3}, which is very high – approaching a metallic surface. Reproduced from Ehrensberger, M. T.; Gilbert, J. L. *J. Biomed. Mat. Res. A*, **2010**, with permission from J. Wiley and Sons.

1.103.9. Mechanically Assisted Corrosion

In the biological milieu, there are significant mechanical factors typically at play when metallic biomaterials are placed. These mechanical factors, besides the direct consequence of their presence (e.g., generation of wear particles), can significantly and dramatically impact electrochemical processes. In loaded medical device applications, the high cyclic-stress nature of the biological environment can give rise to a number of surface mechanical events that may result in mechanical disruption of the oxide film. These events include fretting (small scale cyclic motion between two materials – one of which is oxide covered alloy), wear, and substrate deformation (elastic and plastic). Fretting is a significant problem in devices where there are hard surfaces in contact with the metal device that can both create abrasive fretting of the oxide and develop a restricted crevice geometry. The hard opposing surface may be another metal, or a ceramic. Examples of fretting–crevice corrosion susceptible devices include all modular tapers in total joint prostheses[46–48] crevices created by the bone cement–metal implant interface,[49] screw-countersink geometries,[50,51] and other contact sites in fracture fixation devices and spinal instrumentation, and overlapping vascular stents. Wear processes are also sites where oxide mechanical disruption can occur. These include cases where metal–metal wear surfaces are present (e.g., hip resurfacing, metal-on-metal total hip replacements).

1.103.9.1. Modeling the Electrochemical Response to Scratching

When oxide films are disrupted, the exposure of the underlying metal to the biological milieu results in some very significant electrochemical events. Immediately after oxide disruption (see **Figure 19**) there are three main reactions that appear or increase dramatically. First, the active dissolution reaction (metal to metal ions in solution) increases at the site of disruption. Second, the oxide film reaction proceeds to reform the oxide and recover the site of the breach. Third, both of the above oxidation reactions release free electrons that remain behind in the metal. This results in an overall decrease in the OCP of the implant and an increase in the rate of the reduction reactions present on the surface that eventually consume these excess electrons and bring the surface back into overall dynamic equilibrium (i.e., where the sum of all anodic and cathodic currents balance). It is important to note that during and immediately after oxide disruption, the interface is not in overall equilibrium. Anodic reactions (repassivation and ionic dissolution) will occur at rates that have been measured to be up to 10^8 times those present at intact oxide films.

There have been several models proposed for the behavior of the oxide film during and after mechanical disruption. A relatively simple and direct model was first proposed by Ambrose.[52] Here, the surface starts in a complete oxide-devoid

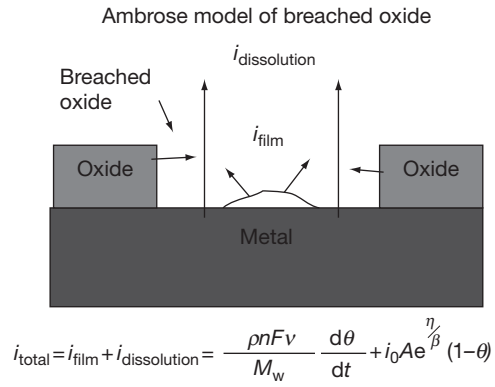

Figure 19 Ambrose's representation of a breached oxide and the repassivation currents that arise. Both film currents and dissolution currents are present and the fraction of surface disrupted, θ, varies with time as the surface repassivates. Reprinted, with permission, from STP 1301 – Modularity of Orthopedic Implants, © ASTM International, West Conshohocken, PA.

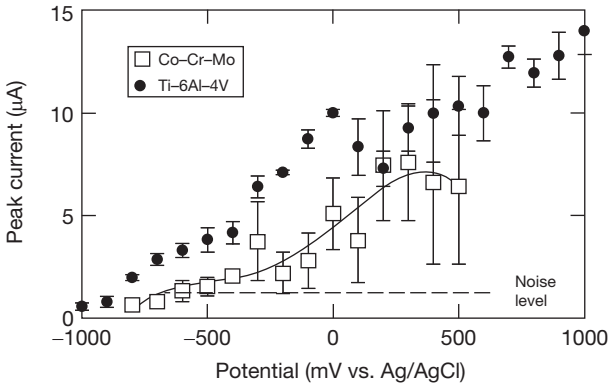

Figure 20 Scratch test results at fixed load and scratch length and varying potential for Co–Cr–Mo and Ti–6Al–4V in PBS at room temperature. Note that the peak scratch currents increase with voltage (Co–Cr–Mo from −500 mV and Ti–6Al–4V from −900 mV). Above +500 mV, CoCrMo loses its passive oxide and the peak currents drop (not shown). Ti peak currents continue to increase across voltage range tested. Note the similarity in the R_p (**Figure 18**) and these peak currents. The peak depends on the area scratched, the thickness of the oxide reforming, and the valence of the cation. Reprinted, with permission, from STP 1301 – Modularity of Orthopedic Implants, ©ASTM International, West Conshohocken, PA.

state. The fraction of volume repassivated (θ) varies with time. It is assumed that the ionic dissolution reaction follows a Tafel-like behavior through the breached surface.

$$i_{diss} = i_o^{diss}(1-\theta)e^{\frac{V-V^{eq}}{\beta}} \quad [23]$$

and the oxide film currents, i_{film}, depend on Faraday's law and the time rate of regrowth of the oxide film

$$i_{film} = \frac{nF\rho v}{M_w}\frac{d\theta}{dt} \quad [24]$$

where ρ is the film density, υ is the total volume of oxide to grow, M_w is the molecular weight of the film, and n is the charge per cation. Thus, the total current associated with the oxidation processes of repassivation is just the sum of the film and dissolution currents densities:

$$i = i_{film} + i_{diss} = \frac{nF\rho v}{M_w}\frac{d\theta}{dt} + i_o^{diss}(1-\theta)e^{\frac{V-V^{eq}}{\beta}} \quad [25]$$

where i_O^{diss} is the dissolution exchange current density across bare metal, V is the voltage away from the equilibrium potential for the bare metal dissolution reaction (for $V_{Ti}^{eq} = -1.6\,V$), and β is the Tafel constant for this reaction. This first-order differential equation results in an exponential time decay of the total current (i.e., $i = i^{max}e^{-t/\tau}$)[53] when the surface is held at a fixed potential. While there are many assumptions associated with this model, it gives a good interpretation of the process and it has been used to explore the voltage, solution, and oxide surface dependent responses to high speed scratching of the surface oxide.[53–55] It does not account for the voltage excursions nor does it deal with the reduction reactions that must increase as a result of the sudden increase in electronic charge in the metal. To study the current transient response under fixed voltage, we developed an electrochemical scratch test system that imparts a small (50 μm) scratch in about 0.5 ms under the conditions of controlled contact load and geometry, solution chemistry, and applied voltage. The results of this work have shown, for instance, that there is a contact stress of about 1 GPa required to disrupt the oxides, that the repassivation process is highly dependent on the voltage and can detect the voltage below which oxides do not repassivate. These results also show the upper potential (for 316L SS and CoCr) where the oxides begin to lose their passivating ability (note Ti surfaces do not exhibit a similar effect – the oxides on Ti surfaces repassivate up beyond 1000 mV). Goldberg and Gilbert[54] found that the addition of proteins increase the repassivation time constants from about 1–2 ms to about 4–5 ms. The effect of voltage on the peak scratch current for Ti and CoCr surface in PBS are shown in **Figure 20**. Here, one can see that Ti does not show scratch currents below −1 V, while for Co–Cr–Mo the cutoff is −600 mV.

1.103.9.2. The Consequences of Mechanically Assisted Corrosion *In Vivo*

There are numerous reports of severe corrosion in metallic biomaterials when mechanically assisted corrosion processes are present. These began many decades ago in the study of retrieved fracture fixation devices.[56] Starting in the early 1990s evidence of modular taper corrosion began to appear in retrieved components. This form of corrosion has since been found to occur for all major alloy types, regardless of the alloy combination and can occur in stainless steel modular intramedullary rods.[57] The consequences of this type of corrosion include induction of osteolysis. It is important to note that osteolysis can be induced even in the absence of any other source of particles. Examples of modular taper corrosion are shown in the micrographs of **Figure 7**. Numerous types of corrosion processes have been observed including pitting attack of 316L SS, CoCr and Ti, selective dissolution from CoCr, and intergranular corrosion of CoCr ultimately leading to fracture.[58] In a recent study, we were able to show that such

severe, low pH conditions could be developed with Ti–6Al–4V and that hydrogen uptake and embrittlement are possible *in vivo*.[21]

There have been studies of the mechanism of mechanically assisted corrosion[59–61] of modular tapers where laboratory experiments were performed with electrochemically instrumented total hip replacements. Here, modular hip implants were placed into a cyclic loading condition and the head–neck junction was isolated in terms of its electrochemistry. The current generated at the taper, and the overall shift of the implant voltage can be directly measured in these tests. Typical results from such an investigation shows currents that are biphasic in relationship to the applied load (i.e., currents increase on the increasing and decreasing loading phases of the loading cycle). The voltage of the overall device shows a progression to more negative potentials as the loading increased. This overall shift in potential can be explained by the increased rate of oxidation that occurs due to repassivation and ionic dissolution through the breached zone. This increases the number of liberated electrons present, lowering the potential and increasing the reduction currents until they can consume the free electrons. As long as the mechanically assisted corrosion increases the oxidation rate, the potential of the implant will become more cathodic (negative) to increase the reduction rate and maintain quasi-equilibrium. The overall change in implant voltage will depend on the extent of oxidation currents and the area available for reduction reactions to consume the generated free electrons. If the overall reduction area available is small, or the overall area fraction abraded is large, then the voltage shifts will be much larger and can approach −1000 mV or more depending on the material.

Thus, an important result that must be clearly understood is that when metallic implants are loaded and their oxides are abraded, the voltage of the implant *in vivo* can vary through a wide range of potentials. This result is very important in terms of how the biological milieu reacts to these voltage excursions. Large negative potentials may have adverse effects on the local adsorbed proteins and any adjacent living cells (see below).

1.103.10. Effects of Prior Electrochemical History

Oxide thin films on metallic biomaterials, as can be seen from the above, are complex and affected by a complex set of behaviors and reactions. This complexity is compounded by several other factors related to the biological milieu. The main medical alloys, namely Ti-alloys (Ti–6Al–4V, cp-Ti, NiTi, TiAlNb, TMZF), Co–Cr–Mo, stainless steels, Zr alloys, Ta alloys, etc., all form oxides via the high-field growth behavior. In several of these cases, the oxide is dominated by a single chemistry (e.g., cp-Ti has TiO-based oxides) and in others the chemistry of the oxide is variable and comprised of more than one cation (e.g., Co–Cr–Mo oxides, Fe–Cr–Mo oxides, etc.). A few words related to the chemistry of these medical alloy oxides is in order. Ti-oxides are thought to be comprised primarily of TiO_2 type oxides with some reduced oxides possibly present toward the metal–oxide interface (e.g., Ti_2O_3, TiO, etc., Pan *et al.*[62]). Indeed, titanium is known to have a number of reduced forms of oxides that are possible[44] and these may arise within the thin film depending on the voltage conditions. For Co–Cr–Mo oxides, the chemistry of these oxides can vary from predominantly Cr_2O_3 to mixed oxides of Cr_2O_3, CoO, etc. Through-thickness and lateral variations of the chemistry of these oxides are possible. Indeed there is some evidence that prolonged exposure of Cr-containing alloy oxides will tend to become more enriched in Cr-oxides than in the other elements due to the strong passivating tendency of Cr on the surface.[63] NiTi surfaces are also known to show changes in oxide chemistry with prior electrochemical treatment and immersion with the Ni constituent becoming depleted with time and leaving behind primarily TiO_2.

Another important parameter that affects the oxide chemistry and properties is what can be referred to as the 'prior electrochemical history,' by which is meant the voltage–solution–time history of the surface. Electrochemical history will also affect oxide thickness, chemistry, and properties. For example, anodization of Ti using high voltage will lead to the growth of oxides. However, many other electrochemical histories should be acknowledged. For example, mechanical abrasion of oxides is known to induce significant shifts toward cathodic potentials, and sustained cathodic bias can dramatically reduce the impedance of the oxide surface and will alter its electrochemical interaction with the biological system as a consequence. Our recent work has shown that oxide growth in solution will depend on the enforced voltage applied across the metal–oxide–solution interface. In fact, oxide growth during repassivation processes will depend on the voltage across the interface. Electrochemical scratch test methods have shown that there are potentials above which oxide films repassivate and below which they do not (see **Figure 20**). For Ti surfaces, this voltage is about −1000 mV while for Co–Cr–Mo it is about −600 mV (vs. Ag/AgCl).

Another aspect of electrochemical history has to do with the hydration processes associated with oxide thin films.[4,64] Here, we know that when oxides go from nonhydrated to hydrated, the surface morphology of the oxides is altered and this likely indicates additional changes in structure, chemistry, and properties of the oxide films. This hydration process is voltage dependent.

1.103.11. Oxide Film Structure and Formation

Oxides grow in processes that depend on the substrate crystal structure, the relative mismatch between oxide and metal (i.e., the so-called Pilling Bedworth ratio of volume of oxide per cation to volume of metal per atom). Typically the PD ratio is greater than 1 and thus the oxide film tends to be put into compressive residual stress as it grows from the metal. These stresses and the lattice mismatch can result in different types of oxide growth which can be categorized as layer-by-layer growth (Frank–Van der Merwe), Island growth (Volmer–Weber), and layer-by-layer followed by island growth (Stransky–Krastinow). Ti-oxide on titanium appears to be governed by the third mechanism and results in a compressive residual stress in the oxide. These stresses and the general mechanics of the oxide–metal interface are important in terms of dictating the resistance of the surface to mechanical abrasion. For example, Ti-oxides are relatively poorly adhered to their metallic substrates while CoCrMo oxides are highly

adherent. This difference, along with differences in metal modulus, work hardening, and metallurgical state, is a main reason why Ti surfaces do not work well as wear surfaces, while CoCr surfaces are excellent. Thus, the mechanics of these thin films are important in terms of the overall electrochemical behavior in the biological milieu.

1.103.12. Effects of Solution Redox System

The biological milieu may have significant effects on the overall electrochemistry of the interface and the susceptibility of the metal to corrosion. In particular, the biological system can bring to bear large quantities of superoxide anions and other ROS when it is stimulated by any number of factors (e.g., particles, ions, infection, recent implantation, etc.). The role and effect of ROS-based species on the corrosion of implant surfaces has not been well studied even though there have been efforts to modify Ti oxides with hydrogen peroxide, and there have been studies of the catalytic effect of oxides on reduction of super oxide anions.[65] Montague *et al.*[66] looked at the effect of H_2O_2 on fretting corrosion and found increased corrosion rates in the presence of H_2O_2. Recent work by the author has shown that hydrogen peroxide, in conjunction with cathodic conditioning voltages can induce selective dissolution of the beta phase of Ti–6Al–4V[16] with the proper combination of hydrogen peroxide concentration and prior voltage history. Recent retrieval studies have shown severe pitting of Ti–6Al–4V alloys which appears to have the features of selective dissolution of the beta phase present (see **Figure 21**). Thus, conditions which give rise to large inflammatory responses may add to the factors that lead to severe corrosion attack of these alloys. To demonstrate this effect, we tested Ti–6Al–4V in PBS solutions containing various levels of hydrogen peroxide. The resulting polarization plots (**Figure 21**) clearly show that there are increases in corrosion sensitivity with moderate increases in hydrogen peroxide levels (0.003 M) and as the molarity of the solution increases, the corrosion rates increase, as do the reduction currents (depending on the voltage applied). Thus, it is likely that ROS-based chemistry will significantly affect the corrosion characteristics of the alloys *in vivo*.

1.103.13. Biological Consequences: Oxidation and Reduction

It is clear that the main known consequences of corrosion of implant materials are the effects of the metal ions (cations) and particles that result from the oxidation half-cell. Clearly these ions and particles have serious biological consequences which we are only now beginning to understand. For example, metal ions and particles can themselves induce osteolysis in adjacent bone. Metal ions can have both immunogenic effects and inflammatory effects. Recent work by Caicedo *et al.*[67] have indicated that there may well be a new pathway of effect of metal ions beyond the simple and simplistic metal sensitivity ideas described to date. Also, in recent reports related to hip resurfacing arthoplasty, Clayton *et al.*[68] indicate that severe pseudotumor formation can occur adjacent to the metal-on-metal articulating implants used in these applications.

Clearly, cations and particles are deleterious to the biological milieu and more work is needed to fully understand the consequences of their presence both in the peri-implant space, and more systemically. However, there are other potential consequences to the electrochemistry of metallic biomaterials that have been ignored or not appreciated until recently. This includes the reduction half-cell reactions and their consequences on the adjacent biology. Gilbert *et al.*[69] published a paper: "The reduction half-cell in biomaterials corrosion" which looked at the consequences of having increased reduction reactions at an implant surface. In that work, it was shown that oxygen levels can be significantly altered as the voltage of the implant became more negative and they were virtually

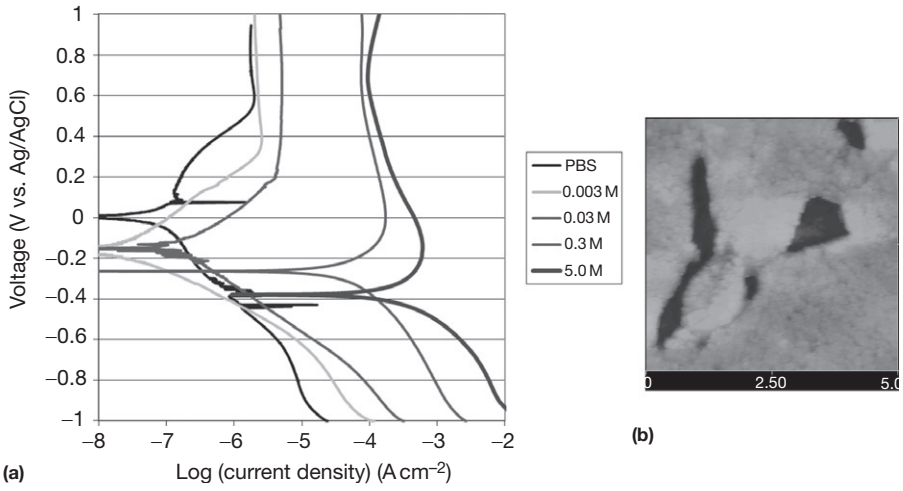

Figure 21 (a) Polarization plot for Ti–6Al–4V in PBS with varying levels of H_2O_2 present representing different levels of inflammatory species. Note that even 0.003 M solution increased oxidation and reduction currents and at high concentrations (over 0.3 M), the surface became very active. (b) 5 um AFM image of Ti–6Al–4V after exposure to 0.3 M H_2O_2 showing selective dissolution of the beta phase and thickening of the oxide film.

depleted at −1000 mV. This severe potential was also shown to have adverse (albeit not well characterized) effects on bone-like cells cultured directly on Ti surfaces held at −1000 mV for 2 h. Recent work, by Ehrensberger and Gilbert,[11] has revisited this study to show that Ti is NOT 'the most biocompatible' material, as is mentioned in virtually all scientific articles on this material, when the voltage of the surface is controlled and held below −300 mV (vs. Ag/AgCl). That is, if bone-like cells are cultured on cp-Ti surfaces held at fixed potentials, the cells will die when the potential is held below −300 mV for prolonged periods (see **Figure 22**). Here, MC3T3 cell viability was assessed using an MTT assay and showed that cells cultured below −300 mV for 24 h died, whereas cells on cp-Ti above −300 mV were not affected. Cell death can be induced in as little as 2–4 h when the potential is held below −600 mV.[70] This work shows that reduction reactions ongoing at an implant surface can induce bone-like cells to die if they are adjacent to the polarized surface. This is in contrast to the well know DC electrical bone stimulation devices which apply a cathodic bias via electrodes in proximity to a fracture non-union and are shown to induce bone formation.[71,72] Clearly, there are differences in the two situations. In DC stimulators, the electrodes are near to, but not in contact with the cells, and the entire living system was available to respond to the electrodes, whereas the *in vitro* tests were more constrained. *In vitro* is clearly not representative of the biological milieu. Nonetheless, these *in vitro* studies clearly point to the strong effects that reduction currents and reduction potentials have on the biological system (see **Figure 22**, from Ehrensberger and Gilbert[11]).

Thus, the paradigm of metallic biocompatibility needs to be reconsidered to include the strong effects reduction reactions have on the biological system. These effects have not seen significant investigation as most biocompatibility studies have focused only on the products of oxidation and not the consequences of reduction currents ongoing at implant surfaces. There are numerous ways that the biological system can be affected by reduction currents. Protein adsorption and blood clotting,[39,40,73] for example, are known to be sensitive

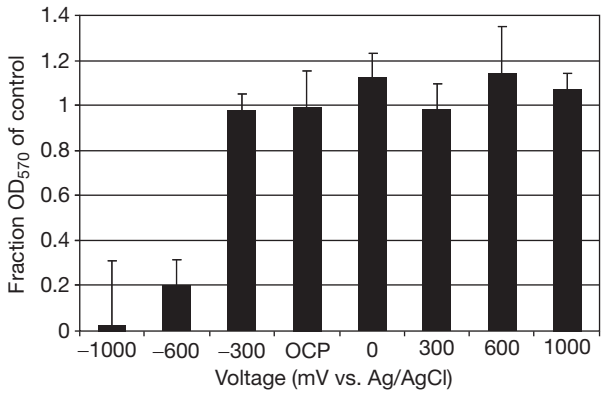

Figure 22 MTT viability assay for MC3T3-E1 cells cultured on cpTi for 24 h at different voltages. Viability was compared with a tissue culture plastic control. Note that the cells were viable for 24 h for voltages between −300 and +1000 mV. An approximate 80% decrease in viability was shown between −300 and −600 mV. Reproduced from Ehrensberger, M. T.; Gilbert, J. L. *JBMR-A* **2009**, with permission from J. Wiley and Sons.

to the potential of the interface. Electrochemical atomic force microscopy studies have recently shown[39,40] that voltage affects the rate and morphology of fibrinogen adsorption. Stankovich and Bard,[74] showed that proteins are susceptible to reduction reactions; in particular, the disulfide bonds that often make up the backbone of the protein can be reduced to sulfur–hydrogen bonds. The possibility of alteration of adhesion proteins, amino acids, membrane potentials, and behavior, as well as the possibility of direct charge transfer into the living cell may all act to disrupt and alter cellular life processes. As degradable metals (e.g., Mg) whose OCP can range as low as −1.5 V are being considered for implantation, the increased reduction reactions that will accompany the use of these alloys need to be carefully and completely understood. At present, there is very little known about the effects of reduction on the biological milieu because of the lack of appreciation of its consequences and a lack of understanding of how implant voltages and oxidation reactions may give rise to large increases in reduction reactions.

1.103.14. Summary

This chapter has attempted to provide a broad background and underpinning to the theory and behavior of metallic biomaterials and their electrochemical behavior in the biological milieu. The surfaces of these materials are highly complex, governed by numerous high energy and dynamic processes that can elicit significant effects within the biological system. To understand metallic biomaterial surfaces, one needs to appreciate the oxide thin film, its semiconducting properties, its high electric field growth characteristics, the consequences of its mechanical breach, and the processes and events that can occur when these surfaces are exposed to the biological milieu. In real medical devices where high cyclic loads are applied throughout the life of the device, the metal surface can be exposed to severe environments that can lead to severe corrosion and even hydrogen embrittlement. Understanding how these processes arise and what factors govern their appearance may help in designing surfaces that are better able to withstand the harsh and unforgiving conditions developed by the body. Recent work has been presented that shows that the consequences of the oxidation reactions (i.e., ions and particles) can have significant deleterious effects on the biological system and that the Faradaic currents themselves and the associated reduction reactions that are present may have profound effects. This leads to a new paradigm of metallic biocompatibility where it is not ONLY "the more corrosion resistant the more biocompatible" that defines the success of these devices. Oxidation AND reduction are both important and mechanical factors, in conjunction with biologically based reduction processes, may result in severe attack and degradation of metallic medical devices.

1.103.15. Appendix: Derivation of Mott–Schottky Equation

The Mott–Schottky equation comes from an analysis of the space-charge layer in a semi-infinite oxide adjacent to a surface

charge – much like the analysis of the electrical double layer in a solution adjacent to a charged surface.

Starting with the 1D Poisson's equation for the voltage distribution in a charged material

$$\frac{d^2V}{dx^2} = -\frac{\rho}{\varepsilon\varepsilon_o}$$

where ρ is the charge density, ε is the dielectric constant, and ε_o is the permittivity. For a semiconductor, the charge density for an n-type semiconductor can be approximated as

$$\rho = eN_D\left(1 - e^{-\frac{eV}{kT}}\right)$$

Thus, Poisson's equation becomes

$$\frac{d^2V}{dx^2} = \frac{eN_D}{\varepsilon\varepsilon_o}\left(1 - e^{-\frac{eV}{kT}}\right)$$

Using the identity

$$2\frac{dV}{dx}\frac{d^2V}{dx^2} = \frac{d}{dx}\left(\frac{dV}{dx}\right)^2$$

Integrating (with $V = dV/dx = 0$ in the bulk) yields

$$\left(\frac{dV}{dx}\right)^2 = \frac{2eN_D}{\varepsilon\varepsilon_o}\left(V - \frac{kT}{e}\left(1 - e^{-\frac{eV}{kT}}\right)\right)$$

Using Gauss' law for a charged surface

$$\frac{dV}{dx} = \frac{Q}{A\varepsilon\varepsilon_o}$$

The space-charge layer forms when V deviates from the flat-band potential (V-Vfb), and the capacitance is defined as

$$C = \frac{dQ}{dV}$$

which yields the Mott–Schottky equation:

$$C^{-2} = \frac{2}{A^2\varepsilon\varepsilon_o eN_D}\left(V - V_{fb} - \frac{kT}{e}\right)$$

Glossary

Hysteresis The lag in response exhibited by a body in reacting to changes in the forces.

Minimally invasive procedure Any procedure (surgical or otherwise) that is less invasive than open surgery used for the same purpose.

Orthodontics The dental specialty and practice of preventing and correcting irregularities of the teeth.

Pseudoelasticity An elastic (reversible) response to an applied stress, caused by a phase transformation between the austenitic and martensitic phases of a crystal.

Shape memory alloy An alloy that 'remembers' its original, cold-forged shape, returning to the predeformed shape by heating.

Stent A wire metal mesh tube used to prop open an artery during angioplasty.

Abbreviations

Af	Austenite finish
As	Austenite start
BFR	Bend and free recovery
COF	Chronic outward force
CT	Computed tomography
DSC	Differential scanning calorimetry
HAZ	Heat-affected zone
ISM	Induction skull melting
Mf	Martensite finish
MRI	Magnetic resonance imaging
Ms	Martensite start
NiTi	Nickel–titanium
PBS	Phosphate-buffered saline
RRF	Radial resistive force
SFA	Superficial femoral artery
SHS	Self-propagating high-temperature synthesis
SMA	Shape memory alloy
SVG	Saphenous vein graft
TTT	Time–temperature–transformation
VAR	Vacuum arc remelting
VIM	Vacuum induction melting

1.104.1. Introduction

This chapter will provide an introduction to shape memory alloy (SMA) systems with an emphasis on nickel–titanium alloys. Unique performance characteristics and manufacturing technologies will be reviewed, followed by a description of significant applications in cardiovascular, orthopedic, and orthodontic fields. Long term *in vivo* durability of the material will be addressed, including fatigue and corrosion performance, as well as biocompatibility aspects.

1.104.2. Fundamentals of Shape Memory Systems

The unique properties of SMAs revolve around what is known as the martensite transformation, whereby a solid state change from one phase to another is induced through a change in temperature or stress. Irrespective of the alloy system, the higher temperature phase is identified as austenite, while the lower temperature state is martensite. The transformation is diffusionless, with no long-range diffusion of atoms, but is instead due to a small, but long-range, shift in the crystallographic structure. In most commercial SMAs, the crystal structure of the austenite is a cubic B2 or caesium chloride (CsCl) while the martensite is a more complex twinned monoclinic structure. The transformation is thermoelastic, with the martensite structure growing continuously as the temperature is reduced and converting back to austenite as the temperature is reversed. It is first important to note that the transformation itself does not provide shape change, but it does provide the twinned martensitic structure that is central to shape memory and superelastic behavior. At a microstructural level, this twinned martensite structure has a platelike appearance. From a crystallographic perspective, the opposing sides of the twin boundaries of the structure are mirror images of each other. Figure 1 schematically illustrates the austenite-to-martensite transformation, with changes in temperature. In addition, this diagram demonstrates how the transformation is exploited to bring about macroscopic shape changes. When the structure is deformed in the martensite condition, the twin boundaries readily shift such that the twins are predominantly oriented in one preferential direction; this process is known as de-twinning. In the case of the NiTi system, twinned martensite can be deformed to a strain of ~8%, and importantly, this is achieved with no dislocation movement or the development of slip bands. If the strain goes beyond this, the de-twinned martensite will start to elastically deform and ultimately plastically deform. Upon heating of the deformed martensite, the structure reverts to austenite as it becomes more thermodynamically stable; in doing so, the deformation induced in the martensite fully recovers with the material returning to its undeformed state – thereby giving the shape memory effect. Once the shape has recovered, thermal cycling will not cause further shape change, and the material would need to be deformed in the martensitic state again in order to reactivate the effect.

The transition between the two phases does not occur sharply, but is typically spread over several degrees with proportional volume fractions of the phases coexisting within this range. The other feature of note is that the 'forward' and 'reverse' transformations do not occur at the same temperature, that is, the austenite-to-martensite change occurs at a lower temperature than the reverse martensite-to-austenite transition. This hysteresis effect and the incremental nature of the transformation are both schematically shown in Figure 2. The critical temperature points here are the austenite start (As), austenite finish (Af), martensite start (Ms), and martensite finish (Mf). These characteristic temperatures are central to most discussions on SMAs and are critical in accurate specification of the materials.

The shape memory effect now described could be considered as being primarily a thermal memory in that application of heat activates the deformed martensite to change shape. However, a mechanical memory effect is also achievable, with martensite being stress induced by deformation of the material in the austenite condition. At a crystallographic level, the transformation is the same as thermally inducing martensite, and therefore recoverable strains of up to ~8% can also be achieved in this manner. In effect, the stress is transforming the austenite into martensite and immediately de-twinning the martensite, to provide the high levels of deformation. Once the stress is released, the material reverts to the more

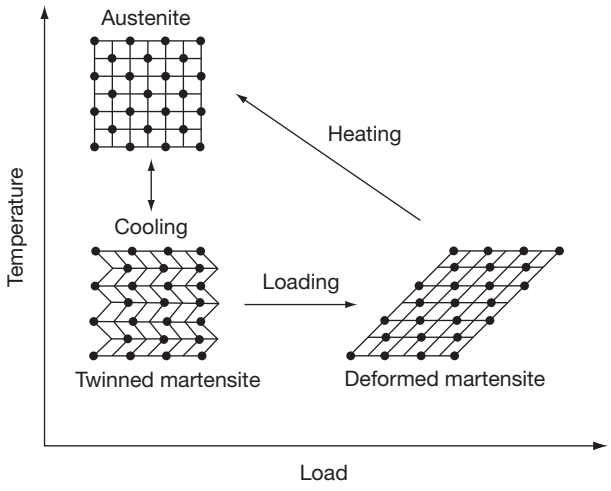

Figure 1 Schematic of the shape memory effect, showing the influence of temperature and stress on the crystal structure and shape.

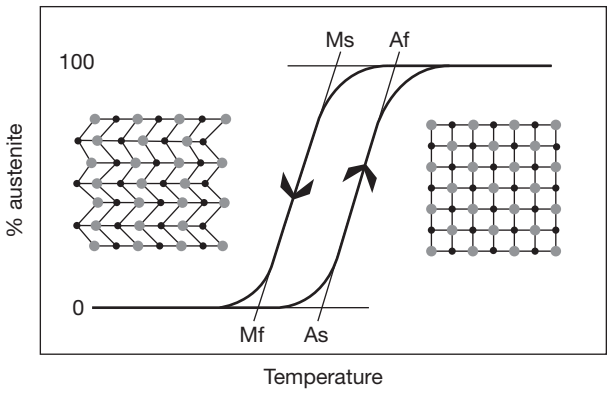

Figure 2 Transformation temperatures and the hysteresis effect.

thermodynamically stable austenite condition and the induced deformation fully recovers. While the mechanism of attaining this level of recoverable strain is not hookean or elastic, the effect is most widely known as superelasticity or is occasionally known as pseudoelasticity. Similar to that already described for thermally induced martensite, if the level of recoverable strain is exceeded, the stress-induced de-twinned martensite will start to deform elastically and ultimately deform plastically.

Just as there is a hysteresis effect with thermally induced transformations, there is similarly a hysteresis when the transformation is stress induced. This superelastic hysteresis is illustrated in **Figure 3** which shows the superelastic strain being induced up to Point A. If the stress is released, the hysteresis can be seen, whereby the superelastic strain recovers at a lower stress level than at which it is induced. These stress levels are respectively identified as the loading and unloading plateau stresses. If the material is stressed above the load plateau, the de-twinned martensite elastically and plastically deforms and ultimately fails, as indicated by Point B in **Figure 3**.

There is, however, an optimum temperature range over which superelastic behavior is observed. The stresses required to induce martensite and de-twinning are lowest at the Af point; at increasing temperatures above Af, the austenite becomes more thermodynamically stable such that higher stresses are required to transform the material to martensite. This has the effect of raising the level of the load and unload plateaus and it can therefore be seen that shifting the Af point, relative to the operating temperature, is one method of influencing mechanical capability of the material. At higher temperatures, a point is reached where the austenite is so stable that martensite cannot be stress induced and the austenite starts to deform by conventional slip mechanisms with no superelasticity present.

In summary, it can be seen that the structure and behavior of shape memory materials is highly dependent upon the inherent transformation temperatures of the material, as these in effect control the materials' response to applied stress and temperature. For example, a material which operates typically in the shape memory mode can be made to behave superelastically by either reducing Af or increasing the ambient temperature. This introduction to the principles of shape memory and superelasticity is brief, but is sufficient background for the biomaterials scientist or engineer needing to get an appreciation of medical applications for the materials. There is an extensive quantity of literature available describing the crystallographic and mechanistic aspects of the underlying transformations; the reader is referred to the reviews of either Wayman and Duerig[1] or Hodgson *et al.*[2] for further introductory material on these aspects.

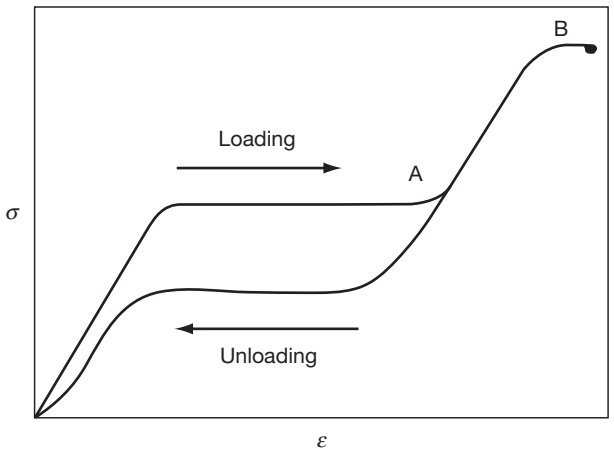

Figure 3 Superelastic behavior for a material above its Af temperature.

Finally, a brief mention needs to be given to the two-way shape memory effect. As indicated earlier, shape memory is primarily a one-way process, that is, after heating and recovery of deformed martensite, no further shape change will be obtained unless the cooling and deformation step is repeated. Under certain conditions, some shape memory materials can be processed to give a two-way memory effect, such that the material changes shape solely due to control of temperature. Extensive thermomechanical treatments are needed to induce this behavior, usually involving thermal cycling, from below Mf to above Af, with the material constrained in one of the configurations required.[3] Applications for this effect have, however, been limited due to the relatively low recoverable strain achievable (typically <3%) as well as the loss of the effect with increased thermal cycling.[4] The majority of commercial medical device applications for shape memory materials rely on the conventional one-way effect and on superelasticity.

1.104.3. Practical SMAs

There are several alloy systems that exhibit shape memory effects, though very few have achieved successful engineering application; fewer still have been used in medical device applications. There are a number of copper-based shape memory systems, with Cu–Zn–Al and Cu–Al–Ni being the most commercially successful. Copper-based alloys have traditionally been viewed as relatively inexpensive due to low raw material costs and easy processing. These materials have found applications mainly in engineering actuators;[5] however, a Cu–Al–Mn alloy has been utilized for development of a cardiovascular guidewire, exhibiting ductility and superelastic properties similar to conventional guidewire materials.[6] There are also a number of iron-based shape memory materials, including Fe–Mn–Si and Fe–Mn–Si–Cr–Ni, though these materials tend to have low recoverable strain and require complex thermomechanical treatments.[7]

However, by far the most significant SMA to date is that based on equiatomic and near-equiatomic nickel and titanium compositions. These NiTi materials have accounted for the majority of commercial applications, particularly in the medical device industry, and this trend is likely to continue. NiTi has been successfully used in engineering actuator applications since the 1970s, but it was not until the early 1990s that its potential in the medical device field started to become realized. The material was originally developed at the US Naval Ordnance Laboratory, leading to it being now widely known as NiTiNOL. The early historical development of nitinol is reviewed by Kauffman and Mayo,[8] presenting a unique insight into the somewhat fortunate discovery and initial development of the material.

From a metallurgical perspective, NiTi is classified as an intermetallic material with the respective atoms bonded to each other in a long-range ordered structure; this is unlike many common alloys where the solute atoms randomly substitute for atoms of the solvent crystal structure or sit in the interstices of the crystal structure. The properties and performance of the material are highly sensitive to the ratio of nickel and titanium and therefore the composition needs to be very tightly specified; the most widely used NiTi material has 50.8 at.% nickel and 49.2 at.% titanium. In addition to thermomechanical treatments, small adjustments in this composition can be used to shift the characteristic transformation temperatures of the material.

1.104.4. Manufacturing, Processing, and Performance of Nitinol

1.104.4.1. Melting Methods and Compositional Effects

Normally, details of melt practices and compositional control are of little interest to the scientist or engineer developing specific medical device applications. However, given the high sensitivity of NiTi to these particular aspects, a brief review is useful. NiTi is most usually produced by either vacuum induction melting (VIM) or vacuum arc remelting (VAR). The VIM process involves placing the charge materials in a graphite crucible and applying heat via external induction coils. The stirring effect of the induction field leads to highly homogenous melting and mixing; however, the main disadvantage of this method is that the material tends to pick up small amounts of carbon from the graphite crucible. This usually results in the formation of TiC inclusions. The VAR process involves compacting the charge materials into a consumable electrode and striking an arc between this electrode and the base of the crucible. The crucible is copper lined, with water cooling, eliminating the risk of carbon contamination. As molten metal is formed, the relative electrode position is adjusted, thereby moving the molten zone along its length; this has the effect of pulling all impurities into the final molten zone (which can be discarded), leading to a very high-purity material. The main disadvantage of the VAR process is that only part of the ingot is molten at any one time, thereby resulting in less alloy homogenization than is possible with VIM. This creates the risk of transformation temperature variations throughout the material; multiple repeat VAR steps can be used to address this aspect. A VIM/VAR combination process can also be used to produce NiTi, with the initial homogenous induction melted material being remelted to reduce impurities. However it should be noted that contamination from oxygen is also highly detrimental to NiTi materials and each additional melting or remelting step increases the risk of such contamination. The potential benefits of an induction skull melting (ISM) process have been reported by Kramer.[9] ISM has features of both VIM and VAR in that the charge is induction melted within a copper water-cooled crucible. As the charge melts, a thin solidified skin or 'skull' forms at the crucible walls, around the material, protecting the molten material from contamination. Exceptionally high power is needed to achieve induction effects through the copper crucible, but a clean and homogenous material is achieved. The study by Kramer did show that the ISM material had a lower carbon content and a lower number of overall inclusions, compared to VIM material, but the inclusions tended to be larger in size. This was attributed to nonoptimized forging of the ISM material, which would be further addressed. In any event, it is important to note that ISM is not yet used to manufacture commercial material and the VIM and VAR processes are being widely and successfully used. However, in instances where composition and inclusion content becomes critical to fatigue, corrosion, or transformation temperatures, then an insight into these melting options can be useful.

While the effect of contaminants and inclusions on aspects such as fatigue may be widely appreciated, the secondary effects are more subtle, though just as significant. To appreciate this it must first be realized that shifting nickel content (to a Ni-rich composition) by only 1.0% can decrease transformation temperatures by as much as 100 °C, also illustrating how composition may need to be controlled to levels of 0.01% to achieve sufficient control on transformation behavior.[10] This is schematically illustrated in Figure 4.

Most impurity elements, including oxygen and carbon, tend to preferentially react with the titanium, creating titanium-based inclusion compounds. This leaves the adjacent matrix material richer in nickel and therefore it can produce a significant drop in transformation temperatures. In addition to oxides or carbides, which are the most common, the formation of hydrides or nitrides leads to similar effects, as does the presence of trace levels of iron, cobalt, or chromium. In virtually all of these instances, the precipitated compound also results in an increase in strength, but with an associated drop in ductility.[11]

1.104.4.2. Production of Semifinished Wrought Products

After melting, the cast ingot is processed, using primarily conventional metalworking technologies, to obtain wrought

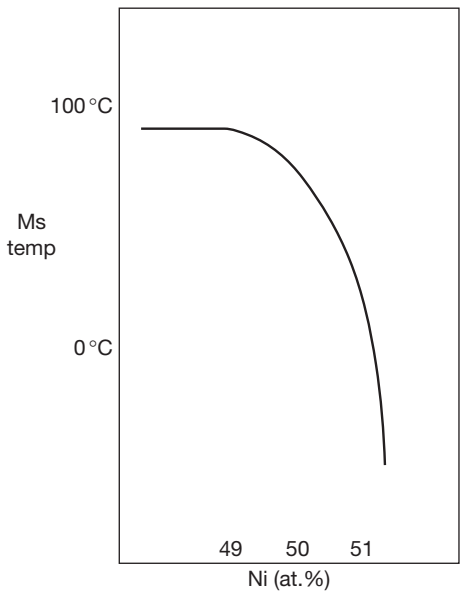

Figure 4 Illustration of dramatic effect that nickel content has on transformation temperature.

products such as wire, strip, or tubing.[12] The ingot is typically hot rolled or forged in the temperature range 800–950 °C, breaking down and refining the cast structure and thereby improving the mechanical properties. Once reduced to a suitable size, the bar or rod is further processed by cold working methods such as drawing and rolling. However, nitinol has a high work-hardening rate, and several passes with interstage anneals (600–800 °C) are needed to get the material down to the required dimensions. The final tube, wire, or strip products are usually available with a variety of polished or oxided surface finishes and there are now several suppliers worldwide. However, it should be noted that there are fewer facilities producing the original ingot material, and often, material from different suppliers can originate from a single melt source and therefore have similar melt chemistries and inclusion contents. The subsequent hot and cold working may have altered inclusion size and distribution as well as altered mechanical properties through control of residual cold work. The level of cold work is usually in the 30–45% range.

1.104.4.3. Heat Treatment to Control Performance

Cold worked nitinol does not exhibit full shape memory or superelastic behavior and needs to be heat treated to activate these effects. While the heat treatment itself is not particularly complex, there are a number of metallurgical phenomena taking place, all of which combine to control the thermal and mechanical properties of the final structure. At the most basic level, the heat treatment is used to set the final desired shape of the product, that is, the shape to which it would thermally recover after being deformed in a martensitic state, or mechanically (superelastically) recover after being released from a constrained condition. This shape setting is achieved through the annealing effects that take place during the treatment; the release of cold work through dislocation recovery allows the material to retain this heat-treated shape. In addition, the reduction in dislocation density allows for easier crystallographic movement, in particular allowing the austenite–martensite transitions to take place. Longer times or higher temperatures tend to provide better shape retention, but of course a balance needs to be achieved in order to avoid full annealing or recrystallization effects, as some residual cold work is needed in order to maintain optimum material strength levels. In addition to annealing and recovery processes, the heat treatment is also used to tune in the transformation temperatures of the material. While chemical composition and residual cold work will have already defined a window for transformation behavior, this heat treatment serves to further tune transformations to the desired level, through nucleation and growth of nickel-rich precipitates. Pelton *et al.*[13] have presented an excellent overview of these heat treatments for nitinol wire, particularly with respect to obtaining properties and transformation temperatures generally suitable for medical devices. The temperature for such treatments can range from 300 to 600 °C, though most are typically at 500 °C. Durations can be as short as 2 or 3 min or as long as 2 or 3 h, though they are typically in the 5–30 min range, depending on the temperature and the desired properties. The interaction of time and temperature and its effect on transformation temperature is explained through the manner in which the nickel-based precipitates form during the treatment, particularly for the widely used nickel-rich 50.8 at.% Ni composition. At lower temperatures, diffusion processes are slow, and while precipitates do nucleate they are slow to grow to significant sizes. Relatively long durations are therefore required to obtain measureable effects on transformation behavior. At high temperatures, the more rapid diffusion processes somewhat inhibit precipitate nucleation, with the outcome being similar to low temperatures, that is, relatively long durations are needed. Therefore, at intermediate temperatures the diffusion and nucleation process provide a better balance, leading to more rapid precipitation effects. Such heat treatment effects can be best presented in a nitinol time–temperature–transformation (TTT) diagram as shown in **Figure 5**.

In the example shown here, peak precipitation is at ~400 °C, with Af being shifted by 20 °C for durations of up to 70 min. Often however, in production environments, the slightly slower precipitation region of ~500 °C is selected in order to give less sensitivity to time deviations, that is, to give a more robust manufacturing process. This higher region is also preferred over the lower temperatures so as to ensure adequate recovery and shape setting as described earlier. The shifts in Af relate directly to the manner in which the nickel-rich precipitates deplete nickel from the adjacent material, creating a titanium-rich matrix. These nickel-based precipitates do also contain titanium, but the composition is typically such that more nickel is consumed than titanium. There are a number of different precipitates that may form, but the most predominant composition is Ni_4Ti_3; Khalil-Allafi *et al.*[14] have performed a thorough study of the formation and evolution of this Ni_4Ti_3 precipitate during aging of nitinol. In addition, analysis of precipitate volume fractions was used to calculate the extent of matrix nickel depletion and this was correlated with observed shifts in transformation temperature. With higher temperature treatments (i.e., 500–600 °C) the precipitate chemistry shifts, initially the Ni_3Ti_4 dissolves and this is followed by precipitation of Ni_3Ti_2 and Ni_3Ti. Pelton *et al.*[13] have used this precipitation sequence to explain the 'cusp' observed

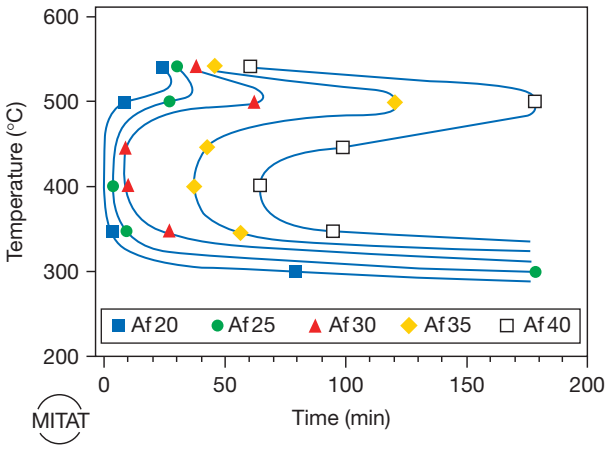

Figure 5 Time–temperature–transformation diagram for 50.8 at.% Ni–49.2 at.% Ti wire. This particular material had an Af of 11 °C before the aging treatments. Reproduced from Pelton, A. R.; DiCello, J.; Miyazaki, S. *Minim. Invasive Ther. Allied Technol.* **2000**, *9*(1), 107–118.

above 500 °C in the TTT diagrams, such as seen in Figure 5. As the Ni_3Ti_2 and Ni_3Ti become the more favored composition, they draw even more nickel from the matrix, thereby leading to an overall faster shift upwards in the transformation temperatures. Related to this, there is an intermediate set of conditions where the Ni_3Ti_4 has dissolved, but the more Ni-rich precipitates have not yet formed. This is reported by Drexel *et al.*,[15] showing lower Af values from treatments at 550 °C for 2–20 min, while obtaining similar shaped TTT diagrams. Beyond 20 min, the Af rapidly shift upwards again. The specific treatments and transformation temperature response described here will not hold for every material or device, due to influences of composition and residual cold work; however, the general trends will be observed and need to be appreciated when developing a heat treatment process and performance requirements for any device.

At this stage, a brief mention needs to be given to the R-phase, which is an intermediate rhombohedral crystal structure sometimes detected upon cooling from austenite down to martensite. The transition from austenite to R-phase is a martensitelike transformation, involving small crystallographic displacements, with Otsuka[16] describing this phase as effectively being in competition with martensite. Its presence is promoted by heat treating of cold-worked materials in the 400–500 °C range or by aging of slightly nickel-rich compositions in the same range. As with the martensite transformation, the austenite to R-phase transformation also provides for shape memory and superelastic effects. However some differences are observed, most notable being that the recoverable strain for the R-phase transformation is typically <1%, providing much less scope for actuation of engineering or medical devices. As a result, this transformation has not been widely investigated or understood. Another key difference is the low hysteresis involved, that is, the reverse transformation occurs at nearly the same temperature, unlike martensite–austenite transitions which have extensive hysteresis effects. As a consequence of its more subtle presence, the R-phase is often not clearly observed in mechanical tests of materials or devices. However, a study by Šittner *et al.*[17] suggests that it cannot be completely ignored, as a minimum in elastic modulus was observed at the Rf temperature. This could have implications for device performance should this Rf temperature coincide with the operating temperature.

Finally, some practical considerations relating to heat treatment. As can now be appreciated, the performance of any nitinol medical device is highly dependent on the temperature and duration of heat treatment. Therefore, equipment and methods need to be used that will allow sufficiently tight control over these parameters. As a general rule, techniques that allow for rapid heat up and cooling are preferred, thereby minimizing ramp-up and cool-down durations, which could lead to uncontrolled or undesired effects. Equipment such as fluidized baths and salt baths are therefore most often used, with water quenching usually employed at the end of the cycle. The other key aspect of the heat treatment is the fixturing that is used to keep the structure in the desired final shape. The design and operation of this will be specific to each type of device, but again the effect that the fixturing may have on heat-up and cool-down rates needs to be understood in order to achieve proper process control.

1.104.4.4. Characterization Methods and Some Basic Material Properties

1.104.4.4.1. Transformation temperatures

Given the extreme sensitivity of nitinol to the nickel and titanium contents, as well as to the thermomechanical history, accurate measurement and specification of performance can be challenging. While precise chemical analysis is essential at the ingot development stage, the chemistry becomes a secondary factor as the material is processed through to semifinished product and ultimately to the final device configuration. Specification of the transformation temperatures then becomes important and in many instances, for the semifinished product, these are more critical than composition. In most

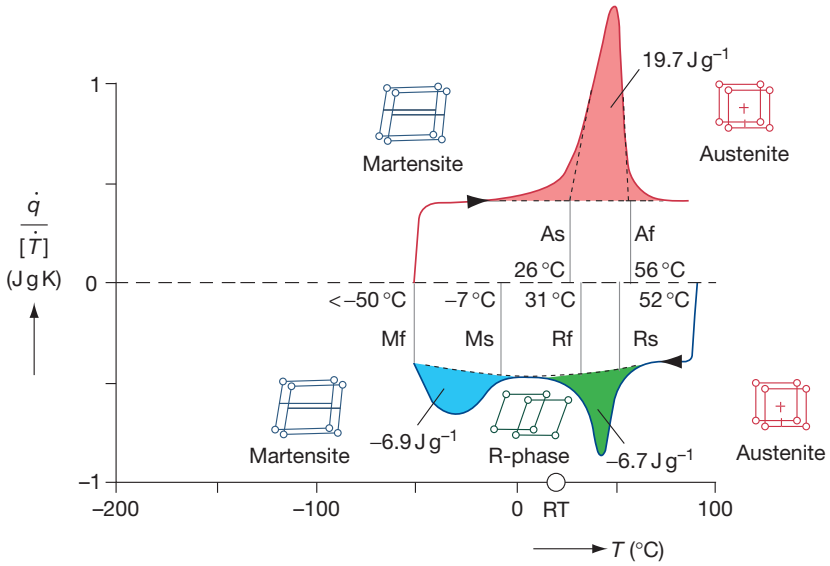

Figure 6 Schematic differential scanning calorimetry curve showing all crystal structures and transition points. Reproduced from Shaw, J. A.; Churchill, C. B.; Iadicola, M. A. *Exp. Tech.* **2008**, *32*, 55–62.

situations a high degree of interaction is needed between the material supplier and the device developer so that target transformation temperatures and mechanical properties can be accurately achieved, at the end of all the processing and shape setting steps that may be involved. The performance of wire or tubing will shift considerably during device manufacture and while a supplier will only guarantee properties of the 'as-received' material, knowledge of the subsequent processing will allow better tuning of earlier thermomechanical treatments so that the desired performance can be achieved. Agreement on the specification and on measurement method for transformation temperatures is therefore essential. Normally the Af point is the most important to specify for medical devices, that is, for shape memory actuation, the Af may need to be below body temperature and the difference between the two temperatures may define the level of the actuation force obtained. In many instances, the start and finish temperatures for both austenite and martensite phases may be specified.

Differential scanning calorimetry (DSC) is widely used for measurement of all the transformation temperatures, usually scanning down in temperature first to capture Ms and Mf and then scanning up to record As and Af. **Figure 6** schematically presents a typical nitinol DSC curve, also showing the presence of R-phase.

While DSC methods are widely used for measurement of thermal events in many materials, there are several test factors that can influence the data obtained. Marquez *et al.*[18] and Shaw *et al.*[19] have presented detailed reviews of the critical factors involved in nitinol sample preparation and in test parameters. For example, care must be taken not to induce additional cold work into the sample during preparation and oxides should be removed as they may impact heat transfer during the test, thereby affecting the measured transformation values. High heating rates can give sharp peaks, but may induce hidden thermal lag effects, leading to inaccurate values. In any event, scope for discrepancies have been reduced in recent years with the introduction of an ASTM,[20] specific to nitinol. This method, and the technique in general, does however have limitations in that it is really only suitable for material in an annealed condition and does not well capture effects of residual or applied stress, which on a macroscopic scale can increase transformation temperatures.

An alternative approach for measuring transformations is to use what are known as 'active' methods. These are active in the sense that they measure recovery motion on a sample as it transforms from martensite back to austenite. It is, therefore, more appropriate in many situations where the ultimate performance of a device involves shape memory or superelastic actuation at a given temperature; it is a more direct measure and captures the complete processing history of the sample or device. It is, therefore, suitable for use on as-received semifinished material or on processed devices. Rice and Sczerzenie[21] initially developed such a technique for wire samples while Chen *et al.*[22] developed a similar approach for tubes and cylindrical stent structures. The methods simply involve cooling of the sample to the martensite phase and deforming to a controlled strain, followed by heating back up to above the Af temperature. As the sample heats up and the material transforms, it recovers to its original shape. A transducer is used to measure this recovery motion, giving a plot of displacement versus temperature. The precise profile of the curve will of course depend on the sample configuration and the nature of the deformation or strain imparted to it, but typically the austenite transformation points, both start and finish, are readily identified. **Figure 7** illustrates this schematically. The test can also be used to detect R-phase transition points, if these are present in the material.

As the actual measured Af is dependent on the applied strain, it is always advisable to use a method that captures strain and motions representative of how the device will be clinically used. For example in the case of stents, it can be useful to deform the stent to a configuration similar to that which it may experience when loaded in a delivery system. As with the use of DSC, an ASTM[23] has been developed to provide guidance and consistency for performing these tests. Of note, the methods are generally known as bend and free recovery (BFR) tests, to distinguish from methods that involve recovery into a constrained configuration. (In these tests, the force generated by a recovering but constrained sample is measured, to discern the transformation points.) Drexel *et al.*[24] have performed a critical evaluation of the ASTM BFR method, highlighting and assessing the key test variables; overall, this study confirmed the value of the test and the standard methodology. Finally, it should be noted that transformation temperatures measured by DSC are not likely to correspond exactly with those obtained by BFR methods, though correlations may be established. Either method can be used for specification purposes, once the merits of the respective approaches are appreciated.

In relation to specific transformation temperature values, there are no standard recommendations for medical device applications; the interaction of device design, actuation forces requirements and the transformation temperature itself make each situation different. However, when considering peripheral vascular stents, currently the main medical application for nitinol, it is usual to have an Af value at least 5–10 °C below body temperature. This ensures that the device is fully

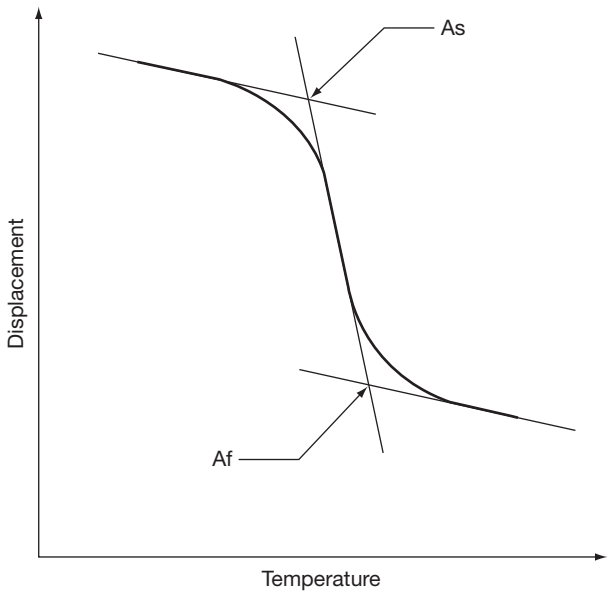

Figure 7 Displacement versus temperature curve from an active Af test, indicating the austenite start and finish temperatures.

deployed and exerting an optimum force against the vessel wall at body temperature. Depending on the profile of the austenite transformation peak, the As point may be a further 10–20 °C below the Af. In this situation, the Ms and Mf temperatures may be down in the −50 to −80 °C region. The mode of actuation obtained with these characteristic temperatures would be classified as shape memory, with the device needing to reach body temperature to achieve the precise performance required. However, it would not be unusual for devices to have much lower austenite transformation temperatures than these (i.e., Af well below room temperature), such that the deployment behavior is primarily superelastic.

1.104.4.4.2. Tensile behavior

Aside from characterization of transformation temperatures, it should now be evident that measurement and control of tensile behavior is equally important and is tightly related to the transformations. The shape memory and superelastic responses have already been described, and given the virtually infinite number of combinations on cold work, heat treatment, and composition, the literature abounds with endless data for tensile mechanical properties. In some respects these data are of little use to the biomedical scientist or engineer conceptualizing or developing a new device, unless there is some very specific aspect of this new application directly comparable to the literature. Some generalizations and useful specific examples can of course be highlighted. First however, some specific aspects of tensile testing of nitinol need mention. The shape and magnitude of the curve will of course depend on the relationship between the test temperature and the transformation temperatures, that is, whether the material is exhibiting shape memory or superelasticity. When tested in the martensitic condition, nitinol will have a relatively low elastic modulus and will superelastically deform at low load (by de-twinning of the martensite). If unloaded, the superelastic deformation will be retained but can be thermally recovered upon heating (i.e., shape memory). If loading had been continued beyond the end of the superelastic deformation point, the martensite would now start to elastically deform and ultimately fail due to tensile overload. When testing close to the Af temperature, with a predominantly austenite structure, martensite will be stress induced at the loading plateau, giving recoverable strains of up to about 8%. Upon unloading, this deformation will recover at the lower (unloading) plateau, giving the characteristic superelastic performance. Again, if loading had been continued, the martensite would then behave elastically, before plastically deforming and failing. Testing of nitinol above the Af temperature will continue to provide a superelastic effect, but the level of the load and unload plateau will increase with temperature. This increase in plateau levels with increasing temperature is due to the increasing stability of the austenite and the associated difficulty in transforming it to martensite. This is known as the 'stress rate' effect; it is widely documented, and the investigations of McKelvey and Ritchie[25] and Gall *et al.*[26] provide a detailed insight for some practical nitinol materials. With further increases in temperature, the deformation obtained is due to an increasing amount of austenite plastic deformation and reducing superelastic effect, such that some permanent set takes place when the load is released. Eventually a temperature is reached where martensite cannot be stress induced and deformation of the austenite is purely elastic or plastic. This full range of tensile behavior is shown in the set of curves presented in Figure 8.

Given the unusual tensile behavior on nitinol, compared to conventional metals, there are a number of specific issues to be aware of when performing such tests. Perhaps most obvious, but still meriting mention is that the test temperature needs to be appropriate for the intended use of the data and that the temperature needs be measured accurately. Next, monitoring of strain needs to be carefully considered to ensure that the superelastic region and any additional elastic and plastic regions are fully recorded. One of the other main potential complications arises from the thermal nature of the transitions; as austenite is stress induced to martensite, heat is given off which has the potential to influence load measurements, that is, based on the influence of temperature on load plateaus. Similarly, on reverse loading through the transition, heat is absorbed. The standard approach to addressing this problem has been to use relatively slow strain rates, allowing time for this heat to transfer to the ambient environment, whatever that temperature may be. As with other aspects of nitinol, an ASTM[27] has recently been introduced to provide guidance and consistency in all these aspects. However, Johe[28] has performed a detailed strain rate study and proposes that some of the strain rates specified in this standard are unnecessarily conservative. It is, therefore, an area in which there are likely to be ongoing revisions.

1.104.5. Minimally Invasive Device Applications for Nitinol

1.104.5.1. Cardiovascular Stents

1.104.5.1.1. Deployment considerations

The extensive use of nitinol in cardiovascular stent applications can be directly attributed to its characteristic shape memory and superelastic behavior. The possibility of achieving small compressed device configurations, inserting these with minimal trauma, and then having them recover to their larger deployed functional configuration has intrigued physicians and device designers for many years now. In addition, the unique superelastic 'durability' has made nitinol even more attractive in applications where device flexibility, conformance, and crush resistance are critical. However, to fully appreciate how nitinol is ideally suited to stent applications, the strains and loads involved during all stages of stent deployment need to be considered. Duerig *et al.*[29] have presented an excellent overview of this from the perspective of superelastic stent design, as well as introduced the concept of 'biased stiffness.' Details of stent delivery systems are beyond the scope of this chapter, but in summary, the stent is first compressed down to a small diametrical profile and retained within the delivery tube or sheath. Upon tracking of the catheter to the treatment site, the stent is deployed in the artery by either pushing out the stent or retracting the sheath. The stent is usually oversized, so that the unconstrained diameter of the stent would be larger than that of the vessel, thereby developing a force between the stent and the vessel wall which keeps the stent in position. All of these steps can be considered further with reference to Figure 9, which illustrates a plot of stent hoop force versus stent diameter. It can initially be seen that the shape of this plot mirrors the

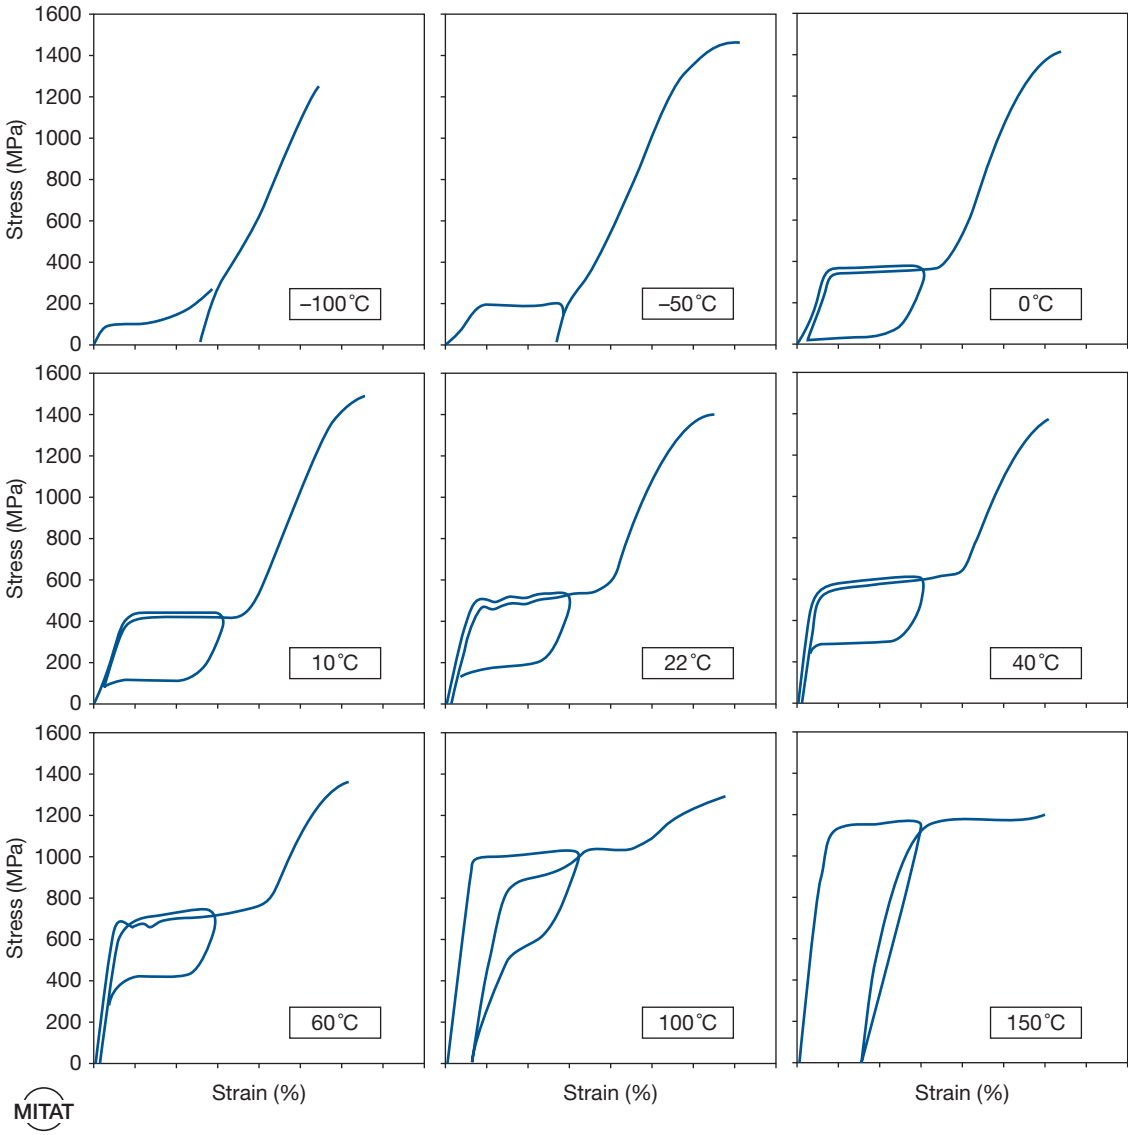

Figure 8 Influence test temperature on tensile properties, for a material with As of −22 °C and Af of 11 °C. Reproduced from Pelton, A. R.; DiCello, J.; Miyazaki, S. *Minim. Invasive Ther. Allied Technol.* **2000**, *9*(1), 107–118.

typical uniaxial stress–strain curve of superelastic nitinol. Upon loading, the stresses and strains arise from the hoop forces that develop within the stent structure as the stent is deformed during crimping into the catheter sheath. Upon unloading, the stresses and strains relax as the stent is released from the constraining catheter sheath and expands within the lumen.

As the stent is initially compressed to fit into the catheter, it deforms elastically and when the stress reaches the level of the load plateau, the superelastic deformation commences. This accounts for the bulk of the deformation strain taken by the stent during crimping. There may be some further elastic deformation of the stress-induced martensite also taking place, but this obviously needs to be controlled to avoid the risk of plastic deformation which could affect subsequent stent size and shape. As the stent is released from the catheter, the stresses drop, following the path of the unloading curve. As the expanding stent reaches the vessel diameter, the expansion process stops (Point C in Figure 9), and the opening force exerted by the stent against the vessel wall is now defined by the level of the unloading plateau. This is known as the chronic outward force (COF) and it can now be appreciated that this COF will remain constant against the vessel wall for a substantial range of oversizing, that is, depending on stent design, the difference between the vessel diameter and the unconstrained (larger) stent diameter may be range of a number of millimeters, but the force exerted will remain constant. This is an exceptionally attractive feature of stent design, that can only be achieved with nitinol; it provides some tolerance on stent sizing when selecting a device diameter to suit a particular vessel size. Furthermore, as diameters are likely to vary more in diseased vessels than in healthy ones, it gives some assurance that consistent forces will still be obtained irrespective of the vessel profile along the stented segment. This is not to underestimate the importance of vessel sizing, which is still a

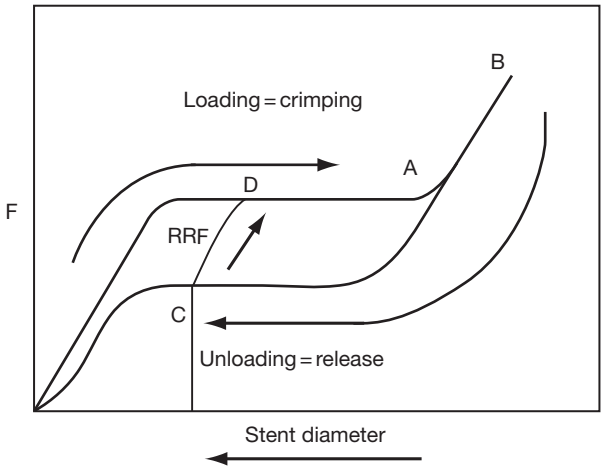

Figure 9 Superelastic stress–strain behavior for a stent (8 mm) being loaded into a catheter and then deployed with a vessel, of smaller diameter. Adapted from Duerig, T. W.; Tolomeo, D. E.; Wholey, M. *Minim. Invasive Ther. Allied Technol.* **2000**, *9*(3/4), 235–246.

critical aspect that can affect tissue response and stent fatigue life; but it does provide more consistency to designers and physicians.

Returning to Figure 9, further unique features of nitinol can be seen when the effect of external compression forces on the vessel are considered. The stent will rapidly develop a resistance to such compression forces, as stresses in the nitinol will follow the path from Points C to D, returning to the load plateau level. Therefore, depending on the magnitude of the load plateau, it can be seen that substantial resistance stresses will be generated before superelastic deformation would recommence. This is known as the radial resistive force (RRF) and essentially provides crush resistance to superelastic nitinol devices (and to shape memory-activated devices, provided they are operating above Af). This crush resistance feature is important for most stents, but is particularly significant for carotid stents. The carotid arteries have less protective tissue (bone, muscle, or organs) around them than most other stented vessels. This risk of stent deformation from external forces or injuries is therefore high and the effect could be critical, if blood supply to the brain becomes restricted. As a general rule for all stents, it is therefore desirable to have high RRF values and relatively low COF levels, highlighting the importance of measurement and control of the load and unload plateaus in the material. This ability of nitinol stents to provide different behavior depending on the loading conditions as described is known as 'biased stiffness.'

To close on deployment aspects, a brief comparison with balloon-expandable stents needs to be mentioned. When a balloon-expandable stent is deployed in a vessel, there is a small elastic recoil, as the balloon is deflated and withdrawn. This causes the stent diameter to reduce slightly and in an extreme case could result in the stent dislodging. Designers can minimize this effect through optimization of the stent pattern and design, while physicians sometimes try compensating for it through slight overinflation of the device. In any event, it cannot be fully eliminated. On the other hand, nitinol stents show no recoil when deployed in a vessel; the combination of superelastic strain and vessel to stent sizing ratio will ensure that the device exerts an outward force, keeping it fully open. This is a significant clinical procedural advantage that nitinol offers over balloon-expandable stent materials.

1.104.5.1.2. Manufacturing methods

Given the extensive use of nitinol in cardiovascular stents and bearing in mind the high sensitivity of the material to heat treatment, a brief review of stent-manufacturing processes is useful. The majority of nitinol stents are now laser cut from tubes, typically using Nd-YAG lasers. The effect of heat absorbed by the material during this process needs to be carefully considered. Schuessler[30] has presented an overview of laser processing of nitinol and has included an assessment of thermal effects in the laser cut heat-affected zone (HAZ). This HAZ can extend several micrometers deep, and metallurgical evaluations confirm the structure to be substantially altered; evaluations of Af reported by Schuessler[30] indicate that transformation temperatures can be pushed upwards by several degrees. This highlights the importance of fully removing the HAZ layer during subsequent electropolishing. Removal of laser-cutting dross and surface oxidation by electropolishing is just as essential for nitinol devices as it is for other materials. In addition to implications for fatigue and corrosion resistance, which will be described later, smooth and clean electropolished surfaces minimize thrombogenic and inflammatory responses. Electopolishing of nitinol is typically performed in mixtures of alcohols and acids, though most processes tend to be proprietary and there is a scarcity of detailed published information. Hassel[31] does briefly describe the use of nitric or sulfuric acid with methanol, or perchloric acid with ethanol, as techniques that have been successfully used. The nitric and methanol mixture is usually run at −30 °C, which in many instances will mean that the material is in the martensitic state during polishing. This leads to another interesting feature, specific to nitinol, though not widely investigated or reported; Pohl *et al.*[32] have shown that the surface finish and texture of electropolished nitinol are influenced by the crystal structure present during the process. Specifically it was shown that surfaces polished in the martensitic state develop a relief pattern, as the structure warms up and converts to austenite. While both processes were deemed to give satisfactory surfaces, it was also noted that polishing in the martensitic state seemed to give better results than processing in the austenite condition, when more material needs to be removed. Finally, electropolished devices are most often passivated, to improve corrosion resistance and enhance biocompatibility. There are many ways to implement this surface treatment, but the process objective is to remove free surface nickel and to preferentially oxidize the titanium, thereby creating a predominantly titanium oxide surface. Treatments in oxidizing chemicals such as nitric acid are widely employed, as reported by Trepanier *et al.*[33] and O'Brien *et al.*[34]

While nitinol heat treatment has already been described, the positioning of this step in the overall process flow needs to be considered. Normally, heat treatment is carried out after laser cutting and before surface finishing. This ensures that any chemical pickling or cleaning step, employed as a pretreatment for electropolishing, will remove all dross and oxides including

those oxides that may develop during heat treatment. However, the number of heat treatment steps required will depend on the tube diameter selected, relative to the desired final stent diameter. One option is to laser cut from a tube size of the same diameter as the finished stent size. This configuration requires only one heat treatment step, primarily to tune in the transformation temperatures and to impart some stress relief and shape setting. The other alternative is to laser cut from a smaller tube diameter and to gradually expand out the stent to the required diameter. This expansion may take several steps, with the stent being put on increasing-sized mandrels for each step and being given a shape setting and stress relief heat treatment each time, typically at ~500 °C. Once the desired size is achieved, the device is given the final heat treatment, to tune in transformation behavior. This has the obvious disadvantage of adding more steps to the overall manufacturing process, as well as requiring development of an initial laser cutting tool path that is different to the ultimate stent geometry required. This approach does, however, generate less scrap metal during laser cutting, and the smaller diameter tubes are also usually less expensive. Originally this sequence developed as only small diameter tubes were available, but now, even though larger tubes are readily available, some manufacturers continue with this gradual expansion route, for the reasons outlined. Aside from cost aspects, there may, however, be some device performance issues also to be considered when deciding upon the processing route. Favier *et al.*[35] compared the two routes, by simulating the different aging effects that occur in stent sections that are exposed to several such deformation and heat treat cycles and in sections that are not strained during the process. The study showed that strained and heat-treated material aged more rapidly than material that was just heat treated, thereby increasing Af at a more rapid rate in these regions. This effect can of course be accounted for during the development of an overall heat treatment schedule for a device. It does, however, point to the potential for inhomogenous material properties across the device, as well as less scope for intentional shifting of transformation temperature, if it is already being pushed upward by the expansion steps.

1.104.5.1.3. Cardiovascular stents: clinical examples

While there is a vast number of nitinol stents developed and approved, there are surprisingly few available for cardiovascular use. The majority are approved for nonvascular indications, such as biliary stenting, and do not meet the regulatory requirements for cardiovascular devices. This situation developed over time, due to off-label use of these nonvascular stents in vascular applications, resulting in devices with the lowest level of design and development input being used in the most challenging anatomical applications. The end result was a high number of device failures, leading ultimately to tighter control of such off-label use.[36] The situation has therefore improved in recent years with an increasing number of stents being specifically designed and developed for a whole range of peripheral vessel anatomies. Even still, there are many design challenges to be addressed in these applications.

Some of the initial nitinol stent designs and features have been reviewed by O'Brien[37] and Stoeckel *et al.*[38] While many new additional designs are being developed, the basic principal features remain the same. These cardiovascular devices

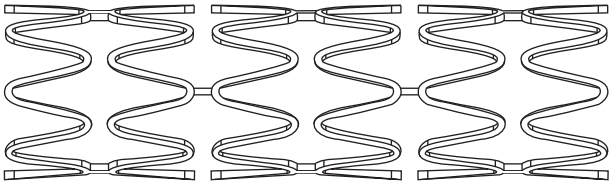

Figure 10 Typical stent pattern showing individual segments and connectors.

are mainly tube-based designs, that is, laser cut, as already described. (Wirebased designs are more widely used in nonvascular applications and will be reviewed in a later section of this chapter.) These tube-based designs typically consist of cylindrical segments or rings composed of several struts spanning around the device circumference. The mechanical performance of this ring will primarily control the radial stiffness of the device. These rings are connected to each other via 'connector' or 'bridge' struts; the design and number of these will influence the axial stiffness or flexibility of the stent. Figure 10 schematically illustrates these stent design features.

While the Radius™ stent was the first nitinol stent developed specifically for coronary arteries, it enjoyed only moderate clinical and commercial success. Angiographic studies suggested that the device continued to slightly expand for a number of months after implantation, leading to a greater neointima formation.[39] While this neointima had minimal effect on lumen diameter, the trend was undesirable and usage of the device diminished. A variation of this device was developed specifically for stenting of saphenous vein grafts (SVGs). These vessels have a high incidence of reocclusion after the bypass surgery; in addition, stenting of these is known to be problematic due to risk of dissection and embolization of plaque particulate. Fabric-covered stents were therefore developed with the aim of trapping any particulate against the vessel wall. The Symbiot™ nitinol stent was such a device, with a poly tetra-fluoro ethylene (PFTE) covering on the inner and outer surfaces. Ultimately, however, clinical studies on this covered device failed to show an advantage over conventional stents, with regard to reducing embolization; covered balloon-expandable devices fared similarly in this indication.[40] Perhaps these initial setbacks in coronary applications had an impact, as there have been no significant approvals for nitinol coronary stents in several years. However, as nitinol technologies and expertise have continued to develop, the inherent flexibility of the material is now being exploited in a much wider spread of demanding applications in the peripheral vasculature. This ongoing evolution of the technology and a growing appreciation for its benefits have also given a recently renewed interest in coronary applications. A number of novel devices for stenting of coronary bifurcations are in development[41] as well as a unique low-profile, small-vessel stent which is electrolytically detached from a guide wire, rather than deployed from a sheath.[42]

Without doubt, however, the area of biggest application development for nitinol over the last 10 years has been the field of peripheral artery stenting. Balloon-expandable stents were being used in many peripheral indications for several years, but the only competing self-expanding product was

the Wallstent, a braided device made from Elgiloy, the cobalt–chromium alloy. This stent derived its self-expanding capability from the high elasticity of the material (high elastic modulus and high strength), rather than from superelasticity. An early review of vascular stent usage in carotid, subclavian, renal, iliac, femoral, and popliteal arteries shows the majority of devices to be either Palmaz balloon-expandable or Wallstent devices, with nitinol stents barely getting a mention.[43] Nitinol, however, provided designers with much more scope for control and tuning of deployment, flexibility and radial force characteristics, and it was only a matter of time before competitive nitinol devices appeared. One of the first and most widely used nitinol peripheral vascular devices was the SMART® (Shape Memory Alloy Recoverable Technology) stent. This laser cut device has a typical zigzag strut pattern, with the segments connected to each other by bridging struts. The end struts are slightly flared to aid securement against the vessel. Phatouros *et al.*[44] describe the device and one of the first clinical uses of it, which was in a carotid stenting application. The high conformability of the device to the vessel curvature was noted as being a significant advantage over other devices, which tended to straighten and stiffen the stented artery. The longer-term outcome with using the SMART® stent in carotid arteries has also been demonstrated in a number of studies; for example, Drescher *et al.*[45] showed exceptionally low restenosis rates at 6-month follow-up. By way of illustration, **Figure 11** shows angiographic images of a stenosed internal carotid artery before stenting, immediately after stenting and at 6-month follow-up.

The SMART stent has since also been included in several clinical trials covering a wide range of peripheral applications. Sabeti *et al.*[46] reported on a femoropopliteal artery trial comparing a number of nitinol devices, including the SMART stent, against the Wallstent and concluded that the nitinol devices performed better with higher vessel patency at long-term follow-up. The case for nitinol stents was also strengthened by a similar study, using the absolute design, which showed superior outcomes compared to balloon angioplasty when used in the superficial femoral artery (SFA).[47]

There have now been a number of other nitinol stents developed and approved for various peripheral indications. Some of these may have only been initially approved for nonvascular biliary applications, but as off-label use of these stents has now been restricted, manufacturers have been going back, gathering data, and obtaining the approvals for vascular indications. Readers are advised to refer to manufacturers' current literature or to check regulatory agency websites, to verify approved indications for any particular device. However, these peripheral vascular applications did suffer a temporary setback in recent years when it became apparent that a high incidence of strut fractures was being observed. As mentioned, this was in part due to use of stents designed and verified for other anatomies, but was also due to a fundamental lack of understanding of the loading condition present in many of these peripheral vessels, that is, even devices like the SMART® stent, developed and tested initially for peripheral (iliac) applications, showed a significant incidence of strut fracture, especially in the SFA. This was first reported by Duda *et al.*[48] at 6-month follow-up in a trial comparing drug-coated and bare SMART® stents in the SFA. Stent fractures were observed in 6 out of 33 patients, with a fracture defined as one or more broken struts per stent. The fracture rate was evenly split between the two test groups, but it was observed that fractures typically occurred in overlapping stents. In addition, the possible role of vessel 'compression and movement' was acknowledged, this perhaps being the earliest recognition of the challenges with this particular vessel. A follow-up trial restricted the use of overlapping stents and significantly lower fracture rates were observed.[49] However, the failures are not attributable purely to stent overlap, but more to the exceptional nonpulsatile forces exerted on the vessel during regular ambulatory motion. Allie *et al.*[50] present an overview of the anatomy in the vicinity of the SFA, summarizing the compression, torsion, tension, and bending loads to which the vessel is subjected. In addition, the same study reviewed repeat angiography on over 100 patients with nitinol stents implanted in the SFA (not just the SMART® stent); fractures were detected in 72 out of 110 patients. The study concluded that flexible

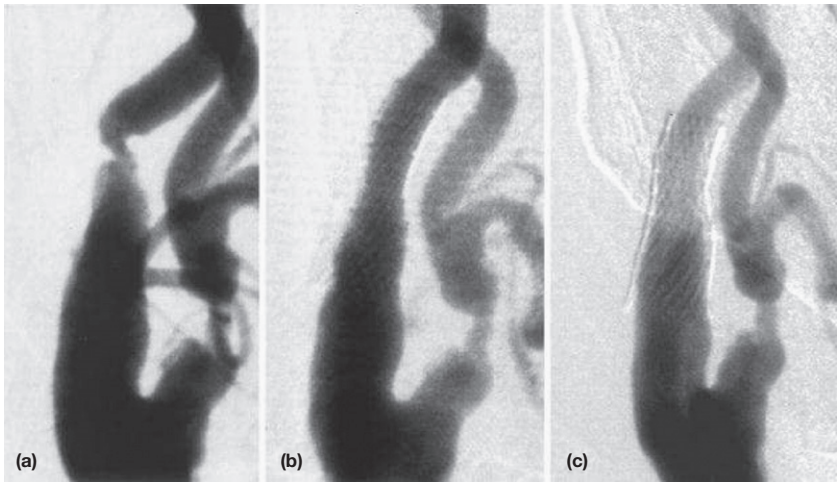

Figure 11 X-ray angiographic images of internal carotid artery (a) before stenting, (b) immediately after SMART® stent placement, and (c) at 6-month follow-up showing high vessel patency. Reproduced from Drescher, R.; Mathias, K. D.; Jaeger, H. J.; *et al. Eur. Radiol.* **2002**, *12*, 2451–2456.

stent designs resulted in less fractures. The significance of the fractures was put even more into perspective by Scheinert *et al.*[51] when it was established that strut fractures increased the risk of restenosis: a particularly challenging finding, given the typically high restenosis rates and the ineffectiveness of drug-coated devices in this indication.

It must, however, be emphasized that nitinol is not particularly susceptible to fracture. The failures observed in the SFA, and even in other coronary and peripheral vessels, are recognized to be due to the vessel-specific multiaxial loading, to which the implanted stents are subjected. Such a variety of loading conditions was not previously recognized and was largely ignored during device development and particularly during fatigue testing. Significant challenges do exist in relation to understanding and quantifying the appropriate loads and deformations of the relevant vessels, as well as translating that information to realistic *in-vitro* fatigue tests. Fatigue and long-term durability aspects of nitinol will be dealt with in more detail in a later section of this chapter. However, in summary, device developers and regulatory agencies now have a high awareness of these issues, and as new devices come to the market, they are being subjected to an increased level of scrutiny.

There are a number of other important vascular anatomies in which nitinol stents are being implanted, most notable being the placement of stent grafts in the abdominal and thoracic aorta, for aneurysm treatment. These devices typically consist of a nitinol frame to which the graft fabric is attached. Once implanted, this device seals off the weakened aneurysm section of the vessel, reducing the risk of rupture and ultimately allowing the aneurysm to repair. By way of illustration Figure 12 shows a CT image of an infrarenal aortic aneurysm, showing the severely dilated vessel, as well as an angiogram and CT image after placement of the stent graft. Treatment of aneurysms in the thoracic aorta is usually done with a conventional straight stent-graft,[52] while treatments in the abdominal region often use modular devices,[53] consisting of an upper body component and individual lower parts that can extended through the bifurcation region, into the individual iliacs if necessary. However, such stent-graft devices have had their own share of problems during development and clinical trials; some have even been taken off the market.

From a nitinol perspective, early concerns revolved around observations of corroded and fractured struts, noted on X-rays or on explanted devices.[54] Ultimately these observations were attributed to poor surface finishing and lack of adequate passivation on early devices – material quality and heat treatments may also have played a role. It is clear, however, that while subsequent devices may have had other issues, the corrosion aspect was addressed and has not since been observed. Jacobs *et al.*[55] present a detailed review of these corrosion aspects and other difficulties encountered with development of early versions of the devices; the most significant problem has been wear and fatigue damage of the graft material, which can ultimately lead to leakage back into the region between the fabric and the vessel wall. Device migration can also be an issue. Strut fractures are still observed, though these are usually associated with regions of high tortuosity in the vessel – pointing again to the need for better understanding of vessel deformations and optimization of designs. While several of these nitinol devices have been developed and explored in clinical trials, very few have achieved regulatory approval. However, as computed tomography and magnetic resonance imaging provide more accurate information on vessel anatomy and deformations, device designs are continuing to evolve and nitinol will be extensively used in this application.

The field of intracranial stenting also merits mention here, though it might be more accurately classified as relating to the neurovascular system rather than cardiovascular. Similar to coronary and peripheral vessels, the intracranial arteries are prone to atherosclerotic disease, and this may be a contributory factor in the occurrence of stroke. Balloon-expandable stents have been used to treat these lesions; some have been coronary devices, used off-label, while others have been designed specifically for intracranial applications. The Wingspan stent system is a nitinol device developed for this indication. Bose *et al.*[56] describe this stent and the outcome of the key clinical trial in which it was used. The results proved promising and the advantages of nitinol over balloon-expandable systems are cited as key factors in the outcome; these included flexibility, conformance to variable diameters and tortuous lesions, and the avoidance of high deployment pressures. Nitinol stents are also being used in conjunction

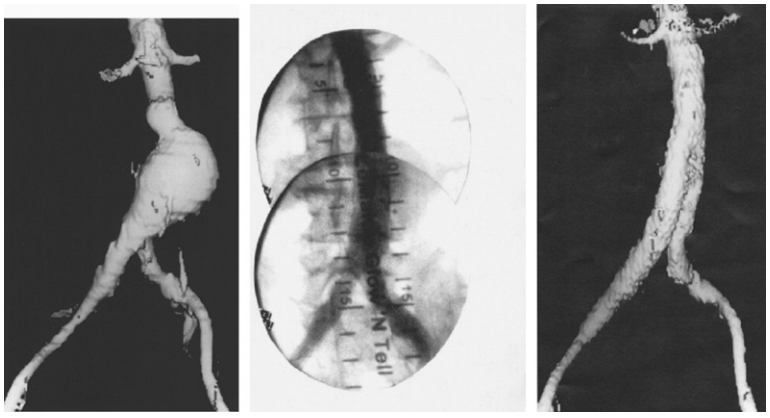

Figure 12 Stent-graft treatment of aortic aneurysm showing CT image of initial condition (on left) and angiogram and CT image after treatment. Reproduced from Allen, R. C.; White, R. A.; Zarins, C. K.; Fogarty, T. J. *J. Endovasc. Surg.* **1997**, *4*, 195–202.

with detachable coil treatment of wide-necked intracranial aneurysms. The treatment involves deployment of a fine coil of wire within the aneurysm to intentionally embolize and seal the defect. In the case of wide-necked aneurysms, the use of a stent can help with positioning and retention of the coils. The Neuroform stent has been developed for this treatment. Akpek *et al.*[57] present details of this stent and initial experiences with using the device in conjunction with embolization coils. Again, the flexibility and conformability of the nitinol device are indicated to be significant advantages over balloon-expandable stents in this application. However, given the high risks associated with neurovascular interventions, it should be noted that like the Wingspan device, this stent has a very restricted scope of use.

1.104.5.2. Other Cardiovascular Devices

In addition to stents, there is a wide range of existing and developing cardiovascular applications for nitinol, with many of these developed even before stenting became a standard procedure. The use of nitinol in vena cava filters goes back to the 1980s with the introduction of the Simon Nitinol Filter™.[58] Vena cava filters are implanted for prevention of pulmonary embolism – being placed in the vena cava to trap and break down blood thrombi, before they reach the lungs. Typically they are used in patients for whom anticoagulation therapy is not feasible. Several different materials have been successfully used for vena cava filters, but nitinol devices offer lower delivery catheter profiles, due to the manner in which the nitinol filter structure can be readily folded down into a small shape and recover upon deployment, either through shape memory or superelasticity. Figure 13 illustrates a number of different filter configurations, showing the conical or umbrella-shaped structures that trap the blood clots.

Interestingly, the Simon Nitinol Filter™ was initially deployed using a chilled saline infusion, thereby converting the material to martensite and reducing the device stiffness during tracking to the delivery site. Developments in both catheter and filter mean this is no longer necessary, but this filter is still in use today, although there are now several other competing nitinol filters available. Some of these are designed to be retrievable, where the flexibility of nitinol can again be an advantage.

More recently, the use of nitinol in filters has been in relation to development of embolic protection devices. These have been developed mainly for use during carotid stenting where the impact of embolized plaque debris could be fatal. They typically consist of a metal frame structure, to which a fine porous polymer membrane is attached. This device is deployed distal to the lesion, and during the stenting procedure, any loose plaque particles are trapped within the filter, which allows blood to pass through. At the end of the procedure, the filter is then collapsed and retrieved through the catheter, with the trapped debris retained. The self-expanding and flexibility aspects of nitinol are key features in such designs and it is probably reasonable to conclude that nitinol actually enabled development of these devices. The only other option available prior to this was to use occlusion balloons to seal off the artery during the procedure – not an ideal solution due to risks associated with temporarily stopping cerebral blood flow. Several such filter devices are now available, all utilizing nitinol frames[59]; clinical studies have demonstrated their safety and efficacy, and they are also being used in other stenting applications where there is a risk of plaque rupture.

The diversity of nitinol applications in the cardiovascular anatomy is highlighted by the final two uses described herein. A relatively early application has been its use in the mesh frame of a septal occluder device, used for closing of atrial septal defects. Fischer *et al.*[60] describe the features and experiences with the Amplatzer® system, one of the first occlusion devices to use nitinol – and still widely used today. The device consists of two disk-shaped structures, woven from fine nitinol wire, with polyester fabric attached, to aid in thrombus formation and sealing of the defect. The connected disks are deployed sequentially from a catheter, positioning one at each side of the chamber wall. The use of nitinol provides for easier deployment and smaller delivery systems, which is a critical aspect, as the treatment is most often required in smaller, pediatric patients. There are now several such occluder devices on the market. Finally, to briefly mention heart valve replacement, a highly challenging application where nitinol is starting to be used. Heart valve disease has traditionally been treated using replacement mechanical valves, which have provided good durability but have been susceptible to thrombosis. The use of more compatible biological materials has therefore evolved in recent years, with either human or animal tissue being utilized. When using animal tissue, usually either bovine or porcine, the tissue itself is supported on a metal frame for implantation – this is in effect a stent structure, but with the valve attached. Grube *et al.*[61] describe initial experiences with the CoreValve device, one of these first bioprosthetic-nitinol valves. While balloon-expandable stent frames have been used in this application, the advantages of nitinol and self-expansion are cited as being better securement, lower risk of leaks or migration, and a reduced risk of damaging the valve leaflet material itself during deployment.

1.104.5.3. Nonvascular Stents

There is a wide range of nonvascular vessels and tracts within the body where nitinol devices are being used, mainly utilizing superelastic behavior. These include biliary, ureteral, esophageal, and pulmonary applications, with stenting usually being a palliative treatment to open up a vessel that is being obstructed by a tumor or by other degenerative diseases. Many of these stents were developed before laser cutting became the stent-manufacturing norm, and therefore they are made from wire, using knitting, braiding, and winding technologies. Miyazawa *et al.*[62] describe use of the Ultraflex™ stent in treatment of malignant bronchial occlusions. In this application, the 'biased stiffness' feature of nitinol is again worth mentioning; as a tumor presses against the structure, a high-compression resistance will develop while a much lower radial force will be exerted away from the obstruction, preventing damage to the mucosa lining. In addition, the superelasticity of nitinol is a key feature of this device. During coughing events, these airway vessels can completely collapse before recovering to full diameter – the highly superelastic device

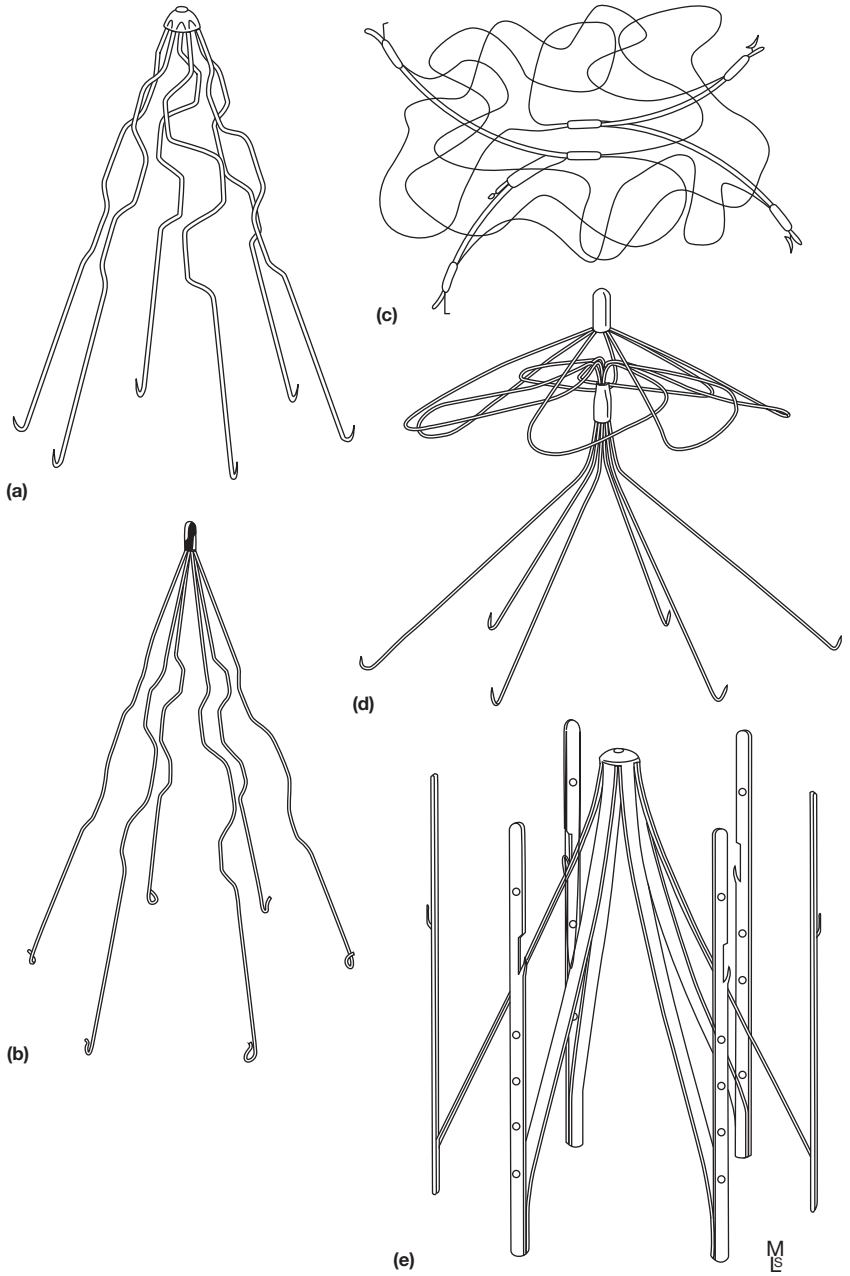

Figure 13 Example of a number of different vena cava filters: (a) stainless steel greenfield, (b) titanium greenfield, (c) bird's nest (stainless steel), (d) Simon nitinol filter, and (e) Vena Tech (Phynox). Reproduced from Streiff, M. B. *Blood* **2000**, *95*, 3669–3677.

handles this well, opening back fully, with no permanent deformation. The Ultraflex design is also used for esophageal stents, where similar challenges exist. The peristaltic motion of swallowing creates high repetitive deformations that few other materials could readily handle. Cwikiel *et al.*[63] describe initial experiences with the stent. Covered versions of the device were subsequently developed to minimize tumor in-growth through the knitted wire structure. Aside from the Ultraflex devices, there are many other nonvascular stents on the market, with an increasing amount being made from nitinol. Lee[64] describes the features and selection aspects of several of these, specifically those designed for esophageal treatments. Kozarek[65] reviews a number of balloon expanding and self-expanding designs used for treatment of biliary obstructions. While long-term durability and fatigue aspects are not seen as critical for nonvascular devices, there have been instances of wire breaks and device fragmentation. Rasmussen *et al.*[66] report on biliary stenting patient follow-ups, ranging from 1 to 21 months, and observed fractures in 8% of patients. In addition, it was suggested that fracture could be a contributory factor in recurrent obstruction. Reddy *et al.*[67] and Chhetri *et al.*[68] report on observations of fractures in esophageal stents. While it is noted that such fractures are a rare occurrence, these findings do suggest that there is scope for continued improvement of device designs and material processing aspects.

1.104.6. Orthodontic Applications for Nitinol

Though perhaps not as popularized as cardiovascular applications, nitinol has been widely used in orthodontic applications for several decades now. Kusy[69] presents a thorough review of the historical evolution of orthodontic materials, indicating the significant role that nitinol now has in this market. Nitinol is an ideal material for archwires. By tuning of the unload plateau level, nitinol archwires can be applied to give a continuous force against the teeth. As the teeth gradually realign to the desired position, this level of force is kept constant over a substantial strain range. This provides an improved level of comfort to the patient as well as minimizing the number of readjustments needed over time. In addition, the shape memory effect can be used where fitting and adjustments are made in the soft martensitic condition, and when the device warms up to body temperature high retaining forces are developed, as the material converts to the austenitic phase.

There are a wide range of nitinol archwire products on the market, utilizing shape memory and superelastic effects, with ranges of unload forces (and therefore transformation temperatures) tuned to suit many different patient needs. Wires with Af at approximately body temperature are classified as martensitic, typically imparting low forces and therefore often used in early-stage treatments. Devices with lower Af (i.e., at room temperature) are classified as austenitic, providing higher forces at body temperature and often used in later stages of a treatment. While mechanical aspects may be reasonably predictable, long-term corrosion and surface degradation are the main challenges facing these devices. The ideal archwire surface needs to be smooth with minimal friction against the brackets to which it is attached. Friction at this interface can inhibit the gradual sliding adjustment that is necessary to accommodate the realignment of the teeth and maintain a constant level of force. Any deterioration of the surface condition may therefore have an impact on the overall efficiency of the device. Therefore, aside from potential implications for biocompatibility performance, corrosion is also undesirable due to the manner in which it can impact the surface and mechanical behavior of the device. Huang[70] has studied the surface characteristics and corrosion response of a number of commercial archwires in artificial saliva with a range of acidities. Significant differences between the wires were observed, with some showing relatively poor pitting and crevice corrosion resistance – especially in lower pH environments. However, this study did not show any link between as-received surface roughness and corrosion performance, with the roughest of the wires performing well in the corrosion tests. Es-Souni *et al.*[71] studied two different commercial archwires, showing that the wire with a rougher surface and with more inclusions present did have a worse corrosion resistance. While these findings may seem at odds with each other, direct comparisons are difficult given the variety of materials and test methods used. Overall, however, such studies do suggest that the level of control and consistency on surface condition is not as high on some of these components as it is for cardiovascular devices. Eliades *et al.*[72] examined retrieved archwires that had been *in vivo* for up to 6 months, noting extensive degradation of the surfaces. Roughness was increased due to the presence of mineralized deposits, microcracks, and due to both pitting and crevice corrosion. However, the study did not correlate these observations with clinical performance of the devices. The effect of fluoride ions on archwire corrosion performance has also been studied, given the widespread use of fluoride-containing mouthwashes. A detailed study by Schiff *et al.*[73] compared several archwire and bracket material combinations in a number of different commercial mouthwash solutions. Interestingly, the study did show that some mouthwashes were more corrosive than others, with the nitinol archwires exhibiting high nickel ion release when used with stainless steel or cobalt–chromium brackets. The investigators suggest that orthodontists should consider prescribing specific mouthwashes depending on the archwire and brackets materials being used. Nitinol archwire fractures have also been observed *in vivo*, though a detailed investigation by Zinelis *et al.*[74] did not determine the precise failure mechanism, other than noting that all failures were typically brittle in nature. To conclude, nitinol is being widely and successfully used in orthodontic applications, though longer-term mechanical performance and biocompatibility of these devices merits continued exploration.

1.104.7. Orthopedic Applications for Nitinol

Nitinol is of interest for orthopedic applications due to its high strength combined with superelastic strain recovery, as well as its lower elastic modulus, compared to other traditional implanted metals. This lower modulus provides for the possibility of less 'stress shielding' effects between load-bearing implants and the adjacent bone. While monolithic nitinol devices are of interest for such applications, greater potential lies in the use of porous nitinol structures, which can additionally provide enhanced osseointegration. Bansiddhi *et al.*[75] have presented a comprehensive review of developments in this field. Work in this area is focused on methods for producing the porous structures, on surface modifications to reduce nickel release, and on studies to assess and optimize the biological response. There are several powder metallurgy-based methods for producing porous nitinol, but the most widely used method is self-propagating high-temperature synthesis (SHS). This process involves the ignition of a compressed powder mixture to produce an exothermic self-sustaining reaction, which propagates through the material to create the final porous structure. Nickel and titanium powder ratio, powder size and shape, as well as preheating temperature and ignition technique can all influence the nature of the porosity obtained. Chu *et al.*[76] and Bassani *et al.*[77] describe both production and characterization of porous nitinol structures created by SHS. The objective is to maximize the amount of interconnected porosity while retaining good compressive strength; most target applications are compressive load-bearing structures. Chu *et al.*[76] report on creating a material with 57% porosity, giving a compressive strength of 208 MPa (higher than compact human bone) and with an elastic modulus of only 2.26 GPa, which matches well with 1–2 GPa for bone.

One concern with these structures is the potential for increased nickel ion release, due to the large surface area obtained with the open porosity. While nickel release from cardiovascular nitinol devices has often been debated, it has

never been established to be a significant aspect of device biocompatibility. On the other hand, with surface areas of these porous structures being orders of magnitude greater than typical cardiovascular devices, the risks are more substantial. Incomplete synthesis may also leave some residual elemental nickel or nonstoichiometric compounds in the structure. Approaches for minimizing nickel release typically focus on enhanced oxidation of titanium in order to create a protective titanium oxide layer – these include thermal oxidation and oxygen ion implantation techniques. Vapor-deposited coatings of titanium nitride and titanium oxide have also been explored, as well as hydroxyapatite coatings. Bansiddhi *et al.*[75] include a review of these approaches, particularly those for which nickel release data are obtained. While all show promise, aspects such as long-term durability and impact on shape memory or superelastic properties also need to be considered.

Several *in vivo* animal studies have been performed to assess bone in-growth with these porous structures. Ayers *et al.*[78] report on a study in which samples with varying amounts of porosity were implanted in rabbit craniums, to assess potential applications in the field of craniofacial reconstruction surgery. Analysis 6 weeks after implantation demonstrated immature bone in-growth to all structures, with no evidence of macrophage reactions. In a similar study, aimed at assessing suitability for load-bearing bone grafts, Kujala *et al.*[79] implanted samples in rat femur, but for a much longer duration of 30 weeks. The best bone–implant contact was obtained in the samples with the highest level of porosity. Likibi *et al.*[80] compared bone fusion for a commercially available porous nitinol (Actipore™) against a conventional titanium intervertebral lumbar fusion device, in a sheep model. While both components performed well, the porous nitinol demonstrated better osseointegration. The Actipore™ material is currently the only commercially available porous nitinol and is being explored in clinical trials for spinal fusion procedures. Munroe *et al.*[81] investigated the corrosion response of this Actipore™ material with a number of different surface passivation treatments. A combined process of etching followed by boiling in water and nitric acid passivation gave the best corrosion resistance. **Figure 14** illustrates some typical porous nitinol structures including those present in the Actipore™ material.

In addition to these applications for porous material, some unique orthopedic applications are also being considered for conventional nitinol. Kujala *et al.*[82] report on the possibility of using a nitinol intramedullary nail to help correct bone deformities. A study of this concept in rat femurs involved implanting of the device in a straightened martensitic condition; upon heating up to the austenite phase, the device changes to a slightly curved shape, thereby applying a gradual bending force to the bone. The ability to remodel the bone in this manner was demonstrated. Nitinol is already being widely used in commercial orthopedic staples, with a number of different types now approved by regulatory bodies. After positioning across a fractured bone, these staples can be activated through shape memory or superelasticity, to apply a compressive force that pulls the fracture faces together. Russell[83] presents a thorough review of the design approaches and clinical aspects for some of the main commercially available staples. There are many other orthopedic fixation applications currently being explored, where the unique force control of nitinol is being exploited. These include devices such as a long-bone fracture fixation component described by Fu *et al.*[84] and superelastic rings for cranioplasty procedures presented by Morawiec *et al.*[85]

1.104.8. Clinical Imaging of Nitinol Medical Devices

Accurate imaging of medical devices is an important aspect during and after interventional procedures. This is particularly critical for small minimally invasive devices, such as stents and filters, as physicians rely heavily on imaging techniques to visualize deployment of the devices. Similarly, for any monitoring or follow-up procedures, the device needs to be accurately imaged. X-ray has long been the standard method and is adapted for real-time imaging through fluoroscopic techniques. The method relies on attenuation of X-rays by the device structure, and in this regard, nitinol has only moderate X-ray attenuation compared to stainless steel or cobalt–chromium. The density of a material can be used as an approximation for X-ray attenuation; 6.5 g cm^{-3} for nitinol compares unfavorably with 8.0 g cm^{-3} for 316L stainless steel or 9.1 g cm^{-3} for L605 cobalt–chromium. Therefore under fluoroscopic angiography, nitinol devices can be difficult to observe, particularly those with relatively thin strut designs. There have been several different approaches to enhancing the radiopacity of these small devices, but the most widely used method is the attachment of small 'markers' of highly radiopaque materials in the form of bands, clips, or rivets to the stent structure at specific locations. Often these are put at each end of the stent so that the precise length of the device can be clearly visualized even if the main stent structure is not so visible. Stoeckel *et al.*[38] describe some of the usual materials and configurations used

for a number of commercial nitinol devices. Tantalum has the advantage that it does not generate significant galvanic interaction with nitinol. In addition, it is possible to weld the tantalum markers to the nitinol, if required. Siekmeyer *et al.*[86] present a useful study comparing the features of welded and riveted marker bands, using tantalum and gold.

Platinum or platinum–iridium alloys are also used where higher radiopacity is needed, though they do have the potential to generate more galvanic effects. Wiskirchen *et al.*[87] present a comparative *in-vitro* imaging study on a number of nitinol and stainless steel stents, highlighting the influences of stent design, mass, and strut thickness on visibility as well as illustrating the benefits of tantalum markers. Coating of nitinol with radiopaque materials has also been explored; however, this can lead to additional considerations for biocompatibility and also raises the possibility of galvanic corrosion at coating defects, where unfavorable cathode-to-anode ratios could develop. Process complexity and cost must also be considered when exploring such options. Cheng *et al.*[88] report on a tantalum coating applied to nitinol, using physical vapor deposition techniques; significant improvements in device visibility were demonstrated. Another perhaps more promising approach, though limited to wire-based devices, is the use of composite tube structures, with nitinol on the outside and a radiopaque core on the inside. This approach preserves the nitinol outer surface, thereby not altering biocompatibility aspects. In addition, the risk of galvanic effects is significantly reduced as exposure of the more cathodic radiopaque materials is minimized. Schaffer and Gordon[89] have described development and characterization of such a composite tube, using platinum as the radiopaque core. These NiTi-DFT®-Pt materials demonstrate excellent visibility, though care must be taken in selecting the appropriate size of core so that expected shape memory or superelastic properties are not impaired.

X-ray fluoroscopy will continue to be the imaging technique of choice during minimally invasive interventions. However, for noninterventional imaging, such as for prescreening or follow-up procedures, techniques such as CT and MRI are being increasingly used. The compatibility of nitinol devices with these imaging modalities is therefore of increasing interest. During clinical CT imaging, metallic structures can create image artifact which is typically proportional to the radiopacity of the material. In the case of some devices, this can obscure clinical interpretation of the data, such as assessing stent lumen patency for evaluation of restenosis. In this instance, the modest radiopacity of nitinol is actually an advantage as it leads to low levels of artifact. Maintz *et al.*[90] have presented a comprehensive *in-vitro* study assessing the CT imaging compatibility of several different coronary stent designs. Only two nitinol devices were evaluated, but these were among only a small number of devices that showed good compatibility. It should be noted, however, that the presence of radiopaque marker bands can somewhat negate this advantage, as these can lead to image artifact at specific points.[91]

A different set of challenges arise with MR imaging of devices. Here the magnetic characteristic of the material and the electrical conduction paths throughout the device become critical features. Material magnetic susceptibility is an important characteristic for all implants, as it can impact on device safety through magnetic-induced movements or heating effects. In addition, inherent device magnetism can produce image atifact due to localized disruption of the magnetic fields within the MRI scanner. Fortunately, nitinol has relatively low magnetic susceptibility due to the absence of ferromagnetic elements such as iron. Magnetic susceptibility-induced artifacts are therefore relatively low. However in the specific case of stents, or other devices with mesh-based patterns, additional MR-specific issues arise. These structures can attenuate the radio-frequency signals, which are integral to the MR imaging process, such that signal from the inside of these devices can be diminished. In effect this can impair MR visualization within the device, such as required for assessment of restenosis within stents or characterization of thrombus within filters. Melzer *et al.*[92] have presented an overview of both the magnetic and shielding effects for a range of nitinol devices, illustrating clearly the levels of artifact that can be created. Lenhart *et al.*[93] have carried out an evaluation on a range of commercial stents, including several made of nitinol. The nitinol devices typically resulted in the lowest image artifact, with the best lumen visibility. The extent of the shielding artifact is highly design-dependent and the problem is not unique to nitinol, but nitinol has the greatest potential to be part of the solution to this issue, as a low magnetic susceptibility material is still essential. Immel and Melzer[94] describe some of the novel approaches to altering the shielding behavior of devices; integrating these with nitinol shows promise in terms of achieving full lumen visualization.

1.104.9. Long-Term Durability and Biocompatibility of Nitinol

1.104.9.1. Fatigue Behavior of Nitinol

The fatigue response of nitinol has long been of interest, given the potential for unique effects from different phases and from stress-induced transformations. The subject has become even more important in recent years, given the increased occurrence of peripheral cardiovascular stent fractures, as already discussed. In addition to the near-endless combinations of material properties, microstructure, loading conditions, temperatures, and surface finishes being tested, there are also several different test methodologies to deal with. These include options on testing of actual devices or testing of material coupons and whether to use the traditional fatigue life approach (i.e., strain–life curves) or to use fracture mechanics approaches to evaluate critical stress intensities and crack growth rates. The fracture mechanics methodology has primarily been explored by Robertson and Ritchie[95], establishing fatigue crack growth thresholds and crack growth rates for nitinol in a variety of loading conditions. While this approach generates fundamentally sound data, it is difficult to utilize this information for the majority of nitinol devices, especially for stents. Using the data to predict device lifetime depends on having accurate information on the shape, dimensions, and location of flaws such as microcracks or inclusions in the material. This can be practically very difficult for such small components, where stent strut dimensions are typically $<100\,\mu m$. The critical crack size in such instances is therefore relatively small, and given that small cracks tend to grow at much faster rates, Paris Law crack growth rates are not highly relevant. Gong *et al.*[96] and James and Sire[97] have recently

clarified that traditional fatigue life approaches are therefore best for vascular devices, and in this regard, these methods are therefore also applicable to most current discussions on fatigue behavior of nitinol.

As with any material, there are a number of useful studies in the literature reporting on the traditional factors that influence fatigue performance, such as inclusion content,[98] hydrogen contamination,[99] and surface roughness.[100,101] However, the similarities with conventional metallic materials do not go much further, with some unique behavior being observed in nitinol. Foremost among these is the influence of mean strain and strain amplitude on the number of cycles to failure. First it should be noted that when the fatigue data relates to nitinol stent applications, the mean strain comes from the oversizing of the stent within the vessel, while the strain amplitude is controlled by the range of vessel diameter change, between the systolic and diastolic pressures. It can therefore be appreciated that the mean strain is generally compressive and the extent of this would vary depending on the degree of oversizing. The zero-mean strain condition has little relevance to nitinol stents, though is sometimes tested to put other data into perspective. Perry and Kugler[102] were among the first to investigate mean and amplitude relationships, using samples representative of the cell geometry of a specific stent, thereby representing the mean and amplitude strains that the cell structure experiences. Among the findings was the unusual observation that fewer samples failed when tested at a mean strain of 3.4% compared to those tested at a mean strain of 2.0%, when applying an alternating strain of 0.6%. This is unlike conventional metallic materials where higher mean strains generally result in more failures, for a given alternating strain, that is, as described by the traditional Goodman relationship. However, there is some doubt about the applicability of the data for stent applications as it appears that in this instance, the mean strain has been applied in a tensile mode, that is, opening out the cell structure rather than compressing it, as would occur when a stent is *in vivo*. Subsequent studies by Pelton *et al.*[103,104] have made these aspects clearer, in addition to presenting finite element analysis (FEA) analysis to support the strain conditions selected. These studies evaluated uniaxial fatigue behavior of samples representing individual cells (diamonds) of a stent structure, as well as pulsatile fatigue evaluation of complete stents. A range of mean strains and alternating strains were applied and all were tested at 37 °C. The subcomponent cells and the stents had Af in the range 26–32 °C. Extensive data were obtained and presented in a number of graphs for strain amplitude versus number of cycles to failure; however, the best insight is obtained when these data are presented as a constant life diagram as shown in **Figure 15**. This diagram shows data for the individual subcomponent cells (or diamonds) at the various conditions of mean strain (zero and compressive) and alternating strain. The data shows that these nitinol samples have a constant fatigue life at a strain amplitude of ±0.4%, for mean strains up to about 1.5%. At higher mean strains, the fatigue life is shown to actually increase, contrary to expectations based on traditional metals.

The mean and alternating strain values applied to the stents covered the same range as tested for the subcomponents, though it was noted that this included values that would exceed those expected under typical *in vivo* conditions. The stent data

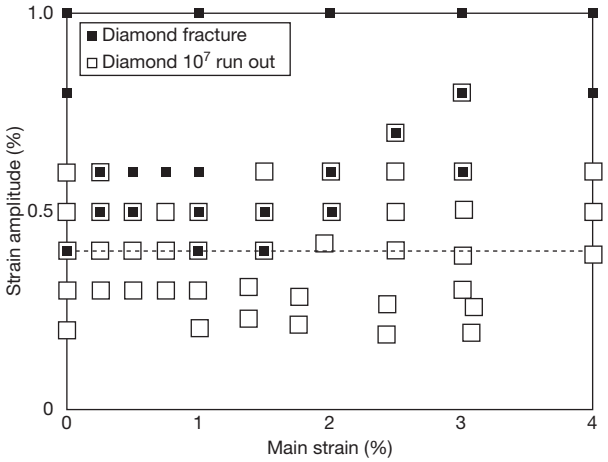

Figure 15 Constant-life diagram for stent cell subcomponents. Samples that survived beyond 10^7 cycles are shown as open squares, while samples that failed at $<10^7$ cycles are shown as solid shaded squares. A 10^7 fatigue strain limit at 0.4% alternating strain is shown. Reproduced from Pelton, A. R.; Schroeder, V.; Mitchell, M. R.; Gong, X. Y.; Barney, M.; Robertson, S. W. *JMBBM* **2008**, *1*, 153–164.

supported the subcomponent findings in that no failures were again observed below the strain amplitude of ±0.4%. This study did not include microstructural or crystallographic evaluations, but the investigators suggest that the observation of improved performance, above ~1.5% mean strain, is attributable to the formation of stress-induced martensite and the ability of this phase to better accommodate the cyclic deformations. A fatigue study by Morgan *et al.*[105] on nitinol wire with an Af of 12 °C did find some trends consistent with these mean strain observations. The results showed that higher mean strains (within the range 2–6%) gave longer fatigue life, when tested at low strains amplitudes (±1.0% and below). A constant life limit for strain amplitude was not described.

The impact of phase transformations was also highlighted in a study by Wick *et al.*[106] in which materials with different Af values were tested. The data showed that nitinol with higher Af performed better, consistent with the argument that martensitic structures have better fatigue resistance. In addition, it is proposed that nontransforming martensite (i.e., martensite that exists at the test temperature without needing to be stress induced) is superior to transforming martensite.

In summary, the fatigue behavior of nitinol is highly complex, with performance influenced by a wide range of material and test variables. While some data, which point to alternating strain limits at various mean strains are emerging, more data are needed to verify these findings. This subject is particularly important in the field of cardiovascular stents, where the influence of multiaxial loading now also needs to be fully considered. Traditionally stents were tested in purely pulsatile mode, normally with the stent held in a straight configuration. This will need to shift to include additional multiaxial loading and for testing of devices in curved and tortuous configurations. In addition, device manufacturers will need to demonstrate a broader understanding of the conditions that actually induce fatigue failures rather than just aiming to pass a specific minimum number of cycles.[96,107]

1.104.9.2. Corrosion Behavior of Nitinol

At the outset it must be stated that nitinol is in general a highly corrosion-resistant material with an *in vivo* performance that is typically comparable to stainless steel or titanium materials. However, its corrosion resistance is highly sensitive to material impurities and to the nature and integrity of the oxide that is created by surface processing. This fact was highlighted in the early stages of nitinol stent development, with reports of pitting corrosion on explanted aortic aneurysm stent grafts.[54,108] These findings were ultimately attributed to poor surface finishing and passivation of these early devices, and no further cases of *in vivo* corrosion failures have been reported in the literature.

The influence of ingot melt practice on inclusion content has already been described, and this is an important aspect when considering corrosion resistance. These carbide and oxide inclusions are regularly the sites of corrosion attack; Shabalovskaya *et al.*[109] have presented an analysis of the different types of inclusions present, clearly illustrating the manner in which they may act as initiation sites. Localized composition variations in the surrounding matrix (i.e., depletion of matrix constituents) can be sufficient to create galvanic effects between the particles and the matrix. These inclusions will be present even on well-polished and passivated surfaces. Though an ASTM[110] for nitinol does provide limits on the size and volume fraction of inclusions, there is some doubt as to whether the limits are sufficiently stringent.

While use of materials with minimum inclusion content is the first step towards optimizing corrosion performance, the next objective is to develop a passive surface through enhancement of the native titanium oxide layer. Given the manner in which titanium readily and rapidly oxidizes, there will always be some titanium oxide present on the surface. The precise composition, uniformity, distribution, and thickness of this surface oxide will, however, depend on the material processing route and especially on final surface treatments. As a general rule, the best corrosion performance is obtained from surface oxides with minimal free nickel or oxidized nickel contents, that is, maximizing the titanium oxide. Furthermore, thicker oxide layers are not necessarily good as these tend to be brittle and readily crack; optimum corrosion resistance is typically obtained from oxide layers that are <10 nm thick. Shabalovskaya *et al.*[111,112] and Pérez *et al.*[113] have presented extensive studies of oxide composition and the related corrosion performance from a wide range of surface treatments, including thermally oxided, chemically etched, sand blasted, mechanically polished, and electropolished. It is immediately clear upon reviewing these data that a significant spread in performance is obtained; for example, values for breakdown potential, as measured by cyclic potentiodynamic polarization testing, can range from as low as 100 mV to over 1000 mV. Interpreting trends and establishing correlations is complicated, not just by the differences in the specific surface treatments, but also by the differences in test coupons (geometry and manufacture), material compositions, inclusion contents and test environment. Pound[114] carried out a study of mechanically polished and electropolished wire and demonstrated that use of either 0.9% NaCl solution or phosphate-buffered saline (PBS) will give significantly different results, with the NaCl generally being the more severe environment. This study also included a review of data obtained in other media such as Hank's solution, further highlighting the variations in performance. However, from the perspective of implantable nitinol devices, some of the published data can be disregarded – particularly surfaces that would not be considered suitable for implantation. For example, cardiovascular applications usually demand smooth surfaces, to meet expectations in relation to fatigue, thrombogenicity, and delivery system interactions. Electropolishing is therefore the usual process of choice, irrespective of corrosion implications – though of course the corrosion performance of electropolished surfaces can be modified through appropriate passivation treatments. On the other hand, some nonvascular applications may have lower surface finish expectations and mechanically polished or chemically etched surfaces may suffice. In summary, device developers are strongly advised to focus on their specific application and environment and to carry out their own assessment to ensure that all material, design, thermomechanical, and surface treatment effects are appropriately captured. The published literature does then provide a useful guide in understanding the effects of the many variables and in identifying performance targets from surfaces or devices with some relevance to the application. In addition to the forementioned studies, Shabalovskaya *et al.*[115] have presented a comprehensive review of nitinol surface treatments encompassing typical as-received, heat-treated, and polished surfaces, through to surfaces modified with ion beams, laser treatments, or surface coatings.

As indicated, however, electropolished surfaces are often the most relevant to implantable devices, and these therefore merit some further detail. First, it must be stated that the corrosion performance of a well-electropolished surface can be hampered by the presence of inclusions. Shabalovskaya *et al.*[111] highlight this well, with a comparison to chemically etched surfaces. These etched surfaces may be rougher, but for the samples concerned, had better corrosion resistance than the electropolished surfaces. This was attributed to the etched surfaces having lower inclusion content due to the manner in which etching removes some of the soluble inclusions as well as regions of matrix inhomogeneity around them. Electropolishing, on the other hand, removes only the conductive metal around the inclusions, leaving more of them revealed at the surface. This can help explain why a surface that appears to be well polished, and perhaps passivated, results in an occasional low breakdown potential when polarization tested.

Perhaps one of the most comprehensive studies of electropolished nitinol surfaces is that of Eiselstein *et al.*[116] which compared mechanically polished and electropolished samples (with similar inclusion levels) in a series of long-term immersion and cyclic polarization tests. In summary, all mechanically polished samples showed breakdowns at potentials <800 mV ($n = 130$), while only 13% of the electropolished samples ($n = 290$) showed breakdown. Interestingly, the study did also show that extended immersion of nitinol in such physiological solutions actually increases the measured breakdown potentials. This indicates that the solution has a passivating effect, most likely leaching out free nickel and allowing additional titanium oxide to form. Similar observations have been reported by Warner,[117] who recorded a shift in breakdown potential from an average of 446 mV up to 680 mV after 672 h immersion in PBS, for surfaces with a thermally grown

oxide. Finally, in relation to electropolished surfaces, additional passivation treatments are always recommended, to maximize the amount of titanium oxide at the surface. As already reviewed in the section relating to stent manufacture, relatively simple treatments in oxidizing chemicals such as nitric acid work well, leaching out residual surface nickel and oxidizing additionally exposed titanium.

While there are other corrosion tests that can be used to assess nitinol for implant applications, measurement of the breakdown potential, in cyclic polarization tests, is by far the most widely used. There is, however, often debate as to what is an acceptable level, not just for nitinol, but for any metallic implant. In summary, there is no clinically or regulatory based minimum established, however, a minimum value of 600 mV has been proposed.[118,119] Data sets from nitinol testing have been used in establishing this proposed minimum.

Considering that it is a relatively 'new' implant material, the corrosion performance of nitinol is being rapidly understood and accepted in most situations. There are, however, some aspects for which there is very little information. Specifically, these relate to the performance of the material in situations where either fretting corrosion or galvanic effects (or both) may be possible. A fretting situation could arise, for example, in cardiovascular stenting where overlapping stents are used; the pulsatile-induced motion of the stents may be enough to cause oxide breakdown and wear damage at the overlap. Similarly, galvanic effects could arise should a nitinol stent be in direct contact with another stent, of a different material. In a fundamental study of mechanical damage and repassivation effects, Schroeder[120] has evaluated the performance of fresh mechanically abraded surfaces at different time-points in PBS. The results showed that a passive film started to reform relatively fast and developed progressively for ~6 days, at which point it leveled off. While this is a very positive finding, breakdown potentials were not measured, neither did the study assess how repeated abrasion/fretting may impact performance. A more practical study performed by Trépanier *et al.*,[121] evaluated the breakdown potential on nitinol stents that had been overlapped with each other during axial fatigue testing. The results showed that the breakdown potential decreased from ~900 to 650 mV due to the induced fretting damage. Again, however, the long-term *in vivo* corrosion response during fretting or abrasion cannot be accurately predicted from this data. However, on a positive note, this work did also demonstrate that nitinol repassivates well in situations of cervice-induced pitting.

In relation to the potential for galvanic interactions between nitinol and other materials, Venugopalan and Trépanier[122] have measured corrosion currents from coupling of nitinol to stainless steel, titanium, tantalum, platinum, platinum–iridium, and gold–palladium alloy. Equal cathode and anode areas were used. Perhaps not surprisingly, the current densities measured were exceptionally low ($<35\ \mathrm{nA\,cm^{-2}}$) when nitinol was connected to stainless steel, tantalum, or titanium. When coupled with the more noble metals, currents were over an order of magnitude higher, with NiTi–Pt giving the highest value of $836\ \mathrm{nA\,cm^{-2}}$. Still, these currents are exceptionally low and were insufficient to initiate corrosion of the nitinol. A study by Carroll and Kelly[123] showed similarly low levels of current for nitinol–gold couples. In addition, these findings were supported by inspection of nitinol–gold couples that had been immersed in saline for up to 12 months; no evidence of corrosion was observed. Thus while galvanic effects under stable oxide conditions seem most unlikely, there is probably a need for more information on the possibility of galvanic coupling in situations where oxides are being damaged through fretting or wear contact.

1.104.9.3. Biocompatibility Aspects of Nitinol

The generally biocompatible nature of nitinol has now been well demonstrated; many years of preclinical and clinical experience have been gained in a range of different biological environments. These applications have been supported by many fundamental cellular interaction studies. Ryhanen *et al.*[124] performed extensive cell proliferation studies in osteoblast and fibroblast cell cultures, using samples of nitinol that had only been mechanically polished. No inhibition of cell proliferation or cell growth was observed due to contact with the metal. This study also monitored nickel release and while levels of nickel ions were initially higher than that observed for stainless steel samples, the release rate dropped after 4 days to the same level as the steel. This behavior correlates well with observations of increased passivity and corrosion resistance, during immersion in physiological solutions, as described earlier. In further agreement with such observations, Shabalovskaya[125] has ranked nitinol has having lower pathological potential than stainless steel. While it is well recognized that nitinol does release nickel ions, even when no visible corrosion is occurring, the extent of this is put into perspective by a study from Okazaki and Gotoh.[126] This investigation measured ion release from a number of stainless steels, cobalt–chromium alloys, and nitinol in a variety of simulated physiological solutions. The nitinol showed lower release of nickel ions than the stainless steels or the cobalt–chromium alloys in cell culture medium, PBS, 0.9% NaCl and Ringers solution. Higher release from the nitinol was only observed, with 0.9% NaCl, when the pH was pushed below 4.0 by adding HCl. Similarly, a study by Messer *et al.*[127] showed nitinol to have the lowest nickel ion release into endothelial cell culture, compared to stainless steel and cobalt–chromium.

However, while there has been several other cell assay studies that establish the biocompatibility of nitinol,[128–131] it must be recognized that there have also been some reports of allergic response to nitinol implants. Kim *et al.*[132] report on the allergic reaction of a patient after having a nitinol ductal occluder device (a similar device to the septal occluder, described earlier) implanted. The skin lesions that developed in this instance were readily treated with medication, and a skin patch test did confirm that the patient had a hypersensitivity to nickel. Interestingly, when medication was stopped after 3 months, the symptoms did not reoccur. This is perhaps further support of the data that show nickel release rapidly diminishing over time. In a review of sensitivity reactions to metallic endovascular devices, Honari *et al.*[133] documents two further cases where allergic response was directly attributable to implantation of such closure devices. While acknowledging that such reactions are rare and sometimes relatively minor or transient, the authors provide recommendations on metal sensitivity tests for patients prior to receiving any metallic implant. In this regard it is worth noting that nickel sensitivity

reactions are not limited to nitinol, and Honari *et al.*[133] also document studies relating to stainless steel and cobalt–chromium stents. The issue of nickel sensitivity and possible correlations to in-stent restenosis has long been debated, though never clearly resolved. Koster *et al.*[134] presented some of the first data on this subject, suggesting a possible link on the basis that patients with positive patch test results had a higher frequency of in-stent restenosis. However subsequent studies by Norgas *et al.*[135] and Iijima *et al.*[136] failed to show a correlation between positive patch test results and restenosis. All of these studies were primarily concerned with coronary stenting, and no nitinol stents were included in the test groups. However, given that nitinol typically releases less nickel than stainless steel or cobalt–chromium, it seems unlikely that nitinol devices could have restenosis issues directly attributable to their nickel content or to nickel release. To conclude, while each device may have its own unique features, including important surface oxide characteristics, in general the biocompatibility of nitinol is at least comparable to that of many typical implantable materials.

1.104.10. Summary and Future Directions

Shape memory effects can be observed in several alloys but from a medical device perspective, nitinol is the only significant shape memory material. The use of nitinol in a diverse array of medical devices has been described. The majority of the applications to date have been in the cardiovascular field, and this trend is likely to continue given the growing demand for peripheral interventional technologies. However, it is likely that ongoing developments in the production of porous structures will also enable an increasing number of applications in orthopedics.

There are many aspects of current nitinol technologies that require further investigation and development. These range from continuous improvements needed in design and manufacturing methodologies through to collection and understanding of more extensive fatigue data. Thermomechanical treatments merit further development – particular those aimed at producing refined grain structures. Schaffer[137] describes how nanocrystalline structures can provide an increase in the amount of superelastic recoverable strain as well as improvements in fatigue resistance.

Given the sensitivity of the material to precise nickel concentration there will probably be very little shift from the mainstream equiatomic or slightly nickel-rich compositions. There are, however, some novel developments under way that could eventually see broader application. These include a number of different ternary alloy compositions, with the third element being added to modify specific characteristics. For example, Haider *et al.*[138] report on exploration of NiTiTa alloys to improve radiopacity and NiTiCu compositions to increase corrosion resistance. Lin *et al.*[139] describe NiTiPt alloys also aimed at enhancing radiopacity; these alloys have shown narrower hysteresis between load and unload plateau which may also provide additional design options for devices. To conclude, nitinol has proven to be a unique material, enabling many highly worthy medical device developments, and this trend is likely to continue.

Glossary

Arthroplasty The surgical intervention aimed to restore the function of a body joint, for example, hip arthroplasty, knee arthroplasty, etc.

Sintering A thermal treatment process aimed to reduce the free surfaces of the body, achieving its densification. During sintering mass transport takes place depending on the differences in surface energy into the porosity, by diffusion due to the gradient in concentration of the chemical species into the body mass. The process takes place between one-half and two-thirds of the melting temperature, and is then suitable for shaping refractory materials.

Total hip replacement A medical device aimed at the substitution of the hip joint. It is formed by a stem to be inserted into the femur, which is surgically adapted to its shape, by a socket (or cup) to be fixed into the acetabulum after reaming, these two components form a spherical bearing (or joint).

Total knee replacement A medical device aimed at the substitution of the knee joint. It is formed by a femoral component that is fixed to the distal end of the femur replacing both condyles, by a tibial component (tibial tray) fixed to the proximal part of the tibia which is hosting the tibial plateau (fixed or mobile) onto which the femoral component is sliding. A fourth component of the implant is the patellar one, to be implanted in the inner part of the patella and articulating against the troclea between the femoral condyles.

Abbreviations

AMC	Alumina–matrix composite
ATZ	Alumina-toughened zirconia
CoC	Ceramic-on-ceramic THR bearing. Also synonym of alumina-on-alumina THR bearing
CoP	Ceramic-on-polyethylene THR bearing
FDA	United States Food and Drug Administration
IDE	Investigational device exemption
LPSN	Liquid-phase-sintered silicon nitride
LTD	Low-temperature degradation
Mg-PSZ	Magnesia-stabilized partially stabilized zirconia

MHRA	Medicine and Healthcare products Regulatory Agency	**THR**	Total hip replacement
MoP	Metal-on-polyethylene THR bearing	**TKA**	Total knee arthroplasty
PE	Polyethylene (all medical-grade types)	**TKR**	Total knee replacement
RBSN	Reaction-bonded silicon nitride	**UHMWPE**	Ultra high molecular weight polyethylene
ROM	Range of motion	**XLPE**	Cross-linked PE
TD	Theoretical density	**Y-TZP**	Yttria-stabilized tetragonal zirconia polycrystal
THA	Total hip arthroplasty	**ZTA**	Zirconia-toughened alumina

1.105.1. Introduction

Dense, hard and stable also in chemically aggressive environment at elevated temperature, alumina ceramic seemed the ideal material to the pioneers of the biomaterials science, when chemical stability and biologic inertia of the implants were the main requirements to be satisfied.

In orthopedic applications, alumina is a well-established material, with 40 years of clinical record so far, as components of the joints of total hip replacements (THR); newer applications can be foreseen in the near future, thanks to the introduction of high-performance alumina matrix composites. The success of alumina in THR bearings is relevant, especially in some European countries (Austria, France, Germany, Italy, Switzerland) where more than 50% of the hip implants make use of ceramic ball heads, and in Asian countries such as Korea where 72% of THRs have an alumina ball. Also, in countries where the introduction of ceramic bearing components took place later (USA, China, India, Eastern European countries) the use of ceramic heads and CoC bearings shows a growing trend (Table 1).

The use of alumina is so common in orthopedics that in scientific papers the use of the term 'ceramic' without any other specification to indicate alumina is accepted. The use of the term may be tricky because of the many ceramics that are, or have been, or are proposed to be used in the fabrication of bearing for joint replacements besides alumina (e.g., Y-TZP, Mg-PSZ, Si3N4, ZTA, ATZ, etc.). In this chapter we will follow the current use, that is 'ceramic' will mean 'alumina,' if not specified otherwise (Figure 1).

The first mention of the use of alumina as a biomaterial can be traced back to the German patent application made by Rock,[1] but alumina remained unexploited in clinical applications until the 1960s, when Lyman W. Smith[2] developed Cerosium, a silica aluminate containing up to 65% porosity filled with epoxy resin, to be used as a bone substitute. In the same year, Eyring and Campbell[3] developed alumina temporary osteotomy spacers, which were implanted in a small number of patients, while Sandhaus[4] developed and started the clinical use of a screw-shaped alumina dental implant, the concept of which originated several designs in the following years.[5]

During the 1960s, the hip arthroplasty procedure was gaining importance among the orthopedic community, addressing hip-related problems in millions of patients facing pain, disability, and limitation of activity. However, this procedure, which has proved to be one of the greatest successes in the field of surgery in recent times, did not produce the expected outcomes in the early stages. Catastrophic bearing wear was the most critical complication of the early devices, and many scientists concentrated their efforts on the research of better bearing couples.

In the early 1970s, alumina was the most advanced ceramic material, thanks to the availability of the high alumina powder, Degussit Al23, which helped to overcome many limitations of the earlier ceramic precursors. It was in this context that Dr. Pierre Boutin, an orthopedic surgeon working in Pau, a town in southern France, had the opportunity to discuss the feasibility of an alumina-on-alumina THR bearing with one of his patients, a top manager of CGE France, whose factory was

situated nearby. Their combined efforts led to the production of the first alumina-on-alumina bearing for total hip arthroplasty (THA).[6] Both the stem and the cup were fixed to the bone by cement (Figure 2).

In the same years, several pioneers like Langer in Keramed, Heimke in Friedrichsfeld, Dörre in Feldmüle, and Maier in Rosenthal were working in a big research program launched in Germany to develop alumina clinical implants. Both the stem and the cup of the hip replacements were designed to achieve cementless fixation in the host bone, that is, by a screw-like profile of the cup (Figure 3).

Some of the early devices, for example, hip replacements completely made out of polycrystalline alumina,[7] never went beyond the developmental stage but the device named 'femoral cap endoprostheses' completely made out alumina was used in eight cases of massive bone resections following chondrosarcoma or carcinoma metastases, and resurfacing alumina cups were used for hemiarthroplasty of the hip[8] (Figure 4).

As these developments were in progress in Europe, Japanese researchers were also developing alumina devices, some of them by using single crystal alumina.[9] The most impressive devices obtained by this original approach were single crystal alumina stems used for hip replacements implanted after resection of bone tumors, while polycrystalline alumina knee condyles, coupled to a alumina tibial plateau hosting an ultra high molecular weight polyethylene (UHMWPE) tibial component were used in alumina knee replacements and talar component has been used in ankle prostheses since the early 1980s.[10] Single crystal alumina was also used to manufacture blade and screw-shaped dental implants.[5]

The clinical use of these early large and heavy monolithic devices allowed surgeons and engineers to assess the clinical advantages of alumina-on-alumina bearings in terms of wear reduction and absence of particle-induced osteolysis. Unsatisfactory outcomes were due to the component design or to failures in the cementation. Nevertheless, in younger patients with good bone quality – in whom good primary stability in the cortical bone was achieved – several positive clinical results had been reported.[11–13]

Along the 40 years of clinical use of alumina, many improvements had been introduced in the material technology, which aimed to increase reliability of the products by increasing the ceramic density – result obtained by reducing and by making more homogeneous the grain size – and by increasing the purity of the material. In the beginning, the

Figure 3 The Prof. Mittelmeier's alumina-on-alumina bearing. Note the design of the cup, intended to achieve the device integration by the acetabular bone.

Figure 4 The Prof. Saltzer's 'recapping device,' to be implanted onto the surgically shaped femural shaft.

developments were focused on the selection of appropriate raw materials. The proper selection of the raw materials represents a critical step in any technology, and in the case of medical grade alumina a significant milestone in the development process was reached around 1980 when, thanks to the introduction of high purity powders for ceramic production and to the improvements in process control, the so-called 'second generation alumina' was obtained.

A significant step in the development of medical-grade alumina was marked by the introduction of hot isostatic pressing (HIP) in the production, a thermal treatment performed at extremely high pressures (about 1000 MPa) with temperature slightly below the sintering temperature, and this allows the obtaining of high density, limiting the development of the grain size. A further improvement that contributed to significantly increase the reliability of alumina components was the use of the laser for engraving the component's identification marks. Marks to identify, for example, manufacturer, size, and production lot were historically done by engraving the component before firing. Concerns arose about the effects of these marks that could act as stress risers on the service life of the component when combined with the notch sensitivity and brittleness inherent in alumina. The application of the new laser marking technique has allowed manufacturers to reduce the effect of markings on the mechanical behavior of the ceramic components, as it allows for a more rounded, less deep, and smoother profile on the markings, demonstrating an important addition to the reliability of alumina ceramic components in clinical use.

But the single most important development in improving the reliability of ceramic components was the introduction of proof test, a nondestructive test to be performed as a part of the final control on finished components, aimed to discard all those components where a flaw larger than a predetermined critical size may hamper the expected lifetime and performances. It is known that both the strength and lifetime of ceramic components is determined by the number of flaws within the material.

The development of the test on the basis of the fracture mechanics theory has been extensively discussed by Kleer *et al.*[14] and by Schaefer *et al.*[15]

Briefly, it has been shown that the two main stresses in the head are a tensile stress in the upper part of the inner bore (the dome) due to the forces transmitted by the cup, and a tensile orthoradial (hoop) stress in the taper due to the force exerted by the spigot on the ceramic. To obtain such a stress distribution close to the load bearing capability of the component under test, it has to be overloaded in a manner that ensures that the parts are not damaged in any way during the test, yet eliminating the possibility of an internal flaw not being detected.

Forces must be applied to the ceramic surfaces without damaging the component (head or cup) or the finish of the articulating surface, for example, by hydrostatic pressure, as explained by Schaefer *et al.*[12]

The introduction of laser marking, HIP, and proof testing of components in the manufacturing process around 1995 lead to 'third generation alumina,' which is still today on the market.

The key developments described above are only a few in the list of constant improvements made to alumina–ceramic components over the years, and are a part of the overall Quality Assurance System that encompasses the whole design, development, manufacturing, and post marketing monitoring of this kind of products. The Quality Control System, which monitors the compliance with the specifications of chemical composition, grain size, density, geometrical parameters, surface finish, sphericity, and such other aspects, throughout the manufacturing process, is only a part of it.

The definition of a set of reference standards for medical grade alumina played a pivotal role in this process. The first standard on alumina for clinical implants was issued in Germany in 1979 as DIN 58835. The standard ISO 6474, largely based on DIN 58835, was issued in 1980, and was followed by the similar standard ASTM F603. The current version of ISO 6474 was released in 1994, and is today under revision due to the improvements introduced in the manufacturing process. ISO 6474 is circulating as a DIS (Draft International Standard), while a ISO 6474 – Part 2 is under preparation to provide a reference for composite alumina–zirconia materials now available for biomedical applications, and known as ZTA (zirconia-toughened alumina) if alumina is the main constituent, or as ATZ (alumina-toughened zirconia) when the main constituent is zirconia.[16,17]

The main disadvantage of alumina is its brittle fracture mechanics that limits the flexibility of ceramic components during design. The persistent demand placed upon the implant manufacturers for new ceramic devices with increased reliability and longevity and sometimes a challenging design has pushed the industry to develop composite ceramic materials of higher strength, obtained by the introduction of zirconia as a reinforcing and toughening phase into the alumina matrix. Zirconia, notwithstanding its much lower hardness (1200 GPa), is characterized by toughness and bending strength that is twice that of the alumina due to the phase transformation toughening peculiar to this material.[18]

Considerable work was conducted during the second half of the 1980s in France and in the 1990s in Italy on ZTA as a biomaterial.[19–22] In ZTA, the constrained phase transition of zirconia grains from tetragonal to monoclinic (the native crystallographic form of zirconia) has to overcome stiffness of the alumina matrix which is much higher than that of zirconia. The compressive field, forming an energy barrier to cracks, is then enhanced by increasing the toughness of the material in a manner comprehensively described by De Aza *et al.*[23] An optimum compromise has to be sought between alumina and zirconia grain size, the zirconia–alumina ratio, and the additives.[21,22] Moreover, the increase in toughness and bending strength due to the presence of zirconia comes at the price of the decrease in hardness, related to the zirconia concentration in ZTA.

ZTAs have been proposed for dental and orthopedic applications.[23–26] Begand *et al.*[27] developed a zirconia–alumina composite mostly constituted by zirconia, a material belonging to the class of ceramics and identified by the general name ATZ. This material, which is now in use for the manufacture of THR ball heads, is a result of the dispersion of alpha–alumina (20 wt%), in a matrix of yttria-stabilized tetragonal zirconia polycrystal (Y-TZP), mostly tetragonal (66 wt%) and cubic (12 wt%), the balance being monoclinic zirconia and Yttria with an homogeneous structure and average grain size less than 0.5 μm.

So far, the alumina–zirconia composite with the longest clinical record is known by the trade name BIOLOX®delta.[28]

On February 2010, more than 1 million BIOLOX®delta components had been released in the market worldwide. BIOLOX®delta has a peculiar microstructure, constituted by a matrix of fine grained alumina (average grain size about 4.5 μm) containing a second phase of Y-TZP grains (average grain size about 0.3 μm) and a third phase of platelet-shaped crystals of strontium aluminate having a maximum length of 5 μm.[29] In this composite, the toughening and reinforcing actions are performed by two independent synergic mechanisms, that is, phase transformation of the fine and evenly dispersed Y-TZP grains (about 17 vol%) and crack bridging due to the presence of platelet-shaped grains that constitute about 3 vol% of the material, the balance being alumina and other oxides of which the CrO_2 forms a solid solution with alumina that gives the characteristic pink color to BIOLOX®delta. It is used to compensate for the decrease in hardness, thus allowing the use of this composite in the manufacture of CoC bearings (Table 2).

1.105.2. Properties of Alumina

1.105.2.1. Physical Properties

The clinical application of alumina is based on its biocompatibility, density, strength, and wear resistance. Alumina (aluminum oxide, Al_2O_3) may occur in many metastable phases. All these phases irreversibly transform into alpha–alumina if heated above 1200°C, a close-packed hexagonal arrangement of oxygen ions which is a very high thermodynamically stable phase, and is the material selected for biomedical application. α-Alumina (known also as corundum, or emery if containing impurities) forms several gemstones, for example, ruby, the red color of which is caused by the presence of Chromium and sapphire, the blue color of which is due to Titanium. Alpha–alumina is aluminum metal in its highest oxidative state where no more oxidative reactions are possible and the chemical and physical stability of the material being the maximum achievable. The strong ionic and covalent chemical bonds between Al_3^+ and O_2^- gives the material a high melting point, hardness, and resistance to the attack of strong inorganic acids, such as orthophosphoric or hydrofluoric acid.

In the lattice of alpha–alumina, each aluminum cations Al_3^+ is surrounded by oxygen anions O_2^- forming two regular triangles on both sides, twisted by 180° and lying on parallel planes. The surface layer of O_2^- anions allow the chemisorption on the surface of OH^+ groups, and the bonding of water molecules or proteins. In other words, the surface has an high wettability, higher than that of several metallic alloys.

This behavior, coupled with the high hardness of alumina (2000–2200 GPa), makes this ceramic an ideal material for the components of the arthroprostheses joints. The high hardness makes the alumina components extremely resistant to scratching from foreign bodies thus saving the extremely smooth surface finish achievable by diamond polishing (typical values: $R_a = 0.02$ μm, $R_t = 0.5$ μm). Both these characteristics (wettability and hardness) are prerequisites for the extreme low wear of the prosthetic bearings making use of alumina components.

Further physical characteristics of alumina which are relevant for *in vivo* behavior are density and porosity, both important for the mechanical performances of the ceramic products. Especially, the open porosity fraction that allows the penetration of liquids and gases below the surface and inside the ceramic has a strong influence on the long-term strength of alumina and is a characteristic to be carefully controlled in view of the use of alumina devices in the physiologic environment.

Medical grade alumina may contain a maximum concentration of 0.5 wt% sintering additives. These are mainly Magnesium and Chromium oxides. Magnesium oxide (MgO) is used as sintering additive to control the deleterious discontinuous grain growth and to achieve optimum results in terms of density and grain size, while Chromium Oxide (Cr_2O_3) is introduced in the matrix to compensate the decrease in hardness due to the introduction of MgO (Table 3; Figures 5 and 6).

1.105.2.2. Mechanical Properties

Alumina shares several characteristics with other polycrystalline ceramic materials, such as moderate tensile and bending resistance and the brittle fracture behavior, which is the main disadvantage of the mechanical properties of alumina.

Alumina is a ionic-covalent solid that does not yield under load as metals and alloys do. The strong chemical bonds in alumina are the roots of several of its characteristics such as the

Table 2 Synopsis of the evolution of alumina ceramics as a biomaterial

low electric and thermal conductivity, the high melting point that makes it practically impossible to shape alumina by casting, and the high hardness that characterizes this material and makes its machining complex and costly.

The brittleness of alumina is the main concern of engineers while designing alumina components. In metals, crack energy is dissipated by yielding at the crack tip, while alumina components may fail without any previous plastic deformation at the location of high tensile stresses, such as surface defects, notches, internal flaws, or on the occurrence of thermal shocks. Moreover, as polycrystalline ceramics contain a number of flaws characterized by a large scatter in size and by a random location within the solid body, the relationships between stress distribution, failure probability, and strength in ceramics need to be discussed on statistical basis.[32]

As a biomaterial, alumina ceramic has undergone great improvements in its mechanical properties during the 40 years of clinical use as described in **Section 1.105.1**. The remarkable increase in bending strength (from less than 400 MPa to more than 630 MPa in pure alumina components) is due to the improvements in the selection of raw materials used as precursors and in the sintering process that resulted in marked reduction in grain size and in the increase in density, which is close to the theoretical one.[29]

However, it was the introduction of the alumina composite in clinics that made it possible to overcome the limits of alumina in terms of mechanical properties, for example, the toughness and bending strength of BIOLOX®delta are more than twice that of the former BIOLOX®forte (**Table 4**).

Table 3 Physical properties of alumina

Property	*Units*	*Value*

1.105.2.3. Stability in Wet Environment

Among the characterstics that form the rationale behind the use of alumina in clinical application, the key point is the long-term stability of this material within the human body. The strength degradation of alumina in a wet environment is strongly dependent on density and on open porosity as discussed by several authors.[33,34,35] The liquids that may permeate the material through the open porosity may interact with the microstructural defects (flaws) that are intrinsic to

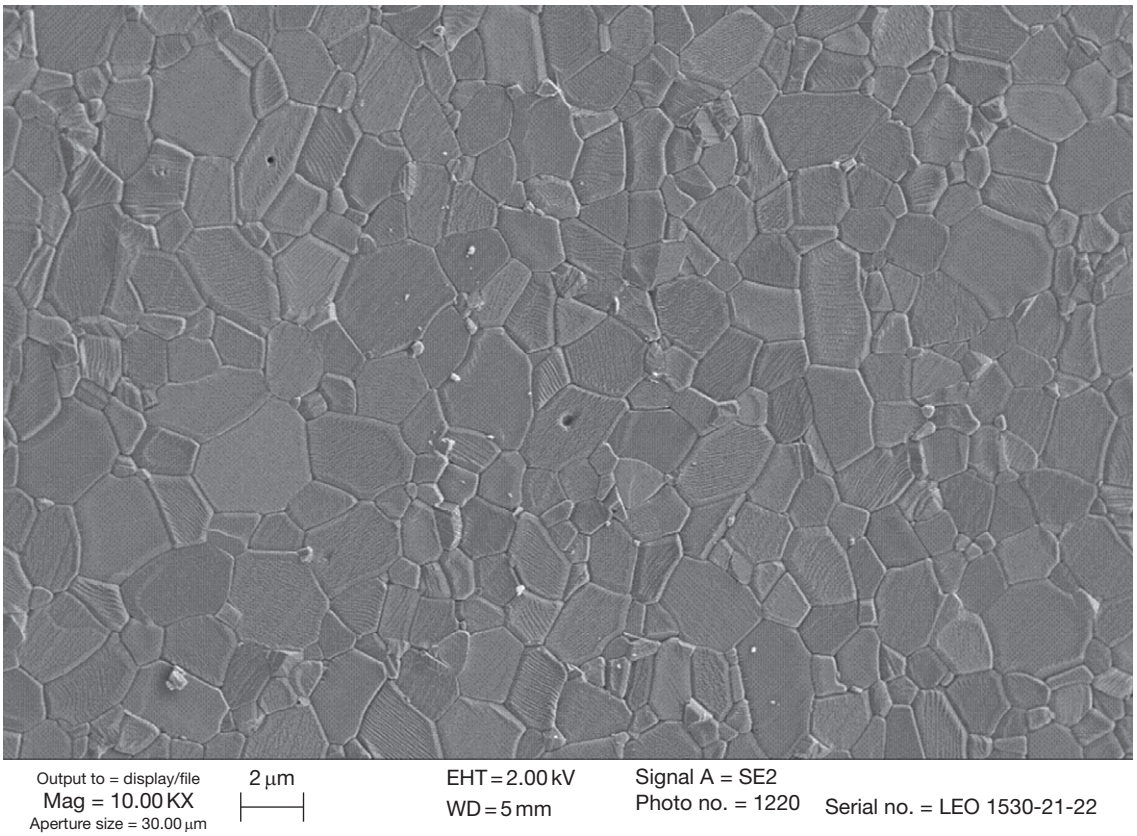

Figure 5 Microstructure of a contemporary medical-grade HIP-treated alumina (Courtesy Dr. L. Pilloni, ENEA, Rome, Italy).

ceramics because of their production technology. In a brittle material – such as alumina – subcritical cracks or flaws may grow at a speed much lower than the one leading to instantaneous failure. This behavior – known as subcritical crack growth (SCG) – depends on several variables (e.g., chemical species concentration, environment, temperature) and leads to the strength degradation of the component until it fails, thereby limiting its service life (see **Chapter 1.106, Zirconia as a Biomaterial**).

Especially during the early years of use of alumina ceramics in clinical applications, SCG was a relevant problem, although not of the same level for all the materials manufactured at that time. The introduction of high purity powders, and limiting to 0.1 vol% the content in calcia, alkali, and silica by the standard ISO 6474 in 1980, allowed for the control of the problem of strength degradation in alumina.

To achieve the grained, homogeneous, high-density, pore-free structure that characterizes medical grade alumina, the ceramic precursors used must be free from impurities such as CaO, NaO, and SiO_2 that play an important role on stability. CaO interactions with the aqueous environment, calcium migration, and segregation were found responsible for strength degradation by Sinkaroy *et al.*[36] and by Osterholm and Day,[37] while SiO_2 increased indirectly the risk of fatigue fracture, as during sintering it limits densification and promotes grain growth. Moreover, silica and alkalis (e.g., NaO) may segregate at grain boundaries and their dissolution in physiologic liquids may lead to accelerated fatigue fracture.[30] For the same reason, the content in MgO and the thermal cycle have to be tuned to avoid increase in solubility of the MgO in alumina, which leads to the formation of AlMgO spinel.

The issue of hydrothermal stability was also carefully investigated for the new alumina composites because of the presence of Y-TZP in their matrix and of the low temperature degradation behavior of this ceramic in the presence of the wet environment. It is noted that in BIOLOX®delta, due to the low content of Y-TZP (17 vol%) and to the stiffness of the alumina matrix, this behavior is very much limited and also the accelerated aging treatments in the most severe conditions (grinding, polishing, aging at 134°C in water up to 100 h) have been almost ineffective on the mechanical behavior of the material.[29]

In the case of ATZ, the situation is quite different because of the higher content in zirconia. Notwithstanding the presence of alumina in the composite that operates a limiting action on the extent of the phase transformation,[38] the increase in monoclinic phase is significant (monoclinic phase increase from 0.6 wt% to 58 wt%) with detrimental effects on the mechanical properties. The mean bending strength of the material shows a marked decrease in time, that is, 11% after 30 h and 18% after 30 or 100 h aging, respectively.[27]

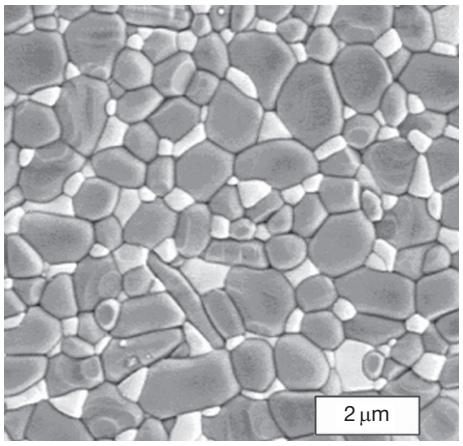

Figure 6 Micrograph of BIOLOX®delta, showing the platelets and the zirconia grains (white) forming the reinforcing and toughening phase in the alumina matrix (Courtesy Ceramtec Gmbh, Germany).

1.105.2.4. Wear Behavior of Alumina

In the processes leading to osteolysis and aseptic loosening of the implants, a relevant role is played by the cascade of cellular events following the release of large amounts of small particles in the joint, for example, due to the wear of the bearing. Aseptic loosening is the main cause of arthroprostheses failures, a problem of particular economic and social relevance, as revision arthroplasty is a costly and challenging surgery, with outcomes poorer than the primary surgery.

The relevance of the problem fostered wear studies aimed to predict the clinical performances of bearings in well-controlled laboratory conditions and to make a screening of the behavior of the different bearings. This resulted in a challenging task in terms of the difficulty in modeling the complexity of human articular joints. For this reason simulator testing of arthroprostheses' bearings needs to control a relevant number of parameters. A review on wear of orthopedic bearings[39] enlist 37 different parameters influencing laboratory tests, such as

Table 4 Mechanical properties of medical grade alumina and alumina composites

Data from Kuntz *et al.*[29] and Begand.[27]

the status of the surfaces, the type of contact between the surfaces, the materials, the geometrical characteristics of the joint, the loads and their variation in time, and the motion patterns. Deionized water, used in the early tests in joint simulator, does not represent the synovial fluids. The composition of the serum that forms the joint environment during the tests and of the additives mixed in it are further variables making the comparison between different laboratories sometimes difficult. The degradation of the serum for the heating due to the surface friction may strongly bias the results of wear tests: that is, the precipitation of calcium phosphates in the heated serum may alter the roughness of the ceramic head surface and increase the wear of polyethylene, while the formation of proteins layers may protect the cup in a way that does not occur *in vivo*.

The differences that can be remarked upon, between the results of laboratory tests performed in well-controlled conditions and clinical wear of bearings may be explained in terms of patient-related factors that influence clinical wear, for example, age, activity, pathology, etc. Moreover, in the laboratory setting there are no third bodies that may scratch the surface of heads and increase the wear of the bearing. This led to the development of 'nonstandard' simulator test for a better reproduction of the clinical situation, where studies on the effects on wear of third bodies, or of the microseparation of the bearing surfaces during the swing phase of the gait cycle due to the laxity of the joint can be performed.

1.105.2.4.1. Simulator tests on alumina-on-PE bearings

There is general agreement that when coupled with ceramic heads the wear of UHMWPE (PE) cups is reduced in comparison with metallic heads. The comprehensive review of laboratory and clinical data made by Clarke and Gustafson[40] shows that ceramic-on-polyethylene (CoP) bearings have in average half the wear of metal-on-polyethylene (MoP) bearings. The results obtained in laboratory tests of CoP bearings "document dramatic reductions in wear volume offering the prospect of increase polyethylene longevity and decreased potential for osteolytic response."[41]

About 70% of hip implants make use of PE for the acetabular component. As PE wear strongly depends on the roughness of the counterpart (the ball head), substantial effort has been devoted to improve the surface finish in the development of surface treatments of metallic heads (i.e., ion implantation, nitriding, etc.). Nevertheless, only the use of alumina heads so far allows 50% reduction of PE wear, thanks to the smooth finish and to the resistance to scratching of the alumina surface, and to the lubrication of the bearing due to alumina wettability.[42]

Third bodies, such as wear or cement debris and bone chips, can be present in the joint and remain embedded in the surface of the polyethylene cup, transported through the bearing interface, damaging the surfaces of metallic ball heads, for example, the presence of zirconia of barium sulphate particles, introduced in the bone cement to make it opaque to X-rays, may enhance the abrasive action of the debris. Alumina ball heads, because of their resistance to scratching, have proven to be extremely effective in preventing the negative effect of third bodies on PE wear.

The study of Minakawa *et al.*[43] clearly highlights these aspects. The Author measured the roughness of metallic and ceramic ball heads retrieved during revision surgeries. The roughness of alumina heads in damaged zones (0.023 μm) was about 1/20 of the roughness of damaged metallic heads ($R_{pm} = 0.4–0.556$ μm).

Similar observations were made by Wang *et al.*[44] who reported that when coupled with cross-linked PE (XLPE) cups and in presence of bone cement particles the wear rate of CoCr/XLPE bearings was 118 mm^3/million cycles while that of Alumina/XLPE was 35 mm^3/million cycles, indicating a lower potential for wearing of PE acetabular cups in the long term because of the superior resistance to surface damage of ceramics.

1.105.2.4.2. Simulator tests on alumina-on-alumina bearings

The biphasic behavior that characterize the wear of ceramic-on-ceramic bearings was already described by Boutin,[6] who reported a relatively high linear wear in the first million cycle while in the test the wear was 'undetectable.' The presence of an initial wearing-in phase (the run-in phase) was observed in the first 0.5–1 million cycle by several other investigators, and was analyzed in detail by Clarke *et al.*[45] who also reviewed the results of previous authors.

Nevelos *et al.*[46] studied the wear of BIOLOX®forte ceramic-on-ceramic bearings (CeramTec AG, Plochingen, Germany) using different joint clearances. In the first million cycles the run-in wear behavior was observed (0.14 mm^3/million cycles) followed by extremely low steady state wear (0.05 mm^3/million cycles). In former tests performed by the author in the same experimental conditions, the wear of metal/PE was 35 mm^3/million cycles. No difference depending on the clearances of the bearings tested (20 and 30 μm) was detectable. The reduction in wear using CoC bearings was also shown by the already cited study of Wang *et al.*[44] who measured alumina-on-alumina wear rate of 0.1 mm^3/million cycles, while the wear rate of alumina/XLPE and of MoM bearings tested in the same experimental conditions were 5.62 and 7.40 mm^3/million cycle, respectively.

Hip simulator tests also show favorable wear performances of the bearings based on the alumina matrix composites, although not all the materials show similar performances. The results of the study by Kaddick and Pfaff[47] demonstrated the very low wear of ceramic-on-ceramic BIOLOX®delta bearings, with a 150× reduction in wear debris volume of several orders of magnitude with respect to the alumina-PE bearings. In hip simulator tests, the volume of PE wear particles released when coupled with the alumina matrix composite BIOLOX®delta resulted in 60% of the one released when coupled with pure alumina (BIOLOX®forte).

1.105.2.4.3. Microseparation tests on alumina-on-alumina bearings

The wear tracks in alumina-on-alumina bearings frequently appear as stripes of variable width. Nevelos *et al.*[46] correlated this feature (stripe wear) with the separation of the bearing surfaces during the swing phase of the gait. If the soft tissue allows enough laxity to the joint, the ball will hit the rim of the acetabular cup before its relocation after the heel strikes the ball. The repeated impacts may damage the surface finish and

cause grain pullout eventually resulting in the stripe wear on the ceramic-on-ceramic joint. This behavior explains the differences that can be observed between the wear measured in some retrieved explants (up to 1 mm^3/year) and the wear measured in hip simulators.

The model of microseparation was implemented in a hip wear simulator in Leeds allowing researchers to observe for the first time in a laboratory test wear patterns and rates similar to the ones observed clinically by Nevelos *et al.*[46] Further studies performed with surface separation up to 500 µm show that steady state wear of alumina-on-alumina bearing is increased from 0.05 mm^3/million cycles in standard simulation mode, to 1.3 mm^3/million cycles in severe separation mode.[48]

The mechanical behavior of alumina matrix composite resulted in a very low wear in tests performed in microseparation mode. Stewart *et al.*[49] – who tested in microseparation BIOLOX®delta bearings – measured wear rates of 0.32 mm^3/million cycles in the run-in phase and 0.12 mm^3/million cycles in the steady state wear phase. BIOLOX®forte bearings tested in the same microseparation conditions were showing higher wear rate of one order of magnitude. Also, the wear stripes on the components were different between the two ceramic tested: the wear stripes on BIOLOX®delta were more shallow than the ones observed on BIOLOX®forte heads; this behavior appears to be related to the improved mechanical properties of the nanocomposite BIOLOX®delta.

Other zirconia-toughened alumina (NZTA) ceramics tested under the same conditions (microseparation mode) show wear rates almost twice that of BIOLOX®delta. No significant differences in hardness and fracture toughness between the NZTA tested and BIOLOX®delta were observed, but the flexural strength was two-third only. In comparison to NZTA, BIOLOX®delta has a much finer and homogeneous alumina matrix grain size and evenly distributed zirconia grains, these latter forming large agglomerates in NZTA.[50]

1.105.2.5. Biocompatibility

The *in vivo* biocompatibility of alumina is an already well established behavior since the beginning of the seventies.[51,52] The high oxidative status of alumina gives high chemical inertia to alumina ceramics, that are frequently taken as negative reference in biocompatibility testing of orthopedic biomaterials (see **Chapter 4.401, The Concept of Biocompatibility**; **Chapter 4.402, Biocompatibility and the Relationship to Standards: Meaning and Scope of Biomaterials Testing**; **Chapter 4.403, The Innate Response to Biomaterials**; **Chapter 4.404, Adaptive Immune Responses to Biomaterials**; and **Chapter 4.405, Leukocyte–Biomaterial Interaction *In Vitro***).

1.105.2.5.1. In vitro *tests*

Extraction procedures performed by media suitable for cell culture have shown the absence of release from alumina, and a very low cellular reactivity. The *in vitro* tests were performed using different cell lines (e.g., macrophages, lymphocytes, fibroblasts and osteoblasts), different cell conditions during the tests, and materials different both in physical forms (powders or dense ceramics) and with different chemical–physical characteristics (e.g., reactive surface, chemical composition, impurity content, etc.).[53]

The concentration of powders resulted relevant for cellular response. Dose dependent cytotoxicity was observed on human lymphocytes stimulated with phytohemoagglutinine in the presence of partially stabilized zirconia and alumina powders,[54] as well as on fibroblasts cocultured with ceramic extracts.[55] Similar dependence of cellular response on ceramic powders concentration was observed for macrophages apoptosis[56] and more recently by Kranz *et al.*[57] who observed cytotoxic reactions to corundum particles challenged to murine macrophages depending on particle size, the more cytotoxic being the nanometric ones because of their very high reactive surface for a given volume (see **Section 1.105.2.6**) (**Table 5**).

1.105.2.5.2. In vivo *tests*

The *in vivo* tests were performed on ceramics in different physical forms and in several sites of implantation, to analyze adverse reactions in soft tissue and/or bone, and systemic toxicity.

When implanted in soft tissues, dense alumina ceramics are surrounded by a layer of connective tissue that transforms in a fibrous membrane. Implants of alumina in bone performed in non-loaded sites show that bone comes into contact

with the ceramic without fibrous interposition. A thin proteoglycan layer is present at the bone–biomaterial interface, as expected from a 'nearly inert' material. Bone apposition at implant interface is enhanced by the stresses due to loading.[70]

The tissue reaction to the injection of alumina particles in several animal sites is characterized by the absence of acute toxicity: granulocytes and lymphocytes have been observed in numbers lower than after the injection of metals. Also at the higher reactive surface alumina elicit the weakest tissue response in comparison to metals and polyethylene: it was remarked that alumina particles did not induce the fibrosis observed after injection of polymeric or metallic particles.[70]

This behavior of ceramic powders was observed also by Warashina *et al.*[71] who implanted in rat calvaria powders of alumina, zirconia, polyethylene and Ti-alloy (Ti6Al4V).

Absence of acute or systemic toxicity was also observed after the implant of alumina or zirconia in bone. Hulbert *et al.*[51] observed the absence of systemic toxicity after the implantation of ceramic disks and tubes of different porosity in the paraspinal muscles of rabbits, and the dependence on pore size of the tissue ingrowth in ceramics.

Absence of acute sistemic adverse tissue reactions to ceramics were also reported after subcutis, intramuscular or intraperitoneal and intra-articular injection of alumina and zirconia powders in rats and/or mice, as well as by implants made into the paraspinal muscles of rabbits, rats or in rabbit's bone (see Piconi and Maccauro[53] for a comprehensive review) (Table 6).

1.105.2.5.3. Carcinogenecity

The issue of cancer development after joint replacement, especially related to metallic implants, was raised long time ago. So far, the only (and alone) case concerning a possible carcinogenic effect of ceramic in about 40 years of clinical use was that described by Ryu *et al.*[72] who associated the presence of a ceramic hip implant to soft tissue sarcoma.

Griss *et al.*[52] who analyzed the long term *in vivo* reactions to ceramics did not describe tumours and reported the absence of tumor induction by alumina powders. No carcinogenic reaction was observed after the subcutaneous injection of alumina powder in Sprague-Dawley rats[69] (Table 7).

1.105.2.6. Reaction to Ceramic Wear Debris

In spite of the excellent outcomes of the great majority of arthroplasties, the wear of the bearing surfaces is still among the major problem that limit their long term survival. Schmalzried and Callaghan[73] calculated that a well-functioning metal-on-polyethylene hip bearing may produce about 500,000 wear particles per step. The cascade of cellular events following the release of such large amounts of small particles in the joint leads to bone loss (osteolysis) and to implant loosening, which is the main cause of arthroprostheses failures, a problem of particular economic and social relevance, as revision arthroplasty still is a challenging surgery with outcomes poorer than primary surgery.

The reactions to wear debris had been described exhaustively by several comprehensive reviews.[73–76] The evidence collected show that size, shape, and nature of the debris, influence the rate of bone loss. In the case of polyethylene debris, the hypothesis that osteolysis takes place only if the density of debris in the tissue is above a threshold value was advanced and this resulted in the interest for bearings with a reduced wear rate.

Besides local effects, systemic effects of wear debris are relevant. Due to the pressure gradients generated by the motion of the articular joint during daily activity of the patient the wear debris dispersed in the fluid surrounding the joint can be transported by the fluids into body regions that form the 'effective joint space.'[73] A similar behavior had been reported formerly by Willert and Semlitsch[77] who observed that particles accumulate in periarticular tissues, leading eventually to granulomas associated with necrosis and fibrosis, can also migrate through vessels giving rise to systemic reactions.

Wear debris from hard-on-hard bearings (metal-on-metal and ceramic-on-ceramic) are characterized by a very fine size, most of their total volume being constituted by micron- or sub micron-size grains. Hard-on-hard bearings are intended for use in younger patients as they are the ones with longer life expectations, and the study of the chronic effects of these small particles has become very relevant.[74,78] Concerns had been raised especially about wear debris coming from metal-on-metal bearings,[79–81] while it is acknowledged that local and systemic reactions to alumina wear debris are reduced, in comparison to the ones observed in the presence of metal and polyethylene (UHMWPE) debris.

Table 7 Summary of carcinogenicity tests of alumina and zirconia

Maccauro *et al.*[26]	Ceramic	*In vitro*	Mutagenesis, carcinogenesys

Based on data from Piconi *et al.*[53]

Alumina wear debris have been found less active than UHMWPE debris in promoting the differentiation of osteoclasts, especially in the low concentration typical of the low wear of alumina bearings.[82] These findings correspond well to the ones reported by Fisher *et al.*[83] who demonstrated the negligible biological activity of ceramic-on-ceramic wear debris in comparison with standard polyethylene (60×) and to cross-linked polyethylene (13×).

The results reported by these Authors are in agreement with the ones reported formerly by Germain *et al.*[84] who observed that at equivalent volume concentration, the CoCr debris was more cytotoxic than the alumina ones, while Mattews *et al.*[85] reported that a concentration of alumina wear debris ten times higher than the one of polyethylene debris of the same size is necessary to stimulate osteolytic cytokines production by human peripheral blood mononuclear cells.

On the other hand, Krantz *et al.*[77] observed that cytotoxic reaction depends on particle size in murine macrophages challenged with corundum particles; the nanometric ones being the more cytotoxic. It is noted that depending on the grain size, ceramic powders may develop a significant surface area per mass unit, a feature that enhances the reactivity of powders in comparison to sintered ceramics. Especially the nanometric powders may develop specific surface area of some hundreds of square meters per gram.

A critical role in the transport of debris from the site of production into the peripheral organs is played by the blood vessels.[86] The presence of many vessels in the periprosthetic membrane containing debris may be considered an inflammatory aspect of the tissue response, typical of reaction to metals[88] related to the cytotoxicity of the particles and to the release of humoral factors after phagocytosis by macrophages. This behavior was observed also by Maccauro *et al.*[87] using an *in vivo* model designed for the gradual release of ceramic debris in the articular joint. This author reported the formation of fibrous tissue as 'poor' in vessels in the absence of contaminations from metals or polymers. Few giant cells were observable, a finding in agreement with Lerouge *et al.*[88] who reported that foreign body cells are typically associated to polyethylene, PMMA, and large metal particles, but rarely to ceramics. This finding was reported also by Christel[70] who in autoptic observations made on stable THR after 12 years of clinical use noted that ceramic debris were concentrated around capillaries in the ligament capsule in presence of a low local inflammatory reaction, while in failed THRs lymphocytes and plasma cells infiltrates were observed only when metallic debris were simultaneously found.

Baldini *et al.*[89] never observed massive osteolysis in a series of 30 failed alumina-on-alumina arthroplasties. Bone resorption leading to failure was due to infections either to secondary implant instability or malpositioning. In this series, a few ceramic wear debris were detectable, without any tissue reactions. Also in the few cases of severe wear foreign body multinucleated cells were absent, this being the main difference with failed metal-PE THAs.

In observing the tissues retrieved during 134 revision surgeries of ceramic-on-ceramic THRs implanted between 1974 and 1993. Fritsch *et al.*[90] noted that giant cells – considered strictly related to osteolysis – were detected only in a few cases, associated to bone cement particles in cemented THRs. Histology of this series of negative cases put in evidence no tissue necrosis and only slight fibrosis was detected indicating the high biocompatibility of alumina wear debris (0.5–2 μm), present within active macrophages.

The absence of vessels in the periprosthetic tissue surrounding alumina particles in alumina–alumina joints led De Santis *et al.*[91] to hypothesize that ceramic debris did not migrate from the production site. These findings, coupled with the chemical stability of ceramic oxides higher than the one of metals may be considered as indicative of the absence of systemic toxicity of ceramic debris in the long term (see **Chapter 6.606, Biological Effects of Wear Debris from Joint Arthroplasties**).

1.105.3. Clinical Application of Alumina Ceramics

The early alumina-on-alumina bearings had clinical outcomes that can be defined as 'mixed' at best. The review of the results of the French clinical series made by Nizard *et al.*[92] show that in 172 patients with more than 10-year follow-up, the revision of 15 acetabular cups for aseptic loosening was necessary and that there had been five component fractures. These results match the ones of the review of the German experience[93]: in the first series (109 patients, minimum 10-year follow-up) the aseptic loosening of the femoral component accounted for 24 revisions along with five fractured components.

Several lessons could be learned from these early clinical experiences. The failures observed were essentially related to the poor clinical performance of the acetabular component (French series) or of the femoral component (German and USA series) and were not related to the use of alumina on alumina bearings: the series reported by Miller *et al.*[94] consisted of 102 patients who experienced 26% aseptic loosening for the femoral stem but no fracture of any of the ceramic components within the first 3 years after implantation. It is also noted that the high incidence of fractures (3–13%; see Piconi *et al.*[95]) of the generation of alumina heads belongs to materials made in absence of any voluntary or consensus standard, and that the fractures reported in some series took place in components made by companies that are no more operational.[96] Besides this, the wear rate of these early alumina ceramic couple was very low compared to metal-UHMWPE couples (2.6 μm/year for the cup; 5.4 μm/year for the head), and complications related to aseptic loosening was drastically decreased by the application of ceramic in younger patients.

The solutions to these problems become the reference targets of the orthopedic ceramic manufacturers in the 1980s. Improved design of the fixations of both the acetabular and the femoral components reduced the incidence of loosening, as well as the adoption of patient selection criteria by the surgical community (younger, more active). Moreover, some ceramic manufacturers who were determined to continue in the field of orthopedics devoted their efforts first to standardize and then to improve alumina ceramics.

The experience in the United States with the early ceramic-on-ceramic (CoC) monolithic cup and cementless stems (Autophor) was poor and eventually led to the removal of the system from the market. Nevertheless, THRs using ceramic femoral heads coupled to polyethylene (CoP bearings) have

been used in the United States from 1989, when FDA gave its clearance limited to these devices. The experience cumulated by surgeons in non-US countries was demonstrating the benefits of modern CoC bearings for young and active patients with a dynamic lifestyle. Leading surgeons in Europe and in Japan, aware of the benefit this technology, offered it to their patients and continued to use CoC joints in THR since the 1980s, contributing in this way to the well-being of their patients and to the development of alumina as a biomaterial.

1.105.3.1. Technology of Alumina for THR Bearings

The use of alumina in the fabrication of ball heads and inlays for THR bearings is the main application of this ceramic as a biomaterial, and is today among the European leading technologies in biomedical engineering. The main manufacturer worldwide (CeramTec AG, Plochingen, Germany) alone is quoted to have sold more than 6 million alumina components of the different alumina BIOLOX® types so far (July 2010). Alumina components for THR bearings are manufactured by several companies worldwide each one making use of its proprietary process, characterized by specific choices in terms of starting materials, consolidation route, machining tolerances, quality control, and acceptance criteria. It is worthwhile then to outline the generic flow sheet which is used for the production of medical grade alumina components (Table 8).

The technology of alumina – and of most advanced ceramics – is based on the consolidation of powders, a process that can be summarized in three steps: pre-processing of the powder, shaping, and firing of the ceramic body.

Depending on the consolidation route and on the desired behavior of the final product the powder undergo several treatments that may include the blending of sintering aids (i.e., MgO forming a liquid phase that enhances mass transport at high temperature, thus allowing for the control of grain growth), of processing additives specific to the shaping process (i.e., waxes, as plasticizers of the mass and lubricant of the dyes), and of additives that will give peculiar properties to the ceramic.

The most common route for shaping ball heads and inlays is dye-pressing the 'ready-to-press' powders in cylindrical dyes. To optimize the feeding of the dye, the powder should have a good flowability. To this aim, the powders and the additives are blended in a slurry, which is then granulated by spray-drying to obtain particles uniform in size, that should be weak enough to be crushed, leaving no voids in the product. The dye-pressing product is the so-called 'green body,' with density being 50–60% of the theoretical density (TD). As the green body volume exceeds the one of the final component, the shrinkage that occurs during sintering due to the migration of porosity out of the ceramic must accurately be taken into account in designing the dyes.

Notwithstanding its low density, the green body has enough mechanical resistance to be handled and machined in the form of ball heads or of inlays. The machined parts are then submitted to a thermal treatment (sintering) that will bring them to high density. Sintering is usually performed in an oxidizing atmosphere in gas-heated kilns but continuous (tunnel) furnaces are also in use for high volume production. In these furnaces the green bodies are loaded on trays that are transported by a belt conveyor across a kiln tunnel formed by a series of chambers (zones) heated at different temperatures: time-temperature sequence depends on the speed of the conveyor and on the length of the chambers.

However, process parameters for sintering (temperature and time) alone do not guarantee that density, median grain size and grain size distribution can be optimized at the same time. For this reason, optimized grain size and distribution is obtained at a reduced sintering temperature, while the final density is achieved by a further thermal treatment performed under high pressures at a relatively high temperature (slightly below the sintering temperature), the so-called HIP. It is noted that HIP-treated BIOLOX®forte alumina made by CeramTec AG has a density of 3.97 $g\,cm^{-3}$ and average grain size less than 1.8 μm, while the former pressureless sintered BIOLOX®II had density of 3.95 $g\,cm^{-3}$ and average grain size of 4 μm (see Table 4).

After cooling, the spherical surface is diamond polished to the desired grade, the inner cone is ground to the expected tolerances in terms of roundness and linearity.

An alternative route consists in sintering balls of the desired diameter and then to hard machine the conical bore in the balls. This option allows a great flexibility in production to ceramic manufacturers, as ball diameters are standard, while the tapers – whose specification depend on the type of implant – can be machined on demand.

After machining and finishing, identification marks are engraved by laser. This marking method, as explained above, was a remarkable improvement in the reliability of alumina ceramic components, as engraved markings were acting as notches in the surface of the component. This step is followed by proof testing to detect the presence of internal flaws. It is noted that this testing procedure is not applied to 100% of the product by all the manufacturers of THR alumina components.

1.105.3.2. Design of Ceramic THR Bearings

The optimization in design and the evolution in technology have made available today's modular implants where the optimal material and size combination can be selected, depending on the options of the surgeon. Thanks to the taper connection, a stem may host metallic or ceramic heads that can be coupled with ceramic, metal, or polyethylene inserts hosted in modular acetabular sockets. Due to the number of available size this give rise to a family of bearings, providing the selection of the wear couple that better suits the

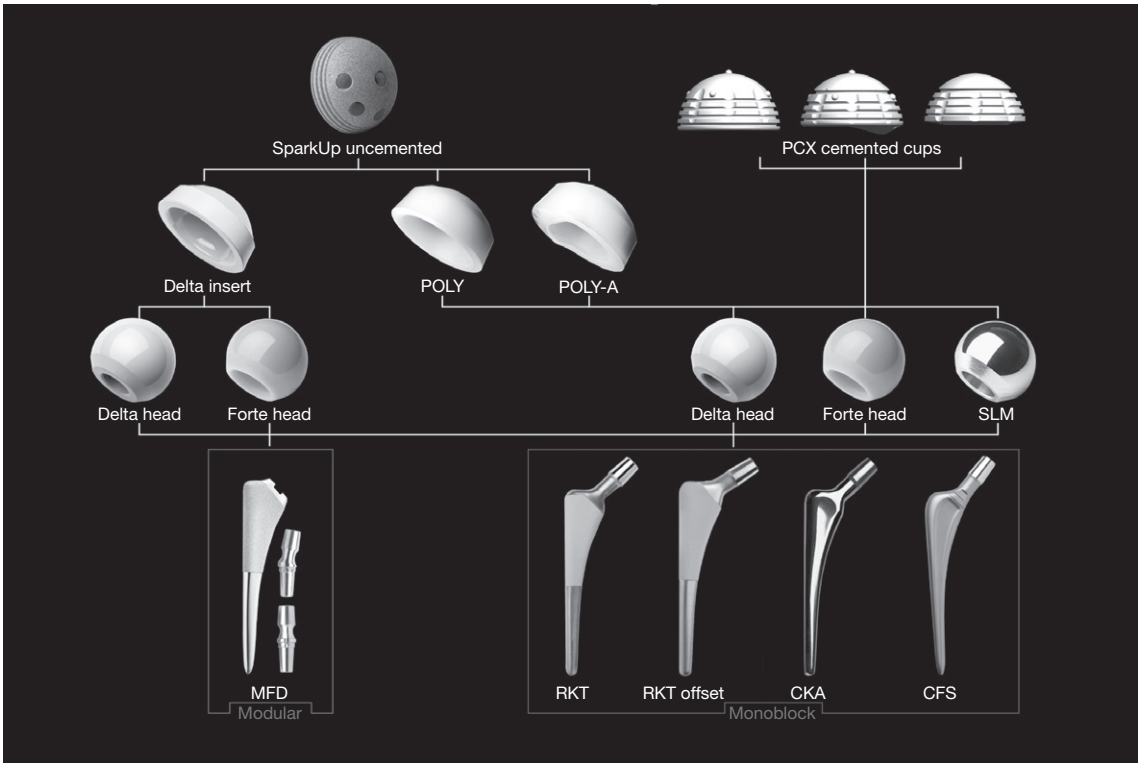

Figure 7 A modern modular Total Hip Replacement system, showing the different bearing solutions (Courtesy SAMO Biomedica SpA, Bologna, Italy).

needs and the anatomy of the patients. It is noted, however, that couplings shall not be made at random, but carefully following the instructions given by the implant manufacturer (Figure 7).

The introduction of ceramic ball heads raised the problem of metal–ceramic fixation, that found its solution by the introduction in THR technology of the Morse taper connection, made by German researchers in the early 1970s. The taper connection is stable in the long time, since ball-to-stem movement are eliminated. It is easy and quick to perform, easing the handling of the implant in the surgical theatre. Moreover, it makes no use of adhesives or solders that may pose problems of stability in the long term.[96]

Alumina ball heads are manufactured in five diameters from 28, 32, 36, 40, 44 mm. For any diameter, the internal depth of the conical bore can be selected in four steps, identified by the resulting neck length of the implant, that is, +5 (XL, Extra Long neck), +3.5 mm (L, Long neck), 0 mm (M, Medium neck), and –3.5 mm (S, Short neck).

The loads due to patient activity are transferred to the ceramic head generating two main tensile stresses in the ceramic head, for example, in the head dome, and homoradial (hoop) stresses close to the taper surface.[97,98] The stress distribution and intensity within the ceramic head depend on the friction between the taper surfaces and on the design of head, – for example, it is known that the frequency of fracture of 28 mm heads is higher than the one of 32 mm heads or bigger, and that the fracture frequency of medium neck (M-neck) heads is lower than the one of L- and S-neck heads. Although much of the attention is devoted to the ceramic, the metallic trunnion also plays a major role because stresses depend on taper characteristics such as stiffness, extent of the contact, cone angle, surface roughness, roundness, and straightness. It is noted that as the perfect matching of the metal trunnion and of the ceramic taper is only an ideal representation of the reality, the unavoidable tolerances in machining the metallic and ceramic surfaces through which the loads are transferred are relevant for the stress distribution in the system.[96]

To compensate the deviations due to machining tolerances, implant manufacturers take advantage of the ductility of metals, that is, providing grooves in the trunnion surface ('structured' taper). Provided that the angle of the bore into the head is slightly wider than the trunnion one, when the head is positioned onto the trunnion and loaded the tip of the grooves will be deformed progressively. In this way the contact area is increased and stress concentrations are avoided. Richter *et al.*[99] reported that the burst loads of alumina heads coupled to titanium alloy tapers is higher than the one observed for CoCr alloys due to the higher ductility of titanium alloys, and that the fracture load is higher in tapers with higher roughness. Also the head-trunnion friction torque is increased by the plastic deformation of the metal, improving the rotational stability of the coupling. A real diffusion joint is obtained in this way, as it is evident observing the marks of transferred metal in the taper of retrieved ceramic heads.[100]

Most of the considerations made above can be extended to the acetabular component of ceramic-on-ceramic bearing. Contemporary ceramic sockets for THA are metal backed devices, made out of a metallic shell hosting the ceramic insert. The socket may be pre-assembled (the so-called monoblock cups) or may have a modular design: a ceramic insert (or inlay)

is fixed into the metal back by a taper connection. Each implant system is characterized by its own design details, for example, presence of a rim to protect the ceramic from impingement, intermediate shells or rings between the ceramic and the metal back, etc. Morse taper must be self-locking, but it must also be possible to remove the components intraoperatively, or at the time of revision surgery, if necessary. For this reason 1:3 taper (about 18°) was selected for sockets, allowing the ceramic insert removal by, for example, a stroke on the rim of the metal back[96] (**Figure 8**).

The safety of modular sockets hosting ceramic liners depends on the roundness, straightness, roughness of the metal-ceramic interface, in a way similar to the one already described for ball heads. Moreover, the design of the mechanical interlock between the liner and the metal back has to assure the stability of the inlay, for example, when seated into the metal back the inlay has to resist to pull out, to torsion moments, to lever out moment due to the forces exerted on it when implanted.

Besides the taper connection, the manufacturers of ceramic-on-ceramic bearings have to take care of the clearance of the joint, for example, the difference between the head diameter and the inner diameter of the socket. This parameter is of paramount relevance for the performance of the bearing, as it allows the wedging of fluids in the bearing interface, assuring, in this way, the joint lubrication. To assure the optimal lubrication properties, the ball head should have a diameter slightly smaller than the cup's head; if equal, or bigger, the ball will stick into the cup, or will wear in a catastrophic way at the best, while a too large clearance may have a catastrophic influence on the stress distribution, due to the load concentration in the top of the insert dome.[99] Today, thanks to the improvements in the manufacturing process, deviation from roundness are in the order of a micron, allowing for the control of the clearance of ceramic-on-ceramic bearings, where the optimal value is between 20 and 80 μm.

The contemporary trend in THR design is to increase the bearing diameter, and ball heads 36 or 40 mm in diameter are now common in hip arthroplasty. This option has proven to be effective in the reduction of implant dislocations that are among the major complications in THR.[101,102] The increase of the head diameter is an effective way to increase the 'jumping distance' of the joint, for example, the displacement necessary to permanently dislocate the head from the socket. A further advantage of the increase of the head-to-neck diameter ratio is an increased range of motion (ROM), with reduction of the risk of impingement and consequent damage of the cup rim and of the stem neck. This is especially relevant for young and active patients, or for patients demanding high joint mobility due to their resting position (squatting).

It is noted, however, that the benefits of ROM are not directly proportional to the increase in ball head diameter, that is, the gain in ROM passing from 32 to 42 mm is lower that the gain when the diameter is increased from 22 to 32 mm. Moreover, the anatomy of the patient may be a limiting factor. The best benefit/diameter ratio looks to take place for a bearing diameter no more than 40–44 mm, a value that also allows to limit the overall diameter of the implant, a feature relevant both to save the patient's bone stock and for the implant intended for smaller anatomies (e.g., female or Asian patients).

The independence of the wear of THR ceramic bearings on the diameter[103] makes them interesting candidates for large diameter bearings, but the mechanical behavior of pure alumina did not allow the manufacture of components having the small wall thickness requested. This has been made possible by the introduction of alumina matrix composites in clinics and so far a relevant part of ceramic bearings for THR is manufactured 36 mm in diameter or more.

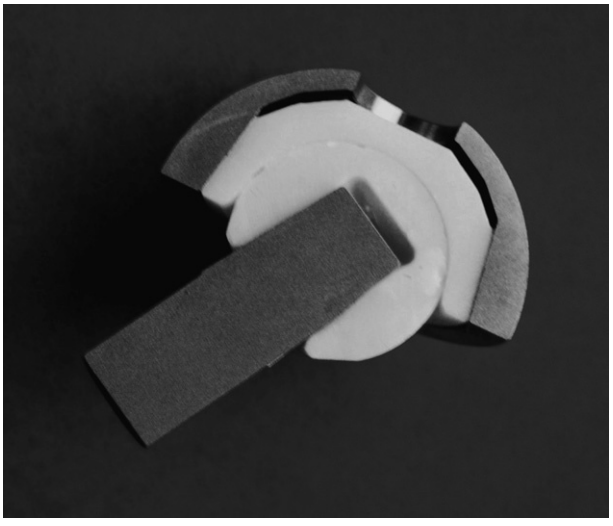

Figure 8 Cross-section of a ceramic-on-ceramic bearing, showing the ceramic-to-metal taper connections.

1.105.3.3. Clinical Results

The review of the long-term French experience in alumina THR bearings reported by Sedel[12] is very impressive, especially taking into account the state of the art in the early 1980s, the time of implant production. The results at 20-year follow-up reported were excellent: taking revision surgery for whatever reason as endpoint, the survival rate of cups was 85.6% (cementless cups) and 61.2% for cemented cups, while survival rate of cementless stems was 84.9% in comparison to 87.3% for the cemented ones. The wear of the ceramic components was undetectable. A further retrospective analysis of improved implants, implanted from 1990 to 1992 in young patients (mean age 46) was showing 93% survival rate at 9 years (taking revision surgery for any cause as endpoint), while taking aseptic loosening as endpoint the survival rate was 98.4%.

Long-term results obtained by a THR implant belonging to the first generations (Autophor 900-S) have also been reported by Petsatodis *et al.*[11] who reviewed at 22.25 years (mean survival time) a cohort of patients who underwent the implant of this cementless THA. The cumulative rate of survival (84.4% at 20.8 years) is remarkable, and the few cases of focal osteolysis leading to revision demonstrate the effectiveness of alumina bearings especially in young and active patients. The results are of special interest because they were obtained from an Autophor implant. The design of this device underwent several changes in time, with a significant evolution in clinical results. Mittelmeier *et al.*[104] in the retrospective analysis of

4000 Autophor THR at a maximum of 19 years reported the decrease in incidence of aseptic loosening from 35% using Autophor Type 1 (1974–7) to 15% with Type 2 (1976–84) and then to 2% with Type 3, implanted after 1984.

Alumina heads give positive clinical outcomes, and when coupled to PE they decrease the wear rate of the polymeric counterface. The reduction of wear debris-induced osteolysis can, for example, be observed also in the results reported by Suckel *et al.*[105] who evaluated retrospectively a series of 320 CoP THRs implanted in 303 patients, at a mean follow-up of 15 years, observing a 98% survival rate of both the femoral and of the acetabular components of the implants, as well as in the work of Ihle *et al.*[106] who analyzed a cohort of 93 consecutive uncemented THRs performed with the same PE cup running against alumina or CoCr-alloy ball heads, both at 32 mm diameter. At an average 19.3-year follow-up, the revision rate in the CoP group was 13.8%, while it was 46.2% in the MoP group. The wear rate of the PE cup when coupled with metallic heads, measured by computerized analysis of XR images, was 0.190 mm/year and 0.107 mm/year when coupled with ceramic heads, about 40% less linear wear.

However, it is in ceramic-on-ceramic bearings that the wear behavior of alumina are exploited at their best. This is shown, for example, by the work by Benazzo *et al.*[107] who retrospectively analyzed their 10-year experience with contemporary alumina implants. In their clinical series of 511 ceramic-on-ceramic THRs there were no cases of aseptic loosening, no radiological sign of cup or stem mobilization, the three implant revision performed were due to infection (two cases) or periprosthetic fracture (one case). Similar findings were reported by Lewis *et al.*[108] who investigated in a prospective randomized study the clinical outcomes of CoC bearings versus CoP bearings. Fifty-six THRs were followed with annual controls, the X-radiographs taken on the interview underwent computerized analysis. The results at 10-year follow-up show that the average ceramic/PE wear is fivefold the one of ceramic-on-ceramic bearings, while the two revision performed (one in each patient group) were not related to the type of bearing implanted.

An interesting insight on CoC bearings is given by the analysis of a series of 2984 CoC and 3432 MoP implants by Toni *et al.*[109] At 7-year follow-up the survival for THR with CoC bearings was 96.07% versus 92.61% for the MoP ones. The global incidence of aseptic loosening in THR with CoC bearings was less than one-half (45.5%) of the one observed in THR with MoP bearings, leading the Author to remark that the decreased risk of revision due to the use of alumina-on-alumina bearings instead of metal/polyethylene bearings justifies the selection of ceramic bearings on an economical basis.

A modern alumina-on-alumina THR bearing was approved for use in the USA on February 2003 by the Food and Drug Administration. The review by D'Antonio *et al.*[110] of the results in the 5 years range (5–8 years) found signs of femoral osteolysis only in 0.6% of the patients treated with CoC implants in comparison to 22.1% of the patients used as control and treated with MoP bearings. The corresponding revision rates were 1.8% versus 7.4% for CoC and MoP groups, respectively. These data were confirmed by the report, of Murphy *et al.*,[111] about the outcomes of 194 THRs implanted in 173 patients enrolled in the prospective Investigational Device Exemption study performed under the supervision of FDA which shows that the survivorship of CoC implants in hips that did not experience prior surgery was 99.3% at a maximum 9-year follow-up.

The complication rates of a CoC cementless implant that was the object of the FDA pre-market clinical trial were recently retrospectively analyzed by Mesko *et al.*[112] A total of 930 THRs implanted in 848 patients by nine surgeons was analyzed at 5- to 10-year follow-up, confirming the positive advantage of alumina-on-alumina bearings on the metal/PE control bearings. The Kaplan–Meier survivorship at 10 years taking revision of any component of the implants for any reason was 96.8% in the ceramic-on-ceramic group, while it was 92.1% in the metal/PE group (see **Chapter 6.604, Ceramic Prostheses: Clinical Results Worldwide**).

1.105.3.4. Complications

1.105.3.4.1. Failures in THR bearings

There is a little but finite risk of fracture in the use of ceramic component in THR bearings. This risk is low in comparison to the risk of fracture of stems, either to the catastrophic wear of PE inserts, and has to be weighted against the reduction of the risk of wear debris induced osteolysis. The Swedish Arthroplasty Register data show that loosening and osteolysis accounts for more than 80% of the THR revisions 6 years postoperatively onward.[113]

The fracture of the ceramic head is today a rather rare event, associated with severe traumas like road accidents or accidents in sports such as skiing, soccer playing, horse riding. If on the one side this testifies the sense of well-being and the good general health condition of THRs bearers today, it is noted that a few fractures are still too much.

Before 1980 the frequency of ceramic heads fractures was absolutely too high especially for the products of some manufacturers that have stopped to market ceramic components for THR bearings since a long time ago. The introduction in 1980 of the ISO 6474 standard for medical grade alumina established a set of quality requirements that limited the number of failures[95] but a wide scatter is still present in the data reported in the literature during the following years, indicative of the uncertainties present in this kind of evaluations. This behavior appears linked to the size of the study: numerous series do not show fractures, while the small ones show higher fracture rates, and it may be then hypothesized that some follow-up studies may present a bias depending on technical factors linked to the surgery.[96]

It is noted that the reliability of ceramic heads, belonging to the first generations, is higher than the one of other THR components – that is, of stems, of PE inlays – in the same age and that perception of the risk of fracture of ceramic components overestimate the real incidence of this event. It can be speculated if the spontaneous association of the concepts of 'brittleness' and 'ceramic' is coming from the everyday experience with dishes and cups. The study performed by Heck *et al.*[114] that involved about one-half of the members of the American Association for Hip and Knee Surgeons shows that taking as reference the observed rate of head fractures (0.22%),

the probability of fracture of the metallic stem or of catastrophic failure of the PE insert are respectively about 22 and 32% much higher. It is noted that 3 out of the 11 ceramic fractures were related to femoral heads implanted on suboptimal quality tapers.[115] Then the adjusted rate of head fractures (non-HIP-treated alumina) results are 0.15%. The low incidence of fractures of ceramic components is put in evidence also in the analysis by Castro *et al.*[116] of 1717 adverse events related to THRs reported to the FDA. The results shows that only 1% of adverse events was related to ceramic failures, while 18% were related to the failure of the femoral component (stem fracture, head dissociation, neck fracture, head wear) and 38% were failures of the acetabular cup. It is noted that these last figures may be biased by the low number of ceramic heads in use in the USA at that time.

Both the abovementioned studies are related to ceramic heads made before 1995, belonging to the so-called 'second generation alumina.' The data related to the HIP-treated 'third generation alumina' demonste the effectiveness of the improvements introduced in the manufacturing process. BIOLOX®forte heads[115] show a well-defined trend in the reduction of the number of fractures from 2000 to 2005, which is today about 0.02% (2/10,000). Most of the fractures are related to 28 mm diameter heads with neck length other than medium size (see **Section 1.105.3.2**). The increase in femoral head diameter, besides the advantage on stability and range of motion of the joints, brings an increase in reliability of the heads, the failure rate of 28 mm alumina heads being about fourfold the 32 mm one. The decreasing trend reported may then be due to several synergistic factors, for example, due to the improvements in the overall manufacturing process and quality control, to the extension in the use of 32 mm heads, and to the surgeon's improved knowledge on the use of ceramic bearings. The use of ceramic components requires the knowledge of several procedures to be carefully followed during their handling in the surgical theatre to avoid disastrous failures.[117]

The results of the investigational device exemption (IDE) study of a 28 mm CoC bearing made out of the alumina matrix nanocomposite BIOLOX®delta have been recently reported by Hamilton *et al.*[118] The prospective, randomized, multicenter trial was focused on a single model of cementless acetabular component (Pinnacle®, DePuy, Warsaw, IN) coupled to five different cementless stems. The study enrolled 263 patients (264 hips) who were treated in eight centres. A CoP (XLPE) bearing was implanted in the control group. There were four revisions in the CoC group and two in the control group. Four events related to the ceramic liners and the surgeon's difficulty in obtaining a correct seating into the metallic shell had been reported. In three cases, the problems were settled intraoperatively, while the correction of fourth one – a liner eccentric in the shell at the time of surgery, fractured 12 months postoperatively – demanded the revision surgery. The implant survival rate is similar in the two groups (97.6% CoC, 97.7% CoP).

A further cohort of patients who too were a part of the IDE study was reviewed at a mean follow-up of 6 years.[119] The bearing in the implants under study was formed by a BIOLOX®delta head articulating in a BIOLOX®forte insert. The socket was of the sandwich type. The control group received a Y-TZP head articulating on XLPE insert. Six years postoperatively the two groups did not show significant difference. The major event was the atraumatical fracture of a BIOLOX®delta head (28 mm, S-neck). It is, however, noted that the introduction in clinics of the new ceramic nanocomposite BIOLOX®delta has a positive effect on the head reliability: the rate of fracture of BIOLOX®delta ball heads is 0.003% or 3/100,000 based on the reports received by the manufacturer on 650,000 ball heads of this material released to market on February 2010.[120]

In the acetabular side, the fracture of ceramic inlays is a rather uncommon event. The reported frequency of rim chipping during surgery due, for example, to errors in the alignment of the inserts into the metal shells during surgeries was about 0.018% in the period 2000–5. Garino *et al.*[115] remark that in comparison to BIOLOX®forte heads the failure rate of BIOLOX®forte inserts decreased from 2000 to 2006, and it can be speculated as to how much the 'learning curve' of surgeons using CoC bearings may have contributed to this trend.

Nevertheless, it is noted that the safety of the insert depends on the design of the whole acetabular component: the introduction of a new design originated an unexpected high number (up to 2.6%) of intraoperative rim chipping in a series of devices in the USA, as did the use of compliant fiber metal cup that led to 1.3% fracture rate.[121] High incidence of insert fractures (3–6%) was also reported for some design of the so-called sandwich cups.[119] In these devices a PE cup is placed between the metal back and the insert – sometimes the PE is molded directly on the outer part of the insert – to reduce the dynamic stresses at the bone-shell interface.

It was hypothesized that in some design the high flexibility of the metal back and its deformation by the loads of the gait – especially in case of rim loading of the inlay due to malpositioning of the socket – may lead to the dislocation of the insert within the metal back,[122] to load concentration in the rim zone, and to fracture. The deformation of the metallic shell can be enhanced by the underreaming of the acetabular bed. Laboratory tests have shown[123] that the retentive forces do not change significantly, but questions arise on the insert stability in the long term due to the shell deformations observed on the testing apparatus. It is noted that this was observed in components positioned in a laboratory setting, then in conditions quite different from the surgical theatre ones.

1.105.3.4.2. Noises in THR bearings

In the last 5 years the orthopedic community, especially in the USA, has focused its interest on the noises that can come from hip replacements. The incidence of this almost always transient behavior is rather low overall (0.5%), but in some studies much higher values has been reported. In the beginning noises (e.g., squeaking) were associated with hard-on-hard bearings only, but several reports (see, e.g., Glaser *et al.*[124]) have shown that noises of several nature can be audible from whatever type of THR bearing.

Several hypotheses had been advanced about the nature of the phenomenon that looks multifactorial. A landmark was put by the study of Walter *et al.*[122] by acoustic analysis. They tested four different types of femoral and four acetabular components observing absence of emission of audible

frequencies from well-assembled modular components, either from any of the unassembled ceramic heads or liners. The implant tested had different thickness, as the use of thinner components in modular implants is a solution adopted both to save the patient bone stock and to improve the stress distribution in bone. An 'audible resonance' was on the other hand generated by the shells made out of titanium alloy, the frequency of the sound was inversely related to the shell thickness (and stiffness). Also the titanium stems tested generated audible frequencies. It is noted that some implants generate *in vivo* squeaking noises at the extreme of their range of motion, where edge loading on the insert can occur. It is also noted that in a number of retrieved noisy implants there are evidences of impingement – more evident in some cup design with protected insert rim – and of edge loading due to malpositioning. Most of the ceramic components retrieved had transfers of metal on the articulating surfaces. These findings led the author to see the concurrent origins of the noises in liner malpositioning on surgery, in edge loading, or in joint laxity.

The results of this study have a good correspondence with the ones presented by Restrepo *et al.*[125] who observed a seven times higher incidence of noisy hips in patients implanted with a low stiffness THR, in comparison with patients who underwent the implant of a much stiffer stem and cup. These findings led this author to hypothesize that the frictional forces generated at the ball–insert interface by an interruption of the lubricating fluid film, due to metal contamination of the ceramic surface, decreasing its wettability, or the alteration of the surface finish due to edge loading, microseparation, and stripe wear, are transmitted to the elastic metallic components that start vibrating in the audible range of frequencies. The low stiffness of the implant due to its construction by titanium–molybdenum–zirconium–iron (TMZF) alloy instead of the traditional Ti–Al–V alloy, the use of a smaller taper for head fixation, the design of stem and of implant neck justify this hypothesis.

Till date, the multifactorial nature of noise generation is debated and its incidence also seems to be sharply decreasing. It is noted that in the EU Countries where the use of ceramics has become a well-established practice, this phenomenon was registered only episodically and does not, however, compromise the integrity of the implants.

1.105.3.5. Tips and Tricks in Alumina Bearings

The ability of a ceramic bearing to satisfy the patient demand for a long time depends on several factors such as the manufacturing, implant design, and surgery. The proof testing adopted in production today, allows for the elimination of defective parts before their release to the market. The effectiveness of this control procedure is demonstrated by the progressive reduction of fractures reported in the last years. Moreover, it was remarked by Garino *et al.*[115] that almost one-half of the fractures takes place within 12 months from surgery, then it is likely that the origin of the failure lies in the abnormal stress distribution in the head, for example, disturbance of the head–trunnion interface that will lead to stresses higher than fracture strength of the material should a sudden overload take place after the implantation.

This may happen for several reasons, linked to the modularity of the implants and to their handling in the surgical theatre, as underlined by the MHRA in the UK.[126] It is of uppermost relevance to avoid the contamination of the taper: it has been shown[120] that particles of bone cement, serum, bone chips, fat tissue, or water in the taper interface can decrease the burst load of ceramic heads down to 40% of the original value, while the residual burst load of the head on a taper that has been scratched during the THR handling is only 20% of the original one.

The reliability of the ceramic components can also be compromised by a number of other actions,[117] for example, the use of metallic mallets in positioning of ball heads on metallic taper or by thermal shock due to fast cooling after autoclave sterilization.

A third critical aspect to achieve the expected implant performances depends on the surgical technique: both extreme accuracy and careful attention to the smallest details are demanded.

In handling the acetabular metallic shell, attention should be paid to not to damage both the inside rims of the taper. Should the use of additional screws be necessary, it is mandatory to check that there is no screw head protrusion inside the acetabular cup. The removal of the soft tissues close to the cup rim is recommended to avoid the contamination of the taper interfaces, as well as repeated washing and drying to remove any fat and clots. The liner shall be gently placed into the shell. Special care has to be taken about orientation, as edge loading of the socket and impingement upon the components depend on this parameter: perfect THR component adaptation and orientation, and soft tissue tension are required.

In ceramic–ceramic, the positioning of the cup is critical, as it influences the stress distribution of the bearing interface. Both the inclination and the anteversion of the cup shall be taken into account.

Inclination is related to the position of the cup in the sagittal (lateral) plane: when the cup is too vertical, the concentration of stresses in the rim may originate edge wear, while dislocation may happen both for too horizontal or for too vertical cups. Anteversion of the cup is also very important, as a malpositioning can cause dislocation, early wear, and also impingement of the neck zone of the stem with the socket rim. It is important to remember that not only the too vertical cup but also a too anteverted or retroverted cup is a cause of stress concentration and potentially early wear.[96] Moreover, would the cup be too anteverted the stress will be concentrated on a small portion of the bone.

The most common mistakes in cup positioning are placing the cup too vertical and too retroverted: this appears relevant for the risk of dislocation. That is, a malpositioned cup raises the rate of short-term and long-term complications, but a too vertical cup increases the stresses on the rim of the ceramic insert, with potential problems of wear. On the other hand when the cup is too horizontal, the anterior wall and the superior wall are far out from the bone, and this of course decreases the stability of the component.

To avoid impingement and to obtain the maximum range of motion, there is a range of socket anteversion for each couple of socket abduction and femoral anteversion angles. The papers by Pitto *et al.*[127] and by Garino[128] constitute an

exhaustive review of the issue of cup orientation, and what the optimum positioning is, is still a topic of debate. The recommendations expressed by different authors reported by Pitto *et al.*[127] indicate cup abduction angles in the range from 30° to 50° and anteversion angles between 10° and 30°, both depending on the patient's anatomy.

A further parameter to be carefully controlled is the correct seating of the insert in the metal back because any tilting of the insert in the metal shell will cause the insert failure. Passing the finger of the socket rim to check that the rim of the shell and the rim of the insert are flush, then correcting any malpositioning, is a simple and effective way to enhance intraoperatively the reliability of the implant.

Care is to be taken in avoiding the pairing of components from different manufacturers, or in selecting wear couples unauthorised by the manufacturer of the device. That is, besides the nominal diameter, manufacturing tolerances are unavoidable and are different for each implant and for the same manufacturer also. Randomised coupling may lead to catastrophic wear and to the failure of the implant: it is noted that the now abandoned ASTM F 1636-95 standard was listing 29 different taper angles in the range from 4° to 6° for use in THRs, a difference quite impossible to note by the naked eye, but that changes dramatically the stress distribution should mistakes be made in coupling.[129]

1.105.3.6. Revision Strategies

The revision of ceramic components[130] is characterized by several specific features as the cause of revision are usually not related to osteolysis due to the little debris production in ceramic-on-ceramic joints, but more often to mechanical aseptic loosening of the socket, bearing dislocation, impingement, or to the fracture of the ceramic components. In case of socket loosening, if the revision is performed in a short time, few ceramic debris may be expected, and it may be possible to retain socket and head. For longer loosening time, if socket is damaged or tilted it has to be replaced, while the head substitution may be avoided if the ceramic is undamaged.

In case of fracture of the ceramic insert, the best choice is to replace it by a new one, and to replace the ceramic ball head too: it is likely that the insert debris constrained in this case between two hard surfaces may have damaged the articular surface of the head.

In the case of a fractured ball head, besides the need of fragments removal, the replacement of the insert by a new one, whatever its nature (polyethylene or ceramic), is recommended. The insert replacement also must be performed if the preexisting insert appears in good conditions at visual examination. Allain *et al.*[131] recommend cup substitution even if it appears undamaged in case of a fracture of ceramic head, and the implant of a CoCr-alloy head, joined to the extensive removal of the synovia to eliminate the maximum of debris. This option is valuable only if it is not possible to implant a new ceramic ball head, for the residual risk of early failure of revision surgery due to severe wear of the metallic heads by the ceramic debris that remained trapped in the polyethylene cup surface, as in the several cases that have been already reported.[132–134]

The substitution of the fractured ball head by a new ceramic one if the taper looks undamaged was performed in selected cases from more than 20 years. Sedel[135] reported not to have had fractures in a 15-year follow-up of ceramic heads implanted on tapes that resulted undamaged at the time of revision surgery. Nevertheless, the manufacturers of ceramic bearings and MHRA[126] recommend not to install a new ceramic head on the used taper because of the damage made to the taper surface by the fragments of the broken ceramic components. The ridges at the scratch rims will act as stress risers at the taper interface compromising the reliability of the new ceramic head. To install a new ceramic head, if the implant does not have modular neck/taper component, the stem substitution is demanded. This decision to remove a usually stable stem is not an easy one: stems holding ceramic bearings are usually stable because of the absence of debris-induced osteolysis.

The solution has come with the introduction in the market of ceramic heads of special design, to be implanted on the used taper with an intermediate titanium sleeve, provided that the level of taper damage allows this technique. In this way, the taper becomes much larger in diameter, which corresponds to a decrease in thickness of the ball head wall, then the use of the new alumina composites for the construction of these devices (e.g., BIOLOX®option, CeramTec AG) was necessary. The sleeves are designed to obtain different neck length, in such a way that during surgery it would be possible to select the correct lateralization of the implant. Moreover, with such sleeves it is possible to have additional neck length (from +5 to +7 mm) adding extra-length size to ceramic heads. The early clinical results reported show the positive outcomes of this technique, that may also be suitable for primary implants[136,137] (**Figure 9**).

1.105.3.7. Alumina in Knee Replacements

The implant of a total knee replacement (TKR) is today a standard surgical procedure to overcome the mobility limits

Figure 9 BIOLOX®option ball heads, with internal titanium alloy sleeve (Courtesy CeramTec AG, Plochingen, Germany).

in patients suffering from osteoarthritis of the knee that have already been treated for a long time to reduce pain and control inflammation of the joint. TKR has proven to be overall a successful surgical procedure, with positive outcomes in terms of function and correction of deformities, if any. So far, about 900 000 TKR implants are performed each year worldwide, and in some counties the yearly number of TKR implants is higher than that of THRs.

The first use of alumina in the knee is due to Langer, who performed the implants of unicondylar ceramic tibial components in 73 cases from 1972 to 1980 in the Orthopedic Clinic of the University of Jena.[138] The use of these devices, made by the company Hermsdorf in the former German Democratic Republic, was stopped in the 1980s, due to the availability of modern TKR in that country. It is then acknowledged that the path for the development of a ceramic TKR was started in Japan in the late 1970s by Prof. Hironobu Oonishi, a pioneer in the development of ceramic devices, who implanted a first series of devices manufactured by the company Kyocera. These TKRs (the so-called KOM-1) were made of an alumina tibial plateau hosting a polyethylene platform on which was articulating an alumina femoral component, and were implanted cementless in 134 patients.

Several versions of this implant were set up in time:[139] the kinematics was improved, a titanium-alloy tibial tray was introduced and design was modified for cemented fixation of both the tibial and of the femoral components. These improved versions have been implanted in 534 joints until 2006. The latest evolution of the KOM (KU type, JMM Co) with the femoral components made in Y-TZP has been implanted since 2001 in Japan.

The use of a ceramic knee replacement has several potential advantages; first, an improved lubrication of the articulating surface due to the high wettability of ceramic surface by the synovia liquid and then a lower wear rate of the PE liner of the tibial component. A reduction in PE wear can also be expected for the better scratching resistance of the ceramic surfaces, in comparison to metallic alloys, that will save the polished surface of the articulating condyles. Moreover, it is known that the degree of finish achievable in ceramic surfaces is far beyond the ones achievable in metals. The absence of scratching or of increased roughness on the condyles of a KOM-type femoral component implanted in 1979 in a young patient and retrieved after 23 years of clinical use was reported by Oonishi *et al.*[140] who on the other hand, observed worn areas of different severity in CoCr femoral components retrieved after 3 years of clinical use.

The issue of wear is becoming more and more relevant as more younger patients are today candidates for TKR. These patients not intended to change their active lifestyle and have high expectations from surgery, that is, to recover their original conditions and be able to practice sports like downhill skiing or golf.

A further reason for the selection of ceramics is linked to the growing incidence of allergic reactions to metal ions, and of the wide metallic surface that patients may develop for the presence of different metallic implants in several anatomical districts of the body.

Notwithstanding the improvements introduced in the technology, the intrinsic brittleness of alumina was the bigger limit for the development of a knee replacement out of this material. Thanks to the higher strength and impact resistance of alumina matrix composite[141] it was possible to start the manufacture of alumina TKR devices with reduced thickness, reducing the patient's bone resections.[142] The early clinical results of a first device of this kind (Multigen Plus, Lima Corp.) have been reported recently.[143] Forty patients had been treated in two centers on the basis of a common selection and surgical protocol. The implant is made by a femoral ceramic component (BIOLOX®delta, CeramTec AG), a PE tibial component, and a Ti-alloy tibial tray. The femoral component and the tibial tray are both cemented to the bone. Twelve months postoperatively, there were no device-related complications in the patient cohort under study, and significant improvement of the physical functions was reported both in the 3- and 12-month evaluations (**Figure 10**).

1.105.3.8. Alumina in Other Medical Devices

On the wake of the promising results obtained by the alumina dental implants by Sandhaus, several researchers started the development of alumina dental implant devices. In the United States, Hulbert, Klawitter, Driskell developed different devices but the largest success was obtained by the so-called Tübingen implant, made by the company Friedrichsfeld (Mannheim) under the trademark Frialit®.[5] The comprehensive research program launched in Germany that led to the development of BIOLOX® alumina heads and sockets for THRs, also led to the development of several prototypes of alumina devices for other applications, such as middle ear implant for the replacement of the ossicular chain, keratoprostheses. Anchor- and screw-shaped dental implants have also been developed by the company Feldmüle (now CeramTec AG, Plochingen) (**Figure 11**) (see **Chapter 6.619, Materials in Dental Implantology**).

The mechanical behavior of alumina was the main limit for all those devices. Especially for dental implants the high stiffness of alumina did not allow the expected load transfer to the host bone. Besides this, to support masticatory loads, the implants were rather bulky, the transverse sections sometimes exceeded the thickness of normal maxillae.

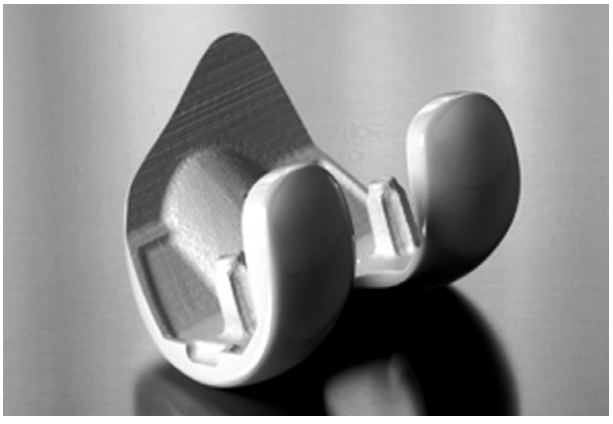

Figure 10 Ceramic (BIOLOX®delta) femoral component for total knee replacement (Courtesy CeramTec AG, Plochingen, Germany).

Figure 11 Alumina endodontic pins, anchor- and screw-shaped dental implants manufactured during the 1970s and 1980s (Courtesy CeramTec AG, Plochingen, Germany).

The Japanese approach to the alumina dental implants was based on the technology of synthetic sapphire (alumina single crystals). Blade-, tap-, and screw-type dental implants made out of synthetic sapphire were manufactured by Kyocera and were in clinical use in Japan since 1972, and in the United States since 1980. These implants had relevant aesthetic advantages on the metallic contemporary device, their gingival emergence being clear and transparent. Recently, Takahashi *et al.*[144] reported the follow-up of a series of 65 tap-type porous sapphire dental implants, three of them still in place after 21–23 years.

However, alumina dental implants have been outpaced by the modern titanium implants: new momentum to this technology in dentistry was given by the introduction of Y-TZP in dental implant production.[5]

So far, the only application of alumina medical devices within the human body besides the orthopedic ones is in orbital implants. These devices must have high biocompatibility, high porosity (to reduce overall weight), and hardness to provide movement of the artificial eye.[145]

Another aluminum oxide application had been attempted as a porous coating of the struts of drug eluting vascular stents, aimed to host and release the drug inhibiting the restenosis of the blood vessel. The coating was obtained by oxidation of pure aluminum metal that was applied on the stent's struts.[146]

New applications can come only by contemporary alumina matrix composites and extending the flexibility in design will allow engineers and surgeons to set up new ceramic components. An example of the design flexibility allowed by the new alumina–matrix composite ceramics is the Self-Adjusting Cup System,[147] a three-component bearing designed to achieve implant stability against dislocation in the most difficult situation. The bipolar system is composed of two ceramic-on-ceramic bearings (22.22 and 32 mm in diameter), the insert external diameter being limited to 41 mm only. Also application in the cervical spine[148] and in dental implants[149] are under study and will soon be tested in clinics.

XRD	X-ray diffraction
ZTA	Zirconia-toughened alumina

1.106.1. Introduction

1.106.1.1. The Discovery of Phase Transformation in the 1970s: A Revolution in the Ceramic Field

Zirconia has been one of the most important ceramic materials for well over a century. The discovery of transformation toughening in 1975[1] heralded visions of new high-performance applications of zirconia, ranging from bearing and wear applications to, most recently, biomedical applications. Garvie and his colleagues discovered transformation toughening in calcia-stabilized zirconia, as described in their famous 'ceramic steel' paper. It was followed by intense efforts to understand and describe the mechanisms of phase transformation, its effect on mechanical properties, and its application in a large variety of zirconia ceramics with different alloying elements. In this respect, without being exhaustive, the pioneering works of Garvie, Swain, and Hannink in Australia and Lange, Green, and Evans in the United States form the groundwork of today's knowledge (see, e.g., Green *et al.*,[2] Lange,[3] and McMeeking and Evans[4]). The idea behind phase transformation toughening was first to maintain the tetragonal phase of zirconia in a metastable state after sintering, thanks to the addition of a stabilizing oxide (e.g., CaO, MgO, and Y_2O_3). The tetragonal phase could then transform to the stable monoclinic one under stress. Associated to a large volume expansion inducing compressive stresses, the stress-induced phase transformation

created the conditions for an increase of strength and toughness never reached before with ceramics. Toughness and strength of more than 6 MPa √m and 1 GPa, respectively, could be obtained with yttria-doped zirconia, to compare with 4 MPa √m and 600 MPa for the best alumina ceramics, opening a new avenue for structural applications.

1.106.1.2. The Logical Development as a Structural Bioceramic

Following the fundamental work of the late 1970s, attempts to apply zirconia as a biomaterial were conducted as early as 1984[5] in the form of magnesia partially stabilized zirconia (PSZ). However, mainly based on higher strength at room temperature, 3 mol% Y_2O_3-stabilized zirconia (3Y-TZP, TZP standing for tetragonal zirconia polycrystal) became the material of clinical choice in the 1990s, for the large-scale processing of hip joint femoral heads.[6] Its use made possible the production of small hip implants (such as 22.22 mm femoral heads, leading to a reduction of volumetric wear of UHMWPE sockets) and knee joints that did not have adequate mechanical resistance when made with alumina. There is experimental evidence that the ultimate compressive load of zirconia ball heads is 2–2.5 times higher than that of alumina ball heads of the same diameter and neck length.[6] More than 600 000 zirconia hip joint heads were implanted between 1990 and 2001, but its use in orthopedic surgery has since been reduced by more than 90% after a failure episode in 2001–2002 described below, highlighting the lack of long-term stability of 3Y-TZP *in vivo*.[7] Given the lack of mechanical properties of alumina alone and the critical lack of stability of 3Y-TZP alone *in vivo*, companies developing orthopedic implants turned to composite materials with the aim of reinforcing alumina with zirconia phase transformation toughening.[8] At the same time, zirconia in dental application has been booming during the last 10 years, based on three main properties: better esthetics and corrosion resistance than metals and better crack resistance than other ceramics. The use of zirconia allows the fabrication of long bridges, abutments, and even implants with a sufficient mechanical resistance.[9] The failure episode of zirconia femoral heads had a clear negative impact in orthopedics, but almost none in the dental field. It is undoubtedly because of the lower criticality of a dental device failure for the patient and also a lack of information exchange between the two communities.

1.106.1.3. Phase Transformation and Aging: The Two Sides of Zirconia

The main features of phase transformation and aging are given in Figure 1. The best mechanical properties of zirconia are achieved only if some grains are able to transform under

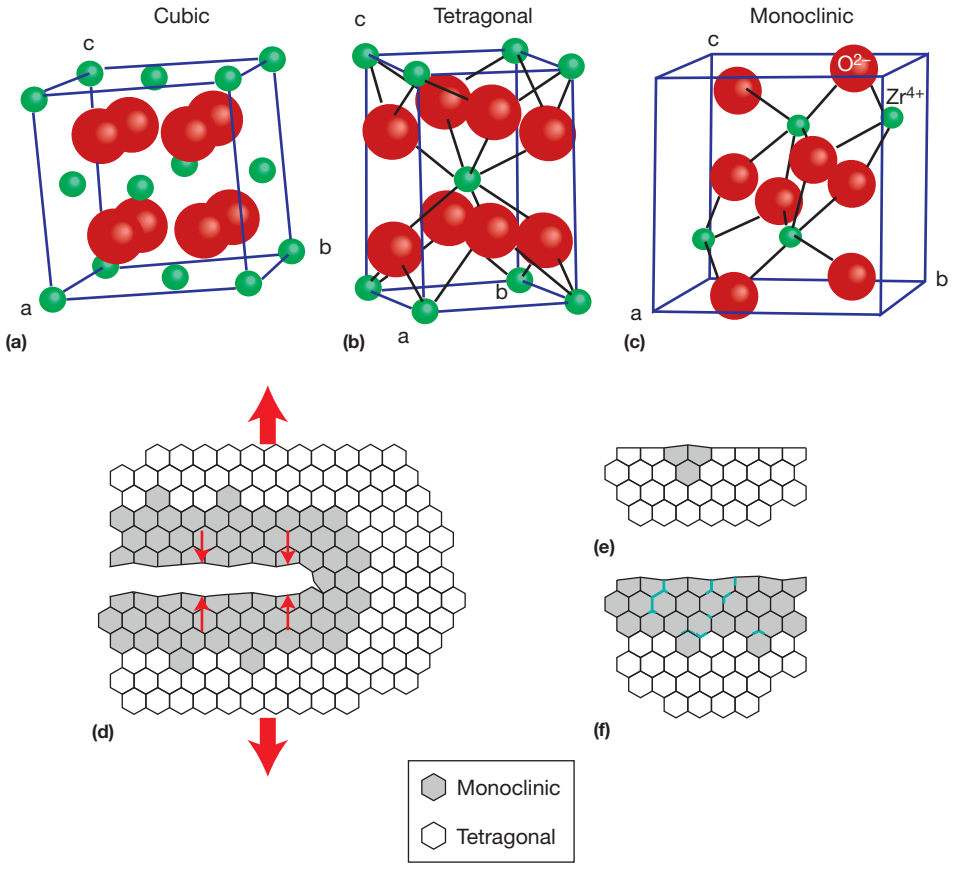

Figure 1 (a–c) The three major polymorphs of zirconia and the two alternative means by which metastable tetragonal phase can transform to monoclinic phase. (d) Phase transformation toughening and (e, f) aging.

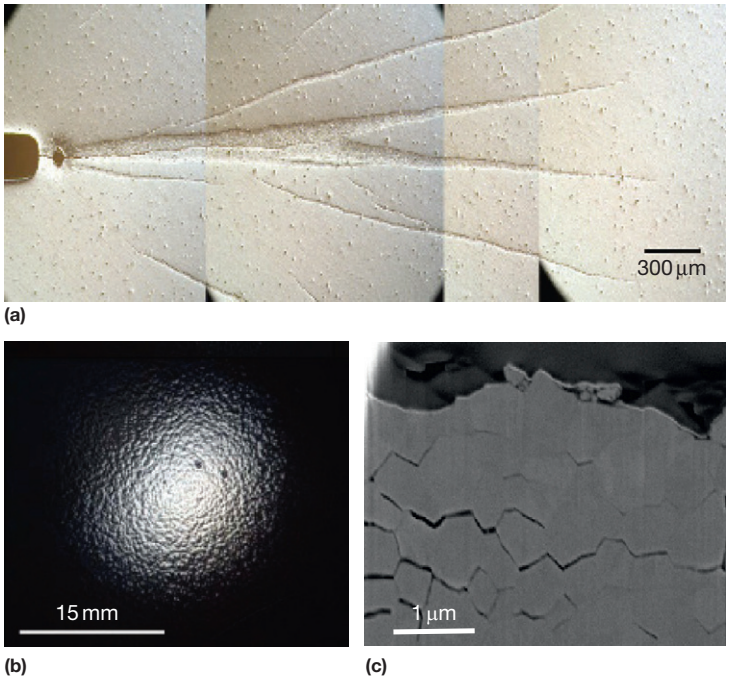

Figure 2 (a) Scanning electron microscopy picture of phase transformation around a propagating crack in a ceria-doped zirconia. Reproduced from El Attaoui, H.; Saâdaoui, M.; Chevalier, J.; Fantozzi, G. *J. Eur. Ceram. Soc.* **2007**, *27*(2–3), with permission from Elsevier. (b) Optical microscopy image (Nomarski contrast) of a 3Y-TZP femoral head after 20 h aging at 134 °C in autoclave. Courtesy D. Douillard, INSA-Lyon. (c) Focused ion beam slice of a 3Y-TZP dental implant after severe aging, showing microcracking beneath the surface. Courtesy B. Van De Moortele, ENS-Lyon.

stress from the tetragonal metastable state toward the stable monoclinic one. This is the concept of phase transformation toughening. Without the help of phase transformation, cubic zirconia, for example, exhibits toughness on the order of 2 MPa √m. In other words, zirconia can be used as a structural bioceramic only if it is not completely stable. However, this necessary metastability of the tetragonal phase at room temperature can result in the transformation of the surfaces in contact with water (or body fluids). This phenomenon, which was first described by Kobayashi *et al.*[10] at 250 °C, is known as 'aging' or 'low-temperature degradation' (LTD) and is partly responsible for the failure episode of 2001–2002 in orthopedics, when hundreds of 3Y-TZP femoral heads processed under specific conditions failed after 1–2 years *in vivo*.[11] Stress-induced transformation and aging are in fact two alternative means by which the metastable tetragonal phase can transform to monoclinic. The positive side is the phase transformation under stress, which enables zirconia to resist high loads, while the negative is the possible transformation at the surface, leading to microcracking and roughening, as will be discussed later. Figure 2 illustrates these two sides of the phase transformation, with a positive, large transformation zone around a propagating crack in (ceria-doped) zirconia, and detrimental roughening of a Y-TZP femoral head and microcracking beneath the surface after aging. The stake is therefore to process zirconia ceramics able to transform under applied stresses but with the lowest sensitivity to water. *A posteriori*, knowing now the effect of yttria on tetragonal phase stability in the presence of water, it becomes quite clear that the choice of Y-TZP for orthopedics might not have been the best one.

1.106.2. Crystallography and Phase Transformation of Zirconia

Many of the properties of zirconia ceramics are related to their crystallography, and in particular to the phase transition from a tetragonal phase to the monoclinic one. (Other properties, such as ionic conductivity that makes zirconia ceramics so useful for solid electrolyte fuel cells and oxygen sensors, are a result of the presence of numerous oxygen vacancies, introduced by the presence in the material of trivalent cations stabilizing the cubic phase at low temperature.)

In this section, we describe the crystallography of zirconia phases, and show its influence on the two major properties that control the lifetime of zirconia-implanted devices: resistance to crack propagation (influenced by the transformation toughening) and hydrothermal aging (also called LTD).

1.106.2.1. Crystallography and Phases Stability

There are at least five known solid phases of zirconia ceramics. Under normal processing conditions (pressureless or low-pressure environment and conventional thermal cycles), only three phases (cubic, tetragonal, and monoclinic) are generally observed, depending on temperature and addition of a stabilizing oxide. We will focus here only on these three phases as they are the only ones of interest for biomedical applications. They are schematically described in Figure 1.

In pure zirconia (i.e., without any stabilizing oxide), from low to high temperature, the stable phases are the monoclinic (m) phase (up to 1170 °C), the tetragonal phase (t)

(from 1170 to 2370 °C), and the cubic (c) phase (above 2370 °C and up to the melting point at 2680 °C).

The c-structure is a calcium fluorite-type structure (face-centered cubic, 225, $Fm3m$), where the zirconium ions occupy the summits of the cube and the center of the faces, while oxygen ions are located in the tetrahedral sites. However, the O ions are slightly displaced from the (0.25,0.25,0.25) position toward a higher z (typically 0.25,0.25,0.28), which may be due to the tendency of the Zr atoms to form sevenfold coordination.

Compared to the c-structure, the t-structure presents an elongated c-axis and can thus be described as a distorted calcium fluorite structure (zirconium ions being organized in a face-centered tetragonal lattice). This description facilitates comparison to the 'parent' cubic phase. However, considering half the face-centered lattice, one obtains a body-centered tetragonal organization of the Zr ions, described in the $P4_2/nmc$ (137) space group (**Figure 1**). Both descriptions are commonly used in the literature, and, for example, the (111) plane in the face-centered description corresponds to the (101) plane in the body-centered one.

It is not yet sure whether the m-structure is a homogeneous single phase or if it forms a series of incommensurate, solid solutions. However, it can be described in the $P2_1/c$ space group. In this structure, the Zr atoms are in sevenfold coordination with the O sublattice (eightfold in the CaF_2 structure).

Sintering zirconia generally involves temperatures above the tetragonal-to-monoclinic (t–m) transformation temperature. Thus, zirconia is tetragonal at the sintering temperature and the t–m transformation occurs during cooling. This transformation results in a very large volume increase (around 5%) that inevitably provokes a cracking of dense, pure zirconia bodies. It is possible to avoid transformation-induced cracking by either sintering below 1170 °C (the material remains monoclinic during the whole sintering cycle, which leads to non-transformable, low strength and tough ceramic) or retaining the tetragonal or the cubic phases at room temperature by alloying with alliovalent cations (which avoids the t–m transformation during cooling). The latter approach is the basis of the use of zirconia as a technical ceramic, and was first described by Ruff and Ebert[12] almost a century ago. The tetragonal phase is in fact metastable, and may be able to transform to monoclinic, if either mechanical or chemical energy is provided, to t-grains. This is the basis of phase transformation toughening, but also of aging.

The t–m transformation is martensitic in nature. It is most often described by the phenomenological theory of martensitic crystallography.[13,14] Shortly, crystallographic correspondences exist between the parent (tetragonal) and the product (monoclinic) phase. They can be described by habit planes and directions (shape strain). The three possible lattice correspondences in zirconia are ABC, BCA, and CAB, which correspond to a change of the (a_t, b_t, c_t) lattice axis of the t-phase into the (a_m, b_m, c_m), (b_m, c_m, a_m), and (c_m, a_m, b_m) axes of the m-phase, respectively. Each of these lattice correspondences may occur along two different habit planes. This leads to six different configurations, and in total 24 variants (as in the tetragonal symmetry, a, b, $-a$, and $-b$ are crystallographically equivalent). Note that variants are auto-accommodating: even if for each variant a shear strain of around 0.16 results from the transformation, for two auto-accommodating variants the resulting shear strain is near zero, and only the dilatational strain (~0.05) has to be taken into account. This means that the transformation-induced cracking is mostly because of the dilatational component of the transformation strain.

The first thermodynamic model of t–m transformation in zirconia was proposed by Lange,[3] considering a rather idealized case (a spherical tetragonal particle). The change of total free energy (ΔG_{t-m})as a result of the transformation is given by eqn [1]:

$$\Delta G_{t-m} = \Delta G_c + \Delta U_{SE} + \Delta U_S \quad [1]$$

where ΔG_c (<0 at low temperature) is the chemical free energy (dependent on temperature and composition), ΔU_{SE} (>0) is the strain energy associated with the transformed particles (dependent on the surrounding matrix, the size and shape of the particle, and the presence of stresses), and ΔU_S (>0) the change in energy associated with the surface of the particle (creation of new interfaces and microcracking).

The balance between ΔU_S and ΔG_c explains why it is possible to retain tetragonal pure zirconia powders at room temperature (ΔU_{SE} is zero), up to grain sizes around 24 nm.[15,16] In bulk-sintered ceramics, such low grain sizes are almost impossible to retain. Associated with possible internal residual stresses, this makes it impossible to stabilize the tetragonal phase without the help of stabilizing oxides that increase ΔG_c (or decrease $|\Delta G_c|$), or without the existence of additional compressive stresses (due, e.g., to a stiff matrix) that decrease ΔU_{SE}.

Bulk monolithic zirconia ceramics of practical use for engineers can only be obtained by stabilizing the t-phase by a number of stabilizing oxides (or dopants). In view of this model, one can expect the dopants to stabilize t-zirconia by decreasing $|\Delta G_c|$.

When considering zirconia alloyed with another oxide, the transformation temperature for pure zirconia does not hold true anymore. In fact, in most of the zirconia-stabilizer systems, we have to take into account two kinds of phase diagrams to be able to predict the exact phase composition of the systems.[11] The first one is the classical phase equilibrium diagram that indicates the composition and amounts of the different phases at equilibrium. The most recent version of this diagram is shown in **Figure 3**. It indicates, for example, that a 3 mol% Y_2O_3-stabilized zirconia held at high temperature (i.e., 1500 °C) should be constituted of 88% of tetragonal phase containing 2.4 mol% Y_2O_3 and 12% cubic phase with 7.5 mol% Y_2O_3. The same zirconia with an overall 3 mol% Y_2O_3 content should be constituted at room temperature of a monoclinic phase containing almost no Y_2O_3 and a cubic phase containing 18 mol% Y_2O_3. But reaching this equilibrium should take hours at high temperatures and many thousand years at room temperature. Thus, metastable phase diagrams are also needed and are being considered today. These diagrams indicate the t–m transformation temperatures for each composition of the tetragonal grains (see **Figure 3**). These t–m transformation temperatures in the metastable phase diagram are called T_0^{t-m}. Above T_0^{t-m}, the tetragonal phase is stable (referring to the thermodynamic approach of Lange, $\Delta G_c > 0$). Below T_0^{t-m}, the stable phase is monoclinic ($\Delta G_c < 0$), although a metastable tetragonal phase can be retained ($\Delta G_c < 0$, but $\Delta U_{SE} + \Delta U_S > |\Delta G_c|$; thus, $\Delta G_{t-m} > 0$).

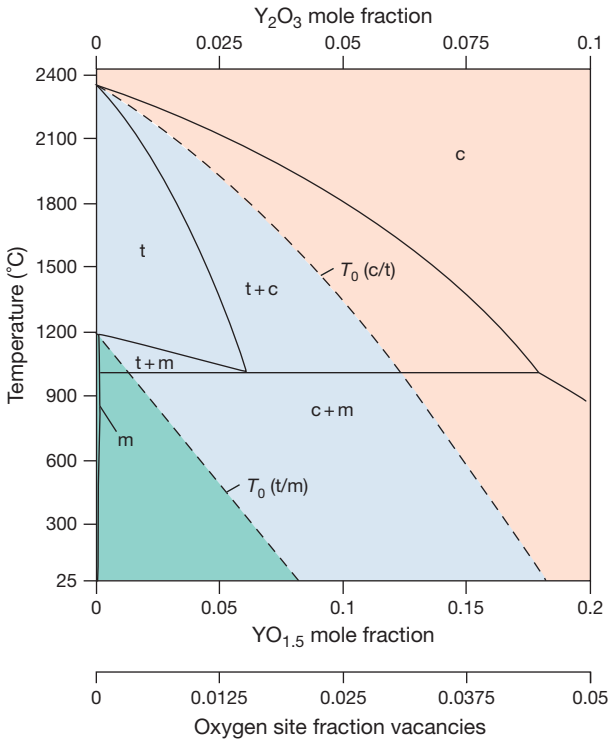

Figure 3 Most recent zirconia–yttria phase diagram (continuous lines) and metastable phase diagram (dotted lines). Reproduced from Chevalier, J.; Gremillard, L.; Virkar, A. V.; Clarke, D. R. *J. Am. Ceram. Soc.* **2009**, *92*, 1901–1920, with permission from Wiley.

For example, the following features are seen in **Figure 3**:

- Starting with a homogeneous powder containing 3 mol% Y_2O_3, sintering at 1400 °C for only 5 h will not allow reaching the equilibrium phase diagram at this temperature. The sintered body will still present at 1400 °C a homogeneous distribution of yttria. Thus, the t–m transformation temperature to be taken into account is the one related to the tetragonal phase containing 3 mol% Y_2O_3 (around 400 °C). In this case, the tetragonal phase is stable above 400 °C (T_0^{t-m} temperature for 3 mol% Y_2O_3), but only metastable below 400 °C.
- Sintering at higher temperature (e.g., 1500 °C for 5 h) will result in the high-temperature equilibrium being reached (a mixture of tetragonal phase containing 2.4 mol% Y_2O_3 and cubic phase containing 7.5 mol% Y_2O_3). Thus, upon cooling, the t-phase becomes metastable below 600 °C (the cubic phase becoming metastable below around 750 °C; see T_0^{c-t}). (For more detailed information on the use of stable and metastable diagrams, please refer to Chevalier *et al.*[11] (Figure A3).)

Such T_0^{t-m} temperatures give a clear indication of the stability of the t-phase as a function of the thermal history followed during processing: sintering at high temperatures for long durations results in a higher T_0^{t-m} temperature traducing a lower (meta)stability of the t-phase at room temperature. As the tetragonal phase is only metastable at room temperature, an additional driving force (e.g., tensile stresses) may trigger the t–m transformation.

1.106.2.2. Stress-Induced Phase Transformation and Toughening

Stress-induced phase transformation and phase transformation toughening have been described in detail by Green *et al.*[2] We give here only the necessary basics. As described earlier, the presence of tensile stresses in the vicinity of a crack relieves some or all of the mechanical constraints on the metastable tetragonal phase and allows it to transform to the monoclinic phase, leading to the formation of a transformation zone (see **Figure 1**). Obviously this cannot occur if the t-phase is stable, but takes place only in its metastability range, below the T_0^{t-m} temperature. The transformation induces compressive stresses that act to hinder crack propagation, as schematized in **Figure 1**. In the phase transformation toughening model developed by McMeeking and Evans,[4] the stress-induced phase transformation leads to a shielding K_{Ish} of the applied stress intensity factor K_I, meaning that the real stress intensity factor at the crack tip K_{Itip} is lower than that applied by the external forces, according to eqn [2]:

$$K_{Itip} = K_I - K_{Ish} \quad [2]$$

Both this theoretical model and experimental results[17] show that increasing the applied stress intensity factor leads to a larger transformation zone and thus larger shielding effect, which is in fact proportional to the applied K_I (eqn [3]):

$$K_{Ish} = C_{sh}K_I \quad [3]$$

where the proportionality constant C_{sh} depends on the Young modulus (E), Poisson ratio (ν), volume fraction of the transformable particles (V_f), volume expansion associated to the transformation (e^T), and a critical local stress leading to transformation (σ_m^c), via the following equation:

$$C_{sh} = \frac{0.214EV_f e^T(1+V)}{(1-V)\sigma_m^c}\left(\frac{\sqrt{3}}{12\pi}\right) \quad [4]$$

A given zirconia will be all the more tough if the critical local stress leading to phase transformation (σ_m^c) is low. In turn, σ_m^c depends on the magnitude of the undercooling below the T_0^{t-m} temperature: large undercooling below T_0^{t-m} will result in a high propensity toward t–m phase transformation, and thus in low σ_m^c and large transformation toughening.

The effect of phase transformation toughening is seen while comparing crack propagation velocities in different zirconia ceramics in V–K_I diagrams. For example, the difference between the good crack propagation resistance of 3Y-TZP (TZPs stabilized with 3 mol% Y_2O_3) and the modest one of cubic zirconia comes from phase transformation toughening.[18] It was also seen that increasing the grain size in 3Y-TZP results in increased phase transformation toughening efficiency,[17] and thus better resistance to crack propagation and better toughness. This could originate from the higher sintering temperature and soaking time used for the coarser-grained zirconia ceramics, that should have resulted in a higher phase partitioning (Y-rich cubic phase plus Y-poor tetragonal phase), resulting in turn in a higher T_0^{t-m} temperature (thus a higher undercooling and a lower σ_m^c).

1.106.2.3. Surface Transformation in the Presence of Water and LTD

The presence of water can trigger the t–m phase transformation at the surface of zirconia. This is especially true and well

documented in the case of Y-TZP. In contrast with the t–m transformation 'in the bulk' in the vicinity of a propagating crack, t–m transformation 'at the surface' in the presence of water leads to degradation of the materials properties. The main features of this 'aging' process are given in Figure 1.

The mechanism by which the presence of moisture leads to a transformation of Y-TZP remains to be firmly established. One of the hypotheses currently most favored is that the filling of oxygen vacancies by 'water-derived species' (hydroxyl, oxygen, or hydrogen ions) probably leads to both decrease of ΔG_c (by modifying the local oxygen configuration around Zr ions) and an accumulation of internal tensile stresses (decrease of ΔU_{SE}) in the grains in contact with water (with the maximum tensile stresses in those grains roughly estimated at 300–500 MPa[19]). However, some authors claim that exposure to moisture increases lattice parameters of the tetragonal phase[20] while others claim that lattice parameters decrease under the same conditions. More detailed experimental work and computational atomic scale simulations are necessary to resolve this crucial issue. In any case, it is clear today that diffusion of water-derived species leads to a progressive change of the stability of the tetragonal grains: metastable t-grains at the surface can become unstable and transform to the m-phase after a certain exposure time. The volume increase accompanying the transformation results in a surface uplift and large stresses that can provoke the creation of cracks along the grain boundaries.[7,11] In turn, tensile stresses appear in the neighboring grains and cracks facilitate the penetration of moisture further into the material: the process is repeated as moisture ingress goes on and tensile stresses are accumulated. As it is likely that the moisture can flow through grain boundary cracks much faster than by diffusion, it is likely that the observed activation energy for LTD is determined by diffusion of the moisture species into the lattice of the individual grains.

Aging kinetics may be characterized by quantifying the amount of monoclinic phase on zirconia surface versus time, using techniques such as X-ray diffraction (XRD) or Raman spectroscopy. All the results obtained to date show that the kinetics can be fitted with the standard Mehl–Avrami–Johnson (MAJ) equations for a nucleation and growth process (eqn [5]):

$$f_m = 1 - \exp\left(-(bt)^n\right) \quad [5]$$

where f_m is the fraction of tetragonal phase that has transformed to monoclinic phase, t is the time of exposure to moisture, and the exponent, n, and the value of the constant, b, depend on the microstructural features of the material and on the temperature. Values of n range between 0.5 and 4.[21]

For 3Y-TZP, aging is faster around 250 °C. At lower temperatures (say below 150 °C), the phenomenon is thermally activated and the value of the constant, b, follows an Arrhenius law:

$$b = b_0 \exp\left(-\frac{Q}{RT}\right) \quad [6]$$

where b_0 is a constant, Q is an apparent activation energy, R is the gas constant, and T is the absolute temperature. The reported activation energies are around 100 kJ mol^{-1} (~1 eV), similar to the activation energy for oxygen vacancy diffusion extrapolated from higher temperatures.[22]

At temperatures higher than 250 °C, aging becomes slower. Combining experimental data at different temperatures on a time–temperature plot shows that transformation kinetics form 'C-shaped' curves. This behavior can be interpreted in terms of balance between the driving force for t–m transformation (which is larger at lower temperature, where the undercooling of the t-phase below the T_0^{t-m} temperature is high) and the growth rate (lower at low temperature due to lower diffusion kinetics).

The nucleation and growth of small monoclinic spots on tetragonal zirconia surfaces exposed to water, fully consistent with the MAJ kinetics, can be observed by techniques such as optical interferometry[22] or atomic force microscopy.[23] Observations by scanning electron microscopy further show that transformation first extends at the surface and then into the bulk. Careful atomic force microscopy observations also indicate that nucleation occurs preferably at the grain junctions and corners (where the residual tensile stresses are higher), and that the transformation then extends across individual grains.[23] The transformation then proceeds by a neighbor-to-neighbor propagation, as shown in the movie in Annex 1.

Although hydrothermal aging has been known since the early 1980s, its influence on the durability of orthopedic implants was neglected until the early 2000s, when a series of fractures of zirconia ball heads occurred early after implantation (around 2 years). These failures were later determined to have been caused by an accelerated aging of balls that were not sufficiently densified during sintering.[11] It appears now that femoral heads processed under 'normal' conditions might also suffer aging.[24,25] The mechanism and its effect on dental devices are less documented but there is evidence that some specific processing or surface modification might promote aging in dental grade zirconia. This will be the subject of Section 1.106.4.2.

Aging is intrinsic to 3Y-TZP. However, it depends largely on the microstructure and hence on the process. It can be minimized under the following conditions:

- The grain size remains small.
- The density is high, and more importantly there is no percolative porosity.
- There are no tensile residual stresses in the parts of the material exposed to water.
- There is no cubic phase (the t-grains that surround cubic grains are depleted in yttrium, and can transform more easily).

1.106.3. Different Types of Zirconia and Zirconia-Based Composites

Figures 4 and 5 schematically present the typical microstructure of different zirconia ceramics and their denomination, together with their standard temperature, composition, and processing conditions. The different types of zirconia ceramics differ in the dopant and its concentration, and the temperature of processing.

1.106.3.1. Alloy Additives for Zirconia

The oxides stabilizing zirconia tetragonal or cubic phase can be classified in several categories, depending on the valence of the cation and on the solubility of the stabilizer in the zirconia

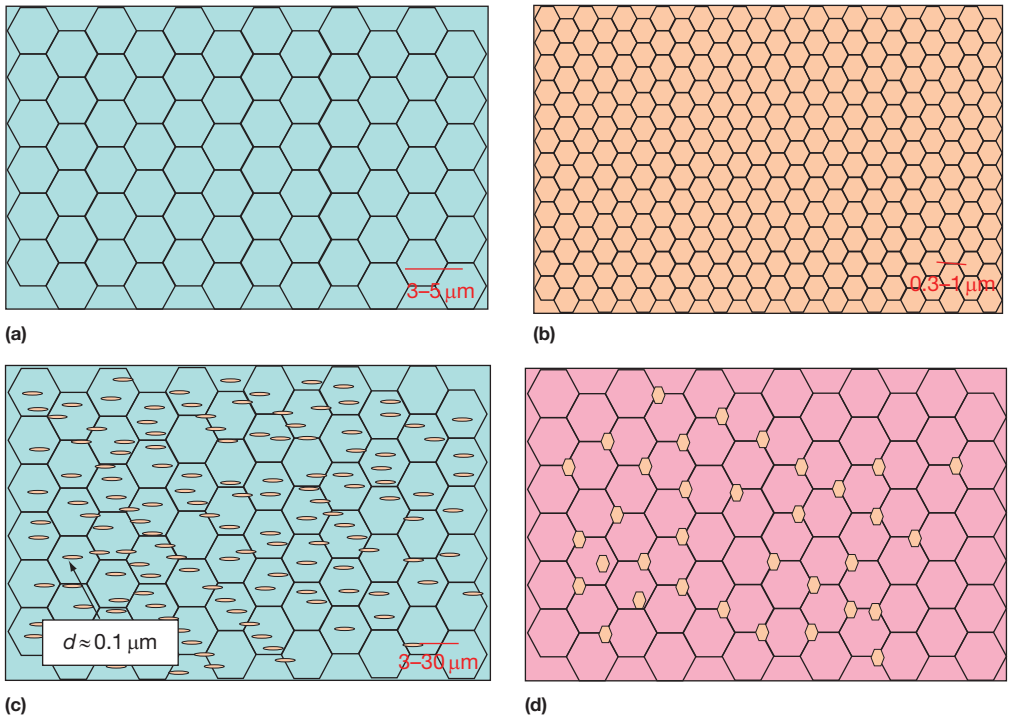

Figure 4 Schematic representation of the microstructures of the main types of zirconia ceramics and composites. Only TZP, PSZ, and ZTA exhibit phase transformation toughening. (a) Cubic, fully stabilized zirconia (FSZ; i.e., with 8 mol% Y_2O_3); (b) tetragonal zirconia polycrystal (TZP; i.e., with 3 mol% Y_2O_3 or 12 mol% CeO_2); (c) partially stabilized zirconia (PSZ), with tetragonal precipitates in a cubic matrix (i.e., with 8 mol% MgO); (d) zirconia-toughened alumina (ZTA), with tetragonal zirconia grains in an alumina matrix.

lattice. Calcium and magnesium are the only divalent cations used; they are of low solubility in zirconia at sintering temperatures, and they generally form PSZ ceramics, which consist of tetragonal grains in a cubic matrix (see **Figures 4** and **5**), at high temperature. This structure can be retained at low temperature or tetragonal precipitates can transform toward the monoclinic symmetry upon cooling, depending on the temperature and time of sintering. Some 'aging' treatments (say 'long thermal treatments' after sintering) can be conducted to favor the presence of the monoclinic phase at ambient temperature. In this case, the PSZ is no more prone to phase transformation toughening (tetragonal precipitates are already transformed after cooling). Trivalent cations of interest are mostly yttrium, but scandium, gadolinium, gallium, and iron can be found in special applications. They possess an intermediate solubility, and give rise to either tetragonal zirconia polycrystals (TZP) or PSZ ceramics, depending on the thermal history (see **Figures 4** and **5**). Tetravalent dopants such as cerium possess the highest solubility in zirconia and produce TZP ceramics. For example, zirconia can dissolve up to 15% of titanium oxide in the tetragonal phase and up to 18% in the cubic phase, and tetragonal zirconia doped with 18 mol% ceria can be found. Both Ce and Ti stabilize efficiently the tetragonal phase (although not as efficiently as Y).

Moreover, costabilization of t-zirconia with yttrium and Ti or Ce has also been considered. In these materials, the grain size is increased by the presence of Ce or Ti; however, because of the higher stability of the Ce- or Ti-doped Y-TZP, large tetragonal grains may remain stable (up to 10 μm grains, as compared to the maximum tetragonal grain size of 1.5 μm in a 3Y-TZP). Aging resistance of Y-TZP is improved by the addition of either Ti or Ce,[26] but the mechanical properties decrease, as can be expected from the higher stability.

Most stabilizers of zirconia tetragonal phase act through a decrease of 'oxygen overcrowding' around zirconium cations, either through the introduction of oxygen vacancies[27] or through the expansion of the cations lattice. In a very good series of two papers, Li *et al.*[28,29] used X-ray absorption spectroscopy to examine the effect of trivalent and tetravalent dopant ions on the local environment of zirconium ions. Local atomic structures around the Zr^{4+} and around dopant cations in zirconia solid solutions were determined. These included undersized (Fe^{3+}, Ga^{3+}) and oversized (Y^{3+}, Gd^{3+}) trivalent ions as well as undersized (Ge^{4+}) and oversized (Ce^{4+}) tetravalent ions. They concluded that in the presence of trivalent dopants, oxygen vacancies are generated for charge compensation. These vacancies are associated with the Zr cations in the case of oversized dopants, and with two dopant cations in the case of undersized dopants. With both configurations, the number of zirconium cations coordinated by seven oxygens (instead of eight) increases, which stabilizes the tetragonal or even the cubic phases. The closer association of oxygen vacancies with Zr is responsible for the more effective stabilization effects of oversized trivalent dopants (around twice as effective as with undersized trivalent cations). In tetravalent cations-doped zirconia, oxygen vacancies are scarce and cannot account for the stabilization of the tetragonal phase. Instead, it was shown that adding oversized cations dilates the cation network and thus decreases the oxygen overcrowding around Zr ions.

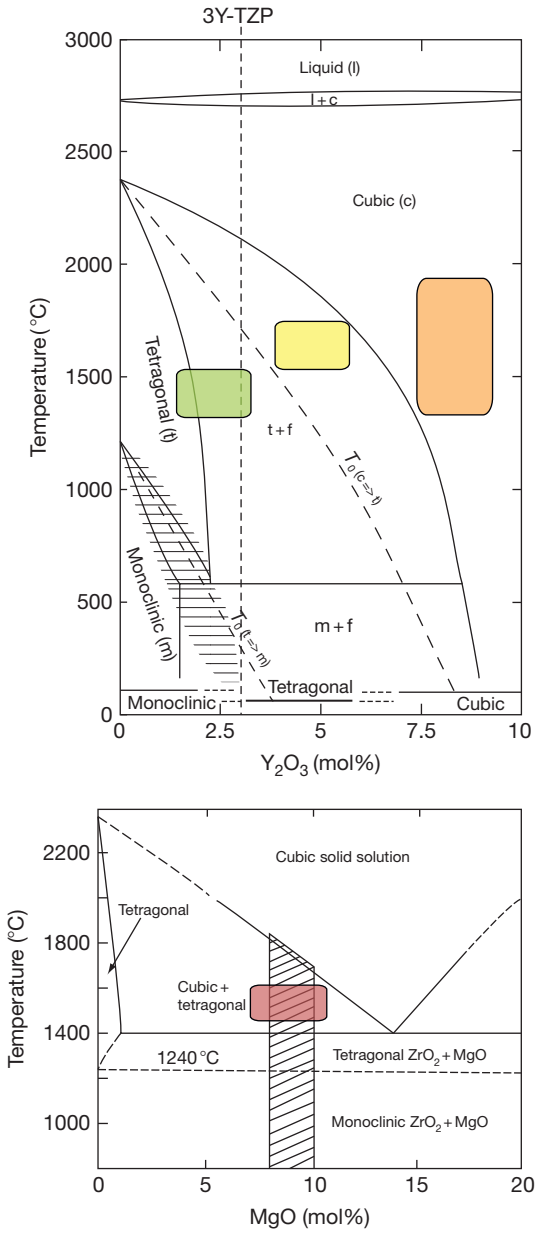

Figure 5 Temperature and compositions ranges for the process of (a) Y-TZP (green area), Y-PSZ (yellow area), and Y-FSZ (orange) ceramics and (b) Mg-PSZ (pink) ceramics.

Thus, doping with trivalent oversized cations, such as Y^{3+}, is most efficient in relieving the oxygen overcrowding (via both oxygen vacancies generation and dilatation of the cation network). The same stabilizing efficiency is obtained with 1.5 mol% of Y_2O_3 or 10 mol% of CeO_2; this exemplifies the crucial role of oxygen vacancies in stabilizing t-zirconia (the presence of Ce^{4+} brings no vacancies) and explains the prevalent use of yttria-stabilized zirconia ceramics in practical applications. On the other hand, it is clear that Y_2O_3 is not the only dopant able to stabilize the t-phase at room temperature.

Other stabilizing mechanisms exist, such as the creation of ordered phases (as is the case when doping with undersized tetravalent ions such as Ge^{4+} or Ti^{4+}), but this mechanism is of less interest when considering zirconia as a biomaterial (to our knowledge, Ge-stabilized zirconia only exist in the laboratories, and do not provide sufficient mechanical properties).

As mentioned above, one of the major difficulties in processing and using zirconia ceramics is maintaining the delicate balance between the t-phase stability necessary to resist aging and the t-phase transformability necessary for phase transformation toughening. However, it is possible to get out of this compromise by creating zirconia ceramics that possess a constant stability with time, even in the presence of water: within certain limits, a high transformability is preferable if the material is insensitive to aging. One way to achieve it is to use zirconia stabilized with tetravalent ions (e.g., Ce^{4+}) or with mixed tri- and pentavalent ions (e.g., $Y^{3+} + Nb^{5+}$). This way, the t-phase can be stabilized at room temperature but is readily transformable under applied stress, while the absence of oxygen vacancies will prevent the occurrence of aging.

1.106.3.2. Partially Stabilized Zirconia Ceramics

Divalent cations such as Mg^{2+} and Ca^{2+} were historically the first to be used for 'technical' zirconia ceramics. Indeed, phase transformation toughening was discovered in Ca-doped zirconia, and Mg-doped zirconia was the first one to be used in orthopedics. Most Mg- and Ca-doped zirconia are PSZ. PSZ is composed of nanometric precipitates of tetragonal or monoclinic phase embedded in a cubic matrix (see **Figures 4** and **5**). Such zirconia ceramics are generally obtained with the addition of lime or magnesia. They are often submitted to a second thermal treatment (so-called 'aging,' with no relation with the aging process described as an LTD in the presence of water) after sintering in order to control the number, crystallography (tetragonal and/or monoclinic), and size of the precipitates. Note that yttria-stabilized zirconia can also be obtained in the PSZ form, if it contains enough yttria (between 4 and 7 mol% Y_2O_3), is thermally treated at a temperature high enough to be fully cubic, and then cooled in a way that allows the formation of small tetragonal precipitates.

Although it possesses a lower strength than 3Y-TZP, Mg-PSZ is a valid alternative for the realization of heads of hip prostheses, because of its higher toughness[30] and higher crack propagation threshold (respectively 8 and 6 MPa $\sqrt{m}$, vs. 5 and 3.5 for 3Y-TZP). It was considered for orthopedic applications as early as 1984, but set aside for Y-TZP on strength arguments. There is a renewed interest in this material, as, compared to Y-TZP, Mg-PSZ is immune to aging.[31] Mg-PSZ prostheses explanted after 5 years *in vivo* do not show any sign of aging.[32] On the other hand, it has been shown that at around 200 °C, exposure to water can lead to a depletion of Mg from the surface and thus a transformation of the surface tetragonal precipitates to the monoclinic phase,[33,34] which seems not to be relevant so far, for usual industrial applications. Its deep yellow to orange color impairs its possible application in the dental field (especially when crowns and bridges are considered).

1.106.3.3. Tetragonal Zirconia Polycrystals

Tetragonal zirconia polycrystals (TZPs) are often considered monoliths of the tetragonal phase, although the phase diagram

and the sintering conditions for Y-TZP dictate that they most often contain a secondary cubic phase (see Figure 3 or 5). Most of the TZPs investigated so far are those stabilized with yttria or ceria, sintered at temperatures at which the tetragonal phase is the major or the only phase. Y-TZP is of special interest, as this is the one chosen for the processing of hip prosthesis heads and, more recently, of dental devices. This choice initially results from the higher strength of Y-TZP as compared to Mg- and Ca-PSZ. It was later made easier by the availability of high-quality powders. Actually, after the original work on PSZ, most of the practical knowledge on phase transformation toughening and on aging has been acquired on Y-TZP.

3Y-TZP possesses the best combination of toughness and strength among oxide ceramics, as a direct benefit of fine grain size (sintering fully dense, submicron 3Y-TZP is much easier to achieve than for other oxide ceramics) and transformation toughening. Being easy to polish, 3Y-TZP became in the 1990s the natural candidate for the fabrication of ceramic hip joints. Unfortunately, all these advantages are today balanced with its lack of stability in the presence of water. Ce-TZP (typically 10 and 12 mol% Ce-TZP) does not possess such hardness and strength as 3Y-TZP mainly because its grain size is larger. However, being stabilized by a tetravalent cation, the t-phase can transform under stress (transformation toughening) but remains essentially stable in the presence of water (no aging *in vivo* for realistic durations).

1.106.3.4. Zirconia-Dispersed Ceramics

Taking advantage of phase transformation toughening is also possible in composites containing particles of transformable zirconia tetragonal phase in a nontransformable matrix. This is possible if the size of the zirconia particles ranges between two critical values: the highest is the size for spontaneous transformation to the m-phase during cooling, and the lowest is the size for which no transformation to the m-phase is possible (even under stress). Both critical sizes depend on the stiffness of the matrix, the amount of zirconia particles, and the composition of the zirconia particles. Generally zirconia particle size of a few tenths of microns is adequate.

PSZ materials can be considered one of these composites, where the nontransformable matrix is made of cubic zirconia. But the most used is undoubtedly zirconia-toughened alumina (ZTA) (in which tetragonal zirconia particles are embedded in an alumina matrix, as schematically shown in Figure 4).

In such composites, zirconia particles have to be stabilized in the tetragonal phase. This can be done classically by using a stabilizing oxide (yttria of course, but ceria is more widespread).[35,36] Another approach is to let the high stiffness alumina matrix stabilize pure zirconia particles (simply by increasing ΔU_{SE}): the composites can then be completely insensitive to aging, as the zirconia phase is devoid of oxygen vacancies.[37] Of course, the stability of the tetragonal phase is more difficult to handle: on the one hand, small zirconia particle size and no agglomeration of the zirconia particles are mandatory to retain the tetragonal phase; on the other hand, too small t-zirconia particles will not transform even under stress, leading to a composite with poor mechanical properties.

1.106.4. The Use of Zirconia as a Biomaterial: Current State of the Art

1.106.4.1. The Use of Zirconia in Orthopedics: From Yttria-Doped Zirconia to Zirconia-Toughened Alumina

The story of zirconia in orthopedics started with Mg-PSZ in 1984, mainly in the United States and Australia, without reaching large-scale clinical application. The rapid shift toward 3Y-TZP in the late 1980s was due to a much better strength, lower grain size resulting in supposedly better wear properties, and technical advantages in terms of sintering. 3Y-TZP possesses strengths at least twice that of Mg-PSZ and grain sizes as low as 0.3 μm even under standard sintering conditions (as compared to 30–40 μm for the cubic grains of Mg-PSZ), and can be processed at temperatures as low as 1400 °C, versus 1800 °C for Mg-PSZ. Besides, ultra-pure 3Y-TZP powders were available in large quantities, while Mg-PSZ powders often contained silica impurities. One must remember that at that time, aging of Y-TZP had already been discovered, as described by Kobayashi at 250 °C, but not considered as relevant for orthopedic applications.

From the early 1990s to 2002, more than 600 000 zirconia hip joint heads were implanted worldwide. Main producers were Saint-Gobain Desmarquest in France, Kyocera in Japan, Metoxit in Switzerland, and Morgan Technical ceramics in the United Kingdom. If in the first decade, 3Y-TZP was considered the 'new ceramic solution' by many orthopedic surgeons, several critical issues finally put a stop to its use in the early 2000s. First, in May 1997, the US Food and Drug Administration (FDA) reported on the critical effect of the standard steam sterilization procedure (134 °C, 2 bar pressure) on the surface roughness of zirconia implants for the first time. This occurred because 'exposure to steam and elevated temperatures may lead to a phase transformation in the crystal structure of the zirconia material.' FDA and other sanitary agencies over the word then strongly advised against resterilization of zirconia femoral heads in hospitals. Second, in August 2001, the Therapeutic Goods Administration in Australia issued a 'hazard alert' on 'spontaneous disintegration of zirconia femoral heads' in some batches manufactured in a new tunnel furnace in 1998 by Saint-Gobain Desmarquest. More than 800 failures were reported, most of them occurring 12–36 months after implantation. In some specific batches (i.e., TH 2957 or TH 93038), the failure rate was higher than 30%. All sanitary agencies recommended immediate recall of all unimplanted zirconia femoral head prostheses manufactured by Saint-Gobain Desmarquest and advised orthopedic surgeons to inform all patients implanted with a Saint-Gobain Desmarquest Prozyr® head prosthesis that they should seek urgent medical attention. The fabrication of Prozyr® heads (90% of the market of zirconia heads), even with the reliable batch furnace (BH) process, was stopped in early 2002. The different panels of experts constituted by Saint-Gobain, orthopedic companies, and sanitary agencies later clearly demonstrated that the 'spontaneous disintegrations' were in fact failures due to an accelerated aging in these particular batches, related to a lack of densification in the center of the heads. More information on these process-related failures can be found in Chevalier *et al.*[11,24] These dramatic events shed light on the strong

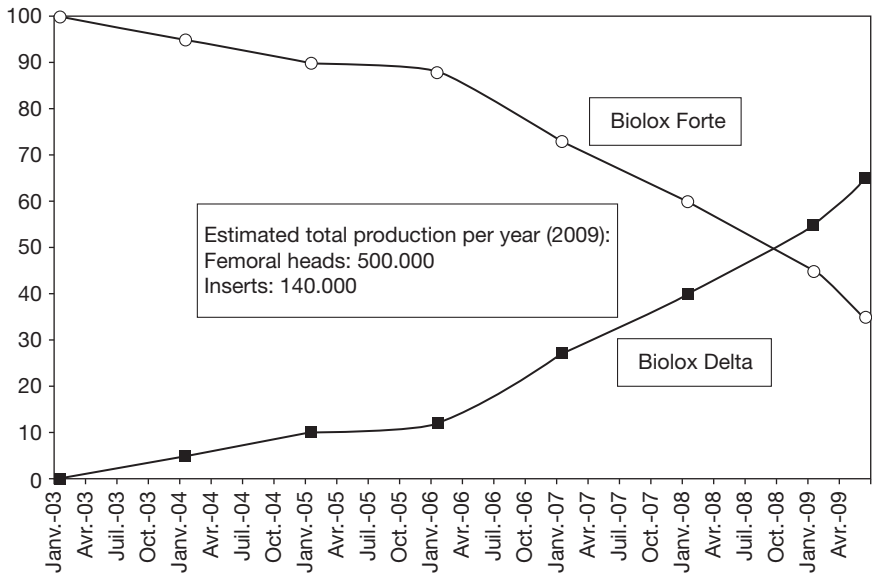

Figure 6 Evolution of the production (in %) of Biolox Forte® (Alumina) and Biolox Delta® (zirconia-toughened alumina) during the past 7 years.

influence of process parameters on the stability of zirconia *in vivo* and the question of the 'natural' aging of 'good' heads remained open.[7] Recent reports unfortunately suggest that significant aging occurs even *in vivo* at the surface of implants processed under 'normal' conditions, leading to increased wear and aseptic loosening.

Concurrent to the 'fall' of zirconia, the need for high mechanical performance ceramic for femoral heads and other orthopedic components led to the development of ZTA composites. Starting from the early 2000s, being more or less confidential until 2005, this material took a more and more important part of the ceramic heads market. The market share of ZTA femoral heads is now roughly equivalent to that of alumina heads and is still growing. Biolox Delta® produced by Ceramtec AG (which is a ZTA material containing strontium platelets and chromium oxide as reinforcing agents), represents two-thirds of their ceramic production for orthopedic devices (see Figure 6). ZTA heads compensate for their higher price by increased mechanical performances as compared to alumina heads (thus allowing more critical designs) and better stability as compared to zirconia. The microstructure of Biolox Delta® together with two examples of products not realizable with alumina are shown in Figure 7. Note the pink color due to the addition of some chromium oxide in the composition. Although it should be emphasized that the stability of such yttria-stabilized ZTA composites versus hydrothermal aging may not be complete,[38,39] to our knowledge no *in vivo* study has yet demonstrated any critical effect.

1.106.4.2. The Use of Zirconia in the Dental Field: From Dental Restoration to Implants

In addition to mechanical specifications, dental applications require esthetic properties. For example, strength of more than 500 MPa is generally required for posterior crowns and must be accompanied by translucency and appropriate color. The white to ivory color of most oxide ceramics gives them a clear advantage versus metals, which is the reason why metal-free dental prosthetic restorations have been strongly developed in the past 10 years. It is assumed (even if difficult to quantify) that 15 000–20 000 zirconia restorations are made every day. Indeed, metal-free restorations preserve soft tissue color closer to the natural one than porcelain fused to metal restorations. Moreover, ceramics do not suffer corrosion and/or galvanic coupling as do metals. The clinical demand for all-ceramic

restoration is increasing and ceramics are becoming important restorative materials in dentistry. Y-TZP ceramics possess the best combination of mechanical and esthetical properties among polycrystalline oxide ceramics. 3Y-TZP ceramics with a translucency reaching 12–15% are available,[40] and their color is easily adjustable by doping, for example, with iron or rare earth, meeting the demand for long-lasting, natural-like restoration. In addition, it cannot be underemphasized that 3Y-TZP can be easily shaped by CAD/CAM process.[41,42] Basically, a wax model of the patient's teeth is made and 3D measurements of the model are entered in a computer. These data are then used to control the precise machining necessary to obtain pieces with the right shape. The machining can be done either on presintered[43–45] or on fully dense zirconia blocks.[46] By presintered 'blanks,' we mean zirconia blocks thermally treated so as to form necks between the zirconia grains in the first sintering stage, thus being much stronger than green bodies but much easier to machine than fully dense pieces. Presintering is generally performed around 1100 °C, leading to a density of roughly 55%. The shrinkage that occurs during sintering imposes to machine presintered pieces with dimensions approximately 20% larger than the final dimensions; thus the final dimensions (after sintering) are not fully controlled. Machining of fully dense blocks is technically more difficult, wears the machining hardware at a much higher rate, and may introduce microcracks in the material.[47] However, it offers higher precision and simpler thermal treatments as only one-step sintering is sufficient. For technical (and economical) reasons, CAD/CAM on presintered blanks is now most often preferred. Most current zirconia restorations are veneered with a glass-ceramic to achieve perfect matching with natural teeth. An example is shown in **Figure 8**. However, the translucency and colors reached today by some zirconia offer the possibility to develop unveneered restorations in the future, in which zirconia ensures both mechanical functions and esthetical properties.

The long-term clinical success of 3Y-TZP for dental restorations has recently led several companies to develop zirconia dental implants as an alternative to the 'gold standard' titanium or titanium alloys. If the esthetic interest of zirconia for restorations or even abutments is indisputable, it appears less clear for implants, inserted in the jaw, except in some clinical cases (e.g., front teeth and 'gingival smile'). Expected advantages are a perfect resistance to galvanic corrosion (which is discussed without consensus for titanium) and the possibility to avoid the presence of any metal in the mouth. The osteointegration of zirconia is as good as titanium, thanks to the oxide nature of the surface,[48] but certainly not intrinsically better. The search for a still better integration has led researchers and companies to develop methods to increase surface roughness and/or to create microporosity. Among them, we may cite sandblasting,[49] chemical etching,[48] spraying of a bioactive phase, or coating by a porous zirconia layer. The development of zirconia for dental implants is young, and there is a dearth of clinical studies assessing its long-term reliability versus titanium.

Figure 8 Hybrid (crown and inlay retained), full-ceramic three-unit bridge showing the zirconia core and the veneering, esthetic layer. Reproduced from Höland, W.; Schweiger, M.; Watzke, R.; Peschke, A.; Kappert, H. *Expert Rev. Med. Devices* **2008**, *5*, 729–745, with permission of Expert Reviews Ltd.

If aging has been very well documented in orthopedic applications, as clearly controlling the lifetime of implants, the lack of studies for dental applications is striking. Even though a few general papers devoted to dental zirconia underline the need to 'keep in mind that some forms of zirconia are susceptible to aging and that processing conditions can play a critical role on the LTD of zirconia,'[50] the problem of aging in dental zirconia is still underemphasized so far. In part, this is due to the availability of new aging resistant 3Y-TZP, such as TZ3Y-E from Tosoh. It is also certainly due to a lack of exchanges from one community to another. The aging consequences are much less dramatic in dental applications, especially when restorations are concerned, but large-scale failure events such as those of Prozyr® heads in 2001 would be a critical issue for the material and ceramics in general. A recent paper by Lughi and Sergo[51] critically reviews the relevant aspects of aging in dentistry and provides some engineering guidelines for the use of zirconia as dental materials.

We have to keep in mind that every step of the process is influencing the microstructure, hence the stability of zirconia versus aging. The trends followed by companies to obtain highly translucent zirconia (sintered at high temperatures, with large grains and sometimes partially cubic) or porous surfaces to enhance bone in-growth or chemical and mechanical treatments at the surface (in the company, the dental laboratory or by the clinician himself) will inevitably affect its stability.

The bad story of 3Y-TZP in the orthopedic field has had at least one positive output: the aging mechanisms are now well understood and several tools are now available to assess the resistance of a given zirconia to aging. We recommend, for example, the use of XRD combined with accelerated aging tests in autoclave to systematically assess the stability of process/product combination. In parallel, the search for aging-free and robust zirconia must be pursued.

1.106.5. Future Directions

1.106.5.1. Tough, Strong, and Stable Zirconia Ceramics and Composites: The Necessary Challenge

The differences observed both *in vitro* and *in vivo* from one zirconia to another have shown that some 3Y-TZP zirconia products behave well. It is difficult to talk about 'aging-free' zirconia as the transformation occurring upon aging consists of a 'natural' return to the monoclinic equilibrium state.

However, the transformation kinetics can be much affected by microstructural issues and they can be sufficiently low to avoid any problem during the lifetime of the product. Recent revision of the ISO standard for 3Y-TZP (ISO 13356, revised in 2008) now includes the critical issue of aging and accelerated tests to assess the long-term reliability of a given zirconia. Such accelerated tests are mandatory before launching a given 3Y-TZP to the market. They are simple: 1 h of autoclave treatment at 134 °C has roughly the same effect as 2–4 years *in vivo*[22]; 5 h steam sterilization avoids heavy and long experiments to assess the aging sensitivity of a given zirconia prior to commercialization. XRD analysis was traditionally used to follow quantitatively the transformation. More sensitive methods were proposed in recent years. In particular, optical interferometer and atomic force microscopy, generally used for roughness measurements, are powerful tools to quantify the first stages of aging. Raman spectroscopy is also a powerful tool to monitor transformations at the surface or even in-depth and transformation-induced stresses.[52] Associated with standard scanning electron microscopy and XRD analysis, they should be conducted also for the scientific analysis of explanted materials. 3Y-TZP as a dental material should benefit from these new developments and from the knowledge acquired by scientists on this material over the last 10 years as a result of the unfortunate problems encountered in orthopedics. On the other hand, it seems clear that the strong negative events in orthopedics have definitively put an end to 3Y-TZP in this field and other options must be found. It has to be said that the issue of aging stands to the use of yttria as a dopant. Yttrium, as a trivalent ion, creates oxygen vacancies that help hydroxyl group diffusion in the lattice. Ceria-doped zirconia ceramics exhibit superior toughness (up to 20 MPa $\sqrt{m}$) and reduced aging sensitivity (due to the tetravalent character of cerium ion). There is thus still a door open for zirconia ceramics improved with a good combination of toughness and stability. The major drawbacks of Ce-TZP ceramics as compared to Y-TZP are the lower strength (typically 600 MPa as compared to 1000 MPa for Y-TZP) and the lack of translucency. Both aspects are certainly related to the difficulty of producing Ce-TZP with a grain size as small as that of 3Y-TZP. Grain size of (almost) fully dense Ce-TZP generally lies above 1.5–2 µm, when 3Y-TZP can exhibit grain size lower than 0.5 µm with full density. Efforts should be made to process Ce-TZP with sufficiently high density and small grain size to develop tough, strong, and stable zirconia ceramics. Unfortunately tetravalent Ce^{4+} is reduced to Ce^{3+} under reducing atmosphere, leading again to stability problems. Therefore, innovative sintering techniques such as spark plasma sintering or even hot isostatic pressing are hardly applicable to reduce grain size and improve densification. Composites, based on Ce-TZP with another oxide, may be a promising alternative at least to refine their microstructure and improve their strength (unfortunately, they will remain opaque). This is the case of Ce-TZP–alumina composites.[35,36] One approach to avoid oxygen vacancies introduced by yttria doping is to select co-dopants and to combine trivalent and pentavalent ions to minimize the total concentration of vacancies required for charge compensation. Works have focused on Y^{3+}/Nb^{5+}[53] or Y^{3+}/Ta^{5+}[54] co-doping. The resistance to LTD of equimolar $YO_{1.5}$–$TaO_{2.5}$-stabilized tetragonal ZrO_2 ceramics in air has been demonstrated to be highly superior to that of the standard 3Y-TZP. However, further effort is required on the new co-doped zirconia ceramics before going for practical use in medical devices. Indeed, not only aging, but also toughness, strength, wear resistance (orthopedics), and esthetic properties (dental) are required for such applications.

Composites, based on the combination of zirconia with another oxide, may be clearly the way to benefit from zirconia transformation toughening without the major drawback associated with its transformation under steam or body fluid condition. In the recent literature concerning alumina–zirconia composites for biomedical applications, different compositions have been tested, from the zirconia-rich to the alumina-rich side. Major ceramic companies are developing such materials and the composites developed may be ATZ (alumina-toughened zirconia) or ZTA (zirconia-toughened alumina). ATZ composites are a combination of 3Y-TZP and alumina. They are therefore sensitive to aging even if the kinetics are significantly slower than that of 3Y-TZP as a monolith.[55] The impact of the transformation is also less negative, as roughness is not strongly affected even after long duration of aging. ZTA are either a combination of undoped or yttria-doped zirconia with alumina. Being the minor phase, the content of Y_2O_3 in zirconia can be lowered. It depends on the zirconia content: the larger the zirconia content, the larger is the amount of Y_2O_3 needed. Undoped zirconia can be stabilized in a zirconia matrix provided the grain size and the zirconia content are sufficiently low. Stabilization is possible thanks to the stiff alumina matrix, but high zirconia contents cannot be reached (tensile stresses due to thermal mismatch balancing the benefit of the stiff matrix). The optimum zirconia content for high toughness stands around 10 vol.%.[56] With such compositions, toughness higher than 3Y-TZP and full stability are achieved. Very few studies have been devoted to aging in ZTA systems, but they show that, even if limited, some degree of degradation can be observed, depending on microstructural features. As an example, aging may be significant in a 3Y-TZP–alumina composite, above 16 vol.% zirconia.[57] This critical content is related to the percolation threshold above which a continuous path of zirconia grains allows transformation to proceed. The presence of zirconia aggregates, especially if the zirconia is stabilized with yttria, should also be avoided.[58] Biolox Delta®, which is an advanced version of ZTA composites produced by Ceramtec and the new standard in orthopedics, is not fully 'aging free.'[38] Accelerated aging tests and extrapolations toward *in vivo* situations predict a slow transformation of Biolox Delta® products, and we might foresee an increase of monoclinic content from 10 to 15 vol.% in heads before implantation to 15–25 vol.% after 10 years. There is a dearth of retrieval analysis performed on Biolox Delta® heads to assess this issue and give a clear indication of *in vivo* kinetics. This is fortunately because of the very low failure rate associated with Biolox Delta®. Of importance also is the mechanism by which the transformation proceeds as compared to that in 3Y-TZP monoliths and the consequences of the transformation: the composite does not show large surface uplifts, as it is the case for 3Y-TZP and no loss in strength is observed even after long aging treatments, equivalent to 40 years *in vivo*.[38]

In conclusion, aging and its consequences must be investigated for each specific zirconia-containing material, without prior speculative assumptions, as kinetics and impacts may

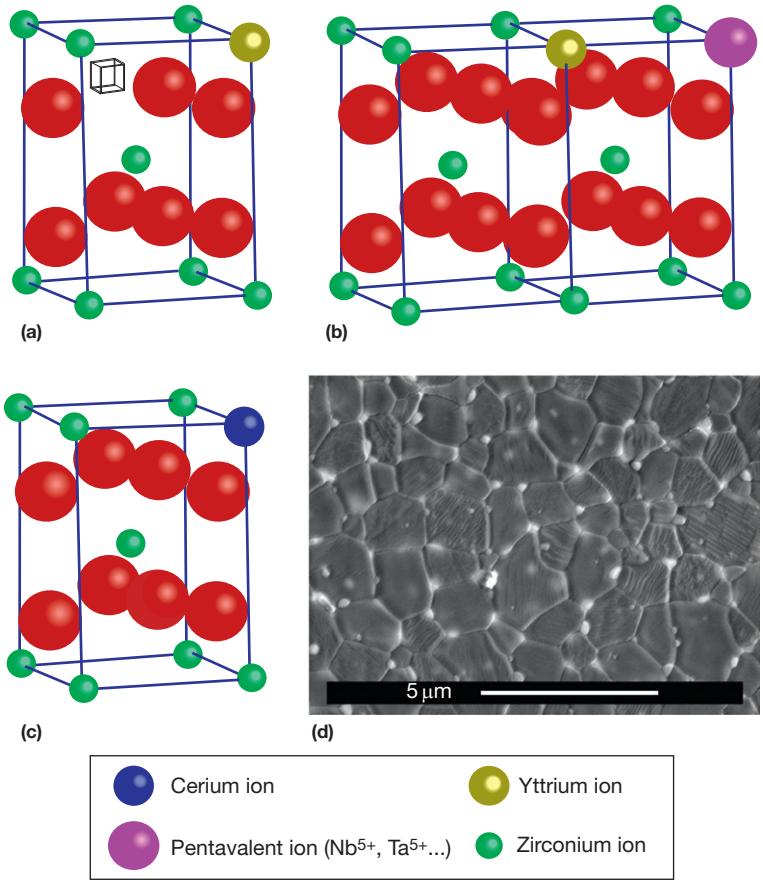

Figure 9 The search for tough and stable zirconia-based ceramics: from (a) yttria-stabilized zirconia (with oxygen vacancies) toward (b) zirconia stabilized by a combination of tri- and pentavalent ions or (c) ceria-doped zirconia ceramics or composites or (d) zirconia-toughened alumina.

vary from one composition to another. It appears also that there is no commercial zirconia-based material today fully free of aging. Such tough, strong, and stable zirconia ceramics and composites are options for the next decade. They are schematically presented in Figure 9.

1.106.6. Conclusion

Among biomaterials, biomedical grade zirconia has led to a major controversy among scientists, industrialists, and clinicians. On the one hand, biomedical grade zirconia exhibits the best mechanical properties of oxide ceramics; this is the consequence of phase transformation toughening, which increases its crack propagation resistance. On the other hand, because of this ability to transform, zirconia is prone to aging in the presence of water: this has been unfortunately verified *in vivo* with some critical consequences. These two sides of zirconia have been described here.

3Y-TZP as a monolithic ceramic has disappeared from the orthopedic field because of aging-related failure events in some particular products. In the absence of any clinical report of aging in dental applications, 3Y-TZP still has a strong potential as a biomaterial, because of its excellent mechanical and esthetic properties. Because scientists and companies are now aware of aging and because of the improvement in the monitoring of the degradation, one should expect that no critical issue appears in this field in the future, provided sufficient attention is given to it.

1.106.7. Further Reading

This short chapter highlights the two major aspects of zirconia ceramics: phase transformation toughening beneficial for mechanical properties and aging (or LTD) that can be considered as its Achilles heel. More in-depth understanding of transformation toughening is possible from the book 'Transformation Toughening of Ceramics,' from Green *et al.*[2] and from the recent review paper from Kelly and Rose.[14] The authors of the current chapter have recently published a review on aging and its negative impact on orthopedic implants[24] and on the two sides of the t–m phase transformation in a feature paper.[11,38] Clinical data and retrieval analysis may also be obtained from Clarke *et al.*[25] Review papers on the use of zirconia in dental applications can be found in Denry and Kelly[50] and Höland *et al.*[41]

Glossary

Carbon The number six element in the periodic table. It consists of six valence electrons, which are arranged in the $1s^2 2s^2 2p^2$ electronic configuration. Carbon can be found in a variety of forms, including in nearly completely amorphous materials and in entirely crystalline materials.

Chemical vapor deposition (CVD) The process in which a high-purity material is deposited onto a substrate as a result of a chemical reaction or as a result of decomposition of a volatile precursor.

Diamond-like carbon (DLC) A variety of amorphous carbon films, which contain sp^3-hybridized atoms. In addition, these materials may contain varying degrees of hydrogenation as well as alloying materials.

Fluidized-bed reactor A furnace chamber in the form of a vertical cylinder, which contains ceramic particles suspended in a fluid-like form by an inert gas. Substrates are suspended on the fluidized bed of particles; coating of the substrate occurs by means of chemical vapor deposition after introduction of a volatile precursor gas.

Microcrystalline diamond (MCD) A crystalline form of carbon containing a high fraction of sp^3-hybridized atoms; grain sizes on the order of 0.5–2.0 μm are observed. It should be noted that sp^2-hybridized atoms as well as

amorphous carbon are commonly observed at the grain boundaries.

Nanocrystalline diamond (NCD) A crystalline form of carbon-containing sp^3-hybridized atoms; grain sizes below 100 nm are observed. This material has a lower degree of sp^3 bonding compared to microcrystalline diamond due to sp^2-hybridized atoms and amorphous carbon at the grain boundaries.

Pyrolysis The thermal decomposition of a substance into more basic compounds. Pyrolysis is the form of decomposition used for chemical vapor deposition of pyrolytic carbon from fullerenes or from hydrocarbon gases.

Pyrolytic carbon A turbostratic form of carbon, which consists of randomly layered graphene sheets that are formed with sp^2-hybridized atoms. Pyrolytic carbon is similar in form to graphite; however, defects in the graphene layers result in kinked sheets or curved sheets.

Thin film Surface coating with a thickness of between a fraction of a micrometer and a few micrometers. Thin films are deposited on substrate materials in order to modify the surface properties of the substrate materials.

Ultrananocrystalline diamond (UNCD) A crystalline form of carbon-containing sp^3-hybridized atoms; grain sizes below 10 nm are observed. Among MCD, NCD, and UNCD, UNCD has the lowest fraction of sp^3-hybridized atoms due to sp^2-hybridized atoms and amorphous carbon at the grain boundaries.

Abbreviations

a-S:H	Hydrogenated amorphous silicon
CVD	Chemical vapor deposition
DLC	Diamond-like carbon
EELS	Electron energy loss spectroscopy
ELAM-1	Endothelial cell adhesion molecule-1
FTIR	Fourier transform infrared
ICAM-1	Intercellular cell adhesion molecule-1
LIBAD	Low incidence beam angle X-ray diffraction
LTI	Low-temperature isotropic
MCD	Microcrystalline diamond
MEMS	Microelectromechanical systems
MPECVD	Microwave plasma-enhanced chemical vapor deposition
MWNT	Multi-walled nanotube
NCD	Nanocrystalline diamond
NMR	Nuclear magnetic resonance
PDMS	Polydimethylsiloxane
PECAM-1	Platelet endothelial cell adhesion molecule-1
PECVD	Plasma-enhanced chemical vapor deposition
PF_4	Platelet factor 4
PLD	Pulsed laser deposition
PMMA	Polymethylmethacrylate
PTFE	Polytetrafluoroethylene
RDF	Radial distribution function
RF PA CVD	Radio frequency plasma-activated chemical vapor deposition
SWNT	Single-walled nanotube
ta-C	Tetrahedral amorphous carbon
ta-C:H	Hydrogenated tetrahedral amorphous carbon
TXB_2	Thromboxane B_2
UHMWPE	Ultrahigh molecular weight polyethylene
ULTI	Ultra-low-temperature isotropic
UNCD	Ultrananocrystalline diamond
UV	Ultraviolet
XPS	X-ray photoelectron spectroscopy

1.107.1. Introduction

Carbon is the sixth most common element found on earth; it is found in greater than 90% of all known chemical substances.[1,2] What makes carbon interesting from a biomaterials standpoint is the range of forms in which it is found. Carbon has two naturally occurring crystalline allotropic forms, graphite and diamond. It can be found in a variety of forms, including entirely amorphous materials and completely crystalline materials.[3] In recent years, fullerene (C_{60}) and carbon nanotube materials have been synthesized; these materials have attracted a significant amount of attention from the research community.

The existence of carbon structures with a variety of physical and chemical properties is attributed to the electronic behavior of the carbon atom. Carbon is the number six element in the periodic table. It contains six electrons, which are arranged in the electronic configuration of $1s^2 2s^2 2p^2$. In the ground state of a carbon atom, two 2p electrons occupy $2p_x^1$ ($m = 1$) and $2p_y^1$ ($m = -1$) states. When a carbon atom forms covalent bonds with other atoms (e.g., hydrogen atoms or other carbon atoms), not only the two 2p electrons but also the 2s electrons may participate in bond formation. The energy gap between the 2s levels and the 2p levels in carbon atoms is only 8 eV. The 2s electron of the carbon atom can be easily excited to the 2p level, forming four unpaired electrons. The four unpaired electrons form chemical bonds with other atoms by means of hybrid orbitals. A hybrid orbital is a linear combination of atomic orbitals. A carbon atom may exhibit one of the three types of hybrid orbitals: sp-hybridized orbitals, sp^2-hybridized orbitals, and sp^3-hybridized orbitals. In sp orbital hybridization, mixing of the s orbital and the p_x orbital takes place; two equivalent sp hybrid orbitals with an angle of 180° result. Two of the four unpaired electrons occupy the two hybrid sp orbitals; the other two electrons occupy the 2p orbitals. The sp hybrid orbitals can form two σ bonds. The other two 2p electrons can give two relatively weak π bonds. In the sp^2 hybridization, three electrons in the s, p_x, and p_y orbitals form three hybrid orbitals.

Three of the four unpaired electrons are in the hybrid orbitals and the other one is in the 2p orbital. The angle between the orbitals is 120°. Three sp^2 hybrid orbitals create three σ bonds; one 2p electron gives a π bond. All of the four unpaired electrons of the carbon atom participate in sp^3 hybridization by forming four sp^3 hybrid orbitals in the arrangement:

$$\left.\begin{aligned}\varphi_1 &= s + p_x + p_y + p_z\\ \varphi_2 &= s + p_x - p_y - p_z\\ \varphi_3 &= s - p_x + p_y - p_z\\ \varphi_4 &= s - p_x - p_y + p_z\end{aligned}\right\} \quad [I]$$

The angle between the sp^3 orbitals is 109.5°. The four sp^3 orbitals give four strong σ bonds when the carbon atom creates covalent bonds with other atoms. The three types of orbital hybridizations for a carbon atom are schematically illustrated in Figure 1.

The hybrid orbitals of a carbon atom commonly form σ bonds when carbon atoms undergo chemical bonding with other atoms. The electrons in the 2p orbitals contribute to π bonds. In acetylene (C_2H_2), the two hybrid sp orbitals of the carbon atom form two σ bonds with one hydrogen atom and another carbon atom. The two singly occupied 2p electrons form two π bonds between the two carbon atoms (H–C≡C–H).

One of the carbon polymorphs is graphite. The crystalline structure of graphite is hexagonal (6/m 2/m 2/m), with a lattice parameter of $a = 2.461$ Å and $c = 6.708$ Å. In each hexagonal plane, three unpaired electrons of a carbon atom form three σ bonds with the three nearest neighbor carbon atoms by means of sp^2 hybrid orbitals. These σ bonds are stronger than those in diamond. The electrons in the p_z orbitals form distributed π bonds within the hexagonal sheet. The π bonds are weaker and the electrons forming these bonds are delocalized; due to this electronic arrangement, graphite is an electrically conducting material. The hexagonal sheets are connected with one another through weak Van der Waals forces. The weak Van der Waals forces facilitate slipping of graphene sheets past one another. On account of this arrangement, graphite is a soft material. In addition, the layered structure of graphite allows it to exhibit lubricating behavior.

Diamond is another polymorph of carbon. The lattice structure is named diamond structure, with a lattice constant of 3.567 Å. Diamond is the hardest known material. The high hardness of diamond comes from its crystalline structure and from the strength of the chemical bonds that hold the carbon atoms together. The carbon atoms within diamond exhibit sp^3 hybridization. The four unpaired electrons of each carbon atom form four σ bonds with the four nearest carbon atoms.

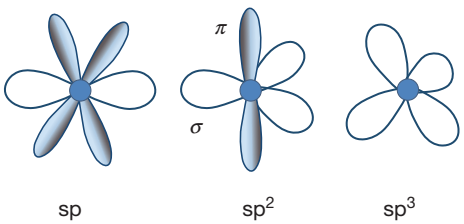

Figure 1 Schematic showing sp, sp^2, and sp^3 hybridization from s orbitals and p orbitals.

The covalent sp^3 bonds of diamond make it extremely hard; the material behaves as a single isotropic covalent molecule.[4] The rigid network of covalent bonds in carbon makes it an excellent material for applications such as cutting or grinding. In addition, the high wear resistance of diamond makes it an attractive material for hip prostheses, knee prostheses, and other joint prostheses.

Fullerenes are another form of crystalline carbon which will be covered extensively in Chapter 5.523, Carbon Nanotubes: Applications for *In Situ* Implant Sensors. Buckyballs are a type of fullerene that comprise a family of spheroid or geodesic carbon molecules containing five-membered pentagonal rings and six-membered hexagonal rings. They require 12 pentagonal rings in order for the structure to close into a spheroid. Buckyballs possess a variable number of hexagonal rings.[5] This class of carbon materials has been evaluated for use in a variety of technological applications (e.g., plastic solar cells, donor–acceptor systems, and quantum computing), biological applications (e.g., DNA photocleavage, HIV protease inhibition, neuroprotection, and apoptosis), and medicinal applications (e.g., improvements to magnetic resonance imaging contrast agents and encapsulation of radiopharmaceutical drugs for nuclear medicine).[6] The carbon nanotube is another class of carbon material that is receiving significant interest in the scientific community (see Chapter 3.330, Carbon Nanotube-Based Sensors: Overview). In nanotubes, rolled graphene sheets form cylinders with high length to radius ratios, excellent strength, and unusual electrical properties. Single-walled nanotubes (SWNT) and multi-walled nanotubes (MWNT), which consist of concentric cylinders, have been demonstrated. Carbon nanotubes have numerous technological and biological applications, including uses in nanoelectronics; field emitters; composite materials; and physical, chemical, and biological sensors, among others. Carbon can exist in other allotropes, including amorphous carbon, carbyne, and lonsdaleite.

This chapter focuses on the use of carbon materials in biomedical applications. Specifically, the use of pyrolytic carbon, diamond-like carbon (DLC), microcrystalline diamond (MCD), nanocrystalline diamond (NCD), and ultrananocrystalline diamond (UNCD) in medical applications is described. Pyrolytic carbon is a form of turbostratic carbon formed from pyrolysis of hydrocarbons or fullerene gases. DLC is an amorphous carbon material, which contains sp^3-hybridized carbon atoms; in addition, it may contain a variable amount of hydrogen. MCD, NCD, and UNCD are composed of sp^3-hybridized carbon crystals with microscale or nanoscale grain sizes. The structure, mechanical properties, biological properties, production processes, and biomedical applications of these carbon materials are addressed in detail. While the focus is placed on the use of these carbon materials in thin films and coatings, attention is also given to the general properties of carbon and its applications as a biomaterial.

1.107.2. Pyrolytic Carbon

1.107.2.1. Introduction

Pyrolytic carbon is an allotropic form of carbon that consists of turbostratic graphene sheets. This material is produced via pyrolysis of hydrocarbon precursors. Pyrolytic carbon is a

man-made material that was originally considered for use in biomedical devices over 40 years ago by the company General Atomics.[4] It is primarily utilized as a coating material, which can be applied to substrate materials such as graphite, carbon fibers, and carbon–carbon composites.[5] Types of pyrolytic carbon materials that are commonly used in biomedical engineering applications include low-temperature isotropic (LTI) carbon and ultra-low-temperature isotropic (ULTI) carbon.

Pyrolytic carbon exhibits a turbostratic structure. In this structure, sp^2-hybridized crystals form graphene sheets that are layered in a random manner. In some respects, the structure of pyrolytic carbon resembles that of graphite. Both allotropes are composed of graphene sheets; the graphene sheets in graphite demonstrate consistency in the hexagonal crystal structure throughout each layer. On the other hand, pyrolytic carbon exhibits defects in the lattice structure within the layers. These defects result in curved or kinked sheets. The term 'turbostratic' refers to the kinked or curved crystalline structure of the material layers, which causes larger gap distances between the layers than would be present if the sheets were perfectly parallel. The layer spacing between graphene layers in graphite is 3.35 Å; in comparison, the layer spacing is 3.48 Å in pyrolytic carbon.[4] In a similar manner to graphite, the layered sheets of graphene in pyrolytic carbon are held together by Van der Waals forces. It should be noted that graphite exhibits consistently smooth layers of graphene, which allow the layers to slip past one another and endow graphite with lubricating behavior. On the other hand, the kinks and defects within the graphene layers of pyrolytic carbon prevent the graphene layers from easily slipping past one another. As a result, the strength, hardness, and wear resistance properties of pyrolytic carbon are greater than those of graphite. In addition, pyrolytic carbon exhibits crystallite sizes of 25–40 Å.[4] Small crystallites form during the deposition process; the resulting polycrystalline features exhibit a random orientation. The isotropic behavior of pyrolytic carbon is attributed to the random orientation and the small crystallite sizes of these growth features.

1.107.2.2. Production of Pyrolytic Carbon

The term 'pyrolysis' refers to thermal decomposition of a substance; pyrolytic carbon coatings are produced using this mechanism. This material is formed via thermal breakdown and dehydrogenation of gaseous hydrocarbon or fullerene precursors in an oxygen-free environment. Examples of hydrocarbon precursors that are commonly used in the production of pyrolytic carbon are propane, propylene, acetylene, and methane. In the presence of oxygen, hydrocarbon gases decompose into water and carbon dioxide. By thermally decomposing hydrocarbons in the absence of oxygen, the carbon atoms go through a decomposition cascade in which the carbon atoms from the gaseous precursor can form arrays that exhibit crystallite growth features.[4]

1.107.2.2.1. Fluidized-bed production of pyrolytic carbon

Pyrolytic carbon is commonly deposited on a substrate using what is known as a fluidized-bed reactor. A fluidized-bed reactor consists of a furnace chamber in the shape of a vertical tube that is heated to 1000–2400 °C.[4,7] The fluidized bed is created using ceramic particles within the furnace chamber. A carrier gas (e.g., argon, nitrogen, or helium) is pumped through the chamber, suspending the particles. As the gas flows between the particles, they move throughout the chamber in a fluid-like manner. The hydrocarbon precursor is added to the gas flow, enabling pyrolysis to occur within the furnace. The fluid-like bed of particles provides a mechanism for suspending the substrate material that is to be coated.

The microstructure of pyrolytic carbon is dependent on the fluidized-bed reactor deposition parameters. In particular, the characteristics of the pyrolytic carbon produced from fluidized-bed reactors are affected by the pyrolysis conditions. The variables of interest for controlling the structure of pyrolytic carbon have been discussed by Bokros[3]; they include the nature and concentration of the hydrocarbon precursor, the pyrolysis temperature, the time in which the gaseous precursor is exposed to temperatures that result in pyrolysis, and the ratio of the deposition substrate surface area to the volume of gas in the pyrolysis chamber.

Laminar, isotropic, or granular pyrolytic carbon may form depending on the processing conditions. Generally, laminar structures form at low temperatures and high pressures, granular structures form at high temperatures and low pressures, and isotropic structures fall in the middle range; it should be noted that variations in hydrocarbon gas concentration and the area of the fluidized bed can influence processing parameters.[8] Laminar structures are created due to aligned deposition of planar molecules, which form in the gas phase during pyrolysis.[8] Granular structures with distinct grains form during ordered growth, which are associated with a temperature gradient between the substrate and the decomposing gas, low supersaturation of the gas phase, and high mobility of molecule deposition on the substrate surface.[8] Isotropic pyrolytic carbon forms as a result of random deposition of gas-phase carbon droplets onto the substrate surface; this material is of greatest interest for biomedical applications.[8]

Owing to the high processing temperature, it is difficult to fabricate components entirely made of pyrolytic carbon, and it is not possible to produce thick pieces of pyrolytic carbon that can be machined into desired geometries.[7] As pyrolytic carbon is commonly used in coating form, an acceptable substrate material must be selected that is compatible with chemical vapor deposition (CVD) pyrolysis conditions. A material that is often used as a substrate for pyrolytic carbon coatings is polycrystalline graphite; this material is capable of withstanding the temperatures and pressures associated with the fluidized-bed reactor process. Polycrystalline graphite is a substrate material that can be levitated within the fluidized bed by the ceramic materials; uniform deposition of the pyrolytic carbon coating is possible, as hydrocarbon precursors pyrolyze around the substrate material. This material also exhibits a coefficient of thermal expansion closely matching that of pyrolytic carbon, which results in minimal extrinsic (thermal) stress and good coating adhesion.[7]

1.107.2.2.2. Tumbling and stationary bed production of pyrolytic carbon

Fluidized beds are commonly used to produce pyrolytic carbon.[3,7–13] Production using tumbling beds and stationary beds has also been investigated. Tumbling bed reactors use a rotating

coating chamber that allows the substrate material to move slowly along the chamber wall during rotation. The substrate material tumbles back to a neutral position, allowing coating of the material during collisions with the carbon gas-phase droplets.[14–20] This coating process allows for deposition of isotropic pyrolytic carbon. The bed tumbles at low speeds (0.2–100 rpm).[14–19] Stationary beds have also been used for pyrolytic carbon deposition; in this case, the substrate material is held in an immobile position. While stationary beds may be used for deposition of isotropic pyrolytic carbon,[17] there is greater difficulty in promoting collisions between gas-phase droplets of the carbon species and the substrate material during pyrolysis. As a result, stationary beds often produce pyrolytic carbon with columnar, granular, or filamentous structures that contain soot by-products; these materials exhibit poor mechanical properties in comparison with isotropic pyrolytic carbon.[8,18]

1.107.2.3. Mechanical Properties of Pyrolytic Carbon

Pyrolytic carbon used in biomedical applications must exhibit appropriate mechanical properties, including strength, modulus of elasticity, toughness, hardness, wear resistance, and fatigue resistance. Alterations in pyrolytic carbon-processing parameters may be used to modulate density, porosity, degree of anisotropy, as well as mechanical properties.

A material used in biomedical applications must exhibit sufficient strength to function in the environment in which it is utilized. The flexural strength of pyrolytic carbon, the stress prior to fracture during bending, is high enough to support structural components for various implant applications. It should be noted that the mechanical properties of materials required for an implant will vary depending on the implant application. Table 1 contains a comparison of glassy carbon, vapor-deposited carbon, silicon-doped LTI carbon, as well as LTI pyrolytic carbon, which is the most common type of pyrolytic carbon used in biomedical applications. Silicon is utilized as a doping agent in order to modulate the mechanical properties of pyrolytic carbon.

Table 1 Comparison of properties of low-temperature isotropic (LTI), glassy, and vapor-deposited turbostratic carbons

Property	*Glassy carbon*	*Vapor-deposited carbon*	*LTI carbon*	*LTI carbon with silicon*[a]
Density ($g\,cm^{-3}$)	1.4–1.6[b]	1.5–2.2[c]	1.7–2.2[c]	2.04–2.13
Crystallite size (L_c) (Å)	10–40	8–15	30–40	30–40
Flexural strength, ($\times$ 1000 psi)	10–30[b]	50 to >100[c]	40–80[c]	80–90
Young's modulus ($\times 10^6$ psi)	3.5–4.5[b]	2.0–3.0[b]	2.5–4.0[c]	4.0–4.5
Strain to fracture (%)	0.8–1.3	2.0 to >5.0[c]	1.6–2.1	2.0
Fatigue limit/ fracture strength	1.0	1.0	1.0	1.0
Strain energy to fracture ($\times$ 100 psi)	1–2	>10	4–8	8
Hardness, DPH	150–200[b]	150–250[c]	150–250[c]	230–370[c]

1.107.2.4. Biological Properties and Biomedical Applications of Pyrolytic Carbon

1.107.2.4.1. Cardiovascular applications of pyrolytic carbon

Pyrolytic carbon has been considered for use in biomedical devices because of favorable evidence regarding its interaction with tissues, cells, and proteins. In particular, pyrolytic carbon has been considered for use in cardiovascular medical devices due to its excellent hemocompatibility. Early studies demonstrated that pyrolytic carbon possesses excellent blood compatibility; these properties were attributed to adsorption of proteins onto the surface of the material.[4] Studies involving adsorption of blood proteins suggested that pyrolytic carbon adsorbed proteins onto its surface; as a result, the material did not induce coagulation or thrombogenesis.[21] In a more recent study, the interaction between endothelial cell adhesion proteins and polyethylene terephthalate coated with pyrolytic carbon was investigated.[22] This study evaluated human umbilical vein endothelial cell expression of several molecules, including platelet endothelial cell adhesion molecule-1 (PECAM-1), endothelial leukocyte adhesion molecule-1 (ELAM-1), and intercellular adhesion molecule-1 (ICAM-1). PECAM-1 helps regulate adhesion of endothelial cells to other endothelial cells as well as to leukocytes. ELAM-1 is involved in adhesion of neutrophils, monocytes, and lymphocytes to endothelial cells. ICAM-1 plays a role in the adhesion of leukocytes to endothelial cells. Cenni *et al.* investigated the expression of these molecules by human umbilical vein endothelial cells, because they reflect inflammation associated with cell–material interaction. Cytofluorometry was used to measure the presence of PECAM-1, ELAM-1, and ICAM-1 molecules in cultures of human umbilical vein endothelial cells on pyrolytic carbon-coated polyethylene terephthalate. Their results showed no significant changes in expression of PECAM-1, ELAM-1, or ICAM-1, indicating that pyrolytic carbon-coated polyethylene terephthalate did not result in unfavorable expression of proteins that could disrupt connections between endothelial cells or stimulate an inflammatory response. These results are important in evaluating the use of pyrolytic carbon in applications that involve endothelialization.

Cenni *et al.*[23] examined adhesion of platelets and stimulation of coagulation factors by pyrolytic carbon-coated polyethylene terephthalate. Platelet adhesion was determined using plasma-rich protein. Platelet aggregation was examined using thromboxane B_2 (TXB_2) and platelet factor 4 (PF_4) immunoassays; TXB_2 and PF_4 are involved in the blood coagulation cascade. The results of this study indicate that pyrolytic

carbon-coated polyethylene terephthalate exhibited a reduction in platelet adsorption, as well as lower levels of TXB_2 and PF_4. However, platelet adsorption and expression of aggregation factors were significantly higher in pyrolytic carbon-coated polyethylene terephthalate than in control materials. Although pyrolytic carbon improved the hemocompatibility of polyethylene terephthalate, aggregation of proteins on the pyrolytic carbon surface was noted.

Over the last 40 years, pyrolytic carbon has been used as a coating on prosthetic heart valves and other cardiovascular medical devices due to its chemical inertness and biocompatibility. A study by Fernandez *et al.*[24] indicated positive results in 90% of the 110 patients who received a pyrolytic carbon tilting disk Bjork–Shiley aortic prosthesis. The study indicated beneficial results when compared to previous heart valve designs, which were associated with thrombogenesis, occluded blood flow, or implant deterioration. A reduction in thrombogenesis was also attributed to the use of pyrolytic carbon. It should be noted that some of the successes of pyrolytic carbon-coated prosthetic heart valves are attributed to reduced valvular regurgitation, which is associated with a reduction in clearance in pyrolytic carbon-coated disk occluder/orifice ring designs when compared with polyoxymethylene disk occluder/orifice ring designs.

The wear properties of heart valve prostheses containing pyrolytic carbon have also been considered. An implant retrieval study by Schoen *et al.*[25] compared the wear properties of eight pyrolytic carbon disk occluder and cage prostheses with those of a Teflon disk and cage prosthesis. Seven of the eight replacements had been implanted for a range of 30–85 months and one had been implanted for 44 days. The Teflon prosthesis was obtained postmortem from a patient who had the prosthesis for 34 days. Examination using dissecting microscopy, scanning electron microscopy, and analytical surface profilometry showed that there was insignificant wear on the occluders and struts of the pyrolytic carbon prosthetic valves. On the other hand, the Teflon valve demonstrated wear on the struts. Their study provided further evidence regarding the efficacy of pyrolytic carbon in prosthetic valve applications.

Antoniucci *et al.*[26] evaluated tubular stainless steel stents that were coated with turbostratic carbon. These stents, which went by the trade name Carbostent™ (Sorin Biomedica, Sallugia, Italy), were implanted in 112 patients; angiographic follow-up examinations at 6 months were performed in 108 patients.[26] The carbon-coated stents demonstrated low rates of 10% and 11% for target lesion revascularization and restenosis, respectively. The results of the study indicate that carbon-coated stents may be useful for minimizing thrombus formation and restenosis. A later study by Bartorelli *et al.*[27] examined the efficacy of stenting procedures involving the Carbostent™ and aspirin therapy for treatment of coronary artery disease. This study, termed the Aspirin alone Treatment After Carbostent Stenting (ANTARES) study, sought to determine the effectiveness of the carbon coating on the Carbostent™ device for prevention of thrombus formation. A total of 165 Carbostents™ in 110 patients were examined in this study. Postoperative analysis indicated that stenting with the Carbostent™ and antithrombotic therapy with aspirin were associated with an absence of thrombosis at the 30-day follow-up.[27]

1.107.2.4.2. Orthopedic applications of pyrolytic carbon

Pyrolytic carbon has been investigated for use in orthopedic medical devices. Isotropic pyrolytic carbon is alloyed with silicon in order to improve wear resistance and to better match the mechanical properties of bone. Pyrolytic carbon has been utilized in interphalangeal joint prostheses, which are used to reduce joint pain and improve movement in arthritic joints. Mixed results have been noted for pyrolytic carbon-containing proximal interphalangeal joint prostheses with regard to pain relief and range of motion following joint arthroplasty. In a 13-month postoperative follow-up study involving 18 joints in eight patients by Tuttle *et al.*,[28] only 50% reported a reduction in pain. There was no net increase in the average range of motion following surgery. There were also reports of squeaking in several of the joints; in addition, two of the joints experienced loosening. In another report, 50 proximal interphalangeal joints in 35 patients were studied at least 2 years after implantation.[29] In this study, 79% overall patient satisfaction was reported. In addition, statistically significant improvement in both pinch strength and grip strength was noted. There were also reports of improved range of motion; however, this trend did not reach levels of statistical significance. Secondary procedures were necessary for 28% of the joints; in addition, revision arthroplasty was necessary for 8% of the joints. **Figure 2** displays images of the proximal interphalangeal joint prostheses used in the study.[29] Although secondary procedures were required in some cases, the overall results indicated that there was potential for the use of pyrolytic carbon in proximal interphalangeal joint replacement prostheses. In addition, pyrolytic carbon has been investigated for use in metacarpophalangeal joints,[30] in scaphoid trapezium implants,[31] in the femoral head articulating surfaces of hip joint prostheses,[32] and in femoral implants to enhance bone ingrowth.[33–35]

1.107.2.4.3. Shortcomings of pyrolytic carbon

Although pyrolytic carbon has demonstrated utility in a variety of biomedical applications, concerns regarding the mechanical

Figure 2 (a and b) Views of the pyrolytic carbon prostheses. Note the bicondylar semiconstrained articulation similar to a total knee arthroplasty design. The distal component is on the left of the figure and the proximal component is on the right of the figure. Reprinted from Bravo, C. J.; Rizzo, M.; Hormel, K. B.; Beckenbaugh, R. D. *J. Hand Surg.* **2007**, *32*A(1), 1–11. Copyright (2007), with permission from Elsevier.

and biological properties of this material have been described in the literature. A lack of bone fixation to pyrolytic carbon-coated proximal interphalangeal joint prostheses may lead to loosening of the implants, failure of the implants, and need for revision surgeries.[36] In addition, blood flow and impact stress may lead to cavitation and pitting of pyrolytic carbon heart valves. Pitting of pyrolytic carbon heart valves can lead to fracture of the material and failure of the implant.[37] Infection is also a concern for pyrolytic carbon heart valves; for example, endocarditis can lead to serious health complications or death.[38,39] Bacterial biofilms (e.g., *Staphylococcus aureus*, *Staphylococcus epidermidis*, and *Pseudomonas aeruginosa*) have been shown to form on the surfaces of pyrolytic carbon heart valves.[40] Adhesion of platelets on the surfaces of pyrolytic carbon heart valves has also been raised as a concern. Despite reports that pyrolytic carbon is favorably hemocompatible, platelet activation on the surfaces of pyrolytic carbon heart valves has been noted; activation of platelets plays an important role in thrombus formation.[41,42]

1.107.3. Diamond-Like Carbon

1.107.3.1. Introduction to DLC

'DLC' is a term that is used to refer to a range of amorphous carbon films that contain sp^3-hybridized carbon atoms; these materials may contain varying degrees of hydrogenation as well as alloying components. DLC is a man-made product that can exhibit properties similar to those of diamond. Diamond-like hydrocarbon was first identified in the early 1950s by Schmellenmeir; significant efforts involving processing and characterization of DLC began in the 1990s.[1] Significant progress involving industrial production of diamond has also taken place in the past 20 years.[1] The use of DLC in biomedical devices (e.g., as a coating on implant components such as cardiac stents and joint replacements) is an emerging area of investigation.[1] The high hardness, wear resistance, and favorable biological properties of DLC have made it an interesting option for use in biomedical applications. DLC draws its unusual properties from the sp^3-hybridized carbon atoms within the material. DLC films exhibit large variations in several parameters, including the sp^3-hybridized carbon atom/sp^2-hybridized carbon atom ratio, the degrees of hydrogenation, and the presence of doping elements; these parameters have significant effects on biomedically relevant properties (e.g., mechanical properties).[43] Tetrahedral amorphous carbon (ta-C) and hydrogenated ta-C (ta-C:H) are forms of DLC that contain high percentages of sp^3-hybridized carbon atoms. ta-C:H is similar to ta-C; hydrogen atoms bonded to some of the carbon atoms in hydrogenated ta-C.

1.107.3.2. Production and Characterization of DLC

Several thin film deposition techniques have been utilized for depositing DLC films.[44,45] DLC is a thermodynamically metastable material; formation of sp^3-hybridized carbon atoms requires nonequilibrium processing technologies due to the high activation energy barrier for converting sp^2-hybridized carbon atoms to sp^3-hybridized carbon atoms. Films obtained using electron beam evaporation, an equilibrium process, contained 100% sp^2-hybridized carbon.[45] Commonly used methods for DLC growth include cathodic arc deposition, ion beam deposition, sputtering deposition, plasma-enhanced CVD (PECVD), and pulsed laser deposition (PLD). A common feature of DLC-processing methods is that DLC films are obtained from carbon or hydrocarbon ions that possess energies of ~100 eV.[44] Ion bombardment is considered to be a critical physical process for producing sp^3-hybridized carbon atoms in DLC films. Robertson proposed that the formation mechanism of sp^3 bonds is low-energy subsurface implantation or 'subplantation.' Subplantation of carbon ions during film growth is associated with an increase in mass density and formation of sp^3-hybridized carbon atoms.[44] At high ion energies, thermal effects are produced that lead to a reduction in the fraction of sp^3-hybridized carbon atoms.

Another key factor is the ordering of sp^3 sites in DLC; this ordering determines the electronic properties of the material.[44,45] Data on ordering of sp^3 sites in DLC films can be obtained using X-ray, neutron, and electron diffraction techniques. The structure and chemistry of DLC films can be characterized using diffraction techniques, electron energy loss spectroscopy (EELS), nuclear magnetic resonance (NMR), X-ray photoelectron spectroscopy (XPS), Fourier transform infrared spectroscopy (FTIR), visible Raman spectroscopy, or ultraviolet (UV) Raman spectroscopy.[44,45] Diffraction techniques, including X-ray, electron, and neutron diffraction, are commonly used to analyze the structure of amorphous materials; neutron diffraction provides a higher resolution than the other two techniques. Using diffraction, bond length and the number of nearest neighbors can be obtained from a radial distribution function (RDF). RDF or reduced density function describes the variation of atomic density as a function of distance. The RDF may be obtained from the Fourier transformation of reduced elastic scattering intensity, $\varphi(s)$, using the following equation[46,47]:

$$G(r) = 4\pi r[\rho(r) - \rho_0] = 8\pi \int_0^\infty \varphi(s) \sin(2\pi rs) \mathrm{d}s \qquad [1]$$

$\varphi(s)$ related to diffraction intensity $I(s)$ by means of the following relationship:

$$\varphi(s) = s\left[I(s) - Nf^2\right] / \left(Nf^2\right) \qquad [2]$$

In this equation, Nf^2 is the scaled atomic scattering intensity. The reciprocal quantity is given by $s = 2 \sin\theta/\lambda$. In this equation, θ is the angle between the incident and the scattering beam and λ is the wavelength.

The RDF consists of a series of local maxima.[44] The first peak is attributed to first neighbor or directly bonded atoms; the distance obtained from the first peak corresponds to the bond length (r_1). The coordination number of the first neighbor (N_1) can be obtained by calculating the area under the first peak. The bond angle (ϕ,) can be obtained from the distance of the first neighbor (r_1) and the second neighbor (r_2,) using the following relationship: $r_2 = 2r_1 \sin(\phi/2)$. The coordination number of the second neighbor (N_2) can be obtained using the following relationship: $N_2 = N_1(N_1 - 1)$. ta-C films showed values similar to those of diamond in terms of first nearest neighbor distances, second nearest neighbor distances, and coordinate numbers,

which indicated that ta-C contains a high fraction of sp^3-hybridized carbon atoms. Glassy carbon exhibited values closest to those of graphite.

1.107.3.2.1. Raman spectroscopic characterization of DLC

Raman spectroscopy is a nondestructive light scattering technique that is commonly used for examining the bonding between carbon atoms in DLC films and other carbon-containing solids. Many Raman spectroscopy studies have involved the use of the 514.5 nm line of an argon-ion laser. The Raman peak at 1332 cm^{-1} in diamond is attributed to the zone center optical phonon mode of T_{2g} symmetry.[44] Single crystalline graphite exhibits two Raman active modes with E_{2g} symmetry; however, the energy difference between these two modes is so small that the frequency separation is often not measurable. The two E_{2g} modes of graphite are observed as a single peak around 1580 cm^{-1}.[45] This Raman peak is frequently referred to as the G- or graphite band. Graphite is also associated with a small peak around 1350 cm^{-1}, which is known as the D- or disordered band; this band is attributed to the A_{1g} mode of graphite. It is attributed to small crystallites or boundaries.[45]

As pointed out by Ferrari and Robertson,[48] the G-mode is associated with in-plane bond stretching motion of sp^2-hybridized carbon atoms in pairs and the D-mode is associated with breathing motion of sp^2-hybridized carbon atoms in rings. The atomic behavior associated with each mode is shown in Figure 3. G-mode motion can occur in any pair of sp^2-hybridized carbon atoms. D-mode motion is prohibited in perfect graphite; it is observed in rings. G- and D-bands have been observed in the visible Raman spectra of many disordered carbon films. It is interesting to note that none of the features in the visible Raman spectra of disordered carbon materials is directly related to sp^3-hybridized carbon atoms.[45] Information about the presence of sp^2-hybridized carbon atoms in carbon-containing materials can be indirectly determined by analyzing the G- and D-Raman bands. Ferrari and Robertson[48] have classified the Raman spectra of disordered carbon materials into three categories, which describe variations in the peak positions of the G- and D-bands and the I(D)/I(G) ratios as a function of the degree of disorder. In the first category, the G-band position increases from 1580 to 1600 cm^{-1} as the carbon grain size progressively decreases from perfect graphite to nanocrystalline graphite. Because the degree of disorder increases as the grain size decreases, the D-peak intensity increases from zero and the I(D)/I(G) ratio increases. In the second category, the vibration density of states decreases as a result of the loss of aromaticity as well as increased disorder.

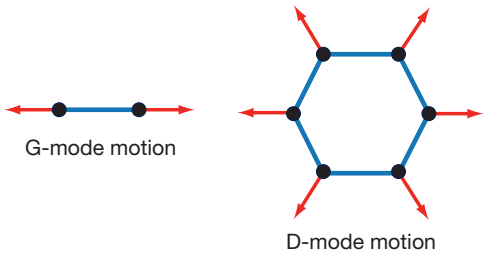

Figure 3 Schematic indicating carbon atom motion in G- and D-Raman modes.

The G-peak position shifts to lower energies; in addition, the I(D)/I(G) ratio is reduced. Materials in the third category contain a large fraction of sp^3-hybridized carbon atoms; in these materials, the I(D)/I(G) ratio is near zero. Instead of rings, the sp^2-hybridized carbon atoms are found in chains.[44] Spectra of materials containing a large fraction of sp^3-hybridized carbon atoms exhibit symmetric G-peaks.[44]

UV Raman spectra are obtained through the use of a frequency-doubled argon-ion laser ($\lambda = 244$ nm), which has a relatively high photon energy (5.1 eV) that can effectively excite the σ states from both sp^2-hybridized carbon atoms and sp^3-hybridized carbon atoms. Direct observation of sp^3 bonding in DLC films has been reported using UV Raman spectroscopy. A Raman peak at 1050–1200 cm^{-1} has been observed in the UV Raman spectra of materials with a high sp^3 content[44,45]; this peak, which is known as the T peak, has been attributed to sp^3 bonding.

1.107.3.2.2. Nuclear magnetic resonance and electron energy loss spectroscopy of DLC

NMR and EELS are commonly used for evaluating the structure of DLC and other carbon-containing materials. NMR is used to observe alterations in magnetic resonance frequencies that are associated with chemical bonding. The NMR signal is only obtained from C^{13} atoms, which make up approximately 1.1% of all of the carbon atoms. NMR spectroscopy requires large sample sizes to reach a satisfactory signal. This requirement limits the use of NMR spectroscopy with DLC thin films. EELS is commonly used for determining the sp^3/sp^2 ratio.[44] Both low energy loss spectra and near K edge ionization spectra may be used to obtain information on chemical bonding states. It should be noted that EELS requires very thin samples and is a destructive technique.

1.107.3.3. Properties of DLC

The mechanical, electronic, and optical properties of DLC are closely related to the sp^3/sp^2 ratio, which in turn is dependent on the substrate material, growth method, and growth parameters (e.g., growth temperature and ion energy). Theoretical and experimental information on the electronic structure of DLC is extensively discussed elsewhere.[44,45,49]

1.107.3.3.1. Electronic properties of DLC

Theoretical simulations of DLC materials have been performed using cluster model and direct calculation of carbon networks.[44] In the cluster model, σ and π states are separately considered.[49] In this model, the sp^2 sites are located in planes within a sp^3 bonded matrix. The optical gap and electronic properties are determined by the arrangement of the sp^2 sites; the sp^3 matrix is responsible for the mechanical properties of the material. A simple relationship has been derived for the band gap of the aromatic cluster,[44]

$$E_g \approx \frac{2\gamma}{M^{1/2}} \approx \frac{2\gamma}{L_a} \qquad [3]$$

In this equation, γ is the nearest neighbor $V(pp\pi)$ interaction, M is the number of sixfold rings in the cluster, and L_a is the cluster diameter or the in-plane correlation length. A wide

energy gap is formed by sp^3-hybridized carbon atoms; on the other hand, the gap associated with sp^2-hybridized carbon atoms varies with the configuration of the cluster. Both experimental and simulation results showed that the band gap of DLC decreased with an increasing fraction of sp^2-hybridized carbon atoms.[44] The optical gap (E_g) can be extracted from the optical absorption spectra. The relationship between absorption coefficient (α), photon energy (E), and optical gap is as follows:

$$\alpha E = B\left(E - E_g\right)^2 \quad [4]$$

In this equation, B is a constant.[44,45] The undoped DLC film is a p-type material in which the Fermi level is 0.22 eV above the effective valence band edge semiconductor.[44,45,50,51] A narrow $\pi-\pi^*$ gap is located between the wider $\sigma-\sigma^*$ gap. The π states in these materials are localized due to the orientation dependence of π interaction.[44] The mobility gap is determined by the σ states. Two types of defects exist in DLC films. Weak form disorders create localized band tails. Defects such as dangling bonds usually form deep levels. The electrical properties of DLC film can be modified by the introduction of dopants. For example, nitrogen has been introduced into DLC as an electron donor; however, the doping efficiency of nitrogen is poor.[44]

1.107.3.3.2. Mechanical properties of DLC

In general, DLC exhibits high hardness values. The mechanical properties of DLC are determined by the fraction of sp^3-hybridized carbon atoms. An empirical relationship for hardness (H) can be written as

$$\frac{H}{Y} = 0.07 + 0.06 \ln\left(\frac{E}{Y}\right) \quad [5]$$

In this equation, Y and E are yield stress and Young's modulus, respectively.[44] For DLC, the relationship between H and E is $H = 0.16E$; consequently, hardness is proportional to Young's modulus. Using the constraint-counting model, the Young's modulus of DLC has the following relationship with the average coordination number $\langle r \rangle$,[44]

$$E = -k(\langle r \rangle - 2.4)^{1.5} \quad [6]$$

This relationship between elastic modulus and coordination number has been experimentally confirmed.[51] The average coordination number increases with the sp^3/sp^2 ratio; consequently, DLC films with larger sp^3 fractions have higher hardness values. A hardness value of ~60 GPa can be obtained when the fraction of sp^3-hybridized carbon atoms exceeds 80%.

Internal compressive stresses as high as 10 GPa commonly exist in DLC films. Owing to the internal compressive stresses, DLC films demonstrate poor adhesion on many substrates. Three-dimensional molecular dynamic simulation has indicated that compressive stresses arise from competition between generation and recovery of defects[52]; these compressive stresses are dependent on the kinetic energies of the incident ions. Intrinsic compressive stresses limit the use of DLC films in several technical applications, including use as protective hard coatings. Adhesive failure takes place when the mechanical energy density of the film exceeds the energy required to create two new surfaces.[45] Depending on the nature of the interface between the DLC film and the substrate, there is a critical film thickness; delamination takes place if the thickness of the coating is larger than the critical thickness. Several studies have evaluated mechanisms for increasing DLC film thickness. One mechanism for obtaining DLC films with high thicknesses involves increasing the interfacial strength between the DLC film and the substrate. Argon ion cleaning has been used to produce fresh substrate surfaces and improved interfacial strength.[53] Buffer layers have also been utilized for increasing the adhesion of DLC films. For example, buffer layers containing silicon, tungsten, and chromium form carbides during deposition that increase interfacial bonding.[44,45,53,54] One approach for increasing the film thickness involves reducing internal compressive stresses. Stress relaxation may be accomplished by means of thermal annealing.[55–57] Complete stress relaxation was achieved after the materials were annealed at a temperature of 600–700 °C. EELS and Raman spectroscopy studies showed that this annealing process was associated with minimal structural modification.[45] Stress relaxation can be also achieved by incorporating dopants within DLC films; for example, codeposition of DLC and metals such as tungsten or titanium has been shown to be an effective method to reduce the internal stresses.[45]

1.107.3.4. Applications and Biological Properties of DLC

DLC is utilized in a variety of technological applications. For example, incorporation of DLC within field-effect transistors has been proposed.[58] Other electronic applications include the use of DLC in antifuses, field emission displays, and ULSI devices.[44] DLC has also been investigated for use in stretchable electronic devices (e.g., biomedical sensor arrays), which may be used to conform to surfaces with arbitrary geometries.[59] Electronic components may be applied to stiff subcircuit components (e.g., those fabricated out of DLC), which are placed on elastomeric stretchable substrates; conformational changes to the device can be performed while limiting strain to the electronic components that are located on the stiff DLC subcircuit components.[59]

Many applications of DLC involve the use of this material as a protective coating. For example, DLC films have been commercially utilized as protective coatings in the microelectronics industry.[45,60] DLC can be used as protective coatings on magnetic storage disks. As DLC films exhibit high hardness, wear resistance, and chemical inertness, they are very attractive for use as coating material for biomedical devices.[61]

1.107.3.4.1. Orthopedic applications of DLC

DLC has high wear resistance and a low friction coefficient. For amorphous hydrogenated DLC, the friction coefficient varies between 0.05 under vacuum and 0.1–0.15 under normal atmospheric humidity.[44] For ta-C, the friction coefficient is 0.1–0.15 under vacuum and slightly decreases under normal atmospheric humidity. The use of DLC films in artificial joint prostheses has been evaluated by several investigators.[62–65] One issue facing conventional articulating joint prostheses is the formation of wear debris. Ultrahigh molecular weight polyethylene (UHMWPE) particulates in knee and hip joint prostheses may be formed at a rate of 10^{10} particulates per year.[61] As DLC provides high wear resistance and low

coefficient of friction, this material is being considered for use on the articulating surfaces of joint prostheses.[61] Several studies have been performed to evaluate the efficacy of DLC as a coating material for use in total joint prostheses. Saikko *et al.*[63] investigated the wear properties of UHMWPE using an anatomical hip wear simulator. Femoral heads fabricated out of Co–Cr–Mo alloy, alumina, and DLC-coated Co–Cr–Mo alloy were examined against UHMWPE acetabular cups in bovine serum without additives; the results of this study indicate that the wear properties of these femoral heads are similar.

Sheeja *et al.*[64] evaluated the wear properties of DLC-coated Co–Cr–Mo alloy disks on UHMWPE pins and uncoated Co–Cr–Mo alloy disks on UHMWPE pins in simulated body fluid. Similar wear rates were observed for sliding pairs containing DLC-coated Co–Cr–Mo alloy and uncoated Co–Cr–Mo alloy; it should be noted that the corrosion resistance and the hardness of DLC-coated Co–Cr–Mo alloy were higher than those of uncoated Co–Cr–Mo alloy. The corrosion rate of DLC-coated Co–Cr–Mo alloy was reduced by approximately a factor of 10 000 in comparison with uncoated Co–Cr–Mo alloy. Furthermore, the sliding life was significantly reduced for DLC coatings applied to Co–Cr–Mo substrates with surface roughness values greater than 35 μm.[64] Another study by Sheeja *et al.*[66] examined the effect of coating Co–Cr–Mo alloy disks as well as UHMWPE pins. The wear on both surfaces was greatly reduced with DLC-coated Co–Cr–Mo alloy disks and UHMWPE pins compared with uncoated Co–Cr–Mo alloy disks and UHMWPE pins. If only the UHMWPE pin is coated, the wear rate for the pin is reduced; however, the Co–Cr–Mo disks undergo increased wear. The results of these two studies indicate that coating only one surface of a UHMWPE/Co–Cr–Mo sliding pair with DLC does not significantly improve wear performance. On the other hand, pin-on-disk testing showed improved wear properties for sliding pairs that contain DLC-coated UHMWPE and DLC-coated Co–Cr–Mo alloy.[66]

On the other hand, work by Oñate *et al.*[67] suggests that DLC is appropriate for reducing wear. DLC-coated Co–Cr alloy was examined; the wear performance of this material against UHMWPE in a knee wear simulator was investigated. Materials in this study were tested in a knee wear simulator for up to 5 million cycles; distilled water was used as a lubricant. DLC-coated Co–Cr alloy, titanium nitride-coated Co–Cr alloy, and uncoated Co–Cr alloy were compared. Nitrogen ion implantation was also utilized for modification of Co–Cr alloy and UHMWPE. The result of the study indicated that the DLC-coated material was able to reduce the wear of UHMWPE compared to uncoated material or titanium nitride-coated material. Ion implantation of Co–Cr alloy and UHMWPE was also shown to be an effective mechanism for reducing wear.[67] Tiainen *et al.*[68] also indicated favorable wear and corrosion properties for DLC-coated implant materials. DLC-coated metal femoral heads on UHMWPE acetabular cups were shown to reduce wear by a factor of 10–600 compared with that of uncoated metal femoral heads on UHMWPE acetabular cups. DLC-on-DLC-coated metal surfaces demonstrated a 10^5–10^6 lower wear rate in comparison with metal-on-metal surfaces. DLC-coated metallic implants can reduce the corrosion rate by a factor of 100 000 in comparison with uncoated metallic components. Despite the variability of the data in previous studies, DLC offers significant promise as a coating material for orthopedic applications.

1.107.3.4.2. Cardiovascular applications of DLC

Biomaterials used in cardiovascular implants (e.g., stents or guidewires) must demonstrate appropriate hemocompatibility, particularly an absence of platelet activation and thrombosis (as discussed in **Chapter 4.401, The Concept of Biocompatibility** and **Chapter 4.406, Protein Interactions with Biomaterials**). DLC has been investigated for use as a coating material in cardiovascular applications due to its favorable blood interaction properties. In addition, DLC may serve as a protective coating on metallic implants due to the fact that it can limit corrosion of metallic implant materials.

Interactions between an implant material and blood may lead to platelet activation.[69] In the case of metallic implant materials, release of metallic ions from the implant surface can lead to platelet activation and thrombus formation.[69,70] For example, Ferguson *et al.*[71] examined the release of ions from commonly used medical implant alloys, including alloys of chromium, cobalt, iron, molybdenum, nickel, titanium, and zirconium. Metallic cylinders of these materials were implanted into the skeletal muscle of albino rabbits; after 4–6 months, the materials were removed. Increased metal ion levels in peri-implant tissues were noted for metal alloys, including metal alloys that are considered to be corrosion-resistant. Particularly high metal ion concentrations were observed in tissues that surrounded titanium implants. These results suggest that the biological environment plays a significant role in implant degradation. In addition, cobalt, chromium, and nickel ions may serve to stimulate the release of E-selectin, GMP-140, and ICAM-1; these molecules are involved in adhesion of cells such as leukocytes and platelets to endothelial cells.[70] For example, interactions between an implant material may result in adhesion of platelets to the surface of the material; this process may be followed by platelet activation and release of granule materials (e.g., ADP).[72] Such interactions are unfavorable and could result in formation of a thrombus (blood clot).

DLC coatings have been deposited on the surfaces of stents and guidewires for the purpose of limiting platelet activation and minimizing thrombus formation. Gutensohn *et al.*[69] examined the hemocompatibility of uncoated 316L steel intracoronary stents and DLC-coated 316L steel intracoronary stents; release of metal ions (e.g., chromium, nickel, molybdenum, and manganese) was evaluated. Atomic adsorption spectrophotometry revealed that release of chromium and nickel ions was significant in uncoated stents; minimal release of these ions was observed in DLC-coated stents. Furthermore, flow cytometry showed that the concentrations of activation-dependent antigens, CD62p and CD63, were higher for uncoated stents than for DLC-coated stents. These results indicate that DLC coatings may be used to provide an increase in biocompatibility and a decrease in thrombogenicity.

Schaefer *et al.*[73] evaluated nickel–titanium shape memory alloy (nitinol) stents that were coated with DLC in a small clinical trial (see **Chapter 1.104, Shape Memory Alloys for Use in Medicine** for further details on shape memory alloys); in this study, DLC-coated stents were used for treatment of two

patients with superficial femoral artery occlusions. Implantation of the DLC-coated nitinol stents was successful; 6-month and 12-month postoperative follow-up studies for the two patients indicated no restenosis and 100% primary patency.[73] The authors of this study acknowledged that additional work is necessary to further confirm the efficacy of DLC-coated nitinol stents for treatment of peripheral artery occlusive disease.[73]

Blood-contacting biomaterials may also undergo interactions with macrophages and other inflammatory cells. Ball *et al.*[74] investigated the interaction between vascular stents and the J774 macrophage cell line. In this study, the metabolic activity of the macrophages in response to uncoated 316L stainless steel stents, ta-C-coated stainless steel stents, and polyurethane-coated stainless steel was investigated. Cells were shown to become activated at higher levels on uncoated stainless steel stents than on polyurethane-coated steel or ta-C-coated stents. The metabolic activity of macrophages on the ta-C-coated surfaces was comparable to that on the commercially available polyurethane-coated surfaces. These results indicate that ta-C-coated stainless steel elicits a lower inflammatory response from macrophages than did uncoated stainless steel.

Medical guidewires may also benefit from DLC coatings. These devices are utilized for placement of stents, catheters, or other medical devices into the body. Guidewires must exhibit several properties, including biocompatibility, chemical inertness, flexibility, low surface roughness, and low coefficient of friction values.[75,76] Medical grade stainless steel is commonly used for medical guidewire devices; this material is utilized in both uncoated and polymer-coated forms.[75] Various polymers (e.g., polytetrafluoroethylene, PTFE) have been investigated for use as guidewire coatings; however, poor adhesion between the polymer coating and the steel substrate has been noted.[77,78] As previously mentioned, the release of metal ions from a medical device can result in platelet activation and inflammation. The use of DLC as a coating material for stainless steel guidewires can reduce metal ion release, provide a chemically inert surface, and impart low coefficient of friction values. McLaughlin *et al.*[75] investigated deposition of DLC coatings onto stainless steel guidewires by means of PECVD. DLC-coated medical grade 306V stainless steel was shown to exhibit better adhesion and lubricity than did PTFE-coated material; no decrease in guidewire stiffness was noted.[75] Hasebe *et al.*[79] described deposition of DLC and fluorinated DLC (F-DLC) coatings on SUS316L stainless steel wires. A radio frequency PECVD process was utilized to deposit 40–50-μm-thick DLC and F-DLC coatings. *In vitro* studies indicated that DLC steel wires and F-DLC steel wires exhibited lubricity improvements of ~30% when compared with uncoated steel wires. Incorporation of fluorine or silicon within DLC films can serve to improve blood-contacting properties as well as film adhesion to steel wires.[76]

Although DLC has shown beneficial properties for use in cardiovascular medical devices, cracks in DLC films and delamination of DLC films remain significant concerns. Cracking and spallation of DLC coatings may occur as a result of tensile strains and shear strains on DLC-coated devices.[80,81] To address these issues, studies have investigated pretreatment of the substrate material, incorporation of a silicon interlayer between the substrate and DLC coating, and doping of the DLC coating with silicon.[80,81] Doping of DLC with silicon and incorporation of a hydrogenated amorphous silicon (a-Si:H) interlayer were associated with improved adhesion of DLC coatings to stainless steel substrates as well as crack prevention.[81] Attachment of platelets was decreased and attachment of microvascular endothelial cells was increased in silicon-doped hydrogenated DLC in comparison with undoped hydrogenated DLC. It should be noted that immersion of silicon-doped hydrogenated DLC-coated materials in biofluids resulted in a reduction in film adhesion of up to 75%.[81] Spallation of DLC coatings on 304 stainless steel substrates was decreased by incorporating a silicon interlayer with a thickness of at least 32 nm.[80] In addition, a pretreatment protocol involving argon plasma cleaning of steel substrates was shown to reduce spallation of DLC coatings.[80] Efforts are underway to improve adhesion of DLC films so that these materials can successfully endure stresses that are associated with implantation and use in the body.

1.107.3.4.3. Additional applications of DLC

DLC coatings may find use in other medical devices, including soft contact lenses.[60] *In vitro* studies have shown DLC to be chemically inert; *in vitro* studies involving macrophages, monocytes, fibroblasts, and osteoblasts have shown that DLC is associated with an absence of cytotoxicity and inflammatory stimulation.[82] DLC-coated materials may also be used for treatment of complex bone fractures.[82] In addition, DLC-coated materials may be used to increase longevity and improve effectiveness of medical probes, catheters, and coronary implants.[82] DLC has also been alloyed with antimicrobial metals such as silver; not only does incorporation of silver reduce compressive stresses, but also silver provides antibacterial activity.[83–85] Although significant work has already been completed, continued investigation is necessary to develop and commercialize DLC-based medical devices.

1.107.4. Microcrystalline, Nanocrystalline, and Ultrananocrystalline Diamond

1.107.4.1. Introduction to MCD, NCD, and UNCD

MCD, NCD, and UNCD are carbon-based coating materials that have been considered for use in a variety of medical applications. Diamond exhibits many characteristics that make it appropriate for use in medical applications, including high hardness, chemical inertness, biological inertness, and high wear resistance. MCD thin films exhibit grain sizes that are on the order of micrometers; typical grain sizes are between 0.5 and 2.0 μm.[86,87] NCD thin films commonly contain grain sizes below 100 nm; 50–100 nm grain sizes are commonly observed.[88] Thin films containing diamond grains with sizes below 10 nm, commonly between 3 and 5 nm, are known as UNCD films.[88]

MCD, NCD, and UNCD thin films consist of sp^3-hybridized diamond crystallites; the grain sizes of these materials are in the micrometer to nanometer range. The grain boundaries between crystallites contain sp^2-hybridized carbon impurities and hydrogenated carbon species. Materials with smaller grain sizes contain a higher number of grain boundaries as well as a higher percentage of sp^2-hybridized carbon atoms and amorphous carbon impurities.

1.107.4.2. Production of MCD, NCD, and UNCD

As previously mentioned, graphite and diamond are crystalline allotropes of carbon. At normal atmospheric temperatures and pressures, graphite is the stable crystalline form of carbon and diamond is a metastable form of carbon. At high temperatures and pressures (e.g., thousands of degrees Celsius and gigapascals of pressure), diamond is the stable crystalline form. High temperatures and pressures must be utilized in order to create diamond under thermodynamic equilibrium conditions. Single crystal and polycrystalline diamond aggregates have been produced by means of static compression of materials such as C_{60}, graphite, glassy carbon, and amorphous carbon under high pressures (8–20 GPa) and high temperatures (1000–3000 °C).[89]

Carbon materials may be dissolved within catalyst materials, which reduce the pressure and temperature necessary for diamond processing. Catalyst materials include transition metals belonging to Group VIII of the Periodic Table, alloys of carbide-forming elements, magnesium, oxygen-containing materials, and hydrides.[89] Processing of carbon in conjunction with catalyst materials requires temperatures and pressures on the order of 1200–1500 °C and 5–6 GPa, respectively.[89]

MCD and NCD thin films are commonly produced by vapor deposition processes, which involve decomposition of hydrocarbon or fullerene precursor gases. Growth of diamond thin films on substrates can be achieved through the use of a carbon source gas in conjunction with a carrier gas (e.g., argon, hydrogen, or nitrogen); the gas is heated to radicalize the hydrocarbon or fullerene precursor materials and form reactive species. The radicalized carbon species interact with the surface of the substrate and form the diamond thin film.

1.107.4.2.1. CVD and film growth

There are a few methods that have been utilized for processing of NCD and MCD thin films. CVD is an approach that is commonly used for processing diamond thin films; it involves the use of a carbon-containing gas that is mixed with a carrier gas (e.g., hydrogen or argon). The size of the grains in diamond thin films can be modified by altering the processing parameters. Based on the chemical composition of the gas mixture, the renucleation process can either be suppressed or maintained. During the CVD process, the crystals grow larger and the film becomes thicker; the nanocrystalline grains increase in size and form microcrystalline grains. If the film thickness is kept sufficiently thin, then the grain sizes will fall within the size range of NCD.

As mentioned by Williams *et al.*,[88] renucleation can be suppressed during diamond thin film growth through the use of a dilute methane and hydrogen gas mixture. The high concentration of the hydrogen in the mixture results in preferential etching of graphite; hydrogen also acts to terminate carbon dangling bonds, abstract hydrogen from carbon–hydrogen bonds, and etch sp^2-hybridized carbon from the thin film surface.[87] Graphite formed during processing is more favorably degraded, resulting in growth of the diamond layer.[90]

Renucleation of the crystals can be suppressed through the use of a hydrogen-rich gas mixture; renucleation can also be encouraged for processing of diamond thin films with grain sizes that correspond to the UNCD size range. Through the use of a mixture with a lower concentration of hydrogen, the formation of graphitic bonding can take place, typically along grain boundaries. By allowing these sp^2-bonded regions to be created, without the degrading action of the hydrogen gas, additional nucleation sites can form in the film. The renucleation process is therefore able to commence, allowing for smaller crystallite sizes, and subsequently smaller grain boundaries. Figure 4 displays the concept of renucleation with differences in grain sizes between nanocrystalline and UNCD. The constant renucleation process allows for grain boundaries characteristic of NCD without limiting the thickness of the film. According to Gruen,[91] it is generally agreed upon that without renucleation, grain size of thin film diamond increases as the film thickness increases. However, by ensuring high renucleation rates (on the order of $10^{10}\,cm^{-2}\,s^{-1}$) during the growth of the film, NCD films can be deposited in excess of 1 μm in thickness. Gruen[91] noted, however, that to ensure that heterogeneous nucleation of the crystallites and thus NCD thin films, the deposited films generally needed to be produced with thicknesses greater than 3 μm. Films with thicknesses beyond this value that maintain their nanocrystallinity ensure that the renucleation is proceeding appropriately. When films are produced in this manner, the grain sizes can be kept low on the nanoscale and UNCD can be produced. Figure 5 displays SEM images of nanocrystalline and UNCD produced via CVD.

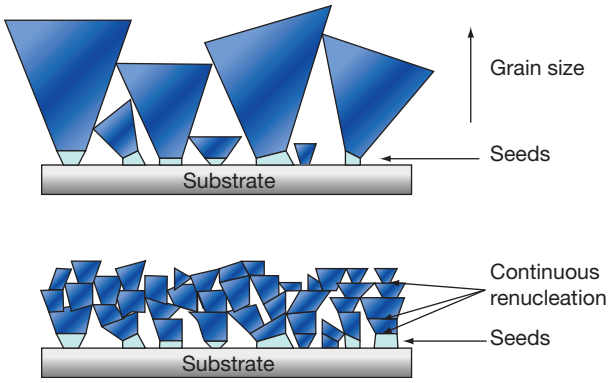

Figure 4 Schematic of the difference between nanocrystalline diamond (NCD) and ultrananocrystalline diamond (UNCD) nucleation. Reprinted from Williams, O. A.; *et al*. *Diam*. *Relat*. *Mater*. **2008**, *17*, 1081. Copyright (2008), with permission from Elsevier.

In the same way as NCD, applying MCD films to desired substrates can be accomplished by combining a hydrocarbon gas with an inert gas during the CVD process. Controlling the renucleation process by adjusting the chemical composition of the gas mixture used to form the CVD plasma, the substrate temperature, and the system pressure can allow control of the grain size. As discussed with regard to NCD and UNCD, frequent renucleation allows for smaller grain sizes, maintaining diamond films with features within the nanometer size range. However, if the renucleation phase is not reinitiated as frequently, the grain sizes increase and allow the diamond grain growth to cross into the microcrystalline size range. As the diamond is deposited and grows thicker, the crystallites compete with one another during their growth process.[92,93] If the renucleation is suppressed, the crystallites will continue to grow and impede the growth of one another. Crystals with

rapid growth rates in directions normal to the substrate surface will overtake the crystals growing in other orientations, they will grow larger, and the number of crystals will decrease as the film is grown thicker.[93] Eventually, instead of having many nanometer-size crystallites, a smaller number of larger crystallites are formed within the micrometer size range.

As discussed with NCD, initiation of the renucleation phase can be suppressed during diamond thin film growth by employing a high percentage of hydrogen within the carrier gas mixture.[88] Higher concentrations of the hydrogen result in etching of sp^2-hybridized graphitic material; diamond growth is continued. With hydrogen present in the mixture, sp^2-hybridized carbon species are limited, reducing the prevalence of nucleation sites deposited on the growing diamond crystallites, allowing the crystals to grow larger and grain sizes to form in micrometer dimensions.[90] As the film grows thicker, so do the sizes of the crystal grains.

1.107.4.2.2. Hot-filament CVD of diamond films

Several types of CVD processes are utilized for deposition of MCD, NCD, and UNCD thin films. Hot-filament CVD is a process that involves the use of a heated filament or wire for decomposition of a hydrocarbon precursor gas.[94–96] Figure 6 shows a schematic of a hot-filament CVD system. Initial work involving hot-filament CVD of diamond microcrystals on silicon, silica, diamond, and molybdenum substrates was performed by Matsumoto *et al.*[96] Using a gas mixture containing methane and hydrogen (0.05–0.005, CH_4–H_2 ratio), a flow rate range of 4–200 $cm^3\,min^{-1}$ at standard temperature and pressure, a chamber pressure of 0.5–750 torr, and substrate temperatures of 600–1000 °C, Matsumoto *et al.*[96] were able to deposit diamond microcrystals with various morphologies. Diamond crystal morphology may be varied by altering the hydrocarbon precursor gas, reaction chamber pressure, substrate temperature, and other processing parameters.

Kang *et al.*[97] demonstrated deposition of both microcrystalline and NCD thin films on silicon wafer substrates, which had been seeded with diamond particles from 0.5 µm diamond slurry. In one study, the chamber pressure was varied from 40 to 400 torr; the hydrogen gas flow rate (100 sccm), methane gas flow rate (4 sccm), and a temperature of 1100 °C were maintained at constant values.[97] MCD was successfully deposited in a pressure range between 40 and 200 torr; NCD was obtained above 200 torr.[97] In addition, NCD and MCD films were successfully deposited by varying the substrate deposition temperature between 1020 and 1220 °C under a constant pressure of 200 torr. NCD was observed at 1140 °C and MCD was observed at 1200 °C; the transition from NCD to MCD occurred over the temperature range between these two temperatures.[97] MCD features were observed up to a temperature of 1220 °C.

Amaral *et al.*[98] described processing of NCD films and MCD films on Si_3N_4 substrates by means of hot-filament CVD. Gas mixtures containing argon, methane, and hydrogen; gas flow ratios of $Ar/H_2 = 1.2$ and $CH_4/H_2 = 0.04$; and gas flow rates of either 50 or 100 $ml\,min^{-1}$ were utilized in this study. The filament and substrate temperatures were maintained at 2200 and 650 °C, respectively. The filament was located 5 mm from the substrate. A constant gas pressure of 5 kPa was used in this study. NCD films were successfully grown into continuous films using a deposition time of 4 h. Micro-Raman spectroscopy and low-incidence beam angle X-ray diffraction (LIBAD)

confirmed the composition of the NCD films. Abreu *et al.*[94] described the use of a hot-filament CVD process to produce nanocrystalline films on Si_3N_4 substrates. In this study, an argon–methane–hydrogen gas mixture with volume ratios of $Ar/H_2 = 0.1$ and $CH_4/H_2 = 0.04$ as well as a gas flow rate of 50 ml min^{-1} were used.[94] A tungsten filament temperature of 2300 °C, a substrate temperature of 750 °C, and a chamber pressure of 50 mbar were used in this study. A 18-μm-thick NCD film was obtained using a deposition time of 22 h.[94]

1.107.4.2.3. Microwave PECVD of diamond films

Microwave PECVD (MPECVD) is another type of CVD process that can be used to prepare MCD, NCD, and UNCD thin films.[99–106] In this process, the precursor gas mixture is ionized to form a plasma; microwave energy is used to modulate film deposition. A bias voltage is applied to the substrate material, which serves to attract the ionized species to the substrate surface. MPECVD can be used at lower substrate temperatures than other deposition processes. Furthermore, it can be used to coat surfaces with deep depressions, complex geometries, or three-dimensional topologies.

Liu *et al.* described processing of UNCD using MPECVD. In this study, the H_2 concentration was varied from 0 to 20%. The CH_4 level was maintained at 1% and the Ar concentration was varied to maintain a 250 sccm flow rate. An input power of 800 W, a chamber pressure of 13.3 kPa, and a substrate temperature of ~900 °C were used in this study.[103] Achatz *et al.* utilized MPECVD for deposition of UNCD thin films using an argon-rich $Ar/N_2/CH_4$ gas phase. Flow of CH_4 gas was maintained at 1.4 sccm; the argon and N_2 flow rates were varied in order to maintain an overall flow rate of 100 sccm. The quartz substrate was maintained at 800 °C.[99,107] Xiao *et al.*[108] described deposition of UNCD thin films on silicon substrates using MPECVD at substrate temperatures between 400 and 800 °C; a gas mixture containing 1% methane and 99% argon was used in this study.

1.107.4.2.4. Additional diamond film production methods

Radio frequency plasma-activated CVD (RF PA CVD) is another method that has been utilized for depositing NCD thin films onto substrate surfaces. Mitura *et al.*[109,110] reported processing of NCD coatings using this approach; in this study, they utilized a radio frequency (13.56 MHz) plasma to decompose a methane source. Mitura *et al.*[110] described deposition of NCD coatings containing 97% diamond onto 316L stainless steel substrates. Deposition of MCD has also been reported using direct ion beam deposition.[111] For example, Feng *et al.* generated argon, hydrocarbon, and hydrogen ions with a Kaufman ion source; MCD films (particle size ~1 μm) in an amorphous carbon matrix were grown on (100) silicon substrates. PLD is another method that has been used for processing of NCD thin films. PLD is a type of physical vapor deposition process, which involves ablation of material using laser energy in a vacuum chamber. After vaporization of the material, an energetic plasma plume is produced; this plume subsequently forms a film on the substrate. Hara *et al.*[112] described processing of 4–5-μm-thick NCD films on diamond substrates using PLD. In this study, an ArF excimer laser (energy = 200 mJ) was used to ablate a rotating graphite target.

1.107.4.3. Mechanical and Biological Properties of MCD, NCD, and UNCD

MCD, NCD, and UNCD thin films must exhibit appropriate mechanical and biological properties for use in the human body. Bulk diamond exhibits several desirable properties, including high hardness (Vickers hardness = 10 400 kg mm^{-2}), wear resistance, corrosion resistance, stable electrical resistance, and excellent thermal conductivity.[113–115] In addition, diamond also exhibits low coefficient of friction values ($u(s) < 0.1$).[113–115] Owing to these desirable properties, diamond has been considered for use in several biomedical applications.

In addition, diamond shows more favorable biological properties than many other materials that are commonly utilized in biomedical applications. For instance, many polymeric and metallic materials elicit a response from immune cells when introduced into the body (as discussed in **Chapter 4.403, The Innate Response to Biomaterials**; **Chapter 4.404, Adaptive Immune Responses to Biomaterials**; and **Chapter 4.405, Leukocyte–Biomaterial Interaction *In Vitro***); on the other hand, diamond has been shown to induce limited responses from neutrophils, polymorphonuclear leukocytes, and monocytes.[116–120]

Several studies have evaluated the hemocompatibility, cytotoxicity, and *in vitro* behavior of cells in contact with diamond materials. Tang *et al.*[119] compared the biocompatibility of CVD-prepared MCD with that of titanium and 316 stainless steel; titanium and 316 stainless steel are commonly utilized in implantable medical devices. Their investigation examined adsorption and denaturation of fibrinogen. They also evaluated adhesion and activation of cells by means of *in vitro* and *in vivo* studies; less cell adhesion and activation was observed on diamond than on the other materials. The diamond was shown to adsorb and denature small amounts of fibrinogen. Garguilo *et al.*[121] used contact angle goniometry to examine fibrinogen adhesion to the surface of MPECVD-prepared polycrystalline diamond. In their study, titanium-coated silicon substrates experienced notable fibrinogen adhesion; on the other hand, fibrinogen adsorption on diamond was negligible.

Neuronal cell growth on diamond has also been investigated. For example, Specht *et al.*[122] coated single crystal diamond surfaces with laminin; these surfaces were seeded with mouse cortical neuron cells; proliferation of neurites on the laminin-coated diamond surface was observed. Ariano *et al.*[123] demonstrated that rat hippocampal neurons and chick ciliary ganglion neurons are able to survive, proliferate, and function on diamond surfaces, which were coated with adhesion molecules such as poly-D-lysine, poly-DL-orthonine, or laminin.

Nordsletten *et al.*[118] investigated the monocyte interaction with diamond particles. In this study, interleukin-1β production and release by monocytes after exposure to particles of hydroxyapatite, silicon carbide, and diamond was examined. Phagocytosis of each type of particle was observed; diamond was noted to not stimulate the production and release of interleukin-1β, which is associated with bone resorption and orthopedic implant loosening.[118]

Amaral *et al.*[124] investigated the growth of L929 fibroblast cells and human gingival fibroblast cells on NCD thin films. Adhesion, proliferation, and viability of cells on NCD thin

films were evaluated; these films were deposited on silicon nitride (Si_3N_4) substrates using hot-filament CVD. In this study, materials were evaluated using the MTT assay, scanning electron microscopy, and confocal laser scanning microscopy. Scanning electron microscopy and confocal laser scanning microscopy revealed that cell morphology and adhesion of cells on NCD-coated substrates and standard tissue culture plates were comparable. MTT assays indicated that proliferation rates of L929 fibroblasts and gingival fibroblasts on NCD thin films and polystyrene culture plates were similar.

In another study, Amaral *et al.*[125] investigated the biocompatibility of NCD films using MG63 osteoblast-like cells and human bone marrow cells. Cells were grown in culture on NCD, which was deposited on silicon nitride (Si_3N_4) using hot-filament CVD. Microscopic examination of cell morphology, MTT analysis of proliferation and viability, and analysis of alkaline phosphatase activity showed better cell function on NCD-coated materials than on control materials. The authors suggest that the surface of the NCD-coated film, which has a surface roughness similar to that of bone, may facilitate osteoblast proliferation and function. Kalbacova *et al.*[126] evaluated the effect of NCD surface termination on osteoblast cell survival and growth. Osteoblast cells grown on hydrophilic oxygen-terminated NCD films exhibited improved viability and proliferation in comparison with as-deposited hydrogen-terminated NCD films.

Smisdom *et al.*[127] evaluated the growth of transfected Chinese hamster ovary cell cultures using hydrogen-terminated MCD thin films, oxygen-terminated MCD thin films, hydrogen-terminated NCD thin films, oxygen-terminated NCD thin films, and glass control materials. This work sought to determine whether transfected Chinese hamster ovary cells could be successfully cultured on diamond film surfaces without treatment with laminin, collagen, poly-D-lysine, or poly-L-lysine; laminin, collagen, poly-D-lysine, and poly-L-lysine are commonly used as surface treatments to promote cell attachment and growth.[127] Direct diamond-tissue contact would facilitate the use of diamond in implantable biosensor applications.[127] Hydrogen-terminated MCD and NCD films were deposited on silicon substrates using MPECVD; films were terminated with oxygen using potassium nitrate and sulfuric acid treatment. MTT, flow cytometry, and [^{3}H]-thymidine assays at 5 days of culture indicated no statistically significant differences in transfected Chinese hamster ovary cell proliferation, viability, or protein content on MCD surfaces or NCD surfaces than on glass control materials.[127] Some differences in cell proliferation and viability were observed at 7 days of culture. Additional investigation regarding the use of diamond in biological applications is necessary.

1.107.4.4. Biomedical Applications of MCD, NCD, and UNCD

1.107.4.4.1. Biosensor applications

Diamond electrodes have been considered for use in biosensor applications due to the semiconducting behavior, chemical inertness, and biological inertness of diamond. For example, diamond thin films have been investigated for use in biosensors for electrochemistry and biological molecule detection applications. Chatterjee *et al.*[128] evaluated the use of high-purity MCD films, low-phase purity MCD films, and NCD thin film electrodes for electrochemical analysis of riboflavin redox reactions. Their work examined the effectiveness of boron-doped microcrystalline hot-filament CVD-grown films and boron-free nanocrystalline films, which were grown using MPECVD techniques. Chatterjee *et al.* noted that adsorption of molecules and fouling of electrode surfaces pose a problem during the electrochemical analysis of biological molecules. The nonfouling properties of diamond suggest that it may be appropriate for use as an electrode material. Chatterjee *et al.* reported that high-phase purity MCD had very limited riboflavin adsorption, low-phase purity MCD had a moderate degree of riboflavin adsorption, and NCD had a high degree of riboflavin adsorption.[128] Adsorption of biological molecules on the electrode surface may be associated with difficulty in acquiring accurate information on an electrochemical reaction. The presence of nondiamond phases at grain boundaries in low-phase purity MCD films and NCD films may contribute to riboflavin adsorption. These efforts indicate that diamond films may be useful for electrochemical analysis of biological molecules; this material may find use in *in vitro* and *in vivo* biosensing applications.

NCD thin film electrodes have also been investigated; in many biosensor applications, attachment of biological molecules to the NCD surface is desirable. For example, Hartl *et al.*[129] described the use of green fluorescent protein and catalase in combination with NCD for use in amperometric measurements of solutions that contain hydrogen peroxide. Hydrogen peroxide is a by-product of many oxidase enzyme reactions in the body (e.g., breakdown of glucose); sensing of this molecule may be useful for detection of biological activities. Green fluorescent protein emits green light after absorbing blue light, enabling detection of protein attachment to an NCD surface with conventional fluorescence microscopy techniques. Hartl *et al.* confirmed protein molecule immobilization on an NCD electrode surface using green fluorescent protein. This study also demonstrated immobilization of catalase, which catalyzes the breakdown of hydrogen peroxide into water and oxygen, on the surfaces of NCD electrodes; hydrogen peroxide was amperometrically measured in concentrations between 0.3 and 150 mM using the electrodes.[129] In a similar study, Rubio-Retama *et al.*[130] immobilized horseradish peroxidase onto an NCD electrode for measurement of solutions containing hydrogen peroxide. The immobilized horseradish peroxidase allows for electron transfer and amperometric measurement of H_2O_2 in solution. In addition, Jian *et al.*[131] successfully demonstrated immobilization of glucose oxidase on UNCD electrode surfaces; these materials have potential use in *in vivo* glucose sensing applications. Popov *et al.*[106] modified NCD/amorphous carbon composite films with chemical linkers (e.g., 1-amino-3-cyclopentene hydrochloride) using UV irradiation. Ribonucleic acid molecules were subsequently attached; these structures may have potential use in bioanalytical assays.

1.107.4.4.2. Orthopedic applications

The high hardness, wear resistance, corrosion resistance, and low coefficient of friction values for diamond make it a promising material for use in orthopedic implant coating applications. In particular, diamond is being considered for use in articulating joint surfaces that encounter stresses because

of movement of the implant during its functional lifetime. Diamond is the hardest known material and exhibits excellent wear resistance. Diamond also exhibits low friction values. For applications in which one implant surface experiences contact with another implant surface (e.g., the articulating surface of a ball-and-socket joint), high wear resistance and low coefficient of friction values may serve to minimize production of wear particles and degradation of the implant surface. Deposition of diamond thin films onto the articulating surfaces of a joint prosthesis could reduce the friction and wear, thereby increasing the life span of the prosthesis and reducing the need for revision surgeries.[132] NCD and UNCD are desirable for this application because of their small grain sizes and low surface roughnesses.[133] Fries *et al.*[132] discussed the use of NCD as a coating on temporomandibular joint prostheses. They have suggested the need for the implant coatings to have low roughness, high hardness, corrosion resistance, and strong adhesion to the joint surface. Fries *et al.*[132] successfully demonstrated deposition of NCD on a Ti–6Al–4V substrate, which exhibited a geometry similar to that of a temporomandibular joint prosthesis component, by means of microwave plasma CVD.

1.107.4.4.3. Further biomedical applications

In addition to the biosensor and implant coating applications mentioned previously, diamond is being considered for use in a variety of other biomedical applications. On account of its favorable characteristics, including high chemical inertness, optical transparency, high thermal conductivity, and hydrophobicity in hydrogen-terminated form, NCD has been investigated for use in microfluidic lab-on-a-chip devices and microelectromechanical systems (MEMS).[134,135] Diamond can be made to resist nonspecific binding by DNA; hydrophobic surfaces may be created through hydrogen termination and fluorine termination. Khanna *et al.*[135] investigated the use of NCD for developing a chromatin immunoprecipitation lab-on-a-chip device. Chromatin immunoprecipitation is important for understanding cancer biology and diagnosing cancer. Nonspecific binding of DNA on NCD as well as a variety of materials typically used in microfluidic device fabrication (e.g., silicon, silicon dioxide, polydimethylsiloxane (PDMS), polymethylmethacrylate (PMMA), SU-8, and glass) was investigated. The results of the study indicated that nonspecific DNA binding was lowest on NCD, indicating that it is the most appropriate material for use in a high-sensitivity microfluidic device.

UNCD may be used as a surface coating in MEMS as well as MEMS that is used for biological applications (bioMEMS).[134] Bajaj *et al.*[134] compared cell growth on UNCD with that on platinum/titanium and (100) p-type silicon wafers. Platinum/titanium and (100) p-type silicon wafers are typically used in MEMS. Their work indicated that HeLa, PC12, and MC3T3 cells most favorably interacted with UNCD with respect to cell attachment, cell spreading, nuclear coverage, and cell rounding.[134] The high surface roughness of UNCD and the hydrogen termination of the UNCD surface may have contributed to the high biocompatibility of UNCD. Although additional testing is needed to better understand the cell–UNCD surface interactions, UNCD shows promise for use in bioMEMS applications (see **Chapter 3.315, Biological Microelectromechanical Systems (BioMEMS) Devices** for examples of bioMEMS devices).

There are many possibilities available for the use of diamond in biomedical applications due to its excellent biocompatibility and mechanical properties. For example, diamond has favorable blood interactions, leading to potential use in blood-contacting applications. Diamond thin films show promise in applications such as heart valves, vascular grafts, and stents.[69] For example, Jowzik *et al.*[136] developed an NCD-coated titanium alloy artificial heart valve using plasma-assisted CVD. The diamond coating remained on the entire surface after mechanical fatigue testing.

1.107.5. Summary of Carbon and Diamond

Carbon has been used as a biomaterial for many decades due to its unusual chemical, biological, and mechanical properties. Pyrolytic carbon, DLC, MCD, NCD, and UNCD have been considered for use in medical device applications. Pyrolytic carbon was the first carbon material to find extensive use in biomedical device applications, including cardiovascular and orthopedic devices. Initial studies involving pyrolytic carbon suggested that it was a hemocompatible material; as a result, pyrolytic carbon has found extensive use in prosthetic heart valves. More recent studies involving protein adhesion have brought the hemocompatibility of pyrolytic carbon into question. Long-term anticoagulant therapy is required for patients with pyrolytic carbon-coated heart valve prostheses in order to prevent thrombogenesis. Diamond and DLC have also garnered attention for use in orthopedic, cardiovascular, and sensor devices due to their unusual chemical, biological, and mechanical properties. Polycrystalline diamond coatings with micrometer-scale grains were initially investigated. In recent years, the biological properties of NCD and UNCD have been investigated. In the future, DLC, NCD, and UNCD will find use in medical device applications. In addition, pyrolytic carbon will continue to see a significant role in medical device applications. Scalable methods for the growth of DLC, NCD, and UNCD must be developed for these materials to be successfully translated to commercial use.

TKA	Total knee arthroplasty
TKR	Total knee replacement
UHMWPE	Ultra-high-molecular-weight polyethylene

1.108.1. Introduction

Total joint arthroplasty is a successful and accepted procedure for the treatment of advanced osteoarthritis. Improvements in the implants are desired despite this success to keep pace with the increasing demands and expectations of patients. One limitation for the longevity of joint replacements is related to articular wear, the debris from which can lead to osteolysis and subsequent aseptic loosening. A detailed discussion of wear-related osteolysis can be found in the **Chapter 6.606, Biological Effects of Wear Debris from Joint Arthroplasties**. Efforts to reduce wear have focused primarily on improving

implant design and the quality of the ultra-high-molecular-weight polyethylene (UHMWPE) often used as one of the bearing surfaces. It is also important to consider the influence of the hard bearing counterface surface that articulates against the polyethylene (PE) in order to reduce the generation of wear debris even further and thereby reduce the potential for osteolysis and loosening.

The hard bearing surface can produce wear of the PE surface during articulation through both abrasive and adhesive mechanisms. Wear mechanisms of polyethylene that apply to prosthetic joints are reviewed in the **Chapter 6.603, Ultra-high Molecular Weight Polyethylene Total Joint Implants**. Positive asperities on the hard counterface can abrade the PE surface, which is softer, producing abrasive wear debris. Friction between the articulating surfaces shears off particles, producing adhesive wear debris. Improved lubrication reduces friction and tends to reduce adhesive wear. Hard 'third-body' particles in the joint space that intrude between the articulating surfaces can embed in the PE producing abrasive wear of the hard counterface, with the resulting increased hard surface roughness in turn tending to increase friction and abrasive wear of the PE.

Examination of explanted arthroplasty components has shown that roughening of the hard counterface occurs clinically, and that many observed scratches have a shape and orientation that can increase PE wear.[1–11] Not only does volumetric wear of PE increase with increasing counterface roughness, but it also has been found that increasingly sharp peaks associated with counterface scratches increase the tendency for the production of submicron debris that may be related to osteolysis. These findings suggest that a hard counterface that resists roughening and provides lower friction with PE should reduce abrasive and adhesive wear and thereby prolong the lifetime of the joint replacement.

A metallic cobalt–chromium (CoCr) alloy (Co–28% Cr–6% Mo) is the standard material for hard bearing joint replacement components. The oxide ceramics alumina and zirconia are the most popular alternatives to CoCr. Their harder surfaces resist roughening and tend to produce less friction by having better 'wetting' characteristics with lubricating fluids in the joint. These ceramics have demonstrated improved wear performance over metal surfaces in laboratory and clinical investigations.[12–20] The adaptation of monolithic ceramics has been slow because their brittle nature has limited implant designs and created concerns for component fracture.

The desired alternative would combine the fracture toughness of metals with the wear performance of ceramics. One approach for achieving this is to combine a thin ceramic surface on a metallic substrate. While simple in concept, providing a clinically and commercially successful combination has proven challenging.[21] Besides having the desired tribological wear properties already discussed, the materials must be biocompatible and have suitable mechanical properties and structural stability. As a practical matter, these components must be fabricated with reliable consistency and at a reasonable cost.

A critical feature for alternative technology is the durability of the ceramic film on the metallic substrate. The ceramic must adhere to the metal so that it does not chip or spall from the surface under the stress and strain experienced during surgical implantation and clinical use. The film itself must be cohesive within itself to resist fracture and shear during articulation with PE and third-body particles. Not only would adhesive or cohesive failure of the ceramic film negate its potential wear advantages, but also it would liberate hard third-body particles into the joint that could increase abrasive wear of the unprotected metal. Because no material is damage-proof, it is desirable that the film be able to tolerate localized accidental damage to the surface without progressive adhesive or cohesive failure.

In some applications, it is desirable to avoid the use of a PE bearing altogether. This is the motivation for the hard–hard bearing combinations of metal-on-metal (MoM) and ceramic-on-ceramic (CoC) that use monolithic metal and ceramic. One important example is hip resurfacing (HR) arthroplasty where MoM is currently the only option. Both MoM and CoC bearings generate orders of magnitude less wear debris than the standard CoCr–UHMWPE articulation.[22–24] Concerns with CoC bearings include a small risk of brittle fracture and the squeaking phenomenon, whereas MoM bearings have been associated with elevated metal ion levels. Because the metals and ceramics used are less compliant than PE, the resulting mechanical loading is much more demanding in hard–hard applications. This challenge is illustrated by the fact that hard–hard applications have been introduced for hips and not for knees. The ball-in-socket nature of a hip implant produces lower and more consistent stress concentrations on the surfaces. Thus, a ceramic thin film application that could be used in a hard–hard application, while desirable, would be even more challenging than for bearing against PE.

1.108.2. State of the Art – Processing, Microstructure, Biocompatibility, and Mechanical Properties of Ceramic Coatings

1.108.2.1. Surface Modification Processes

There are countless variations of processes and materials that have been proposed, investigated, or implemented to create ceramic films on the surface of a metal.[21] One type of method is to deposit or overlay a ceramic coating onto the metal surface (**Figure 1**). This can be thought of as an 'exogenous' film. The mechanical properties of the ceramic are typically much different from those of the metal, causing a potential for adhesive failure between the two materials under load or during

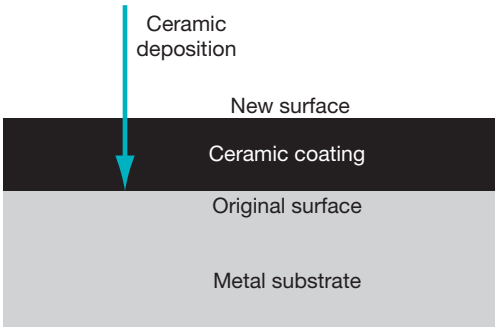

Figure 1 Depositing a ceramic layer onto the original metal surface produces an 'exogenous' ceramic surface film. Examples of this are physical vapor deposition and chemical vapor deposition.

articulation. Sometimes, multiple coatings are deposited to enhance adhesion or to make the transition in properties more gradual. Another method of creating the ceramic film is to diffuse or inject a nonmetallic element such as nitrogen into the surface and cause a phase transformation of the surface from metal to ceramic (Figure 2). This can be thought of as an 'autogenous' film. The rate of diffusion typically restricts this process so that either the film is very thin or the processing time is very long. One advantage of this approach is that a diffusional gradient with an associated gradient in properties often underlies the film to aid in adhesion. These exogenous and autogenous approaches can be used together as well. For example, a ceramic can be deposited onto the surface and then diffused partly or fully into the metal, or a diffusion zone can be created on the surface of the metal before a coating is applied.

1.108.2.1.1. Ion implantation

The basic concept of ion implantation is to use a highly energetic beam of ions to bombard a surface and become incorporated on and into it.[25] This modifies the surface structure and chemistry, but does not modify component dimensions or bulk material properties because it is conducted at low temperature (Figure 3). With sufficiently high beam energy, atoms in the surface can be sputtered away and the crystal structure can be disrupted. At lower energies, a nonmetallic element can be implanted into a metal surface to increase its hardness and wear resistance, and to reduce friction.

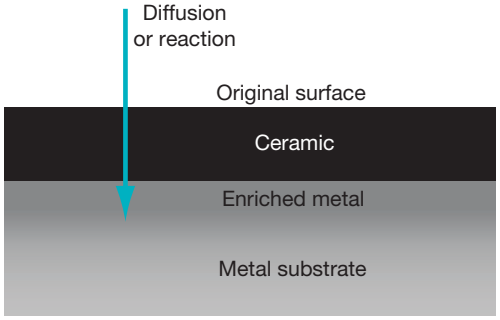

Figure 2 Diffusing a nonmetallic element into the original metal surface beyond its saturation limit transforms it into an 'autogenous' ceramic surface film. Examples of this are thermally driven oxidation and electrochemically driven anodization.

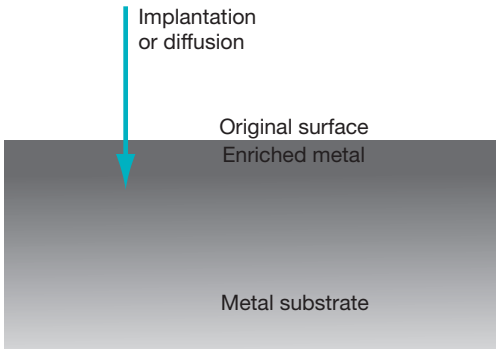

Figure 3 Diffusing a nonmetallic element into the original metal surface below its saturation limit modifies the surface composition and properties without causing a phase transformation. An example of this is nitrogen-ion implantation.

The ion implantation process is conducted in a vacuum chamber and consists of three basic steps. First, ionized plasma is formed by stripping electrons from source atoms. Each ion is typically a single atom or molecule. Next, the ions are accelerated and focused into a beam using a potential gradient column and a series of electrostatic and magnetic lens elements. Lastly, the ion beam is directed onto and scanned over the target surface. This implants the ions onto the surface and into the crystalline structure of the target surface. The concentration of the ion species at the surface increases with implantation time. It is a line-of-sight process, so specialized fixturing is needed for uniform treatment of complex geometries. The energy and composition of the ions and the composition of the target affect the depth of ion penetration. Typically, this depth is less than a micron.

The primary commercialization of ion implantation in the orthopedic industry involves implanting nitrogen ions into CoCr alloy (LFIT – low friction ion treatment, Stryker, Mahwah, NJ), although it also has been applied to Ti alloys.[26,27] In this application, insufficient nitrogen is implanted to create a continuous ceramic nitride film. It is discussed in this chapter to illustrate the potential of altering the metal surface properties. The ions penetrate to a depth of 200 nm into the CoCr metal, creating crystalline lattice strains that harden the metal. One measurement indicated that the microhardness of the surface was doubled by the treatment.[27] The ions also increase the surface energy of the metal, causing the surface to become more hydrophilic, so the synovial fluids can more effectively lubricate the interface. In one case, laboratory testing indicated a reduction in the coefficient of friction against UHMWPE to be approximately 25%.[27] These types of effects are typical of the general features intended by creating a ceramic film.

1.108.2.1.2. Physical vapor deposition

Deposition methods of surface modification are based on adding a new material to the surface as a coating and do not involve the substrate material constituents. The coating substance is transported from a source material and deposited on the substrate surface. Physical vapor deposition (PVD) is a generic term for a large family of vacuum deposition techniques where a solid source (target) is converted into vapor by physical means.[28,29] Typical source materials are pure metals or alloys such as titanium, zirconium, chromium, and titanium–aluminum. To produce a hard coating, a reactive gas (nitrogen, oxygen, or hydrocarbon) is introduced during the evaporation process. The gas reacts with the ionized metal vapor to form a compound that is then deposited on the substrate as a thin film. The coating process consists of three main steps: (1) evaporation – removal of material from the target; (2) transportation of the plasma constituents to the substrate; and (3) condensation of the coating on the substrate.

The available PVD methods differ in the means of producing metal vapor, the main technologies being sputtering, electron beam (E-beam) evaporation, and arc evaporation (AE). Depending on the technology used, plasma material of different quality is generated. The positively charged constituents of

plasma tend to travel to the negatively charged substrate in straight lines making PVD a 'line-of-sight' process. This means that only areas exposed to the plasma will be coated.

Sputtering is one of the most versatile PVD processes available for various metallic and ceramic (carbide and nitride) thin films preparation.[30] In PVD by sputtering, the source material is converted into vapor by bombarding with high-energy particles or ions. A glow discharge is produced in an argon atmosphere at low pressure, with the target being the cathode. The argon ions are accelerated in the direction of the target by the electrical field and knock atoms out of the target. The addition of concentrated magnetic fields near the target increases the deposition rate (magnetron sputtering) by increasing the density of the plasma and power density on the target surface. Sputtered films are typically denser and have a better adhesion on the substrate than evaporated films; however, they have higher compressive stresses and a higher level of impurities as the inert sputtering atoms can be built into the growing film.

In PVD by evaporation, the conversion into vapor phase is achieved by applying heat to the source material.[31] In electron-beam evaporation (EB-PVD), metal vapor plasma is produced by melting the source material in a crucible using a focused high kinetic energy beam of electrons. Coatings produced by EB-PVD are smooth, dense, and defect free. The coating thickness, however, is limited to the volume of the crucible, and film adhesion is weak because of the low level ionization of metal vapor achieved by the e-beam.

In cathodic arc PVD, an electric arc is used to vaporize materials from a solid target. The cathodic spot is small (0.1–10 μm) and the resulting high current densities lead to the local melting of the cathode surface and subsequent evaporation and ionization of the source material. The arc spot continuously moves on the cathode surface because of the different resistance to current flow of a liquid versus a solid. Magnets are used to confine the arc to the cathode surface and influence its motion. Here, a solid cathode source allows placement of cathodes in any orientation to ensure proper plasma density leading to coating uniformity at the substrate. A major drawback of this technique is the emission of micrometer-sized liquid droplets of the target material from the arc spot. These macroparticles can be trapped in the growing film and extend through the coating, thereby strongly deteriorating its physical and mechanical properties.

PVD processes are typically carried out at low substrate temperatures (180–500 °C), which allows for coating deposition without detrimentally affecting bulk properties. On the other hand, only physical (rather than chemical) bond is created between the coating and the substrate often leading to weak coating adhesion.

1.108.2.1.3. Diffusion surface modification

Diffusion surface treatments aim to produce corrosion-resistant, wear-resistant, and hardened surface layers by superficially diffusing new elements (nitrogen, carbon) into the substrate at elevated temperatures. In contrast to deposition techniques (e.g., PVD), substrate material constituents are actively involved in the modified layer formation. Nitriding – diffusing nitrogen atoms into the metal surface – is one of the most widely used surface hardening techniques. The diffused nitrogen reacts with the metal and forms metal nitrides to impart hardness on the surface up to a certain depth determined by the metal properties. There are several commercial nitriding methods, the difference lying in nitrogen supply. In salt bath nitriding, the source of nitrogen is molten salt; in gas nitriding, nascent nitrogen is produced by dissociation of ammonia, and in plasma nitriding (ion nitriding), molecular nitrogen is split into ions in an electromagnetic field.[32,33] Plasma nitriding is the preferred nitriding route for stainless steels and titanium alloys. The process is conducted in a heated vacuum chamber in a glow discharge at a very low pressure and under high voltage. High-voltage electrical energy is used to form plasma through which nitrogen ions are accelerated to impinge on the workpiece.[34] This ion bombardment heats the workpiece and cleans the surface providing active nitrogen which then penetrates inside by diffusion. The nitriding current, temperature, and process time determine the depth of the nitride case. Plasma nitriding, by nature, is faster than traditional gas nitriding because of activation of the main reactive species. The benefits of plasma nitriding include lower processing temperatures and correspondingly lower mechanical distortion, as well close control of microstructure allowing nitriding with or without compound layer (TiN–Ti_2N in the case of titanium substrate) formation. Because of the growth of the layer from the bulk material, there is no danger of the layer spalling off as in the case of PVD treatments. Furthermore, a hardened diffusion zone supports the compound layer.

PIRAC (powder immersion reaction-assisted coating) nitriding has been proposed as an alternative nitriding method.[35] In PIRAC nitriding, a workpiece is annealed in a chromium steel container that prevents oxygen penetration while allowing for inward diffusion of atmospheric nitrogen. As a result, oxygen-free monatomic nitrogen environment is created on-site, without the use of vacuum pumps and nitrogen gas supply.

1.108.2.2. Specific Wear-Resistant Surface Modification Processes

1.108.2.2.1. Oxidized zirconium

Oxidized zirconium was developed for orthopedic applications to provide improvements over CoCr alloy for resistance to roughening and frictional behavior, and for biocompatibility without the mechanical limitations of brittle monolithic ceramics.[36–39] The manufacturing process begins with zircon-containing beach sand as the raw material that is refined to zirconium metal which then is fabricated into a prosthetic joint replacement (Figure 4). The wrought zirconium alloy (Zr–2.5% Nb) is oxidized by thermal diffusion in heated air to create a cohesive and adherent zirconium oxide ceramic surface of about 5 μm thickness (Figure 5). The oxide is not an externally applied coating, but rather a transformation of the original metal surface into zirconia ceramic. The oxide is thick enough to provide the desired tribological properties against UHMWPE or cartilage, but is thin enough that the component retains its metallic toughness and resilience. This technology has been in global commercial use for over 10 years under the trade name OXINIUM (Smith & Nephew Orthopaedics, Memphis, TN), and is used for in both knee and hip applications.

Although similar in manufacture and properties to titanium, zirconium exhibits several unusual processing attributes,

Figure 4 Zircon-containing sand (left) is the raw material that is refined to zirconium metal which is then fabricated to make an oxidized zirconium implant (right). Reproduced with permission from Hunter, G.; Dickinson, J.; Herb, B.; Graham, R *Titanium, Niobium, Zirconium, and Tantalum for Medical and Surgical Applications*, ASTM STP 1471; Zardiackas, L. D., Kraay, M. J., Freese, H. L., eds.; American Society for Testing and Materials: West Conshohocken, PA, 2006; pp 16–29.

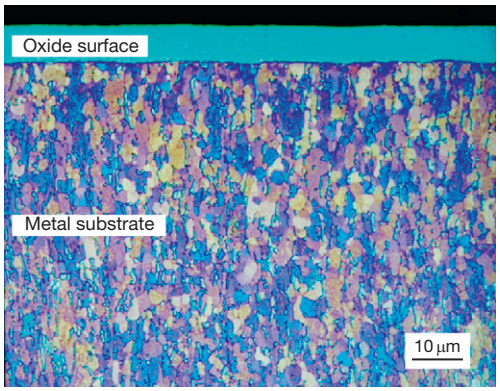

Figure 5 Oxygen naturally diffuses into the zirconium alloy when the alloy is heated in air, causing the original metal surface to transform to zirconium oxide (zirconia) ceramic (the outer surface is at top in this cross-sectional optical micrograph that is heat-tinted to show the metal microstructure). Reproduced with permission from Hunter, G.; Dickinson, J.; Herb, B.; Graham, R. *Titanium, Niobium, Zirconium, and Tantalum for Medical and Surgical Applications*, ASTM STP 1471; Zardiackas, L. D., Kraay, M. J., Freese, H. L., eds.; American Society for Testing and Materials: West Conshohocken, PA, 2006; pp 16–29.

including its oxidation behavior.[40,41] Small amounts of niobium and oxygen are alloyed with the zirconium metal to create a two-phase microstructure of hexagonal close-packed α-Zr and body-centered cubic β-Zr with sufficient strength and other mechanical properties for use as an orthopedic prosthesis.[42] Like titanium, the metallic elements of zirconium and niobium are very biocompatible with minimum biological availability and electrocatalytic activity because of their passive oxide layers with extremely low solubility and excellent protective ability.[43–45] The biocompatibility of the alloy both with and without an oxide was found to be at least equivalent to that of titanium alloy (Ti–6% Al–4% V) and CoCr.[36,38]

The ceramic surface is formed by heating the zirconium alloy in air to a temperature above 500 °C to allow oxygen to diffuse into the surface. Once the surface becomes saturated

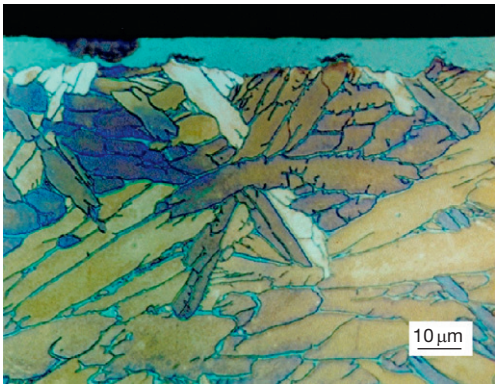

Figure 6 This centrifugal casting of the zirconium alloy produced a nonuniform oxide with internal cracks (the outer surface is at the top in this cross-sectional micrograph that is heat-tinted to show the coarse cast microstructure). Reproduced with permission from Hunter, G.; Dickinson, J.; Herb, B.; Graham, R. *Titanium, Niobium, Zirconium, and Tantalum for Medical and Surgical Applications*, ASTM STP 1471; Zardiackas, L. D., Kraay, M. J., Freese, H. L., eds.; American Society for Testing and Materials: West Conshohocken, PA, 2006; pp 16–29.

with oxygen, the metallic surface transforms into a dense ceramic that is predominantly monoclinic zirconia.[40,41] This crystal structure is fully stable, unlike the metastable tetragonal crystal structure of yttria-stabilized zirconia components.[46] Individual grains in the microstructure of stabilized zirconia have a tendency to transform to the monoclinic structure under certain conditions such as those during autoclave sterilization procedures. The transformation can result in reduced strength and increased surface roughness. This cannot happen to the monoclinic oxide on oxidized zirconium.

The desired oxide cohesiveness is created by the proper combination of many factors at the original metal surface.[37] Castings have a coarse microstructure that allows nonuniform oxide growth, which can lead to crack formation within the oxide (Figure 6). During oxidation, very smooth or contaminated surfaces can produce esthetic and functional flaws in the oxide. An appropriate selection of time and temperature during oxidation can produce an oxide of uniform thickness without internal flaws. Continuing oxidation at a given temperature eventually leads to a transition in oxidation behavior during which the oxide starts cracking and growing rapidly and nonuniformly. Therefore, clean and moderately rough articular surfaces on fine-grained wrought material are oxidized at a tightly controlled time and temperature in order to produce a high integrity oxide of consistent thickness.

Oxidized zirconium components are made from wrought alloy because the local rate of oxide growth and the resulting oxide microstructure are affected by the metallic microstructure.[37] The refined metallic microstructure produces a fine-grained (essentially nanostructural) oxide (Figure 7). The fine-grained structure provides some effective ductility so that the oxide can deform modestly without cracking. The diffusion process allows for a uniform oxide layer to form, even on complex shaped components. This oxide is comprised primarily of a staggered columnar microstructure oriented perpendicular to the outer surface.[40,41] It is left in a compressive stress state without pores or voids internally or at the

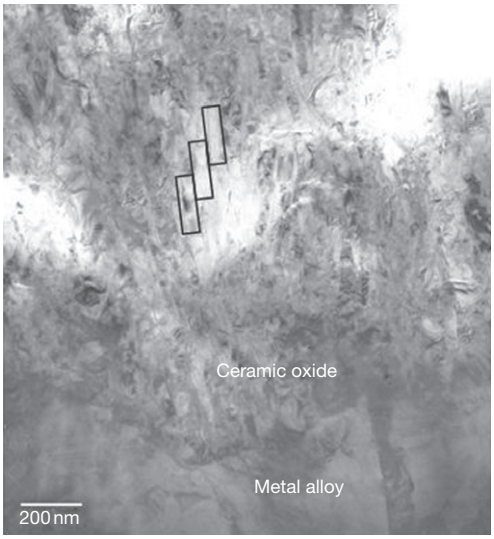

Figure 7 The oxide on zirconium exhibits excellent integrity which is due in part to grains that are columnar, staggered, nanostructural in size, and generally perpendicular to the surface. Three examples of the oxide grains are outlined in this transmission electron micrograph from the ceramic–metal interface. interface. An oxygen diffusion gradient beneath the oxide provides a gradual transition to the underlying metal mechanical properties. All of these microstructural features enhance cohesion and adhesion of the oxide even under shear and mechanical strain.

Because of the strength, toughness, and stability of oxidized zirconium, it can be used to produce components that duplicate the design of ones made from CoCr. In contrast to the limitations exhibited by monolithic ceramics such as alumina and zirconia, oxidized zirconium heads do not exhibit brittle fracture during crush tests.[46] Biomechanical testing and finite element analysis demonstrate that knee femoral components made from oxidized zirconium and CoCr have equivalent device fatigue strength, with both exceeding a strength of 450 MPa for 10 million cycles (Mc).[47] Continuous loading of a single oxidized zirconium knee condyle up to 20 kN can cause it to bend to an angle of 45°, but the condyle does not break and the oxide remains attached and functional (Figure 8). Having oxidized zirconium components with the same designs as CoCr components allows a surgeon the flexibility of offering the advantages of a ceramic bearing with metallic component strength using a similar design that obviates the need for unique surgical procedures and associated training.

Like other oxide ceramics, oxidized zirconium can reduce friction (and thereby adhesive wear of UHMWPE) relative to that of metal surfaces by roughening less and better maintaining a lubricating film.[12] Laboratory studies have shown that the oxide exhibits better wetting behavior in lubricating fluids (Figure 9) and can produce up to 50% less friction against UHMWPE than does CoCr.[48–53] In the joint, lubrication is provided by synovial fluid wetting the counterfaces. The lubricating quality of synovial fluid can vary greatly between individuals, placing the prostheses at greater risk for wear in certain patients.[53] Oxidized zirconium also was found to be less sensitive than CoCr to these variations, and maintained a lower coefficient of friction when articulated with UHMWPE even in poor lubricants. Other laboratory studies have shown that oxidized zirconium may provide similar benefits for reducing friction during direct articulation against cartilage.[54]

1.108.2.2.2. Titanium nitride (TiN) coatings

Hard ceramic coating with the longest (over 15 years) clinical history of use in joint arthroplasty is titanium nitride, TiN. Already in 1988, a patent was granted for a method of applying a thin layer of TiN onto orthopedic implants.[55] Joint replacements (hip, knee, ankle) with TiN or Ti(Nb)N-ceramized articulating surfaces are commercially available from Corin Medical, Endotec and Van Straten (Figure 10).

1.108.2.2.2.1. PVD TiN coatings

TiN-based layers are applied by means of a PVD process on CoCr or Ti alloy, each company using its own proprietary procedure. For example, Endotec uses a proprietary, reproducible PVD process to deposit a 6–10 µm thick UltraCoat® TiN coating on articulating surfaces of its hip, shoulder, and knee systems. TiN-coated surfaces are designed to articulate against UHMWPE or against similarly coated metallic components. The rationale behind using titanium nitride as a wear-resistant coating is its high hardness (HV 2400–2800), high scratch resistance, low friction coefficient, and enhanced wettability characteristics with synovial fluids. TiN is FDA approved: it is considered to be physiologically inert, it is not listed as a carcinogen, and neither acute nor chronic exposure induces toxic effects. TiN coatings are golden colored, and they can be deposited on CoCr or titanium alloy joint replacement components. One disadvantage of CoCr alloys is that Co, Cr, and a small amount of Ni that they always contain are known to cause allergic reactions. Coating CoCr articulating surfaces with TiN has been reported to reduce the release of these metal ions into the body fluids while preserving the alloy wear resistance characteristics.[56,57] Alternatively, CoCr alloy can be

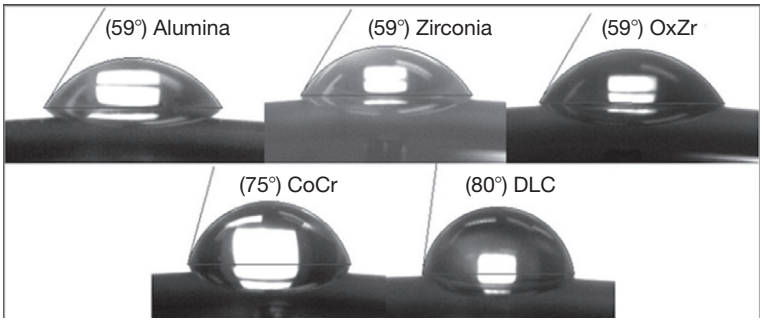

Figure 9 Oxide ceramics are wetted better than is CoCr by a serum–water solution, as indicated by lower sessile drop contact angles, thereby improving lubrication. Mater*. **309–311**, 1199–1202, with permission from Trans Tech Publication.

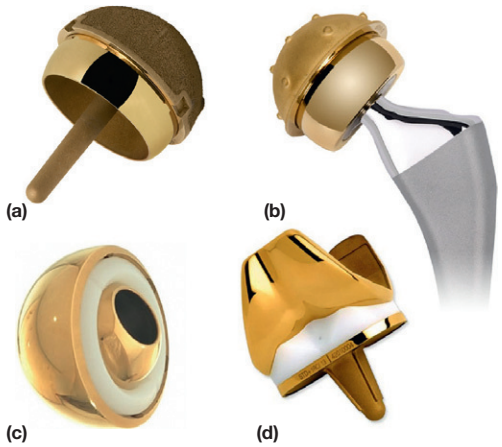

Figure 10 (a) TiNbN-coated CoCoMo alloy ACCIS hip resurfacing device (Van Straten Medical); (b) TiNbN-coated CoCoMo alloy total hip replacement (Van Straten Medical); (c) TiN-coated Ti alloy articulating unit of total hip replacement (Endotec); and (d) TiN-coated Ti alloy total knee replacement (Endotec).

substituted altogether with a Ti alloy. Titanium alloys (e.g., Ti–6Al–4V) are currently used in implant surgery because of their low density, relatively low elastic modulus, and excellent biocompatibility and corrosion resistance. However, their tribological behavior has frequently been reported to be poor, because of a high coefficient of friction and poor performance under abrasive and adhesive wear.[58] The coating of articulating joint replacement components made of Ti alloys with a thin TiN layer is expected to provide them with the required high wear resistance. TiN-coated Ti alloy parts are offered as substitutes to the traditional CoCr components in both knee and hip systems for nickel-sensitive patients or where large-diameter femoral heads are indicated (heavy, active patients).

A crucial factor for the length of life and the performance of the coated component is the coating's adhesion to the substrate.[59] Failure of a hard coating–soft substrate system under many tribological situations is seldom caused by conventional wear but by fracture of the coating (cohesive failure) or debonding of the coating from the substrate (adhesive failure).[60] Practical adhesion of a coating to the substrate is a function of fundamental adhesion (i.e., chemical bonds across the interface) and numerous other factors such as stresses in the coating, thickness and mechanical properties of the coating, and mechanical properties of the substrate. As the low-temperature PVD process does not generally involve diffusion phenomena and chemical reactions, the adhesion between the substrate and the hard layer is weak. To facilitate the formation of strong chemical bonds at the coating–substrate interface, modern PVD processes entail thorough and expensive cleaning operations that remove contaminations from the substrate surface thereby increasing surface reactivity.

To date, there are very few open literature reports concerning the examination of TiN-coated bearing surfaces of joint replacements that have been recovered following surgical revision. *In vivo* data on wear performance of TiN coatings is also very limited. Despite incidental clinical and simulator test evidence of the durability of TiN-coated femoral components,[61–63] the majority of available retrieval observations and joint simulation results show that coating breakthrough and detachment (adhesive failure) of PVD TiN films can occur in the body thereby reducing the wear properties of the implant (**Figure 11**).[57,64–68]

Premature coating detachment in areas where the coated surface is exposed to mechanical wear is the dominant and most worrisome failure mode as the flaking of the hard coating can lead to an aggravated wear situation. The underlying (softer) substrate becomes exposed and partial delamination of the coating leads also to surface roughening which increases the wear rate of the counterpart material. In addition, hard coating flakes can work as abrasive particles on the surfaces in tribological contact.

High residual stresses associated with ceramic PVD coatings on metal substrates[69] could be one of the reasons of TiN layer failure. Tensile stress in the coating causes through-thickness microcracking while compressive stress tends to promote microcrack propagation along the interface. It has been shown by a scratch test that 1.2–1.7 μm thick TiN coatings applied on Ti alloy substrates by arc ion plating (AIP) are prone to localized adhesive failure.[70] In addition, the wear behavior of TiN layer, both in abrasion and adhesion, is strongly deteriorated by the presence of coating defects such as pinholes and embedded microparticles (**Figure 12**).[50,71] These defects are typically formed because of deposition of droplets during the coating process and their subsequent removal or leveling-off by postcoating polishing.

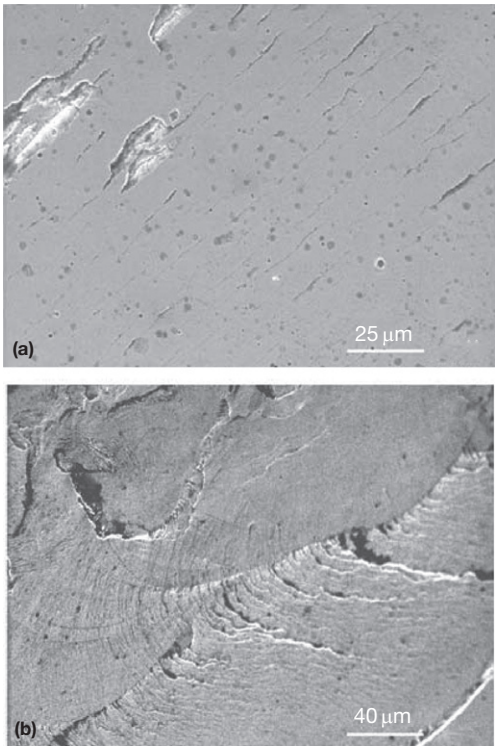

Figure 11 SEM micrographs of AEPVD TiN-coated femoral head after 2 million cycles articulation against TiN-coated insert in a hip simulator. Coating detachment is clearly visible. Under the synergistic action of corrosion and wear, both pinholes and prior mechanical damage (caused, e.g., by third-body abrasion *in vivo*) make TiN-coated implant surfaces more vulnerable to subsequent corrosion. In these defects, galvanic corrosion between the relatively passive coating and the relatively active small exposed substrate surface can lead to blistering and localized loss of the TiN coating (Figure 13(a)).[70,71]

Figure 13(b) schematically displays how coating defects gradually lead to delamination of the coating.

Accelerated corrosion of the underlying substrate at microdefects present in PVD TiN coating was observed for both Ti alloy and CoCr substrates.[70,72] The process of the localized TiN layer loss is assumed to be further promoted by the relaxation of residual stress in the coating.

The less than optimal wear performance of PVD TiN-coated articulating implants is also attributed to the low hardness of the substrate immediately beneath the hard nitride thin film and the sharp transition of hardness and elastic modulus

across the PVD coating–substrate interface.[73] The sudden change of properties is due to the fact that little or no diffusion across the film–substrate interface and, subsequently, no subsurface strengthening take place at the low temperature of the PVD coating process. When load is applied to the hard TiN PVD film on a relatively soft, metallic substrate, plastic deformation is always initiated in the substrate material at the coating–substrate interface. The yielding substrate is unable to support the coating while the hard TiN film is unable to accommodate the deformation, so the coating fractures just like the shell of a boiled egg and triggers catastrophic third-body wear.[74] This typically occurs under point contact loading caused by debris particles between the articulating surfaces, or contact with hard components like the rim of the metal shell of the cup, or in the area of point-and-line contact in total knee arthroplasty (TKA). The 'eggshell-effect' is more pronounced for the softer substrates, for example, Ti alloy. The failure of EB-PVD TiN films (Tecvac Ltd, Cambridge) on Ti6Al4V substrates after cyclic loading tests[58] demonstrates the need to provide substrates with enhanced load-supporting characteristics.

1.108.2.2.2.2. Diffusional TiN coatings

It has been suggested that surface treatments that modify the surfaces to an increased depth are capable of providing better wear resistance than plain TiN PVD-coating deposition.[75,76] Nitrogen-ion implantation, for example, is able to convert Ti alloy surface into a hardened compound nitride layer; however, the depth of modification at typical energies of 50–100 keV is only 0.1–0.2 μm providing little improvement in load support from the substrate.[77–79] The required support to the hard TiN coating may be achieved by nitrogen-diffusion-hardening methods providing a more gradual hardness change across the subsurface layer (**Figure 14**). Depending on the nitriding temperature and time, a several micrometer thick compound layer is obtained on the surface followed by a several tens of micrometers thick diffusion zone – solid solution of nitrogen in titanium, α-Ti(N).[80–85] The compound layer consisting of two distinct titanium nitrides (TiN and Ti_2N) and the α-Ti(N) zone are clearly seen in **Figure 15**. Unlike the case of PVD, the compound (nitride) layer that grows from the bulk material is supported by the hardened diffusion zone so that there is no danger of the layer spalling off. At relatively low temperatures (≤700 °C), no continuous titanium nitride layer is formed on the surface and the increase in hardness is attributed only to the diffusion of nitrogen into the alloy.[86] For successful diffusion treatment, nitrogen has to be in the atomic or ionic state. This is achieved by ammonia dissociation (in gas nitriding) or plasma excitation (in plasma nitriding). Compared to gas nitriding, plasma nitriding is more environmentally friendly (does not use ammonia that may be harmful to the workers) and results in less surface roughening. Still, plasma nitriding has several important drawbacks including limited temperature control, inhomogeneous plasma distribution, and expensive equipment.

A method that can become an attractive alternative to conventional nitriding techniques is PIRAC. In PIRAC nitriding, highly reactive monatomic nitrogen is supplied by decomposition of an unstable nitride (e.g., Cr_2N) and/or by selective diffusion of the atmospheric nitrogen.[35,87,88] Ti alloy parts to be coated are placed in a stainless steel container, sealed and

annealed at 700–900 °C (Figure 16). In addition, the container is filled with a chromium nitride (Cr_2N) powder. The steel of the container has a high content of chromium that reacts with the atmospheric oxygen to form a stable Cr oxide, Cr_2O_3. This reaction prevents oxygen from penetrating through the container walls, so that a very low partial O_2 pressure ($\leq 10^{-5}$ Pa) is maintained inside the container without application of any vacuum pumps.[35] At the same time, N atoms can easily diffuse through the container walls because of the rather low affinity of Cr (which is the only nitride-forming element in the foil) for nitrogen. The diffusion of N from the atmosphere leads to a gradual build-up of monatomic nitrogen pressure inside the container. This is accompanied by the decomposition of the Cr_2N powder as long as nitrogen pressure has not reached the equilibrium pressure of Cr_2N dissociation at the corresponding temperature (e.g., ~3 Pa at 900 °C.[89] Reactive diffusion of nitrogen atoms into titanium alloy results in the formation of a Ti–N coating. As PIRAC is not a line-of-sight process it allows uniform coating of complex shape parts. Similarly to plasma-nitrided (PN) surfaces, PIRAC nitrided Ti surface consists of a several micrometers thick outer compound layer (TiN–Ti_2N) and a several tens of microns thick inner solid solution layer (α-Ti(N)) (Figure 17). Beneath the ceramic, a nitrogen-enriched Ti gradually transforms into the metal alloy, preventing an abrupt mismatch in properties. This hardened N-rich titanium layer (Figure 18) provides an optimal support for the ceramic coating and prevents its collapse and delamination. The low level of residual stresses in PIRAC coatings on Ti6Al4V substrate compared to the PVD TiN layers[88] is an additional factor in the excellent adhesion of PIRAC coatings. In contrast to PVD, PIRAC coatings are not externally applied layers but are grown from the substrate itself and are characterized by an excellent conformity and strong adhesion. Strong adhesion of PIRAC TiN coatings was demonstrated by the absence of delamination in a three-point bending test (Figure 19).[88]

1.108.2.2.2.3. Duplex TiN coatings

To improve the ability of PVD TiN-coated Ti alloys to bear highly localized loads, 'duplex' treatments which combine PVD (or chemical vapor deposition (CVD)) coating with a diffusion treatment (nitriding) of the underlying surface have been proposed.[90–92] The nitrided layer confers graded properties with increasing hardness from the substrate to the

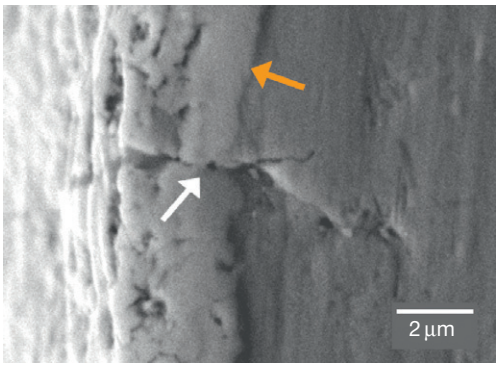

Figure 19 SEM cross-section of Ti6Al4V alloy PIRAC nitrided at 900 °C, for 2 h after bending test illustrating excellent TiN coating adhesion. Technol.* **2000**, *126*, 210–218, with permission from Elsevier.

outermost surface thus providing the required support to the hard PVD coating. It has been reported that plasma nitriding pretreatment of Ti6Al4V and Ti5Al2.5Fe2 substrates provided an optimal support of TiN layer produced by plasma-assisted CVD (PACVD) and a good adhesion.[93] Along the same lines, it has been shown by indentation tests that the adhesion of TiN coatings deposited by plasma-enhanced CVD (pulsed d.c. PCVD) on PN Ti6Al4V alloy was substantially stronger than TiN adhesion to the untreated substrate.[94] As a result, a marked improvement in the wear resistance of PN-PCVD duplex treated alloy in pin-on-disk test against a steel ball was achieved.

Cassar *et al.*[95] compared the reciprocating-sliding wear performance of ~3 μm thick PAPVD TiN coatings deposited on bare and duplex triode PN Ti6Al4V alloy. Duplex-coated disks exhibited a strongly improved wear resistance compared to the PVD-coated ones. Moreover, prenitriding process was beneficial even when the coating had been partially worn. While the

coatings directly deposited on Ti alloy were quickly removed across the entire contact area, the wear of the duplex coatings was constrained to within the central region and the coating adjacent to this region was still capable of supporting the applied load.

1.108.2.2.3. Diamond-like carbon coatings

Diamond-like carbon (DLC) (Figure 20) has emerged as a potential coating material for joint replacements because of its high hardness (1500–3500 HV), low frictional coefficient, high wear and corrosion resistance, biocompatibility, and excellent smoothness. A comprehensive overview of biomedical applications on DLC coatings can be found in Hauert,[96] Grill,[97] Hauert,[98] Dearnaley and Arps,[99] Roy and Lee[100]. DLC film comprises a mixture of sp^2 (graphitic-like) and sp^3 (diamond-like) carbon bonds (Figure 20(b)) and is deposited by using high energy carbon species.[101,102] DLC films are produced by a number of techniques such as ion beam deposition, radio frequency plasma-enhanced CVD (r.f.-PECVD), filtered cathodic vacuum arc (FCVA), ion plating, plasma immersion ion implantation and deposition (PIIID), magnetron sputtering, ion beam sputtering, pulsed laser deposition, and mass selected ion beam deposition. For detailed description of DLC deposition methods, see Chapter 1.107, Carbon and Diamond. The hydrogen content in DLC films varies up to 40%. Because of its amorphous structure, DLC films can be easily doped and alloyed with different elements. This leads to a wide range of properties depending on its sp^3, sp^2, and hydrogen content together with element incorporation.

The tribological behavior of DLC is different from that of other hard materials. Under tribological conditions, usually the softer of the two materials will be worn. In the case of DLC, the wear products have a graphitic nature and are transferred to the partner surface forming a so-called transfer layer on the partner surface.[102] The DLC then slides on this transfer layer that protects the softer partner surface from wear and the harder DLC-coated surface wears off at an extremely low rate. Additionally, the graphitic wear products of DLC act also as a solid lubricant. The build up and especially the adhesion of this transfer layer depend critically on the environmental conditions.[100,102]

Despite the excellent tribological behavior of DLC in dry air, catastrophic failure of DLC coatings is often observed when sliding in aqueous environments.[103,104] The instability of DLC coatings in aqueous environment is believed to be caused by the degradation of the interfacial strength because of water molecules penetration via through-film defects. A representative example of DLC film defects is given in Figure 21.[105] Here, the large hole was possibly formed from the ejection of a microparticle. The smaller pinhole was formed as a result of the film growth mechanism.

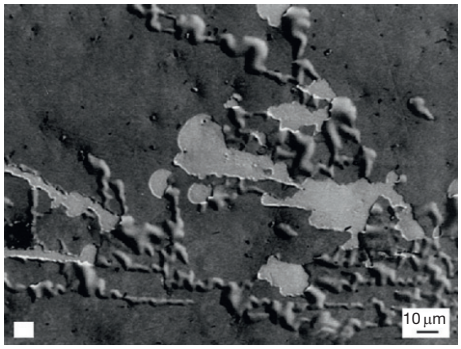

Figure 22 SEM micrograph showing delamination of 100 nm thick DLC coating on Ti6Al4V alloy disk after 1 million cycles sliding against UHMWPE pin in distilled water. Reproduced from Xu, T.; Pruitt, L. *J. Mater. Sci. Mater. Med.* **1999**, *10*, 83–90, with permission from Springer.

Improvement of the deposition technique (e.g., multistep coating) can be effective in reducing the through-film defects and enhancing the film stability. In addition, DLC coatings can exhibit a wide range of atomic bond structure and properties depending on the deposition condition. Another aspect to be addressed is the adhesion of DLC coating with biomaterials. Because of high residual compressive stress, the coating can spontaneously delaminate if the adhesion is insufficient (Figure 22).[106] The spallation, delamination, and corrosion of the DLC coatings during their long-term use in medical implants are to be carefully considered for the future biomedical applications.

1.108.2.2.4. Multicomponent hard coatings

An exciting and novel area of research deals with the synthesis of multicomponent, bioactive nanostructured films (MuBiNaFs) by sputtering of composite self-propagating high-temperature synthesis (SHS) targets.[107–111] SHS provides a highly dense, uniform structure that exhibits the required mechanical, thermal, and electrical properties needed for such composite PVD target materials. A radically new approach in the development of new nanostructured materials is to add nanocomponents. It has been shown that the introduction of nanosized powders into electrode material can modify the material structure favorably affecting the quality of produced coatings.[112]

MuBiNaFs were deposited by magnetron sputtering of composite targets $TiC_{0.5} + X$ and $(Ti,Ta)C + X$ {where $X = CaO$, TiO_2, $Ca_{10}(PO_4)_6(OH)_2$, ZrO_2, Si_3N_4, and $Ca_3(PO_4)_2$} in an Ar atmosphere or reactively in a gaseous mixture of $Ar + N_2$. The application of ion implantation assisted magnetron sputtering (IIAMS) of SHS composite targets offers a flexible approach to surface improvement of metal implants. This technique facilitates the production of dense, well-adhered films with controlled elemental composition. TiC/CaO nanocomposite films were also deposited by means of a hybrid PVD/plasma activated CVD(PACVD) technique, which combines dc magnetron sputtering of a SHS composite target $TiC_{0.5} + CaO$ with a subsequent high density inductively coupled plasma (ICP) in order to excite and ionize the sputtered species to a higher degree.[113–115]

By varying the target compositions and PVD process parameters, the structure and properties of films can be elegantly engineered and the size of crystallites can be reduced to nanometer scale.[116] This extremely small crystallite size results in a significant fraction of atoms locating at the grain boundaries. The effect of the film–biomedium interaction depends on surface characteristics, such as composition, charge, and structure. These characteristics can be adjusted over a wide range depending on different ion–plasma deposition conditions.

The MuBiNaFs films exhibit excellent tribological properties that, in combination with high level of biocompatibility and bioactivity, make them promising candidates for load-bearing implants.[117–122]

1.108.2.3. Simulation and Testing of Wear-Resistant Surface Modifications

1.108.2.3.1. Durability comparisons

Durability of surface modifications is a key performance attribute. The typically hard and chemically inert nature of ceramic surfaces makes them ideal for resisting the roughening influences of third-body abrasives and of corrosive wear that affect metal surfaces. As one example, nanohardness testing indicates that the zirconia surface on oxidized zirconium is over twice as hard as CoCr on the articular surface.[123] Other ceramics, such as titanium nitride and alumina, can be even harder.[21] Harder surfaces are more scratch resistant, but this alone does not mean that they are more abrasion resistant. The hard surface also must resist shear during articulation and cracking during loading.

A bone cement abrasion test was developed to assess the resistance of various materials to an aggressive third-body abrasive challenge.[124] Bone cement particles represent some of the most abrasive third bodies that might be present in a joint because of the crystalline nature of the polymer and the inclusion of radiopaque powder such as zirconia or barium sulfate.[5] The abrasive effect of third-body debris is approximated by rubbing the tip of bone cement pins against flat plates of the hard counterface material, simulating the counterface abrasion caused by a particle of bone cement embedded in the PE component (Figure 23). The pins are made with a spherical tip so that the initial Hertzian contact stress is 82 MPa which, as the tip is worn flat, drops through the range of stress during testing that would be found in prosthetic joints. One million cycles (Mc) of this test is assumed to be equivalent to 1 year for a typical joint arthroplasty patient, but that assumption is unimportant when comparing different surfaces using a test of fixed length.

Plates of conventional CoCr and oxidized zirconium were subjected to 10 Mc of this bone cement abrasion test.[125] The ceramic surfaces on the oxidized zirconium plates were not penetrated and exhibited over 4900 times less volumetric wear and over 160 times less roughening than the CoCr plates (Figure 24). This indicated that the oxide ceramic surface provides superior resistance to roughening compared to CoCr as well as being durable in the presence of bone cement debris.

Vapor deposited nitride coatings on both CoCr and titanium alloy plates representing a variety technologies used or proposed for use on orthopedic bearing surfaces were subjected to this bone cement abrasion test.[124,126] The coatings

also tended to improve abrasive resistance relative to non-coated plates, but all of the tested coatings were compromised within 1 Mc (Figure 25). It was common to find debris from the abraded coatings embedded in the bone cement pins. It is reasonable to suppose that the wear volume for these specimens would have increased significantly if the tests had continued to 10 Mc because the hard protective coating would no longer have been present on the plates to resist abrasion from the pins and embedded coating debris. On the basis of these test results, the nitride coatings appeared to have less resistance to the shear of articulation despite their greater hardness relative to oxidized zirconium. The nitride coatings did not chip or delaminate away from the plates, indicating that they had good adhesion, but the coatings appeared to rub off over time, indicating that they had poor cohesion.

This difference in performance might be due the differences in their microstructures.[21,126] The nitride coatings subjected to this test have a heterogeneous structure with numerous nodules and pores (Figure 26). The heterogeneous structure may be inherent in the vapor deposition process because of embedment of solid particles, or chemical segregation from the elevated temperatures and long processing durations. By contrast, the transformed ceramic on oxidized zirconium has a uniform, nanostructural, high integrity grain structure with a perpendicular orientation relative to the articular motion.[40,41] It is reasonable to suppose that an applied nitride

coating with a homogeneous, fine-grained, high integrity microstructure might exhibit improved durability in this test.

The behaviors of diamond and DLC coatings have been more difficult to interpret because their characteristics differ on the basis of processing technology and composition.[21,127] Some of these coatings are difficult to polish after application to a curved surface, and when these coatings were subjected to a bone cement abrasion test without being polished first, they caused rapid wear of the bone cement pins.[124,126] Most diamond and diamond-like coatings were not penetrated after 10 Mc of testing unless they had inclusions such as graphite nodules, indicating that heterogeneous coatings tend to have poor cohesion. It was not uncommon to find that a cohesive coating which was not breached during testing had flaked off of small regions either in the wear track or around the edges of the plates. This suggests that adhesion can be more of a challenge than cohesion for diamond and diamond-like coatings.

A popular method of assessing the adhesion of coatings to a substrate involves using a hardness test indenter to push an indentation crater into the surface.[21,128] The material displaced from the crater heaves up around it and under the coating, providing an aggressive challenge to adhesion of the coating to the substrate. Oxidized zirconium and most nitride coatings used in orthopedics perform very well in this test. Although cracks are often observed around the crater because of the extensive plastic deformation of the substrate, evidence of chipping or delamination typically is not observed (Figure 27). The extreme hardness of diamond and diamond-like coatings makes it challenging to create an indentation crater using a hardness test indenter, so they are difficult to assess in this test.

A modification of the bone cement abrasion test was used for a more vigorous adhesion test of whether the ceramic surface on oxidized zirconium plates would chip or spall if damaged.[128] Before testing, a groove was milled through the oxide and aligned perpendicular to the pin motion so that the bone cement pin crossed the groove with each stroke. The milled groove had not widened after 10 Mc, indicating that the oxide around it remained adherent and could tolerate localized damage or loss without catastrophic failure (Figure 28).

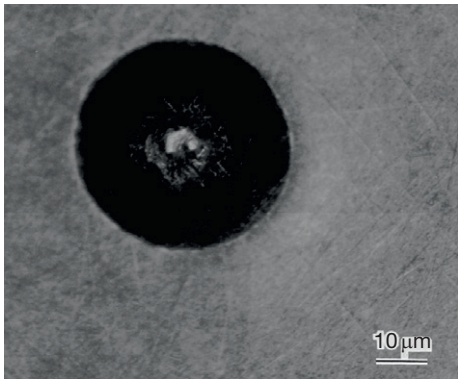

Figure 27 The absence of chipping and spalling around the indentation test crater on oxidized zirconium indicates excellent adhesion of the oxide despite extensive deformation of the substrate. Reproduced from Hunter, G. *Trans. Soc. Biomater.* **2001**, *24*, 540, with permission from Society for Biomaterials.

A galvanic relationship is created by placing different materials in contact, such as occurs between the ceramic film and a metal substrate or a mating component in a taper junction. This relationship can cause accelerated corrosion if the galvanic potentials are significantly different, particularly if relative mechanical articulation (fretting corrosion) or restricted spaces (crevice corrosion) are involved. Ceramic coatings can provide good protection against these types of corrosion, but the presence of pinhole defects in the coatings also can lead to localized blistering and pitting.[21,127,200] Laboratory testing is recommended in conditions that are at least as demanding as those encountered in the intended application.

Oxidized zirconium samples were subjected to a series of corrosion tests to characterize their behavior in static and dynamic conditions, both in neutral and acidic environments.[129–131] The zirconium alloy behaved as the anode when coupled with the other orthopedic alloys, helping to protect them. This behavior is attributed to a high thermodynamic activity but slow electrochemical reaction kinetics in the passive state. In static tests, the concentrations of zirconium and niobium ions in the solution were below detection limits, indicating that the anodic current on the zirconium alloy was consumed mainly by the formation of a passive film. This helps protect breaches in the oxide from galvanic attack. An extreme test combines the cyclic loads of a taper junction fretting test with the potential of crevice corrosion from an acidic solution under elevated temperature.[132] In this test, oxidized zirconium heads produced fewer features of chemical attack on stainless steel trunnions than did the clinically acceptable combination of stainless steel heads and trunnions (Figure 29). This indicates that oxidized zirconium should perform at least as well as other orthopedic material combinations under clinical conditions.

1.108.2.3.2. Wear simulation tests

Determining if hard coatings are effective in reducing the wear of joint replacements requires the use of reliable wear testing techniques. Joint simulators are the standard tools for

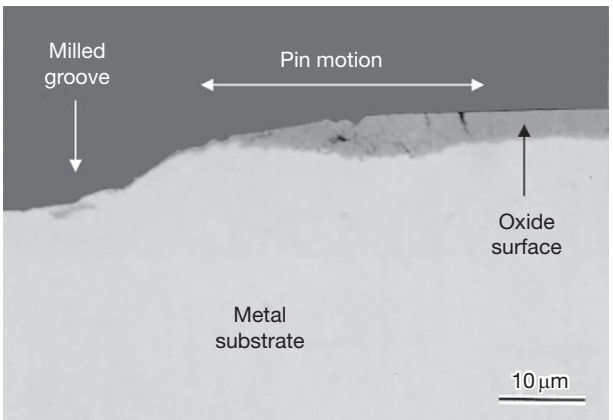

Figure 28 The oxide tolerated localized damage without catastrophic failure by protecting the bone cement abrasion test surface within the wear track on an oxidized zirconium plate right up to the edge of a milled groove, as seen in this cross-sectional optical micrograph. Reproduced from Hunter, G. *Trans. Soc. Biomater.* **2001**, *24*, 540, with permission from Society for Biomaterials.

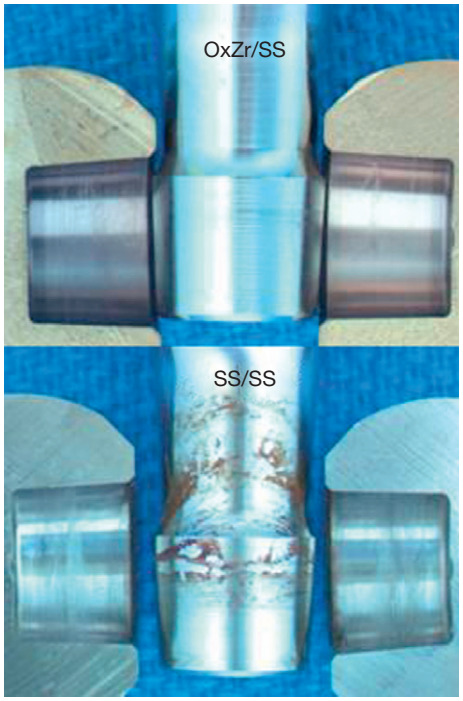

Figure 29 Minor fretting scars and minimal chemical activity are evident after an extreme fretting corrosion test with oxidized zirconium heads on stainless steel trunnions (above). Extensive chemical activity is evident under the same conditions with stainless steel heads on stainless steel trunnions (below). Reproduced from Pawar, V.; Jones, B.; Sprague, J.; Salehi, A.; Hunter, G. In *Medical Device Materials*; Helmus, M., Medlin, D., eds.; ASM International: Materials Park, OH, 2005; Vol. 2, pp 403–408, with permission from ASM International.

evaluation of wear resistance. Joint simulators are designed to reproduce the physiological kinematics and physical forces acting on the joint during movement; however, they are still limited in their ability to simulate the lubrication conditions, the loads, and the motions that occur over a broad range of daily activities. Moreover, tribology and wear mechanisms are different for different joints, so results obtained on a hip simulator are not always relevant for a knee (or other joint) replacement. Thus, in order to properly assess the potential of a hard coating to reduce *in vivo* wear rates, simulator tests should be conducted under a variety of conditions.

1.108.2.3.2.1. Oxidized zirconium

Knee simulator tests have been used to help understand how OxZr counterfaces compare to the standard CoCr counterfaces for wear of the PE components. The pioneering study was conducted using a simulator that mimics the rolling and plowing motions of knee prosthesis kinematics.[133] Early OxZr prototypes made from castings were used in this study, and the oxide was thinner and had less integrity than that developed later. In addition, the PE liners were gamma irradiated in air. Despite these material limitations, the OxZr components produced significantly fewer wear features and none of the macroscopic PE delamination observed in the tests with CoCr components. It also was noted that the CoCr surfaces became roughened during testing while the OxZr surfaces were not affected.

After full development of the manufacturing processes, a study was conducted using a four-axis, displacement-controlled, physiologic knee simulator.[134] Components were tested for 6 Mc of 90% walking-gait and 10% stair-climbing activity, and PE wear was measured periodically during the test by weight loss and by wear particle characterization. In comparison to CoCr, OxZr produced an aggregate wear rate of PE that was 85% less. This comparison had a 90% confidence level because the test parameters generated lower wear rates and more measurement variability than desired. It was noted that all of the OxZr components generated lower PE wear rates and produced less burnishing of the inserts. In contrast to the OxZr surfaces, the CoCr surfaces were found to have become roughened during testing even though the lubricant was filtered before testing. Analysis of the wear debris also indicated that OxZr produced fewer small PE particles and less total volume of particles, but the sample size was too limited for statistical significance.

A separate study was conducted on a different component design in the same type of simulator, but the test parameters were modified to produce greater wear rates and less measurement variability using just a walking-gait motion.[135] In comparison to CoCr, OxZr produced a mean wear rate that was 42% less when measured either gravimetrically or volumetrically. This reduction is substantial, although less than the 85% comparison of the previous study. The later study may be more representative of the 'normal' performance advantage of OxZr knees because it achieved a 95% confidence limit and the relative performance is similar to that found with hip simulators.[136] This study continued, however, to show that the knee wear rates were sensitive to test conditions. The wear rate using OxZr was 62% less than that using CoCr under conditions of greater rotation and an additional varus moment. This indicated that the performance advantage for OxZr might increase for conditions associated with 'more demanding' patient kinematics.

Besides kinematics, another 'more demanding' condition occurs commonly as the femoral component surface becomes roughened. CoCr femoral components were tumbled in an abrasive alumina powder before simulator testing.[137] The resulting roughness values were within the clinically relevant range. The components were tested for 5 Mc using the same displacement-controlled simulator protocol as used with the first test series. OxZr components tumbled using the same procedure became roughened less, and produced an aggregate wear rate of PE that was 89% less ($p < 0.05$). Because the components were preroughened, particle analysis was conducted on the wear debris without the complicating presence of numerous abrasive particles in the test lubricant. In comparison to CoCr, OxZr produced 44% fewer PE particles ($p < 0.05$). A separate test with preroughened components was conducted for 5 Mc using a force-controlled simulator.[138] Compared to CoCr, OxZr produced an average wear rate that was 82% less ($p < 0.001$) in this test.

Lee *et al.*[139] compared the effects of OxZr and CoCr total knee replacement (TKR) femoral components of a similar design (Genesis II, Smith & Nephew) on the wear of UHMWPE inserts (on CoCr baseplates) using a force-controlled knee simulator during an enhanced force walk cycle simulation. The enhanced walking cycle is more aggressive than the standard

walking cycle and provides a 25% increase in anterior–posterior shear force and 25% increase in external–internal rotation. Simulation tests were run in 30% fetal calf serum for 4 Mc, and PE wear was assessed gravimetrically.

OxZr components showed increased resistance to scratching compared to CoCr. This difference was evident already after 1 Mc. The wear of UHMWPE tibial inserts articulating against OxZr femoral components was measurably lower than for CoCr femoral components (Figure 30), probably as a consequence of reduced scratching. The results suggest that the increased scratch resistance of OxZr has the potential to increase the longevity of TKRs.

DesJardins *et al.*[140] conducted knee joint simulator study using conventional UHMWPE to quantify the effect of surface roughening of OxZr and CoCr on TKR wear performance. OxZr and CoCr femoral components of a similar design (Genesis II, Smith & Nephew) were tumbled in an abrasive alumina powder before simulator testing. The tests were run against cruciate-retaining UHMWPE tibial inserts on Ti6Al4V baseplates in 50% bovine calf serum. PE wear was assessed gravimetrically.

After 5 Mc of wear testing, the roughened OxZr femoral components were found to reduce the rate at which UHMWPE wear debris was generated by 82.0% when compared to the roughened CoCr femoral components (Figure 31). The average weight loss rates for the roughened OxZr and the roughened CoCr groups were 16.6 ± 7.6 and $92.0 \pm 24.4\ \text{mg Mc}^{-1}$, respectively ($p < 0.00001$).

Collectively, these knee simulator tests indicate that OxZr components can reduce wear of the PE counterface by 40–90% depending on test conditions. Similar wear reductions have been found for monolithic ceramic femoral components in knee simulator tests.[141,142] These results indicate that OxZr may contribute to reducing wear-related clinical complications such as debris-induced osteolysis. It is interesting to note that the performance advantage for OxZr relative to CoCr seems to increase as the testing conditions become more demanding. This trend indicates that OxZr may be of particular help to 'high demand' patients who are most in need of assistance for prolonging the survival of their prostheses.

Hip simulator comparisons of OxZr to traditional metal CoCr alloy also have been important in anticipating its *in vivo* properties for PE wear. The earliest study was conducted with 32-mm heads in 100% bovine serum using a displacement-controlled, physiologic hip simulator.[136] Both nonirradiated UHMWPE and highly crosslinked PE were tested, as well as both smooth and roughened heads. Components were tested for at least 5 Mc at 1 Hz using ISO and Bergmann loading profiles alternating every 100 000 cycles. PE wear was measured periodically during the test by weight loss and by wear particle characterization. In comparison with CoCr, OxZr produced wear rates of nonirradiated UHMWPE that were 45% less with smooth heads and 61% less with roughened heads ($p < 0.01$), with fewer particles in both cases (Figure 32). With crosslinked PE, wear rates were not detectable except for the roughened CoCr heads, but OxZr heads produced 27 and 63% fewer particles when comparing smooth and roughened heads, respectively (Figure 32). Even

after extending the test to 20 Mc, a linear regression of oxide thickness measurements on roughened OxZr heads indicated that less than 0.0023 μm Mc^{-1} of oxide thickness was removed, a change so small that it was within the resolution of the spectrometer system.[143] Therefore, the thickness of the ceramic oxide should be durable over the life of the implant.

A study by Clarke *et al.*[144] evaluated both smooth and roughened 36-mm heads made of OxZr and CoCr coupled to highly crosslinked PE acetabular liners. A total of 6 Mc of testing were done for each combination in the physiologic environment of 50% alpha-serum (400 ml). The authors concluded that smooth CoCr and both types of OxZr heads produced negligible amounts of weight loss (less than the fluid absorption by the liners). However, roughened CoCr heads produced a 'dramatic' wear rate for the highly crosslinked liners.

Bourne *et al.*[145] assessed the roughening damage to heads that can occur as a result of postoperative dislocation. They noted that the damage on any material can be of significant extent, but that the damage tends to occur on the inferior half of the head where the effect on wear would be less critical. Using profilometry and scanning electron microscopy, they found that the resulting metal transfer on CoCr heads produced mostly peaks surface while the OxZr heads produced more valleys below the articulating surface. Testing a laboratory model of a dislocation event on the crown of the heads (the worst case location) using a hip simulator showed that the wear of nonirradiated UHMWPE produced by damaged OxZr heads was not statistically distinct from that produced by smooth CoCr heads and was reduced over tenfold by using highly crosslinked liners.

A study by Lee *et al.*[146] assessed OxZr bearings for their resistance to aggressive abrasion and wear performance as compared to zirconia toughened alumina (Biolox(r) Delta)

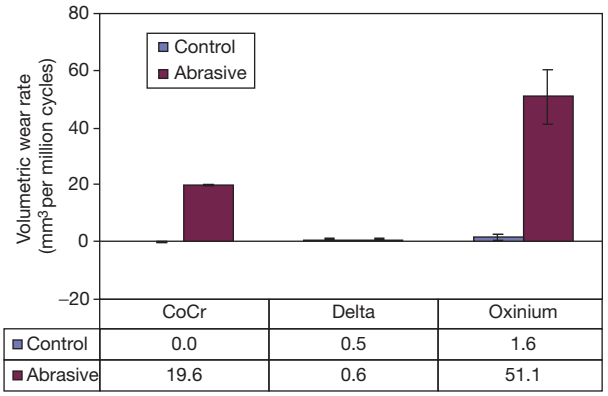

Figure 33 Wear rates (over 2 million cycles hip simulation) of crosslinked UHMWPE sockets articulating against pristine (control) and abraded CoCr, alumina (Delta), and OxZr (Oxinium) femoral heads. Reproduced from Lee, R.; Essner, A.; Wang, A.; Jaffe, W. L. *Wear* **2009**, *267*, 1915–1921, with permission from Elsevier.

and ion treated CoCr in a hip wear simulator for 2 Mc. Wear rates of the crosslinked PE liners were low and near zero when worn against nonabraded femoral components (all less than 1.6 mm^3 Mc^{-1}) (Figure 33). There was no statistical difference in wear rates using these three different femoral head materials ($p = 0.18–0.37$). A force-controlled diamond indenter was then utilized to produce damage on the femoral heads similar to that found in OxZr clinical retrievals with repeated head dislocation. Abrasion of the femoral component with the diamond indenter markedly increased PE wear rates for OxZr and CoCr bearings (51.1 and 19.6 mm^3 Mc^{-1}, respectively), and had no effect on PE wear for the bulk ceramic bearings (0.6 mm^3 Mc^{-1}). The soft metallic substrate of OxZr

yielded to the pressure of the indenter and caused the surface film to be compromised. The damage of OxZr components exceeded that of the CoCr control components because the substrate metal was softer. The study indicated that increased liner wear can be expected if the surface film is compromised within the bearing area on an OxZr head.

1.108.2.3.2.2. Titanium nitride coating

A limited number of hip or knee simulator comparisons of TiN-coated materials to traditional CoCr alloy or other coating options can be found in open literature, and their results are rather contradictory. First hip simulator studies of titanium nitride coatings running against UHMWPE were conducted by Pappas *et al.* back in 1990s.[147,148] The coatings were applied on wrought Ti6Al4V alloy by a proprietary PVD process, and the tests were conducted in distilled water. The average wear of UHMWPE obtained in these two studies is shown in **Figure 34**. The results of the earlier, 10 Mc study[147] showed that under the same testing conditions, the wear of UHMWPE articulating against TiN-coated 32 mm femoral heads was three times lower than for the CoCr alloy heads of the same diameter. In the second study,[148] 47 mm diameter femoral HR cups with a polished 8 μm thick TiN coating were run against UHMWPE inserts for 48 Mc. The wear of the TiN coating was <2 μm, and no delamination was observed. Minor wear, scratching, and burnishing of the TiN surface were visible to the naked eye after 35 Mc. As no reference CoCr femoral cups were used in this 48 Mc test, the wear of UHMWPE was compared to the results for the CoCr heads from the previous, 10 Mc study, and was found to be significantly lower. Because of the different geometry of the femoral components (47 mm diameter TiN-coated Ti6Al4V cups vs. 32 mm diameter CoCr heads), however, the validity of such a comparison is questionable.

Another hip simulator study[149] compared, among others, the wear performance of TiN coatings on 28 mm diameter CoCr femoral heads articulating against UHMWPE acetabular cups. Approximately 10 μm thick TiN layers were deposited by arc evaporative PVD (AEPVD). Simulation studies were run for up to 5 Mc in 25% (v/v) bovine serum. Wear loss of PE was determined volumetrically.

The wear volume change of the UHMWPE acetabular cups as a function of time and the mean steady state UHMWPE wear rates (2–5 Mc) are shown in **Figure 35(a)** and **35(b)**. It can be seen that TiN-coated heads produced PE wear two times higher than the control uncoated heads. Although the authors observed no coating failure, a strong increase and a large scatter of the total height of the surface roughness profile, R_t (from 0.490 ± 0.240 μm before testing to 2.063 ± 5.077 μm after testing), strongly suggest that localized loss of the TiN coating has occurred. At the same time, no roughening of the uncoated CoCr heads was observed after 5 Mc which might explain the lower UHMWPE wear associated with these heads compared to the TiN-coated heads.

The same authors observed cohesive failure of a similar ~10 μm thick AEPVD-deposited TiN coating on a 28 mm CoCr femoral head (**Figure 36**), after 2 Mc wear simulation against an uncoated CoCr insert.[150] The wear of the TiN-coated heads was lower than that of the uncoated heads, but it caused relatively high wear of the corresponding CoCr inserts. It was hypothesized that droplets remaining on the as-deposited TiN coating surface might have been an initial originator of cohesive failure.

In a different study,[57] the same authors tested AEPVD TiN-coated 28 mm diameter CoCr femoral heads articulating against similar coated CoCr inserts in 25% (v/v) bovine serum. Wear loss was determined gravimetrically and converted into volume loss. The wear rates (+95% confidence limits) for the first Mc (bedding-in), the second 1 Mc (steady state) and over 2 Mc (overall) are shown in Figure 37. It can be seen that both the coated heads and the coated inserts demonstrated much lower wear compared to the traditional MoM prostheses. By the end of the 2 Mc period, the overall wear of the coated couples was ~20-fold lower than for the uncoated ones. Also, the concentrations of Co, Cr, and Mo ions from the TiN-coated combination were at least 20-fold lower. At the same time, some localized damage to the TiN coating (Figure 11) was seen on the coated heads even after the relatively short period of 2 Mc corresponding to no more than 2 years *in vivo*. It may be hypothesized that larger areas of coating delamination and correspondingly higher wear would be observed if the test was continued for a longer time period.

Oñate *et al.*[151] tested the wear behavior of TiN coating in a simplified knee wear testing machine where the contact between femoral condyles and tibial plates is approximated by a ball-on-plate geometrical contact. A 3–4 μm thick TiN layer was produced by a proprietary ion plating PVD process. TiN-coated and -uncoated CoCr femoral heads of 32-mm diameter were subjected to a combined rolling-sliding motion against UHMWPE plates. The tests were run in distilled water as the lubricant for up to 5 Mc. Wear evaluation of UHMWPE plates was carried out by weight loss measurements. High wear loss occurred in the case of PVD TiN-coated CoCr wearing against UHMWPE (Figure 38). After 5 Mc, TiN coating induced a UHMWPE wear five times higher than the control (uncoated) material. When the worn surfaces of the TiN-coated balls were observed, small areas of approximately 70 μm without a coating were detected. These areas corresponded to hard phases of the CoCr microstructure in which the coating had not nucleated or adhered properly. According to the authors, detachment of the coating particles from these areas

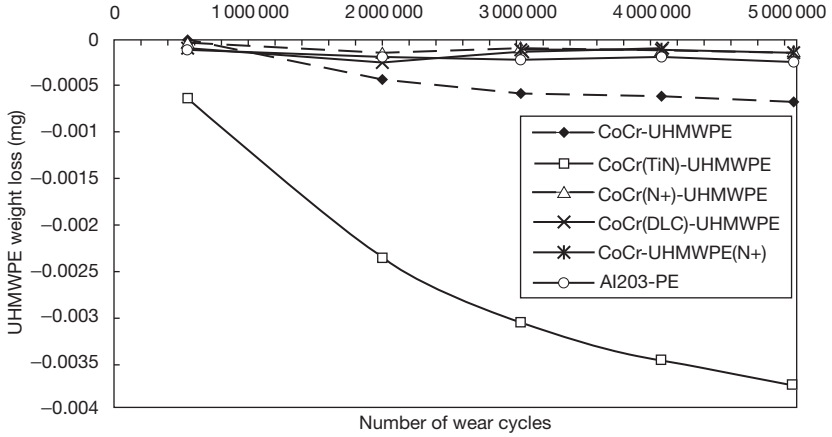

Figure 38 Weight loss of UHMWPE plates articulating against alumina, CoCr, and surface engineered femoral heads as a function of number of cycles in a knee wear simulator. Reproduced from Oñate, J. I.; Comin, M.; Braceras, I.; *et al. Surf. Coat. Technol.* **2001**, *142–144*, 1056–1062, with permission from Elsevier.

was responsible for the presence of scratches and the high weight loss of the UHMWPE plates.

Very recently, Weisenburger *et al.*[152] reported the results of extended simulator testing of total hip replacements (THRs) and TKRs metallic components with PVD TiN-based coatings. MoM THRs comprising TiN-coated heads and liners (44 mm diameter) were tested on a hip simulator, and TiNbN-coated 65 mm femoral components were tested on a force-control knee simulator against conventional UHMWPE tibial inserts. As claimed by the authors, the tested TiN-based coatings are commercially available for clinical use in some parts of the world including Europe. The tests were conducted in bovine serum ($20\,g\,l^{-1}$ protein) at 37 °C, and wear was measured gravimetrically. Uncoated MoM THR components and TKR femorals were used as controls.

Over 5 Mc, the TiN-coated THRs wore at a rate of ~8.5 mg Mc^{-1} while uncoated THR components wore at a lower rate of ~3.2 mg Mc^{-1}. Over 8 Mc, UHMWPE tibial inserts paired with TiN-coated femoral components wore at ~11.2 mg Mc^{-1} while the control insert wore at ~9.0 mg Mc^{-1}. Remarkably, all TiN-coated components clearly showed loss of coating in the articulating region which increased in size as the tests progressed. The higher wear observed with TiN-coated specimens must have been caused by third-body wear (evidenced by scratches) from the coating removal debris. The authors suggested that the coating process had to be altered to create a more durable coating able to withstand many years of articulation within the body.

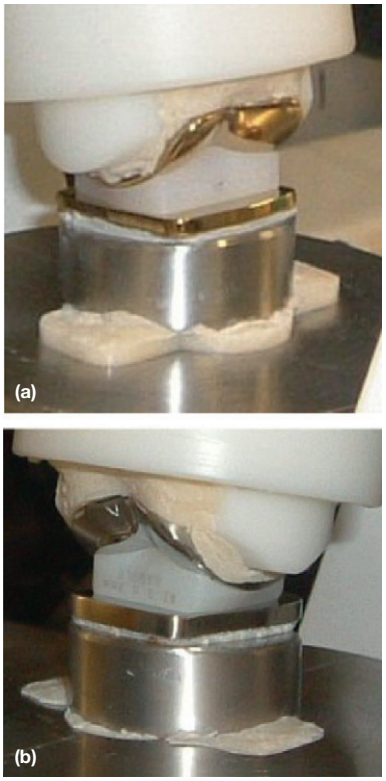

Figure 39 Wear simulation test set-up of a total ankle replacement (TAR): (a) TiN-coated Ti alloy (Buechel Pappas, BP); (b) CoCr alloy (Mobility, DePuy International). Reproduced from Bell, C. J.; Fisher, J. *J. Biomed. Mater. Res. Appl. Biomater.* **2007**, *81B*, 162–167, with permission from Wiley.

Bell and Fisher[153] performed wear simulation comparison of a total ankle replacement (TAR) whose talar and tibial components were CoCr alloy (Mobility, DePuy International) with the Buechel Pappas (BP) TAR whose metallic components were made of PVD TiN-coated titanium alloy (**Figure 39**). It is important to mention that TiN-coated BP prosthesis is one of the few TAR designs with a good clinical history. The simulator tests were run in 25% (v/v) bovine serum for 6 Mc. No statistically significant difference was observed between UHMWPE wear bearing against TiN-coated titanium alloys and that against uncoated CoCr alloy.

The results of different wear simulation tests with PVD TiN-coated joint prostheses are summarized in **Table 1**.

As mentioned in **Section 1.108.2.2**, surface treatments that modify the surfaces to an increased depth are capable of providing better wear resistance than plain TiN PVD-coating deposition. Unfortunately, practically no wear joint simulation studies of nitrogen-diffusion-hardened bearing surfaces have been reported in literature. The only exception is the work of Gutmanas and Gotman[160] where 32 mm diameter PIRAC nitrided Ti6Al4V femoral heads (with a 2–2.5 μm thick titanium nitride layer) were tested against UHMWPE cups in a hip simulator. After 2 Mc in distilled water, PIRAC TiN–UHMWPE couples produced approximately five times less PE wear than the control 316L steel–UHMWPE couples. Importantly, no signs of coating delamination were observed after 4 Mc suggesting better adhesion than for PVD TiN layers.

1.108.2.3.2.3. DLC coating

1.108.2.3.2.3.1. DLC-coated metal against UHMWPE

Saikko *et al.*[154] coated 28 mm diameter CoCr femoral heads with a 3 μm thick DLC layer by a proprietary, hybrid PVD–CVD process. The heads were tested in a hip simulator against metal-backed UHMWPE cups in Calf serum diluted 1:1 with distilled water (protein content close to that of synovial fluid). Wear of UHMWPE was estimated gravimetrically. Uncoated CoCr and alumina heads were used as controls. DLC produced the highest average gravimetric PE wear rate over 3 Mc; however, the differences between the three head materials were not large (~58, 56, and 48 mg/10^6 cycles for DLC-coated CoCr, uncoated CoCr, and Al_2O_3, respectively). After the tests, all heads proved to be practically unchanged in visual and microscopical examination. The authors concluded that, as a counterface for PE, their experimental DLC coating was fairly similar to alumina and CoCr.

Dowling *et al.*[155] carried out wear tests of DLC-coated 22 mm diameter stainless steel femoral heads against UHMWPE cups in a multistation hip simulator in distilled water. DLC films of 150–200 nm thickness were deposited using the saddle field source. UHMWPE wear was evaluated by the change in dimensions of the plastic cups. DLC-coated heads exhibited significantly lower wear than their uncoated counterparts (~5 vs. 70 mm^3 after 6 Mc). The wear observed with DLC coatings was comparable to that obtained with femoral heads made from zirconia.

Dorner-Reisel *et al.*[156] tested DLC-coated CoCr femoral segments for total knee joint replacements against UHMWPE inlays in knee wear simulator in bovine serum solution for

Table 1 A summary of literature reports on wear simulation tests of PVD TiN-coated and DLC-coated joint prostheses

Material couple	*Conditions*	*Result*	*References*	*Remarks*
TiN-coated Ti6Al4V THR head against UHMWPE insert	Hip simulator, distilled water, 10×10^6 cycles	Less wear than with uncoated CoCr alloy	147	
TiN-coated Ti6Al4V HR cup against UHMWPE insert	Hip simulator, distilled water, 48×10^6 cycles	Less wear than with uncoated CoCr alloy	148	TiN-coated 44 mm HT cup compared to 32 mm CoCr head from Ref.148
TiN-coated CoCr THR head against UHMWPE insert	Hip simulator, 25% v/v bovine serum, 5×10^6 cycles	More wear than with uncoated CoCr alloy	149	Roughening of TiN-coated head – TiN layer delamination?
TiN-coated CoCr THR head against CoCr insert	Hip simulator, 25% v/v bovine serum, 2×10^6 cycles	More wear than with uncoated CoCr alloy	150	Cohesive failure of TiN layer
TiN-coated CoCr THR head against TiN-coated CoCr insert	Hip simulator, 25% v/v bovine serum, 2×10^6 cycles	Less wear than for uncoated MoM pair	57	Localized damage to TiN coating
TiN-coated Co–Cr femoral head against UHMWPE plate	Knee simulator, distilled water, 5×10^6 cycles	More wear than with uncoated CoCr alloy	151	Some TiN layer detachment
TiN-coated femoral head against TiN-coated acetabular liner	Hip simulator, bovine serum, 5×10^6 cycles	More wear than with uncoated CoCr alloy	152	Loss of TiN coating Substrate material not reported (Ti6Al4V or CoCrMo?)
TiNbN-coated femoral component against UHMWPE insert	Knee simulator, bovine serum, 5×10^6 cycles	More wear than with uncoated CoCr alloy	152	Loss of TiN coating Substrate material not reported (Ti6Al4V or CoCrMo?)
TiN-coated CoCr talar/tibial components against UHMWPE bearing	Ankle simulator, 25% v/v bovine serum, 6×10^6 cycles	Same wear as for uncoated CoCr alloy	153	
DLC-coated CoCr femoral head against UHMWPE cup	Hip simulator, diluted calf serum, 3×10^6 cycles	Similar wear as with uncoated CoCr alloy and alumina	154	
DLC-coated 316L femoral head against UHMWPE cup	Hip simulator, distilled water, 6×10^6 cycles	Less wear than with uncoated 316L steel	155	
DLC-coated CoCr femoral segment against UHMWPE inlay	Knee simulator, bovine serum solution, 5×10^6 cycles	Less wear than with uncoated CoCr alloy for thin DLC More wear than with CoCr alloy for thicker DLC	156	
DLC-coated CoCr femoral head against UHMWPE cup	Hip simulator, 25% v/v bovine serum, 5×10^6 cycles	More wear than with uncoated CoCr alloy	149	Possible delamination of DLC layer
DLC-coated CoCr femoral head against UHMWPE plate	Knee simulator, distilled water, 5×10^6 cycles	Less wear than with uncoated CoCr	151	
DLC-coated Ti6Al4V cup against alumina ball	Hip simulator, ASF and calf serum, 6×10^6 cycles	DLC coating failed after 100×10^3 cycles	157	
DLC-coated CoCr ball-on-socket pairs	Hip simulator, bovine serum based fluid, 20×10^6 cycles	Less wear than with uncoated CoCr alloy	158	
DLC-coated 316L ball-on-socket pairs	Hip simulator, diluted bovine serum, 15×10^6 cycles	Very low wear	159	No control uncoated pairs were tested
DLC-coated CoCr THR head against CoCr insert	Hip simulator, 25% v/v bovine serum, 2×10^6 cycles	Less wear than with uncoated CoCr alloy	150	

5 Mc. DLC-coatings were deposited by plasma decomposition of the gaseous hydrocarbon methane in three different thicknesses – 0.8, 2.7, and 4.5 μm. Wear loss was estimated by weighing the UHMWPE inlays. The test results are shown in **Figure 40**. In comparison to the uncoated CoCr femoral segments, DLCs with a thickness of 0.8 and 2.7 μm on the CoCr femoral components reduced the UHMWPE wear. Surprisingly, the 4.5 μm thick DLC coating caused a drastically increased wear. This result was explained by changes in the heat transfer. The authors assumed that the heat transfer might be reduced with DLC coating thickness and because of lower fraction of defects, such as pinholes, in thicker DLC coatings.

Galvin *et al.*[149] reported a hip simulator study of 28 mm diameter CoCr femoral heads coated with a ~10 μm thick amorphous DLC (aDLC) film by PACVD. Simulation studies were run against UHMWPE acetabular cups in 25% (v/v) bovine serum for 5 Mc. As can be seen in **Figure 35**, DLC-coated heads produced PE wear three times higher than the control uncoated heads. It is worth mentioning that an increase and, especially, large scatter of the total height of the surface roughness profile, R_t, obtained following the simulation test suggest that local delamination of the DLC layer had occurred.

DLC-coated 32-mm diameter CoCr femoral heads were tested in a simplified knee wear testing machine against

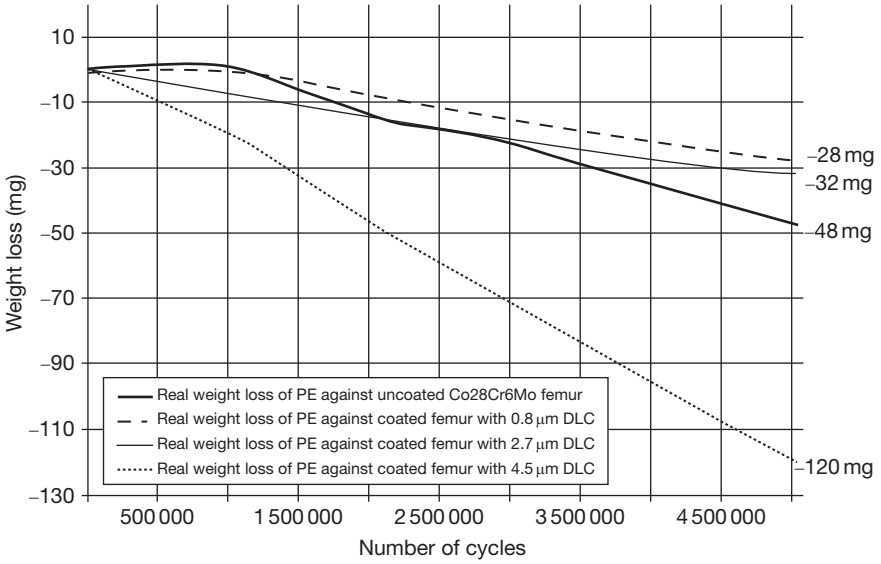

Figure 40 Weight loss of UHMWPE inlays articulating against uncoated and DLC-coated Co28Cr6Mo femoral segments as a function of number of cycles in a knee wear simulator. Reproduced from Dorner-Reisel, A.; Schürer, C.; Müller, E. *Diam. Relat. Mater.* **2004**, *13*, 823–827, with permission from Elsevier.

UHMWPE plates.[151] DLC coating of 3–4 µm thickness was PVD deposited from acetylene in a radio frequency (RF) plasma discharge on a metallic interlayer. The tribological tests were run in distilled water for 5 Mc. As shown in Figure 38, the weight loss of UHMWPE articulating against DLC-coated CoCr head was significantly lower than in the case of uncoated CoCr (0.130 vs. 0.690 mg). PE material on the DLC coating was almost negligible.

1.108.2.3.2.3.2. DLC coating in hard-on-hard bearings

Österle *et al.*[157] ran hip simulator tests of DLC-coated Ti6Al4V cups against 44 mm diameter alumina composite ceramic balls (BIOLOX® delta, CeramTec AG) in artificial synovial fluid (ASF) and new born calf serum. DLC (a-C:H) coating of 2 µm thickness was deposited on a 0.5 µm Ti interlayer by high-frequency PACVD. Three of four joints failed during hip simulator testing already during the first 100×10^3 cycles, because of peeling off the coating from large areas of the cups. The authors concluded that the premature failure of DLC-coated cups during hip simulator testing was due to insufficient polishing of the parts prior to coating. One such failure is shown in Figure 41 revealing local delamination of the coating at the substrate–coating interface.

It was claimed that, in the case of the nonwear-resistant titanium alloy substrates, the sole application of a thin hard coating is not sufficient. A possible solution might be surface modification of a several microns thick supporting layer, for example, by plasma nitriding prior to coating with DLC.

In Thorwarth *et al.*,[158] 4 µm thick DLC (a-C:H) layers (hardness of 23 GPa) were grown in an acetylene plasma on ball-on-socket implant pairs made from CoCr (radius of curvature 14.5 mm). Metallic interlayers were used to provide stable layer adhesion. For comparison, a rough 16 µm DLC layer exhibiting 'cauliflower' structure ('rough DLC') was also investigated. Hip simulator tests were run in 30 g l^{-1} protein-containing bovine serum based wear testing fluid at 37 °C.

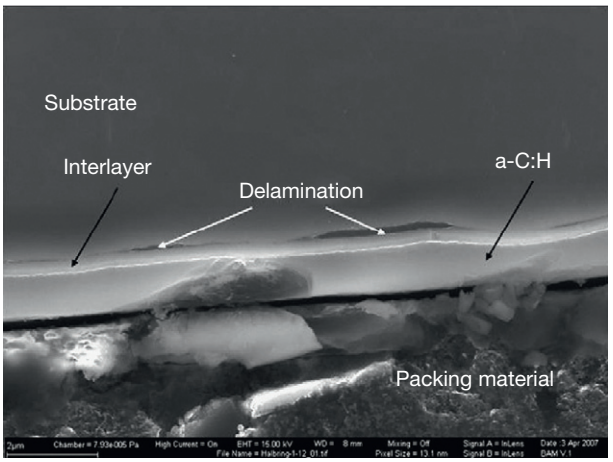

Figure 41 Local delamination of DLC coating on Ti6Al4V cup after 100 000 cycles articulation against alumina ball in a hip simulator. Reproduced from Österle, W.; Djahanbakhsh, M.; Hartelt, M.; Wäsche, R. *Wear* **2008**, *265*, 1727–1733, with permission from Elsevier.

Total wear volumes for uncoated MoM and DLC-on-DLC (DoD) friction pairs up to the full test runtime of 20 Mc are shown in Figure 42. The smooth DoD friction pairs exhibited significantly reduced wear ($p < 0.001$) compared to the uncoated variants. In comparison, the 16 µm 'cauliflower' DLC layer, having a much higher surface roughness from the beginning, showed a wear volume much higher than the smooth DLC coatings ($p < 0.05$) but still half of the MoM pairs ($p < 0.001$).

The low wear resistance of uncoated implants led to a large increase of metal wear after about 7 Mc. After roughening, MoM pairs required additional, tribologically active molecules (e.g., proteins) to establish a sufficient surface separation. Without these compounds, stick–slip was observed, leading

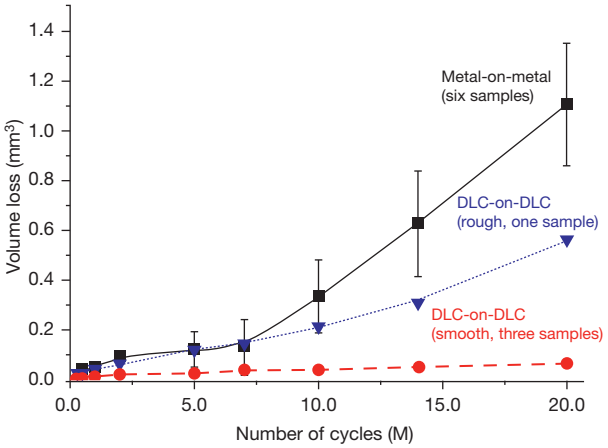

Figure 42 Volume wear loss of ball-on-socket implant pairs made from uncoated and DLC-coated Co28Cr6Mo alloy as a function of number of cycles in a hip wear simulator. Reproduced from Thorwarth, G.; Falub, C. V.; Müller, U.; *et al*. *Acta Biomater*. **2010**, *6*, 2335–2341, with permission from Elsevier.

to significantly higher wear generation. In contrast, DLC-coated implants were much more tolerant toward the absence of such molecules. A few scratches that did not penetrate into the substrate and sparse local defects were observed on smooth DLC surfaces after 20 Mc. These defects appeared at about 1 Mc and did not lead to layer delamination for DLC coatings with good interfaces not susceptible to stress corrosion cracking (SCC).

Lappalainen *et al.*[159] deposited 40–100 µm thick amorphous diamond (AD, 80–85% diamond bonding) coatings on custom made stainless steel acetabular cups and 28- or 35-mm femoral heads by the filtered pulsed plasma arc discharge method. Proper intermediate layers and high plasma ion energies were used in the beginning to achieve extreme adhesion. Wear testing was done in commercial hip joint simulator in diluted bovine serum (protein content of 35 mg ml^{-1}) for 15 Mc. No uncoated controls were tested. Linear wear rates were evaluated by the change in the depth of 60–200 nm deep marker scratches on the surfaces of the balls. An extremely low volumetric wear (estimated on the basis of the linear wear) of 10^{-4} mm^3 Mc^{-1} was obtained. Comparing this *in vitro* wear rate with the clinical data for conventional metal-on-UHMWPE and MoM hip prostheses, the authors conclude that high-quality AD coatings can reduce the amount of wear debris from articulating surfaces so as to be close to negligible.

Fisher *et al.*[150] performed hip simulator studies of 28 mm diameter CoCr head-on-socket couples where the femoral heads were modified using 2 µm thick PACVD DLC coating. After 2 Mc articulation in 25% (v/v) bovine serum, the wear of such half-coated couples was at least one order of magnitude lower compared with that of the traditional MoM reference bearings. Correspondingly, the concentration of three major elements Co, Cr, and Mo in the serum lubricant of the DLC-half-coated couple was reduced by an order of magnitude.

The results of literature reported wear simulation tests with DLC-coated joint prostheses are summarized in **Table 1**. It can be seen that the results on the wear of DLC–UHMWPE articulating couples are contradictory. The common trend in these studies is that when the experiments are done in water, the wear of PE is somewhat reduced. However, when protein-containing fluid (e.g., serum) is used, no significant improvement compared to uncoated control samples can be seen. It has been hypothesized that with protein-containing lubricants and real loads (used in hip simulators) the formation of the transfer layer responsible for wear protection of the softer surface sliding against DLC is inhibited.[127] In these authors' opinion, the approach in improving the wear of UHMWPE articulating components via DLC coating of the partner surface is a dead-end. The superior way of realizing the potential of DLC in joint replacements is, therefore, to use DLC coatings on both articulating surfaces. Indeed, in joint simulation tests, DoD couples exhibited a significantly reduced wear. It is important to mention, however, that DLC coatings might be successful in simulator experiments but still fail *in vivo*. This is due to the existence of pinholes providing corrosion paths through the coating to the substrate. Such corrosion paths can lead to galvanic effects, delamination, and eventual failure of the coating.[127] Furthermore, it takes a long time for the lubricating fluid to diffuse through microscopic pinholes. As simulator experiments are strongly accelerated compared to the *in vivo* situation, their duration might be too short for the corrosion processes to have effect. To reduce the probability of existence of through-film defects, the application of thicker DLC coatings has been advocated.[127]

1.108.2.3.2.4. Chromium nitride based coatings

Chromium nitride (CrN) and carbonitride (CrCN) PVD-deposited coatings were studied in simulation tests as bearing surfaces for hip replacements. These coatings are claimed to generally have better cohesive strength and toughness compared to TiN, with only slightly reduced hardness.[57]

CrN-coated (AEPVD, ~10 µm) 28 mm diameter CoCr femoral heads were tested against UHMWPE acetabular cups in 25% (v/v) bovine serum for 5 Mc.[149] Similar to TiN- and DLC-coated heads, the CrN-coated heads showed no reduction in PE wear compared to uncoated CoCr (**Figure 35**). An increase of the total height of the surface roughness profile, R_t, might suggest some local loss of the CrN surface layer.

A different picture emerged for CrN-coated MoM articulations. In Fisher *et al.*,[57] 28 mm diameter CrN- and CrCN-coated (AEPVD, ~10 µm) CoCr femoral heads were tested against similarly coated CoCr inserts in 25% (v/v) bovine serum. After 5 Mc, the coated THR combinations showed a 36-fold reduction in wear rate compared to the MoM control. Although no significant damage was found to the coating, several isolated cohesive coating failures on femoral heads already occurred after 2 Mc.

Another paper reports wear simulation study of AEPVD CrN-coated (>10 µm) 39 and 55 mm diameter HR CoCr devices in 25% (v/v) bovine serum.[161] After 10 Mc, the CrN-coated bearings had 80% lower wear than the MoM controls. The Cr and Co ion levels in the lubricant of the CrN bearings were 73 and 98% lower than in the MoM controls. No damage to the CrN coating was mentioned. It has been concluded that thick AEPVD CrN coatings have great potential for the reduction of wear and ion release of MoM hip replacement implants.

1.108.2.4. *In Vivo* Performance of Wear-Resistant Ceramic Coatings

1.108.2.4.1. Animal studies

There is a dearth of animal studies evaluating the efficacy of hard ceramic coatings in reducing the wear of joint prostheses. This could be due to the lack of accepted animal models for human total joint replacement (TJR) performance.[162–164] The existing reports on *in vivo* performance of hard coatings for orthopedic applications are limited to the assessment of their biocompatibility.[165–168]

In a pilot animal study,[169] 12 dogs received THRs with TiN PIRAC-coated Ti6Al4V femoral heads articulating against UHMWPE acetabular cups. Two animals were lost to analysis because of postoperative complications. The other ten dogs retained normal walking, running, and jumping capabilities until sacrificed 2–3.5 years after the total hip arthroplasty (THA) surgery. No radiographic or clinical signs of aseptic loosening were observed during the follow-up period. The excised TiN-coated heads preserved the initial golden color and were only lightly abraded as observed under scanning electron microscope (SEM) (**Figure 43**). Importantly, no delamination of the TiN layer occurred *in vivo*. Histological findings included a fairly small amount of metal/PE debris and active osteoblastic (bone-building) activity around the implants.

In another research, *in vivo* performance of TiN PIRAC-coated MoM THR was studied in a rat model.[170] The animals were sacrificed 18 weeks after THA surgery, following daily treadmill exercise that amounted to approximately 7 million

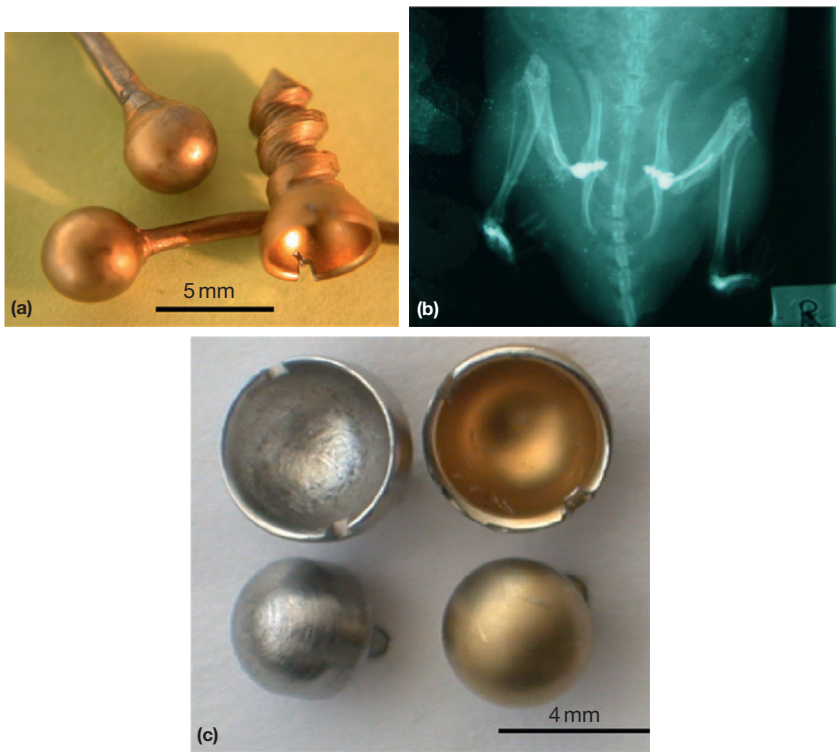

Figure 44 (a) PIRAC TiN-coated Ti6Al4V rat THR prostheses; (b) an X-ray of a rat after bilateral THA; (c) postmortem retrieved rat stainless steel (left) and TiN-coated Ti6Al4V (right) THR prostheses. Surface scratches in (c) are an artifact of the retrieval procedure.

stress cycles on hip joint. The excised TiN-coated articulating components remained smooth and did not show any sign of coating delamination. This is in contrast to the control steel-on-steel (316L) joint prostheses where pronounced surface roughening was observed (**Figure 44**). The encouraging results of the two animal studies with PIRAC TiN coatings[169,170] suggest that hard diffusion coatings are a promising alternative to PVD ceramic coatings.

1.108.2.4.2. Clinical performance

The primary purpose of bearing surface modifications is to decrease wear, both to reduce the debris produced that can elicit a potentially negative biologic response, such as particles and metal ions, and to reduce changes in the bearing geometry that can impact gait kinematics. This should provide increased longevity and survivorship of the prosthetic devices. Laboratory testing can indicate how the surface modifications may behave, but ultimate verification must rely on clinical performance. There are few publications dealing with clinical performance of surface modifications considering the number of technologies and devices that have been used clinically. The following is a review of some of these publications.

The clinical behavior of orthopedic components with articular surfaces modified by ion implantation provides insight into how components with a ceramic surface film may provide benefits. One short-term study (minimum 3-year follow-up) reported that nitrogen ion treated CoCr heads produced approximately 28% less linear penetration into UHMWPE liners than nontreated CoCr heads did.[26] The advantage of this radiographic approach is that it can provide a measure of bearing wear without surgical intervention. Another study examined the surfaces of clinically retrieved hip components.[171] The nitrogen ion implanted CoCr heads had harder surfaces and, while they exhibited scratches, the scratches tended to have less depth. It also was noted that the surface hardness and depth of nitrogen enrichment tended to decrease with length of implantation, with some heads showing no evidence of the ion treatment remaining. It would be interesting to see if the wear advantage of the ion implanted heads seen in the radiographic study was maintained or if it diminished with longer term follow-up. In either case, the greater potential durability and resistance to roughening of a ceramic film might provide even better clinical performance.

Assessing the performance of ceramic coatings is complicated by the variety of coating compositions, substrate compositions, coating processes, coater expertise, and component types.[21,127] Very few clinical studies are published comparing coated and conventional bearing components directly, particularly considering the large number of coated components that have been used globally for decades. Some publications involve only retrieved components from a small number of patients, potentially skewing the understanding of that coating toward anecdotal experience rather than typical performance.

Only one published study was found with a direct comparison of bearing prostheses with nitride coatings to those of noncoated CoCr.[66] Titanium nitride coatings were found to have been breached on the modular heads of several revised hip components, but the comparison was complicated by issues involving the bone cement and cementing technique. Some studies of titanium nitride coated components report good clinical outcomes, but they do not describe the condition of the articulating surfaces in any detail.[61,63,172] It is difficult from this to assess whether the nitride coating will be durable long-term or provide significant reductions in UHMWPE wear in a THR or TKR. Two retrieval analyses reported scratching or breaching of the titanium nitride coating on modular heads at short to medium durations.[64,65] These studies described features that questioned the adhesive and cohesive durability of the coatings even in low demand use.

Very few publications are available on the clinical performance of diamond and DLC coatings as well. Those reports that have been published indicate poor clinical performance.[21,98,173,174] Poor adhesion between the coating and substrate is noted in each case. In at least one case, this appeared to involve corrosion between the coating and metal substrate. In others, stress states existing within the coating or produced between the articulating surfaces were implicated. Recommendations have been made about how to address these deficiencies in coating performance, but a successful clinical implementation has not been reported.

In contrast, the clinical performance of the autogenic ceramic surface film on oxidized zirconium is the subject of various types of published investigations. Comparisons of functional scores and survivorship in THRs and TKRs indicate that oxidized zirconium components are at least comparable to CoCr components in short- and medium-term follow-up.[175–184] One of these studies uniquely reported faster recovery for patients with oxidized zirconium components, but the advantage did not persist.[175] Another study found no difference in volume, size, and shape of UHMWPE wear debris between oxidized zirconium and CoCr hips, but it is not clear if the small amount of retrieved debris was representative of all the debris.[180] Many of the investigators noted that longer term observations will be needed to determine if there are significant differences in outcomes.

Several investigations observed aspects of the clinical behavior of oxidized zirconium components for comparison with reported laboratory test behavior. Radiographic evaluation of THRs indicated trends of less linear penetration into the liner with oxidized zirconium heads than with CoCr heads, in some cases with statistical significance.[183–185] Analysis of components retrieved after clinical use indicated fewer wear features on components articulating with oxidized zirconium than with CoCr, and less roughening of oxidized zirconium surfaces than of CoCr surfaces.[186,187] Synovial fluid temperature in TKR patients was lower with oxidized zirconium components than with CoCr components, indicating less friction with oxidized zirconium.[188] These clinical results were consistent with expectations from laboratory studies and provide some optimism for future performance.

One behavior of concern that has been noted is significant damage and removal of the ceramic surface on oxidized zirconium heads that have been revised subsequent to dislocation and attempts at closed reduction.[145,189–195] This damage was caused by contact of the head with the edge of the acetabular shell, and prompted recommendations for caution and careful monitoring of such patients because of the possibility of greatly increased liner wear. Some of these studies noted that CoCr and ceramic heads also were damaged significantly by this type of event, although not in the same way. An initial

study indicated that the increased liner wear caused by this damage would not be catastrophic, and that the damage of the oxide would not be progressive.[145] Another study that placed the retrieved heads in a hip wear test simulator indicated that the liner wear could be severe, but the orientation of the head was not controlled.[194] When the same type of test was conducted with the heads in their clinical orientation, the increase in liner wear was small because the damage was on the inferior side of the head and outside of the main area of liner contact.[195] It is worth noting that these heads were revised for instability, and long-term liner wear was not a concern. Nevertheless, the articular surface of any material may be damaged by contact with the acetabular shell, so patients who have dislocations with closed reduction should be monitored with care.

Two other performance advantages were noted for oxidized zirconium over CoCr in clinical use. Hypersensitivity to metal ions has been identified as a possible cause of arthroplasty failure in certain patients.[196] Ceramic or nitride-coated components have been used in such cases as a means of limiting ion exposure to the patient. One clinical study of metal-sensitive patients demonstrated that oxidized zirconium components can be used for such patients with cost or performance advantages over the traditional alternatives.[197] The other advantage involves magnetic resonant imaging of patients. It has been demonstrated that oxidized zirconium components can produce less image distortion than CoCr.[175,198,199]

1.108.3. Future Trends

Optimizing the bearing surfaces of joint replacements is an urgent socioeconomic need because of the increasing life expectancy and increased performance demands from the growing number of younger patients to whom the surgery is indicated. Ceramic surface films have a great potential to improve the tribological performance and longevity of artificial joints as they provide the metallic components with a hard, wear-resistant surface while preserving their toughness and fracture resistance. Titanium nitride (TiN) and DLC are the most extensively studied hard coatings for orthopedic applications. Despite their high hardness, excellent biocompatibility, and promising laboratory test results, the worrisome premature failure of such coatings has been observed in clinical and some wear simulation studies. Insufficient adhesion and inadequate load-bearing capacity of the underlying softer metallic substrate are believed to be the major obstacles on the way to successful implementation of hard coatings into clinical practice. Next generation technologies aiming to alleviate the shortcomings of single-layer hard coatings include the introduction of interlayers to reduce residual stresses and improve adhesion, development of multilayer coatings to reduce residual stresses, and application of duplex surface treatments involving primary substrate surface hardening (e.g., plasma or PIRAC nitriding) followed by hard coating (TiN or DLC) deposition. Another direction is changing the coating structure and composition, for example, development of multicomponent coatings, Cr-based (CrN, CrAlN, and CrCN) coatings, and nanocrystalline and nanocomposite coatings. Further improvements in coating processes and process control to ensure the elimination of pinholes and structural inhomogeneities should contribute to the better performance of hard-coated artificial joint components operating in the corrosive clinical environment under tribological contact.

Clinical evidence is growing so that the autogenic ceramic surface on oxidized zirconium is an appropriate technology for orthopedic components that articulate with PE bearings, except maybe in the case of recurrent dislocations with closed reduction. The next step is to determine from longer term studies if oxidized zirconium can reduce PE wear to a significant extent, and if that will result in improved clinical outcomes. Another possibility might be to see if an autogenic ceramic surface like that of oxidized zirconium can be developed for self-articulation in a hard-on-hard bearing application for hips, eliminating PE debris without introducing greater risk for metal ion debris or catastrophic component fracture. This would appear to require a thicker oxide or a harder or stiffer substrate than the zirconium alloy currently in use for oxidized zirconium fabrication.

Glossary

Amorphous material The atomic structure of amorphous materials lacks the long-range atomic order, that is, noncrystalline. Bioactive glass is characterized by an amorphous silicate structure that facilitates a dissolution–precipitation reaction on the material surface in contact with physiological solution.

Bioactive ceramic A chemically active biocompatible ceramic. The chemical reactivity is in favor of cell function and tissue formation. Bone tissues bond directly to the surface of the bioactive ceramic.

Bioactivity A material property that refers to the ability to bond directly to the bone and enhance bone formation.

Crystalline material Crystallized materials are characterized by a long-range atomic order. The crystallization of bioactive glass reduces the rate of bioactivity reactions in physiological solution.

Solid solution Incorporation of foreign atoms within the crystalline structure of the host material. The formation of solid solution affects the chemical stability and the bioactivity property of bioactive ceramics. Silicate–phosphate ionic substitution in hydroxyapatite ceramic enhances the bioactivity property of the material.

Abbreviations

A-W	Apatite-wollastonite
CDHA	Calcium-deficient hydroxyapatite
EDXA	Energy dispersed X-ray analysis
FTIR	Fourier transform infrared spectroscopy
HA	Hydroxyapatite
ICP-OES	Inductively coupled plasma-atomic emission spectrometry
KGC	Ceravital glass ceramic
OHA	Oxyhydroxyapatite
SBF	Simulated body fluid
SCPC	Silica–calcium phosphate nanocomposite
s-HA	Stoichiometric hydroxyapatite
TMOS	Tetramethoxysilane
TTCP	Tetracalcium phosphate
TEOS	Tetraethoxysilane
TCP	Tricalcium phosphate
TRAP	Tartrate-resistant acid phosphatase
XRD	X-ray diffraction analysis

Bioactive ceramics is a family of materials including various calcium phosphates, bioactive glasses, and bioactive glass ceramics. Common property for these materials is the ability to bond to bone and enhance bone tissue formation within this class of materials. The rate of bone bonding, the stimulatory effect on cell function, and the resorbability vary significantly due to structural and compositional variations. The objective of this chapter is to describe the various bioactive ceramics and the methods used to make them and to analyze the effect of compositional and structural variations on their bioactive behavior. In Table 1 we have compiled a summary of most bioactive ceramics together with their typical composition.

1.109.1. Bioactivity

The bioactivity property refers to the ability of the materials to bond directly to bone and enhance bone formation. The bone-bonding ability of bioactive ceramics is extensively described elsewhere (**Chapter 1.114, Bioactivity: Mechanisms**). In essence, if a calcium phosphate layer is not present on the surface at the time of implantation, various reactions will lead to such a surface. These reactions very much involve proteins and cells within the biological environment. The material also releases ions including calcium. Proteins, including attachment proteins adsorb onto its reacting surface and enable cell adhesion, which in its turn triggers an intracellular reaction cascade that promotes bone tissue formation.

Table 1 Chemical composition of selected bioactive ceramics

	Chemical formula/composition
Stoichiometric hydroxyapatite	$Ca_5(PO_4)_3OH$ or $Ca_{10}(PO_4)_6(OH)_2$
Calcium deficient hydroxyapatite	$Ca_{10-x}(HPO_4)_x\,(PO_4)_{6-x}\,(OH)_{2-x}$, with $0 < x \leq 1$
Carbonate hydroxyapatite	$Ca_5(PO_4)_{2.5}(CO_3)_{0.5}(OH)$ or $Ca_5(PO_4, CO_3)_3(OH)$
Fluorapatite	$Ca_5(PO_4)_3F$
Tricalcium phosphate	$Ca_3(PO_4)_2$
Tetracalcium phosphate	$Ca_4P_2O_9$
Octacalcium phosphate	$Ca_8H_2(PO_4)_6 \cdot 5H_2O$
Rhenanite	$NaCaPO_4$
Oxyapatite	$Ca_{10}(PO_4)_6O$
Oxyhydroxyapatite	$Ca_{10}(PO_4)_6(OH)_{2-2x}(O)_x(\blacksquare)_x$, where ▪ represents a vacancy
Apatite-wollastonite (A-W) glass ceramic	In mol%: 34.2 SiO_2, 16.3 P_2O_5, 44.9 CaO, 0.5 CaF_2, and 4.6 MgO
Ceravital glass ceramic (KGC)	In mol%: 46.2 SiO_2, 20.2 CaO, 25.5 $Ca(PO_3)_2$, 4.8 Na_2O, 2.9 MgO, and 0.4 K_2O
Silica-calcium phosphate nanocomposite (SCPC)	In mol%: 3–33 SiO_2,11–31 P_2O_5, 23–62 CaO, and 3–33 Na_2O

Bioactive ceramics are characterized by a dynamic surface. The ionic dissolution of the material surface is closely linked to precipitation of a calcium phosphate (Ca-P) layer. In fact, the deposition of a Ca-P layer on the surface of bioactive ceramics in physiological solution is well documented for bioactive ceramics with enhanced dissolution properties. In general, the dissolution property of these main classes of bioactive ceramics decreases in the order:

Bioactive glass > Hydroxyapatite > Bioactive glass ceramic

Each of the above materials has compositional and processing parameters that affect the dissolution rate. These parameters will be discussed in detail in the following sections. As mentioned, the dissolution of the surface of bioactive ceramics is associated with precipitation of a Ca-P layer onto the surface of bioactive materials. By virtue of this new surface layer bone integrates directly with the material surface. During the deposition of the Ca-P layer onto the material surface other ions present in the biological milieu, including Mg^{2+}, K^+, CO_3^{2-}, and Cl^- are also incorporated. The characteristics of the deposited Ca-P mimic those of the mineral phase of bone in many aspects. The crystals of the calcium phosphate layer are small in size, defective, and formed at the body temperature. Bone cells attach directly to the adsorbed protein on the surface layer.

Bone deposition is enhanced by the high pool of calcium ions provided by the bioactive ceramic. Measurements of the ionic concentrations of tissue culture medium incubated with bone marrow stem cells attached onto silica-calcium phosphate nanocomposite (SCPC) showed that the cells did not affect the dissolution behavior of the material.[1] However, the attached bone marrow stem cells interfered with the back precipitation reaction and inhibited the formation of a Ca-P layer on the material surface.[1] Scanning electron microscope-energy dispersive X-ray analyses showed that, in the absence of cells, a Ca-P layer formed on the surface of the material because of the dissolution–precipitation reaction.[1] Therefore, the role of the Ca-P surface layer in bone tissue is unique in that it enhances specific cell adhesion and that it provides a high pool of

Ca ions. The effect of bioactive ceramics on osteoblast phenotypic expression and mineralized bone tissue formation are well documented.

1.109.2. Bone Formation at the Interface with Bioactive Materials

Owing to the similarity between the mineral phase of bone and the surface chemistry of bioactive materials a fibrous capsule is not formed around the implant. Instead, bone cells attach and deposit extensive bone matrix directly on the material surface. The integrated nature of surface and tissues leads to a strong interfacial bond. Figure 1 is a histomicrograph showing the intimate bonding between bioactive glass and bone. By way of example, the bond strength at the interface between bioactive glass and bone reaches values of 15–25 MPa, much higher than 0.5 and 2 MPa for inert glass and smooth titanium.[2] Most biocompatible ceramics, metals, and polymers are not bioactive, that is, they do not have the ability to bond to bone. Tissue response is typically fibrous encapsulation. Figure 2 shows a fibrous capsule at the interface with polymethylmethacrylate bone cement inserted into bone.[3]

As bioactive ceramic stimulates the activity of bone cells in direct contact with the material, it also stimulates cells away from the material surface. The dissolution of the surface of bioactive ceramic increases the ionic concentration of, for example, Ca and/or Si in the interfacial tissue fluids. These ions have a well known strong effect on bone cell function.[4–7] Therefore, bone cells in the neighborhood of the bioactive ceramic and those in direct contact with the material surface are stimulated to deposit new bone. It has been shown repeatedly that bone defects grafted with granules of bioactive ceramic are filled with bone.[6,8,9] The new bone formation starts at the surface of the granules of bioactive ceramic and continues to grow until it fills the interspace between the granules.[8] Bone growth inside porous bioactive ceramic implanted in bone defects is also common. Bone formation begins at the wall of the pores and continues to grow until it fills the pores. Certain bioactive ceramics such as SCPCs are resorbable with a controlled rate of degradation inside the implantation bed. As the graft material resorbs, it leaves a space for bone cells to deposit new bone.[6] Therefore, using resorbable bioactive ceramics as a bone graft will allow complete tissue regeneration (Figure 3).[6] The mechanism of new bone formation in defects grafted with bioactive ceramic is rather complex. Therefore, extensive studies have addressed this issue by analyzing separately each event that takes place during the interaction between bioactive ceramics and the biological system. The data from these studies provided extensive foundation to the mechanism of bone bonding and tissue formation at the interface with bioactive ceramics.

1.109.3. Testing Bioactivity *In Vitro*

The mechanism of the formation of the hydroxyapatite (HA) layer on the surface of bioactive ceramics was widely studied *in vitro* by immersing the material in physiological solution and analyzing both the material surface as well as the composition of the solution. The most common physiological solution used for bioactivity analysis *in vitro* is the simulated body fluid (SBF). SBF is a tris buffer with pH and ionic concentration similar to the plasma of the blood.[10] Table 2 shows the ionic composition of the SBF and the plasma of the blood. Interestingly, immersion of bioactive ceramic in SBF produces a HA layer on the material surface similar in many aspects to that of biological apatite. The ability of a biomaterial to

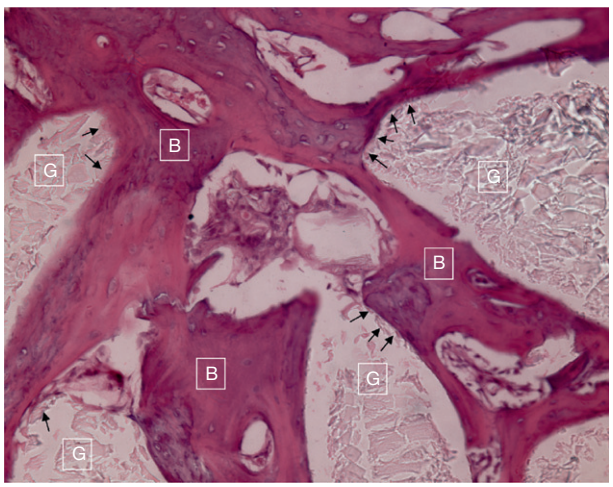

Figure 1 Histomicrograph of rabbit femoral bone defect grafted with bioactive glass granules for 3 weeks. The interspaces between the bioactive glass particles (G) are filled with new mature bone tissue (B) containing haversian systems and blood vessels. Some areas showed high cellular activity and immature woven bone. The arrows point to areas showing direct bonding between the bioactive glass and the new bone. The granules of bioactive glass shattered into small pieces during cutting and processing of the slide due to the brittleness of the material. (H&E stain).

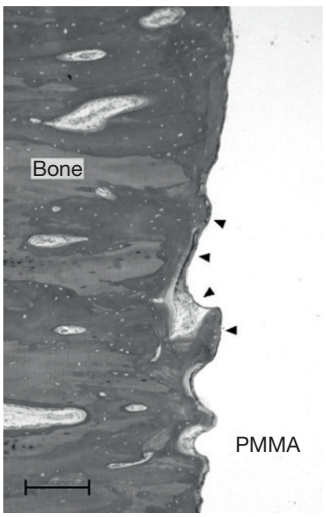

Figure 2 The interface between PMMA bone cement and bone after 2 weeks of implantation in the cortical bone of the tibial diaphysis in goats. A thin fibrous layer (arrow heads) was always present at the interface between bone and PMMA implant. Bar = 200 mm. Reproduced from Ooms, E.; Wolke, J.; Van de Heuvel, M.; Jeschke, B.; Jansen J. *Biomaterials* **2003**, *24*(6), 989–1000, with permission from Elsevier.

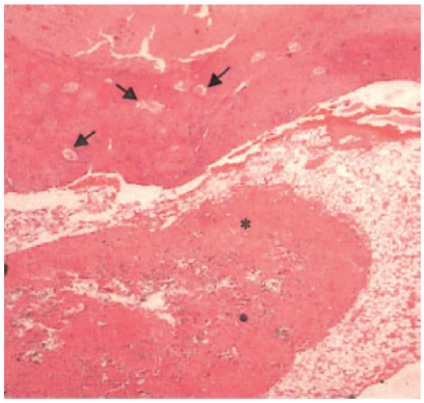

Figure 3 Histology analysis of critical size bone defect created in the rabbit femur and grafted with granules of silica–calcium phosphate nanocomposite (SCPC75) for 3 weeks. The grafted defect was extensively filled with new bone. Bone formed in the internal side of the defect has been completely remodeled and few vascular cavities (arrows) remained. New bone (*) is also present within the marrow cavity that was initially filled with graft material. The architecture of the remodeled cortical bone and marrow resembles that of normal healthy bone. Reproduced from El-Ghannam A. *J. Biomed. Mater. Res. A* **2004**, *69*(3), 490–501, with permission from Wiley.

Table 2 The ionic concentration of simulated body fluid and human blood plasma

Ion	*Simulated body fluid (SBF) (mM)*	*Human blood plasma (mM)*
Na^+	142	142
K^+	5	5
Mg^{2+}	1.5	1.5
Ca^{2+}	2.5	2.5
Cl^-	148.8	103
HOC_3^-	4.2	27
HPO_4^{2-}	1	1
SO_4^{2-}	0.5	0.5

develop a HA surface layer in SBF is indicative of its chemical reactivity and hence, correlates well with the ability of the material to bond to bone *in vivo*. Moreover, the rate of formation of the HA surface layer in SBF correlates well with the rate of bone bonding *in vivo*.[11] Therefore, the rate of development of a HA layer on the material surface when immersed in SBF can be taken as a measure of the degree of bioactivity of bone implant materials. Whereas the actual formation of a surface layer in SBF lends credence to the effect on bone cell function *in vivo*, this *in vitro* test is still not a full simulation of the *in vivo* conditions, and therefore cannot universally address *in vivo* effects of materials and *in vivo* sequences of surface reactions and intracellular events. More details on the validity of the SBF for evaluating bone-bonding ability are described in **Chapter 1.113, Bioactive Layer Formation on Metals and Polymers**.

The deposition of HA layer on the surface of bioactive ceramic in physiological solution *in vitro* involves two components: dissolution of the material surface and precipitation of a Ca-P layer. The dissolution of Ca and P ions into the physiologic solution raises the local ionic concentration of biological fluid at the interface with the implant material to a level that exceeds saturation. The result is the precipitation of amorphous calcium phosphate layer that matures by time to the more thermodynamically stable HA. To the extent that the surface is not a carbonate apatite, the initial rapid dissolution of the material surface is important to initiate the formation of reactive surface layer. If the rate of ion release is slow, the time required for the interfacial ionic concentration to reach the super saturation level may be indefinitely extended. As a result, slow dissolution may delay the formation of the surface layer or in some cases make its deposition impossible due to diffusion of ions away from the surface. Thus, having an implant material with a surface composition made of stable calcium phosphate is not enough to trigger conditions that stimulate the first step to bone formation. The implant material has to have a controlled chemical reactivity that facilitates initial high rate of dissolution. The controlled high rate of dissolution expedites the precipitation of a Ca-P layer that matures into HA (see **Chapter 1.111, Bioactive Ceramics: Physical Chemistry**).

The formation of the amorphous calcium phosphate or HA layer in SBF can be taken as a measure of the chemical reactivity of the material surface and not necessarily as part of the mechanism of bone formation *in vivo*. The last statement is justified by two important facts: First, the presence of serum protein inhibits the formation of the calcium phosphate layer[12,13] and second, attached cells interfere with the deposition of a calcium phosphate layer.[1] Moreover, the dissolution–precipitation reactions are dependent on the properties of both the bioactive material and the simulated physiological solution. Material-related parameters include chemistry, crystalline structure, surface charge, porosity, and surface area. Solution related parameters include protein content, ionic concentration, pH, buffer capacity, and temperature.

1.109.4. Methods of Analysis of the Dissolution–Precipitation Reaction

The surface modifications during the dissolution–precipitation reactions at the interface between bioactive materials and SBF can be analyzed using various methods. The ionic concentration of the physiological solution is typically measured by inductively coupled plasma-atomic emission spectrometry (ICP-OES). The modifications in the surface chemistry and morphology can be analyzed by Fourier transform infrared spectroscopy (FTIR) and scanning electron microscopy with energy dispersed X-ray analysis (SEM-EDXA). **Figure 4(a)** demonstrates the rate of Si release from various bioactive SCPCs immersed in a SBF.[14] **Figure 4(b)** shows a decrease in Ca concentration in the solution due to the precipitation of Ca onto the material surface.[14] FTIR analyses showed that in conjunction with the high rate of Ca uptake by SCPC50 the surface of the material was covered with a HA layer as shown in **Figure 5**.[14]

The dissolution–precipitation reactions can also be followed by recording the changes in the surface charge of the material using ζ-potential measurements. Lu *et al.*[15] measured the ζ-potential of bioactive glass in a SBF. The changes in the

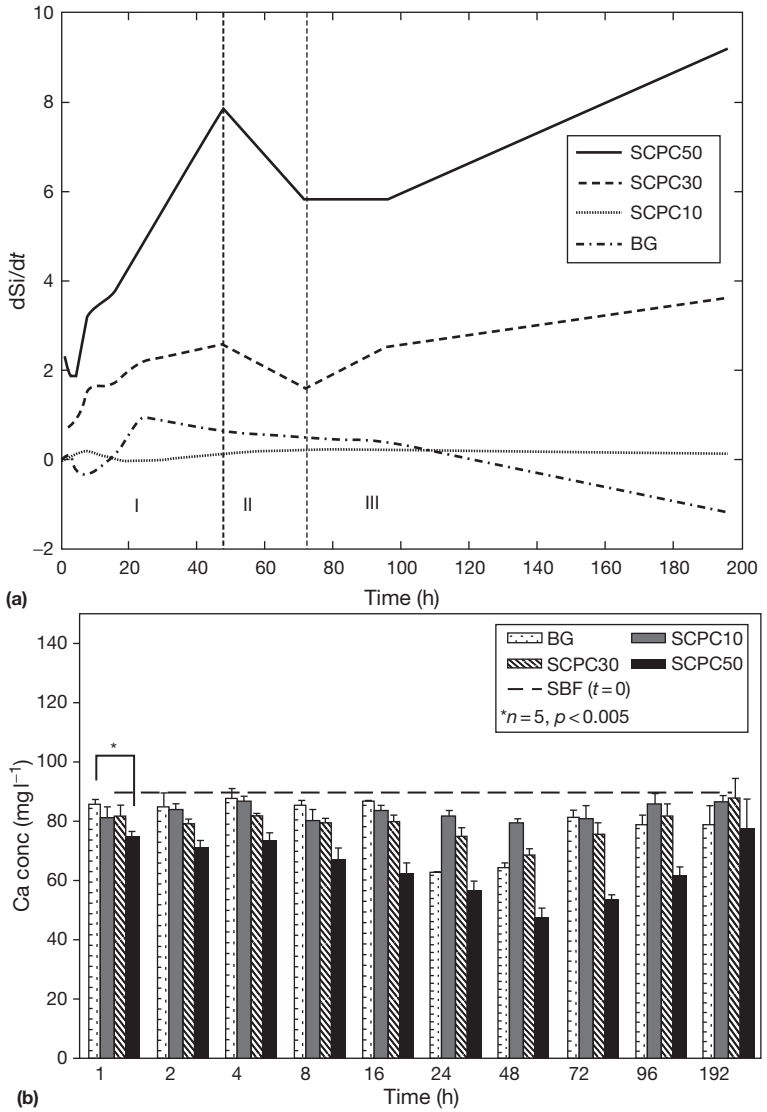

Figure 4 (a) ICP analyses of the Si concentration in SBF incubated with bioactive silica–calcium phosphate nanocomposite (SCPC). The weight ratio of silica/calcium phosphate components are 1/9, 3/7, and 5/5 for SCPC10, SCPC30, and SCPC50, respectively. The rate of Si release has been taken as a measure of the dissolution kinetics of the bioceramics. The dissolution kinetics of SCPC30 and SCPC50 has been divided into three stages. Stage I (0–48 h) was characterized by a high rate of Si release from SCPC30 and SCPC50 due to initial material dissolution. Stage II (48–72 h) involved a marked reduction in the dissolution rate because of the precipitation of the calcium phosphate layer on the material surface. Stage III (72–192 h) was characterized by a controlled bulk degradation of SCPC30 and SCPC50, which resulted in a linear increase in the rate of Si release. SCPC10 showed minimal dissolution in SBF at all time points. Bioactive glass (BG) exhibited a high initial dissolution rate up to 24 h of immersion. However, the dissolution rate was almost zero during 24–48 h, and continued to decrease thereafter up to 192 h. Thus, BG unlike SCPC, showed no evidence of bulk-degradation behavior. (b) ICP analysis of Ca^{2+} concentrations in SBF incubated with various SCPC formulations (see Figure 5a for details) and BG particles (90–425 mm). SCPC50 exhibited significantly higher Ca-uptake compared to BG or other SCPC samples up to 96 h of immersion. During the first 48 h of immersion, the average rate of Ca-uptake from SBF was in the order: BG (1.32 mg/L/h) < SCPC10 (2.04 mg/L/h) < SCPC30 (2.67 mg/L/h) < SCPC50 (4.94 mg/L/h), which indicated a faster initial kinetics of Ca-uptake in SBF solutions incubated with SCPC samples compared to those incubated with BG. Between 48 and 96 h, the kinetics of Ca-uptake decreased markedly for all samples, and after 192 h of immersion, there was no significant difference in the Ca^{2+} concentrations of SBF incubated with the different bioceramic samples. ($^*n = 5$, $p < 0.005$). Reproduced from Gupta, G.; Kirakodu, S.; El-Ghannam, A. *J. Biomed. Mater. Res. A* **2007**, *80*(2), 486–496, with permission from Wiley.

surface charge of bioactive glass were found to correlate well with the modifications in the surface chemistry as analyzed by SEM-EDX, and FTIR during the dissolution–precipitation steps as measured by the ionic concentration of the solution. Initially, the surface of bioactive glass was negatively charged, and then during 3 days of immersion two reversals of the sign of the surface were detected. Figure 6 demonstrates the variations in the ζ-potential of bioactive glass as a function of immersion duration in SBF.[15] The dynamic shift in the sign of the ζ-potential from an initially negative surface to a positively charged surface directly corresponded with the formation of an amorphous Ca-P surface layer. As the amorphous Ca-P

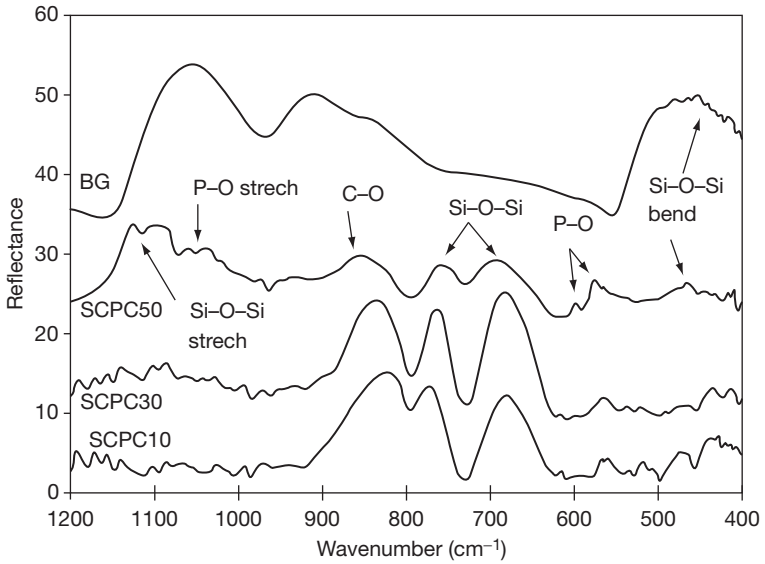

Figure 5 FTIR analysis of various formulations of SCPC after a 2-hr immersion in SBF. Distinct orthophosphate (570 and 590 cm^{-1}) and carbonate (850 cm^{-1}) peaks corresponding to a biological HA were detected on the surface of SCPC50. However, these peaks were not detected for SCPC10, SCPC30, or BG after the same time period. This indicated a much faster kinetics of bioactivity reactions on the surface of Si-rich SCPC50 compared to the other bioactive ceramic samples. matured into a crystalline HA layer, the surface charge changed from a positive to a negative surface.[15] Methods to enhance the chemical reactivity of bioactive ceramics include modifications of the chemistry, crystal lattice parameters and porosity. Porosity of bioactive materials provides high surface area in contact with tissue fluids and therefore enhances dissolution and back precipitation of a HA surface layer.

Mercury porosimetry is widely used to measure percent porosity, pore size distribution and pore area. BET gas adsorption method is used to measure porosity and specific surface area for nanoporous materials.

1.109.5. Bioactive Glasses

1.109.5.1. Composition of Bioactive Glasses

Bioactive glass first synthesized by Hench and associates[16] is the generic name of a class of amorphous material covering a wide range of bioactivity arising from variations of the chemical composition. The most common components of bioactive glass are SiO_2, CaO, Na_2O, and P_2O_5. Figure 7 shows the location of the composition of 45S5 bioactive glass on a ternary SiO_2–CaO–Na_2O phase diagram with a constant 6 wt% P_2O_5. The SiO_2 content determines the chemical stability and bioactivity of the glass. Melt-derived glass which has SiO_2 content larger than 60 wt% is chemically stable and hence is not bioactive. (45S5) bioactive glass with 45 wt% SiO_2 is characterized by a high rate of bioactivity. Figure 8 is a ternary SiO_2–CaO–Na_2O phase diagram showing the bioactivity boundaries of various glass compositions.[17]

Push out test data of glass coupons in rat tibia led to the formulation of a ternary diagram, first published in a review paper.[17] Glass compositions that fall in region A are characterized by a high rate of bioactivity in that a high interfacial bond strength is established within 30 days. Glass compositions in region B contain high silica content and therefore, they are chemically stable and behave as inert materials. Glass compositions in region C are degradable inside the body and can be resorbed in 10–30 days. Compositions in region D have high ratios of $(Na_2O + CaO)/SiO_2$ and therefore they either devitrify or produce nonpractical glasses with very short workability range.

Many additives including MgO, K_2O, B_2O_3, Al_2O_3, Zr_2O_3, CaF_2, and Ta_2O_5 can be added to bioactive glass to improve its mechanical and thermal properties or to enhance the workability range. However, a boundary condition that limits the modification of the composition of bioactive glass is the bioactivity property. For example, addition of more than

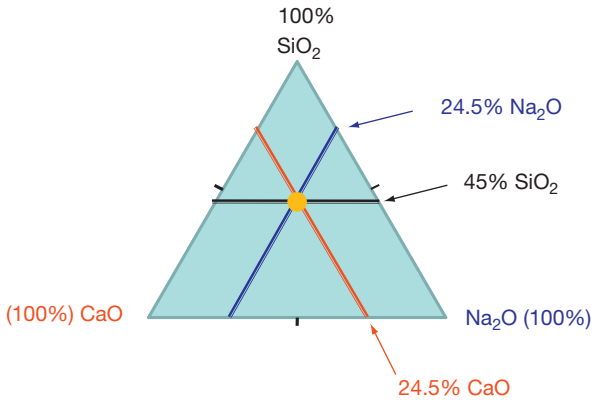

Figure 7 A ternary phase diagram for silicate glass in the system SiO_2–Na_2O–CaO. The composition of a bioactive glass containing 24.5% Na_2O, 24.5% CaO, and 45% SiO_2 in weight percent (at a fixed 6% P_2O_5, not shown) is identified in the diagram.

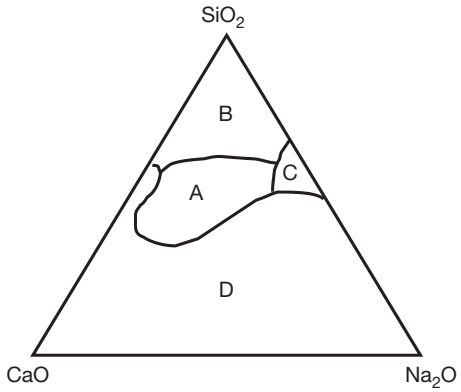

Figure 8 Phase diagrams for Na_2O–CaO–SiO_2 showing four composition regions A, B, C, D, and the corresponding bone-bioactivity property. Reproduced from Hench, L. *J. Am. Ceram. Soc.* **1991**, *74*(7), 1487–1510, with permission from Wiley.

1.0–1.5 wt% Al_2O_3 or 1.5–3.0 wt% multivalent ions such as Ta^{5+} enhances the workability range and the thermomechanical properties of the material. However, Al^{3+} and Ta^{5+} ions have an adverse effect on bone cell viability and function, thereby inhibiting the bone-bonding ability.[18] The substitution of MgO for CaO enhances the chemical stability of bioactive glass and hence lowers the rate of dissolution and overall bioactivity reactions. The decreased solubility of Mg-containing bioactive glass is attributed to the low electronegativity of Mg compared to Ca. Therefore, the percent of ionic character in Mg–O bond is lower than that in the Ca–O bond, which makes the former glass more stable in physiologic solution.

1.109.5.2. Structure of Bioactive Glass

Bioactive glass is like any glass, an amorphous material with short range atomic order. This structure is opposite to the long range atomic order found in crystalline materials. The SiO_2 in bioactive glass serves as a network former giving the glass structure its chemical stability. The CaO and Na_2O serve as network modifiers, which facilitate glass melting during processing and bioactivity in contact with the biological system. A schematic representation of the bonds between SiO_2 and Na_2O and CaO in bioactive glass is shown in Figure 9.

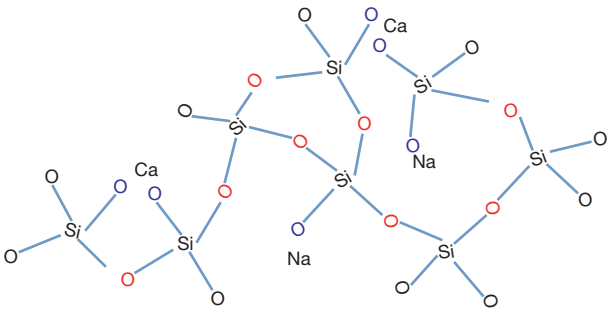

Figure 9 A schematic showing the silicate structure of bioactive glass. The bridging oxygen in the Si–O–Si bond stabilizes the material. Nonbridging oxygen in the -Si–O–Na and -Si–O–Ca- enhances the dissolution in physiological solutions.

The oxygen atom (red color) that connects two silicon atoms in the silicate structure (Figure 9) is called bridging oxygen, while that which connects silicon atom to Ca or Na atom is called nonbridging oxygen. The ratio of bridging oxygen to nonbridging oxygen in the bioactive glass controls the rate of bioactivity reaction *in vitro* and the resorbability of the material. The ratio of the percent of the ionic character to that of covalent character in these bonds increases in the order Na–O > Ca–O > Si–O. Therefore, the bridging oxygen that is connected to two silicon atoms (Si–O–Si) is responsible for the stability of bioactive glass. Bioactive glasses with high percentage of SiO_2 are chemically stable due to the domination of the strong Si–O–Si bond in the material. As the concentration of the SiO_2 in bioactive glass decreases and the Na_2O or CaO increases, the chemical stability decreases and the rate of reactivity increases. However, at a critical low SiO_2 concentration, the high concentration of cations breaks down the silicate structure and the material will lose its ability to make glass (region D in the Figure 8). In such case, as the temperature of the melt cools down, it experiences uncontrolled crystallization (i.e., devitrification).

1.109.5.3. Description of *In Vitro* Bioactivity

Many studies have immersed bioactive glass in SBF (Table 2) and analyzed dissolution kinetics and modifications in the surface properties of the material. Immersion of bioactive glass in SBF revealed one aspect of the mechanism of bioactivity that includes ion exchange and dissolution–precipitation reaction.

1.109.5.3.1. Ion exchange and dissolution–precipitation reaction

Immersion of bioactive glass in the SBF results in an initial partial dissolution of the material surface associated with a precipitation of a calcium phosphate that resembles the mineral phase of bone.[19] As the ionic character in Na–O bond is high (85%), Na ions can easily exchange with H^+ of the H_2O molecule upon contact with tissue fluids. On the other hand, the ionic character in the Si–O bond is about 55% with the

remaining 45% being covalent in nature. The high covalent character of the Si–O bond limits the dissolution of silica. The strength of the Si–O bond renders the release of Si ions from bioactive glass much lower than the release of the Na. The enhanced release of Na ions from the bioactive glass surface has a dual effect: First; it renders the material surface rich on $Si–O^-\ldots{}^+H$ groups and second, it increases the pH of the interfacial fluids. Both the surface Si–OH and the alkaline pH work synergistically to enhance the precipitation of a Ca-P layer on the material surface. The disruption of the silicate network as a result of Na and Ca ions release increases the concentration of hydrated silica (silanol ≡ Si–OH). The Si–OH groups form a highly porous silica gel surface layer that traps Ca ions. Figure 10 is a schematic showing the formation of the silica gel layer and the nucleation and the deposition of a calcium phosphate layer on the materials surface. The calcium phosphate layer starts as amorphous with high Ca/P ratio. However, as the dissolution–precipitation continues the amorphous calcium phosphate layer crystallizes into defective, carbonate-containing HA.[19]

1.109.5.3.2. Protein adsorption

The dissolution–precipitation reactions at the interface between bioactive glass and tissue fluids take place in the presence of serum protein. The range for total protein concentration in serum is 60–85 $g\,l^{-1}$. Calcium binding proteins such as fibronectin (FN) and vitronectin are present in minor concentrations in serum and serve as cell attachment proteins.

Immersion of bioactive glass in tissue culture medium that contains 10% serum slows down the formation of the HA surface layer.[20] The inhibition of the formation of the HA layer is attributed to the chelation of calcium by calcium binding proteins such as albumin.[21] Subjecting bioactive glass to two immersion treatments: first in SBF without proteins, and then in tissue culture medium, significantly enhanced serum protein adsorption.[22] Interestingly, the calcium phosphate layer formed on the surface of bioactive glass shows high affinity to serum FN an attachment protein known to enhance bone cell adhesion and function. As described by Knabe *et al.* (**Chapter 1.114, Bioactivity: Mechanisms**) the concentration of FN on the calcium phosphate layer of bioactive glass facilitates bone cell adhesion and deposition of bone tissue directly onto the material surface.

1.109.5.3.3. Bone cell interaction with bioactive glass in vitro

Some *in vitro* studies have shown an unfavorable cell response to bioactive glass; obviously such data are against the favorable tissue response *in vivo*. Such findings were related to the accumulation of the dissolved ions released from bioactive glass into the tissue culture medium, specifically the hydroxyl ions, which raise the pH of the medium to a level that lyses the cells.[20] Accumulation of dissolved ions does not occur *in vivo* due to the fluid turn over and blood circulation. Therefore, the effect of the accumulation of dissolved ions can be eliminated by reacting the glass in SBF before cell seeding as well as using a high ratio of medium to glass surface area. Seeding bone cells on the surface of bioactive glass that has been covered by a calcium phosphate layer and adsorbed serum protein stimulated bone cell adhesion, proliferation, differentiation, and bone tissue formation *in vitro*.[20–22] A porous template made of bioactive glass with a modified surface was able to reproduce the mechanism of bone formation when seeded with bone cells within 7 days.[20]

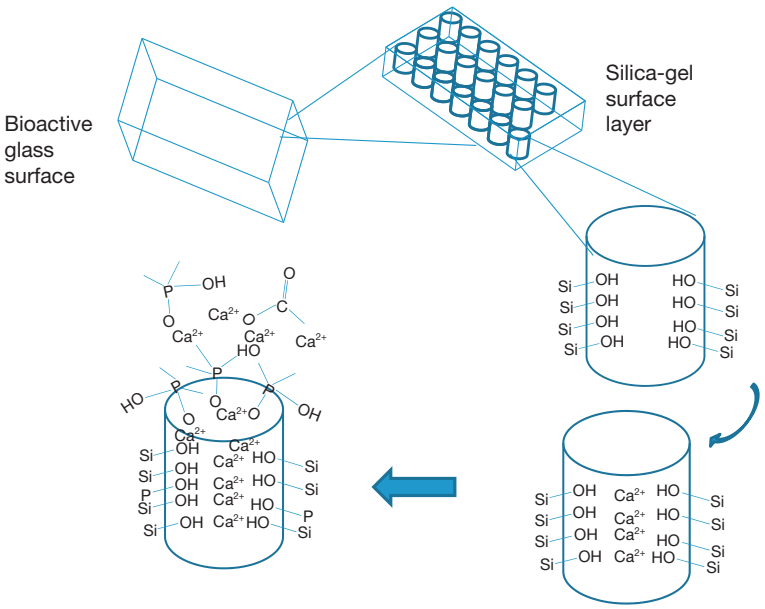

Figure 10 A schematic showing the surface modifications of bioactive glass due to interaction with simulated body fluid. The initial cations release leaves behind a highly porous glass surface rich in silanol groups (silica gel). The pores of the silica gel nucleate calcium-phosphate precipitation onto the material surface. The structure of the deposited calcium phosphate starts as amorphous and then matures into carbonate containing hydroxyapatite.

1.109.5.4. Effect of Preparation Methods of Glass on Its Bioactivity

1.109.5.4.1. Melting method

Bioactive glass is usually prepared by melting. The source of SiO_2 is sand with 99.99% purity. Na_2O and CaO are derived from the corresponding carbonate compounds. Heating up Na_2CO_3 and $CaCO_3$ during glass melting produces fresh and active Na_2O and CaO respectively according to equations [I] and [II] below.

$$CaCO_3 \rightarrow CaO + CO_2 \quad [I]$$

$$Na_2CO_3 \rightarrow Na_2O + CO_2 \quad [II]$$

The byproduct is CO_2 that diffuses as bubbles through the glass melt into the air. Diffusion of the CO_2 bubbles help mixing the melt together to produce homogenous glass. P_2O_5 can be added to the glass batch before melting as an oxide or can be derived from any calcium phosphate compound. The raw materials and corresponding oxide weight and mole percentages used for the preparation of 45S5 bioactive glass are shown in Table 3.

Bioactive glass batch is melted at 1350–1400 °C in a Pt–Rh crucible. After homogenization, the melt is poured in a mold. The rapid cooling of the glass creates strains within the material that deteriorates the mechanical stability. To relieve any strains, the glass is subjected to an annealing treatment at 450–550 °C depending on the glass composition and glass softening temperature. The annealing temperature is usually determined based on the differential thermal analysis of the glass. Figure 11 is a schematic showing the melting and annealing of bioactive glass.

Table 3 Chemical composition and selected raw materials used for bioactive glass preparation

Oxides (wt%)	*Oxides (mol%)*	*Raw material*
45 SiO_2	46.1	Sand (SiO_2)
24.5 Na_2O	24.4	Na_2CO_3
24.5 CaO	26.9	$CaCO_3$
6 P_2O_5	2.6	P_2O_5

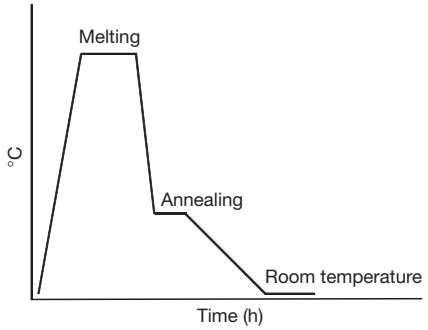

Figure 11 A schematic showing the processing steps involved in the synthesis of bioactive glass by melting. Solid glass objects are required to be annealed after melting to release strains created during cooling the melt. For the preparation of bioactive glass granules, the melt may be quenched in DI water; no annealing treatment is required in that case.

Bioactive glass prepared by melting is dense and does not contain any remnants of organic components or water. Therefore, melt-derived bioactive glass has limited surface area in contact with tissue fluids when used in bulk as an implant. However, using bioactive glass as granules increases the surface area in contact with tissue fluids and cells and therefore facilitates surface reactivity and bone formation.

1.109.5.4.2. Sol–gel method

Preparation of bioactive glass by a sol–gel method is based on a solution reaction between chemical reagents that contain Si, Na, and Ca components at room temperature. The most widely used precursor for silica is tetraethoxysilane (TEOS, $Si(O–C_2H_5)_4$) which is usually reacted with soluble salts of sodium (NaCl) and calcium (Ca_2NO_3). These precursors undergo various forms of hydrolysis and polycondensation reactions. The silicon alkoxide $Si–(OR)_4$ where R is C_2H_5 for TEOS (and CH_3, when the precursor is tetramethoxysilane (TMOS)), is insoluble in water. Therefore, adding water to TEOS will form a sol, that is, a solution with TEOS suspension. The addition of an acid or a base as a catalyst allows the silane to mix with the water and catalyzes the formation of a network of polymers and cross-linkages that leads to the creation of a gel. Using an acid leads to longer chains and fewer cross-linkages, resulting in a gel with smaller pores, while an alkaline catalyst promotes cross-linkages and leads to larger pore-sizes. Hydrolysis of TEOS in water involves attachment of hydroxyl ions to the silicon atom. The degree of hydrolysis of the TEOS may vary from partial to full. Depending on the amount of water and the presence of catalyst, hydrolysis may proceed to completion as represented by the following equation:

$$Si(O-C_2H_5)_4 + 4H_2O \rightarrow Si(OH)_4 + 4C_2H_5OH \quad [III]$$

The hydrolyzed $Si–(OH)_4$ can undergo a condensation (polymerization) reaction to produce a gel.

$$(OH)_3Si-OH + HO-Si(OH)_3 \rightarrow (OH)_3Si-(O-Si-O)_n-Si(OH)_3 \quad [IV]$$

Soluble sodium and calcium ions are added slowly during the hydrolysis step to create Si–O–Na and Si–O–Ca–O–Si bonds. When the particles in the sol form long *polymers* (chains) that span the entire sol, a gel is formed. The gelation reaction proceeds slowly; the sol–gel is usually left for sometime for an ageing process to allow for complete cross-linking of the silicate. The gel is typically heated to 110 °C in order to remove water and alcohol and is then subjected to annealing thermal treatment to create the glass. This treatment is typically performed at temperatures between 350 and 700 °C.[23] The properties of the final bioactive glass product are controlled by processing parameters such as: molecular weight of the reactants, solution pH, solvent concentration, gelation temperature, and duration and drying conditions.

Foaming of sol–gel derived bioactive glasses provides the potential to make a scaffold with hierarchal interconnected porous structure to promote cell adhesion, tissue ingrowth, and nutrient delivery.[24,25] Porosity and structure of foamed sol–gel can be engineered by controlling processing parameters such as temperature at which the foaming process is carried out, surfactant type and concentration, gelling agent type and

concentration, added water concentration and glass composition.[26,27] Example of the foaming technique was described by Jones and Hench,[26] were aliquots of 50 ml 58S sol (60 mol% SiO_2, 36 mol% CaO, 4 mol% P_2O_5) were foamed by vigorous agitation with the addition of 1.5-ml surfactant (Teepol, a detergent containing a low-concentration mixture of anionic and nonionic surfactants), de-ionized water (improves foamability of surfactant), and 5 vol% hydrofluoric acid (HF, a catalyst for polycondensation).[25] It has been shown that small changes in added water concentration can be used at constant temperature and constant concentrations of surfactant and gelling agent to produce different pore networks at reproducible gelling times. The amount of water added to aid the surfactant produced a simplest control over pore size of the foams.[25] Although the foaming process changes the sol–gel process slightly, compared to the production of monoliths and powders, the 58S foam is still highly bioactive as indicated by the deposition of a carbonate-HA layer after 2 h immersion in SBF at 37 °C and 175-rpm agitation.[25]

A major advantage of the sol–gel method over the melting method is the purity of the final product and the ability to expand the compositional range of bioactivity for glasses in the system SiO_2–CaO–Na_2O. The gel-derived glasses contain entrapped nanopores that significantly increase the surface area of the material in contact with tissue fluids. Moreover, the low processing temperature of the gel-derived glass maximizes the number of the silanol (Si–OH) groups on the material surface. The silanol group is critical for the bioactivity reaction of the material. In addition, gel-derived bioactive glass may contain high energy silicate ring structures, which further activate the material's reactivity.

Primary human osteoblasts seeded on porous 58S scaffolds formed mineralized nodules within 10 days of culture.[28] Osteoblasts attached and proliferated on the foams as demonstrated by SEM. Mineralization was also observed when cells were incubated with medium supplemented with certain dilutions of the dissolution products of 58S foam. However, undiluted dissolution products from the foams were toxic to the cells and caused significant apoptosis (programmed cell death).[28] Earlier *in vitro* studies by El-Ghannam *et al.*[20] have demonstrated a similar adverse effect on bone cell function of the accumulation of the degradation products of porous bioactive glass prepared by melting. To alleviate the undesirable modifications in the medium pH and composition due to ion release from the bioactive substrate, it was necessary to preimmerse the bioactive glass in SBF before cell culture and to use high ratio of medium volume to scaffold surface area during cell culture.[7,20]

1.109.6. Bioactive Glass Ceramics

Bioactive glass ceramic is made by subjecting bioactive glass to thermal treatment in order to transform its structure from amorphous to crystalline. The crystallization of bioactive glass improves the mechanical strength significantly. Table 4 is a list of various bioactive glass ceramics and the corresponding mechanical properties.[29] Bioactive glass ceramics bond to bone and have been successfully used as load bearing implants.[10] The crystallization of bioactive glass limits the dissolution rate of the material and, therefore, slows down the surface reactivity.[30] Figure 12 demonstrates the significant decrease in the solubility of bioactive glass as the percentage of crystallization increased.[30] In addition, the negative ζ-potential of bioactive glass ceramic containing as little as 5% crystallization was significantly higher than that of amorphous bioactive glass ($p < 0.02$) (Figure 13(a)).[30] The high surface negativity of bioactive ceramic reduced the amount of protein adsorbed onto the material surface significantly. Figure 13(b) demonstrates the change in the ζ-potential and corresponding amount of protein adsorbed onto the surface of bioactive glass ceramic.[30] Moreover, significant changes in the protein conformation was observed; the ratio of (amide I)/(amide II) functional groups of all proteins adsorbed onto amorphous bioactive glass was greater than that of proteins adsorbed onto

Table 4 Mechanical properties of A/W and bioverit bioactive glass ceramics

Properties	*A/W glass ceramic*	*Bioverit I*	*Bioverit II*	*Bioverit III*

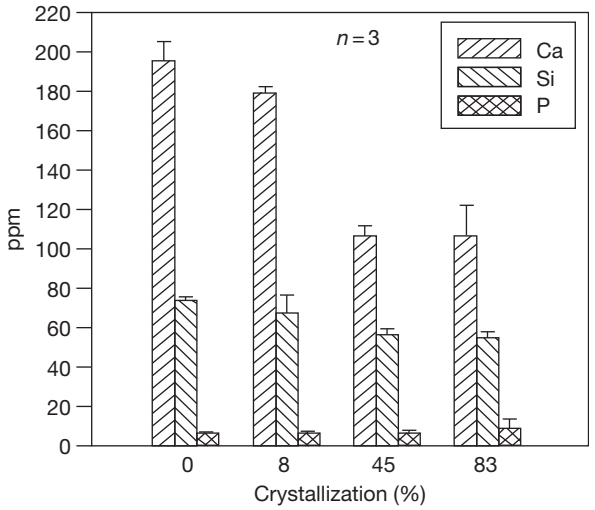

Figure 12 ICP concentration analyses of Ca, Si, and P ions in SBF after immersion of bioactive glass containing different crystallization percentages for 24 h. The amount of Ca and Si ions released from bioactive glass containing 8% crystallization was slightly lower than that released from control untreated bioactive glass. However, the amount of Ca and Si ions released from bioactive glass containing 45% or 83% crystallization was significantly lower than that released from control untreated bioactive glass ($p < 0.001$). P concentration in SBF increased as the crystallization percentage in the immersed bioactive glass increased; however, this increase was not statistically significant. Values shown are means ± standard deviation (SD) of three determinations. Reproduced from El-Ghannam, A.; Hamazawy, E.; Yehia, A. *J. Biomed. Mater. Res.* **2001**, *55*(3), 387–395, with permission from Wiley.

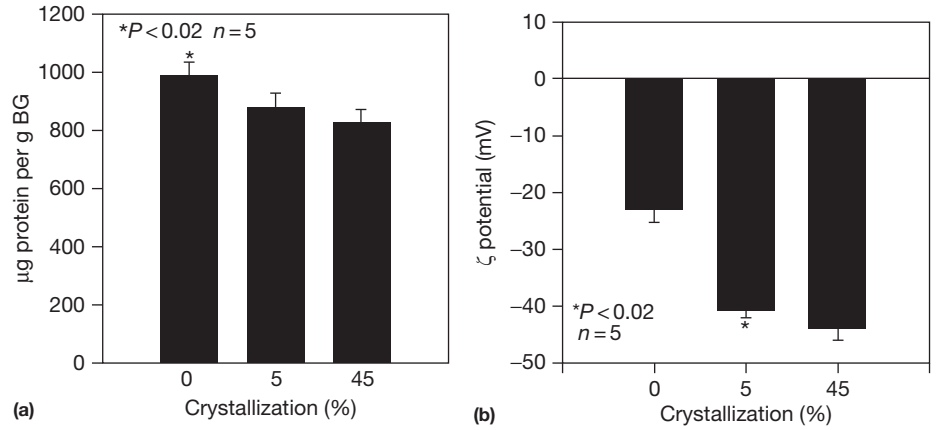

Figure 13 (a) Comparison of the amount of serum protein adsorbed onto thermally treated and control untreated bioactive glass. Control untreated bioactive glass adsorbed a statistically significant higher amount of serum protein than bioactive glass samples containing 5% crystallization ($p < 0.02$). Moreover, there was no significant difference between the amount of serum protein adsorbed onto bioactive glass containing 5% or 45% crystallization. Values shown are means ± SD of five determinations. (b) Zeta potential measurements of bioactive glass immersed in SBF. Bioactive glass containing 5% crystallization had a statistically significant higher negative zeta potential value than control untreated bioactive glass ($p < 0.02$). Moreover, statistical analysis showed that the difference in surface charge between bioactive glass samples containing 5% and that containing 45% crystallization was not significant. Values shown are means ± SD of five determinations. Reproduced from El-Ghannam, A.; Hamazawy, E.; Yehia, A. *J. Biomed. Mater. Res.* **2001**, *55*(3), 387–395, with permission from Wiley.

crystallized bioactive glass (Table 5).[31] The Gaussian curve fitting analysis suggests that the significant expression of amide I, rich in charged and flexible unordered secondary structure of adsorbed FN, stimulated bone cell adhesion and spreading on the surface of amorphous bioactive glass. Bioactive glass ceramic enforces protein conformation that exposes amide II, rich in neutral and stable β-sheet structure and α-helix; this limited cell adhesion and spreading.[31]

1.109.7. Calcium Phosphate Ceramics

Calcium phosphates are crystalline materials with chemical composition similar to the mineral phase of bone, therefore, they are capable of inducing a direct bond with bone. Table 6 shows the main composition of the inorganic components of enamel, dentin, and bone as compared to stoichiometric HA.[32] The rate of bone bonding is enhanced by the controlled dissolution rate of the material. The solubility and bioactivity depends on the Ca/P ratio, inclusion of dopants, and crystallinity of the material. A variety of calcium phosphate ceramics have been employed as implant material. Among them, HA ($Ca_{10}(PO_4)_6(OH)_2$) and tricalcium phosphate (TCP, $Ca_3(PO_4)_2$) are the most widely used.

Table 6 Concentration of the inorganic components of enamel, dentin, bone, and stoichiometric HA

Composition (wt%)	*Enamel*	*Dentin*	*Bone*	*HA*
Calcium	36.5	35.1	34.8	39.6

1.109.7.1. Composition of Hydroxyapatite

Stoichiometric HA has a rigid hexagonal dipyramidal crystalline structure[33] with a molecular formula $Ca_5(PO_4)_3OH$. The crystal unit cell of HA has ten Ca ions ($10Ca^{2+}$) and therefore, its chemical formula is usually written as $Ca_{10}(PO_4)_6(OH)_2$. Stoichiometry of HA refers to exact atomic ratio of Ca/P (10/6 or 1.67) in the unit cell. Deviation from the exact Ca/P ratio destabilizes the crystal and enhances the dissolution of the material. Thus, calcium deficient HA with a Ca/P ratio of 1.60 is slightly more bioactive than stoichiometric HA with a Ca/P ratio of 1.67.

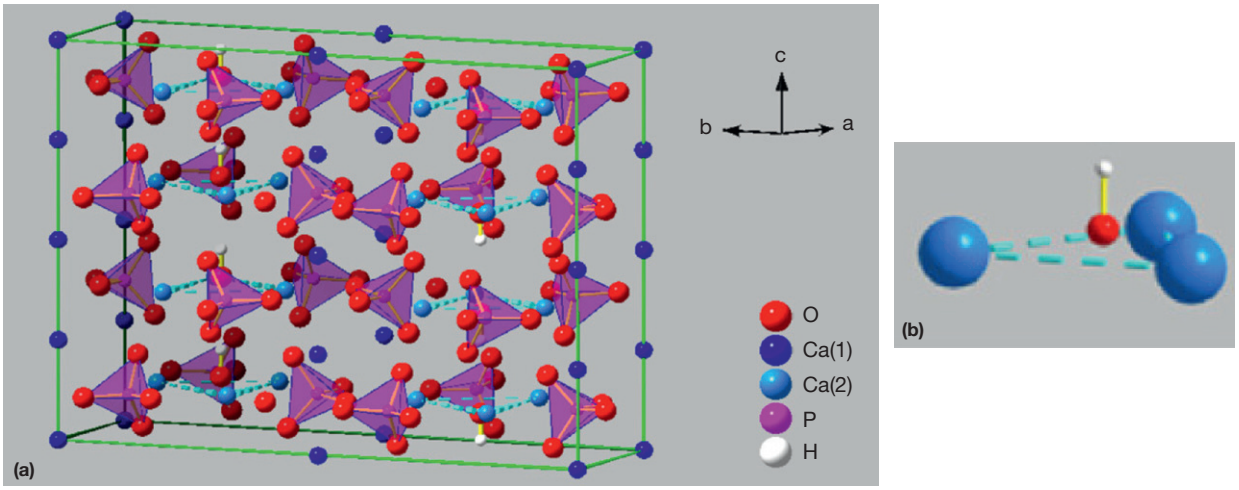

Figure 14 (a) Defect-free 1×1×2 supercell of the monoclinic modification of hydroxyapatite as obtained from full geometry optimization. The phosphate ions are illustrated as transparent tetrahedra. Two types of calcium ions are discriminated, that is, Ca(1) sites which are located between the phosphate ions and Ca(2) sites which form staggered triangles (dashed lines) resulting in channels parallel to the c-axis. Figure 14(b) illustrates that each Ca(2)-triangle embeds a hydroxide ion. Reproduced from Zahn, D.; Hochrein, O. *J. Solid State Chem.* **2008**, *181*(8), 1712–1716, with permission from Elsevier.

1.109.7.2. Structure of Hydroxyapatite

Phosphorous occurs in apatite in tetrahedral coordination, with the central P atom in the 6 h special position. The strong atomic bonds in the phosphate polyhedra are responsible for the rigidity of the apatite structure. Apatite has two types of calcium ions: Ca(1) sites which are located between the phosphate ions and Ca(2) sites which form staggered triangles resulting in channels parallel to the *c*-axis (**Figure 14(a)** and **14(b)**).[33]

Each of the three Ca(2) atoms at the corners of the triangles is bonded to the central anion, for example, OH^-, F^-, or Cl^- in HA, fluorapatite, or chloroapatite, respectively (**Figure 15**).[34] The diameter of these anions correlates well with the chemical stability of the material. The diameter of F^- ion is small enough to fit in the Ca(2) triangle without introducing appreciable alteration of the apatite structure. Therefore, fluoroapatite is a highly stable material with limited bioactivity properties. This also explains the stability of biological fluoroapatite that naturally exists in tooth enamel and which contributes to the protection against tooth decay. The OH^- anion is too large to fit within the rigid plane of the Ca(2) triangle. Therefore, the OH^- anion is displaced above or below the plane causing strains that results in shifts in the position of the Ca(2) ions without affecting the stoichiometry of HA. The accommodation of the OH^- is enhanced by the presence of vacancies and impurity atoms in the material. The atomic rearrangement required to accommodate the hydroxyl group makes stoichiometric HA slightly less stable than fluorapatite.[34]

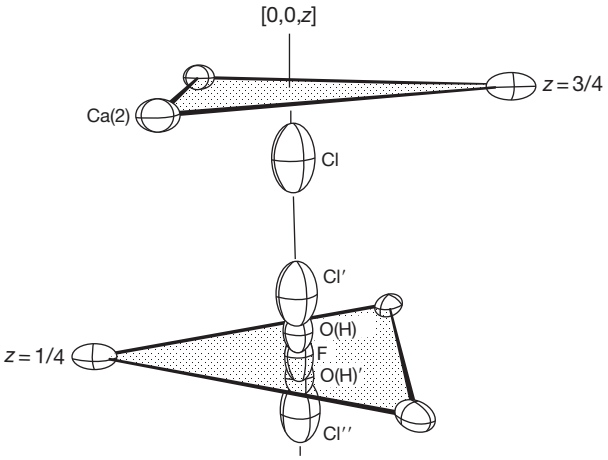

Figure 15 Depiction of possible anion positions in the hexagonal ternary apatite structure. Stippled planes represent mirror planes at $z = 1/4$, 3/4, each containing a triangle of Ca2 atoms (connected by 'bonds'). Atom Cl represents a Cl atom disordered below the mirror plane at $z = 3/4$, and other column anions represent five possible anion neighbors associated with the mirror plane at $z = 1/4$ (Cl′ = Cl disordered above plane; O(H) = OH oxygen disordered above that plane; F = fluorine atoms at 0,0, 1/4; O(H)′ and Cl″ represent OH and Cl disordered below the mirror plane at $z = 1/4$). Reproduced from Hughes, J.; Rakovan, J. *Rev. Mineral. Geochem.* **2002**, *48*(1), 1, with permission from Mineralogical Society of America.

1.109.7.3. Calcium Deficient Hydroxyapatite

Synthetic calcium deficient HA (CDHA) has a Ca/P ratio in the average range 1.5–1.6. The general chemical formulas are usually written as:

$$Ca_{10-x}(HPO_4)_x(PO_4)_{6-x}(OH)_{2-x}(H_2O)_x \quad \text{with } 0 < x \leq 1$$

or

$$Ca_{10-x}(HPO_4)_x(PO_4)_{6-x}(OH)_{2-x}$$

When one Ca ion is missing, it leaves behind two negative charges that need to be balanced in order to keep the neutrality of the crystal.[33] The crystal neutrality is restored by either protonation of one (PO_4^{3-}) group and one OH^- group or by protonation of (PO_4^{3-}) and removal of an OH^- ion, respectively.

The structure and chemistry of apatite allow for cationic (e.g., Na^+, Mg^{2+}, Zn^{2+}, Sr^{2+}) and anionic (e.g., SO_4^{2-}, CO_3^{2-}, SiO_4^{4-}) substitutions. The metal cations substitute for Ca^{2+} and the anions replace PO_4^{3-} and to a limited extent the OH^-. Substitutions in the apatite structure for Ca^{2+}, PO_4^{3-}, or OH^- groups modifies the crystal lattice parameters and changes the solubility and bioactivity properties of the material.

Solid state nuclear magnetic resonance (NMR) spectroscopy showed that natural bone contains only about 20% of the OH ions present in pure HA.[35] The carbonate ions in biological apatite accounts for 3–8 wt% of the material.[36] Carbonate (CO_3^{2-}) can substitute for either the (OH^-) or the (PO_4^{3-}) groups, designated as type A or type B substitution respectively.[37] Polarized infrared (IR) studies suggested that for A type substitution to occur, the planar CO_3^{2-} ions in the anion channels are oriented approximately parallel to the *c*-axis to minimize the steric strain related to the incorporation of this large ion. On the other hand, the substitution of the smaller CO_3^{2-} group for the larger tetrahedral PO_4^{3-} group cause a contraction in the *a*-axis and expansion in the *c*-axis compared to the CO_3^{2-} free apatite.[37] The changes in the crystal lattice parameters introduced by the incorporation of the carbonate group renders the material more soluble and bioactive than carbonate-free apatite.

1.109.7.4. Preparation of Hydroxyapatite

As is described in length in the chapter by Rey *et al.*, solid state reaction between $Ca(OH)_2$ or $CaCO_3$ and $CaHPO_4 \cdot 2H_2O$ or β-$Ca_3(PO_4)_2$ above 950 °C forms HA.[38,39] Formation of HA by wet precipitation method is achieved by the dropwise addition of phosphoric acid (H_3PO_4) to an aqueous suspension of calcium hydroxide ($Ca(OH)_2$) under constant stirring.[40–42] The pH of the solution is maintained by the addition of NH_4OH to ensure the formation of HA according to eqn [III].

$$10Ca(OH)_2 + 6H_3PO_4 \rightarrow Ca_{10}(PO_4)_6(OH)_2 + 18H_2O \quad [V]$$

An alternate method is to mix solutions of calcium nitrate tetrahydrate and di-ammonium hydrogen orthophosphate at pH ~11 according to eqn [IV].

$$10Ca(NO_3)_2 \cdot 4H_2O + 6(NH_4) \cdot 2HPO_4 + 8NH_4OH \rightarrow Ca10(PO_4)_6(OH)_2 + 20NH_4NO_3 + 6H_2O \quad [VI]$$

The precipitate is dried and calcined at 400 °C for 1 h to obtain HA.[43,44] The nature and crystallinity of HA depends significantly on the processing parameters such as temperature, pH, and reaction durations.[45–47] **Figure 16** shows the typical X-ray diffraction analysis (XRD) spectra for HA prepared by wet precipitation method and calcined at 1200 °C.[48]

HA can also be prepared by the hydrolysis of $CaHPO_4$, β-$Ca_3(PO_4)_2$, α-$Ca_3(PO_4)_2$, $Ca_2PO_4(OH)_2H_2O$, $Ca_8H_2(PO_4)_6 \cdot 5H_2O$, or $Ca_3(PO_4)_2 \cdot CaO$ at low temperature (usually <100 °C) resulting in micron sized needle-like crystals. The HA produced by hydrolysis is highly nonstochiometric with the Ca/P ratio in the range of (1.5–1.71).[49] The morphology of HA crystals affects the bioactivity properties and can be controlled by treatment temperature.[50–52] Single phase HA crystallites (10–60 nm) in diameter have been prepared by mixing $Ca(NO_3)_2 \cdot 4H_2O$, and $(NH_4)_2HPO_4$ at 200 °C under saturated water vapor pressure.[53] Micron size HA granules (50–1000 μm) have been prepared by hydrothermal treatment of α-TCP at 105–200 °C.[54,55] HA powder prepared by this method is characterized by a high degree of crystallinity with a Ca/P ratio close to stoichiometric value.

1.109.7.5. Composition and Structure of β-TCP

The TCP family comprises of three polymorphic structures: β-TCP, α-TCP, and α′-TCP; all of which have higher resorption rate than most other calcium phosphate ceramics. Of the TCPs, β-TCP and to a lesser extent α-TCP have widely been used as bone grafts. The stoichiometric formula of β-TCP is $Ca_3(PO_4)_2$ with a Ca/P ratio of 1.5 and a O/P ratio of 4.0. The crystal structure of β-TCP has been well characterized by X-ray and neutron powder diffraction methods.[56–58] β-TCP has a rhombohedral crystal structure with unit cell parameters ($a = b = 10.4352$ Å, $c = 37.4029$ Å, $\alpha = \beta = 90°$, and $\gamma = 120°$).[58] The crystal structure is in the form of two independent columns, column 'A' containing two Ca and one P atoms and a second slightly distorted column 'B' containing six Ca and four P atoms. A schematic of the two columns is shown in **Figure 17**.[58] Ca atoms are located in five crystallographic sites labeled Ca(1)–Ca(5) within the two columns, however, with variable coordination numbers and different energy states.[58,59]

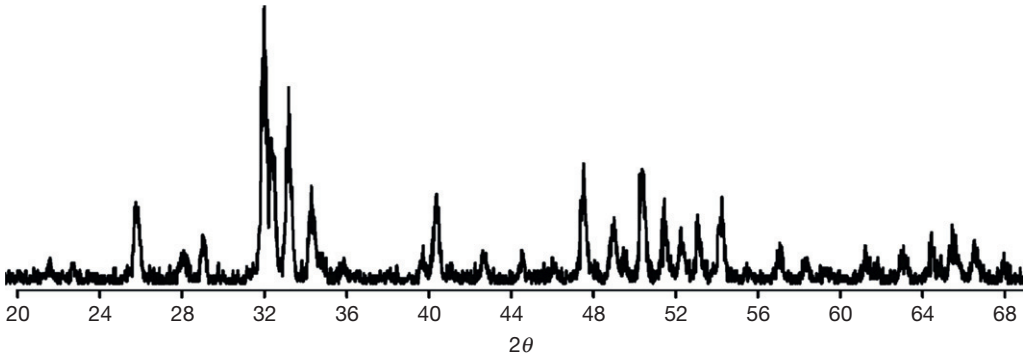

Figure 16 X-ray diffraction patterns of hydroxyapatite prepared by wet method and sintered at 1200 °C showing exclusively sharp, clear reflections corresponding to hydroxyapatite, which confirm the phase purity and high degree of crystallinity. Solid State Chem*. **2003**, *175*(2), 272–277, with permission from Elsevier.

1.109.7.6. Synthesis of β-TCP

β-TCP can be prepared via a wet precipitation method by mixing stoichiometric ratios of $Ca(NO_3)_2$ with $(NH_4)_2HPO_4$ at pH 10 at 60 °C for 2 h, followed by aging at boiling point for 2 h.[60] It can also be produced by a solid state reaction between $CaCO_3$ and $Ca_2P_2O_7$ or $CaHPO_4$ at 1350 °C for 3.5 h or 1000 °C for 24 h respectively.[58,61] **Figure 18(a)** shows the XRD spectra of β-TCP calcined at 1150 °C for 4 h.[62] In addition, amorphous TCP nanoparticles (α-TCP, chemical formula: $Ca_3(PO_4)_2$) can be prepared by flame spray pyrolysis.[63,64] **Figure 18(b)** shows the FTIR spectra of as-prepared and sintered TCP nanoparticles produced by flame spray synthesis. Broad absorption bands for as-prepared powder transformed into distinct peaks characteristic for crystallized β-TCP after calcination at 900 °C.[64]

Dopants can be introduced in the β-TCP crystal structure prepared using either method. Mg or Zn substituted β-TCP is produced by including $Mg(NO_3)_2 \cdot 6H_2O$ or $Zn(NO_3)_2 \cdot 6H_2O$ in the wet precipitation synthesis route respectively.[56,65] Sr substitution in β-TCP has been achieved by sintering β-TCP and α-$Sr_3(PO_4)_2$ at 1000 °C for 15 h.[66] Similarly, Li-, Na-, and K-substituted β-TCP is produced by a solid state reaction between Li_2CO_3, Na_2CO_3, and K_2CO_3 respectively at 1000 °C for 24 h.[57] Discs of β-TCP containing both Sr and Mg substitution have been produced by mixing MgO and SrO with pure β-TCP followed by powder compaction and sintering at 1250 °C for 2 h.[67]

1.109.7.7. Effect of Composition, Dissolution, Protein Adsorption, and HA Crystal Size on Bioactivity

Calcium phosphate ceramics can be transformed into biological apatite by virtue of its reactivity and the associated dissolution, precipitation, and ion exchange in physiological media. Materials undergoing high dissolution in simulated physiological solution also induce back precipitation of a biologically equivalent apatite on their surface.[4] The formation of a bioactive surface layer of apatite on HA *in vitro* depends on the physicochemical characteristics of the material which can be controlled by processing parameters such as temperature and pressure.

Interesting data follow from an experiment in which amorphous HA was calcined at 600 or 900 °C to produce small, defective, or mature undefective crystalline material respectively.[68] The samples were immersed in SBF and the calcium uptake (decrease in Ca concentration in the solution) was taken as an indicator of the deposition of the apatite layer on the material surface. The uptake of Ca by HA decreased with the increase in the pretreatment temperature of HA. This indicates that an increase in the crystallinity of HA aggravates the deposition of surface apatite layer due to the enhanced stability of the material. Moreover, the HA pretreated at low temperature has small and defective crystals and hence, high surface energy. The high surface energy would facilitate rapid formation of surface apatite layer. On the other hand, well crystallized HA prepared at high temperature would require to undergo an initial dissolution to reach the critical super saturation essential for the deposition of the surface apatite layer.[68]

Substitution of Ca by Mg, Zn, Si, and Y has been reported to enhance solubility and bioactivity properties of HA ceramic.[69–74] The dissolution rate of stoichiometric HA (s-HA), β-TCP, α-TCP, oxyhydroxyapatite (OHA), tetracalcium phosphate (TTCP) and of a commercial CDHA was evaluated in tris buffer.[75] In terms of the dissolution of calcium the rate of dissolution decreased in the order:

$$\text{TTCP} > \alpha\text{-TCP} > \text{OHA} > \beta\text{-TCP} > \text{CDHA} > \text{s-HA}$$

However, in terms of the dissolution of phosphate the order was[75]:

$$\alpha\text{-TCP} > \text{CDHA} \approx \beta\text{-TCP} > \text{OHA} \approx \text{s-HA} > \text{TTCP}$$

On the other hand, the Ca/P ratio in the different ceramics varied as follows:

$$\text{TTCP} > \text{OHA} > \text{s-HA} > \text{CDHA} > \alpha\text{-TCP} > \beta\text{-TCP}$$

The differences in the rate of dissolution of Ca and P among these materials have been attributed to the precipitation of another calcium phosphate phase, particularly on CDHA, OHA, and TTCP.

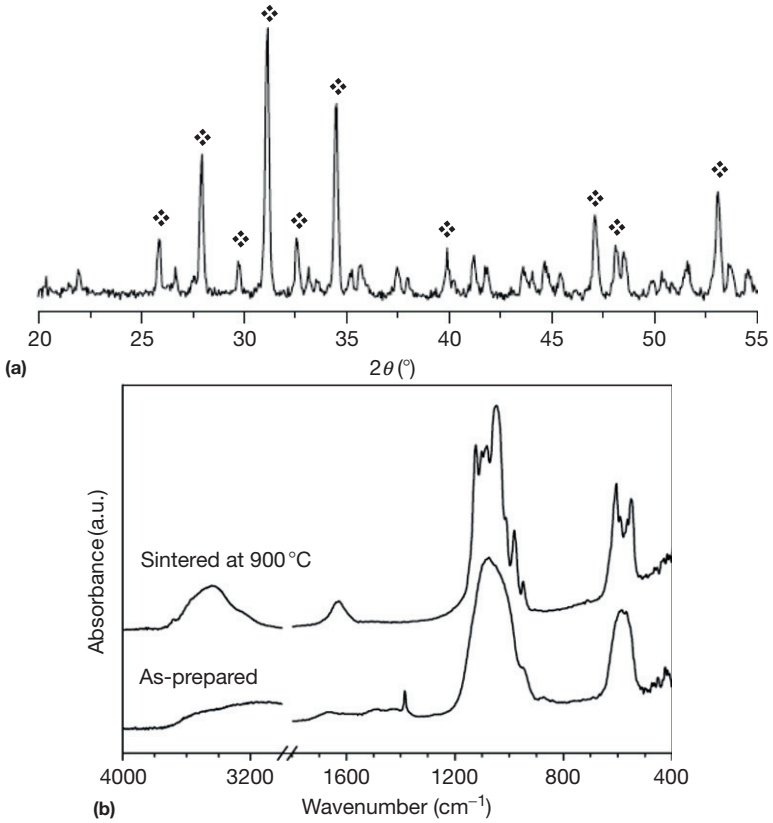

Figure 18 (a) XRD spectra of β-TCP samples after calcinations at 1150 °C for 4 h. The ten most intense diffraction peaks are shown on the patterns. The three maximum diffraction peaks corresponding to the planes (0 2 10), (2 2 0), and (2 1 4) of β-TCP were observed at 31.0°, 34.4°, and 27.8°. (b) FTIR spectra of as-prepared and sintered tricalcium phosphate nanoparticles produced by flame spray synthesis. Broad absorption bands for as-prepared amorphous TCP powder transform into distinct peaks characteristic for β-TCP after crystallization by calcination at 900 °C. Nanotechnology* **2006**, *17*, 2054, with permission from IOP Publishing Ltd.

Ceramic dissolution is a causative factor for the bone-bonding ability of HA.[4,76] The degradation of HA depends on its composition, crystal size, porosity, and preparation methods.[37] De Bruijn *et al.*[77] have reported the bioactivity of HA of varying crystallinity after implantation in rat femora for up to 4 weeks. It was found that amorphous HA coating demonstrates a gradual surface degradation while the high crystallinity HA coating showed negligible degradation. Degradation was also related to the bone apposition, as high bone apposition was present on the amorphous HA coating compared to highly crystalline HA coating.[77]

Protein adsorption onto the surface of bioactive ceramic and the initial cell response and tissue integration with the implant are closely related. The high affinity between functional protein groups like R–COO^- and $R-NH_3^+$ and the Ca^{2+} and PO_4^{3-} sites on the calcium phosphate ceramics enhances protein adsorption.[78,79] It has been proposed that the affinity of the (COO^-) protein functional group to the Ca^{2+} site of the ceramic is larger than that of the (NH^{3+}) of proteins to the PO_4^{3-} sites.[80] However, the hydrophobic segments on the protein molecule can also interact with the surface of inert ceramics and contribute to protein adsorption. Greater adsorption of serum proteins has been observed on HA than on bioactive glass or metals such as titanium (cp-Ti) or stainless steel.[22,81] Figure 19 shows a comparison of the amount of serum proteins adsorbed on HA as compared to untreated or SBF treated bioactive glass.[22] However, there is a difference in the adsorption profile of HA and bioactive glass as described in greater detail in **Chapter 1.114, Bioactivity: Mechanisms**.

1.109.7.8. Apatite Formation and Bone Bioactivity of β-TCP

The bone-bonding ability of β-TCP is well documented,[11,82–84] however, there has been a considerable debate on the apatite-forming ability of β-TCP upon immersion in SBF.[11,84–86] The formation of an apatite layer on β-TCP after immersion in SBF has been demonstrated (Figure 20).[85] Small apatite crystals appeared after immersion for 7 days and continued to grow into larger apatite clusters until day 14.[85] Other studies however, have reported that both β-TCP and natural calcite do not form apatite on their surfaces *in vitro* or *in vivo*.[11] These authors suggested that the bone-bonding ability of β-TCP is related to its high rate of resorbability.[11] The discrepancies in the results related to the *in vitro* deposition of the HA surface layer can easily be understood in view of the differences in the experimental design, conditions under which the material was prepared, and the sensitivity of the SBF. In any event, the formation of the

surface HA should be looked at as an indicator of bioactivity but not necessarily the only indicator. One main attribute for the HA layer that deposits on the surface of a bioactive material is to provide calcium ions necessary for bone cell function and tissue formation. Therefore, the high rate of dissolution of β-TCP will provide calcium ions.

Several studies have shown that the degradation of TCP is solution-mediated and cell-mediated.[82,87,88] However, in view of the high solubility product (2.30×10^{-30}) of β-TCP, solution-mediated resorption is expected to be dominating. The variations in the coordination number and bond energy of the Ca–O bonds in β-TCP enhances atomic debonding of β-TCP in physiological solution, the collapse of the crystal structure, and the initiation of bulk degradation. Although the Ca^{2+} and PO_4^{3-} ions are released rapidly from β-TCP into the physiological solution, the dynamic degradation of the material surface would not enhance the nucleation and crystallization of an apatite layer. It is also possible that the initial calcium phosphate that precipitates on β-TCP is thermodynamically unstable and would not allow persistent apatite crystallization.[86]

Macrophages are triggered and participate in the bulk degradation of the material contributing to the cell-mediated resorption. Many studies have reported that tartrate-resistant acid phosphatase (TRAP) positive multinucleated cells and macrophages adhered to β-TCP after implantation.[82,88] The presence of TRAP-positive cells indicates the role of osteoclasts in the resorption process as TRAP is associated with osteoclastic activity. Moreover, osteoblastic differentiation markers such as type I procollagen and osteopontin have also been detected along with osteoclasts suggesting that bone formation and β-TCP resorption are concurrent processes.

A common method to stabilize the structure of β-TCP is by doping it with metal ions such as Mg, Zn, Sr, Si, etc.[56,59,66] These metal ions substitute some of the Ca bound to the PO_4^{3-} polyhedra and improve thermal stability during processing, mechanical properties, dissolution, and bioactivity characteristics of the material. Yoshida *et al.*[57] have proposed a mechanism for the substitution of up to 9.1 mol% Ca in β-TCP by monovalent or trivalent metal ions, while the divalent metals can substitute up to 13.6 mol% Ca. **Figure 21** shows the decrease in the dissolution rate of β-TCP upon substitution of Ca with 0.1–1.0 mol% Zn indicating the significant improvement in material's stability.[65] It has been suggested that the adsorption of Zn and Mg ions from physiologic solution onto the β-TCP surface enhances Ca substitution and inhibits ceramic dissolution.[89]

The ability of calcium phosphate ceramics to adsorb proteins is an important factor that mediates initial cell response to the material. Many studies have shown that biphasic HA-TCP composite adsorbs significantly higher serum protein than pure HA as shown in **Figure 22**.[90,91] Moreover, it has been shown that β-TCP adsorbs more FN than dense HA; however, the difference was not statistically significant,[62] most probably due to the interference of other parameters including ceramic dissolution and its effect on the medium pH.

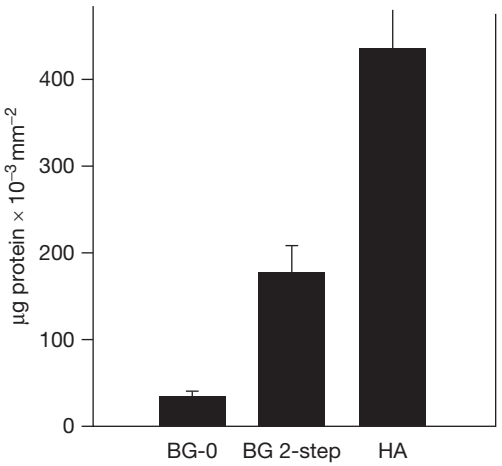

Figure 19 Quantitative analysis of serum protein adsorption onto the surface of bioactive ceramics immersed in tissue culture medium containing 10% serum. HA ceramic adsorbed significantly more serum protein than SBF-treated bioactive glass covered with hydroxyapatite layer (BG 2-step) or control untreated bioactive glass (BG-0) without a hydroxyapatite surface layer. Bioactive glass covered with hydroxyapatite layer adsorbed a significantly higher amount of serum protein than unmodified bioactive glass.

1.109.8. Silica-Calcium Phosphate Nanocomposite

1.109.8.1. Composition

SCPC is a family name for a series of compositions in a multiphase bioactive ceramic system.[1,6,14,92] **Table 7** shows the

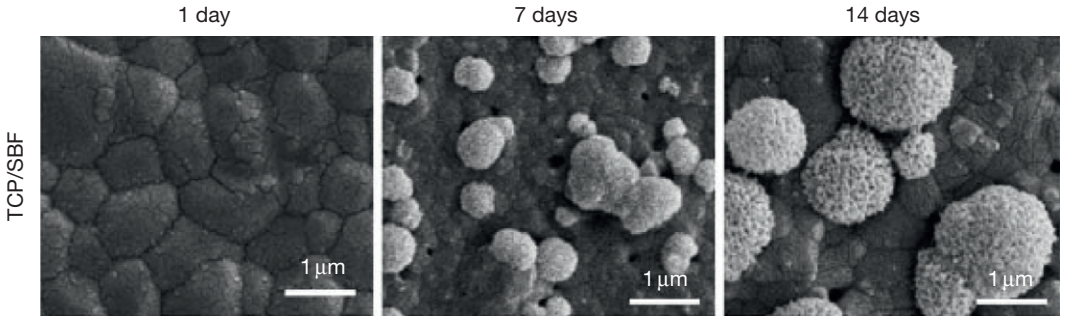

Figure 20 SEM images of apatite growth on the surface of β-TCP when soaked in SBF. Most of the apatite crystals remained submicron-sized, whereas others grew into larger apatite clusters. composition of selected formulations of SCPC. Interestingly, SCPC formulations with high content of silica are more bioactive than calcium phosphate-rich SCPC compounds, HA ceramic or bioactive glass.[1,6,14] The excellent bioactivity and resorbability of the Si rich SCPC are due to the physicochemical properties of its mineral constituents as well as the controlled release of Si from the substrate. Figure 4(a) demonstrates the controlled release of Si from SCPC50 as compared to that released from bioactive glass and other SCPC formulations. Although silica is an essential component of SCPC, the bioactivity property of the material is not dependent on the ionic diffusion from the bulk to the surface as is the case with bioactive glass. Critical size bone defects implanted with SCPC showed extensive bone regeneration and graft material resorption 3 weeks postoperatively.[6] On the other hand, defects grafted with bioactive glass particles for the same time period showed bone formation but with only initial resorption of the graft material.

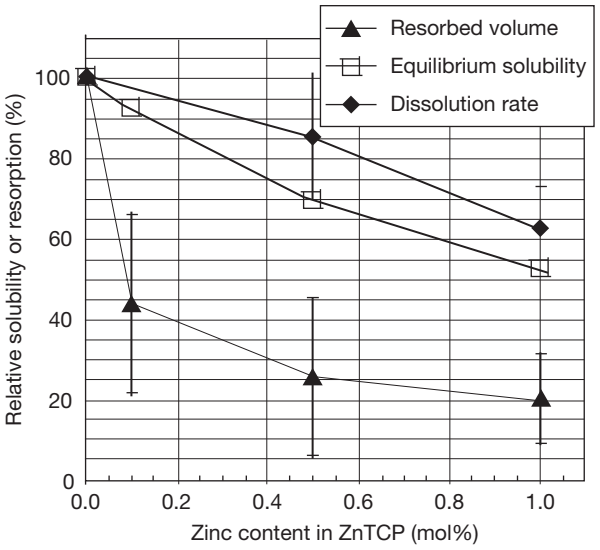

Figure 21 Dissolution rates for TCP discs doped with Zn in the concentration range from 0 to 10 mol%. The samples were immersed in 35 mL of 0.08 M acetic acid and sodium acetate buffer solution at pH 5.5 and 25 ± 3°C in polystyrene bottles for 300 min with a stirring rate of 440 ± 10 rpm. The pH value of the immersing solution was selected to be similar to that associated with osteoclastic resorption. 1.109.8.2. Crystalline Structure

The crystalline structure of SCPC is complex, as it contains solid solutions instead of pure phases. Depending on the initial chemical composition and processing parameters, the SCPC may contain a combination of two or more of the following phases ('ss' stands for solid solution): α-quartz (SiO_2) ss, β-quartz (SiO_2) ss, α-crystobalite (SiO_2) ss, cyclosilicate $Na_3CaPSiO_7$ (clinophosinaite) ss, β-$NaCaPO_4$ (rhenanite) ss, Na_2CaSiO_4 ss, γ-$Ca_2P_2O_7$ ss, β-$Ca_2P_2O_7$ ss, and α- or β-$Ca_3(PO_4)_2$ ss. Among these phases, β-$NaCaPO_4$ ss and α-cristobalite ss are the most thermodynamically stable phases. Formation of solid solutions in SCPC ceramic phases underlies the excellent bioactivity and resorbability properties of SCPC. Solid solutions form during thermal processing of SCPC, when ion diffusion at the grain boundaries between the calcium phosphate and silica takes place. The silicate-phosphate ionic diffusion is an example of the crystal modification during processing. This ionic diffusion results in substitution of solid solution due to the similarity between the ionic radii of silicon ion (0.04 nm) and that of phosphorous ion (0.035 nm). The effect of silicate-phosphate ion substitution is threefold: first, it lowers the crystallization temperature of the silicate and calcium phosphate phases. Crystalline phases that form at low temperature are known to be more bioactive than crystals that form at high temperature. Second, incorporation of foreign atoms (Si or P) in the host phase (calcium phosphate or silica, respectively) introduces strains within the crystal that enhances the fatigue and mechanical strength of the material. But most importantly, the incorporation of the impurity atoms in the

Table 7 Chemical composition in mol% of selected formulations of silica-calcium phosphate nanocomposite

Sample	*SiO_2*	*P_2O_5*	*CaO*	*Na_2O*
SCPC10	3.31	31.13	62.25	3.31
SCPC30	10.74	26.18	52.34	10.74
SCPC50	19.49	20.34	40.68	19.49
SCPC75	32.9	11.4	22.8	32.9

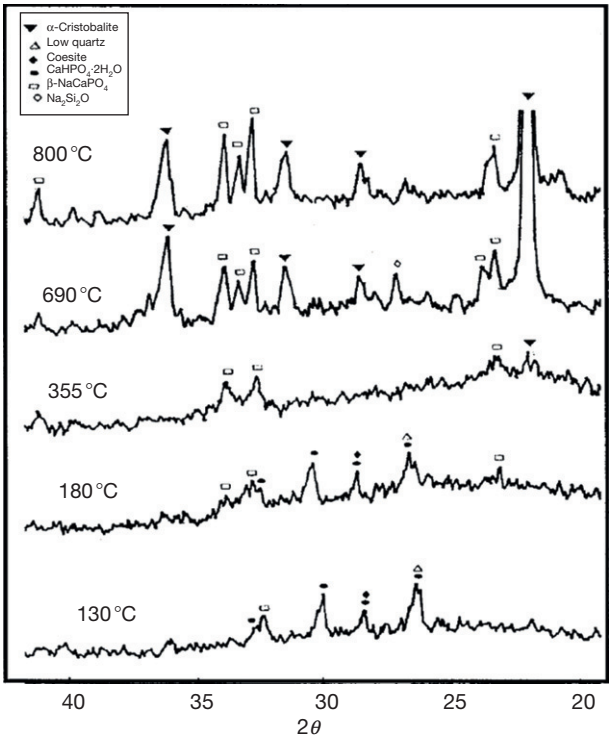

Figure 23 XRD analysis of SCPC75 treated at 130° or 180 °C showed ill crystallization and comprised of brushite ($CaHPO_4$), L-quartz (SiO_2) ss, and rhenanite (β-$NaCaPO_4$) ss. After treatment at 355 °C, $CaHPO_4$ transformed into β-$NaCaPO_4$ ss and low quartz ss transformed into α-cristobalite ss. The intensity of the signal characteristic of β-$NaCaPO_4$ ss and α-cristobalite ss increased, after treatment at 690° and 800 °C, indicating maturation of the crystalline structure of these two phases. Reproduced from El-Ghannam A. *J. Biomed. Mater. Res. A* **2004**, *69*(3), 490–501, with permission from Wiley.

quartz or cristobalite solid solutions enhances the dissolution of the material. In the absence of impurities, quartz is highly stable (beach sand is high purity quartz). The dissolution and bioactivity of (quartz ss) can be controlled by the amount of impurities incorporated in its crystal structure during thermal treatment.

The phases that form when the SCPC reactants are mixed together and treated at temperatures in the range 180–350 °C are highly defective and immature. The ill crystallization at low temperature is reflected on the XRD diagrams, which show broad and low intensity diffraction patterns (Figure 23).[6] This is particularly true for SCPC compounds rich in calcium phosphate where the blend of phases that form at low

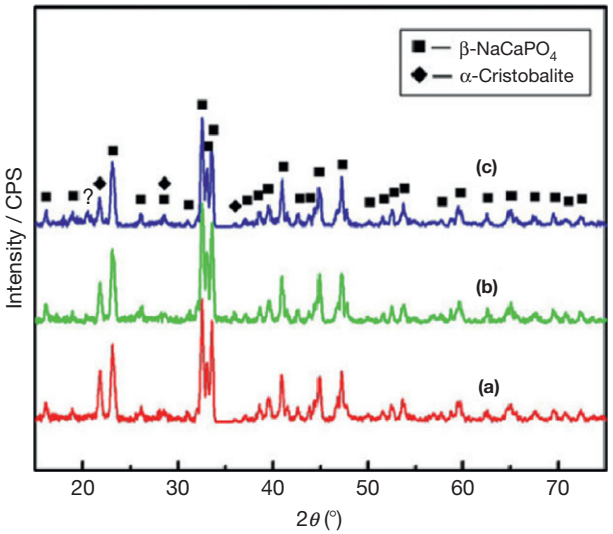

Figure 24 XRD patterns of SCPC50 pressed at 200 MPa and sintered at (a) 900 °C, (b) 1000 °C, and (c) 1100 °C for 3 h. The crystalline phases of the SCPC were mainly composed of β-$NaCaPO_4$ ss and α-cristobalite ss. Reproduced from Liu, X.; El-Ghannam, A. *J. Mater. Sci. Mater. Med.* **2010**, *21*, 2087–2094, with permission from Springer.

temperature includes $CaHPO_4$ and β-$Ca_2P_2O_7$ ss, which are thermodynamically unstable and hence highly biodegradable. When the SCPC material is heated at higher temperature, these preliminary calcium phosphate phases transform into the more stable β-rhenanite.[5] The silica phase that forms at low temperature is α-quartz ss which transforms into α-cristobalite at higher temperature. The most thermodynamically stable phases in the SCPC system are α-cristobalite (SiO_2) ss and β-rhenanite ($NaCaPO_4$) ss. This can easily be noticed as the two phases (α-cristoblaite and β-rhenanite) are consistently formed in all SCPC chemical formulations after thermal treatment at 900–1200 °C (Figure 24).[93] Detailed studies on the effect of temperature and pressure on the crystallization behavior of SCPC have been described elsewhere.[93]

1.109.8.3. Structure and Bioactivity Relationship

The SCPC is composed of nanocrystals of resorbable minerals, which induce unique bioactivity and mechanical properties. Transmission electron microscopy (TEM) analyses showed that the grain size of the SCPC75 is 50 nm (Figure 25).[92] The high density of grain boundaries in SCPC would provide preferential sites for protein adsorption and cell adhesion. X-ray microanalysis of the elemental distribution along the grain boundary showed maximum counts for Ca, Na, and P, whereas the grain bulk was rich in Si (Figure 26). These results indicate that calcium phosphate-containing phases preferred to distribute along the boundaries of the silica grains. The migration of Ca, P, and Na atoms to the grain boundaries may be enhanced by the low melting points of the β-$NaCaPO_4$ and $Na_3CaPSiO_7$ phases.[92] Therefore, unlike bioactive glass, both the surface and the bulk of the SCPC acquired bioactive structure and composition that facilitated bioactivity on the nanoscale level.

1.109.8.3.1. Effect of structure and composition on protein adsorption

SCPC formulations containing $CaHPO_4$ ss adsorbed significantly higher amount of serum proteins than those containing γ-$Ca_2P_2O_7$ ss and α-$Ca_3(PO_4)_2$ ss (Figure 27).[6] The enhanced protein adsorption on $CaHPO_4$ could be attributed to the high ratio of Ca-to-P sites on the material surface.[94] On the other hand, the inhibition of protein adsorption onto the surface of SCPC containing pyrophosphates and TCP is due to the low ratio of Ca-to-P and high surface negativity of $(P_2O_7)^{4-}$ and $[(PO_4)_2]^{6-}$ respectively. The increase in surface negativity of the material makes adsorption of negatively charged glycoprotein molecules a thermodynamically unfavorable reaction ($\Delta G > 0$).[95] On the other hand, as $Ca_2P_2O_7$ ss is transformed into β-$NaCaPO_4$ ss serum protein adsorption is enhanced.[6] The affinity of β-$NaCaPO_4$ ss toward serum proteins would be higher than that of $Ca_2P_2O_7$ ss due to the presence of labile Na atom in the former compound. Protein adsorption was also significantly affected by the crystallization and phase transformation of the silica phase(s). In all SCPC composites, the crystallization of amorphous silica inhibited protein adsorption. However, the degree of inhibition varied depending on the concentration and nature of the crystalline silica phase. Composites that contained α-cristobalite ss adsorbed a significantly higher amount of serum proteins than those contained α-quartz ss. The enhancement of protein adsorption correlates well with the fact that α-cristobalite ss has a comparatively open atomic structure, whereas the atoms in quartz are more closely linked.[96] Moreover, α-cristobalite ss is characterized by a tetragonal structure, with a low degree of symmetry than the hexagonal structure of α-quartz ss. Therefore, in biological solutions, α-cristobalite ss becomes more polar than α-quartz ss and can easily bind to the active sites of the protein molecules. In addition, the formation of crystal defects and solid solutions is expected to increase after treatment at high temperature ($\geq$800 °C), which further activates the material by providing charged surface sites favorable for protein binding. It is also possible that the surface characteristics of SCPC dictate a favorable protein conformation that enhances cell–material interaction and tissue integration.

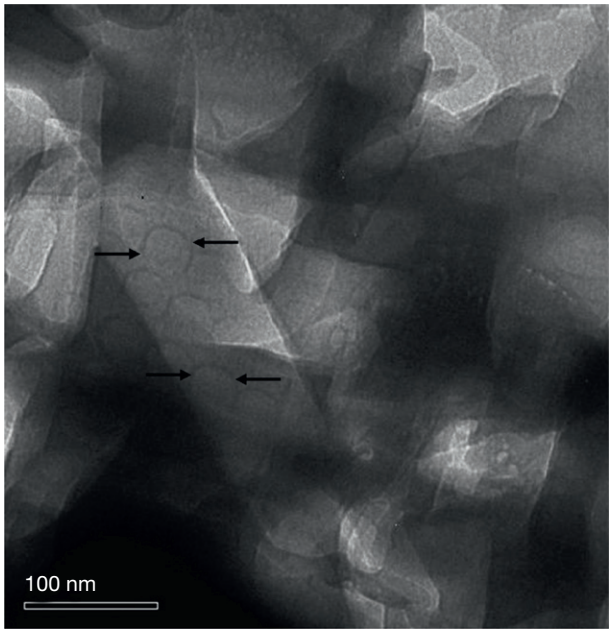

Figure 25 TEM micrograph showing SCPC nanocrystals within the size range of 50 nm. The arrows point to the edge of 50-nm crystals. The scale bar is 100 nm. Reproduced from El-Ghannam, A.; Ning, C.; Mehta, J. *J. Biomed. Mater. Res. A* **2004**, *71*(3), 377–390, with permission from Wiley.

1.109.8.3.2. Effect of structure and composition on bone cell function and tissue formation

The effect of silica-rich SCPC compounds on bone cell function and tissue formation is related to the two crystalline phases that make up the material; β-$NaCaPO_4$ ss and

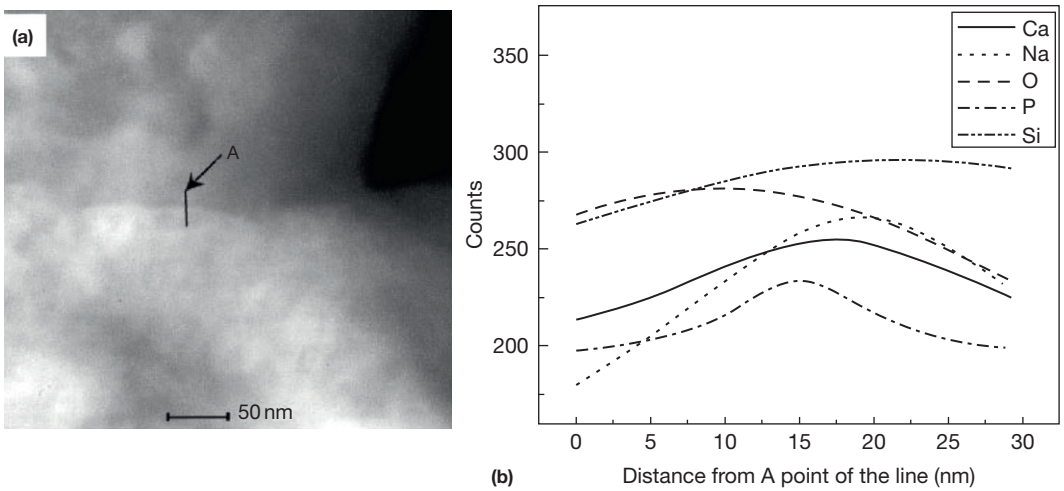

Figure 26 (a) A grain boundary in the SCPC nanocomposite. (b) Lorentzian fitting curves of elemental distributions along the grain boundary in (a). X-ray microanalysis showed that the grain boundary had maximum counts for Ca, Na, and P, whereas the grain bulk was rich in Si. These results indicate that calcium-phosphate–containing phases preferred to distribute along the boundaries between silica grains. Reproduced from El-Ghannam, A.; Ning, C.; Mehta, J. *J. Biomed. Mater. Res. A* **2004**, *71*(3), 377–390, with permission from Wiley.

α-cristobalite (SiO_2) ss. β-$NaCaPO_4$ ss phase has enhanced bioactivity compared to other calcium phosphate phases including TCP due to the presence of the labile sodium (Na), which can easily be exchanged with a proton in the aqueous physiological solution, rendering the surface biologically active thereby promoting osteogenesis and matrix calcification.[6]

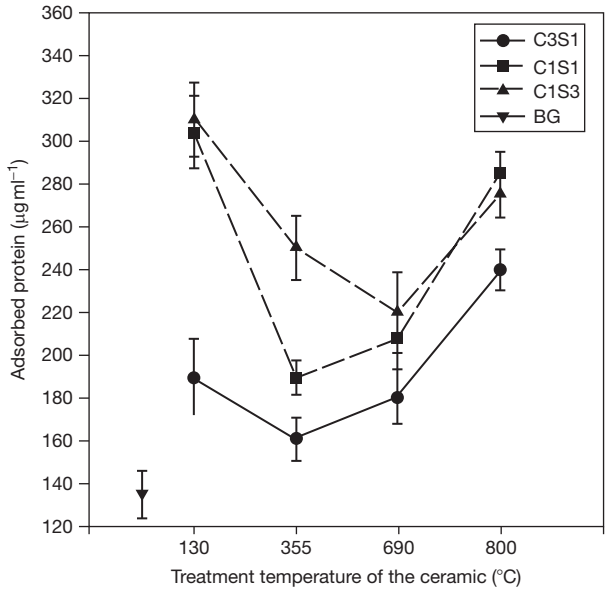

Figure 27 Total protein analysis showed that SCPC adsorbed a significantly higher amount of serum protein than bioactive glass ($p < 0.00001$). Silica-rich C1S3 (SCPC75) adsorbed significantly higher amounts of serum protein than calcium phosphate-rich C3S1 (SCPC25) ($p < 0.003$). The XRD structures of the SCPC ceramics after each thermal treatment are found in [6]. These results indicate that the porosity and modified crystalline structure of silica-rich SCPC enhanced protein adsorption. Reproduced from El-Ghannam A. *J. Biomed. Mater. Res. A* **2004**, *69*(3), 490–501, with permission from Wiley.

As is described in Chapter 1.114, Bioactivity: Mechanisms. It has been shown that β-$NaCaPO_4$ has stimulatory effect on the differentiation of human bone-derived cells, inducing mRNA and protein expression of osteopontin, osteocalcin, osteonectin, and bone sialoprotein, suggesting later osteoblast differentiation.[97,98] In terms of bioresorption, β-$NaCaPO_4$ ss contains Na ions that weaken the bond between Ca^{2+} and the PO_4^{3-} in the crystal surface and, hence, facilitate solution-mediated resorption. Previous studies reported that β-$NaCaPO_4$ has improved bioactivity compared to HA due to its higher rate of solubility in the body.[99,100] Because of its enhanced solubility, β-$NaCaPO_4$ ss can act as a weak interphase for α-cristobalite ss and provide an easy path for structure debonding of SCPC, which facilitates silica dissolution as demonstrated in Figure 4(a). In conjunction with the enhanced silica release, rapid bone regeneration was observed.

SCPC is characterized by high porosity with a unique hierarchical porous structure (50 nm–650 mm) as shown in Figure 28(a) and 28(b).[92] Previous *in vivo* and *in vitro* studies have shown that protein adsorption and cell adhesion increase manyfold when in contact with porous nanobiomaterials compared to in contact with conventional biomaterials.[101,102] The enhanced biological effects were attributed to the high surface area in contact with tissue fluids and cells.

1.109.9. Silica-Xerogel

Earlier in this chapter we described bioactive glass prepared by the sol–gel processing routes. Essential processing steps were drying typically at about 100 °C and sintering in the temperature range 350–700 °C. Sol–gel processing as a processing methodology has existed for a long time.[103] This method has also been pursued to controlled release materials, as described in Chapter 4.428, Sol–Gel Processed Oxide Controlled Release Materials. A critical aspect of the overall processing is to omit any heat treatment steps that would damage the biological

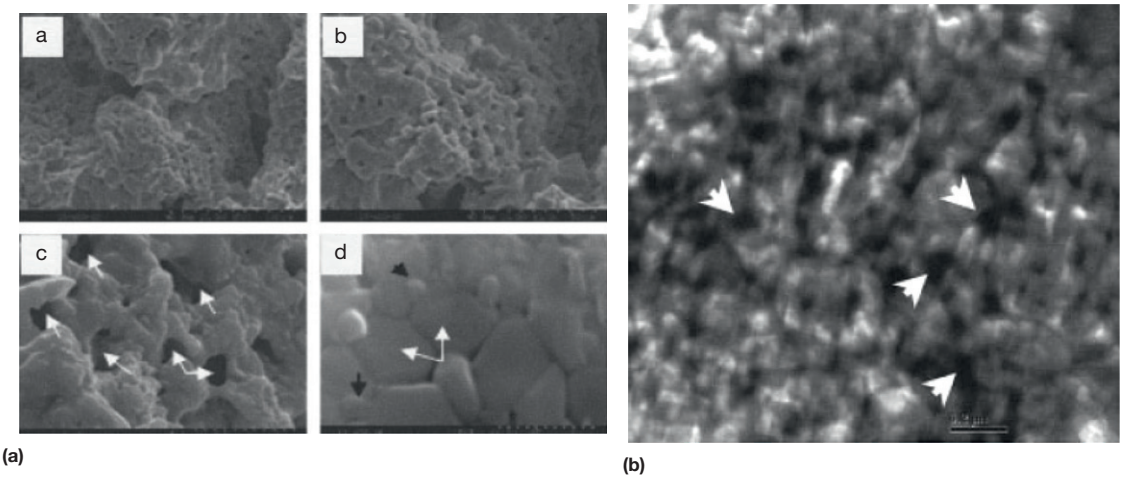

Figure 28 (a) SEM micrographs of the SCPC at different magnifications. (a) Two pores 100 μm in diameter on the surface of the material. (b) The walls of the large pores are very porous. (c) Higher magnification of the wall of the pores demonstrating homogeneously distributed interconnected pores 3 μm in diameter (arrows). (d) Single hexagonal calcium phosphate crystals (0.7 μm) (white arrows) and round-shaped silica crystals (0.2 μm) (black arrows) are in intimate interaction. (b) TEM micrograph of the porous structure of SCPC showing nanopores in the size range 50–100 nm (arrows). Reproduced from El-Ghannam, A.; Ning, C.; Mehta, J. *J. Biomed. Mater. Res. A* **2004**, *71*(3), 377–390, with permission from Wiley.

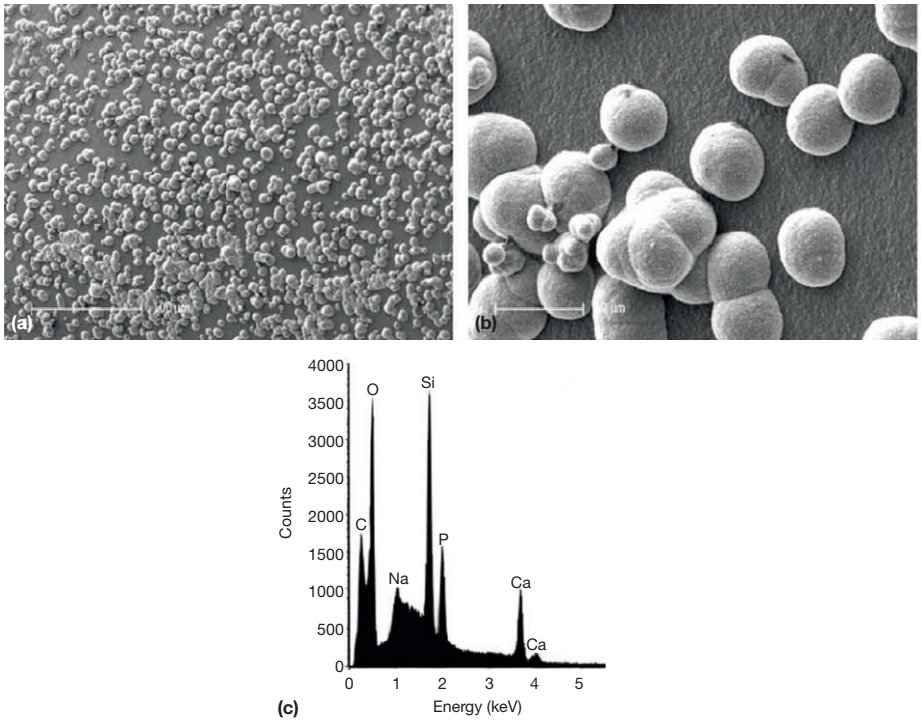

Figure 29 (a) SEM image of the silica xerogel surface after immersion in SBF for 7 days showing the formation of apatite crystals; (b) higher magnification of the apatite crystals. (c) EDX spectra of the surface showed a Ca/P ratio of 1.61 confirming the presence of apatite. Reproduced from Heinemann, S.; Heinemann, C.; Bernhardt, R.; *et al*. *Acta Biomater*. **2009**, *5*(6), 1979–1990, with permission from Elsevier.

function of the molecules being incorporated. By and large, processing conditions also have to be modified from those for synthesizing sintered bioactive glass, in order to achieve release kinetics appropriate for the intended uses. Sol–gel processed materials that are not heat treated are also called xerogels.

Silica xerogels has a highly porous matrix. The nanostructure of silica xerogels can be controlled in various ways, including modifying the molecular ratio of water to alkoxides, such as TEOS and TMOS and by type of catalyst, or by thermal treatment of the xerogels.[104–111]

It is interesting to address whether these materials can have bioactive properties. Various silica xerogels have been studied. They included a 100% silica and silica xerogels with various amounts of Ca and P oxides. Immersion of sol–gel derived silica xerogels in SBF resulted in the precipitation of a HA layer on the material surface.[112–114] Silica xerogel cylinders were immersed in 1× modified SBF.[114,115] The solution was exchanged every 24 h to ensure constant ion concentration and a pH of 7.4. After 7 days of immersion, SEM analyses (**Figure 29(a)** and **29(b)**) showed apatite formation on the material surface.[114] EDX spectroscopy revealed the Ca/P ratio on the surface to be 1.61 (**Figure 29(c)**), which was close to that of HA (Ca/P = 1.67).[114] The formation of the HA layer was attributed to the presence of a large number of silanol groups (Si–OH) on the material surface. The reaction of surface silanols with phosphate is thought to lead to complexation of both phosphate and calcium ions through heterogeneous nucleation.[116] Addition of minor concentrations of Ca and P oxides to silica xerogels accelerated the deposition of the HA layer onto the material surface. FTIR analyses showed a more intense band characteristic for Si–OH group in the Ca-P containing xerogels.[112] In conjunction of the higher expression of the Si–OH group on the material surface, all Ca-P containing xerogels showed a deposition of a HA layer within 24 h. The enhanced precipitation and growth of HA at the surface of Ca-P containing xerogels was preceded by calcium and phosphate release from the xerogels that contained it, and which resulted in supersaturation of the solution.

Other studies have correlated the amount of apatite precipitation on Ca-containing xerogels to the ionic product (IP) of HA.[113] The IP of the HA can be defined as:

$$\mathrm{IP} = \gamma\left(\mathrm{Ca}^{2+}\right)^{10}\gamma\left(\mathrm{PO}_4^{3-}\right)^{6}\gamma\left(\mathrm{OH}^{-}\right)^{2} \times \left[\mathrm{Ca}^{2+}\right]^{10}\left[\mathrm{PO}_4^{3-}\right]^{6}\left[\mathrm{OH}^{-}\right]^{2}$$

where γ is the activity coefficient. $\gamma(\mathrm{Ca}^{2+})$, $\gamma(\mathrm{PO}_4^{3-})$, and $\gamma(\mathrm{OH}^{-})$ at physiological ionic strength are 0.36, 0.06, and 0.72 respectively. The solubility product (K_{sp}) of the HA in an aqueous solution is $10^{-117.2}$ at 37 °C. After soaking silica xerogels containing various Ca contents, all immersing solutions were supersaturated with variable degrees depending on the Ca concentration released from the material during immersion. As the Ca content in the silica xerogel increased, the initial Ca ion concentration of the solution rose, which promoted the early deposition of apatite.

1.109.10. Conclusion

Bioactive ceramics have chemical reactivity in favor of cell function and tissue formation. Ions released from bioactive

ceramics such as Ca and Si have a stimulatory effect on bone cell function and tissue formation. Therefore, the level of bioactivity of ceramic implants depends on the enhanced and controlled solubility of the material. Amorphous bioactive materials have open structure, which facilitates ion release and bioactivity reactions at the interface with tissue fluids and cells. The bioactivity and resorbability of the amorphous bioactive glass is controlled by the atomic bond strength of the material. For crystalline bioactive ceramics the bioactivity and resorbability depend on the atomic arrangement in addition to the atomic bond strength. Parameters such as crystal size, shape, and impurity can be engineered to enhance the bioactivity and resorbability of calcium phosphate ceramics. The SCPCs are designed with modified crystalline phases in the form of solid solutions. The modified crystalline structure and porosity of the material induced excellent bioactivity and resorbability properties.

Immersion of bioactive ceramics in SBF results in the formation of a surface Ca-P layer relatively similar to the mineral phase of bone. The prior formation of this layer stimulated bone cell differentiation and tissue formation. The advantage of the Ca-P layer is twofold: it provides bone cells with a ready meal of calcium ions and it enhances selective adsorption of serum FN, an attachment protein known to enhance bone cell adhesion and function. The mechanism of bioactivity *in vivo* is complicated by the presence of high protein concentration and the presence of multiple kinds of cells. Both proteins and cells interfere with the precipitation of the Ca-P layer on the bioactive ceramic surface. Employment of sol–gel techniques to process bioactive ceramics has enhanced the bioactivity and resorbability properties of the material. Bioactive ceramics prepared by the sol–gel method are highly porous and can be used as a scaffold for drug delivery. Most bioactive ceramics are brittle materials and cannot be used as load bearing orthopedic implants. Bioactive glass ceramic and silica-calcium phosphate nano composite have high mechanical properties suitable for load bearing.

VHN	Vickers hardness number
XRD	X-ray diffraction

Symbols

T_{Growth}	Crystal growth temperature
$T_{Nucleation}$	Nucleation temperature

Hydroxyapatite (HA) has been extensively studied as a bioceramic. HA is closely related to the mineral phase of bone and HA-based ceramics exhibit good biocompatibility and osseointegrate with bone. However, HA ceramics exhibit poor flexural strength typically below 100 MPa and low fracture toughness values typically <1.0 MPa $\sqrt{m}$ compared with cortical bone at ~ 6 MPa $\sqrt{m}$. Consequently, HA-based materials are generally used only as bone substitutes in low loaded situations. Another disadvantage of HAs is that they are produced by a sintering route and are prone to decomposition during sintering and it is difficult to form the complex shapes required for prostheses without resorting to subsequent machining using diamond tipped tooling.

Apatite glass-ceramics are an attractive alternative to sintered HAs. A glass-ceramic may be defined as a polycrystalline solid produced by the controlled crystallization of a glass. Two steps are involved in conversion of a glass to a glass-ceramic.

1. Nucleation
2. Crystal growth

The classic glass-ceramic processing route involves casting the glass to the desired shape followed by a two-step heat treatment. The first step involves crystal nucleation and the second crystal growth. The classic glass-ceramic processing route is shown in Figure 1. Figure 2 shows the rates of crystal nucleation and crystal growth as a function of temperature, and the nucleation temperature $T_{Nucleation}$ and the crystal growth temperature T_{Growth} are marked on the plot.

One of the advantages of this classic glass-ceramic processing route is the ease of forming complex shapes; another is the ability to control the volume fraction of crystal phase(s), size of crystals, microstructure, and residual glass phase composition.

There have been numerous studies of apatite-based glass-ceramics by the ceramics community; however, on very few of these apatite glass-ceramics is there any published information with regard to their biological behavior, either *in vitro* or *in vivo*. A notable exception is the apatite–wollastonite (AW) glass-ceramic.

1.110.1. AW Glass-Ceramic

In 1982, Kokubo *et al.*[1] found that the heat treatment and sintering of glass powder compacts in the system $CaO–MgO–SiO_2–P_2O_5–CaF_2$ resulted in a dense, homogeneous glass-ceramic composed of apatite and β-wollastonite crystals. This type of apatite–wollastonite has become known as AW glass-ceramics and has been very extensively studied (Figure 3). The commercially available material was based on a $SiO_2–P_2O_5–CaO–MgO–CaF_2$ glass of the composition expressed in weight percent as 34.0% SiO_2, 16.2% P_2O_5, 44.7% CaO, 4.6% MgO, and 0.5% CaF_2. This composition is given in mole percent in Table 1.

Favorable properties of this glass-ceramic include good mechanical strength and fracture toughness[2,3] and it possesses the ability to chemically bond with bone.[1,4,5] The mechanical properties of this glass-ceramic are summarized in Table 2.

As a result, the AW glass-ceramic has been used clinically in bone fillers and as a structural material in prosthetic applications.[1,6,7] However, it is important to note that this

glass-ceramic is processed not by the classic glass-ceramic route shown in Figure 1 by first forming the component in the glassy state, but by a sintering route. The glass is formed, ground to a fine powder, and then sintered. The small particle size and large surface area result in surface nucleation of a large number of small wollastonite crystals, which are restricted in size by the particle size.

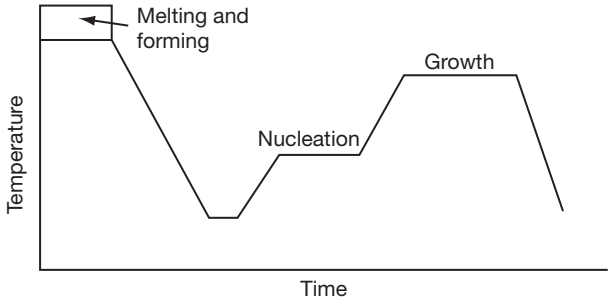

Figure 1 Controlled two-step crystallization process.

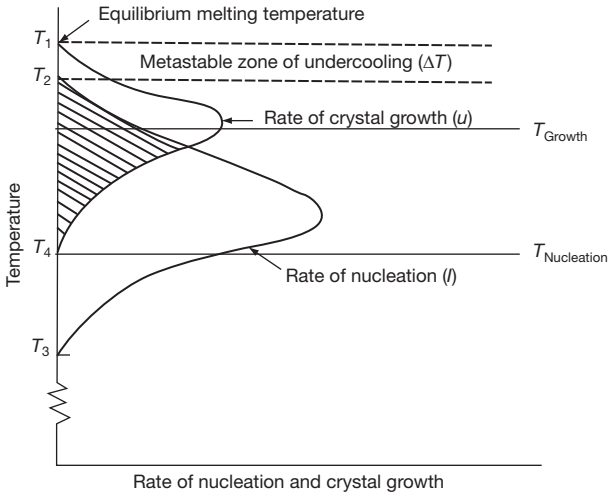

Figure 2 Nucleation and crystal growth rates.

Analysis of a cast bulk crystallized sample of AW glass-ceramic revealed that the surface nucleation and rapid growth of large β-wollastonite crystals caused internal cracks. A similar analysis of heat-treated powder compacts revealed that sintering and full densification occurs at a temperature much lower than the first crystallization temperature (~800 °C).[3] Cast AW components exhibited poor mechanical properties due to cracks at crystal boundaries. However, sintered AW components are difficult and expensive to machine, as a result of the hardness of the material. This made the fabrication of complex shapes required for prostheses expensive and as a result, the AW material is no longer produced commercially.

The apatite phase present in the AW glass-ceramic is thought to be a mixed fluorapatite (FAP)/oxyapatite (OA)/HA. However, as it is impossible to distinguish between these three forms of apatite easily by conventional X-ray diffraction (XRD), the exact nature of the apatite phase is unclear. Examination of the AW glass composition expressed in mole percent is enlightening. The Ca:P:F ratio is 7.03:1:0.05; thus, the composition is calcium rich with respect to the apatite stoichiometry (Ca:P = 1.67) and highly fluorine deficient with regard to the FAP $Ca_5(PO_4)_3F$ stoichiometry (P:F = 3:1). Only about one-sixth of the phosphorus present in the AW composition can be converted to FAP. Given that fluorine is frequently included in low dielectric loss glass compositions to drive out hydroxyl groups, the idea of FAP and HA or mixed hydroxy/FAP crystals being formed in the heat-treated AW glass-ceramic can be discounted. It is more likely, that the apatite present is FAP and OA or a solid solution of these two phases. It must be noted however that OA converts to HA in the presence of water and this may occur at the surface by reaction with atmospheric water prior to X-ray powder diffraction being carried out.

The most useful feature of the AW glass-ceramic is that it combines high bioactivity with good mechanical properties and consequently it has been used clinically for vertebral bodies and to replace bone in the iliac crest.

The final glass-ceramic following heat treatment contains in weight percent Wollastonite 28% ($CaO{\cdot}SiO_2$), Oxy/FAP 34 %

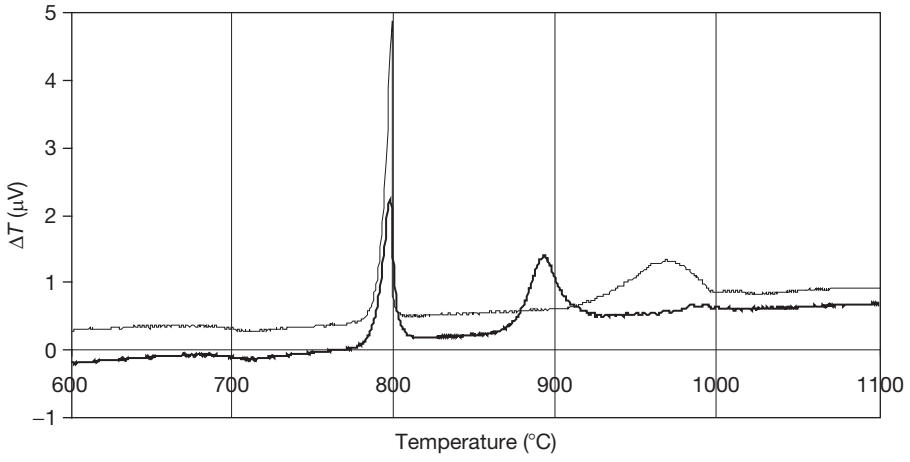

Figure 3 Differential thermal analysis traces of the apatite–wollastonite glass. The bold line indicates a particle size of <45 μm and the lighter line a particle size of 45–100 μm. The first peak corresponds to the crystallization of apatite and the second to apatite and wollastonite.

($Ca_{10}(PO_4)_6(O,F_2)$), and 28% glass of composition MgO 17%, CaO 24%, and SiO_2 59 % by weight.

Kokubo also developed a rapid method of ranking the bioactivity of bioactive ceramics. Kokubo and coworkers developed a simulated body fluid (SBF) solution of similar composition to that of human blood plasma. It was found that, when samples of the AW glass-ceramic were immersed in the SBF, a hydroxyl carbonated apatite layer formed on the surface and the rate at which this occurred could be correlated with the likely activity of the sample *in vivo*. Figure 4 shows a typical glancing angle XRD patterns before and after immersion in SBF of a bioactive glass showing the formation of hydroxycarbonated apatite (HCA) after soaking in SBF. The ability of the AW glass-ceramic to form HCA in SBF solution is thought to result largely from the dissolution of the residual glass phase, which is highly disrupted and has a network connectivity close to 2.0 and therefore would be expected to dissolve releasing calcium ions in a fashion similar to that of bioactive glass. A large number of studies have subsequently utilized Kokubo's SBF as a means of assessment of bioactivity and an ISO standard now exists for this test.

Other workers have developed machinable and castable apatite glass-ceramics, but these systems are based on alumina-containing compositions and release of small amounts of aluminum in soluble form is known to result in defective mineralization of osteoid. Care must be taken to ensure that no aluminum is present in soluble form in the final glass-ceramic. The machinable glass-ceramics are based on apatite and mica.

Table 1 Glass compositions studied in mole percent

Component/name	*MgO*	*CaO*	*SiO_2*	*P_2O_5*	*CaF_2*
AWK1	7.11	49.88	35.46	7.15	0.4

1.110.2. Apatite–Mica Glass-Ceramics

Apatite–mica glass-ceramics were developed as an alternative to the AW system by Vogel and coworkers. Mica glass-ceramics based on tetrasilicic micas and trisilicic mica phases are the basis of commercial machinable glass-ceramics for industrial

Table 2 Comparison of the physical properties of apatite glass-ceramics with cortical bone and hydroxyapatite

Glass-ceramic	*Crystal phases*	*Density*	*Thermal expansion coefficient ($\times 10^{-6}\,K^{-1}$)*	*Flexural strength (MPa)*	*Young's modulus (GPa)*	*Fracture toughness (MPa $\sqrt{m}$)*
Cortical bone	Substituted hydroxyapatite	2–3	–	100–200	7–20	5–7
HA	Hydroxapatite		–	60–120	70 GPa	0.8–1.05
AW	Apatite and wollastonite	3.07	8–10	215	118	2.0

and dental applications. The incorporation of a mica phase is designed to impart machinability to the apatite–mica glass-ceramic. The mica phase is readily cleaved during fracture and redirects the propagating crack preventing catastrophic fracture during machining. However, in machinable glass-ceramics a high volume fraction >50% and an interconnected house-of-cards microstructure are required for good machinability. These materials have a low hardness typically <250 Vickers hardness number (VHN) which generally correlates with machinability. Incorporating a hard apatite phase will disrupt the interconnected mica crystal structure and will increase the hardness and result in much reduced machinability. Vogel and Hoeland produced two apatite–mica glass-ceramics Bioverit I and Bioverit II and one apatite–aluminum phosphate glass-ceramic. Bioverit III is based on a silica-free phosphate glass and exhibits mechanical properties inferior to dense HAs; consequently, it has not been studied in any great detail with regard to its *in vivo* behavior.

Bioverit I contains apatite crystals with a diameter of 1–2 μm and large mica crystals of 10–20 μm. The mica crystals can be trisilicic fluorphlogopite type $Mg_3(AlSi_3O10F_2)K/Na$ or tetrasilicic mica $Mg_3(Si_4O10F_2)K/Na$. Bioverit II consists of apatite crystals and curved fluorphlogopite mica crystals. One of the advantages of Bioverit I and II is that they can be shaped by the surgeon prior to implantation.

All three glass-ceramics exhibit high levels of osseointegration in animal implant experiments. All three glass-ceramics exhibit limited solubility. While data is available for Na^+, K^+, Ca^{2+}, Mg^{2+}, and PO_4^{3-} release from these materials, no data is available for Al^{3+} release. This poses a concern over the long-term release of aluminum from these materials.

Despite this concern, Bioverit I and Bioverit II were widely used in the former German Democratic Republic (GDR) and Bioverit I is marketed and sold today for custom made computer-aided design/computer-aided manufacturing (CAD/CAM) implants.

1.110.3. Apatite–Mullite Glass-Ceramics

Hill and coworkers[8–10] developed castable FAP-mullite glass-ceramics from the SiO_2–Al_2O_3–P_2O_5–CaO–CaF_2 system that bulk-nucleated, via prior amorphous phase separation. The needle-like apatite crystals in these materials give these glass-ceramics high fracture toughness and high strength.[8,11] The high aspect ratio of the FAP crystals which are thought to grow by a screw dislocation mechanism in the *c*-axis is thought to result in high fracture surface energies. Figure 5 shows a fracture surface showing the elongated nature of the hexagonal FAP crystals. The mechanical properties are superior to the AW system. These glass-ceramics can be readily cast to shape using a lost-wax casting process and can be used to form complex shapes

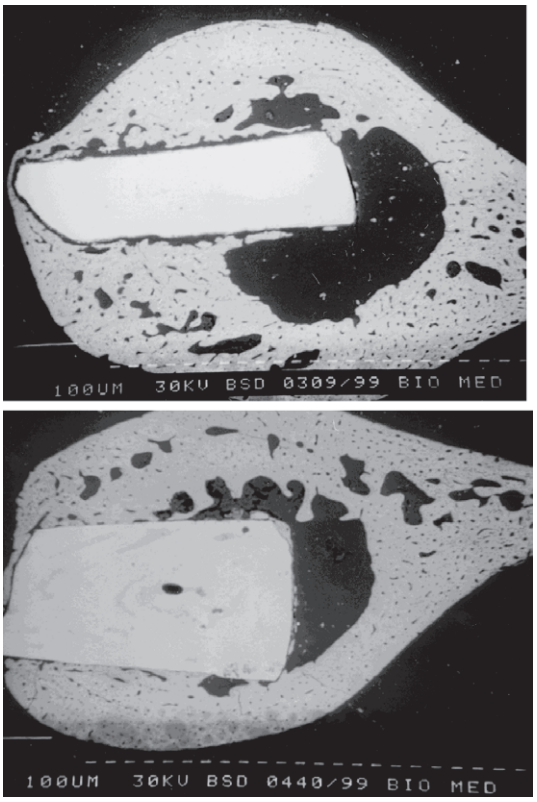

Figure 6 Backscattered scanning electron micrographs of implanted glass (top) and the implanted glass following crystallization to fluorapatite and mullite (bottom).

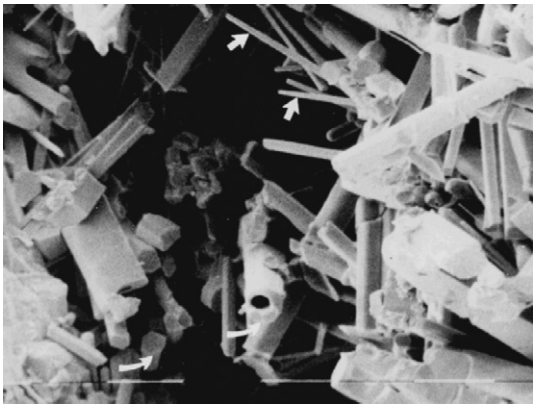

Figure 5 Scanning electron micrograph of elongated fluorapatite (FAP) crystals in a FAP glass-ceramic.

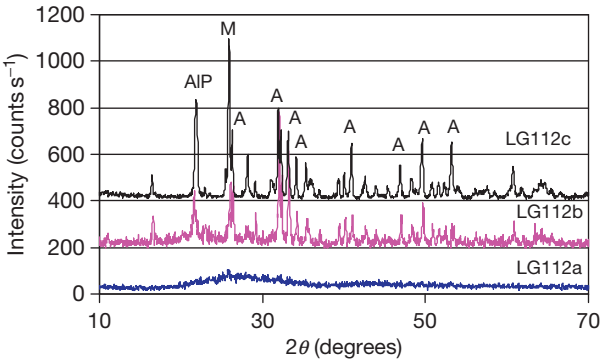

Figure 7 X-ray diffraction patterns of glass (LG112a), low temperature heat treatment (LG112b), and high temperature heat treatment (LG112c). A, FAP; M, mullite; and AlP, aluminum phosphate.

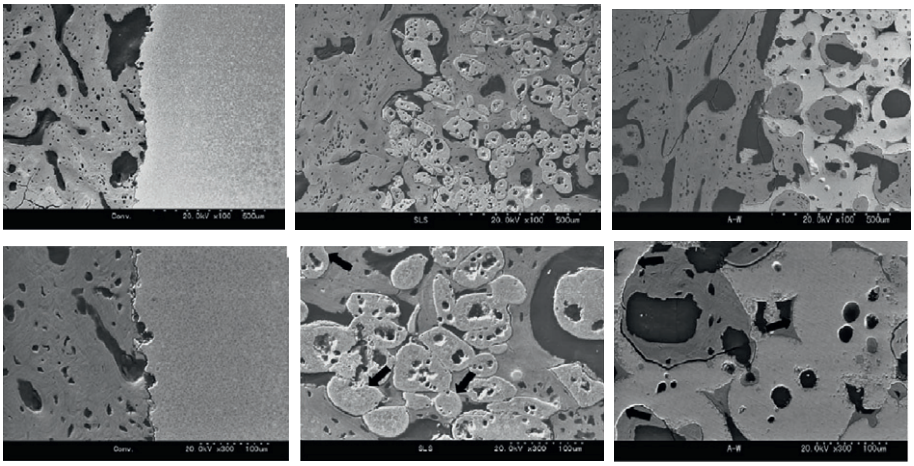

Figure 8 Scanning electron micrographs after 4 weeks of implantation of cast apatite–mullite glass-ceramic (Cast A–M), selectively laser sintered apatite–mullite glass-ceramic (SLS A–M), and apatite–wollastonite glass-ceramic (A–W). Micrographs courtesy of Ruth Goodridge.

with near-nett shapes, overcoming the drawbacks of the AW system. The second phase to form in these glass-ceramics is mullite ($2SiO_2{\cdot}3Al_2O_3$) which is chemically very stable and serves to lock away the aluminum in a chemically stable inert form. The glass-ceramics are chemically stable following appropriate heat treatment; the residual glass phase has a high network connectivity and low aluminum content, and is chemically stable. They do not release any aluminum ions into solution.

The glass-ceramics do not form HCA in Kokubo's SBF test but do osseointegrate *in vivo* without any apparent formation of a fibrous capsule layer. In contrast, some of the glasses are degradable and do form HCA in SBF but do not osseointegrate *in vivo*. An example of an apatite–mullite (AM) glass-ceramic implanted into the femur of a rat and the equivalent amorphous glass of exactly the same chemical composition are shown in Figure 6.

The AM glass-ceramic osseointegrates,[12] while the amorphous glass does not osseointegrate and has been fibrous encapsulated. Glass-ceramics, which crystallized to FAP, but which had not crystallized to mullite in addition to FAP, osseointegrated poorly. Figure 7 shows the XRD patterns for three samples that were implanted; LG112a is the amorphous glass. This sample did not osseointegrate at all. LG112b has been heat treated to give FAP and LG112c has been heat treated to give mullite and a small amount of aluminum phosphate (see also **Chapter 1.109, Bioactive Ceramics**; **Chapter 1.111, Bioactive Ceramics: Physical Chemistry**; **Chapter 1.112, Calcium Phosphate Coatings**; **Chapter 1.113, Bioactive Layer Formation on Metals and Polymers**; **Chapter 1.114, Bioactivity: Mechanisms**; **Chapter 1.115, Calcium Phosphates for Cell Transfection**; **Chapter 4.430, Silica-Based Mesoporous Nanospheres**; **Chapter 1.116, Bioactive Ceramics: Cements**; and **Chapter 1.117, Phosphate-Based Glasses**. LG112b osseointegrated poorly while LG112c exhibited better osseointegration and evidence of osteoconduction from the marrow cavity. It is clear that the presence of FAP can give rise to osseointegration provided there is no release of aluminum.

Goodridge *et al.*[13] investigated both AM glass-ceramics and AW glass-ceramics in the same *in vivo* implant study in the tibae of rabbits. In addition, they also studied the porous selectively laser sintered (SLS) samples for use as tissue-engineered scaffolds. The AM glass-ceramics also did not form HCA after immersion in SBF, nor was there any pH change following immersion and no significant ion release into the SBF solution. Any Al release was below the background levels found in the SBF solution of ~0.2 ppm.

Figure 8 shows the scanning electron micrographs. The cast and heat treated AM glass-ceramic osseointegrates, as does the porous selectively sintered AM glass-ceramic.

The *in vivo* response of apatite glass-ceramics and their ability to stimulate bone formation and to osseointegrate can be summarized as follows:

The *in vivo* response depends on the presence of the apatite phase and the residual glass phase. Increasing the apatite volume fraction in the glass appears to increase the osseointegration. The residual glass phase may add to the osseointegration by promoting apatite formation or may hinder osseointegration if the glass phase degrades and releases ions such as Al^{3+} that are known to inhibit biological mineralization. In the case of aluminum-containing glass-ceramic compositions, it is important that all the aluminum is either locked away in either a chemically inert glass phase or a chemically inert crystalline phase as even trace amounts of the order of 1 ppm of aluminum are known to inhibit the mineralization of the newly forming osteoid.[14]

The SBF test developed by Kokubo is widely used as a predictor of bioactivity and the ability of a bioceramic to osseointegrate. While this test is of value for bioactive glasses and AW glass-ceramics, its value with regard to aluminum-containing glasses and glass-ceramics must be questioned.

Glossary

Isomorph Compounds with identical crystalline structure.
Metaphosphate Salt of the hypothetic metaphosphoric acid HPO_3, often corresponding to chain or cyclic polyphosphates ($P_nO_{3n+1}^{(n+2)-}$ and $P_nO_{3n}^{n-}$ ions).
Nonstoichiometry Always relative to a given stoichiometric composition (see stoichiometry). Compound exhibiting ions or elements ratios different from that of the given composition.
Orthophosphate Salts of the orthophosphoric acid: H_3PO_4.
Polymorph Compounds with identical composition but different crystalline structures.
Pyrophosphate (also called diphosphate) Salts of the pyrophosphoric acid $H_4P_2O_7$.
Rietveld analysis Series of computing techniques permitting to extract from X-ray diffraction patterns of powders of crystalline substances information relative to the size, strains, preferential orientations of crystals, phases ratios, and, in favorable cases, the atoms locations and site occupancy relative to a model structure (these last points were in fact at the origin of Rietveld refinements techniques).
Stoichiometry Proportion of ions or elements in a given compound.

1.111.1. Introduction

Bioactive ceramics based on calcium orthophosphates (Ca-P) have considerably developed in the last decades; their applications have progressively spread, worldwide, and they have become the most implanted bioactive ceramics. The initial use of Ca-P as bioceramics was based on their analogy of composition with bone mineral and the need for versatile and risk-free bone substitute materials immediately available without the constraint of bone graft. One of the major properties of most Ca-P materials is their osteoconductivity, their ability to favor bone healing and to bind firmly to bone tissue. In addition, some Ca-P materials have been shown to be able to initiate bone formation *de novo* in nonosseous sites. Today, Ca-P compounds are mainly used as bone substitute materials in the form of porous ceramics, coatings on metallic prostheses, composite materials with organic macromolecules, injectable calcium phosphate cements and scaffolds for tissue engineering. They are also used in nonosseous applications such as ocular implants, allowing eyes movements. Many other applications have been proposed: drug carriers, tubing for nerve reconstruction, transfection support for cell therapy, adsorption substrates in some types of cancer treatments triggering the immune system. This chapter presents the different Ca-P compounds and their main physical–chemical properties of importance for biomedical applications. This chapter is primarily intended to describe the physical chemistry of these materials. In its last part, this chapter briefly presents other, non-Ca-P, bioactive materials, which are not treated in other parts of this chapter (see also **Chapter 1.109, Bioactive Ceramics**).

1.111.2. Calcium Orthophosphates Used as Biomaterials: Composition, Occurrence, and Brief Synthesis Description

Calcium orthophosphates result from the neutralization of the different acidities of phosphoric acid (H_3PO_4). Different calcium salts are formed corresponding to the progressive replacement of acidic protons by calcium ions. The chemical composition of these calcium phosphates with indications of composition and structures are reported in Table 1. The presentation is divided into two parts: calcium phosphates obtained by low-temperature wet synthesis methods and those obtained by high-temperature dry synthesis methods. Apatites, among the most important calcium phosphate compounds, which can be obtained by these two routes will be treated separately. All of these calcium phosphates do not give bioactive ceramics, but they are involved as intermediary phases or compounds in different types of biomaterials and/or they may appear as impurities.

1.111.2.1. Calcium Phosphates Obtained by Wet Synthesis Methods

1.111.2.1.1. Monocalcium phosphates

The first acidic proton of H_3PO_4 corresponds to a strong acid. The associated calcium salts, monocalcium phosphates, exist as hydrated and anhydrous crystalline phases. The soluble monohydrated monocalcium phosphate (MCPM) can be prepared by partial neutralization of the phosphoric acid with calcium hydroxide, followed by evaporation of water at low temperature, in acidic conditions.[13] The hydrated monocalcium phosphate crystallizes as platelets elongated along the c axis of the triclinic structure. Generally, monohydrated monocalcium phosphate can be obtained by gentle evaporation of acidic calcium- and phosphate-containing solutions.

The anhydrous phase can be obtained with the same method but at a higher phosphoric acid concentration. Some commercial products appear, in fact, as a mixture of the two monocalcium phosphates. Monocalcium phosphate anhydrous (MCPA) also forms by slow thermal dehydration of the hydrated phase above 100 °C. This reaction is reversible and, in moist air MCPA, can be converted back into MCPM. Monocalcium phosphates can incorporate many different mineral ions in their lattice (NH_4^+, K^+, Cl^-, Br^-).[14]

The monocalcium phosphate crystals do not form in living organisms, but these salts are used in biomedical mineral cement compositions.

1.111.2.1.2. Dicalcium phosphates

The second acidity of phosphoric acid corresponds to a weak acid. The neutralization of two acidities of phosphoric acid

Table 1 Main calcium phosphate compounds

Name and chemical formulae	*Most used abbreviations and mineralogical name*	*Structural characteristics (unit-cell dimensions in angstrom)*	*Density ($g\,cm^{-3}$)*	*References*
Monocalcium phosphate monohydrate: $Ca(H_2PO_4)_2$, H_2O	MCPM	Triclinic $P\bar{1}$ $a = 5.6261$; $b = 11.889$; $c = 6.4731$ $\alpha = 98.633$; $\beta = 118.262$; $\gamma = 83.344$	2.23	1
Monocalcium phosphate anhydrous: $Ca(H_2PO_4)_2$	MCPA	Triclinic $P\bar{1}$ $a = 7.5577$; $b = 8.2531$; $c = 5.5504$ $\alpha = 109.87$; $\beta = 93.68$; $\gamma = 109.15$	2.57	2
Dicalcium phosphate dihydrate: $CaHPO_4$, $2H_2O$	DCPD brushite	Monoclinic Ia $a = 5.812$; $b = 15.180$; $c = 6.239$ $\beta = 116.25$	2.3	3,4
Dicalcium phosphate anhydrous: $CaHPO_4$	DCPA monetite	Triclinic $P\bar{1}$ $a = 6.916$; $b = 6.619$; $c = 6.946$ $\alpha = 96.18$; $\beta = 103.82$; $\gamma = 88.34$	2.93	5
Amorphous tricalcium phosphate: $Ca_3(PO_4)_2$, nH_2O	ATCP (ACP)	$Ca_9(PO_4)_6$ clusters, S_6 symmetry	–	6
Octacalcium phosphate (triclinic structure): $Ca_8(PO_4)_4(HPO_4)_2$, $5H_2O$	OCP (OCPt)	Triclinic $P1$ $a = 19.692$; $b = 9.523$; $c = 6.835$ $\alpha = 90.15$; $\beta = 92{,}54$; $\gamma = 108.65$	2.67	7
β-tricalcium phosphate $Ca_3(PO_4)_2$	β-TCP	Trigonal $R3c$[a] $a = 10.439$; $b = 37.375$	3.07	8,9[b]
α-tricalcium phosphate $Ca_3(PO_4)_2$	α-TCP	Monoclinic $P2_1/a$ $a = 12.887$; $b = 27.280$; $c = 15.219$ $\beta = 126.20$	2.86	10
Tetracalcium phosphate $Ca_4(PO_4)_2O$	TTCP (TeTCP)	Monoclinic $P2_1$ $a = 7.023$; $b = 11.986$; $c = 9.473$ $\beta = 90{,}90$	3.05	11
Phospho-calcium hydroxyapatite: $Ca_{10}(PO_4)_6(OH)_2$	Hydroxyapatite	Hexagonal $P6_3/m$[c] $a = 9.418$; $c = 6.881$	3.16	12

[c]The structure of pure stoichiometric HA at room temperature is monoclinic; however, in biomaterials, it is essentially the hexagonal form which is encountered.

with calcium hydroxide leads to dicalcium phosphates. Two crystalline forms exist: dicalcium phosphate dihydrated (DCPD), also called brushite by mineralogists, and dicalcium phosphate anhydrous (DCPA), also called monetite. These sparingly soluble calcium phosphates have some biological importance. Brushite may form as an intermediary phase in ectopic mineralization occurring in slightly acidic media, for example, in dental calculi or urinary calculi.[15] DCPD and DCPA are largely used as biomaterials in mineral cements and coatings and also in composite materials, but these compounds have other applications also, in tooth paste, for instance. These compounds crystallize easily and they can be obtained industrially with a very high purity. They are often used for the preparation of other calcium phosphates.

DCPD crystals can be prepared simply by neutralization of phosphoric acid with calcium hydroxide at pH between 3 and 4 at room temperature. Generally, DCPD can be obtained by double decomposition between calcium and phosphate-containing solutions in slightly acidic media. It can also be formed by conversion of calcium phosphate salts, in acidic media, or by reaction of calcium salts such as calcium carbonate in acidic orthophosphate solutions.

DCPA is most conveniently obtained by dehydration of DCPD at 180 °C. However, it may also be directly precipitated in aqueous acidic solutions (pH 3–4) at mild temperature (60 °C).

The dicalcium phosphates can accommodate different biologically relevant ionic substitutes. Calcium, for example, can be replaced by Sr^{2+} ions and HPO_4^{2-} ions by SO_4^{2-} ions. These phases appear generally stoichiometric and no report has mentioned the existence of cationic or anionic vacancies in these compounds, to our knowledge.

Dicalcium phosphate also exists as an amorphous solid, with interesting properties. This phase can be obtained in nonaqueous media and by mechanosynthesis.[16,17]

1.111.2.1.3. Tricalcium phosphate, whitlockite, and amorphous tricalcium phosphate

The third acidity of orthophosphoric acid is very weak and, although the PO_4^{3-} exists only in a very small amount at pH lower than 11, tricalcium phosphate salts (TCP) can precipitate due to their very low solubility. The term TCP is used here in its strict chemical meaning to designate phases with a chemical composition represented by $Ca_3(PO_4)_2$ with a Ca/P ratio close to 1.5. Several different phases with a composition close to TCP exist (**Table 1**): crystalline TCP (α- and β-TCP) form only at high temperature and it is generally considered that crystalline, pure, TCP salt cannot be obtained by direct precipitation from aqueous media.[18] Although a publication reports the formation of crystalline β-TCP in aqueous media,[19] this result has to be considered with caution, as very often, minor impurities such as magnesium in calcium salts can lead to the formation of whitlockite, a calcium-magnesium phosphate, occurring in nature, isostructural to β-TCP. Although very often the term whitlockite is used to designate the β-TCP, this confusion should be avoided, as significant differences exist between these two phases in terms of composition and properties despite a structural analogy.[20]

Whitlockite forms very easily in biological media and it contains an appreciable amount of Mg^{2+} ions and HPO_4^{2-} ions. The composition can be represented by the following chemical formula:

$$Ca_{18}Mg_2H_2(PO_4)_{14}$$

but other compositions exist. The crystal structure of whitlockite can be accessed on a number of mineralogical Web sites.

In mammals, whitlockite generally appears in ectopic calcifications, for example, in joints and in calculi.

Several preparation methods of whitlockite generally involving coprecipitation of a calcium and magnesium solution with a phosphate solution have been described.[21] The structure of whitlockite has been determined, but its solubility is not clearly known. The conversion of whitlockite into apatite in aqueous solution has never been described and this compound might be possibly considered as one of the most insoluble calcium phosphate-based compounds.[20]

Aqueous precipitation of TCP generally leads to an amorphous phase often designated as amorphous calcium phosphate (ACP) or more accurately as amorphous tricalcium phosphate (ATCP). It is obtained most conveniently by double decomposition between calcium and phosphate solutions in alkaline media.[22] ACP is considered as one of the most important calcium phosphates in living organisms. It has been found in calcifications occurring in primitive organisms[23] and it has also been described as an intermediary phase in the formation of bone mineral in vertebrates.[24] Although it has, since then, been shown that in most cases no amorphous phase could be detected in bone,[25] the existence of this phase as a precursor of bone mineral formation is still debated.[26,27] ATCP is being used as a major or minor phase in calcium phosphate self-setting injectable cements for bone substitution and it also occurs in calcium phosphate coatings obtained by plasma-spray. Owing to its reactivity, it has also been proposed as a remineralizing agent in toothpaste and in several composite materials for dental restoration.[28]

ATCP exhibits a short-range organization of mineral ions, very similar to that occurring in apatite and other calcium phosphates, often referred as Posner's clusters.[29] It has been shown that these clusters correspond to the most stable association of calcium and phosphate ions.[6]

ATCP accepts different mineral ion substitutes and often impurities, which are not always considered and taken into account. Many different ions can replace calcium or phosphate ions in ATCP. For example, cations of biological importance such as Mg^{2+}, Sr^{2+}, Zn^{2+}, or anions like CO_3^{2-} can be incorporated.

It is often difficult to prepare very pure ATCP and several ionic impurities like HPO_4^{2-} and CO_3^{2-} may lead to Ca/P under or above 1.5 respectively. The best method to test the composition of TCP is probably calcination and transformation into crystalline phases as explained in the section relative to high-temperature TCPs.

In addition to ATCP, crystalline TCPs with an apatitic structure exist and have been named 'apatitic TCP.' Some industrial TCP products correspond, in fact, to apatitic TCP. Such compounds are described in the apatite section.

Other ACP phases may exist with lower Ca/P ratio than TCP (and thus containing HPO_4^{2-} and PO_4^{3-}). Several reviews on ACP have been recently provided.[30,31]

1.111.2.1.4. Octacalcium phosphate

In addition to amorphous phases, several crystalline calcium phosphate phases associate HPO_4^{2-} and PO_4^{3-} ions such as whitlockite, octacalcium phosphate, and apatite. Octacalcium phosphate has been the subject of a book edited by Chow and Eanes.[32] The term 'OCP,' refers to a chemical composition, but it is also considered to designate most generally the triclinic crystalline phase associated with this composition (noted here as OCPt). Very often this confusion makes some publication or patents rather imprecise. Like for TCP, OCP represents *stricto sensus*, a chemical composition, and this term has been used to name any compound with a close chemical composition; thus, 'apatitic OCP' or 'amorphous OCP' have been described.[33,34]

The original triclinic phase, OCPt, has initially been obtained by hydrolysis of DCPD in slightly acidic media at 40 °C,[35] but other preparation methods have been developed, especially the double decomposition between a calcium and a phosphate solution in slightly acidic medium at mild temperatures.[36] The structure of OCPt is characterized by the association of alternated apatite layers and hydrated layers containing Ca^{2+} and HPO_4^{2-} ions.[7] OCP has been proposed as a precursor of apatite in several biological mineralization processes, for example, in bone tissue and tooth enamel but also in dental calculi, although some of these identifications appear rather incomplete and uncertain and have not always been reproduced. The use of OCP in biomaterials has been proposed, in injectable bone mineral cements, or for the preparation of thin coatings, due to its high reactivity. OCP coatings have been found to exhibit an osteoinductive behavior.[37] However due to difficulties of preparation and conservation OCP does not seem to have yet found any large-scale industrial use.

The hydration degree of OCP depends on the preparation and storage conditions, and two types of OCP differing by the amount of attached water molecules have been described by Fowler *et al.*[38]

Little is known about the incorporation of mineral ions within the OCPt structure. Most data concern OCP hydrolysate's conversion into apatite.[39] Most OCP preparations lead to a partly hydrolyzed phase that contains an excess of HPO_4^{2-} and OH^- observable by Fourier transform infrared spectroscopy (FTIR) and solid-state nuclear magnetic resonance (NMR). OCP has the ability to incorporate dicarboxylic acids in the hydrated layer.[40] However, these interactions between OCP and organic molecules have not found applications in the biomaterial field.

A last but important type of calcium phosphate compound can be precipitated in aqueous media: apatite, which will be described in a specific section.

All these phases obtained from aqueous preparations exhibit a thermal decomposition at moderate temperature and cannot be transformed into bioceramics by conventional high-temperature treatments (see the thermal properties section). This is not the case of calcium phosphates obtained at high temperature, which can easily be processed and sintered by traditional methods used by ceramists.

1.111.2.2. Calcium Phosphate Obtained by Dry Synthesis Methods

The monohydrogen phosphate and dihydrogen phosphate groups are unstable and condense respectively into metaphosphate and pyrophosphate ions. Thus, all calcium orthophosphates obtained by dry synthesis methods contain the PO_4^{3-} ion. Two main compositions: TCP, tetracalcium phosphate (TTCP), in addition to apatites, are obtained. None of these compositions is naturally present in biological systems.

1.111.2.2.1. Crystalline tricalcium phosphates: α- and β-TCP

Two main crystalline phases belong to this category: α- and $\overline{\alpha}$-TCP, in addition to a very high temperature and unstable $\overline{\alpha}$-TCP phase. A review on TCP has recently been published.[41]

The TCP form easily by heating precipitated TCP (amorphous TCP or apatitic TCP) at high temperatures, or by dry preparation, heating mixtures of any calcium phosphate/carbonate with a 1.5 Ca/P ratio such as, for example,

$$CaCO_3 + Ca_2P_2O_7 \rightarrow Ca_3(PO_4)_2 + CO_2$$

but many other combinations with Ca/P = 1.5 are possible such as

$$Ca_{10}(PO_4)_6(OH)_2 + Ca_2P_2O_7 \rightarrow 4Ca_3(PO_4)_2 + H_2O$$

β-TCP is obtained at temperatures between 850 °C and the transition temperature to the α-TCP, 1125 °C. The metastable α-TCP is most conveniently obtained by quenching TCP heated above the transition temperature. However, heating ATCP between 650 and 700 °C results, also, in the formation of α-TCP. The $\overline{\alpha}$-TCP exists only at high temperature (above 1430 °C) and, unlike α-TCP, it does not seem to have been quenched at room temperature.

Several ion substitutions can occur in each of these phases and may modify the transition temperature. Mg^{2+} and other bivalents ions substituting for calcium, such as Zn^{2+}, Mn^{2+}, and Fe^{2+} ions, for example, stabilize the β-TCP structure, whereas silicate ions substituting for phosphate stabilize the α-TCP structure. Alkali metals -containing β-TCP with a higher solubility than regular β-TCP have also been evidenced and studied.[42,43]

The main impurities associated with TCP can be apatite or calcium pyrophosphate corresponding to a Ca/P ratio respectively higher or lower than that of regular TCP. Apatite can be easily detected by X-ray diffraction (XRD); however, this is not the case of pyrophosphate which is best evidenced by FTIR spectroscopy.

TCP phases are, with apatites, among the most widely used Ca-P biomaterials, mainly as bioresorbable ceramics.[41]

1.111.2.2.2. Tetracalcium phosphate

This phase is easily obtained by heating at high temperature a mixture of calcium and phosphate salts with a Ca/P ratio close to 2, for example,

$$2CaCO_3 + Ca_2P_2O_7 \rightarrow Ca_4(PO_4)_2O + 2CO_2$$

The reaction has, however, to be carried out under dry atmosphere in order to avoid, in the presence of water vapor, the decomposition of TTCP into hydroxyapatite (HA) according to the reversible reaction:

$$3Ca_4(PO_4)_2O + H_2O \leftrightarrow Ca_{10}(PO_4)_6(OH)_2 + 2CaO$$

The TTCP formed at high temperature is generally quenched to prevent any evolution. It is used as an alkaline, Ca-rich

component in multicomponent mineral cements. Owing to the alkaline pH generated by dissolution of TTCP in water, this phase transforms very easily into apatite. Ion substitutions in this phase do not seem to have been much studied.

1.111.2.3. Apatites

The apatites are the most frequently encountered crystalline biological calcium phosphates, and they are also among the most used Ca-P compounds as biomaterials. Apatite is also one of the most extensively studied phases.[20] Apatites are found in all mineralized tissues of mammals and more generally in mineralized tissues produced by vertebrates (bones, tooth enamel fish scales, antlers, defenses, roster of whales) except for egg shell. The presentation is divided into two parts: well-crystallized apatites and nanocrystalline apatites for which surface structure and composition have to be considered.

1.111.2.3.1. Well-crystallized apatites

The chemical composition of apatites is given by the generic formula:

$$Me_{10}(XO_4)_6Y_2$$

where Me represents a bivalent metallic ion such as Ca^{2+}, Sr^{2+}, Ba^{2+}, Cd^{2+}, Pb^{2+}; XO_4 a trivalent anion such as PO_4^{3-}, AsO_4^{3-}, VO_4^{3-}; and Y a monovalent anion such as OH^-, F^-, Cl^-, Br^-. The composition of apatites may include many foreign ions and several solid solutions are possible. The bivalent cations may be replaced partly by trivalent cations (e.g., La^{3+}, Eu^{3+}) or monovalent ones (e.g., Na^+) or by cationic vacancies. The trivalent anions can be partly replaced by bivalent or tetravalent ones such as CO_3^{2-} (type B carbonate apatite), HPO_4^{2-}, or SiO_4^{4-}. The monovalent anions can be replaced partly by bivalent anions such as CO_3^{2-} (type A carbonate apatite), O^{2-}, or anionic vacancies. No large amounts of vacancies have been reported in trivalent anionic sites, probably because of the instability of the lattice resulting from the creation of bulky defects. The maximum amount of cationic and/or monovalent anionic vacancies can be rather large and it may reach 2 per unit formula. This means that apatite with all monovalent anionic sites empty can exist. It seems, however, that such sites in apatites obtained in aqueous media are not empty and can be occupied by water molecules as suggested by Rietveld analyses of calcium-deficient apatites[44] or solid-state NMR studies.

Apatites containing vacancies or ionic substituents can be easily prepared in aqueous media. In order to preserve the electroneutrality of the solid, several charge compensation mechanisms are observed. Only a few examples related to calcium phosphate apatites and biological applications will be given.

For example, the replacement in part of bivalent cations by trivalent ones can be compensated for by the increase of the charge of monovalent anions or by that of trivalent anions:

$$Ca_8La_2\ (PO_4)_6O_2$$

$$Ca_8La_2\ (PO_4)_4(SiO_4)_2(OH)_2$$

The replacement of trivalent PO_4^{3-} anions by bivalent ones results in the formation of both a cationic vacancy (represented by squares in the chemical formulas) and an anionic vacancy in monovalent site, for HPO_4^{2-}- and CO_3^{2-}-containing apatites:

$$Ca_{10-x}\square_x\quad (PO_4)_{6-x}(HPO_4)_x\quad (OH)_{2-x}\square_x$$

$$Ca_{10-x}\square_x\quad (PO_4)_{6-x}(CO_3)_x\quad (OH)_{2-x}\square_x\quad \text{with}\ \ 0\le x\le 2$$

Bone mineral composition has been approximated with some success using such chemical formulas.[45]

However, other phenomena can disturb this rather simple compensation mechanism. For example, additional Ca^{2+} and OH^- ions can be incorporated in the lattice at alkaline pH in carbonate apatites:

$$Ca_{10-x+u}\square_{x-u}\quad (PO_4)_{6-x}(CO_3)_x\quad (OH)_{2-x+2u}\square_{x-2u}$$
$$\text{with}\ \ 0\le x\le 2\quad \text{and}\quad 0\le u\le x/2$$

An internal hydrolysis of PO_4^{3-} groups (giving rise to hydrogen phosphate ions and additional OH^- ions) may also occur with residual water molecules associated with the solid:

$$Ca_{10-x}\square_x\quad (PO_4)_{6-x-y}(HPO_4)_{x+y}(OH)_{2-x+y}\square_{x-y}$$

The precise composition of the apatite unit-cell can be obtained traditionally by determining the density of the solid and the unit-cell dimensions. Although Rietveld refinements can be performed to determine the site occupancy, the simulation becomes rapidly rather complex when several possibilities of charge compensation have to be considered. A homogeneous distribution of foreign atoms is generally assumed, although heterogeneous distribution and atoms clustering can occur in the structure. This is especially the case for nanocrystalline apatites.

Apatite corresponds also to a structure, or more precisely, to a series of structures. Most apatites crystallize in a hexagonal structure and belong to the $P6_3/m$ group.[46] In this structure, the calcium ions can occupy two sites labeled as I and II. Calcium I sites are on the trigonal axis of the structure at (1/4, 3/4, 1/2 and 3/4, 1/4, 1/2 positions). The Ca II ions form equilateral triangles at $z = 1/4$ and $z = 3/4$, on the 6_3 axis of the structure. These ions constitute part of the walls of 'channels' where the monovalent sites are located. They correspond to the narrowest part of the channels with a diameter of 0.27 nm for Ca-P apatites. At $z = 1/2$, the channels appear slightly larger (0.29 nm) and they are limited by a distorted hexagon of oxygens belonging to PO_4^{3-} ions. Owing to the existence of these channels, apatites have sometimes been compared to zeolithes; the channels appear, however, smaller than those generally found in zeolithes and they are monodimensional and obstructed by ions, which limit considerably the exchanges at low temperature and the trapping of molecules. Nevertheless, it has been shown that small molecules such as O_2 and possibly, CO_2 or small organic molecules like glycine, formate ion, and even acetate ions can be trapped in these channels. In addition to the hexagonal structure, several Ca-P apatites, always stoichiometric, such as HA, chlorapatite, and type A carbonate apatite crystallize in the monoclinic structure, $P2_1/b$ group, due to an ordering of the monovalent anions (or bivalent anions and vacancies) in the channels of the structure.[20]

1.111.2.3.2. Nanocrystalline apatites

Except for enamel and a few other mineralized tissues, most biological apatites are nanocrystalline. Several data support the

concept that apatite nanocrystals exhibit a surface hydrated layer very different from the apatite structure forming the core of the crystals. The first model of an apatite surface was provided by Brown who suggested that the surface was close to the hydrated layer found in OCPt structure.[47] Specific surface reactions have been studied in the early fifties by Neuman and Mulryan,[48] and these conceptions have been developed and refined since then to explain spectroscopic data and chemical behavior.[49]

Spectroscopic data suggest that biomimetic apatite nanocrystals are constituted by an apatite core (generally, a nonstoichiometric apatite phase) and a hydrated surface layer mainly constituted by bivalent ions such as Ca^{2+}, HPO_4^{2-}, or CO_3^{2-} (**Figure 1**).

The proportion of hydrated layer has been found to be particularly important in freshly precipitated apatites. Upon aging in solution, the more stable apatitic domains develop, progressively, incorporating ions from the hydrated layer, if they can be inserted in the apatite lattice.

The ions in the hydrated layer appear to be relatively mobile and they can be very easily exchanged by other mineral ions or charged organic groups in adsorption reactions (see **Sections 1.111.4.5.1** and **1.111.4.5.2** on surface properties). In addition, the possibilities of ionic substitutions appear much more numerous in the hydrated layer than in the apatite lattice; thus, ions like magnesium, for example, can easily replace calcium ions in the hydrated layer but they are only incorporated in minute quantities in the apatite lattice; they are preferably located on the hydrated surface of the crystals and then always remain, for a major part, exchangeable.

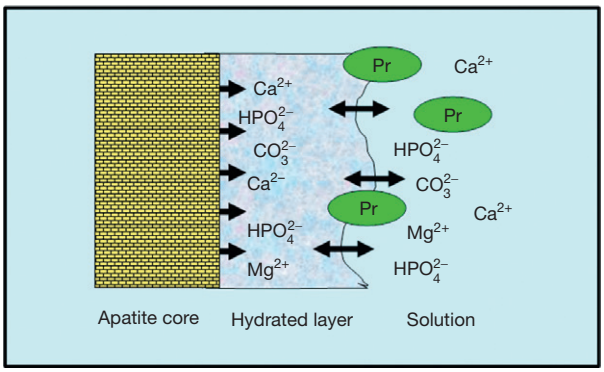

Figure 1 Model of the surface of biological and synthetic biomimetic apatite. The core of the nanocrystals is made of a nonstoichiometric apatite domain constituting a rigid and stable crystalline lattice. The surface is formed by a fragile structured hydrated layer which is destroyed by drying. This layer contains mainly bivalent mineral ions. On aging (maturation) in aqueous media, the very stable apatite domain grow (arrows) incorporating the mineral ions of the hydrated layer which can be inserted in the apatite lattice. The ions of the hydrated layer can be rapidly and reversibly exchanged by ions of the solutions (double arrows) and such reactions alter strongly the structure of the hydrated layer. Charged groups of macromolecules and proteins (labeled Pr) can also participate to such ion exchanges leading to adsorption of molecules on the crystals. The adsorption (or ion exchange) affinity and the amount of molecules (or ions) which can be adsorbed (or exchanged) vary with the extent of the hydrated surface domains. Adapted from Rey, C.; Combes, C.; Drouet, C.; Lebugle, A.; Sfihi, H.; Barroug, A. *Mat Wiss U Werkostofftech* **2007**, *38*, 996–1002.

The surface hydrated layer has been found to be structured in aqueous media, using wet spectroscopic characterization methods with ambivalent features: FTIR spectroscopy suggests the existence of OCPt-like environments, whereas NMR indicates the presence of mineral ions in an environment close to that in DCPD structure.[50] Upon drying, these surface structures are strongly altered and the surface environments appear amorphous-like. These observations point out the necessity to use various techniques to accurately characterize nanocrystalline apatites. It also appears that conclusions regarding the presence of foreign phases cannot be drawn from spectroscopic data alone.

1.111.2.3.3. Synthesis and formation of apatites

Apatites can be prepared by wet and dry methods.

1.111.2.3.3.1. Wet preparations

Wet preparation methods of apatites include direct neutralization reaction between $Ca(OH)_2$ and H_3PO_4 solutions, double decomposition between soluble calcium and phosphate salts, hydrolysis reactions of nonapatitic calcium phosphate phases, or else the conversion of other calcium or phosphate salts; in addition, several sol–gel and nonaqueous methods have been proposed. The neutralization method does not leave any counter-ion residue and any by-product to discard. It thus appears as a good method for industrial preparations; however, it generally gives precipitated apatites with carbonate ions impurities. Double decomposition seems to be the preferred method at the laboratory level and it is often used, also, for industrial production. Continuous precipitation processes using double decomposition have been studied, giving apatites with different chosen compositions (from TCP to stoichiometric HA).[51] Calcium nitrate and ammonium phosphate are the preferred starting salts. Although tiny proportions of nitrate or ammonium ions can be trapped in the precipitate during synthesis, they are easily eliminated by heating. Hydrolysis reactions are also relatively clean methods: they are generally based on the hydrolysis of DCPD or DCPA.[52] However, they require a large amount of water and part of the phosphate is lost in the waste water. Conversion methods are mostly based on calcium carbonate treatment in phosphate-containing solution.[53]

The important parameters for wet methods are the pH, temperature, maturation time in solution, and the way of addition of the reactants, in case of double decomposition. It has been shown that the rate of growth of apatite crystals is rather low, and in many cases, apatite formation proceeds through the hydrolysis of precursor phases, essentially ACP and OCP, having a higher rate of formation but a lower stability.

Apatites are generally obtained at slightly acidic or alkaline pH. The solubility isotherms indicate that HA is the most stable Ca-P compound in aqueous solution at pH greater than 4 at 37 °C. The nonstoichiometry of apatites is directly related to the pH value, and, at neutral or slightly acidic pH, the solids generally contain a large amount of HPO_4^{2-} ions and are nonstoichiometric.

The synthesis temperature also affects the chemical composition, degree of nonstoichiometry, and crystallinity of apatites. The crystallinity is, in general, greatly improved when the apatites are synthesized at rather high temperature, although

the rate of formation and the supersaturation ratio are also important. At, or under, room temperature, the first precipitate formed is, most of the time, an amorphous phase, which is then transformed into more stable apatites at a rate strongly related to temperature and pH. At constant pH, the elevation of temperature leads to apatites closer to stoichiometry.

The importance of the maturation time or aging time in solution is related to the process of formation of apatites involving intermediate nonapatitic phases and/or nonstoichiometric apatite precursors. Aging is associated with an evolution of the apatite toward more stable less soluble ones. Different processes seem, however, to be involved depending on the type of apatites. Three types of aging mechanisms can be distinguished: (i) the development of the apatite domains at the expense of the less stable surface hydrated domains, especially active in nanocrystals, (ii) the chemical evolution leading to more stable apatites closer to stoichiometry, and (iii) the Ostwald ripening process, based on the decrease of interfacial energy of crystals, which favors the growth of large crystals at the expense of smaller ones. The fastest process, especially active in biological systems, seems to be the first one.

The order of addition of the reactants and relative proportions also seem to be important parameters in apatite preparation: when a calcium excess is present in the solution, the apatites obtained are generally closer to stoichiometric ones, whereas such a stoichiometric composition seems more difficult to obtain in the presence of an excess of phosphate ions.

Some impurities are often present in apatites synthesized by wet methods: magnesium, carbonate, and HPO_4^{2-} ions are among the most important ones.

Magnesium is always the major cation impurity, found in variable concentrations, in most commercial calcium salts. Very disappointingly, some providers of such salts do not think it useful to signal the presence of this impurity. We encourage the different actors in the biomaterial field to determine and control the magnesium impurities in their products. This element has some chemical and biological effects, which may modify the properties of biomaterials. It has an inhibitory effect on apatite nucleation and crystal growth and it alters the apatite crystal morphology. It can be located on the surface of the crystals and be readily available, modifying the biological behavior of implants and scaffolds for tissue engineering.

Carbonate impurities are related to reactions with atmospheric CO_2 during preparation and washing of precipitated apatites. Surface carbonation may also occur by simple contact with carbonate-containing solutions. Like magnesium, carbonate is an inhibitor of apatite crystals nucleation and growth. Carbonate can be eliminated by heating at temperature close to 900 °C with a possible partial decomposition of the apatite phase.

Hydrogen phosphate ions result from the precipitation reaction or the internal hydrolysis reaction of PO_4^{3-} ions by water molecules. They are eliminated on heating (see Section 1.111.4.1 on thermal stability of apatites), but as in the case of carbonate, decomposition of the apatite may occur.

1.111.2.3.3.2. Dry preparation

Several dry preparation methods of apatites have been published, essentially for stoichiometric apatites. Basically, they consist in calcination between 900 and 1100 °C of solid reactants in the stoichiometric ratio (Ca/P = 1.67). HA, for example, can be obtained by heating a mixture of calcium carbonate and TCP at 1000 °C under water vapor:

$$CaCO_3 + 3Ca_3(PO_4)_2 + H_2O \rightarrow Ca_{10}(PO_4)_6(OH)_2 + CO_2$$

Fluorapatite (FA) or Chlorapatite (ClA) can be prepared with similar reactions:

$$CaF_2 \text{ (or } CaCl_2) + 3Ca_3(PO_4)_2 \rightarrow Ca_{10}(PO_4)_6(F \text{ or } Cl)_2$$

But many other reactants can also be chosen such as pyrophosphate in preparation of hydroxy- or fluorapatite:

$$4CaCO_3 + 3Ca_2P_2O_7 + H_2O \rightarrow Ca_{10}(PO_4)_6(OH)_2 + 4CO_2$$

or a more complex reaction[54]:

$$14CaF_2 + 18Ca_2P_2O_7 \rightarrow 5Ca_{10}(PO_4)_6F_2 + 6POF_3$$

releasing POF_3 as a gas.

Other interesting processes, concerning apatites, are ion substitutions at high temperature (900–1000 °C). It is thus possible to convert a HA into carbonated (type A), chlorinated or fluoridated apatites, for example,

$$NH_4Cl + Ca_{10}(PO_4)_6(OH)_2 \rightarrow Ca_{10}(PO_4)_6Cl_2 + NH_3 + H_2O$$

NH_4Cl is here sublimated in the oven and if the reaction is made in dry atmosphere, a stoichiometric ClA is obtained. These rather fast reactions do not change the crystal or ceramic characteristics; however, in bulk ceramics, only the surface might be modified due to slow diffusion of the ions.

1.111.2.4. Other Phosphate Compounds

Several other phosphates are of potential interest for biological applications either because they may appear as impurities in Ca-P compounds or because of their properties.

Calcium pyrophosphates contain the $P_2O_7^{4-}$ anion. Dicalcium pyrophosphates $Ca_2P_2O_7$ may appear as an impurity in TCP. Calcium pyrophosphates may also form in ectopic calcifications. Several polymorphs of these pyrophosphates exist. Pyrophosphates have been tested as biomaterials; they are bioresorbable and seem well tolerated.[55]

Polyphosphates can exist as linear chains of phosphate groups: $[P_2O_7(PO_3)_n]^{(n+4)-}$ or cyclic anions $(PO_3)_n^{n-}$. Cyclic polyphosphates give soluble complexes with calcium and they are mainly used in washing powders. Linear polyphosphates may give amorphous glasses or crystalline substances and some of them have been proposed as biomaterials.[56]

Several other calcium-containing orthophosphates are of potential interest:

Rhenanite (or Buchwaldite), $NaCaPO_4$ or Chlor-spodiosite, Ca_2PO_4Cl which could possibly be used in cements; Merillite: $Ca_{18}Na_2Mg_2(PO_4)_{14}$, Brianite $Na_2CaMg(PO_4)_2$.

1.111.3. Characterization Methods of Calcium Phosphates

Characterization of calcium phosphates can be the easiest or the most difficult task depending on the type of compound and the extent of information required. The characterization of DCPD or DCPA phases, for example, is rather straightforward and can be obtained by different techniques. Systems such as

nanocrystalline apatites prepared in close-to-physiological conditions have been shown to exhibit a rather complex composition and structure, involving an apatitic core (generally nonstoichiometric) and a hydrated surface layer-containing anions and cations in positions which do not correspond to the regular apatite structure (see Section 1.111.2.3.2). In this case, no single characterization technique can provide sufficient data, as it only enables to determine one characteristic of the system. Therefore, the conjoint use of several techniques along with chemical analyses is of foremost importance in the quest for precise characterization of complex Ca-P materials. Chemical composition is the first step, followed by XRD, electron microscopy, and spectroscopic techniques such as FTIR, Raman and solid-state NMR spectrometries.

1.111.3.1. Chemical Analysis

The thorough physicochemical characterization of calcium phosphate-based ceramics (as for any other advanced materials) requires, as one of the main steps, to determine precisely the nature and relative amounts of the chemical elements composing the system. Such data then allow deriving the overall chemical formula of the compound studied. This consideration appears especially essential for apatitic materials, which can accommodate a large number of ionic vacancies and which can also tolerate many ionic substitutions.

It is possible to distinguish three types of ions in calcium phosphates of biological origin and in many synthetic apatites:

- major ions like Ca^{2+}, orthophosphates, including PO_4^{3-} and HPO_4^{2-}, CO_3^{2-}, and OH^-,
- minor ions like Na^+, Mg^{2+},
- trace elements such as Sr^{2+}, Zn^{2+}, F^-

The techniques which are possible to use depend on the abundance of the elements.

1.111.3.1.1. Major ions

1.111.3.1.1.1. Calcium

The amount of calcium contained in a given specimen can be drawn by way of many techniques such as atomic absorption spectroscopy (AAS), inductively coupled plasma (ICP) emission spectroscopy, ionometry using a specific electrode, ion chromatography, old but competitive chemical methods like complexometry (e.g., with a complexing agent such as ethylene diamine tetracetic acid (EDTA)), or even X-ray fluorescence or electron microscopy-based techniques (microprobe analyses, energy-dispersive X-ray analyses). Although the latter offer the possibility to observe the spatial distribution of the elements (s) across the sample, they require a precise preliminary calibration step and do not appear generally accurate enough to distinguish phases with close composition or to determine a departure from stoichiometry. The other techniques cited above are thus more frequently used for the routine determination of the amount of calcium contained in a specimen. Determinations based on AAS or ICP seem to provide relatively accurate data, and these techniques are more specific than complexometry where the complexation of other cations may simultaneously occur during the titration, thereby leading to nonspecific cationic content measurements. Direct determinations of calcium ions in solution can also be made by ion chromatography or by ionometry. These methods are not as accurate as AAS or ICP-related methods, but they can be useful for a follow-up of calcium concentration in solutions in contact with Ca-P.

1.111.3.1.1.2. Phosphorus

Phosphorus contained in calcium phosphates is generally present either under the form of orthophosphate ions (PO_4^{3-}, HPO_4^{2-}, $H_2PO_4^-$) or as pyrophosphate ions $P_2O_7^{4-}$. It is then such oxygenated phosphorus species that are generally followed. The total phosphorus content can be determined by some of the methods, which can also be used for calcium such as ICP, or electron microprobe analysis. However, these methods do not allow discrimination between orthophosphate and other phosphorus-containing molecules or ions. Ion chromatography can be used in such a situation.

Orthophosphate ions can usually be satisfactorily and specifically titrated by spectrophotometry of the phosphovanado-molybdenum complex either directly (yellow coloration) or after reduction (blue coloration).[57] All orthophosphate ions present in the system, under any form, are analyzed. Other phosphate groups such as pyrophosphate ions or metaphosphates are not analyzed. When such ions are present, however, a slow hydrolysis may occur in the aqueous medium needed for the analysis, and it is advised to carry out the determination using these spectrophotometric methods just after dissolution. Such hydrolysis reactions could also occur with esters of phosphoric acid.

The HPO_4^{2-} content appears as an important characteristic in several calcium phosphates, especially in dicalcium phosphates, ACP, or octacalcium phosphates. In apatites, the amount of HPO_4^{2-} ions is related to nonstoichiometry, and in nanocrystalline apatites, it may also appear as a characteristic of the surface composition. HPO_4^{2-} in calcium orthophosphates can be determined after thermal conversion into pyrophosphate ions as shown by Gee and Dietz.[58,59] Samples are heated at 500 °C for 3 h (or preferably at 600 °C for 1 h). The amount of pyrophosphate ions is then determined either after separation on an ion exchange resin or simply by difference between the amount of orthophosphate before and after pyrophosphate formation. A limitation to this determination of the HPO_4^{2-} content, however, exists in the simultaneous presence of carbonate ions as side reactions between HPO_4^{2-} and carbonate ions may interfere. Another difficulty is the possible internal hydrolysis of PO_4^{3-} with water molecules attached to the solid during heating. An alternative to the rather time-consuming analytical method proposed by Gee and Dietz exists for nanocrystalline apatite where most of the HPO_4^{2-} ions belong to a surface hydrated layer. The HPO_4^{2-} content can be evaluated from the mathematical decomposition of the ν_4PO_4 band of the FTIR spectrum.[60] Indeed, a rather good correlation could be obtained between the amount of HPO_4^{2-} drawn from chemical analyses and by this FTIR-based method. However, the curve-fitting parameters need probably to be refined for obtaining more precise determinations.

1.111.3.1.1.3. Carbonate

Several methods can be used to determine the carbonate content of calcium phosphate samples. One of the best methods is probably coulometry. The carbonate content of Ca-P samples can be determined using a CO_2 coulometer measuring the CO_2

released upon sample dissolution in acidic media or heating of the sample. The CO_2 released is transferred into a photometric cell in a nonaqueous medium and titrated through an acid–base reaction.[61] A second method is the CO_2 analysis through gaz chromatography or a carbon-hydrogen-nitrogen (CHN) classical analysis system, releasing the CO_2 by heating, although the heating parameters have to be adjusted to be sure to decompose all carbonate ions.[62] Thermogravimetric determination of the CO_2 evolved can be carried on; however, generally, CO_2 and water loss cannot be easily separated, and in this case also, gas chromatography can be used. Another method for total carbonate content is FTIR spectroscopy. The spectral lines intensity of carbonate is determined relatively to that of phosphate bands. The accuracy seems lower than that of chemical methods; however, FTIR spectroscopy allows the determination of the type of carbonate (type A and/or B, see Section 1.111.2.3.1) involved.

1.111.3.1.4. Hydroxide ions

For HAs, the evaluation of the amount of OH^- ions is also important, although this determination is rarely made. The chemical method proposed by Trombe and Montel[63] consists in a substitution of OH^- ions by F^- ions at 1000 °C; when HA or oxy-HAs are heated in the presence of an excess of CaF_2 in a dry atmosphere, FA is formed and H_2O is released:

$$CaF_2 + Ca_{10}(PO_4)_6(OH)_2 \rightarrow Ca_{10}(PO_4)_6F_2 + CaO + H_2O$$

The mass of the released water corresponds to the amount of OH^- ions initially present in the solid. An excess of CaF_2 is used (up to 20%) to be sure that the reaction is completed. The application of this method supposes, however, that there are no other possibilities of reactions. The decomposition of HA at high temperature under vacuum appears also as a possible method, although it does not seem to have been utilized much:

$$Ca_{10}(PO_4)_6(OH)_2 \rightarrow Ca_{10}(PO_4)_6O + H_2O$$

Among other methods, the relative intensity of FTIR OH^- lines at 3570 or 633 cm^{-1} can also be used and applications have been developed for the determination of OH^- in oxy-HA coatings,[64] which can be extended to bone and nanocrystalline apatites. An alternative method is to use the Raman OH^- stretching band at 3570 cm^{-1}. These necessitate, however, calibration curves obtained with well-characterized reference samples (or mixtures of samples) in a preliminary step.

1.111.3.1.2. Minor and trace elements

The determination of minor and trace elements is usually performed by spectroscopic methods such as AAP or ICP-related methods using emission spectroscopy or mass spectroscopy. In some cases, neutron activation analyses have also been used to determine trace elements in biological samples. Fluoride is often found in apatites of biological origin and in the case of a bone disease, fluorosis. This ion is generally determined quite accurately by ionometry using a specific electrode.

1.111.3.1.3. Meaning of the Ca/P ratio

The Ca/P ratio of calcium phosphates is generally considered as one of their major characteristics. The Ca/P ratio of most calcium phosphate phases is generally restrained to a narrow domain of variations. In the case of apatites, however, the Ca/P ratio may vary in a wide domain and it is frequently used to characterize the apatite composition. Two cases shall be considered:

The first one concerns nonstoichiometric apatites with Ca/P ratios lower than that of the stoichiometric composition (Ca/P = 10/6 = 1.667), which occur when the apatite contains HPO_4^{2-} ions in place of PO_4^{3-} ions, as discussed in the section on apatite composition. Considering that phosphate sites do not accommodate large amounts of vacancies, the Ca/P ratio represents then the amount of cationic vacancies.

The second one concerns nonstoichiometric apatites with carbonate ions replacing phosphate groups (type B carbonate apatites). In this case, the Ca/P ratio does not represent the amount of cationic vacancies and it has no simple meaning. However, considering that there are only a few vacancies in the trivalent anionic sites of the apatite structure (all six sites are occupied either by phosphate or by carbonate groups), it is the Ca/(P+C) ratio (where C represents the amount of carbonate ions replacing phosphate groups) which represents the departure from stoichiometry and the cationic vacancies.

In more complex compositions when other cations than calcium, for example Sr^{2+}, are present in the apatite, the atomic ratio related to vacancies to consider is (Ca+Sr)/(P+C).

For nanocrystalline biomimetic apatites, the situation is even more complex due to the surface composition, which cannot be neglected, and which is different from the core of the crystals. An important proportion of bivalent ions is on the surface, but this amount is difficult to estimate, and there is no adequate model describing these compounds. In this case, the (cations)/(P+C) ratio does not have a meaning and it has no correlation with the amount of vacancies in the apatite domains.

Special techniques for the determination of Ca/P ratio using XRD have also been developed and standardized in the case of HA ceramics and coatings (see Section 1.111.3.2).

1.111.3.2. Diffraction Methods

XRD is an essential method for the characterization of calcium phosphate materials. XRD experiments have been performed on monocrystals, polycrystalline bulk ceramics, coatings, or powder samples.[65] The first point is not be discussed here, although it has been involved in the determination of most Ca-P structures (see Table 1 for references). The peak position of XRD diffraction patterns allows the identification of all crystalline calcium phosphate compounds as recorded in the databases of diffraction patterns such as International centre for diffraction data (ICDD), Joint committee for powder diffraction standards (JCPDS) or other. In everyday uses, some specific intense peaks are used to recognize the main Ca-P phases (Table 2).

The identification of phases has been standardized for several biological applications (ISO Standard 13779-3), mainly related to high-temperature processing of apatites as coatings or ceramics. The proposed method is based on the use of reference samples and single peaks integrated intensity ratios and needs the establishment of a standardization curve using known mixtures of phases in presence. However, other

methods have now been developed using the integrated intensity of all the peaks of phases in presence and involving Rietveld analysis. These methods a knowledge of the crystallographic structure, including atomic positions of each crystallized phase.

The determination of the amorphous Ca-P phase content existing in plasma-sprayed coatings, for example, however remains an open question. The standards define only a crystallinity ratio not necessarily related to the amount of amorphous phase as it has been shown in the case of bone mineral 30 years ago. The methods using standardization curves ACP/HA appear rather inaccurate and the best method at present is probably the determination of the heat of crystallization of the amorphous phase by differential scanning calorimetry (DSC) or differential thermal analysis (DTA).[66,67]

Among the difficulties related to phase identification is the distinction of poorly crystalline apatites and OCPt, due to XRD patterns analogies and peak broadening. However, the most intense peak of OCPt, (100), corresponding to a 1.868 nm *d* spacing, has been shown to be characteristic of this phase, although its position may vary with partial dehydration. The observation of this peak might need special settings of the diffractometer to reach low angle. Another difficulty arises from the preferential orientation of the crystals due to several causes, such as the preparation of the samples for XRD, a preexisting crystal orientation like in biological tissues (bone, dental enamel), or the processing of the Ca-P-based biomaterial. Such preferential orientations can considerably change the intensity of the different peaks and can make phase identification and quantification difficult.

In addition to phase recognition, XRD can be used to determine the unit-cell dimensions of the different crystallized Ca-P compounds. These crystallographic parameters can also be used to estimate the effect of ion substitutions on the structure. Such effects have been particularly well documented for the apatite structure. It is well established that the substitution of cation by a bigger one induces an increase of both dimensions of the hexagonal unit-cell. The replacement of a trivalent anion by a bigger one has the same influence. However, when a monovalent anion is replaced by a larger one, it induces an increase of the hexagonal *a* unit-cell dimension and a decrease of the *c* dimension. Generally, substitutions in apatite follow the Vegard's law, and the increase or decrease of the unit-cell dimensions is linearly proportional to the amount of ions introduced. Thus, increments can be determined for different ions of biological interest as shown by McConnel[68] (**Table 3**).

Important information brought by XRD concerns the crystal size and strains, which induce a peak broadening. Basic application in the biological field for the crystal size determination uses Scherrer's method neglecting the contribution of microstrains.[69] More elaborated treatments can be performed considering the effect of microstrains and crystal sizes, which are now included in Rietveld analysis of the XRD diagrams available from different Web sites. Such analysis allows the determination of crystal size in different crystallographic directions, microstrains, unit-cell dimensions, phase composition but also structural information such as the atomic position of substitutes or vacancies in favorable cases. For example, the orientation of carbonate species in carbonate apatites (type A and type B) has been solved using Rietveld analysis of XRD data and the location of vacancies in nonstoichiometric apatites has been determined.[44] The location of Sr in Sr-containing apatites has been determined using Rietveld analysis.[70] Although these very powerful methods have brought valuable information on calcium phosphates, they may sometimes lead to unrealistic solutions, and a critical examination of the data is advised. One of the difficulties, especially annoying in the case of apatites, is that these treatments do not consider the possibilities of a distribution of solid solutions with variable compositions, which is known to exist in bone and synthetic preparations (in fact in all Rietveld analyses, the phases are considered as homogeneous).

Table 2 Useful X-ray diffraction lines for the identification of main Ca-P phases and impurities in ceramics, thermal coatings, and powders

Phase	*JCPDS folder*	hkl	dhkl *(Å)*	*2θ(λ_{Cu} = 1.5406 Å)*
α-Tricalcium phosphate	09-0348	4 4 1	2.905	30.753
β-Tricalcium phosphate	09-0169	0 2 10	2.88	31.027

Table 3 Increments of crystallographic parameters (in Å) of the apatite unit-cell related to cationic and monovalent anionic substitutions for biologically relevant ions

a parameter	F	Δ(OH → F)	OH	Δ(Cl → OH)	Cl	Δ(Cl → F)
Ca	9.370	0.025	9.420	0.105	9.630	0.130
Δ(Sr → Ca)	0.034		0.034		0.024	
Sr	9.710	0.025	9.760	0.055	9.870	0.080
c parameter	F	Δ(OH → F)	OH	Δ(Cl → OH)	Cl	Δ(Cl → F)
Ca	6.880	0.000	6.880	− 0.050	6.780	− 0.050
Δ(Sr → Ca)	0.040		0.040		0.024	
Sr	7.280	0.000	7.280	− 0.045	7.190	− 0.045

The increments are determined for one atom substituted (Δ) (according to McConnel[68]).

Such samples would exhibit peaks broadening falsely interpreted as strains and size effects.

A special, very accurate technique, for the determination of the Ca/P ratio by XRD has been developed and standardized for Ca/P ratios between 1.50 and 2 (ISO standard 13779). Nonstoichiometric apatites are not stable and they decompose on heating at 900–1100°C depending on their Ca/P ratio. If the Ca/P ratio is lower than 1.67, the heated sample is constituted by β-TCP and stoichiometric HA. If the Ca/P ratio is higher than 1.67, a mixture of stoichiometric apatite and calcium oxide is observed. For a Ca/P ratio equal to 1.67, no decomposition is observed.[71] The foreign phases (β-TCP and calcium oxide) can be detected with high precision by XRD and quantified. The accuracy of the method lies on the observation that when the chemical Ca/P atomic ratio varies by about 10% between 1.50 (pure TCP) and 1.67 (pure HA), the phase composition varies by 100%.

A similar technique can be used for the determination of the purity of TCP. Heating at 900 °C shall give only β-TCP phase. Samples with a Ca/P lower than 1.5 give an additional Ca-pyrophosphate phase and samples with a Ca/P ratio higher than 1.5 contain stoichiometric apatite as explained above. However, in this case, the detection of pyrophosphate by FTIR appears much more sensitive than by XRD.

1.111.3.3. Electron Microscopy Techniques

Electron microscopy techniques are widely used by materials scientists with several objectives:

- determination of the crystal morphology, their size and organization, including pores distribution in ceramics
- identification of phases at the microscopic level using electron diffraction
- composition determination using Energy Dispersive Spectrometry (EDS) or Wavelength Dispersive Spectrometry (WDS)
- analyses of crystal defects through lattice imaging at high resolution

Most Ca-P exhibit specific crystal morphologies, which can be used for their identification. Mathew and Takagi[72] (2001) proposed a classification of the most used Ca-P into three major structural types: (1) the apatite-type structure also including apatite-related structures such as OCP and TTCP, (2) the glaserite-type structure in which all the TCP polymorphs can be included, and (3) the Ca-PO_4 sheet-containing compounds including dicalcium and monocalcium phosphate phases. However, this classification cannot be used to determine the crystal morphology of these compounds, as other parameters can control nucleation and crystal growth of these Ca-P phases leading, for example, in the cases of apatite or DCPD, either to needle-like or platelet-like morphologies. Some of the typical and most common morphologies are shown in Figure 2.

Some crystals can show a variable morphology depending on their formation conditions; however, some morphologies can be considered as recurrent: this is the case, for example, of OCPt crystals appearing as platelet crystals forming imbricated leaflet with irregular edges comparable to 'sand-roses.' However, OCPt can hydrolyze into apatite, without change of crystal habit, and these morphologies may also be associated with apatites. DCPD also forms platelet crystals with, generally, larger dimensions than OCP crystals. Precipitated ATCP appears most generally as spherical units (diameter between 20 and 300 nm). Well-crystallized apatites generally exhibit a needle-like morphology with crystals elongated along the c axis of the hexagonal structure. Platelets hexagonal crystals with a short dimension along c have also been reported in special preparation conditions.[73] Upon heating, the morphology of apatite crystals changes considerably: the length is reduced and the width-thickness is increased, resulting in a lower crystal surface energy. The hexagonal shape, however, remains recognizable. Some preparations such as hydrothermal synthesis, slow hydrolysis of more soluble Ca-P salts (DCPD, TCPs), and reactions in fused salts may give apatite crystals a very high aspect ratio (length/width ratio) that can be considered as fibers.[74] In most preparations, the needle-like crystals have the tendency to form dendritic spherical units. Tooth enamel crystals show the typical morphology of apatite with very elongated crystals. Bone crystals, however, appear essentially as platelet crystals with a rather irregular shape, elongated along the c axis of the hexagonal structure, but with different perpendicular dimensions along *a* and *b*. This very unlikely morphology for hexagonal crystals (supposed to possess equivalent *a* and *b* directions) has been considered as an indication of the formation of OCP precursor phases.[20] This morphology is also observed in nanocrystalline synthetic apatites precipitated at physiologic pH and it is not confined to the growth of apatite crystals in bone matrix.

- Identification of phases at the microscopic level using electron diffraction, selected area electron diffraction (SAED), can be performed on Ca-P samples. All these observations can be disturbed by beam damage especially when fragile hydrated phases or nanocrystalline compounds are present.[75]
- Composition determinations using EDS or WDS are often performed. These techniques are used for the determination of main constituents of biomaterials and biological Ca-P compounds: essentially Ca, Mg, P, F, seldom C. Their accuracy is, however, linked to the stability of the Ca-P compound and the sample characteristics (surface roughness, conditions of analyses), and even with the use of adequate standards, the determination of the apatite nonstoichiometry, using these methods, remains difficult.
- High-resolution transmission electron microscopy (TEM) is also a common technique often difficult to perform on very small unstable crystals sensitive to beam damage. The lattice fringes allow an identification of the crystallographic planes, the determination of the d-spacings, the orientations of crystals, and the observation of crystal defects. Amorphous domains have also been observed, at high resolution, at the surface of apatite nanocrystals corresponding probably to the dehydration of the structured layer existing in wet media (see spectroscopic characterizations).

One of the problems of these techniques is the beam damage, which is frequently observed especially with hydrated Ca-P and may lead to the decomposition of hydrated phases or even to the volatilization of phosphorus.[76,77] As calcium phosphates are nonconductive, it is necessary to limit the charge effect. In scanning electron microscopy (SEM), several techniques can be used: (1) coating with an electrically conductive layer, (2) working at low accelerating voltage at short working

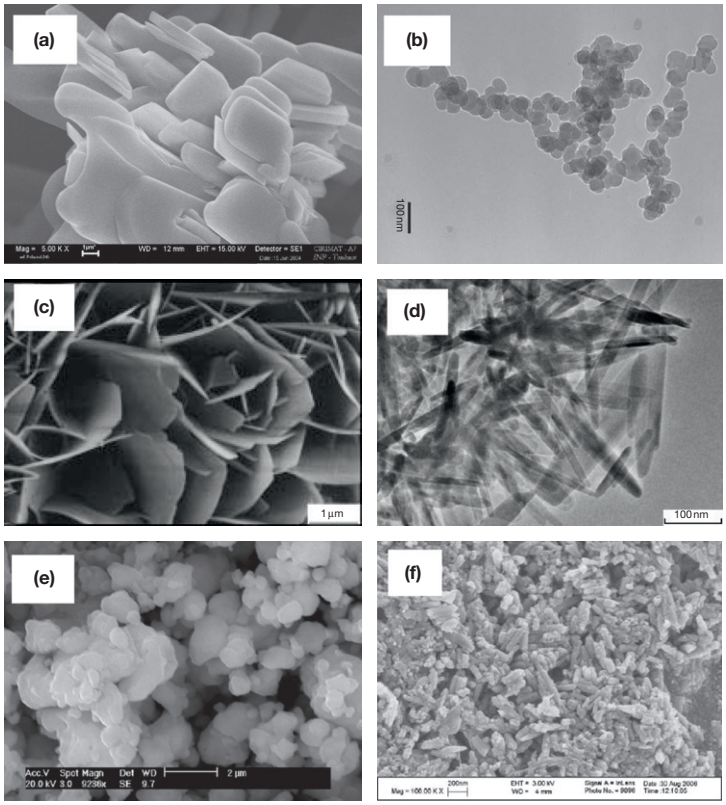

Figure 2 Example of typical morphologies of Ca-P compounds. distance, and (3) working under alterated vacuum. The solution (1) is preferred for morphology examination. The high vacuum may also alter the hydrated Ca-P phases; however, environmental microscopes can be used.

1.111.3.4. Vibrational Spectroscopies

FTIR and Raman spectroscopies allow the identification of most calcium phosphate phases. Generally, these methods focus on the use of internal vibrational levels of molecules and ions which may vary according to the short-range environments of these molecules or ions. Phosphate, carbonate, hydroxide ions, and water molecules are the main species detected by FTIR and Raman spectroscopies.

The PO_4^{3-} group has four main vibrational domains: ν_1 (at about 950 cm^{-1}), ν_2 (400–470 cm^{-1}), ν_3 (1000–1150 cm^{-1}), ν_4 (500–620 cm^{-1}). The main characteristic bands of the FTIR and Raman spectra of different calcium phosphates are shown in Tables 4 and 5.

The phases that cannot be easily distinguished by XRD can be discriminated using FTIR or Raman spectroscopies. This is the case, for example, of OCP and apatite or HA, oxy-HA, and amorphous phases present in plasma-sprayed coatings.[84] In addition to phase identification, these vibrational spectroscopies can be used for phase quantification using standard mixtures and standardization curves based on line intensity ratios. However, the principal advantage of vibrational spectroscopies over XRD is the identification of fine structural details, especially concerning apatites, such as the location of carbonate species on the different sites of the apatite structure, the presence of HPO_4^{2-} species, the quantification of the amount of OH^- ions, or the fine characterization of nanocrystalline apatites.

Carbonate ions, like phosphate, have four main vibrational domains: ν_1 (at about 1050 cm^{-1}), ν_2 (820–900 cm^{-1}), ν_3 (1400–1550 cm^{-1}), and ν_4 (650–750 cm^{-1}). Carbonate ions are always present in biological apatites and they may occupy different types of sites historically labeled as A and B: site A corresponds to monovalent anionic sites of the apatite structure and site B corresponds to trivalent anionic sites (Table 6). However, in addition to these main carbonate locations, several slight deviations have also been distinguished corresponding to different combinations with vacancies or water molecules or simply the combination of the two carbonate substitutions.[87] It has been shown that carbonate may also be incorporated in the surface hydrated layer of nanocrystalline apatite.

One of the most powerful uses of vibrational spectroscopies concerns apatite nanocrystals and poorly crystalline apatites for which XRD lacks accuracy. These methods are able to distinguish surface species and allow their quantification in simple cases. Surface HPO_4^{2-} have been shown to exhibit a specific

Table 4 FTIR spectral characteristics of phosphate ions in different calcium phosphate salts (wavenumbers in cm^{-1})

band, at 534 cm^{-1} in the ν_4 domain of the ion. When carbonate species are included in the hydrated layer of nanocrystalline apatite, they frequently appear in an 'amorphous-like' environment. In addition, FTIR and Raman spectroscopies can be used on wet samples revealing specific structural environments, which are lost upon drying, as shown in **Figure 3**.

Concerning OH^- ion, there is only one vibrational domain corresponding to the stretching of the O–H bond (3400–3650 cm^{-1}). However, a libration line, corresponding to a rotational energy level of the ion in the lattice, is also observed (630–750 cm^{-1}). OH^- bands are essentially detected in apatites and related compounds like partly hydrolyzed OCP. The OH^- stretching and libration movements are very sensitive to hydrogen bonding, and it has been shown in fluoride- and chloride-containing apatites that the OH bands can be considerably shifted away from their position in HA. The OH^- vibration and libration modes are also very sensitive to the nature of the surrounding cations.

Water molecules exhibit three vibrational modes: the symmetric stretching mode (ν_s) and the antisymmetric stretching mode (ν_{as}) have very close energy and they are difficult to distinguish. They generally give a broad absorption band on FTIR spectra (3000–3700 cm^{-1}). The bending movement around 1640 cm^{-1} gives a narrower band. Like OH^-, the water molecules are very sensitive to hydrogen bonding. In some calcium phosphates such as DCPD, the lines due to water molecules appear very specific and allow a clear identification. In other calcium phosphates (OCP, apatite, ACP), however, the water bands appear rather unspecific. Recently, a study of water molecules in nanocrystalline apatites has been published.[88] (see also **Chapter 3.322, Infrared and Raman Microscopy and Imaging of Biomaterials**.)

1.111.3.5. Solid-State Nuclear Magnetic Resonance

Solid-state NMR allows the identification of the short-range environment of different nuclei possessing a magnetic moment, such as ^1H, ^{13}C, ^{31}P, ^{19}F, which can be found in calcium phosphates.[89]

This very powerful technique also gives information on magnetic interactions between neighbor magnetic species. The main lines detected in calcium phosphates and the corresponding assignments are reported in **Table 7**.

Like FTIR, NMR spectrometry is particularly suitable for the study of nanocrystalline and poorly crystalline apatites. Recent data involving spin diffusion have confirmed the concept of the hydrated layer rich in HPO_4^{2-} ions.[91] In bone, several types of water species have been distinguished.[92]

The study of carbonate species by NMR spectrometry has confirmed the existence of the two main types of carbonate sites in apatite named A and B (**Table 7**). In addition, a third

type of carbonate species has been detected in nanocrystalline apatites, confirming the FTIR results. Two-dimensional NMR analysis of carbonated apatites has also established the location of carbonate species in a hydrated domain.[93]

^{19}F solid-state NMR studies of fluoride-containing carbonated apatites have clearly indicated the existence of two crystallographic sites corresponding to fluoride ions in monovalent sites and close to type B carbonate ions.[93]

Solid-state NMR spectroscopy also proved to be particularly useful in the study of the evolution of amorphous phases and the formation of apatite nuclei undetectable by other techniques.

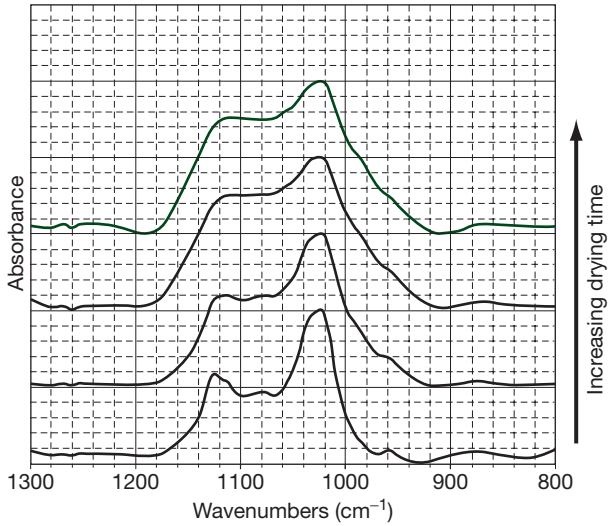

Figure 3 Example of FTIR PO_4^{3-} lines in the ν_3 domain of wet nanocrystalline apatite samples progressively dried in the spectrometer. The fresh wet samples (bottom) show very narrow well-resolved lines which can be associated to phosphate groups belonging to the hydrated layer. On drying (in minutes), the lines become broadened and poorly resolved indicating the destruction of the surface structure and resulting in amorphous-like environments of the phosphate ions.

1.111.4. Properties of Calcium Phosphates

1.111.4.1. Thermal Properties of Calcium Phosphates

The thermal properties of Ca-P are important parameters to consider when processing phosphate materials, or simply when preparing biological samples for different types of analyses. They are schematized in Figure 4.

The monocalcium phosphate monohydrate loses water at 108 °C and the MCPA obtained decomposes into calcium dihydrogen pyrophosphate, and then, due to continuous water loss, into calcium metaphosphate above 186 °C.

The DCPD loses water at 180 °C and transforms into DCPA. At higher temperature, another water loss is observed corresponding to the formation of calcium pyrophosphate.

The ATCP loses water up to its crystallization into α-TCP first and then β-TCP above 800 °C. The formation of the metastable α-TCP before the stable β-TCP might appear surprising. In fact, this phenomenon is rather common and it is observed also, for example, with amorphous zirconium dioxide or in the crystallization of polymeric substances. It is known as 'Ostwald's step rule' or law of successive reactions, stating that in any crystallization process, the state that is generally observed is not the most stable state but the least stable state that is closest in terms of free-energy change to the original state.[94]

The decomposition of OCP is more complex and involves the formation of DCPA and HA, and at higher temperature calcium pyrophosphate, which then partly reacts on HA to give β-TCP.

Considering apatites, two different types of decomposition reactions can be distinguished: reversible decomposition affecting stoichiometric apatites at very high temperature and irreversible decomposition related to nonstoichiometric apatites or apatites-containing thermally unstable ions such as carbonate and HPO_4^{2-}, for example.

1.111.4.1.1. Reversible decomposition of stoichiometric apatites

The stoichiometric HA is thermally very stable and it can be sintered at 1200–1250 °C without strong alteration. However,

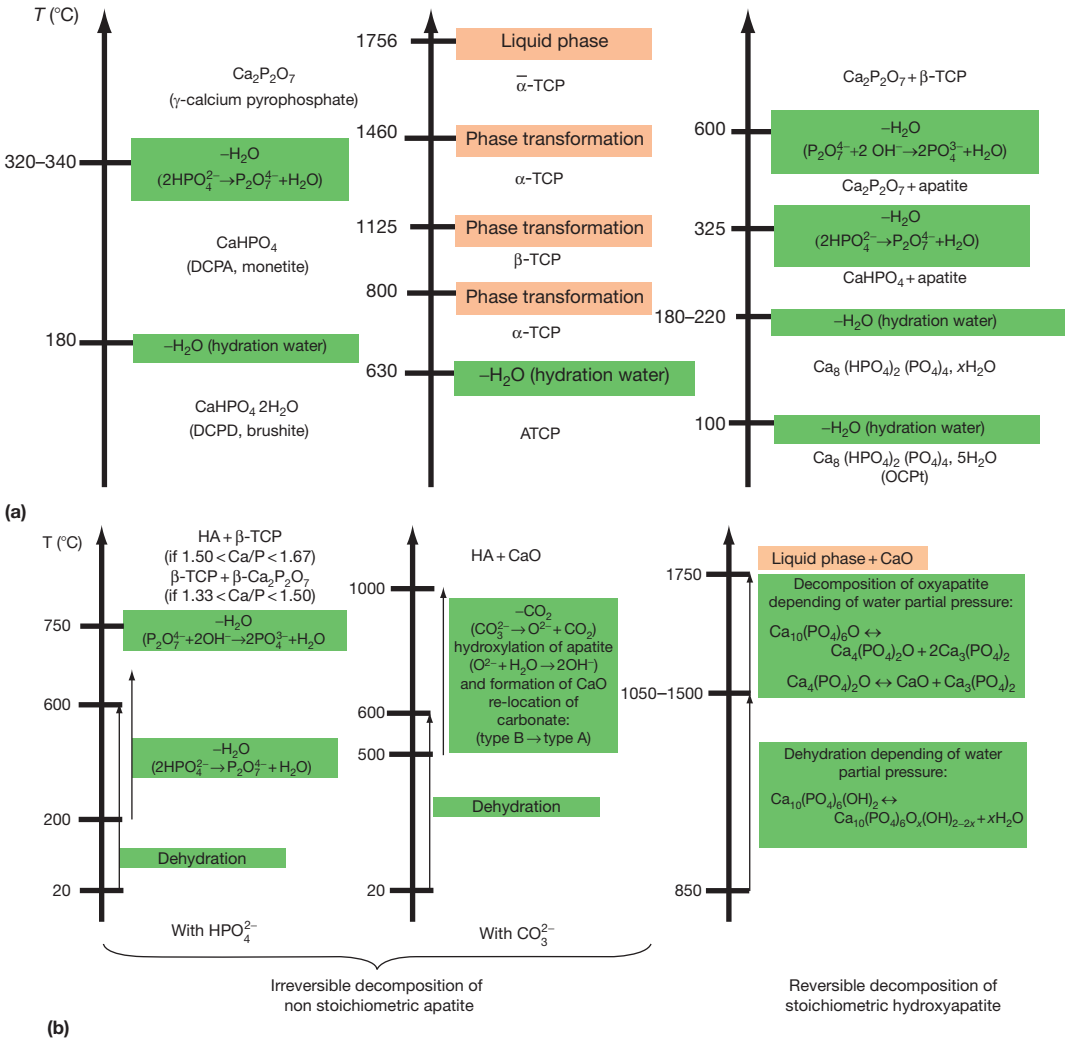

Figure 4 (a) Thermal decomposition of DCPD, DCPA, ATCP, and OCPt. (b) Thermal decomposition of apatites. Depending on their composition (HPO_4^{2-} or CO_3^{2-} or both) vacancies-containing apatite decompose differently, these reactions are always irreversible. At high temperature (above 850 °C) stoichiometric hydroxyapatite decomposes reversibly into different Ca-P compounds depending on the temperature and water partial pressure.

HA is considered to begin to lose water at 850 °C at a very low H_2O partial pressure leading to the formation of oxyapatite.[63] This loss is strongly dependent on the water partial pressure. Then, oxyapatite decomposes into TCP and TTCP at about 1050 °C and, at higher temperature (1720 °C), TTCP decomposes into CaO and a liquid phase.

All these reactions are theoretically reversible and, on cooling under an adequate water partial pressure, the HA structure is reformed, provided there is no fast quenching which prevents the completion of the reverse reaction. A problem which has been raised is the volatilization of P at very high temperatures, for example, in plasma spraying processes.

1.111.4.1.2. Irreversible decomposition of nonstoichiometric apatites

Nonstoichiometric apatites exhibit a complex decomposition behavior depending on their initial composition, as shown in Figure 4(b). All these reactions are related to the instability of calcium-deficient apatites and they are irreversible. The decomposition involves the formation of pyrophosphate in the case of HPO_4^{2-}-rich apatites and the formation of oxide ions in the case of carbonate-containing apatites

$$2HPO_4^{2-} \rightarrow P_2O_7^{4-} + H_2O$$

$$CO_3^{2-} \rightarrow O^{2-} + CO_2$$

Curiously, the pyrophosphate ions are not easily detected in the apatite structure but they can be evidenced by chemical methods. It is only at high temperature that calcium pyrophosphate crystallizes as a separate phase when the Ca/P ratio of the apatite is under 1.5. The formation of oxide ions can lead to the formation of OH^- in the apatite structure, or, in highly carbonated type B apatites with a Ca/P ratio above 1.67, to the separation of a CaO phase.

When HPO_4^{2-} and CO_3^{2-} are both present, cross-reactions can be observed such as

$$2HPO_4^{2-} + CO_3^{2-} \rightarrow 2PO_4^{3-} + CO_2 + H_2O$$

or

$$P_2O_7^{4-} + CO_3^{2-} \rightarrow 2PO_4^{3-} + CO_2$$

In the case of nanocrystalline apatite, the first reactions can occur at very low temperature 100–200 °C.

The end products at 900–1000 °C of the irreversible decomposition of nonstoichiometric Ca-P apatites are only related to the initial Ca/P ratio:

- for Ca/P < 1.5, β-TCP and β-calcium pyrophosphate are obtained
- for 1.5 < Ca/P < 1.67, a mixture of β-TCP and stoichiometric HA is obtained
- for 1.67 < Ca/P, a mixture of stoichiometric HA and CaO is obtained.

These decomposition reactions can be used to determine the Ca/P ratio of an unknown Ca-P phase and some of them have been standardized (see **Section 1.111.3.2**).

The irreversible decomposition of calcium-deficient apatites can be used to prepare biphasic ceramics made of TCP and HA.

1.111.4.2. Solubility

Per definition, the solubility of a solid in an aqueous solution is characterized by an equilibrium between the solid surface and the species in solution, which exhibit a constant ion activity product corresponding to the solubility product (K_{sp}). The K_{sp} is characteristic of a solid compound and is related to its composition; it is not directly representative of the amount of solid dissolved, which may change as the species in solution vary, due, for example, to protonation or deprotonation of orthophosphate groups, the formation of ion pairs in solution, or the change of the activity coefficients of the different ions due to alterations of the ionic strength. The speciation of different entities present in the solution is an important factor. Such alterations are considered in computer programs available on the web. In several cases, however, authors have not really evidenced an equilibrium and they report solubility data, which might correspond to a dissolution rate rather than to real solubility equilibrium. In the case of phases that cannot form in the conditions of the dissolution experiments, for example in physiological conditions (37 °C, pH = 7.4) such as α- and β-TCP, DCPA, and TTCP, an apparent dissolution equilibrium is reached; however, the risk exists to precipitate non detectable amounts of more stable Ca-P phases. The determination of K_{sp} of unstable calcium phosphates, which can be easily hydrolyzed into more stable phases in aqueous media, is particularly delicate (e.g., OCP, ACP) and, in fact, several different solubility products have been reported in these cases.[20,30] Another confusion arises from apparent solubilities often determined in conditions where an equilibrium is not really reached, for example, because of uncontrolled release of CO_2 in dissolution studies of carbonated phases. Other problems of reliability include uncontrolled impurities levels, the consideration of different ion pair formations or ion activities corrections, which are responsible for discrepancies of K_{sp} of sparingly soluble solid phases. Recently, Nancollas has raised a new concern regarding the dissolution process of crystals.

Table 8 Solubility products of different calcium phosphates

Ca-P compound	*Common abbreviation*	*$-log\ K_{sp}$ at 25 °C*	*References*

[a]Expressed for a chemical formula in '$Ca_{10}(PO_4)_6Y_2$.'

A stepwise dissolution behavior has been shown in the case of well-crystallized OCPt assigned to the need of additional energy for the formation of dissolution kinks on a flat crystal surface and resulting in difficulties to determine a solubility equilibrium.[95] In the case of solid solutions and nanocrystalline apatites, other difficulties have been raised, as discussed later in this paragraph. Nevertheless, the solubility products of most stoichiometric well-crystallized calcium phosphates have been determined (**Table 8**), although divergences and discussion are still existing. A recent direct method, especially based on the total dissolution of increasing amounts of crystals until the detection of residual crystals in suspension[104], has given solubility products much lower values than those generally admitted, but this rather unconventional procedure could be biased due to the stabilization of crystals in undersaturated solutions as shown by Tang and Nancollas.[95]

The solubility isotherms of stoichiometric Ca-P compounds have been studied in detail by several authors.[105,106] At physiological pH, the solubility, expressed as the amount of Ca^{2+} and orthophosphate ions in solution at the equilibrium, is found to decrease in the order TTCP > α-TCP > DCPD > DCPA ~ OCP > β-TCP > HA, while FA is itself less soluble than HA. Moreover, among the nonfluorinated Ca-P compounds, stoichiometric HA is the least soluble phase in a wide range of pH values down to pH close to 4. Below this value, DCPA becomes the least soluble phase, although it does not form generally in these conditions, and DCPD appears as the stable phase in solution.

These data permit some general observations. For the same composition, phases with lower density show a higher solubility, for example, considering the dicalcium phosphates or the crystalline TCP, in relation with the hydration or simply the structure. This observation can be related to the degree of cohesion of the structure, assuming that the main factor involved in the cohesion of Ca-P crystals is the electrostatic attraction between anions and cations and if we neglect the events occurring in solution (protonation, ions pairs), which, for the same or similar compositions, should not be crucial. Such a reasoning can be extended to apatites; thus, Ca-P apatites with the smaller unit-cells and, therefore, the higher the cohesion forces the lesser the solubles, and FA is less soluble than HA. Similarly, Ca-P apatites are less soluble than strontium-phosphate apatites, with larger unit-cell

dimensions. This behavior can probably be generalized to apatites-containing vacancies: apatites with a high vacancies content should be more soluble than those with a low vacancies content. Considering carbonate and HPO_4^{2-}-containing apatites with similar Ca vacancies content, type B carbonated apatites, with a smaller unit-cell, should be less soluble and they have been found, in fact, to form preferentially during maturation.[107] The cohesion forces can also be increased by raising the electric charge of the constitutive ions, thus, silicate- and lanthanide-containing apatites are less soluble than regular Ca-P apatites. These considerations neglect, however, the existence of partial covalent bondings between ions in the apatite crystals and the ions interactions with the solution and, although they are indicative, no definitive conclusion should be made based only on electrostatic cohesion forces.

It is also worth mentioning that the presence of foreign ions in the composition of a given Ca-P compound or even in the surrounding solution may noticeably modify the dissolution behavior. For example, in the case of HA, the incorporation of fluoride ions was found to decrease the solubility, while carbonate or else magnesium ions induced an increase in the apparent solubility.[108,109] In the presence of fluoride ions in solution, a decrease in solubility is also observed probably related to a surface alteration of the HA. Such phenomenon involving a very low amount of surface ions impurities may considerably affect the solubility behavior of apatites and they are used in the biomedical field, such as in fluorinated tooth paste, for example, or in apatite coatings of prosthetic devices.

Besides the above considerations, dealing with stoichiometric Ca-P compounds, the solubility behavior of nonstoichiometric, biomimetic, nanocrystalline apatites is also interesting to address due to their resemblance with bone mineral and their high potential in the bioceramic field. However, the physicochemical characteristics of apatite nanocrystals highly depend on their conditions of formation. Several factors can influence the solubility, such as the composition/nonstoichiometry of the nanocrystals and, probably, the surface structure and composition. A detailed analysis of the solubility behavior of such biomimetic apatites indicates that, unlike stoichiometric HA, they do not reach a constant solubility product. In fact, the apparent equilibrium which is attained depends on the amount of solid dissolved (Figure 5); the ionic product at the apparent equilibrium state shifts progressively toward that of stoichiometric HA as the amount dissolved increases. This observation has led to the concept of 'Metastable Equilibrium Solubility' (MES). This behavior has been evidenced and studied in various works (e.g., Baig *et al.*,[111] Chhettry *et al.*,[112] and Hsu *et al.*[113]) and has been related to the level of microstrains in the crystals.[110] However, other explanations are possible such as a variable surface composition and structure or the existence of mixed crystals population with different size, composition, and solubility.

Noncongruent dissolution (i.e., dissolution leading to a mineral ion composition of the solution different from the solid) has often been reported in the case of calcium phosphates. This phenomenon can have several causes, for example, a surface hydrolysis or the preferential dissolution of undetected impurities possibly on the surface of the crystals. In the case of high solid/solution ratios with solids of high specific surface area, noncongruent dissolution can also be related to surface reactions such as adsorption of constitutive ions, as discussed in Section 1.111.4.4.1, or surface hydrolysis or precipitation; but these experimental conditions, favoring the detection of surface reactions, and depending on solid/solution ratios, do not necessarily correspond to an anomaly of dissolution. It shall be emphasized that a dissolution of a homogeneous phase leads to a congruent dissolution as it is most commonly found. Subsequent surface equilibrations of the residual mineral surfaces can alter the composition of the solution and this alteration is dependent on the solid/solution ratio. In the case of phase with an heterogeneous distribution of atoms, however, a 'noncongruent' dissolution may be observed.

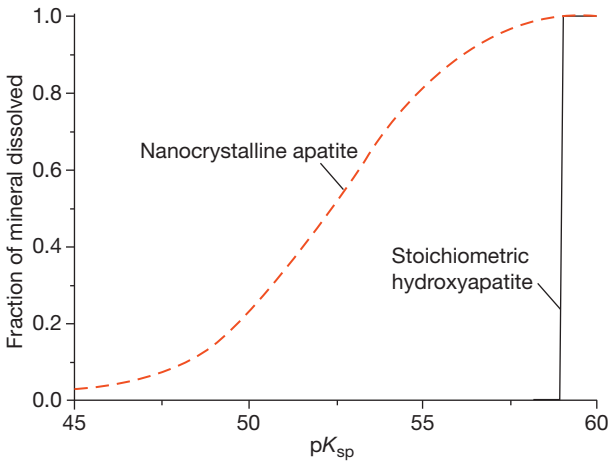

Figure 5 Illustration of the Metastable Equilibrium Solubility (MES) of biomimetic apatites.[110] For a stoichiometric hydroxyapatite, the ion activity product in solution is independent of the amount dissolved. For biomimetic nanocrystalline apatites (from biological or synthetic origin), the ion activity product in solution decreases as the amount of dissolved apatite increases leading to a MES. The shape and position of the MES curves depend on the maturation time.

1.111.4.3. Hydrolysis and Aqueous Conversion

The most soluble Ca-P compounds (ACP, DCPD, DCPA, OCP, TTCP, nonstoichiometric HA) can be transformed into more stable phases in aqueous media. The important parameters are pH, calcium and phosphate concentrations, and temperature. Most generally from slightly acidic pH to alkaline pH, the end term of these conversion reactions is apatite, in agreement with the dissolution isotherms. However, these reactions can lead to apatites with very different compositions depending on the mineral ions in the solution. Thus, in the presence of carbonate and/or fluoride, carbonated and/or fluorinated apatites can be obtained.

Several reaction mechanisms have been proposed for the hydrolysis reactions. Dissolution–reprecipitation seems to be the dominant process for hydrolysis involving phases transformations. Although at physiologic pH, the most stable, least soluble, phase is apatite, even stoichiometric apatite, this phase is rarely obtained in solution, in these conditions, and generally, metastable nonstoichiometric apatites are formed

especially at human body temperature. These conversion reactions may involve intermediary phases according to the Ostwald step rule (see Section 1.111.4.1); thus, the transformation of ACP into apatite at neutral pH is considered to occur through an OCP precursor at pH close to neutrality. In the case of OCP hydrolysis into apatite, a topotactic transformation which could give rise to interlayered crystals of OCP and apatite has been suggested.[114] The HA crystals formed can appear in this case as pseudomorphs of OCP crystals. In the case of apatite nanocrystals with a surface hydrated layer, the evolution in aqueous media appears more complex and is often called 'maturation.' In this case, the hydrolysis is associated with an alteration of crystals characteristics. At physiological pH, maturation has been found to be related to the hydrated layer. The apatite domains develop at the expense of the ions in the hydrated layer and when the hydrated layer has practically vanished, the process stops.[107] Even when maturation has stopped, slower evolution processes remain active like Ostwald ripening. However, if they play a role at geological time scale, their implication in biological minerals is questionable.

Aqueous conversions of Ca-P are mainly used in self-setting Ca-P cements. One may distinguish rapidly hydrolyzable Ca-P such as ACP, α-TCP, which can lead to apatites in less than 1 h at 37 °C and can be used in neutral monocomponents mineral Ca-P cements, and slowly hydrolyzable Ca-P such as DCPD, DCPA, and OCPt, which need generally longer reaction times, higher temperature, or an alkaline pH to react rapidly. These are used in 'acid–base' cements in combination with TTCP, which hydrolyzes relatively rapidly and generates an alkaline pH. This distinction between rapidly and slowly hydrolyzable Ca-P is, however, rather artificial and depends essentially on the characteristics of the crystals, especially the crystal dimensions.

1.111.4.4. Surface Charge and Surface Energy

Interfacial phenomena play a major role regarding the biological properties of Ca-P, especially in adsorption and cell adhesion, and surface charge and surface energy have often been considered as the most important physical characteristics of the surface.

1.111.4.4.1. Surface charge

The surface charge of solids, at the origin of 'zeta potential,' arises from different phenomena: the preferential adsorption/desorption of the constituting ions of this solid in solution, the protonation of surface species like PO_4^{3-} ions, for example, or the surface adsorption of foreign ions or molecules from the solution. For ionic solids such as calcium phosphates, the surface charge is closely related to the concentration, in the surrounding fluid, of specific ions that can interact with the surface of the solid. Such ions are often referred to as 'potential-determining.' A difficulty is the time-dependent variation of the zeta potential, which may result in discrepancies.[115]

The point of zero charge (pzc) defines the conditions of the solution (in particular, the pH value) for which the surface density of positive charges (contribution of cations) equals that of negative charges (anions). It is often regarded as a characteristic parameter for a given surface in a given aqueous solution.

When considering calcium phosphates, most studies have been dedicated to the determination of the surface charge of stoichiometric HA. It should be added here that as HA involves at least three types of potential-determining ions (calcium, phosphate, and hydroxide or proton), a variety of concentration conditions exist for conducing to a condition of zero surface charge,[116] which therefore leads to define a *line* of zero charge (lzc) in the calcium–phosphate–hydroxyl ternary diagram. Chander and Fuerstenau[116] have, for example, calculated the position of this lzc for HA and compared it to experimental data reported by several authors. Some discrepancies were observed between calculated and experimental points, which is probably due to dissimilar affinities of calcium, phosphate, and OH^- ions for the surface (assumed identical in the calculations). The calculated pzc value is found to be around pH 8.5; however, experimental values are often slightly lower. The isoelectric point of stoichiometric HA, for example, is close to pH 7.[117] Generally speaking, it may be stated that the pzc for HA is found in the range 6.4–8.5.[118] The conditions of preparation, washing, and storage of the apatite material as well as the presence of impurities and structural defects seem indeed to play a nontrivial role in the electrochemical properties[118,119] of the surface, which constitute the basis of most zeta potential measurements. In all cases, a negatively charged surface is observed, for HA, beyond the pH corresponding to the isoelectric point and a positively charged surface below it. It is interesting to point out that, under constant pH and ionic strength, a change in the calcium or phosphate concentrations can affect the surface charge of HA significantly. Indeed, an increase of calcium concentration will, in every case, lead to a surface charge shifted toward more positive values (traducing the adsorption of calcium ions on the surface of the solid), while an increase of phosphate concentration would render the surface more negative. These effects were indeed experimentally observed by Somasundaran and Wang.[119]

Ionic substitutions and apatite composition also play a role in the modification of apatite surface charge. For example, the following order was found for the pH values of the pzc of four apatite samples: FA < HA < strontium-HA < barium-HA.[120] Interestingly, this order also corresponds to the order of increasing solubility of the four apatites. For example, the pzc of FA is found in the range 4.5–6.9.[118] Other types of ionic substitutions were also investigated; for example, the surface charge of silicated-HA was found[121] to be noticeably more negative than regular HA in similar conditions, which was assigned to the presence of tetravalent silicate ions exposed on the surface of the solid rather than phosphate ions. Nonstoichiometry may affect the surface charge of apatites, and Ca-deficient apatites, more soluble than stoichiometric ones, have been found to exhibit zeta potential greater than stoichiometric HA.[122]

It is also worth noting that the adsorption of organic molecules on the surface of solids can significantly modify the surface charge of the particles, especially when the molecules exhibit charged functional end-groups (or at least strongly electropositive or electronegative elements). An example of this effect was reported by Mangood *et al.*[123] referring to the adsorption of acetaminophen on HA, leading to a surface noticeably more negatively charged. In contrast, the adsorption

of amino acids[124] or an amine-terminated phospholipid moiety[125] on calcium-deficient apatites were found to lead to surface charges shifted toward more positive values. It must, however, be stated that, in the case of nonstoichiometric nanocrystalline apatites prepared in biomimetic conditions (low temperature, physiological pH, etc.), the existence of a nonapatitic surface layer on the apatite nanocrystals (see previous section on the 'preparation of Ca-P compounds') leads to a more complex system that cannot anymore be adequately defined by using the regular HA surface model, which thus makes it difficult to appreciate the amounts of phosphate or calcium ions actually exposed on the surface (as they are bound to vary depending on the conditions of formation and storage).

Apart from these data regarding apatitic compounds, only the surface charge data related to other calcium phosphate compounds are scarce. Among such works, however, zeta potential measurements have been interestingly performed on octacalcium phosphate (OCP) in solutions equilibrated with respect to that phase.[126] The results of this study pointed out the positively charged surface of OCP under a wide range of pH values (from 5 to 11). In addition, measurements carried out in a solution with increasing Ca/P ratios led to increasingly positive zeta potential values (at a given pH) suggesting the specific adsorption of calcium ions. In contrast, a decreasing zeta potential was observed when decreasing the Ca/P ratio of the solution, possibly related to a more extensive adsorption of phosphate ions in these conditions.

1.111.4.4.2. Interfacial energy

Interfacial energy is also an important parameter to consider when dealing with interactions between a solid surface and the surrounding solution. Yet, only few data are available in the literature on this matter in the case of calcium phosphates. Generally, two main components of the interfacial tension are distinguished, determined by the type of interactions with the surface polar (dielectric bondings) and apolar (van der Waals bonding) components, sometimes completed by a hydrophilic parameter related to hydrogen bonding. Such interfacial energies (with respect to water) have been reported for HA, FA, OCPt, and DCPD, with respective values: 9.0, 18.5, 4.3, and 0.4 $mJ\,m^{-2}$.[127,128] Interestingly, among those four compounds, the lowest interfacial tensions were found for the hydrated phases (OCP and DCPD). A value for the interfacial tension in water was also reported for β-TCP: 3.8 $mJ\,m^{-2}$,[129] also pointing out a lower value than for the apatites HA or FA. The surface tension of a carbonated apatite sample (well crystallized, 3 wt.% CO_3) was also determined,[130] with a value (9.0 $mJ\,m^{-2}$) found similar to that of HA. In all cases, the surface tension of these calcium phosphate compounds was found to correlate well with their solubility in water, the lowest surface tensions being observed for the most soluble phases.

1.111.4.5. Chemical Alterations of the Surface

Two main chemical alterations of the surface of Ca-P have been described in addition to preferential adsorption of constitutive ions discussed in Section 1.111.4.4.1: ion exchange and the adsorption of molecules.

1.111.4.5.1. Ion exchange

The term 'ion exchange' can be used to describe ion substitutions inside an apatite lattice. This is not, however, what is intended here, and ion exchange corresponds to a reaction specifically affecting the accessible ions on the surface of given crystals.

The surface ion exchanges are of utmost relevance in the case of nanocrystalline calcium phosphate apatites, which were found to exhibit a structured, metastable, nonapatitic surface layer that was shown to be highly reactive (see Section 1.111.2.3.2). These phenomena were first studied by Neuman and Mulryan[48] who suggested the possibility of carbonate-HPO_4^{2-} exchanges in biological nanocrystalline apatites. Several studies have explored surface ion exchange capabilities of biomimetic apatites, as illustrated recently in the case of Ca/Mg and Ca/Sr exchanges[88,131], where Mg^{2+} and Sr^{2+} are biologically active ions. Other ion sorptions were also investigated for HA. For instance, exchanges of part of the Ca^{2+} ions with metal ions Cu^{2+}, Cd^{2+}, Pb^{2+}, or else Zn^{2+} were studied.[132,133] The exchange isotherms may generally be well described by using the Langmuir model, and two main constants K and N representing respectively the affinitiy constant and the maximum exchangeable amount have been derived for exchanges performed either on carbonated or noncarbonated apatites. The ion exchange capabilities of nanocrystalline apatites have been related to the development of the surface hydrated layer. Thus, higher amount of ions are exchanged in freshly precipitated nonmatured apatites, where the surface hydrated layer may contain up to 20% of the exchangeable ions; in matured apatites where the apatite domains have developed at the expense of the hydrated layer, the ion exchange capabilities can be considerably reduced especially for carbonate–hydrogen-phosphate or anion exchanges. Curiously, cation exchanges appear to always involve higher amounts than anion exchanges. All these exchange reactions are very fast (the equilibrium is reached in a few minutes) and they do not alter the main characteristics of the apatite domains (crystal size and nonstoichiometry).[134] The ion substitution capabilities in the hydrated layer are considerably larger than those of a Ca-P apatite lattice. Thus, a considerable amount of surface Ca^{2+} can be replaced by Mg^{2+}, whereas Mg^{2+} ions can only substitute for a very small amount of Ca^{2+} ions in the apatite lattice. The reversibility of ion exchange reactions is always very high when the reverse reaction immediately follows the direct exchange reaction. However, when a maturation period occurs after the exchange, two kinds of behavior have been distinguished. When the mineral ion introduced in the hydrated layer can substitute calcium ions in the apatite domains, the reverse exchange reaction can only exchange back decreasing amounts of foreign ions still present in the decreasing hydrated layer. This is the case of Sr–Ca exchanges. When the mineral ion introduced cannot substitute in appreciable proportion the calcium ion in the apatite domain, they stay in the decreasing hydrated layer and remain almost totally exchangeable. This is the case of Mg–Ca exchanges.[135]

Another interesting feature related to ion exchanges is the role of foreign ions either on the promotion or the inhibition of apatite crystal growth. Several ions such as pyrophosphate, carbonate, or magnesium, among others, were thus shown to act as growth inhibitors for apatite crystals.[136]

It is often difficult to determine if the ion exchange reaction corresponds really to a surface ion exchange or to a dissolution–reprecipitation process involving a reequilibration of the surface. This distinction is especially difficult in the case of apatites where continuous solid solutions exist and where surface exchange can modify the surface composition to reach an equilibrium with the solution by modifying only the first surface atomic layers.

1.111.4.5.2. Adsorption

Adsorption phenomena on calcium phosphates are also of major interest, as molecules interacting with these compounds can play a key role in the recruitment and expression of cells, and they are strongly involved in the biointegration of implants. This is especially true for apatites due to their biomimetic nature and their numerous potentialities in the biomedical field.

The adsorption of proteins or other active molecules on apatites is also considered to play a determining role in mineralized tissues as it may control apatite crystal growth and dissolution *in vivo*, and it also appears as a clever way to associate drugs (e.g., antibiotics, antiosteoporotic agents, etc.) and other active agents (growth factors, etc.) to control their range of action. Such adsorption phenomena have thus been the object of a great number of studies. Proteins like osteocalcin, osteopontin, or else, albumin, and other biomolecules (phospholipid, growth factors such as fibroblast growth factor (FGF), vascular endothelial growth factor (VEGF), bone morphogenetic protein (BMP)) have, for example, been shown to adsorb on apatite and interact strongly with its surface (e.g., Boskey *et al.*,[137] Hauschka and Wians,[138] and Romberg *et al.*[139]). Also, as was mentioned above for substituting ions, several macromolecules were found to act either as promotors or inhibitors of crystal precipitation.[136] It has been shown, however, that such classifications can be misleading. Of course, an adsorbed molecule on a given calcium phosphate surface appears to delay in most cases the growth of the corresponding crystalline face; however, adsorption also stabilizes crystal nuclei with a subcritical size, and paradoxically low concentrations of adsorbing molecules in solution were shown to increase the nucleation rate and accelerate precipitation, whereas high concentrations inhibit precipitation.[140] All these adsorption reactions exhibit some common characteristics: they are generally well described by a Langmuir adsorption isotherm and they appear irreversible by dilution, which is often considered as an anomaly with regard to the Langmuir model (Figure 6).

Several factors have been shown to be involved in the adsorption properties of molecules on calcium phosphates either related to the solid surface or to the molecules themselves: surface energy, surface charge, functional chemical groups of the molecules, conformation, competition with other potential adsorbents, etc.

Historically, interfacial energy has been one of the first parameters to be considered in adsorption and, according to Gibbs, adsorption may be considered as determined by a decrease of the interface energy. This global physical view, of interest when weak interactions are involved with the adsorbate, neglects the possibility of strong chemical interactions at the atomic level which very often occur with the surface of Ca-P and determine the major adsorption processes of importance in biology.

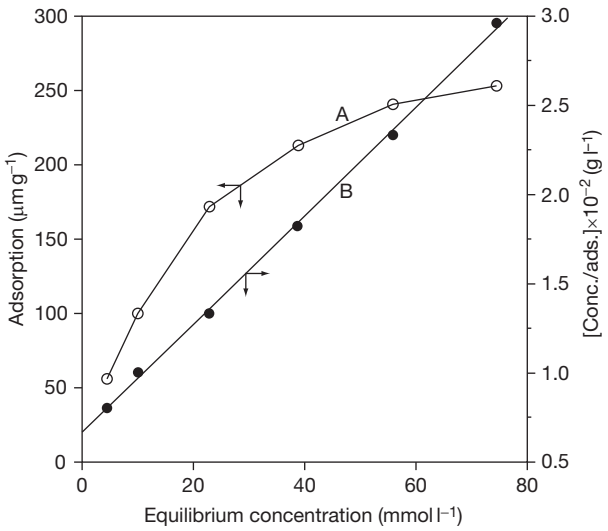

Figure 6 Example of an adsorption isotherm of citrate molecular ions, on apatite from aqueous solutions (22 °C). The isotherms (curve A) correspond to a Langmuir adsorption equation: $Q = KNC/(1 + KC)$ where Q is the amount adsorbed (ordinate), and C is the equilibrium concentration (abscise). Two parameters characterize the adsorption reaction: K, the affinity constant, and N, the maximum amount adsorbed at saturation. Generally, the Langmuir equation is linearized to extract more conveniently the adsorption parameters (curve B): $C/Q = C/N + 1/KN$. Reproduced from Misra, D. N. *Colloids Surf.* **1998**, *141*, 173–179, with permission from Elsevier.

Indeed, due to the ionic nature of Ca-P compounds, two main types of interactions have been distinguished corresponding to electrostatic attraction between negatively charged end-groups and calcium ions on the one side, and/or positively charged end-groups and phosphate ions on the other side. The zeta potential of apatites has thus been and is still considered to play a major role in the adsorption process and most adsorption behaviors have been related to this surface parameter. Once again, however, the correlation between this global physical parameter describing the total surface charge of apatite particles and chemical interactions with specific ions or charged groups at an atomic level is not straightforward. It appears that the global charge of a particle does not give any information on the local distribution of cations and anions on a mineral surface, and as a matter of fact, the zeta potential does not appear to be a decisive parameter: for example, the adsorption of positive molecules on a globally positive apatite surface and, inversely, negative molecules on a globally negative apatite surface have been described.[141,142] Adsorption is also observed on neutral Ca-P surfaces near their pzc. Similarly, the isoelectric point of proteins, by itself, does not give specific information on the ionization state of the different functions of a molecule and should be considered with caution when predicting the adsorption behavior related to a chemical interaction.

Interestingly, the nature of the functional chemical groups exposed by the adsorbent is one of the key parameters to take into account when considering the interaction with a calcium phosphate surface. Phosphate esters and similar groups especially interact strongly with apatite surface, and phosphorylated compounds are considered to play an important role in biomineralization. Among the other functional groups

considered to interact strongly with apatite surfaces are silicate and sulfate. In general, carboxylate groups interact weakly, except when they are associated in polyacids.[143,144] Positively charged groups can also adsorb on apatites but generally less strongly than negatively charged ones.

In numerous examples, the adsorption of negative molecular ions has been related to the release of phosphate ions, demonstrating a chemical ion exchange reaction with the apatite surface. This process has been described in different instances, as for example in the adsorption of polyacids[145], citrate ions[146], zoledronate[147], or serum proteins on apatites. This chemical process seems rather general and supports a chemical description of the adsorption reaction rather than a physical one based on global electrostatic interactions or pure interfacial energy considerations. Adsorption could thus be represented, for example, as a chemical equilibrium as follows (in the case of a one-to-one exchange with surface phosphate groups):

$$A_{sol} + P_{ap} \Leftrightarrow A_{ap} + P_{sol}$$

with A being the adsorbate in a given ionic state either in solution (sol) or on the apatite surface (ap), and P being the phosphate group in a given ionic state either in solution or on the apatite surface. Other ion exchange possibilities have been discussed by Misra[146] in the case of citrate adsorption. These descriptions seem consistent with the use of apatites in chromatography where negatively charged molecules are desorbed using phosphate solutions and positively charged ones using calcium solutions. It has been shown that this ion exchange process could be described by a Langmuir-type isotherm, often observed, and could also explain the apparent irreversibility of the adsorption on dilution of the solution.[148]

Here again, like for ion exchanges, surface reaction and dissolution–reprecipitation can be considered as possible competitive processes. However in this case, unlike for ion exchange on apatites, no solid solutions are generally possible between the calcium phosphate and the phosphate salt of the molecules. Thus, in the case of insoluble calcium salts formation and precipitation with the adsorbate molecules, the apatite phase is progressively destroyed as the new phase forms, leading to the release of phosphate into the solution until a new equilibrium is reached. This event does not generally give a Langmuir-type isotherm with a typical saturation domain. On the contrary, the increase of the amount of adsorbate results in more precipitation of its calcium salt and more destruction of the apatite. In some cases, however, this process could result in a Langmuir-like adsorption behavior, with an apparent saturation domain if there is coating of the apatite surface by the new phase, preventing further reaction. Observation of the solid phase by XRD or electron microscopy generally allows the formation of new phases to be detected (For more details on proteins adsorption, see also **Chapter 3.311, Molecular Simulation Methods to Investigate Protein Adsorption Behavior at the Atomic Level**.)

1.111.4.6. Nucleation Properties

Nucleation and crystal growth are processes involved in normal and pathological biological mineralization; these processes are also of primary importance when calcium phosphate-based bioceramics are in contact with a calcium and phosphate supersaturated solution such as human blood plasma (ceramics implanted *in vivo*) or the considered equivalent synthetic solutions such as simulated body fluid (SBF) or other similar solutions used to test ceramics *in vitro*.

Crystallization at surfaces, that is, heterogeneous crystallization, may be induced at supersaturations lower than those required for spontaneous precipitation (homogeneous crystallization). This phenomenon is generally considered to be related to the lower overall free energy in the formation of nuclei of critical size at the surface of a substrate[149] and it has been related to the interfacial energies. Crystallization on foreign substrates is generally preceded by an induction period which is markedly related to the supersaturation, the temperature, and the presence of additives or impurities. This period has been considered by many authors to be the time needed for the formation of nuclei of critical size, that is, stable nuclei able to grow.

The growth of one crystalline phase on the surface of another may be important especially in physiological mineralization processes. The epitaxial relationships and kinetics of growth of HA on calcium phosphate crystalline phases or on other compounds such as the ones involved in bioactive ceramics (especially $CaCO_3$) have been investigated by Koutsoukos and Nancollas.[150] Epitaxy or oriented crystal growth is a special case of heterogeneous crystallization in which the crystal formation on the substrate is determined by the atoms mapping that offers a good crystal lattice match facilitating the nucleation of a foreign phase. The authors showed that HA can be grown on different calcium salts as substrates (DCPD, calcium fluoride, and calcite) from calcium and phosphate solutions with a low supersaturation; moreover, they showed that the crystallization kinetics are similar to that of HA on HA seed crystals whatever the substrate. However, epitaxial growth of HA on these substrates was not confirmed due to the difficulty to well characterize the grown microcrystalline apatite on the HA. β-TCP on the contrary appears as a poor nucleation substrate for HA[151], although it can be used in heteronucleation of OCPt.

The heterogeneous nucleation of apatite crystals on organic substances has been related to functional groups. Thus, phosphate groups have been found to favor the nucleation of apatite on collagen matrix.[152] More recently, Toworfe *et al.*[153] have shown that apatites form preferentially on surfaces rich in –OH terminal groups, whereas surfaces with $-NH_2$ groups exhibited a low induction capability. Such findings have been associated with the polarization of the surfaces and especially, the acceleration of crystal growth on a negative surface evidenced by Yamashita *et al.*[154] and discussed by Calvert and Mann.[155]

In vitro and *in vivo* crystallization processes can differ substantially. Indeed, two main differences can be noted between *in vitro* and *in vivo* crystallization: (i) the rate of precipitation which is usually faster *in vitro* compared to *in vivo* and (ii) the presence of many proteins and ions *in vivo* that can promote or inhibit mineralization and can alter crystal morphology.

1.111.5. Biological Response and Physical–Chemical Characteristics

Physical–chemical characteristics of materials are directly related to some of their biological properties and determine in part biointegration, biological activity, and biodegradation

of materials. The biointegration of an implant is a crucial property, especially in the case of bone substitutes, and a poor biointegration is responsible for most implant failures. The biointegration of implants is determined on the one hand by mechanical factors: the interlocking of implant surface and biological tissue and on the other hand by chemical factors: the chemical bonding to the tissue constituent. The mechanical integration is mostly determined by the roughness and porosity of biomaterial surfaces initially created on the medical device and it may also be the result of biodegradation irregularities. The chemical bonding to the tissue seems a determining factor and it appears mainly related, in actual bone substitutes, to the ability of the surface to bind directly to the mineral fraction of bone tissue.

Even if bioactivity has different meanings depending on the authors, it is generally recognized that bioactive materials have the property to bind directly to bone tissue without any fibrous interface. Bioactivity is also used to name materials favoring an accelerated tissue repair. These definitions are related to different biological phenomena, namely implant–tissue interactions and implant–cell interactions that can possibly be or not be combined in the same material. It seems important to insist on these two properties. Cell culture dishes, for example, which have been specially treated to favor cell adhesion, allow osteoblast cells to proliferate and produce bone tissue. However, their bone-bonding ability is limited and the materials they are made of will never be a good bone substitute. In fact, once osteoblast cells have reconstructed bone, the interface is essentially implant/tissue and it is mainly the strength of this interfacial interaction which insures bone bonding. Most calcium phosphate compounds involved in bioceramics are not in equilibrium with biological fluids; several reactions will thus occur on the Ca-P ceramic surface. As biological fluids are supersaturated with respect to apatite, the Ca-P ceramics may also serve as templates for the formation of carbonated apatite crystals.

1.111.5.1. Active and Passive Biomaterials with Regard to Ca-P Nucleation

It has been shown that all bioactive materials that bind chemically to bone tissue and promote the formation of a stable interface ('bone-bonding materials') also have the ability to initiate nucleation of Ca-P from biological fluids at their surface. This layer of Ca-P shows characteristics analogous to bone mineral and appears to be composed of nanocrystalline carbonated apatite with a high reactivity. The association of the layer with specific bone proteins enables osteoblast cells (responsible for bone tissue formation) adhesion and activity.[156] Their activity is, however, related to nutritive fluid supply. For some authors, this process is similar to that involved in bone remodeling and the neoformed layer would present a composition analogous to the cement line at the edge of an osteon.[157] However, one can note that the formation of this layer is desirable at the biomaterial surface only for applications as bone substitutes and not for articular or cardiovascular applications for which any calcium phosphate nucleation and deposit must be avoided.

The ability to form this layer is generally considered as a measurement of the biological activity of bioceramics. Two main classes of biomaterials can be distinguished depending on the processes inducing the formation of apatite nanocrystals (see **Table 9** and **Figure 7**): in one case, the implant is only a substrate favoring the heterogeneous nucleation ('passive' biomaterials) and in the other case, it releases mineral ions that locally increase the supersaturation of biological fluids and thus contribute to the fast formation of the apatitic layer ('active' biomaterials) adding mineral ions from the material to the ions of the body fluids (**Figure 7**).

Assuming that the formation of an apatite layer determines the biological activity, 'active' biomaterials could be considered more efficient than 'passive' ones and in fact such a conclusion has been drawn by Hench comparing bioactive glass and HA.[158] However, bone is a living tissue with a remodeling process and one may wonder what may happen at the interface of the 'active' biomaterials and bone after successive remodeling processes. Is the release of mineral ions from the biomaterials still active or is it no more existing after the first contact resulting in surface depletion of active mineral ions? 'Active' biomaterials are probably superior for bioabsorbable implants, whereas 'passive' ones, which will essentially keep their intrinsic nucleation properties even after multiple remodeling events, could be preferred for permanent implants.

Table 9 Classification of biomaterials based on their ability to promote the formation of an apatitic layer analogous to bone mineral on their surface

	Biomaterial	*Active ions*	*Induction process*
'Active' biomaterials	Bioglasses	Ca^{2+}	Diffusion outside the bioglass
	Coral	Ca^{2+}, CO_3^{2-}	Dissolution
	Plaster of Paris	Ca^{2+}	Dissolution
	Ca-P cements	Ca^{2+}, PO_4^{3-}, OH^-	Dissolution
	Alkaline hydrogels	OH^-	Hydrolysis
	Biomaterial	Nucleation ability	Induction process
'Passive' biomaterials	Sintered apatites	Excellent	Epitaxy
	Titanium	Average	Hydrolysis, PO_4^{3-} and Ca^{2+} uptake
	Neutral hydrogels	Good	PO_4^{3-} uptake
	Collagen	Good	Phosphorylated entities
	Polyactiv®	Good	Ca^{2+} uptake

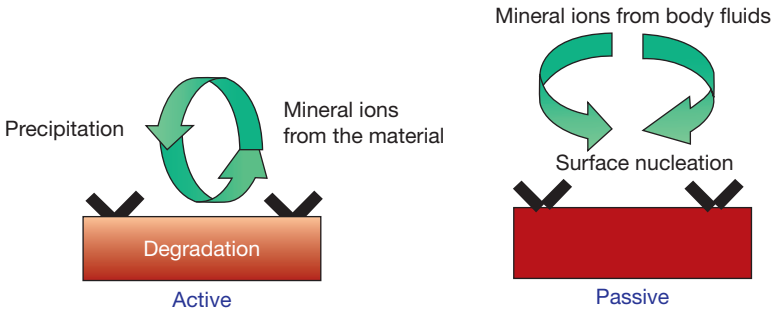

Figure 7 Illustration of 'active' and passive bioactive materials with regard to the nucleation of Ca-P apatites. In active biomaterials, the mineral ions needed for the precipitation of apatite crystals at the surface of the biomaterial can come in part from the material, either by dissolution or by diffusion leading to a surface depletion. In passive biomaterials, the formation of the apatite crystals involves only ions from the supersaturated body fluids, and nucleation ability is exclusively an inherent surface property.

Table 10 Ionic composition of blood plasma and SBF solutions

	Concentration 10^{-3} mol l^{-1}							
	Na^+	K^+	Ca^{2+}	Mg^{2+}	HCO_3^-	Cl^-	HPO_4^{2-}	SO_4^{2-}
SBF	142.0	5.0	2.5	1.5	4.2	148.8	1.0	0.5
Blood plasma	142.0	5.0	2.5	1.5	27.0	103.0	1.0	0.5

1.111.5.2. Simulated Body Fluid Testing

Considering the importance of nucleation and formation of an apatite layer on bioactive materials, an international standard (ISO standard 23317, 2007) has recently been published to evaluate the apatite-forming ability on the surface of biomaterials in a model solution: simulated body fluids (SBF). The SBF solution, proposed by Kokubo *et al.* in the 1990s, contains mineral ions at concentrations nearly equal to those of human blood plasma (see **Table 10**).[159] Indeed it has been shown that this apatite layer can be reproduced on the surfaces of material in SBF solutions and that nanocrystalline apatite thus formed is quite analogous to bone mineral. This inexpensive and fast test has been largely used to estimate the potential biological activity of a material and it is presented as useful for evaluating in a quantitative manner bone-bonding ability of a biomaterial preliminary to animal experiments, although it shall be acknowledged that there are no quantitative studies correlating SBF tests and the *in vivo* biological activity and performance.

The test is quite simple and consists in the immersion of the material to be tested in a SBF solution at 37 °C up to 4 weeks. The formation of the biomimetic carbonated apatite on the surface of the biomaterial can be detected by thin film XRD spectrometry and/or SEM and the rate of formation can be followed by chemical analyses of the solution. This test is commonly considered as a measurement of the bioactivity of a biomaterial; as bioactivity increases, apatite is supposed to form on the material surface in a shorter time in proportion to this increase.

The protocol for the use of this solution to test bioceramics or more generally, biomaterials, is detailed in the ISO standard, although several errors exist in the available version at this date: the amount of trishydroxymethyl aminomethane (TRIS), used to buffer the solution, for example, is incorrect and the way of obtaining the SBF solution appears rather awkward, leading to the elimination of carbonate ions and risks of precipitation. A safer and more correct procedure would consist in preparing two buffered solutions, a cations solutions (half of the sodium chloride, potassium chloride, magnesium chloride, calcium chloride, buffered with half the amount of HCl recommended and TRIS) and an anion solution (half of the sodium chloride, dipotassium hydrogen phosphate, sodium sulfate, buffering the other half of HCl and TRIS, the sodium bicarbonate is added, last, in the buffered anion solution without alteration of the pH) and mixing them just before use.

SBF solutions differ in several points from the composition of blood plasma: the carbonate content is not adequate and proteins are absent. These constituents of blood plasma are important and they have been shown to alter strongly the nucleation and crystal growth process of apatites. The composition of SBF solution has been revised with a view to getting closer to mineral ion concentrations in human blood plasma by decreasing Cl^- concentration and increasing HCO_3^- concentration compared to concentration in conventional SBF solution.[160]

However, reaching the carbonate composition of real blood plasma would need to work under CO_2 partial pressure to avoid a decrease of carbonate content related to its dissociation at physiological pH in solution:

$$HCO_3^{2-} + H^+ \leftrightarrow H_2CO_3 \leftrightarrow H_2O + CO_2$$

Whatever the type of SBF solution (conventional or revised) considered, there is still a major difference between this model solution and human blood plasma: many proteins are present in plasma and the ionic concentrations in SBF solution have been established considering the ionic content of plasma, which includes compounds formed between mineral ions and organic molecules (soluble complexes, ion pairs) of serum altering the amount of free ions in solution and the activities of the mineral ions. It has been demonstrated that ultrafiltrated fractions of blood plasma (excluding mineral ions linked to proteins) had in fact, an ionic product close to that of OCP[161], whereas the actual SBF solutions exhibit a much larger one.

Another criticism made to SBF testing is that the mineral ions concentrations is not constant in the batch as it would be *in vivo* and circulating SBF testings have been proposed. However, the test is supposed to measure the apatite nucleation ability of an implant surface and not really a crystal growth kinetic. In this sense, the batch procedure seems adequate. SBF testing is the only chemical model presented as a measure of the biological activity of an implant surface based on the assumption that the apatite nucleation ability of a surface is related to its bioactivity. As it is an inexpensive and rather rapid testing method, it will probably continue to be extensively used, although it cannot replace animal implantation. The SBF test has been recently criticized by Bohner and Lemaitre who have proposed some improvements.[162]

The chemical reproduction of the reactions occurring on an implant surface placed in the body seems difficult to achieve: the body response to an implantation is a complex phenomenon which varies as time elapses. From a chemical–physical point of view, the composition and pH of the body fluids at the vicinity of an implant surface after the surgical operation is not really known. It is believed that the surgical trauma induces acidic pH, which could be responsible for accelerated degradation of Ca-P materials, but the intensity and duration of these events are difficult to predict, making a modeling of the behavior of an implant surface difficult.

1.111.5.3. Biodegradation

Biodeterioration and biodegradation of implants determine their durability. The first term is generally used when the alteration of the implant is not necessarily wanted and the second when it is one of its advantages. Several processes contribute to biodeterioration and biodegradation: mechanical wear, spontaneous reactions of the implant materials with body fluids, and cell-mediated alterations. Mechanical wear is of course occurring at the interface between mobile parts of a medical device but it is also observed at the tissue–implant interface, and appears mainly related to micromovements (fretting) and results in abrasion wear residues and possible inflammatory reaction. This phenomenon is limited when there is a strong interfacial bonding between the implant and the tissue.

In addition to mechanical wear and surface abrasion, two main processes can be distinguished: one is purely physicochemical (ionic crystal dissolution) and the other one is linked to cellular (and enzymatic) activity at the implantation site (activated resorption).[163] In fact, both aspects are bound to the intrinsic properties of the ceramic, including its grain shape and size, porosity, solubility, structure and microstructure, and also the degradation residues of various constituents in combined materials such as composites or heterogeneous materials.

The overall biodegradation rate *in vivo* has often been directly linked to the solubility behavior of the compound(s) constituting the bioceramic.[164] The different Ca-P compounds exhibit solubility products that greatly differ from one another (see **Section 1.111.4.2**). Compared with blood plasma, with an ionic activity product generally considered to be very close to OCP[161], the calcium phosphate phases, that should spontaneously dissolve are TTCP, DCPD, DCPA, ACP, and α-TCP, in addition to the two very soluble monocalcium phosphates. The other calcium phosphates should not spontaneously dissolve and on the contrary could exhibit a crystal growth. However, the most stable phase remains apatite, and an evolution of OCP and β-TCP toward apatite by surface or topotactic transformation cannot be excluded.

Spontaneous dissolution does not mean, however, that the implant, made of the most soluble Ca-P, necessarily disappears. The supersaturations that are reached locally are so high in body fluids that spontaneous precipitation occurs most of the time and the formation of apatites is observed. On experimental grounds it has been found that the implants containing the most soluble Ca-P (excluding the very soluble calcium monophosphates) are effectively transformed rather rapidly after implantation into poorly crystalline apatites.

The cell activity has also to be considered in biodegradation. Multinucleated giant cells involved in the defense response of the organism and osteoclast-like cells are frequently found in the vicinity of Ca-P bioceramics. These cells have the property to generate very acidic pH, and all Ca-P, including apatites, become rather soluble below pH 4, which explains their progressive dissolution, for example, within osteoclastic resorption pits. In this case, the rate of dissolution becomes the main parameter determining the biological degradation. It is related not only to the solubility product of the Ca-P and more precisely to the undersaturation achieved locally, but also to the crystals characteristics (size, strains) and the implant characteristics (surface exposed, porosity). The undersaturation appears as a crucial factor. The rate of dissolution of stoichiometric HA, for example, is very low and this Ca-P is often considered as a nonresorbable or at least a very slowly resorbable compound. This is only valid, however, for stoichiometric highly crystalline HA and it is not an inherent property of the structure itself. In the case of calcium-deficient HA, the biodegradation can be very high, like in some biomimetic cements, for example. On the contrary, β-TCP is considered to give rapidly resorbing ceramics.

Generally, bioceramics made of Ca-P are made of a multitude of crystals bound to one another, and they are sometimes multiphasic compounds. Several additional physical–chemical phenomena affecting biodegradation can then be involved. The most obvious is probably the decohesion of the material related to the preferential dissolution of the most rapidly soluble constituent, leading to the release of crystals or particulates of the least soluble, more stable, phase. These phenomena

have been found, for example, in the case of HA plasma-sprayed coatings, and they can also manifest in biphasic HA/β-TCP ceramics or in composite materials. Depending on their size these particles can induce different body responses. When the released particles are small enough, they can be phagocitized and they are eventually eliminated. However, when the elimination is not possible or when too numerous particles are released, they may initiate an inflammatory response sometimes devastating. This can occur, for example, with poorly sintered materials or when a Ca-P ceramic is associated with a rapidly absorbed matrix. When the fragments are big enough and cannot be further fragmented, they might remain in place, enkisted in the tissue. Biphasic compounds, especially, have considerably developed in the last years and their resorption can be regulated by the phase ratio. This is the case, for example, of biphasic HA/β-TCP ceramics where the degradation rate can be tailored by modifying the proportion of the more soluble phase, namely β-TCP, which seems to be degraded preferentially upon cellular activity.

The degradation behavior of nonstoichiometric nanocrystalline apatites is also interesting to consider, although apatite nanocrystals may exhibit varying physicochemical characteristics depending on their conditions of formation, which then account for differences in resorption rates *in vivo*. Various parameters can indeed influence the dissolution and biodegradation processes: in particular, the nonstoichiometry of the nanocrystals is a major factor to consider, as the dissolution of such ionic compounds depends on the amount of vacancies. A second effect could be related to the important interfacial energy and the evolution of the dissolution rate with the crystal size. As already mentioned, the presence of foreign ions in the composition of a given Ca-P compound may greatly modify its dissolution behavior. For instance, the solubility and *in vivo* degradation rates of zinc-enriched TCP were found to be significantly lowered as compared to pure TCP.[165] Also, the dissolution of calcium pyrophosphates was found to increase in the presence of ions such as Mg^{2+} or albumin,[166] although the *in vivo* degradation is mostly due to enzymatic activity of those compounds.

Other physical–chemical parameters have been shown to determine the degradation rate of implants *in vivo* such as the porosity and the crystallinity. Considering the porosity, macroporosity (pore diameter in the range 150–500 μm) seems to play a major role especially in the case of ceramics made of insoluble Ca-P in body fluids. The macropores allow cell invasion and increase the number of dissolution sites. The effect of microporosity is more difficult to apprehend: a first effect seems primarily related to a lesser content in material; a second effect is related to the increase of the surface area and of the related dissolution rate. Thus, for the same composition, highly microporous mineral cements are faster absorbed than less porous ones. Crystallinity has been shown to play also a role probably related to the increase of the surface area and dissolution rate but also to crystalline defects and possibly amorphous phase content, as these different characteristics are often considered in the global 'crystallinity' parameters.

A last parameter of importance in biodegradation is cell adhesion. In order to be active, the osteoclast-like cells involved in the biodegradation of Ca-P materials have to adhere to the materials and find favorable conditions. Alkaline pHs especially have been found to strongly inhibit osteoclast activities.[160,167] Thus, Ca-P generating alkaline pH on hydrolysis, like TTCP, for example, found in some mineral cements, may inhibit osteoclasts activity, as long as they are present.

1.111.6. Examples of Applications and Processing

1.111.6.1. Porous Ceramics

Porous Ca-P ceramics are among the most used synthetic bone substitute materials. They are generally obtained by natural sintering at a high temperature of HA, β-TCP, or a mixture of them and stabilized α-TCP. Several types of porosity are found in such ceramics. The definition of porosity in bioceramics appears historically different from the uses determined for other substances like zeolithes. In bioceramics, macroporosity is generally between 200 and 400 μm and allows cell rehabilitation. In addition, microporosity (1–10 μm) is frequently present depending on the sintering conditions: longer sintering time and higher temperatures generally decrease the microporosity. The macroporosity of most industrial ceramics is obtained by replication from a porous polymer, the use of calibrated porosity agents or with foaming agents. Other types of porous Ca-P ceramics have been obtained from natural compounds like the sintering of cow bone, for example, or the conversion of corals (calcium carbonate) skeleton.[168] Several shapes exist for different surgical uses: granules, cylinders, parallelepipeds, edges. Other techniques have been proposed to obtain a more regular porosity, however, they do not seem to have been commercialized yet. The total porosity; of porous Ca-P ceramics is generally comprised between 30 and 80%. As usually observed, the compressive strength decreases when the porosity increases for similar compounds.

HA ceramics are considered as nonbioresorbable and, although osteoclasts adhere on such surfaces effectively, they have difficulties to spread and create resorption pits.[169] HA ceramics may contain two impurities: CaO and TCP, which can be determined by XRD according to ISO standards. CaO rehydrates as $Ca(OH)_2$ in aqueous media with a 40% increase in volume. This phenomenon may result in the fragilization and cracking of the ceramic. TCP is a bioresorbable Ca-P, which might dissolve *in vivo* and facilitate the bioresorption as in biphasic ceramics, as discussed earlier. HA ceramics have been associated with very low levels of SiO_2 that have been shown to improve their biological activity.[170] However, the reasons for these effects remain obscure. The improvements obtained with silicate-substituted apatite at higher ratios have been assigned to the effect of released silicate (for more details on Si-containing apatites, see **Chapter 1.119, Silicon-Containing Apatites**).[171] It seems interesting to mention that the doping of HA with foreign elements cannot be considered as straightforward as for glasses or alloys. For example, if a mixture of HA with SiO_2 is heated, it will result in a mixture of HA and β-TCP due to the fact that it is SiO_4^{4-} anions which will be incorporated and that these anions will substitute for PO_4^{3-} anions in the apatite structure. For example:

$$2.5Ca_{10}(PO_4)_6(OH)_2 + SiO_2 \rightarrow 5Ca_3(PO_4)_2 + Ca_{10}(PO_4)_5(SiO_4)OH + H_2O$$

If one wants to get Zn doped HA by heating HA and ZnO, one has to consider that Zn^{2+} will substitute for Ca^{2+} in the apatite structure and the result will be HA doped with Zn and CaO:

$$Ca_{10}(PO_4)_6(OH)_2 + xZnO \rightarrow Ca_{9-x}Zn_x(PO_4)_6(OH)_2 + xCaO$$

Heating with different oxides may lead to different results and impurities, depending on substitution abilities in the apatite structure.

β-TCP ceramics have been especially developed by Jarcho *et al.*[172] They are bioresorbable. However, unlike it is sometimes written, they cannot spontaneously dissolve in body fluids at physiologic pH. β-TCP can hydrolyze and be converted into apatite in aqueous solution, but this reaction already rather slow at 100 °C (at least 48–72 h are needed) is inappreciably slow at 37 °C. It is only cell activity after implantation, producing acidic pH, which can dissolve β-TCP. As its biodegradation is determined by osteoclast cells activity, like in regular bone, it appears as a ceramic, which adapts to the remodeling rate of bone at the loci of the implantation. Unlike some other Ca-P, like DCPD, for example, β-TCP is unable to favor apatite nucleation by epitaxy. Although the reported data are not consistent, due to its rate of dissolution in acidic media linked to its solubility product, it is considered as a fast resorbing implant; this resorption rate could, however, depend on its composition and especially the Mg content, a major impurity in calcium salt. The main impurities in β-TCP are calcium pyrophosphate and apatite. They can be determined with high accuracy by FTIR spectroscopy and XRD respectively. β-TCP has been associated with active ions such as Zn^{2+}. In some cases, behavior akin to osteoinduction has been suggested for β-TCP;[173] however, the reason of this behavior is not really known.

Biphasic HA-β-TCP ceramics have been proposed by Daculsi and LeGeros.[174] They are bioresorbable and it has been shown that the bioresorption rate was related to the β-TCP content.[175] Generally, this content varies between 20 and 60% in industrial products. All these ceramics are osteoconductive and some of them, generally sintered at low temperature, have been shown to be osteoinductive. (see also **Chapter 5.521, Calcium Phosphates and Bone Induction** treating of calcium phosphates and osteoinduction.) Unlike in pure β-TCP, the presence of HA facilitates the nucleation of apatite in body fluids, and these ceramics, like pure HA ceramics, can bind firmly to bone tissue. The biodegradation has been reported to involve a faster dissolution of the β-TCP phase, followed by HA crystals elimination. Curiously, these biphasic Ca-P are unlikely to contain any other crystalline phase: excess of CaO in the HA fraction would lead to additional HA by reaction on β-TCP at sintering temperature and excess of pyrophosphate in β-TCP would lead to additional β-TCP by reaction with HA.

The high-temperature ceramics can be associated with drugs and growth factors; however, because of their very low specific surface area there is no strong surface interaction and the release is mainly controlled by diffusion through the pores and physical parameters. This release process can be interesting for some substances like antibiotics, for example, but it might appear as a drawback for very active substances like growth factors, compared to other Ca-P materials where adsorption occurs and where the release remains localized and under the control of the organism.

1.111.6.2. Coatings, Example of HA-Plasma Spraying

One of the most efficient solutions to favor biological integration and bioactivity of prostheses and orthopedic implants consists in coatings with Ca-P ceramics. Many different techniques have been proposed and used to deposit such coatings, but plasma spraying of HA appears as one of the most applied and most developed at an industrial scale.[84]

This is a technique in which a DC electric is struck between two electrodes, while a stream of mixed gasses (generally H_2 and Ar) passes through this arc. The arc turns these gas into an ionized mixture (plasma) of high temperature and with a high speed of up to 400 m s^{-1}. The temperature of the plasma rapidly decreases as a function of distance from 20.000 K close to the arc to 2000–3000 K at 6 cm outside the electrodes. A ceramic powder suspended in a carried gas can be incorporated into the plasma and impinged in a partially molten state toward a surface. Many surfaces of metals or ceramics can be coated with a relatively thick layer (50–300 μm) of composition close to that of the powder. Ideally, only a thin outer layer of powder particles gets into the molten state which is necessary to ensure dense and adhesive coatings. The bonding of the coating is mainly due to mechanical interlocking.

HA appears certainly as the major plasma-sprayed Ca-P. One of the main difficulties in HA plasma spraying is the thermal decomposition of HA at high temperature and the mixture of phases, which constitute the coating (**Table 11**).[176] These phases are heterogeneously distributed in the particle reaching the surface and in the coating. At contact with the metal and on the surface, a rapid quenching of the molten fraction leads mainly to an amorphous phase, a slower quenching inside the particle may allow the crystallization of high-temperature phases in their order of stability: CaO (with a very high melting point: above 2500 °C), TTCP and α-TCP, and then β-TCP and oxy-HA. However, when a second pass is made, the surface is reheated and a recrystallization may proceed again. In addition to this decomposition, volatilization of phosphorus has also been evidenced, especially in H_2-rich flames, resulting in a change in stoichiometry; thus, even when using pure HA in the plasma spraying, the resulting coatings may contain an excess of calcium appearing as CaO or TTCP. Depending on processing parameters, many different coatings can be obtained and ISO standards have been published regarding some important physical–chemical characteristics of the coating: the Ca/P ratio, the content in

Table 11 Phases found in plasma-sprayed coating of HA

Phases	*Formation*
Calcium oxide	Decomposition of HA and TTCP Volatilization of P
Calcium hydroxide and calcium carbonate	Reaction of CaO with humidity and CO_2 (on contact with air or body fluids)
Amorphous calcium phosphate	Melting of HA and quenching
α-Tricalcium phosphate	Thermal decomposition of HA
β-Tricalcium phosphate	Phase transition on cooling from α-TCP
Tetracalcium phosphate	Thermal decomposition of HA
Oxyhydroxyapatite	Dehydration of HA
Hydroxyapatite	–

crystalline impurities, and a crystallinity index (ISO 13779-2 and 3), but curiously not really the amorphous phase content. Although several post-treatments have been proposed as remedial and have been shown to restore the apatite structure, they all have some drawbacks and weaken at some point the coating cohesion and adhesion to the metal surface.

The decomposition of HA and the formation of different Ca-P phases, especially the amorphous phase, can have a positive effect, especially on biological activity, as most of these phases will spontaneously release mineral ions and will thus 'activate' the coating (see **Section 1.111.4.1**).[84] However, these phases weaken the coating which may degrade and lead to a deterioration of the implant–bone interface. In addition, the metal-coating interface appears as the weak point of the process and delamination of the coating may occur.[177] In fact, the adhesion of the coating on the metallic substrate is mainly due to mechanical interlocking on the porous implant surface, although chemical bonding cannot be totally excluded. High levels of amorphous phase in the coating lead to improved interfacial adhesion on the metal and biological activity but poor durability. Raising the crystalline HA content, on the contrary, lowers the biological reactivity and weakens the metal-coating interface but the coating can last longer. The solution to this dilemma could be a coating made of several layers with different characteristics as proposed by different authors.[178] (see also **Chapter 1.112, Calcium Phosphate Coatings** and **Chapter 1.113, Bioactive Layer Formation on Metals and Polymers**)

1.111.6.3. Cements

The fast-setting calcium phosphate cements have emerged as an attractive concept essentially as bone filling and reinforcement biomaterials. Ca-P bone cements have developed considerably in the last few years due to their excellent biocompatibility and bioactivity.[105] The applications for the filling of bone defects are very promising, whether in the form of a molded paste placed in the surgery site or in the form of an injectable paste hardening *in situ*.

Several types of reactions can be involved in the Ca-P self-setting materials, which lead to the formation of two main classes of Ca-P cements depending on the end product: apatite cements consisting of more or less crystallized apatite and brushite cements.[105,179] Some examples of apatite and brushite cements are given in another chapter of this volume. It shall be noticed that brushite is not stable in body fluids and that it shall inevitably be transformed more or less rapidly, depending on the size of the implant, into nanocrystalline apatite.

The hardening of mineral cements is generally attributed to the growth of interlaced crystals. This has been shown in the case of some apatite cements where long needle-like crystals can be seen by SEM and in the case of brushitic cement, interlaced large plate-like crystals isomorphous to gypsum crystals responsible for the hardening of plaster can be observed. This mechanism, however, does not seem to be involved in biomimetic cements resulting in nanocrystalline apatite analogous to bone mineral. The high specific surface area and strong interactions between nanocrystals could be, in this case, the main factor of hardening.

Two major types of reaction are involved in phosphocalcium cements formation. The first consists in a reaction between one or more 'basic' calcium compound (i.e., rich in calcium) such as TTCP or even $Ca(OH)_2$ and one or more 'acidic' calcium phosphates (i.e., rich in phosphate) such as MCPM, H_3PO_4, DCPD. In aqueous medium, the reaction between these phases leads to less soluble new phases, whose crystallization brings about the setting. The second type of reaction takes advantage of the metastability of a Ca-P phase in aqueous medium and its rapid conversion into apatite. Two phases, α-TCP and ACP, can be used. Various cement formulations have been proposed, sometimes mixing different Ca-P phases and hardening reactions, and several cements are commercialized: SRS®, Bonesource®, Cementek®, Biobon®, α-BSM® (see **Chapter 1.116, Bioactive Ceramics: Cements**).

Several properties characterize a biological cement, like construction cements, although most of them have not been standardized which do not allow comparison between formulations. The workability is the time during which the paste can be mixed and kept before use; this property is related to the characteristics of the reactions involved in the setting. The ACP conversion, for example, is extremely slow at room temperature, which is related to a long working time. For some brushitic cements, like for plaster of Paris, mixing the paste for too long may break the growing crystals involved in the setting process and may result in lower mechanical properties. Additives, which delay the reactions between constituents at room temperature, can be used to increase the workability. The setting time has been standardized (Gillmore needle test) and corresponds to the time needed to get a compact block. Generally, the chemical reactions are not achieved at the setting time. Several factors determine this property related essentially to the rate of reactions. The addition of soluble phosphate salts in the liquid phase, for example, has been shown to shorten the setting time of 'acid–base' cements, probably through the reaction with TTCP or other calcium-rich phase. The addition of apatite nuclei can also be used like in ACP-based cements, for example.[180] Fluoride ions, through their effect on apatite solubility, may also accelerate the apatite formation and shorten the setting time. The hardening time is related to the evolution of the cement after setting: in construction cements, it corresponds to the time needed to get the nominal mechanical properties, for biological cements, this parameter is not always determined and the mechanical properties may possibly degrade after completion of the chemical reactions. Injectability is an important parameter for biological cements and several techniques have been proposed to determine this parameter in conditions as close as possible to those of the surgical use. One of the difficulties in the injection of an aqueous suspension of a solid phase is the filter-press effect responsible for a variation of the solid/liquid ratio during the injection and eventually the impossibility to continue the injection by applying a reasonable pressure on the syringe. The injectability is related to the viscosity of the suspension and especially the solid/liquid ratio, and the stability of the suspension obtained. Several additives have been used to improve the injectability. The wash-out phenomenon corresponds to the disaggregation or dispersion of the paste during or after its placement; this property is not an intrinsic characteristic of the cement and is also related to the viscosity of the medium in which the cement paste is introduced. It has been shown that the viscosity of the paste has to be higher than that of the medium it is injected in to avoid

dispersion. *In vivo*, wash-out can also be due to the action of blood on the nonset paste. Additives such as gelling agents can be used to avoid wash-out, provided they do not interfere with the setting reaction. The mechanical properties of hardened Ca-P cements depend on their microstructure and especially their porosity related to the solid/liquid ratio. They vary in a large domain in commercial cements (reported compression resistance from 5 to 80 MPa) and they are not suitable for implantation in locations where mechanical loads are high. In addition to these physical chemical properties, biological properties of the Ca-P cements have to be determined and, here also, the absence of standardized methods does not generally allow comparison between different formulations. Among these properties, the most important is bone reconstruction ability associating bone formation with cement resorption. Like in the case of bioceramics, the cohesion of the hardened cement is a determining factor for avoiding the release of too numerous particles and the development of uncontrolled inflammatory reactions. Generally, cement are considered to behave like bone tissue and their degradation has been defined as 'centripetal' resulting in irregular degradation and bone formation from the surface of the implant to the interior with possible cement residues remaining encysted in the newly formed bone. The degradation of apatite cements is related to the microstructural and physical–chemical characteristics of the hardened material. The degradation is faster when the porosity is higher, the crystal size is smaller, and the amount of vacancies in the structure is higher. The amount of vacancies is not simply related to Ca/P ratio as explained earlier (**Section 1.111.3.1**), but to the substitution ratio of trivalent PO_4^{3-} ions by bivalent ones (essentially CO_3^{2-} and HPO_4^{2-} ions). Biphasic cements have been proposed, in analogy with biphasic ceramics, to vary the bioabsorption properties.[181]

The main advantages of Ca-P ionic cements are their easiness of use, their biodegradation combined with the progressive replacement by bone neoformed tissue. Besides, they can easily be associated with therapeutic and/or biologically active components (antibiotics, growth factors, platelets, etc.). Radio-opacifier can also be added to the paste provided they are bioabsorbable; Sr salts have also been proposed. One of the main drawbacks of actual cements are the small size of pores which does not favor cell rehabilitation; the poor mechanical properties and the variability in characteristics and procedures for paste preparation compared to polymeric cements.

1.111.6.4. Examples of Composite Materials with Collagen

Associations of Ca-P compounds and polymers represent an interesting way to confer calcium phosphates' advantageous cohesiveness and mechanical properties in relation with the imitation of bone tissue. In this context, apatite/collagen hybrid systems have been particularly studied by many research groups. The possibility for molecules such as collagen to interact with the ions from the highly reactive surface layer on apatite nanocrystals through ionic functions of proteins (mostly anionic groups) has already been mentioned in this chapter (**Section 1.111.4.5.2**).

Many studies have been aimed at producing biomimetic artificial bone-like tissue involving apatite and collagen taken in varying forms: fiber, gel, or gelatin.[182–186] Several protocols have been used to prepare apatite/collagen hybrids. Testing two methods of preparation of such composites (dispersion of HA in collagen gel or direct nucleation of apatite on collagen fibers), Tampieri *et al.*[186] have shown that the bioinspired method based on the direct nucleation of apatite leads to composites analogous to calcified tissue and exhibits strong interactions between apatite and collagen. Some researchers mentioned the preliminary phosphorylation of collagen in order to generate nucleation sites for mineralization, followed by a subsequent step of apatite nucleation and growth on the collagen by immersion in SBF.[187] Other techniques were also tested, such as electrospinning.[188] They showed that this technique was useful for obtaining composite fibers up to about 30 wt.% loading with HA, while beyond this amount, a preferred bead-like morphology was observed.

In vivo evaluation in weight-bearing sites (in the dog) were performed for testing apatite/collagen composites prepared by a coprecipitation method. The results led to interesting conclusions, especially when associated with BMP-2 growth factor.[189] The controlled release of BMP-2 from the implant was indeed found to facilitate the early formation of callus and hence of newly formed bone, enabling early weight bearing. Nishikawa *et al.*[190] have examined the biodegradation of HA/collagen composites implanted in dogs by a tissue labeling method, and these authors showed that this novel composite allowed bone augmentation.

The interactions between the collagen fibrils and the Ca-P (most generally apatite) are not really known. Quite recently, Dos Santos *et al.*[191] have expressed the possibility to study the apatite–collagen interface by using a FRET technique with luminescent europium-doped apatite. This is a promising idea for deriving a new tool for investigating the interface between collagen and apatite.

These associations have not, however, given materials with the mechanical properties of bone and they have not resulted in decisive advantages compared to bioceramics bone substitutes. (For composite-ceramics associations see also **Chapter 5.520, Bioactive Ceramics and Bioactive Ceramic-Composite-Based Scaffolds**.)

1.111.7. Other Bioactive Ceramic Materials

A number of other bioactive ceramics have been designed more or less specifically for biomedical applications and are used in different implantable systems because of their physical–chemical properties and their good biocompatibility. We limit our presentation to examples of three main types of bioactive ceramics: oxide- and hydroxide-, calcium sulfate- or calcium carbonate-based ceramics.

1.111.7.1. Oxide- and Hydroxide-Based Bioactive Ceramics

As it has been suggested that the hydrated silica layer formed at the surface of implanted bioactive glasses and glass-ceramics plays a very important role in the formation of the bone-like apatite layer, the idea of using pure silica hydrogels as bioactive compounds has emerged. It has been shown that gels of silica, and also other gels of titania or zirconia, after being subjected to heat treatment, can induce the formation of apatite when

these are immersed in a metastable solution analogous to biological fluids.[192] Such bioactive materials are generally obtained by sol–gel processes and they have been shown to favor the heterogeneous nucleation of the apatite. However, when the silica gel is heated to a temperature greater than 900 °C, the formation of the apatite is delayed. The rate of rehydroxilation and the amount of hydroxyl group on the surface of the silica gel appear to control the formation of apatite.[193]

We chose to develop in this subsection the case of titania-based biomaterials, which has been studied in depth especially by Professor Kokubo's group.

It has been shown that sufficiently hydrated titanium dioxide with Ti–OH groups on the surface can join with the bone while it is placed in an osseous site. This property offers the possibility to confer a bioactivity to titanium by a treatment leading to the formation of a gel or a highly hydrated layer at the surface of the implant.[193]

Titania-based materials are easily formed on titanium metal and its alloys by chemical and thermal treatments. Titania gels can be prepared by sol–gel method including a thermal treatment in the range 500–800 °C. Titanium metal with an oxide–hydroxide layer on its surface formed after treatment in NaOH solution and subsequent water or acid treatment can show a high apatite-forming ability in biological environment and bond to bone.[192] The first formation of sodium hydrogen titanate phase on the metal surface has been evidenced by XRD and Raman spectroscopy. It is then transformed into sodium titanate and rutile TiO_2 after heat treatment. The dehydration of sodium titanate and titanium oxide after the final heat treatment is considered to favor apatite formation *in vivo*.

Takadama *et al.* proposed a mechanism describing the apatite formation on titania-based materials.[194] When immersed in SBF solution, the release of sodium ions from the surface occurred via ion exchange with H_3O^+ ions from the solution leading to a local alkalinization of the solution associated with the formation of a large number of negatively charged Ti–OH groups on the surface which can react with positively charged calcium ions from the solution to form calcium titanate. As its concentration increases on the surface, calcium is supposed to react then with hydrogen phosphate from the solution and a calcium phosphate nucleates and grows to give an apatite analogous to bone mineral. Similar mechanisms have been proposed in other studies on the nucleation and growth of Ca-P on titanium surfaces involving either calcium or phosphate binding.[127,195–197]

When implanted *in vivo*, titania-based implant surface showed osteoconductivity, and more recently, osteoinductivity has been evidenced.[198]

Recently, associations of titania with polymer to prepare flexible polyethylene terephtalate fiber-titania) or self-setting composites (polymethylmethacrylate-titania) have been reported.[192] (See also **Chapter 1.113, Bioactive Layer Formation on Metals and Polymers**.)

1.111.7.2. $CaCO_3$-Based Bioactive Ceramics

Different types of natural substitutes for bone tissue are available on the market, generally of animal origin. These are subjected to physical, chemical, or biochemical processes before utilization as biomaterials. Calcium carbonates ($CaCO_3$), particularly those produced by marine organisms such as coral and mother of pearl, have been shown to be biocompatible and bioactive biomaterials, and they have been used for more than 20 years as bone substitutes in the form of powders, porous ceramics, or gels.[199–205]

Three crystalline phases of anhydrous calcium carbonates are encountered in nature: calcite, aragonite, and vaterite. Natural calcium carbonates from certain corals and nacre present the aragonite structure.

The idea that coral can replace defective parts of bone comes from the similarity in the structure of some coral skeletons with cancellous bone allowing colonization by cells and blood vessels penetration.[206] The exoskeleton of coral polyps constitutes blocks of calcium carbonates with regular and interconnected porosity, according to a structure specific for each species. After selecting, cleaning, and shaping, these materials can be implanted in bone locations to serve as a framework for the new bone tissue.

The calculation of the ionic product of blood plasma indicates that it is supersaturated with respect to the three calcium carbonate varieties, although for vaterite, the oversaturation is much smaller than for calcite or aragonite. Then, these compounds cannot dissolve spontaneously. However, in the presence of phosphate ions, the apatite remains the most stable phase and all the three calcium carbonate varieties should transform, at least superficially, into apatite. The main degradation process of calcium carbonate has been assigned to a carbonic anhydrase enzyme, which induces a local dissolution and leave place for newly synthesized bone tissue.[203] Many *in vivo* studies reported that calcium carbonate-based macroporous bioceramics, prepared by physical–chemical treatment of coral, promote bone ingrowth and resorption.[203,205] Another example is coralline HA, a carbonated HA, which is prepared by the hydrothermal conversion of calcium carbonate from coral in the presence of ammonium phosphate.[206,207] It has been suggested that controlling the thickness of HA on a $CaCO_3$ matrix could control the rate of resorption of the implant and its replacement by newly formed bone.

Despite a good mechanical strength, this is not sufficient to allow their use in bones subjected to high mechanical stresses (load-bearing bones). Moreover, their structure is fixed with the considered species and their chemical composition is not well controlled, particularly, with respect to trace elements, and residual organic matrix and implant rejection have been observed possibly due to the presence of organic matter residue.

The mother of pearl, also composed of calcium carbonate and an organic matrix, has been proposed as a substitute for bone. Mother of pearl powder implanted in a bone defect has shown behavior similar to that of a coral.[200]

Although several attempts have been made to produce synthetic calcium carbonate bioceramics, sintering proves to be difficult, and calcium carbonate-based cements, prepared by mixing calcium carbonate phases with an aqueous medium, offer an interesting alternate way to prepare low-temperature carbonate-containing bioceramics. Recently, Combes *et al.* demonstrated the feasibility of calcium carbonate-based biomedical cements consisting of 100% $CaCO_3$ or of a mixture of $CaCO_3$ and calcium phosphate.[181,208] Calcium carbonate compounds have a higher solubility compared to that of apatite and the use of very large proportions of calcium carbonate

(≥20% (w/w) in the dry powder ingredients) opens new possibilities which have not yet been exploited. Cements, unlike materials obtained by high-temperature sintering or natural materials, can be intimately associated with biologically active molecules (specific proteins, antibiotics, etc.) to improve bone reconstruction.[209,210]

1.111.7.3. $CaSO_4$-Based Bioactive Ceramics

Calcium sulfate hemihydrate ($CaSO_4 \cdot 1/2H_2O$), known as plaster of Paris, has been used as a building material for at least 5000 years and used by Egyptians to decorate burial tombs of pharaohs.[211] Dreesman was the first to report a study on the implantation of plaster of Paris as a bone filler material in eight patients.[212] Since this first clinical success, several groups of research have studied different bioactive ceramics for bone filling and repair involving calcium sulfate hemihydrate (CSH) as cement, preset granules, or resorbable composites (CSH-HA or CSH-polymer).[213,214]

The plaster of Paris is prepared from gypsum (calcium sulfate dihydrate (CSD): $CaSO_4 \cdot 2H_2O$) which is mined from the earth or synthesized. When heated at about 160 °C, gypsum is converted in its hemihydrate form (CSH) which is used in plaster of Paris. The chemical reaction responsible for the setting and hardening of calcium sulfate cement is based on the rehydration of CSH:

$$CaSO_4 \cdot 1/2H_2O + 3/2H_2O \rightarrow CaSO_4 \cdot 2H_2O$$

This reaction involving a dissolution–reprecipitation process is slightly exothermic and the resulting bioceramic/cement consists of a network of entangled rod-like CSD (or gypsum) crystals.

CSH exists in two forms, α and β. The α-form is used as dental materials and requires less water and thus leads to denser CSD cement, whereas the β-form uses large amounts of water and leads to less dense material than with the α-form.

Only the dense α-form should be used as bone filler and in non-load-bearing bone sites to guarantee the performance of the cement. In addition, CSH intended for biomedical application must be well characterized and carefully produced.

In vivo, the presence of proteins influences the calcium sulfate-based cement setting, that is, the dissolution and crystallization processes involved, and it has been shown that cement set in these conditions dissolved more quickly. As it is really difficult to avoid bleeding during surgery, the use of preset calcium sulfate cement can lead to slower cement degradation once implanted. Another way to prevent the effect of blood proteins on the setting reaction is to use setting accelerants such as NaCl or K_2SO_4.

The concentration of sulfate ions in blood plasma is not sufficient to reach the solubility product of CSD, thus, calcium sulfate materials should spontaneously dissolve in the body and they are in fact rapidly absorbed.

An interesting review of the clinical use of calcium sulfate as cements or preset granules is presented by Ricci and Weiner.[211] The most recent studies showed that calcium sulfate is fully resorbed *in vivo* within 4–7 weeks in most applications and that its bioactivity is related to the release of calcium ions, local decrease of pH, and local carbonated apatite precipitation. Ricci *et al*. proposed a schematic representation summarizing the processes involved in calcium sulfate-based bone substitute bioactivity (see **Figure 8**).

The main criticism of calcium sulfate as bone substitute is its limitation to small defect filling and rapid resorption exceeding the rate of bone growth into the defect. With a view to extending and controlling the calcium sulfate-based biomaterial resorption properties, composites of calcium sulfate and poly-L-lactic acid (PLLA) consisting either of a nanocomposite of both constituents or of granules of CS coated with a thin layer of PLLA have been studied by Madmidwar *et al*.[213] The authors showed that the full resorption of a nanocomposite consisting of 4% PLLA and 96% of calcium sulfate occurred after 4 months *in vivo*.

Association of this composite or of calcium sulfate cement with biologically active components (growth factors, platelets, antibiotic, etc.) has also been investigated as local controlled release system.[214–216]

In addition to the bioactivity, additional properties of CS have also been pointed out by several authors: CS acts as a barrier membrane in the defect area and allows bone

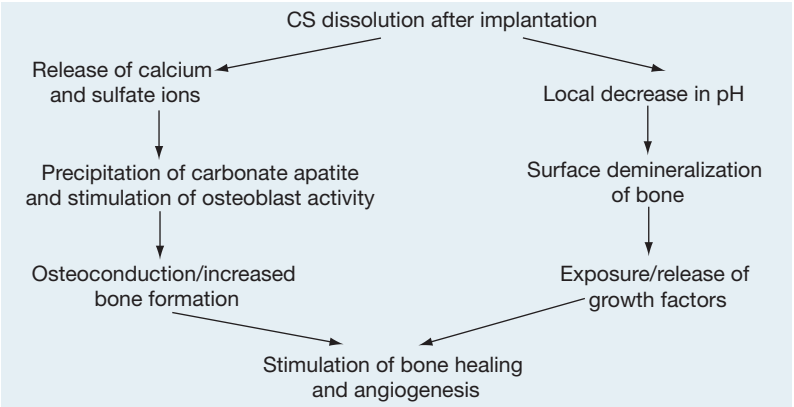

Figure 8 Schematic representation of the proposed pathways of biological activity involving calcium sulfate and stimulating bone formation: calcium and sulfate ions release (left) and pH decrease (right). Reproduced from Ricci, J. L.; Weiner, M. J. In *Bioceramics and Their Clinical Applications*; Kokubo, T., Ed.; CRC/Woodhead: Boca Raton, FL, 2008; pp 302–325, with permission from Woodhead, Cambridge, UK.

generation during healing as an hemostatic agent, probably due to the release of calcium ions known as a coagulant, and as an angiogenic agent.[211]

1.111.8. Conclusion and Future Perspectives

The evolution in the last decade has shown the emergence of substituted Ca-P, and more generally, chemically modified Ca-P, with improved biological properties such as apatite with silicate ions, TCP with Zn ions, and other products. It is probable that such trials to improve the biological activity will be pursued with possibly other types of ions with a biological action or combination of ions. Simultaneously, the mechanisms relaying the improved biological activity related to chemically modified Ca-P are not yet perfectly known in many cases, and the distinction between several effects of doping related to bulk properties of crystals, microstructural characteristics of the ceramics, and surface alterations probably needs to be clarified.

A second route of development concerns nanocrystalline apatites, which exhibit a very high and peculiar reactivity and constitute the main component of bone substance. Advances in this field will probably result in a better understanding of bone biology also which in many cases has focused on cell activity and organic macromolecules specificities, forgetting that the mineral with its high surface area and strong potential interactivity is probably an important actor in several bone regulation mechanisms. Ca-P-based bioceramics with osteoconductive and osteoinductive properties have attracted back the attention of researchers on the role of Ca-P minerals in living organisms, and advances are expected in this field. In addition to their involvement in nanomaterials, Ca-P nanocrystals can also be used in different applications for imaging or cell therapy. The development of the use of nanocrystals raises the problem of their accurate characterization, evolution, and surface properties, and regulations and standards will probably flourish.

A third development domain, already active, concerns the associations of bioceramics with active molecules for different purposes, for example, antiseptic activity or improvement of cell response using growth factors or associations of growth factors with sequenced controlled release.

The Ca-P bioceramics and composite materials are an interesting substrate for scaffolding in tissue engineering, and there is no doubt that these intense research activities will develop our knowledge of cell–material interactions and will probably allow the distinction of crucial parameters involved in cell colonization and differentiation determined by materials with, here also, interesting returns in the domain of bone biology.

Glossary

Biomimetic A process or substance that mimics biological natural systems. For instance, synthetic hydroxyapatite resembles in composition and structure the mineral of bone.

Electrodeposition A process of depositing films on metal surfaces, such as titanium implants, assisted by current or voltage gradients.

Osteoconduction The direct apposition of bone tissue onto the surface of an implant as the opposite of fibrous tissue encapsulation.

Plasma spraying A high-temperature spraying method for depositing coatings, such as calcium phosphate coatings, on orthopedic implants.

Simulated body fluid A supersaturated protein-free, electrolyte solution with ionic concentrations similar to those found in human blood plasma.

1.112.1. Introduction

As populations age in industrial countries, the market for orthopedic prostheses and dental implants is growing steadily at a rate of 15% per year. For instance, total hip arthroplasties or knee joint replacements have turned into a standard surgical procedure with a relatively high success rate.[1] In response to millions of edentulous patients, artificial dental roots are implanted in the maxillary and mandible bone to restore dentition.[2] Despite a very high success rate of >95% over 5 years, the lifetime of orthopedic and dental implant is limited to 10–15 years and the number of revisions is steadily increasing.

Metals are commonly used for manufacturing orthopedic and dental implants. These medical devices are mostly made out of titanium and alloys due to their high mechanical strength and corrosion resistance in the body. All grades of titanium and alloys exhibit a layer of titanium oxide with a thickness of few nanometers. This titanium oxide layer is rapidly formed upon reaction with oxygen in air and acts as a protective barrier. This oxide layer is very adherent and stable in physiological conditions. Although biocompatible, titanium implants lack bioactivity and osteoconductive properties for a rapid bone apposition. At early implantation time, titanium implants are generally encapsulated by fibrous tissue and are not in direct contact with bone tissue.

Calcium phosphate (CaP) coatings, especially those made with hydroxyapatite (HA, $Ca_{10}(PO_4)_6(OH)_2$), are applied on titanium implants to improve their bone-integrative properties.[3–5] As CaPs are similar in composition as the bone mineral, these materials are bioactive and able to achieve an early and functional bone apposition on the implants.[6–9] Following implantation, the release of calcium and phosphate ions into the peri-implant region increases the saturation of body fluids, leading to the precipitation of a biological carbonated apatite onto the surface of the implant (Figure 1). This layer of biological apatite might incorporate endogenous proteins and serve as a matrix for osteogenic cells' attachment and growth. These cells produce the bone extracellular matrix (ECM), resulting in a direct apposition of bone tissue on the CaP coating on titanium implants. The bone-healing process around the implant is therefore enhanced by this biological apatite layer.[10–12] The combination of the high mechanical strength of titanium with the osteoconductive properties of CaPs has proven efficacy to stimulate an early integration and long-term stability of noncemented orthopedic prosthesis.

There are a number of techniques to apply CaP coatings on titanium implants. The most successful method is plasma spraying of HA on orthopedic devices. However, plasma spraying presents some drawbacks such as high processing temperature, relatively thick and heterogeneous coatings, and poor efficiency on tiny or complex-shaped implants.[5,13] To overcome drawbacks of the commercially provided plasma-sprayed HA coating, several other deposition methods have been proposed. One of them is the biomimetic coating, where CaP is deposited on substrates by immersion in a simulated body fluid (SBF). Electrolytic deposition (ELD) is another promising alternative method to plasma-spraying HA. This chapter reviews the methods to apply CaP coatings on orthopedic and dental implants. It also discusses the advantages and drawbacks of each technique in regards to physicochemical

properties, mechanical strength, *in vitro* behavior in SBF or in cell culture, and *in vivo* bone integration. Future trends in the research of CaP coatings in view of addressing difficult clinical situations are finally proposed.

1.112.2. Calcium Phosphates

CaPs are similar in composition to the mineral part of bones and teeth. CaPs are salts of the phosphoric acid H_3PO_4 and thus can form compounds that contain $H_2PO_4^-$, HPO_4^{2-}, and/or PO_4^{3-} ions (Table 1). Most of the CaP compounds can be precipitated from aqueous solutions, while some are only formed at elevated temperatures. The CaP containing $H_2PO_4^-$ ions, such as monocalcium phosphate monohydrate (MCPM), only form under acidic conditions. The MCPM is usually not found in bones, as body fluids are neutral supersaturated calcium and phosphate solutions. In physiological conditions, CaP containing both HPO_4^{2-} and/or PO_4^{3-} ions such as OCP, CDA, or carbonated apatite are the most thermodynamically stable and insoluble phases. Bone tissue consists of a mineralized collagenous ECM produced by osteoblastic cells. In the bone mineralization process, collagen fibers serve as substrates for the nucleation and growth of carbonated apatite crystals that precipitate from body fluids.[14] The mineral part of bones and teeth is related to a type AB carbonated CaP apatite, which can be tentatively represented by the following formula[15]:

$$Ca_{8.3}\square_{1.7}(PO_4)_{4.3}(CO_3)(HPO_4)_{0.7}(OH,CO_3)_{0.3}\square_{1.7}$$

$\square$ = vacancy

Both the crystallinity and composition of bone mineral may vary considerably with age and skeletal sites. Bone mineral crystals contain nonapatitic carbonate and phosphate groups that are very labile and rapidly exchange with ions contained in body fluids.[15] Furthermore, minor or trace elements, such as magnesium and zinc, are also present in bone mineral. Bone crystallites are essentially plate-shaped, with average dimensions of 35–40 nm.[16] These crystals are believed to reinforce the collagen fibers forming a composite with high mechanical properties, as bone tissue is able to support body load as well as considerable forces during motion.

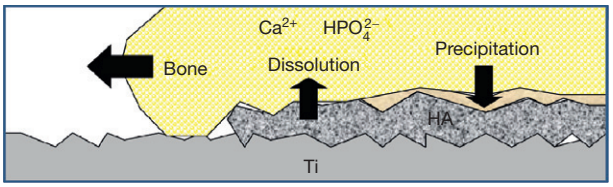

Figure 1 Principle of bioactivity and osteoconduction of CaP coatings on titanium implants. Following implantation, the partial dissolution of HA coating leads to the release of Ca^{2+} and HPO_4^{2-}, precipitation of biological apatite, colonization of osteogenic cells producing the bone extracellular matrix resulting in a direct bone tissue apposition on titanium.

Table 1 Names, abbreviations, composition, Ca/P ratios, solubility, pH, and temperature (°C) stability for synthetic and biological calcium orthophosphates

Name	*Abbreviation*	*Formula*	*Ca/P ratio*	*Solubility −log(K_s)*[a]	*pH and T (°C) stability*
Monocalcium phosphate monohydrate	MCPM	$Ca(H_2PO_4)_2 \cdot H_2O$	0.50	1.14	0.1–2.0 25 °C
Monocalcium phosphate anhydrous	MCPA	$Ca(H_2PO_4)_2$	0.50	1.14	0.1–2.0 > 80 °C
Dicalcium phosphate dihydrate (brushite)	DCPD	$CaHPO_4 \cdot 2H_2O$	1.00	6.59	2.0–5.5 25 °C
Dicalcium phosphate anhydrous (monetite)	DCPA	$CaHPO_4$	1.00	6.90	2.0–5.5 > 80 °C
Octacalcium phosphate	OCP	$Ca_8(HPO_4)_2(PO_4)_4 \cdot 5H_2O$	1.33	96.6	5.5–7.0 25–37 °C
Calcium-deficient apatite	CDA	$Ca_{10-x}[]_x(HPO_4)_x(PO_4)_{6-x}(OH)_{2-x}[]_x$ $(0 < x < 2)$[b]	1.33–1.67	~85.1	6.5–9.5 25–37 °C
Amorphous calcium phosphate	ACP	$Ca_x(HPO_4)_y(PO_4)_z \cdot nH_2O$ ($n = 3$–4.5; 15–20 wt% H_2O)	1.20–2.20	25.7–32.7	5–12 4–37 °C
β-Tricalcium phosphate	β-TCP	$\beta\text{-}Ca_3(PO_4)_2$	1.50	28.9	> 800 °C[c]
α-Tricalcium phosphate	α-TCP	$\alpha\text{-}Ca_3(PO_4)_2$	1.50	25.5	> 1125 °C[c]
Biphasic calcium phosphate	BCP	$\beta\text{-}Ca_3(PO_4)_2 + Ca_{10}(PO_4)_6(OH)_2$	Variable 1.55–1.65	NA	> 800 °C[c]
Hydroxyapatite	HA	$Ca_{10}(PO_4)_6(OH)_2$	1.67	116.8	9.5–12 > 80 °C
Fluoroapatite	FA	$Ca_{10}(PO_4)_6F_2$	1.67	120.0	7–12 > 80 °C
Tetracalcium phosphate	TTCP	$Ca_4(PO_4)_2O$	2.00	38–44	> 1400 °C[c]

NA, not applicable.

[a]The solubility at 25 °C in water is given at the logarithm of the ionic product of the given formula with concentrations in moles per liter.

[b][] represents a vacancy in the crystal lattice of hydroxyapatite.

[c]These compounds cannot be precipitated from aqueous solutions and form only at elevated temperatures.

Synthetic CaP, particularly HA, β-tricalcium phosphate (β-TCP), and mixtures, named biphasic calcium phosphate (BCP), have been successfully used for filling bone defects in various clinical indications. For more than three decades, these biomaterials in dense or porous forms have been clinically applied in orthopedic, spinal, and maxillofacial surgeries as bone substitutes.[17] These ceramics are manufactured starting from well-characterized CaP powders, mixed with pore makers, and sintered at elevated temperatures (e.g., 1000–1300 °C). Following implantation, these CaP ceramics interact with body fluids, partly dissolving and precipitating a biological apatite on their surface that serves as a substrate for osteogenic cells producing the bone ECM. This process, known as bioactivity, guides bone healing into the CaP ceramic by osteoconduction. However, CaP ceramics are intrinsically brittle and relatively weak, making them unsuitable for replacing skeleton parts that experience high loads. Consequently, CaPs have been applied as coatings on mechanically strong metal implants. This approach results in the combination of the high strength of titanium with the biological properties of CaP. Bioactive and osteoconductive CaP coatings applied on titanium devices are able to achieve an early and functional integration of the implant with the surrounding bone.

1.112.3. Titanium Implants

Prior to applying CaP coatings, surfaces of titanium implants are generally grit-blasted with alumina ceramic (Al_2O_3) particles. This treatment consists of blasting with air pressure ceramic particles of 100–200 μm on titanium implants. It aims at increasing the surface roughness to Ra value around 2–5 μm. High surface roughness ensures a good mechanical interlocking of CaP coatings on metals, improving bonding strength and shear resistance. Furthermore, modifying surface roughness has been shown to enhance the osteoblastic differentiation of mesenchymal stem cells and the bone-to-implant contact.[18] Dental implants are often grit-blasted and then etched with strong acids, producing cavities and micropitting on surfaces.[19] Nevertheless, alumina grit-blasting residues are not easily removed from the surface, and alumina particles may interfere with the osseointegration of implants. In order to overcome this drawback, we have recently proposed to use BCP ceramic particles for grit-blasting titanium implants. Grit-blasting titanium implants with BCP ceramic particles gave a high average surface roughness and particle-free surfaces after etching, as CaPs are soluble in acids. Studies conducted both *in vitro* and *in vivo* have shown that BCP grit-blasted surfaces promoted an early osteoblast differentiation and bone apposition as compared to smooth or alumina grit-blasted titanium implants.[20,21]

Alkaline and heat treatments of titanium implants have also been shown to promote CaP deposition *in vitro* from SBF as well as bone apposition. Kokubo and colleagues have treated titanium implants in KOH or NaOH 5 M solutions at 60 °C for 24 h producing an alkali titanate gel, which was stabilized by heating at 500 °C.[22–24] This group developed an SBF, which is a protein-free, electrolyte solution with similar concentrations of ions as in human blood plasma in order to mimic interactions with body fluids (Table 2). SBF is a supersaturated or metastable CaP solution at pH 7.4 and 37 °C. By immersion in SBF, alkali- and heat-treated titanium implants induced the precipitation of carbonated apatite on their surface. Similarly, bone bonding was observed on such treated titanium implants *in vivo*.[25]

1.112.4. Plasma Spraying of CaP Coatings

Plasma-sprayed coatings, mainly HA, have been used in orthopedic surgery to enhance the fixation to the skeleton of noncemented hip and knee prostheses. Many studies have shown that these coatings can successfully favor an early bone apposition on titanium implants.[26] The biological fixation of titanium implants to bone tissue is faster with a CaP coating than without. It is also well recognized that CaP coatings have led to better clinical success rates in the long term than did uncoated titanium implants. These long-term success rates are due to a superior initial rate of osseointegration.[27–29]

Atmospheric plasma spraying (APS) is the most widely applied method to deposit HA coating onto titanium alloy prostheses. As shown in Figure 2, the method consists of injecting the ceramic HA particles into a high-temperature (>10 000 °C) and high-velocity (>800 m s^{-1}) plasma torch. The HA particles partly melt and are projected on the surface of the titanium implants where they condense and fuse together, forming a coating. The plasma-spraying method is highly effective for coating orthopedic prostheses, as CaP layers having a thickness of 50–100 μm can be produced within minutes. However, the high temperature of the plasma torch provokes dehydration and decomposition of HA. The dehydration produces oxyapatite (OA, $Ca_{10}(PO_4)_6O$) and/or oxyhydroxyapatite (OHA, $Ca_{10}(PO_4)_6(OH)_{2-x}O_x[]_x$).[30] The thermal decomposition of HA results also in different phases such as calcium oxide (CaO), α-TCP, tetracalcium phosphate (TTCP, $Ca_4P_2O_9$), and amorphous calcium phosphate (ACP). A sprayed HA particle impacting the titanium surface is composed of a solid core and a solidified shell. Fast cooling at impact results in conservation of high-temperature CaP phases in the solid core, while the solidified shell is mostly composed of an amorphous phase. The fractions of HA, OA-OHA, TTCP, α-TCP, and ACP phases in sprayed coatings is the most important factor that determines the dissolution and biological behavior of coatings. These heterogeneities of CaP phases in plasma-sprayed HA coatings are responsible for differences in dissolution rates *in vivo*. The ACP

Table 2 Ionic composition of human blood plasma and simulated body fluids

Ionic concentration (mM)	Na^+	K^+	Mg^{2+}	Ca^{2+}	Cl^-	HCO^{3-}	HPO_4^{2-}	SO_4^{2-}	pH
Blood plasma	142	5	1.5	2.5	103.8	27	1	0.5	7.2–7.4
SBF	142	5	1.5	2.5	147.8	4.2	1	0.5	7.4

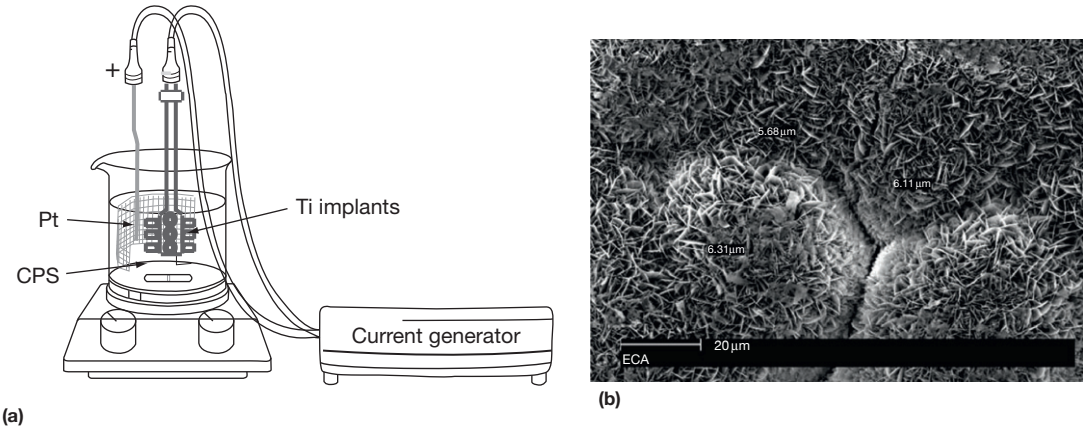

Figure 3 (a) Electrodeposition setup and (b) scanning electron microscopy of a typical ELD coating on titanium.

phase being highly soluble, some crystalline HA particles may be released in the articular synovia, inducing inflammation or delamination of coatings from the titanium implant. Furthermore, the plasma-spraying technique is not very effective for coating tiny dental implants. Coating delamination has been reported in dental situations where the efficacy of plasma spraying is not optimal due to the small size of the dental implants. Loosening of the coating has also been reported, especially when the dental implants have been inserted into dense bone. For all of the aforementioned reasons, the clinical use of plasma-sprayed HA coating on dental implants is marginal. Other drawbacks of the plasma-spraying technique are the impossibility of applying on implants promising CaP phases such as OCP, CDA, or carbonated apatite that precipitate in the body. The high temperatures of plasma spraying prevent the incorporation of biological agents such as antibiotics to prevent postsurgical infections or growth factors to stimulate bone healing. The technique is also not applicable to heat-sensitive implants such as polymers. Finally, plasma spraying is a line-of-sight process that produces uneven coating on porous or beaded metal implants. Therefore, researchers have explored alternative techniques for deposition of CaP coatings onto metal implants. The most promising methods are those that produce CaP coatings at ambient temperatures from aqueous supersaturated solutions.

1.112.5. Electrochemical Deposition of CaP Coatings

Electrodeposition (ELD) is a promising alternative method to plasma-spraying HA. In the ELD process, electrochemical reactions near the electrode induce local pH increase and thus CaP precipitation on the titanium implant. As shown in Figure 3, the ELD process is conducted in supersaturated or metastable CaP solutions and is based on the electrolytic decomposition of water. A platinum electrode (anode) and the titanium implant (cathode) are connected to a current generator. The application of current of several milliamperes results in the following electrochemical reactions. At the titanium cathode, the reduction of water takes place with production of hydrogen gas and rise of pH:

$$2H_2O + 2e^- \rightarrow H_2{}^{\uparrow} + 2OH^-$$

At the platinum anode, the oxidation of water with oxygen gas is observed:

$$2H_2O \rightarrow O_2{}^{\uparrow} + 4H^+ + 4e^-$$

The ELD takes advantage of the pH-dependent solubility of CaP compounds. Resulting from hydroxyl ions' production, the local pH rise leads to an increase in the relative supersaturation of the electrolyte and the precipitation of CaP

on the titanium surface. Most of the ELD have been conducted in acidic CaP solutions and formed brushite coating (dicalcium phosphate dihydrate, DCPD). Such brushite coatings normally need hydrothermal treatments to convert them into apatite. Recently, some studies have reported the direct deposition of apatite coating through ELD in SBF.[31,32] It has been found that the deposited CaP coating was composed of CA, or OCP that converted into CA with increasing time and temperature. Owing to physiological conditions (aqueous solutions, pH, and temperature), the incorporation of bioactive molecules such as proteins into CaP coatings is possible. For instance, bovine serum albumin–DCPD, collagen–OCP, and chitosan–apatite composite coatings were produced by using ELD. Nevertheless, the relatively low solubility of CaP at neutral pH is a limiting factor for ELD. Indeed, supersaturated solutions contain low concentrations of Ca^{2+} and HPO_4^{2-} ions, typically 2.5 and 1 mM, at neutral pH (Table 2). The precipitation of CaP coatings on titanium implants requires a sufficient volume of electrolyte to surface ratio. Based on a rough calculation, approximately 20 ml of electrolyte are needed to coat 1 cm^2 of implant. Applying CaP coatings through ELD on a large number of implants is therefore a challenging issue for industrial applications. Additionally, the hydrogen gas production hampers the deposition of CaP because of the formation of bubbles on the titanium surface. It results in nonuniform and relatively thin CaP coatings (around 10 μm). In order to overcome this problem, Legeros's group has developed a pulsed galvanostatic method to deposit CaP coatings on Ti6Al4V and Co–Cr alloys.[33] This method makes possible a perfect control of the thickness of the deposit on all kinds of complicated surfaces. The time required for coating is very short, and the process presents high reproducibility and efficacy. Other interesting methods to apply CaP coatings on metal implants using current are the electrophoretic deposition (EPD) process and the electrostatic spray deposition (ESD). The first EPD method consists of suspending CaP powders in nonaqueous solutions (e.g., isopropanol, ethanol) and applying an electric field ~10 V cm^{-1} between an electrode and the implant to be coated.[34] As CaPs are predominantly positively charged particles, they are displaced onto the negative metal substrate forming a layer. However, the stabilization of CaP suspensions is not an easy task. The second ESD method is based on the generation of an aerosol composed of organic solvents containing inorganic precursors under the influence of high voltages.[35] Spray droplets are generated by pumping a solution through a nozzle and attracted by a grounded and heated substrate. Leeuwenburgh and colleagues have used the ESD method to produce CaP coatings on titanium. Calcium nitrate or chloride and phosphoric acid were dissolved in ethanol and/or butyl carbitol and processed by ESD while substrate was heated at 300–450 °C. Interestingly, different spray droplets of carbonated apatite were produced on titanium. Both the EPD and ESD methods are efficient processes, as typical deposition time is in the range of minutes. However, the initial adherence of the CaP coatings is poor, and EPD is followed by postheating at 800–1200 °C for 1 h, while ESD requires *in situ* heating at 300–450 °C. The incorporation of bioactive molecules is therefore not possible using ESD and EPD methods. DCPD coatings on orthopedic prostheses and dental implants processed by ELD have reached clinical applications and are commercially available (BIONIT®, DOT GmbH). Nanocrystalline HA coatings have been applied by ELD on orthopedic acetabulum prostheses (BoneMaster®, BIOMET Corp.) and showed higher bone mineral density than that of plasma-sprayed HA-coated devices.

1.112.6. Biomimetic CaP Coatings

In order to avoid the drawbacks of plasma-sprayed HA coatings, scientists have developed a new coating method inspired by the natural process of biomineralization. In this biomimetic method, the precipitation of CaP apatite crystals was obtained onto the titanium surface from SBF. This method involves the heterogeneous nucleation and growth of bone-like crystals on the surface of the implant at physiological temperatures and pH conditions. In order to overcome the problem of low saturation of SBF, calcium and phosphate concentrations were increased by bubbling a weak acid gas, namely, carbon dioxide (Figure 4). Upon exchange of CO_2 with air, the pH of the solution rises and thus saturation of the solution increases, causing the precipitation of CaP coatings onto the implants.[36] The heterogeneous nucleation and crystal growth of the CaP coatings on the titanium surface is initiated by the chemical bonding of nano-sized clusters, forming an interfacial unstructured matrix, stabilized by the presence of magnesium and carbonate ions.[37] The method resulted in uniform and well-attached coating of carbonated apatite on titanium implants, as shown in Figure 4. In addition, this physiological method broadens the variety of CaP phases that can be deposited, such as OCP or bone-like carbonate apatite.[38] It has been shown that such biomimetic coatings are more soluble in physiological fluids and resorbable by osteoclastic cells than high-temperature coatings such as plasma-sprayed HA.[39,40] The osseointegration of titanium implants coated with biomimetic CaP has been investigated in preclinical comparative models. These studies have demonstrated a higher bone-to-implant contact for biomimetic CaP coatings than for uncoated titanium implants.[41] As shown in Figure 5, noncoated metal implants were encapsulated by fibrous tissue, while direct bone apposition was observed on biomimetic CaP-coated implants. Despite these positive results, the osseointegration of titanium implants coated biomimetically has not yet been compared with other surface treatments in preclinical models.

Owing to the physiological conditions of formation, biomimetic CaP coatings may incorporate bone-stimulating agents such as growth factors in order to enhance the bone-healing process in the peri-implant region.[42] Members of the transforming growth factor-β (TGF-β) superfamily, and in particular, bone morphogenetic proteins (BMPs), TGF-β1, platelet-derived growth factor (PDGF), and insulin-like growth factors (IGF-1 and -2), are some of the most promising candidates for this purpose. Experimental data, in which BMPs have been incorporated into dental implants, have been obtained from a variety of methodologies.[43] The limiting factor is that the active product has to be released progressively and not in a single burst. Another possibility may be the adjunction of a plasmid containing the gene coding for a BMP. This possibility is limited due to the poor efficacy of inserting plasmids into the cells and the expression of the protein. In addition, overproduction of BMPs by cells might not be desirable after the bone-healing process. The surface of

implants could also be loaded with molecules controlling the bone-remodeling process. Incorporation of bone antiresorptive drugs, such as biphosphonates, might be very relevant in clinical cases lacking bone support, for example, resorbed alveolar ridges. It has been shown recently that a biphosphonate incorporated onto titanium implants increased bone density locally in the peri-implant region.[44] The effect of the antiresorptive drug seems to be limited to the vicinity of the implant. Experimental *in vivo* studies have demonstrated the absence of negative effects but only a slight increase in dental implant osseointegration. Other experimental studies using plasma-sprayed HA-coated dental implants immersed in pamidronate or zoledronate demonstrated a significant increase in bone contact area. The main problem lies in the grafting and sustained release of antiresorptive drugs on the titanium implant surface. On account of the high chemical affinity of biphosphonates for CaP surfaces, incorporation of the antiresorptive drug onto dental implants could be achieved by using the biomimetic coating method at room temperatures. However, the ideal dose of antiresorptive drug will have to be determined, because the increase in peri-implant bone density is biphosphonate concentration-dependent. In order to prevent postsurgical infections around orthopedic or dental implants, antibiotics may be incorporated into biomimetic CaP coatings. The antibiotic can be gradually coprecipitated with the CaP crystals, forming a layer on the metal implants. This creates the possibility to incorporate an antibiotic uniformly within the biomimetic coating and release it at a controlled rate, thus preventing or stopping local infection postoperatively. Different antibiotics were incorporated into the carbonated apatite coatings and their release was studied *in vitro*. The antibiotics were effective to stop locally the growth of bacteria. These studies evidenced the benefits of using a biomimetic method for coating medical implants. The incorporation of various bioactive molecules into CaP coatings at physiological conditions allowed their sustained, local release and bioactivity in the peri-implant region concomitantly with an improved osseointegration.

1.112.7. Conclusion and Perspectives

Metal implants are only biocompatible and have no osteogenic properties in order to promote bone healing. Their osteointegration or biological anchoring to the skeleton is improved by CaP coatings. The aim is to provide metal implants with surface biological properties for the adsorption of proteins, the adhesion of cells, and the bone apposition. Direct bone-to-implant contact is desired for a biomechanical anchoring of implants rather than fibrous tissue encapsulation. These bioactive coatings on titanium implants are resorbable and stimulate bone apposition onto the implant surface. The biomimetic approach has four main advantages: (i) it is a low-temperature process applicable to any heat-sensitive substrate including polymers; (ii) it forms bone-like apatite crystals having high bioactivity and good resorption characteristics; (iii) it is evenly deposited on, or even into, porous or complex implant geometries; and (iv) it can incorporate bone-growth-stimulating factors.

1.113.1. Introduction

Various kinds of bone-bonding, bioactive ceramics have been developed and are being used clinically as important bone substitutes.[1] Although they can be glass, glass–ceramic, or polycrystalline ceramics, all of them contain calcium, and the majority contain calcium phosphate. They are intrinsically brittle and have poor fracture toughness. Some orthopedic and dental applications need tough and ductile bioactive materials. Metals coated with calcium phosphates have been developed using various methods, such as plasma spraying, sputtering, sol–gel deposition, biomimetic deposition,[2] and alternate soaking processes.[3] Some are already being used clinically under load-bearing conditions. However, the coated hydroxyapatite has a distinct boundary against the metallic substrate; hence, it does not remain stable in the body for long periods (see **Chapter 1.102, Metals for Use in Medicine**; **Chapter 1.109, Bioactive Ceramics**; **Chapter 1.110, Bioactive Glass-Ceramics**; **Chapter 1.111, Bioactive Ceramics: Physical Chemistry**; and **Chapter 1.112, Calcium Phosphate Coatings**).

It has been shown that some gels, such as silica[4] and titania[5] gels, can form bone-like apatite on their surfaces in simulated body fluid (SBF) having ion concentrations nearly equal to those of human blood plasma,[6] as shown in **Figure 1**. This indicates that functional groups, such as Si–OH and Ti–OH, abundant on the gels, induce nucleation of the apatite within the body. Therefore, if their surfaces could be modified with functional groups that enable effective apatite nucleation, it is expected that even tough metallic materials and soft organic polymeric materials could form the bone-like apatite on their surfaces in the body and bond to living bone through this apatite layer.

In the next section, various methods for producing bioactive layers, which form apatite on metallic and polymeric substrates in the body, are reviewed.

1.113.2. Bioactive Layers

1.113.2.1. Bioactive Layers on Metals

1.113.2.1.1. Bioactive layers on titanium metal and its alloys

1.113.2.1.1.1. Sodium titanate layer

Titanium (Ti) metal is generally covered with a thin layer of titanium oxide. It is expected that if Na^+ ions are incorporated into the titanium oxide layer, the resultant sodium titanate layer could form Ti–OH groups on its surface in the body by exchanging its Na^+ ions with the H_3O^+ ions in the body fluid and thus induce apatite formation (see **Chapter 1.114, Bioactivity: Mechanisms** and **Chapter 6.605, Porous Coatings in Orthopedics**).

Kokubo *et al.*[7] were the first to show that a sodium titanate layer is formed on the surface of Ti metal when the metal is soaked in NaOH solution and then heat treated, and that the treated Ti metal forms a bone-like apatite on its surface in SBF. The effects of varying concentration, temperature, periods of soaking in the NaOH solution, and the temperature of the heat treatment on the apatite-forming ability of the Ti metal in SBF were

M.; Miyaji, F.; Kokubo, T.; Nishiguchi, S.; Nakamura, T. *J. Biomed. Mater. Res.* **1999**, *45*, 100–107, with permission from John Wiley and Sons.

investigated.[8,9] These studies showed that soaking in a 5 M NaOH solution at 60 °C for 24 h and heat treatment at 600 °C for 1 h were standard treatments, and that these treatments are also effective in inducing the apatite-forming ability of Ti-based alloys, such as Ti–6Al–4V, Ti–6Al–2Nb–Ta, and Ti–15Mo–5Zr–3Al.[10]

Auger electron spectroscopy (AES) showed that the sodium and oxygen ions penetrated the surface of the Ti metal to a depth of 1 μm after NaOH treatment, and that only oxygen ions penetrated a little deeper during the subsequent heat treatment, as shown in Figure 2.[11] The concentration of both ions continued to decrease gradually with increasing depth from the surface. A distinct boundary was not formed between the surface layer and the metallic substrate. Similar graded surface structures were observed for Ti–6Al–4V[12] and Ti–15Mo–5Zr–3Al alloys[13] subjected to the NaOH and heat treatments. During the NaOH treatment, alloy elements, such as Al, V, Mo, and Zr, were selectively released from the surfaces of these alloys.

Using thin-film X-ray diffraction,[10] it was initially assumed that the phase formed on the Ti metal by the NaOH treatment was sodium titanate hydrogel, and those formed by the subsequent heat treatment were amorphous sodium titanate and rutile. Using detailed analyses of thin-film X-ray diffraction and Raman spectroscopy, Kawai *et al.*[14] later found that the sodium titanate hydrogel and amorphous sodium titanate were actually nano-sized crystalline sodium hydrogen titanate ($Na_xH_{2-x}Ti_yO_{2y+1}$; $0 < x < 2$ and $y = 2$, 3, or 4) and nano-sized crystalline sodium titanate layers ($Na_2Ti_yO_{2y+1}$; $y = 5$, 6, etc.), respectively.

The NaOH treatment formed a fine network structure on the surface of the Ti metal, and subsequent heat treatment did not essentially change this, as shown in Figure 3. The fine network structure was shown to consist of featherlike phases that were elongated perpendicular to the substrate, about 1 μm in length, and the structure was further densified by the subsequent heat treatment, as shown in Figure 4.[15] The structural changes due to the NaOH and heat treatments are shown schematically in Figure 5.

The adhesive strength[16] and scratch resistance[14] of the surface layer formed on the Ti metal by the NaOH treatment increased with the subsequent heat treatment.

When the NaOH- and heat-treated Ti metal was soaked in SBF, apatite started to precipitate in the deep region of the interspaces of the featherlike phases. The apatite filled the interspaces and integrated with the featherlike phases to form a dense composite of apatite and titanate, which grew over the surface layer, fully covering the surface, as shown in Figure 6.[15]

There was no distinct boundary between the apatite–titanate composite and the metallic substrate. Transmission electron microscopy (TEM) confirmed the fact that the apatite so formed took a needle-like shape and had a composition similar to bone mineral, with a Ca/P atomic ratio of 1.65 and small amounts of Na and Mg, as shown in Figure 7.[17]

With respect to the mechanism of apatite formation on the thus-treated Ti metal, Uchida *et al.* first showed that a specific

structure is required for the formation of apatite on sodium titanate in SBF.[18] Later, X-ray photoelectron spectroscopy (XPS),[19] TEM observation,[17] and zeta potential measurement[20] showed that apatite is formed on the treated Ti metal in SBF by a process that is shown in **Figure 8**. Sodium ions are released from the surface of the sodium titanate via exchange with H_3O^+ ions in the SBF to form Ti–OH groups on the surface of the titanate. The Ti–OH groups thus-formed are negatively charged because the pH of the surrounding SBF is increased by the released sodium ions[21]; these then combine with the positively charged calcium ions to form a calcium titanate. As the calcium ions accumulate on the surface of the titanate, the surface is positively charged, and hence, it combines with the negatively charged phosphate ions to form amorphous calcium phosphate. This calcium phosphate is metastable and eventually transforms into a crystalline bone-like apatite. Using XPS[22] and TEM[23] studies, Takadama *et al.* confirmed that a similar process of apatite formation occurs on a Ti–6Al–4V alloy subjected to the NaOH and heat treatments. Using TEM observations, Conforto *et al.*[24] examined the process of apatite formation on Ti metal subjected to NaOH treatment, but not to the heat treatment, in SBF, and they confirmed the formation of calcium titanate prior to the formation of apatite.

Strnad *et al.* showed that preliminary acid treatment enables effective and uniform apatite formation in Ti metal subjected to NaOH treatment but not to the heat treatment, in SBF.[25,26] Müller *et al.*[27] also found that the preliminary acid treatment effectively enabled apatite formation on a Ti–13Nb–13Zr alloy treated with an NaOH solution, in SBF.

Jonášová *et al.* raised concerns over an inflammatory response of the surrounding tissues that could be induced by the sodium ions released from the sodium titanate. They showed that even NaOH-treated Ti metals, which released a fair amount of sodium ions, do not decrease their apatite-forming ability in SBF.[28] This result is applicable to Ti metals subjected to the NaOH treatment, but not to the heat treatment. Kawai *et al.*[14] showed that the subsequent heat treatment greatly increases the apatite-forming ability of NaOH-treated Ti metal in SBF, and that the NaOH- and heat-treated Ti metal displays a high apatite-forming ability even when the sodium ions in the surface layer are decreased, but not completely released. It should be noted here that the sodium ions in the surface layer of the treated Ti metal are liable to be released when the treated Ti metal is stored in a humid environment as it is exchanged with the H_3O^+ ions in the atmosphere. This decreases the apatite-forming ability of the treated Ti metal. However, according to Kawai *et al.*,[14] if the sodium ions on the top surface of the sodium titanate are removed by water treatment after the NaOH treatment, the apatite-forming ability of the treated Ti metal does not decrease, even after the treated Ti metal has been stored in a humid environment for a long period.

Krupa *et al.*[29] showed that the NaOH-treated Ti metal displays high corrosion resistance after heat treatment.

By using these chemical and heat treatments, the bioactive layer can easily be formed uniformly, even on the irregular inner surfaces of porous materials.[30] Both heat treatment for fabrication of the porous body and subsequent treatments for inducing bioactivity can incorporate fairly large amounts of oxygen ions into the Ti metal. However, the incorporated oxygen does not have any adverse effect on the apatite-forming ability of the Ti metal in SBF.[31]

Cell culture experiments have shown enhancements in both differentiation of osteoblasts and bone nodule formation on the apatite layer formed by the NaOH- and heat-treatments in Ti metal, in SBF.[32,33]

These *in vitro* data indicate that the NaOH- and heat-treated Ti metal forms a bone-like apatite layer on its surface, even in the living body, and that it tightly bonds to the living bone through this apatite layer. Actually, when the NaOH- and heat-treated Ti metal was implanted into the tibia of a rabbit, it formed a bone-like apatite on its surface and tightly bonded to the living bone.[34] Under tensile stress, the failure load of the treated Ti metal bonded to the living bone was much higher than that of the untreated Ti metal, higher than that of only NaOH-treated Ti metal, and almost equal to that of the Ti metal formed with apatite on its surface, in SBF.[34–36] The failure load increased with an increase in the period after implantation. Ti-based alloys, such as Ti–6Al–4V, Ti–6Al–2Nb–Ta, and Ti–15Mo–5Zr–3Al, which were subjected to NaOH and heat treatments and implanted into the tibia of a rabbit, also displayed high failure loads under tensile stress.[37] When implanted into a canine femur,[38] the Ti metal and its alloys, subjected to the same treatments, showed high bonding strengths, even under shear stress. An NaOH- and heat-treated Ti metal rod implanted into the medullary canal of a rabbit femur was observed to form a bone-like apatite on its surface within 3 weeks, and to be completely surrounded by newly grown bone within 12 weeks, as shown in **Figure 9**.[39] The push-out failure load of the treated Ti metal was much higher than that of the untreated Ti metal, and it increased with an increase in the period after implantation, as shown in **Figure 10**.[39] At 12 weeks after implantation, the treated Ti metal rod could not be pulled out without being accompanied by bone fragments, as shown in **Figure 11**.

Porous Ti metals subjected to NaOH and heat treatments were fully penetrated, and they bonded with new bone derived from the surrounding bone.[40]

Based on these animal experiments, NaOH and heat treatments were applied to a porous Ti metal layer on the outer cup and on part of the stem of a Ti–6Al–2Nb–Ta alloy of a total artificial hip joint. After successful clinical trials, the resultant bioactive artificial joint has been in clinical use in Japan since 2007, as shown in **Figure 12**.[41]

1.113.2.1.1.2. Calcium titanate layer

The NaOH and heat treatments described above are simple treatments for inducing bioactivity in Ti metal and its alloys. However, some problems remain unresolved. The sodium ions in the sodium titanate are easily released from the surface, not

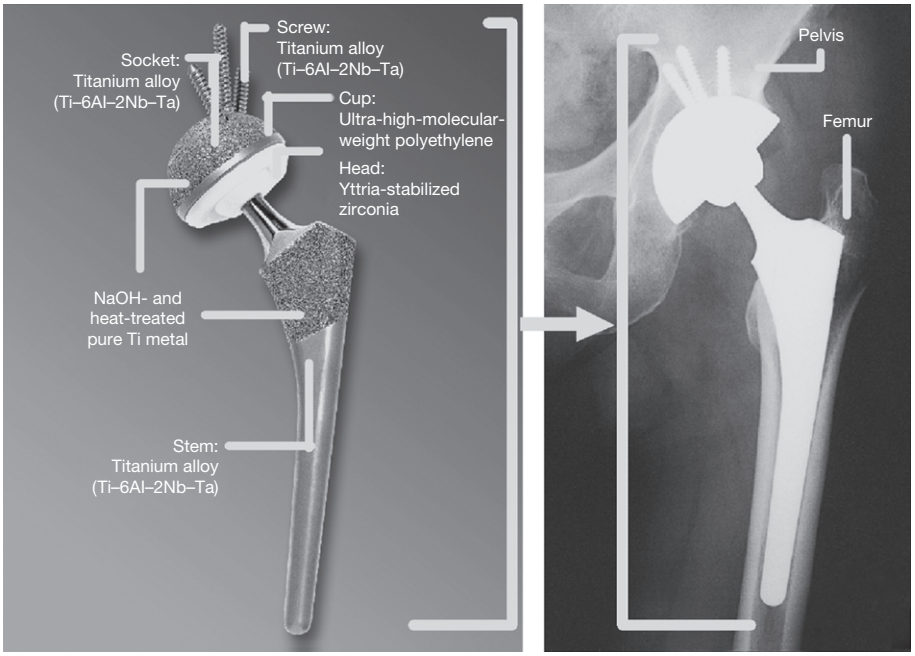

Figure 12 Clinical application of NaOH- and heat-treated Ti metal in hip joint. Reproduced from Kokubo, T. *Mater. Sci. Eng. C* **2005**, *25*, 97–104, with permission from Elsevier.

only in the body after implantation, but also in a humid environment, before implantation, as described in Section 1.113.2.1.1.1. This decreases the apatite-forming ability of the treated Ti metal after implantation and is a problem when the implant is stored in a humid environment for a long time period before implantation. Although partial removal of the sodium ions on the top surface solves this problem, for the clinical artificial joint, it is desirable to develop a more stable, highly bioactive layer.

On the other hand, the release of sodium ions from sodium titanate in the body is liable to be suppressed by the contamination of its surface layer with some other ions, such as calcium, thus decreasing the apatite-forming ability of the treated Ti metal. The aim is, therefore, to develop a highly bioactive layer that is not disturbed by contamination.

The NaOH and heat treatments are effective in inducing the bioactivity of the conventional Ti-based alloys, such as Ti–6Al–4V, Ti–6Al–2Nb–Ta, and Ti–15Mo–5Zr–3Al, but not of the new kind of Ti–Zr–Nb–Ta alloys. Effective treatments for these alloys need to be developed. The formation of a calcium titanate layer on the metal is expected to meet these requirements because the calcium ions can better promote apatite formation in the body by increasing the ionic activity product of the apatite, compared with the sodium ions. The calcium ions might be more stable than the sodium ions and may stay in the surface layer, even in a humid environment.

Hanawa *et al.*[42] were the first to attempt an implantation of calcium ions into the surface of the Ti metal, and they were later followed by Armitage *et al.*[43] and Nayab *et al.*[44] They showed that the calcium ions are incorporated into the surface of Ti metal up to a depth of about 100 nm at a dose of 1×10^{17} ions cm^{-2} under 40 keV, and that the calcium-implanted Ti metal gives greater bone-surface contact by activating bone cell function. However, this method of ion implantation requires expensive and large apparatus.

Sul[45] showed that about 11 at.% Ca ions are incorporated into the TiO_2 layer with a thickness of about 1300 nm on the surface of the Ti metal by micro-arc oxidation in a calcium-containing mixed electrolyte system. The resultant dental implant had a higher removal torque compared with the untreated implant. However, this higher torque cannot be simply attributed to the formation of the calcium-containing TiO_2 layer on the Ti metal because the micro-arc oxidation forms a porous structure with a number of craters on the surface of the Ti metal. Fröjd *et al.*[46] later reported that the calcium-incorporated titanium oxide layer formed on Ti metal by micro-arc oxidation gives larger bone contact than the calcium-free oxide layer. However, Song *et al.*[47] did not observe apatite formation in SBF on the calcium-containing titanium oxide formed by the micro-arc oxidation, but on the surface layer formed with amorphous $Ca(OH)_2$ by the subsequent hydrothermal treatment with water at 250 °C for 2 h.

Nakagawa *et al.*[48] also attempted the incorporation of calcium ions into Ti metal by hydrothermal treatment. They showed that a small quantity of calcium ions could be incorporated into the surface of the Ti metal by hydrothermal treatment with a $CaCl_2$ solution at 200 °C for 24 h, and that the so-treated Ti metal forms an apatite layer on its surface in SBF. Park *et al.*[49] incorporated larger amounts of calcium ions onto the surface of a Ti–6Al–4V alloy by forming $CaTiO_3$ through hydrothermal treatment with NaOH and CaO solution at 180 °C for 24 h. The alloy thus-treated also formed apatite on its surface in Hank's solution and showed an increase in bone-to-implant contact. Ueda *et al.*[50] have observed apatite formation in SBF on Ti metal that was first

treated with a H_2O_2/HNO_3 solution at 80 °C for 50 min and then hydrothermally treated with $Ca(OH)_2$ solution at 180 °C for 12 h. Chen *et al.*[51] showed that calcium ions can be incorporated onto the surface of porous Ti metals by hydrothermal treatment with 0.2 M $Ca(OH)_2$ solution at 250 °C for 8 h.

However, both the micro-arc oxidation and hydrothermal treatments described above need expensive apparatus especially designed for applying electric fields or high pressure.

Rakngarm *et al.*[52] tried to incorporate calcium ions into the surface of the Ti metal and Ti–6Al–4V alloy by simple chemical treatments. The Ti metal and its alloy were soaked in a 5 M NaOH solution at 60 °C and then in a $Ca(OH)_2$ solution at 60 °C. The Ti metal thus-treated and its alloy formed apatites on their surfaces in SBF. However, the solubility of $Ca(OH)_2$ in water is low, and the method used to incorporate calcium ions into the surface of the Ti metal was not revealed. The scratch resistance of the surface layer was expected to be low because the chemically treated Ti metal was not subsequently subjected to heat treatment.

Kizuki *et al.*[53] soaked the Ti metal in a 5 M NaOH solution at 60 °C for 24 h and then in a 100 mM $CaCl_2$ solution at 40 °C for 24 h. Sodium hydrogen titanate, formed on the Ti metal by the NaOH treatment, was isomorphously transformed into calcium hydrogen titanate by the subsequent $CaCl_2$ treatment. Although the Ti metal thus-treated formed apatite on its surface in SBF, the scratch resistance of the surface layer was very low. It was remarkably increased by subsequent heat treatment at 600 °C for 1 h. Unfortunately, the apatite-forming ability in SBF of the Ti metal was lost due to the heat treatment because the calcium hydrogen titanate was converted to calcium titanate and rutile, as shown in Figure 13. Its apatite-forming ability was recovered by subsequent water treatment at 80 °C for 24 h, as shown in Figure 14. A small amount of the calcium ions in the calcium titanate was exchanged with H_3O^+ ions during the water treatment, as shown in the depth profile of the Auger electron spectra in Figure 15. As a result, the calcium ions in the calcium titanate are easily released into the SBF, forming an apatite layer on the surface of the titanate by the same process as that of sodium titanate shown in Figure 8. The final water treatment can be replaced with autoclave treatment for sterilization before implantation. The Ti metal thus-treated maintains its high apatite-forming ability, even after it is stored in a humid environment for a long period of time.

These NaOH, $CaCl_2$, heat, and water treatments were effective in inducing bioactivity not only in Ti metal, but also in the new Ti–Zr–Nb–Ta alloys, such as Ti–15Zr–4Nb–4Ta, Ti–37Nb–2Ta–3Zr–0.3O, and Ti–29Nb–13Ta–4.6Zr.[54,55]

Animal experiments using rabbit tibia confirmed that the treated Ti metal bonded tightly to living bone, without the intervention of fibrous tissue.[138]

1.113.2.1.1.3. Titanium oxide layer

Both sodium titanate and calcium titanate layers release ions, as previously described, which increase the pH of the surrounding body fluid. This could be an unfavorable condition for the cells in the surrounding tissues, especially in the narrow spaces of porous materials. Therefore, it is desirable that a bioactive layer containing no soluble ions is formed on porous materials. Titanium oxides have extremely low solubility in aqueous environments, and some of them exhibit an apatite-forming ability in SBF, as shown for a titania gel in **Figure 1** (see **Chapter 6.610, Trends in Materials for Spine Surgery**).

However, it is not yet clear what kind of titania phase shows the highest apatite-forming ability in the body. Uchida *et al.*[56] showed that a titania gel of an anatase phase has a higher apatite-forming ability in SBF compared with either an amorphous or rutile phase. Rohanizadeh *et al.*[57] reported that an anatase–gelatin slurry displays a higher apatite-forming ability in a supersaturated calcium phosphate solution compared with a rutile–gelatin slurry. On the other hand, Moritz *et al.*[58] reported that a TiO_2 gel layer permits a higher apatite-forming ability in SBF when transformed into a rutile phase from an anatase phase by laser beam irradiation.

Zhao *et al.*[59,60] showed that a plasma-sprayed TiO_2 coating layer with a rutile phase gave a high apatite-forming ability in SBF when treated with acid solutions, such as H_2SO_4 and HNO_3. Wang *et al.*[61] reported that Ti metal, treated with an H_2O_2/HCl solution and heat treated to around 400–500 °C to form anatase, precipitated apatite on its surface in SBF. Wang *et al.*[62] reported that Ti metal, treated with an HF/HNO_3 solution and heat treated to around 400–500 °C to form rutile, precipitated apatite, but only in a narrow gap. Wu *et al.*[63] showed that Ti metal, treated with H_2O_2/$TaCl_2$ solutions at 80 °C after HF–HNO_3 mixed acid treatment to form anatase and rutile, precipitated apatite on its surface in SBF, even without subsequent heat treatment. Lu *et al.*[64] showed that Ti metal, treated with a nitric acid solution (65% HNO_3:H_2O=1:1 in volume ratio) at 60 °C for 600 min but not subjected to heat treatment, also precipitated apatite on its surface in SBF, although the oxide phase was not detected on its surface. Lu *et al.*[65] reported that Ti metal, treated with H_2SO_4/HCl solutions and heat treated at 500 °C to form rutile, precipitated apatite on its surface in SBF. Sugino *et al.*[66] reported that a Ti–15Zr–4Ta–4Nb alloy, which was heat treated at 500 °C to form rutile without acid treatment, precipitated apatite in SBF, but only in the internal surface of the microgrooves. Sul *et al.*[67] reported that a Ti metal dental implant, formed with a thick layer of anatase and/or rutile on its surface by anodic oxidation in a 0.1 M CH_3COOH solution, showed a high removal torque when implanted into the tibia of a rabbit. Yang *et al.*[68] and Cui *et al.*[69] have shown that Ti metal, formed with anatase and rutile on its surface by anodic oxidation with a spark discharge in H_2SO_4 and Na_2SO_4 solutions, precipitated apatite on its surface in SBF.

It is difficult to derive the principle that governs the apatite-forming ability of titanium oxide from these data. However, it seems that acid and/or heat treatments are effective, except in some cases, in inducing the apatite-forming ability of titanium oxide in SBF irrespective of the kind of crystalline phase.

As described above, Ti metal forms sodium hydrogen titanate on its surface when treated with a 5 M NaOH solution at 60 °C for 24 h. The sodium hydrogen titanate has a layered structure, shown in **Figure 16**.[70] It is expected that by using water or acid treatment, the Na^+ ions located in the interlayers of this structure could easily be replaced with H_3O^+ ions to form hydrogen titanate, and that the hydrogen titanate could be transformed into anatase or rutile by subsequent heat treatment. Uchida *et al.*[71] showed that the Na^+ ions in the sodium hydrogen titanate, formed on Ti metal by the NaOH treatment, are completely exchanged with H_3O^+ ions by water treatment at 40 °C for 48 h, and that both anatase and rutile are formed on the surface of the Ti metal by subsequent heat treatment at 600 °C for 1 h. The apatite-forming ability of the sodium hydrogen titanate in SBF was decreased by its transformation into hydrogen titanate and the removal of the Na^+ ions, but was increased by its transformation into anatase and rutile upon subsequent heat treatment. Pattanayak *et al.*[72] found that if the Ti metal was treated with an HCl solution, instead of water, after the NaOH treatment, the apatite-forming ability of the subsequently heat-treated Ti metal roughly increased

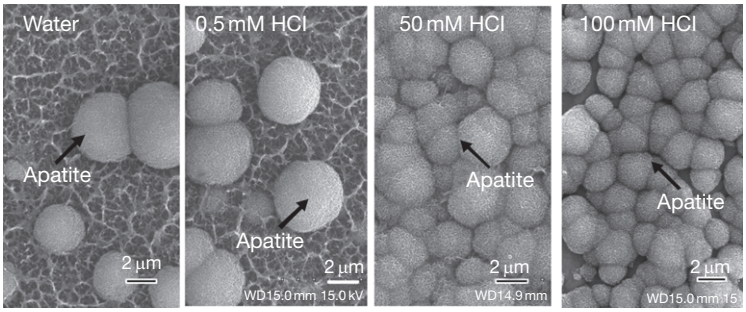

Figure 17 Scanning electron microscopy photographs of surfaces of Ti metals soaked in simulated body fluid for 1 day after NaOH, water or HCl solutions with various concentrations, and heat treatments. Reproduced from Pattanayak, D. K.; Kawai, T.; Matsushita, T.; Takadama, H.; Nakamura, T.; Kokubo, T. *J. Mater. Sci. Mater. Med.* **2009**, *20*, 2401–2411, with permission from Springer.

with an increase in the concentration of the HCl solution in the range of 0.5–100 mM, as shown in Figure 17. The ratio of rutile to anatase, formed after the heat treatment, changed with HCl concentration. However, the apatite-forming ability of the treated Ti metal did not depend upon the rutile/anatase ratio. When HNO_3 or H_2SO_4 solutions replaced the HCl solution, the apatite-forming ability of the subsequently heat-treated Ti metal again increased with an increase in the concentration of these solutions. Further, their apatite-forming abilities did not depend upon the kind of acid solution used.[73] As the concentration of the HCl, HNO_3, and H_2SO_4 solutions increased from 0.5 to 100 mM, their pH decreased from 3.46, 3.50, and 3.10 to 1.16, 1.15, and 1.05, respectively. Titanium oxide has been reported to have a positive surface charge in an aqueous solution with a low pH, as shown in Figure 18.[21] Therefore, it is expected that the Ti metals treated with HCl, HNO_3, or H_2SO_4 solutions (with low pH) after the NaOH treatment could be positively charged on their surface in SBF, after they are subsequently heat treated to form the titanium oxide because Cl^-, NO_3^-, or SO_4^{2-} ions might be adsorbed on their surfaces, only to be dissociated in SBF.

If their surfaces are positively charged in SBF, apatite could be formed on the surfaces by the following process. They would first combine with the negatively charged phosphate ions. As the phosphate ions accumulated, their surfaces would become negatively charged and they could combine with the positively charged calcium ions, thus forming calcium phosphate. The calcium phosphate thus-formed would eventually transform into a crystallite bone-like apatite. This process of apatite formation has been confirmed by XPS spectra of the surface of a Ti metal subjected to NaOH, 50 mM HCl, and heat treatments, as a function of soaking time, in SBF, as shown in Figure 19.[74] This process of apatite formation on positively charged titanium oxide is in contrast with that formed on negatively charged sodium titanate given in Figure 8.

The Ti metals, formed with the titanium oxide by the NaOH, acid, and heat treatments, have practical, useful, high scratch-resistant surface layers, and their high apatite-forming abilities are maintained, even after exposure to a humid environment for long periods.

Fujibayashi *et al.*[75] showed that after implantation into rabbit tibia, Ti metal, formed with anatase on its surface by the NaOH, water, and heat treatments, has a higher bone-bonding ability than Ti metal formed with sodium titanate by NaOH and

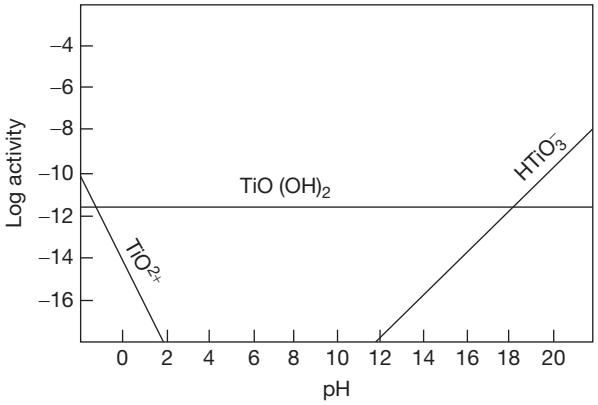

Figure 18 The pH dependence of activity of TiO_2 phase in aqueous solution. Reproduced from Kokubo, T.; Takagi, H.; Tashiro M. *J. Non-Cryst. Solid* **1982**, *52*, 427–433, with permission from Elsevier.

heat treatments at an early stage. Liang *et al.*[76] showed that Ti metal, formed with anatase on its surface by anodic oxidation in a H_2SO_4 solution, also gives a high bone-bonding ability, which is comparable to that of the Ti metal formed with anatase by NaOH, water, and heat treatments.

When the Ti metal cage, which was subjected to the NaOH, water, and heat treatments, was used to segmentally replace a defect in the long bone of a rabbit femur, it was observed to tightly bond to the surrounding bone.[77] Porous Ti metal, subjected to the NaOH, water, and heat treatments, showed greater penetration of newly grown bone compared with untreated porous Ti metal, and it bonded to the newly grown bone in a rabbit femur.[78] Otsuki *et al.*[79] investigated the dependence of bone growth into pores on the microstructure of the porous Ti metal that has been subjected to NaOH, water, and heat treatments. Interestingly, within 12 months[80] of implantation into the muscle of a dog, the same porous Ti metal formed bony tissue. This kind of osteoinduction was observed only to a small extent in the porous Ti metal subjected to the NaOH and heat treatments, whereas, it is more active in porous Ti metal subjected to NaOH, 0.5 mM HCl, and heat treatments, as shown in Figure 20.[81] When it was applied as an implant in the spinal interbody fusion of a canine, the porous Ti metal subjected to the NaOH, HCl, and heat treatments was tightly fixed to the surrounding bone, as shown in Figure 21.[82]

On the basis of these animal experiments, this porous bioactive Ti metal was successfully applied to clinical trials as a spinal interbody fusion device.

1.113.2.1.2. Bioactive layers on Zr metal

Zirconia gel, prepared by a sol–gel method, was also found to form apatite on its surface, in SBF.[83] When it was heat treated up to 600–800 °C, in order to be converted into the tetragonal and monoclinic crystalline phases, it formed apatite more easily.[84] These results indicate that the bioactivity of the zirconium metal can also be induced by some surface treatments. However, zirconium metal only formed apatite on the surface that faced the bottom of the vessel when it was soaked in a 5 M NaOH solution at 95 °C for 24 h.[85] Chen *et al.*[86] reported that zirconium metal forms apatite on its surface, in SBF, when soaked in a 10 M NaOH solution at 60 °C for 24 h and then heat treated at 600 °C for 1 h in vacuum. Hang *et al.*[87] reported that zirconium metal forms apatite on its surface, in SBF, when subjected to micro-arc oxidation in an aqueous electrolyte containing 0.2 M calcium acetate monohydrate and 0.02 M β-glycerophosphate disodium salt pentahydrate at 500 V for 5 min, in order to form a zirconia containing CaO and a phosphate layer on its surface.

1.113.2.1.3. Bioactive layers on Nb metal

Niobium oxide gel, prepared by a sol–gel method, also forms apatite on its surface, in SBF, as long as it is not heat treated above 1000 °C, in order to be transformed into the monoclinic phase.[88] This indicates that some surface treatments can induce bioactivity in the niobium metal also.

However, it does not form apatite on its surface in SBF, even when sodium niobate is formed on its surface by soaking it in 1 M NaOH solution at 60 °C for 24 h.[88] Later, Wang *et al.*[89] reported that niobium metal formed apatite on its surface in

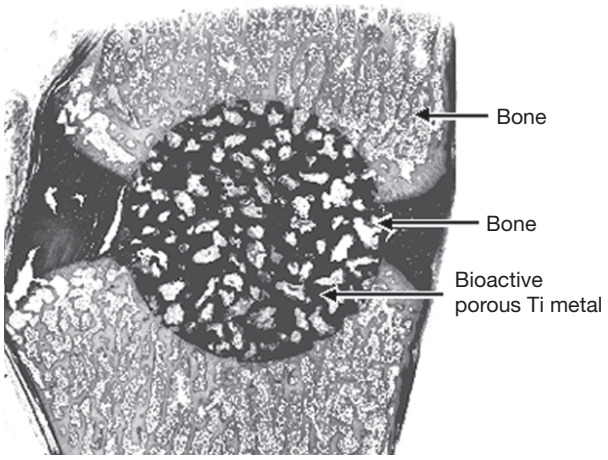

Figure 21 Fusion of spine of dog by a bioactive porous Ti metal. Reproduced from Takemoto, M.; Fujibayashi, S.; Neo, M.; *et al. J. Neurosurg. Spine* **2007**, *7*, 435–443, with permission from American Association of Neurosurgeons.

SBF when it was soaked in a 0.5 M NaOH solution at 80 °C for 24 h and then heat treated at 600 °C for 1 h in vacuum.

1.113.2.1.4. Bioactive layers on Ta metal

Tantalum oxide gel, prepared by a sol–gel method, also forms apatite on its surface in SBF, and its apatite-forming ability increases with an increase in the sodium content of the gel.[90]

Tantalum metal will form apatite on its surface, in SBF, without any chemical treatment, although apatite formation takes a long time. If it is soaked in a 0.2–0.5 mM NaOH solution at 50 °C for 24 h to form a sodium tantalite hydrogel on its surface, the induction period for the apatite formation is largely decreased.[91] When it is subsequently subjected to heat treatment at 300 °C for 1 h, the bonding strength of the surface layer to the substrate is increased without any appreciable decrease in its apatite-forming ability.[92,93] The reason why the NaOH and heat treatments could enhance the apatite-forming ability of the Ta metal was interpreted in terms of apatite nucleation induced by the Ta–OH groups formed on the Ta metal in SBF.[94]

The Ta metal, subjected to the NaOH and heat treatments, was confirmed to bond tightly to the living tibial bone of a rabbit within 16 weeks of implantation.[95]

When the Ta metal was soaked in a 100 mM $CaCl_2$ solution at 80 °C for 24 h after the NaOH treatment, and then heat treated at 500 °C for 1 h, its apatite-forming ability increased appreciably.[96]

1.113.2.2. Bioactive Layers on Organic Polymers

Bakker *et al.*[97] showed that a poly (ethylene oxide)/poly (butylene terephthalate) copolymer forms calcium phosphate on its surface in the body that bonds to living bone through calcium phosphate when implanted into the femur of a goat. However, it was found to swell in an aqueous environment.

Although other organic polymers have not been shown to bond to living bone, it is speculated that any kind of organic polymer can bond with living bone by forming apatite on its surface in the body, if its surface is modified with functional groups that are conducive for apatite nucleation, such as Si–OH, Ti–OH, Zr–OH, Nb–OH, and Ta–OH. By using self-assembled monolayers, Tanahashi *et al.*[98] showed that $COOH^-$ and $H_2PO_4^{2-}$ groups are also effective in enabling apatite nucleation. Subsequently, many attempts to form functional groups on various kinds of organic polymers have been made.

Early attempts were made to form a silicate ion cluster on polymers, such as poly(methyl methacrylate),[99] poly(ethylene terephthalate) (PET), polyether sulfone (PES), polyamide 6 (Nylon 6), polyethylene (PE), poly(tetra fluoro ethylene) (PTFE), and poly(vinyl alcohol) hydrogel, by placing the polymers on $CaO–SiO_2$[100] or $Na_2O–SiO_2$[101] glass particles in SBF. In this method, the $CaO–SiO_2$ or $Na_2O–SiO_2$ glass releases silicate ions that attach to the surface of the polymers. The attached silicate ions induce apatite nucleation on polymers by combining with the calcium ions to form calcium silicate, and then combining with the phosphate ions to form calcium phosphate. This calcium phosphate then transforms into apatite.[102] The polymers thus-treated form apatite on their surface in SBF,[103] or in 1.5 SBF, which has ion concentrations at 1.5 times that of SBF. The adhesive strength of the apatite layer and the polymers was increased by preliminary surface treatment of the polymers with NaOH solution,[104] HCl solution,[105] glow discharge,[106] and ultraviolet irradiation.[107] The PES plates, formed with apatite in 1.5 SBF on its surface by this method, were confirmed to be tightly bonded to the tibial bone of a rabbit.[108,109]However, the silicate ions attached to the polymers by this method are not tightly bonded to the surfaces of the polymers.

In order to obtain polymers modified with Si–OH groups that bond tightly to polymers, tetraethoxysilane, dispersed in silicone, was subjected to partial hydrolysis and polycondensation. However, the red silicone thus-prepared did not form apatite on its surface in SBF, but did so in 1.5 SBF.[110] In addition, the Si–OH groups, formed on ethylene-vinyl alcohol (EVOH) by hydrolysis and polycondensation of tetraethoxysilane, did not form apatite in SBF,[111] but did so only in 1.5 SBF. A calcium silicate layer, formed by the sol–gel method on EVOH pretreated with a silane-coupling agent, formed apatite on its entire surface, in SBF, within 1 day. This is because many of the Si–OH groups are formed on the surface of EVOH by the exchange of the Ca^{2+} ions with the H_3O^+ ions in SBF, and the released calcium ions increase the ionic activity product of the apatite on its surface.[112] However, this calcium silicate is not stable in the body for a long period.

Kawashita *et al.*[113] showed that the carboxyl (–COOH) group-containing polymer gels form apatite on their surface in SBF if they are preliminarily treated with a $Ca(OH)_2$ solution. Based on this result, alginate fibers, containing the carboxyl groups, were shown to form apatite on their surfaces in SBF only when first treated with $Ca(OH)_2$ solution.[114–116]

Kawai *et al.*[117] showed that polyamides containing sulfonic ($–SO_4H$) groups form apatite on their surfaces in 1.5 SBF, but not in SBF. They showed that the apatite-forming ability of the sulfonic groups is lower than that of the carboxyl group.[118] Leonor *et al.*[119] have shown that high molecular weight PE (HMWPE) and EVOH, modified with sulfonic groups upon exposure to sulfonic acid or chlorosulfonic acid, form apatite

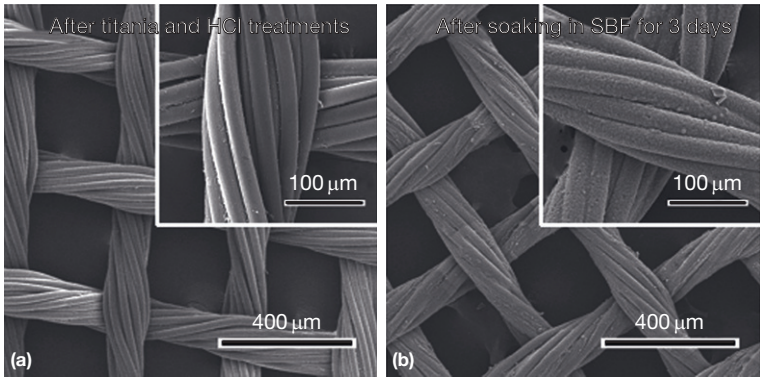

Figure 22 Scanning electron microscopy photographs of poly(ethylene terephthalate) fabric (a) as-treated with titania sol and HCl solution, and subsequently (b) soaked in simulated body fluid for 3 days. Reproduced from Kokubo, T.; Ueda, T.; Kawashita, M.; Ikuhara, Y.; Takaoka, G.G.; Nakamura, T. *J. Mater. Sci. Mater. Med*. **2008**, *19*, 695–702, with permission from Springer.

on their surfaces in SBF when they were preliminarily treated with a $Ca(OH)_2$ solution. However, their apatite-forming abilities in SBF were relatively low.

A titania gel layer, formed by a sol–gel method on EVOH,[120] PET, and Nylon 6[121] treated with a silane-coupling agent, formed apatite on its entire surface in SBF. Here, the titania layer was treated with a 0.1 M HCl solution at 80 °C for 8 days to be transformed into anatase from the amorphous phase. However, the silane-coupling agent can sometimes have a cytotoxic effect. Wu *et al.*[122] showed that a titania layer of the rutile phase is formed on PTFE by dipping the polymer into a solution of titanium tetrachloride ($TiCl_4$) at 60 °C for 3–60 h, and the titania layer thus-formed forms apatite on its surface, in SBF. Balas *et al.*[123] showed that a titania layer, formed by a simple sol–gel method, can strongly adhere to PE, PET, and Nylon 6 without the aid of a silane-coupling agent, and that they fully form apatite on their surfaces in SBF, after the HCl treatment. A two-dimensional fabric of PET fine fibers, which were coated with a titania sol after preliminary treatment with NaOH solution and then subjected to the HCl treatment, was able to be sharply bent without the 'peeling off' of the titania layer, and it fully formed apatite uniformly on the individual fibers in SBF, as shown in **Figure 22**.[124] This indicates that the TiO_2-coated PET fabric forms a bone-like apatite on its surface in the body, and that it bonds to living bone. Actually, when it was implanted into the tibia of a rabbit, it was in direct contact with the living bone, whereas, a fibrous tissue encapsulated the untreated PET. A large load was required for producing a failure at the interface between the TiO_2-coated PET and the bone.[125] This kind of flexible bioactive PET fabric is useful as a unique bone substitute.

1.113.3. Future Perspectives

It is apparent from the cases described above that various kinds of bioactive layers, which form apatite on their surfaces in the living body and bond to living bone, can be formed on different kinds of metals by simple chemical and heat treatments. The so-formed bioactive layers are gradually changed to their metallic substrates without a distinct boundary against the substrates, thus giving high bonding strength to the substrates. In addition, such bioactive layers can be formed on organic polymers by simple chemical and heat treatments. The bioactive layers thus-formed can tightly bond to organic substrates, although their bonding mechanism has not yet been revealed.

The bioactive layers can be formed uniformly, even on the complex inner surfaces of porous materials by the above mentioned chemical and heat treatments. Various kinds of ions, having different novel functions, can be incorporated into the bioactive layers by selecting appropriate solutions for the chemical treatments. In the future, various kinds of bioactive metals and organic polymers with different novel functions could be developed by using these chemical and heat treatments.

Metals and organic polymers, formed with these novel bioactive layers on their surfaces, are expected to be useful in various applications in the orthopedic and dental fields because of their high fracture toughnesses and ductility, properties that are lacking in bioactive ceramics, as well as their high bioactivity.

1.113.4. Additional Reading

Other review papers regarding bioactive layer formation on metals and polymers have been published by the same authors elsewhere.[126–137]

1.114.1. Introduction

The ability to bond to bone tissue and stimulate bone formation at their surface is a unique property of bioactive ceramics. This has led to their wide clinical use in both orthopedics and dentistry. Bioactive ceramics are used as bone grafting materials and as coatings for titanium and its alloy. These coatings have been shown to accelerate initial stabilization of implants by enhancing bony ingrowth and stimulating osseous apposition to the implant surface, thereby promoting a rapid fixation of the devices to the skeleton.[1–7] Most commonly, long-term stable calcium phosphates that display a low biodegradability such as hydroxapatite are utilized for fabricating bioactive calcium phosphate coatings.[1–7] As **Chapter 4.402, Biocompatibility and the Relationship to Standards: Meaning and Scope of Biomaterials Testing** is specifically dedicated to calcium phosphate coatings, this topic is only briefly discussed in this chapter.

The current gold standard for bone reconstruction in orthopedics and cranio-maxillofacial surgery is the use of autogenous bone grafts.[8–10] Of the more than 1 million fractures that are treated with osteosynthetic materials each year in the United States, ~80% of these require adjuvant grafting.[9] Resorption of the alveolar ridge after tooth extraction frequently mandates site development by augmentation before dental implants can be placed.[11–13] Although autogenous bone grafts are currently the standard of care, bone substitute materials are extensively studied in order to avoid harvesting autogenous bone, as there are several disadvantages associated with using autogenous grafts: the additional surgical site, donor site morbidity exceeding that at the treatment site, often times insufficient volume of harvested bone, and, in dentistry, the need for general anesthesia to harvest extraoral bone.[14–16] Among alternative graft choices, synthetic bone substitutes are superior to freeze-dried human allografts or bovine-deproteinized bone xenografts in several respects. They excel in terms of safety profile, as there is no risk of disease transmission or immunological challenges.[17] Consequently, there has been an increasing demand and an ongoing search for synthetic, biodegradable bone substitute materials that degrade in a timely fashion, that is, rather rapidly, but still stimulate osteogenesis at the same time, thereby resulting in bone repair defect regeneration and replacement by fully functional bone tissue[1,16]

Because of their ability to stimulate bone formation, bioactive calcium phosphate ceramics and bioactive glasses (BGs) are excellent candidate grafting materials for bone augmentation.[3,18–21] Among the bioactive ceramics most commonly investigated for use in bone regeneration are β-tricalcium phosphate (β-TCP),[19–26] hydroxyapatite (HA),[3,21,27,28] and BG.[3,18,29,30] All of these materials are biocompatible[19–21] and osteoconductive.[3,18–30] However, they differ considerably in the rate of resorption. HA resorbs very slowly compared to β-TCP[21–26,28] and BG.[3,18,29,30]

Recent improvements in TCP ceramics include products with a high-phase purity (>99%) and homogenous solubility characteristics, so as to prevent premature separation of microparticles from the structural compound.[31] In the past, these types of microparticles have been shown to elicit inflammatory tissue responses.[31] Furthermore, the use of TCP particles with increased porosity has been proposed in order to increase the biodegradability.[31,32] These particles exhibit a material structure with micro-, meso-, and macropores, which is designed to enhance the degradation process. This structure allows for a reduced bulk density. The microporosity allows circulation of biological fluids, increases the specific surface area, and thus accelerates the degradation process. The interconnectivity of the pores creates a capillary force that actively draws cells and nutrients in the center of the particles. The macroporosity is created to encourage the ingrowth of bone by permitting penetration of cells and vascularization.[31]

Particularly, in nonload-bearing applications, a biomaterial used as a bone substitute should be a temporary material serving as a scaffold for bone remodeling. The material must degrade in a controlled fashion into nontoxic products that the body can metabolize or excrete via normal physiological mechanisms.[21] Moreover, this substance should be resorbable and should undergo complete remodeling and substitution by newly formed functional bone tissue.[10,16,21,23] Thus, ideally bioactive calcium phosphate ceramics for use in bone augmentation should exhibit good bone-bonding behavior by stimulating enhanced bone formation at the interface in combination with a high degradation rate, thereby meeting a balance between rapid bone formation and rapid biodegradation.

In modern dentistry, the use of oral implants has become a common treatment to replace missing or lost teeth.[11] Furthermore, resorption of the alveolar ridge after tooth extraction frequently mandates site development by augmentation before implants can be placed.[11–13] Among the various techniques to reconstruct or enlarge a deficient alveolar ridge, the concept of guided bone regeneration (GBR) and sinus floor augmentation procedures has become well-established surgical approach for localized lateral ridge augmentation.[8] Furthermore, augmentation of the maxillary sinus floor with autogenous bone grafts has become a predictable and well-documented approach for alveolar ridge augmentation of the posterior maxilla.[33] Over the last 15 years, the use of TCP and BG45S5 particles as alloplastic bone graft materials for alveolar ridge augmentation and sinus floor elevation procedures has received increasing attention in implant dentistry.[22–26,29,30,32,34–36] This is due to an overall effort to develop augmentation procedures that involve reduced surgical effort, thereby increasing patient comfort in addition to decreasing treatment cost, while yielding the same clinical success rates as conventional procedures that utilize autogenous bone grafts. As a result, over the last decade, an increasing number of clinical studies have been published that provide valuable data regarding the biodegradability as well as the bone regenerative capacity of these materials in a clinical setting as these data were derived from histological studies of human biopsies[22,24–26,29,30,32,34–36] (see also **Chapter 6.620, Dental Graft Materials** for further details).

Even with β-TCP and BG45S5, biodegradation has been reported to be incomplete 9.5, 12, and 25 months after grafting in the human mandible or sinus floor.[25,26,29,30] Collectively, these studies showed that these materials resorb within 1–2 years (see **Chapter 6.620, Dental Graft Materials** for details). Hence, given the clinical findings with current bone grafting materials,[22,24–26,29,30,32,34–36] there continues to be an interest in bone substitute materials that degrade more rapidly, but still stimulate osteogenesis at the same time.[10,16]

As a result, considerable efforts have been undertaken to produce rapidly resorbable bone grafting materials that exhibit good bone-bonding behavior by stimulating enhanced bone formation at the interface in combination with a high degradation rate.

This has led to the synthesis of a series of bioactive, rapidly resorbable glassy crystalline calcium–alkali–orthophosphate materials.[37–47] These are glassy crystalline calcium-alkali orthophosphates that exhibit stable crystalline $Ca_2KNa(PO_4)_2$ phases.[37,38,47,48] These materials have a higher solubility than TCP and therefore they are designed to exhibit a higher degree of biodegradability than TCP.[37,38,47] On this basis, they are considered as excellent candidate materials for alveolar ridge augmentation.[39–46]

Furthermore, various calcium phosphate materials with addition of silicon have been developed with the intent to enhance their bioactivity and mechanical stability.[49–51]

As outlined above, bioactive calcium phosphate ceramics and glasses are known to stimulate bone tissue formation at their surfaces.[52–54] Over the past 15 years, increasing efforts have focused on understanding the underlying mechanisms. In these studies, attention was directed toward the atomic and molecular phenomena occurring at the material surface and their effects on the reaction and signaling pathways of cells and tissues. This implied studies that elucidated any of the cellular activities leading up to tissue formation, including protein adsorption, cell adhesion, differentiation, and extracellular-matrix formation.[52]

Given the great clinical need, obtaining this understanding is of critical importance, as once these mechanisms are identified and studied, it should be possible to alter biomaterial molecular components and surface characteristics in ways that promote optimal cell adhesion, proliferation, and differentiation leading to more expeditious and enhanced bone formation in combination with a desirable biodegradability, and thus, to create bioactive calcium ceramics and glasses that are optimally tailored toward their clinical application.

1.114.2. Mechanisms of Bioactive Behavior

1.114.2.1. Surface Transformation and Protein Adsorption Events of Bioactive Ceramics and Glasses

The nature of the biomaterial and its surface characteristics play important roles in determining bone adaptation to the

implant material. Surface reactivity is one of the common characteristics of bone bioactive ceramics and glasses. It contributes to their bone-bonding ability and their enhancing effect on bone tissue formation. During implantation, reactions occur at the material–tissue interface that lead to time-dependent changes in the surface characteristics of the implant material and the tissues at the interface.[52] With bioactive ceramics and glasses, solution-mediated surface reactions take place after immersion in biological fluids. These reactions include dissolution, reprecipitation, and ion-exchange phenomena in combination with protein adsorption events occurring at the bioactive ceramic surface (**Figure 1**).[52,55–62] A key element of bone bioactive behavior is the development of a carbonated apatite surface after immersion in biological fluids.[52,57–59] Previous review papers summarized these events that were reported to occur at the bioactive ceramic–tissue interface.[52,63] The following list does not imply a ranking in terms of time sequence or importance: (1) dissolution from the ceramic,[57–59,61–68] (2) precipitation from solution onto the ceramic,[57–59,61–68] (3) ion exchange and structural rearrangement at the ceramic–tissue interface,[57–59,61,62,64–66] (4) interdiffusion from the surface boundary layer into the ceramic,[69] (5) solution-mediated effects on cellular activity,[70–72] (6) deposition of either the mineral phase or the organic phase, without integration into the ceramic surface,[67,73–76] (7) deposition with integration into the ceramic,[67,73] (8) chemotaxis to the ceramic surface,[77] (9) cell attachment and proliferation,[69,76,78] (10) cell differentiation,[76] and (11) extracellular-matrix formation.[75–78]

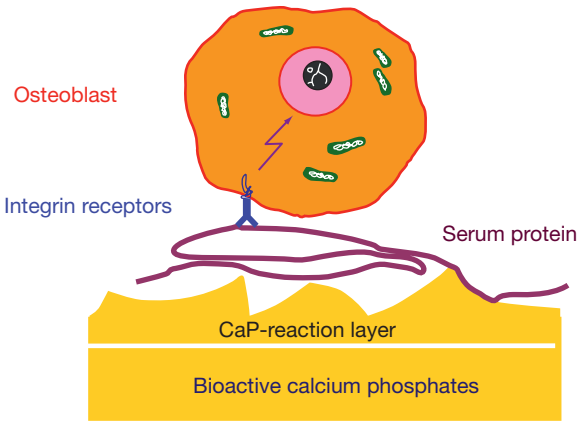

Figure 1 Schematic diagram illustrating the events that take place at the interface between the bioactive ceramics and the surrounding biological milieu and thereby establish bioactive behavior. Contact with biological fluids leads to dissolution and reprecipitation phenomena and results in the formation of a calcium phosphate surface reaction layer and serum protein adsorption. The nature of this surface reaction layer that in its turn influences the structure of the adsorbed protein modulates the structure of the adsorbed serum protein. Thereby, specific adhesive motifs within the molecule are exposed to osteoblasts and osteoprogenitor cells that are migrating to the implant surface, which then has an effect on subsequent cell adhesion via integrin receptors and activation of intracellular signaling pathways. Activation of these intracellular signaling mechanisms modulates cellular differentiation, bone matrix formation, and mineralization resulting in bone bonding and a stimulatory effect on bone tissue formation.

The observation of what occurs at the interface, however, does not represent a mechanistic explanation for the effect that bioactive ceramics and glasses ceramics have on bone tissue formation. We can focus on mechanisms by relying on an increasing body of evidence that suggests that bone-bonding and bone tissue ingrowth enhancement are the result of multiple, parallel, and sequential reactions at the material–tissue interface. These interactions are related to either physicochemical phenomena that occur in the presence or absence of cells or reactions affected by the cellular activity. An important aspect of the overall reaction sequence between these materials and tissues is that in the absence of a biologically equivalent, calcium-deficient, carbonate-containing hydroxyapatite (c-Ap) surface upon implantation, dissolution, precipitation, and ion exchange reactions leads to a biologically equivalent apatitic surface on the implanted material (**Figure 1**). This reaction does not proceed by itself, but is accompanied by parallel reactions, such as adsorption and incorporation of biological molecules and attachment of surrounding cells. Furthermore, cells that have adhered to the ever-reacting material surface interact with the material and produce some of the surface changes. In the inverse direction, that is, from material to environment, there is both a solution-mediated as well as a surface-controlled effect on cellular activity such as cell adhesion and differentiation, organic matrix deposition, and mineralization. The gradual change of the ceramic surface to become a biologically equivalent HA with small crystal dimensions is a rate-determining step in the cascade of events underlying bioactive behavior. All these phenomena, collectively, lead to the gradual incorporation of the bioactive implant material into developing bone tissue.

Moreover, for mechanisms to be uniquely identified, it is important to establish the extent of each of these reactions and the sequence in which they occur.

Formation of a biologically equivalent apatitic surface, a common characteristic of bioactive materials, can be reproduced *in vitro* by immersion experiments using a simulated physiological solution that mimics the typical ion concentrations in body fluids. These *in vitro* physicochemical analyses are useful to explain the observations on *ex vivo* specimens.[59,64,65] Such experiments have shown that the materials with high solubility also readily induce the precipitation of a biologically equivalent apatite on their surface. Using this *in vitro* immersion methodology, considerable evidence has been obtained revealing the mechanisms of surface reactions.[57–59,67] The reactions include dissolution, precipitation, and ion exchange accompanied by adsorption and incorporation of biological molecules.[55,56,71,79,80]

Furthermore, it has been demonstrated that this surface reaction layer does not form as a result of inorganic reactions first, followed by biologically driven events next, but that serum proteins do have a major effect on the properties of the surface reaction layer.

To explore the effect of proteins on the formation of surface reaction layers on BG, the atomic and molecular changes in BG45S5 surface during immersion in protein-free buffer solution and protein-containing culture medium were examined using various complementary techniques including atomic force microscopy (AFM), Rutherford backscattering

spectroscopy (RBS), and Fourier transform infrared sprectroscopy (FTIR).[56] When immersed in serum-free solutions, AFM showed that the surface of BG reacted nonuniformly. After 5 min of immersion, the glass surface showed a rough texture due to the formation of particles on the surface. With increasing immersion time, the particles increased in size and number. Unlike the reaction on the substrates immersed in serum-free solution, a uniform layer of globules, presumably proteins, covered the substrates immersed in serum-containing solutions. As the immersion time increased, the density of globules increased and the layer thickened. RBS of the outermost surface layers revealed that substrates formed Si-rich surface layers in the first hour of immersion in the absence or presence of serum proteins. In addition, the RBS spectra showed that the formation of the calcium phosphate layer was different in serum-containing solutions compared with that in serum-free solutions. FTIR analysis revealed that, in the serum-free solution, crystalline HA was formed by transformation from the initially formed amorphous calcium phosphate. In contrast, immersion in serum-containing solutions only produced an amorphous calcium phosphate.

Given the repeated observation of the absence of crystalline HA when proteins coadsorb, it is unlikely that, *in vivo*, adsorption of biological molecules will take place subsequent to the transformation of an amorphous calcium phosphate-rich layer to carbonated apatite, as was previously suggested.[18] The present data suggest that serum proteins adsorb in tandem with the occurrence of solution-mediated reactions leading to the formation of a silica gel. Amorphous calcium phosphate phases accumulate in this Si-rich matrix.

In solutions more closely approaching the physiological state, the maturation of amorphous calcium phosphate to crystalline HA does not take place readily. The proteinaceous layer that adsorbs onto the glass interferes with the solid to liquid interaction of the amorphous calcium phosphate layer. Whereas amorphous calcium phosphate can form exclusively as the result of physicochemical phenomena in the solid glass phase, it is suggested here that adsorbed serum proteins impede the nucleation and growth reactions by which it would transform to carbonated apatite. The physicochemical reactions in the glass are not blocked however, as Ca and P diffusion leads to a continuously thickening of the Ca–P-rich zone under the adsorbed protein layer. In this context, it is an important aspect that the surface composition and structure of the surface reaction layer in their turn influence serum protein adsorption. There is support for the view that the enhanced cellular and tissue responses to bioactive ceramics are related to enhanced fibronectin (Fn) adsorption at their surfaces.[55,80] Also it is noteworthy that surface chemistry of the biomaterial surface, that is, the surface reaction layer in the case of bioactive ceramics, modulates the structure and activity of adsorbed Fn (**Figure 1**).[81] Hence, the adsorption of the protein layer is also critical in terms of providing attachment sites for bone cells such as osteoblasts and their progenitors (**Figure 1**). The cell adhesion and intracellular signaling events are the subject of **Section 1.114.2.4**.

In addition, the solution-mediated effects require adequate consideration. This involves first, analyzing the release of soluble ions from these bioactive substrata and second, investigating their effect on the cellular response,[52,63,70,82–84] which are discussed in more detail in **Section 1.114.2.3**.

1.114.2.2. The Effect of Bioactive Ceramics on the Expression of the Osteoblastic Phenotype *In Vitro*

Calcium phosphate ceramics[2,4,21,22,24,32] and glass ceramics[29,30,66,85] are known to bond to bone. Differences among these materials are reflected in the rate of bone formation on their surfaces.[4,21,22,24,27,33,34,54] Bioactive calcium phosphate ceramics stimulate bone formation.[4,24,27,32,42,43,54,86] This requires the ability to differentiate osteoprogenitor cells into osteoblasts at their surfaces. Thus, in order to evaluate the stimulatory potential of bioactive ceramics on osteogenesis, it is logical to examine the effect of these materials on osteoblastic differentiation. Consequently, over the last 15 years, various assays have been developed and used, which permit studying the effect of bioceramics on the expression of osteogenic markers *in vitro*.[40,42,52,70,76,87–89]

Osteoblast differentiation is defined by three principal biological periods: cellular proliferation, cellular maturation, and matrix mineralization.[90–92] Differentiating osteoblasts are known to synthesize type I collagen, alkaline phosphatase (ALP), and other noncollagenous extracellular bone matrix proteins such as osteonectin, osteocalcin, osteopontin, and bone sialoprotein.[90–93] These bone–matrix proteins have proven to be particularly useful osteogenic markers to characterize the different stages of osteoblast differentiation.[92] Type I collagen is expressed during the initial period of proliferation and extracellular-matrix synthesis, whereas ALP is expressed during the post proliferative period of extracellular-matrix maturation, and the expression of osteopontin, osteonectin, osteocalcin, and bone sialoprotein occurs later during the third period of extracellular-matrix mineralization.[90–93] Osteopontin peaks twice – during proliferation and then later but prior to BSP and osteocalcin.[91,93] Osteonectin is found in preosteoblasts, osteoblasts, osteocytes, and the newly formed osteoid in matrix.[94] This protein has the ability to bind to collagen and promote HA formation *in vitro*.[94] Bone sialoprotein is characterized by its ability to mediate initial formation of hydoxyapatite crystals[95] and is transiently expressed very early,[91,92,95] and then upregulated again in differentiated osteoblasts actively involved in mineralization.[91,92,95] Consequently, as there is no specific single marker for osteoblasts, the cellular expression of a range of noncollagenous and collagenous proteins as well as ALP has to be assayed, when examining cellular differentiation.

When studying the effect of bioactive ceramics for bone regeneration on cellular behavior it is important to examine cell proliferation and differentiation, first, because these materials should posses the ability to differentiate osteoprogenitor cells into osteoblasts and, second, because proliferation and differentiation of osteoblasts are affected by the chemistry of substrata.[96,97] As a result, numerous authors studied the response of osteoblasts or bone marrow stromal cells to various bioactive ceramics in terms of messenger RNA and translated proteins that form an array of osteogenic parameters as a measure of phenotypic differentiation. It has been demonstrated that various bioactive calcium phosphates significantly affected cellular growth and the temporally dependent expression of an array of bone-related genes and proteins.

Moreover, various investigators were able to show that BGs and glass ceramics,[42,52,63,70–72,76,84,88,89,98] HA,[7,99] various calcium phosphates,[7,99] and calcium-alkali orthophosphate ceramics[40,42,87,88] stimulated osteoblast differentiation *in vitro*.

El-Ghannam *et al.* studied the cellular response to BG45S5 disks that were preconditioned by a two-step procedure that resulted in the transformation of the BG surface to a crystalline, carbonated calcium phosphate apatite onto which serum proteins were adsorbed in a second step.[70,71] The authors demonstrated the greater differentiation for osteoblasts, which were grown on the preconditioned BG45S5 compared to when identical cells were cultured on the native glass[70] or HA surfaces.[71] These findings were corroborated by a study,[89] in which enhanced ALP activity of rat bone marrow stromal cells was demonstrated when these cells were grown on preconditioned BG45S5 disks compared to when identical cells were cultured on tissue culture plastic, that is, polystyrene controls.

In recent years, several studies have been performed that examined the effect of rapidly resorbable calcium-alkali orthophosphate bone substitute materials on the expression of osteogenic markers characteristic of the osteoblastic phenotype and compared this behavior with that of the currently clinically used materials such as β-TCP and BG45S5. These studies showed that several calcium-alkali orthophosphates supported osteoblast differentiation to a greater extent than TCP.[40,87,88] Recently, it was demonstrated that the glassy-crystaline calcium-alkali orthophosphate material GB9, which contains the crystalline phase $Ca_2KNa(PO_4)_2$ and a small amorphous portion containing silica phosphate, had a significantly greater stimulatory effect on osteoblastic proliferation and differentiation compared to β-TCP,[42,87] preconditioned BG45S5,[42] and other calcium-alkali orthophosphate materials of varying composition[42,87] (see **Chapter 6.620, Dental Graft Materials** for more details).

1.114.2.3. Solution-Mediated Effects of Bioactive Behavior

In this context, it is also of considerable interest to explore the effect of soluble ions released from these bioactive ceramics on the cellular response.[71,72] Several investigators used experimental setups and *in vitro* models that allowed for dissociating between solution-mediated and surface-mediated effects on the cellular response. This is in contrast to the *in vivo* setting, in which it is not possible to dissociate between these two effects. Hence, when addressing this issue, utilizing adequate *in vitro* models offers a significant advantage over *in vivo* experiments.[52,71,72,83] Xynos *et al.*[84] demonstrated that BG45S5 stimulated osteoblast proliferation and differentiation when culturing primary human osteoblasts on the BG ceramic substrate. Ducheyne *et al.*[63] and El-Ghannam *et al.*[71] had shown this effect with a rodent cell line and shown it to be associated with cell membrane receptor activation. In order to determine whether this stimulation of osteogenesis by BGs occurs through direct contact between substrate and cells or through ions released during their biodegradation, Xynos *et al.* studied the relationship between this stimulation of osteogenesis and ionic products of BG dissolution.[82,83] They reported that these ionic products increased osteoblast proliferation.[83] They suggested that this effect was mediated by insulin-like growth factor II whose expression was upregulated.[83] Furthermore, they observed enhanced gene expression of various growth factors and extracellular-matrix regulators including cell surface receptors, signal transduction factors, and transcription factors.[82]

Radin *et al.*[89] performed a study in which rat bone marrow stromal cells were cultured in the presence but not in contact with BG45S5 disks. These cells showed enhanced osteoblast differentiation compared to cells, which were grown in the presence of tissue culture plastic controls. However, even greater osteoblast differentiation was noted, when cells were cultured in physical contact with the BG45S5 disks. They also examined the release of BG dissolution products into the cell culture medium and concluded that both surface- and solution-mediated effects play a major role in the osteogenic effect of BG. These data emphasize the synergistic nature of the solution- and the surface-mediated effects of BG45S5 on osteoblast function. Yao *et al.*[72] took these experiments a step further and showed that cells that were cultured on porous BG45S5 substrata released signaling factors into the cell culture medium that caused enhanced cell differentiation of osteoblasts, which were cultured in the presence of these cell-seeded scaffolds but physically separated at the bottom of the cell culture dish. This enhancement of cellular differentiation was greater compared to when cells were solely cultured in the presence of the BG45S5 scaffold.[72]

1.114.2.4. Intracellular Signaling Events Regulating the Stimulatory Effect of Bioactive Ceramics on Cell Function

To decipher the complexity of the reactions at the bioactive ceramic–bone interface, it is logical to first analyze the surface transformation and protein adsorption events and then to study the cellular response of osteoblasts to these bioactive surfaces (**Figures 1** and **2**). Although numerous studies have investigated cellular responses to bioactive ceramics, little is known about the intracellular signaling events that take place in osteoblasts at these bioceramic surfaces. As outlined above, numerous authors were able to show that BGs and glass ceramics, HA, various calcium phosphates, and calcium-alkali orthophosphate ceramics were able to stimulate osteoblast differentiation *in vitro*.[7,32,40,42,43,52,63,70–72,76,84,86–89,98–100] However, the intracellular signaling events that follow osteoblast attachment to these bioactive ceramics, leading to differences in osteoblast activity and function, are not known. Because cell signaling affects cell proliferation and differentiation, it is important to understand the cell signaling pathways, which are affected or activated by osteoblast–implant material interactions.[101]

The cellular interactions between osteoblasts and the biomaterial surface are thought to be mediated primarily by membrane-associated adhesion receptors belonging to the integrin superfamily.[101–104] Integrins are transmembrane heterodimers composed of an α- and a β-subunit and are connected to the cytoskeleton.[105,106] Bone cells express the following integrin receptors: $\alpha_1\beta_1$, $\alpha_2\beta_1$, $\alpha_3\beta_1$, $\alpha_5\beta_1$, $\alpha_v\beta_3$, and $\alpha_v\beta_5$.[106–108,107–109] The interaction of osteoblasts with implant surfaces is mediated largely by the β1 subfamily.[101,103,104] It is furthermore noteworthy that surface

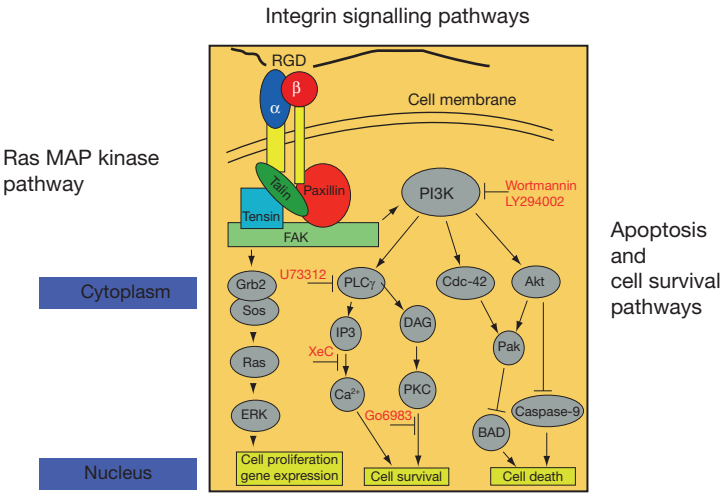

Figure 2 Integrin signaling pathways. Binding of the integrin receptor activates focal adhesion kinase (FAK) along with other focal adhesion proteins. FAK activates the cell differentiation (Extracellular signal-regulated kinase or Ras/MAPkinase) pathway in addition to PI3K (phosphatidylinositol 3-kinase)-cell survival pathway, which results in the depression of apoptosis.

chemistry of the biomaterial surface modulates the structure and activity of adsorbed Fn.[81,110]

Integrins $\alpha_5\beta_1$ and $\alpha_v\beta_3$ bind to and compete for the central cell-binding domain of the Fn molecule.[112] The differences in Fn conformation alter integrin binding and therefore can lead to selective binding of the $\alpha_5\beta_1$ integrin or $\alpha_v\beta_3$ integrin or binding of both $\alpha_5\beta_1$ and $\alpha_v\beta_3$ integrin.[81,111] Furthermore, osteogenic cells require signals from non-RGD-binding integrins, notably $\alpha_2\beta_1$, for robust differentiation. The GFOGER recognition site of type I collagen specifically targets the $\alpha_2\beta_1$ integrin receptor, thereby supporting focal adhesion kinase (FAK) activation, expression of osteoblast-specific genes, and matrix mineralization. Recent findings suggest that selective binding of the $\alpha_5\beta_1$ integrin or $\alpha_2\beta_1$ integrin[113,114] leads to upregulation of osteoblastic differentiation and matrix mineralization as well as enhanced bone formation *in vivo*.[113–118] In addition to their role as adhesion receptors, integrins are also involved in transducing signals from the extracellular matrix to the interior of the cell,[119,120] resulting in the activation of cascades signaling molecules and pathways and thereby regulation of gene expression, thus modulating cellular migration, proliferation, differentiation, and apoptosis (**Figures 1** and **2**).[106,120–122]

Interaction between osteoblasts and bone matrix components via integrins leads to a rearrangement of cytoskeletal components and activation of specific signaling proteins localized at focal adhesions and FAK (**Figure 2**).[101,123] Activation of FAK is considered to play a critical role in the control of adhesion-dependent cell survival and proliferation.[122,123] It has been demonstrated that osteoblast adhesion to titanium alloy and Fn resulted in the activation of FAK and mitogen-activated protein (MAP) kinase signal transduction pathways.[101] FAK associates with several signaling proteins (e.g., the src-family of protein-tyrosine kinases: Src-homology collagen (Shc) and growth factor receptor-bound protein 2 (Grb2)) (**Figure 2**). One downstream signaling protein in the integrin-generated signaling pathway is the adaptor protein Shc. Mitogen-activated protein kinase (MAPK) p44 (extracellular signal-regulated kinase 1 (Erk1)) and p42 MAPK (Erk2) are important mediators of cellular responses to intracellular signaling proteins. FAK interaction with Shc creates a Grb2-binding site thus linking FAK to the Ras/MAPK (mitogen-activated protein kinase) pathway (**Figure 2**).[124] The Shc–Grb2 complex induces Ras activation via Grb2-associated son of sevenless (SOS), a cytoplasmic GTP (guanosine triphosphate) exchange protein.[125] Ras then stimulates the Erk1/Erk2 MAP kinase cascade, which plays an important role in cellular differentiation and growth (**Figure 2**). Activated MAP kinases (Erk1/2) translocate to the nucleus and are then able to phosphorylate and activate transcription factors including c-fos and c-jun, members of the activator protein-1 (AP-1) transcription factor complex, which control gene expression (**Figure 2**).[101,102] The AP-1 complex initiates early transcription events that lead to cell proliferation and/or can affect differentiation. Moreover, AP-1 has an important role in osteoblast differentiation and bone development. AP-1 sites are known to be present in the promoters of many bone-specific genes such as type I collagen, ALP, osteocalcin, and osteopontin.[101,102] In addition, possible interaction with the p38 pathway is important.[126,127] Ivaska and coworkers[128] demonstrated a novel signaling mechanism in human osteosarcoma cells (SaOS-2) mediated by $\alpha_2\beta_1$ integrin involving isoform-specific activation of the p38 signaling protein. More recent data suggest a possible interaction between the Ras/MAPK pathway and the p38 pathway.[126]

Moreover, the effect on apoptosis is of importance. Activation of the PI3K/Akt (phosphatidylinositol-3-kinase/protein kinase B) survival pathway results in the depression of apoptosis.[129] Consequently, activation of this pathway would be expected by bioactive ceramics, which stimulate osteogenesis. Thus, studying the activation of various antiapoptotic factors such as Bcl-2 and Bcl-x_L is also of considerable importance.

The effect of bioactive bone substitute materials on these signaling pathways controlling osteoblast function and differentiation is not fully understood at present. Elucidation of these reactions has been hampered by the inadequacy of the experimental techniques that could be used. Excellent

techniques to study integrin-mediated adhesion and the intracellular pathways that are triggered were only recently established[101,103,127,129–133] In addition, advanced surface analytical methods have been combined with molecular biological techniques only over the last decade. Doing so, however, greatly contributed to achieving a better understanding of the surface transformations of bioactive, resorbable ceramics, and the protein adsorption events associated with the immersion in biological fluids.[52,55,56,59–62] Recent research efforts combined these two powerful analytical methodologies (advanced surface analytical methods and molecular biological assays). The understanding resulting from combining these methods to examine integrin-mediated cell adhesion and intracellular signaling mechanisms with methods to analyze protein adsorption events and surface and solution-mediated reactions has greatly helped to unravel the complex reactions at the bioactive ceramic–bone interface. Hence, a series of studies was performed to elucidate the mechanisms by which various bioactive calcium phosphates including four calcium-alkali orthophosphate materials (**Table 1**), TCP, BG45S5, and a bovine-derived HA (commercial name BioOss), whose excellent osteoconductive properties have been demonstrated by numerous *in vivo* studies, stimulate the intracellular signaling pathways, which regulate osteoblast differentiation and cell survival.[44–46,134] This included investigating: (1) solution-mediated surface transformations, (2) serum protein adsorption events, (3) integrin-mediated cell adhesion mechanisms, and (4) intracellular signaling mechanisms. To this end, in order to first reveal the precipitation mechanisms, the kinetics of formation and the composition, and thickness and morphology of the reaction layer which forms on the ceramic surfaces in a biological milieu, two measurements were performed on these bioactive calcium phosphates: (1) analysis of the surface characteristics of the bioceramics by FTIR, scanning electron microscopy, and energy dispersive X-ray analysis (2) and determination of the ions released from the resorbable ceramics by atomic absorption spectrophotometry (AAS) and UV-visible spectrophotometry. These immersion experiments were intended to quantify, first, the resorption of the bioceramics and, second, the phenomenon of reprecipitation. These dissolution/precipitation experiments for immersion times were run up to 3 weeks.

Three types of solutions were used for these immersion experiments including 0.05 M Tris buffer (T), T supplemented with physiological electrolytes (TE), and TE supplemented with 10% fetal calf serum (TES). All materials were immersed at a surface area-to-solution volume ratio of 0.1 cm^{-1}. Postimmersion solutions were analyzed for changes in calcium and silicon concentrations using AAS. After 21 days of incubation, the structure and composition of the surface reaction layers were determined using FTIR.

Subsequently, serum protein adsorption to these novel substrata after immersion in the serum-containing tissue culture medium for 1 and 24 h was determined utilizing sodium dodecyl sulfate–polyacrylamide gel electrophoresis and Western blot analysis using antibodies against Fn, vitronectin (Vn), collagen type I (Col-I), and bovine serum albumin (BSA). This was followed by conducting blocking studies to investigate the role of different integrin molecules in mediating cell attachment of osteoblasts to the different test materials using adhesion blocking monoclonal antibodies against β_1, $\alpha_2\beta_1$, $\alpha_5\beta_1$, and β_3. In addition, Western blot and quantitative densitometric analyses were used to determine the effect of these bioceramics on the expression and activation of key intracellular signaling molecules of the Erk-differentiation pathway, the alternate p38 pathway, the PI3K (phosphatidylinositol 3-kinase)/Akt survival pathway, as well as antiapototic factors in osteoblasts after 30 min, 1, 3, and 24 h of incubation.[44–46,134] This included studying the expression of FAK and phosphorylated-FAK, Erk and phosphorylated Erk, phosphorylated c-Jun N-terminal kinase, (p-jnk), c-fos (Erk-differentiation pathway), p38 mitogen-activated-kinase (p38MAPK) and phosphorylated p38 (alternate p38 pathway), PI3K, Akt, phospho-Akt (PI3K/Akt survival pathway), as well as Bcl-x_L, Bad (apoptosis markers).[46,134]

When immersed in T, all calcium-alkali orthophosphates tested showed a time-dependent dissolution behavior (**Figure 3(a)–3(d)**). When immersed in TE, β-TCP and GB9 showed a time-dependent uptake of Ca ions, whereas GB14 and GB9/25 displayed only a minor uptake (**Figure 3(a)–3(d)**). FTIR spectra of GB14 (**Figure 5(a)**) and GB9 (**Figure 5(b)**) before and after 21 days of immersion showed that bioactive surface transformations occurred both in TE and TES, whereas GB9/25 (**Figure 5(c)**) showed detectable phase transformation that were not associated with HA formation. A crystalline apatitic phase was also observed on BioOss® (**Figure 5(d)**). Hence, the results of these studies showed that GB9 surfaces displayed calcium (**Figure 3(b)**) and silicon ion (**Figure 4**) release as well as calcium uptake (**Figure 3(b)**) and bioactive surface transformations after immersion both in TE and in TES (**Figure 5(b)**). This was associated with considerable Fn (**Figure 6(a)**) and extensive type I collagen serum protein adsorption (already after 1 h) (**Figure 6(b)**), while vitronectin adsorption was minor.[44–46,134] As a result, cell adhesion was mainly mediated through integrin $\alpha_5\beta_1$ and (to a slightly lesser

degree) through $\alpha_2\beta_1$, while β_3 played a minor role (Figure 7), which in turn then leads to a cumulative or even synergistic effect, that is, enhanced activation of the Ras/MAPkinase pathway (Figure 8(a) and 8(b)) in combination with activation of the p38 pathway (which is thought to be activated after cell adhesion to $\alpha_2\beta_1$) (Figure 8(c)) as well as activation of key signaling factors of the PI3K/Akt-cell survival pathway (Figure 8(d)) and of antiapoptotic factors (Figure 8(e)) and thereby also to the greatest antiapoptotic effect. Consequently, among others, enhanced activation of Erk (Figure 8(a)), c-fos (Figure 8(b)), p38 (Figure 8(c)), Akt (Figure 8(d)), and the antiapoptotic factor Bcl-x_L (Figure 8(e)) was noted.[46,134] Taken together, GB9 displayed the greatest stimulatory effect on the activation of all signaling pathways examined (cell differentiation, cell survival, and p38 pathway) as well as the greatest antiapoptotic effect. This was in agreement with the findings of previous studies outlined above, in which GB9 had a significantly greater stimulatory effect on osteoblastic proliferation and differentiation *in vitro*[42,87,88] as well as the best bone-bonding behavior and the greatest stimulatory effect on bone formation and expression of osteogenic markers *in vivo*,[43,46] while exhibiting the highest biodegradability when compared to β-TCP, BG45S5, and the other calcium-alkali orthophosphate materials.[41,43,46]

1.114.2.5. Correlation of *In Vitro* and *In Vivo* Events: The Effect of Bioactive Ceramics on the Osteoblastic Phenotype *In Vivo*

Correlating *in vitro* data with *in vivo* phenomena adds to our understanding of the bone–bioactive ceramic interface considering the hypothesis that enhanced osteoblastic cell differentiation *in vitro* leads to more and more expeditious and more copious bone formation at the bone–biomaterial interface *in vivo*. In order to test this hypothesis, correlation of the *in vitro* and *in vivo* data is, of course, needed. This includes (1) correlating quantitative expression of the osteogenic markers *in vitro* with the amount of bone formed after bioceramics implantation, and (2) quantifying the expression of these markers in histological sections obtained from *in vivo*

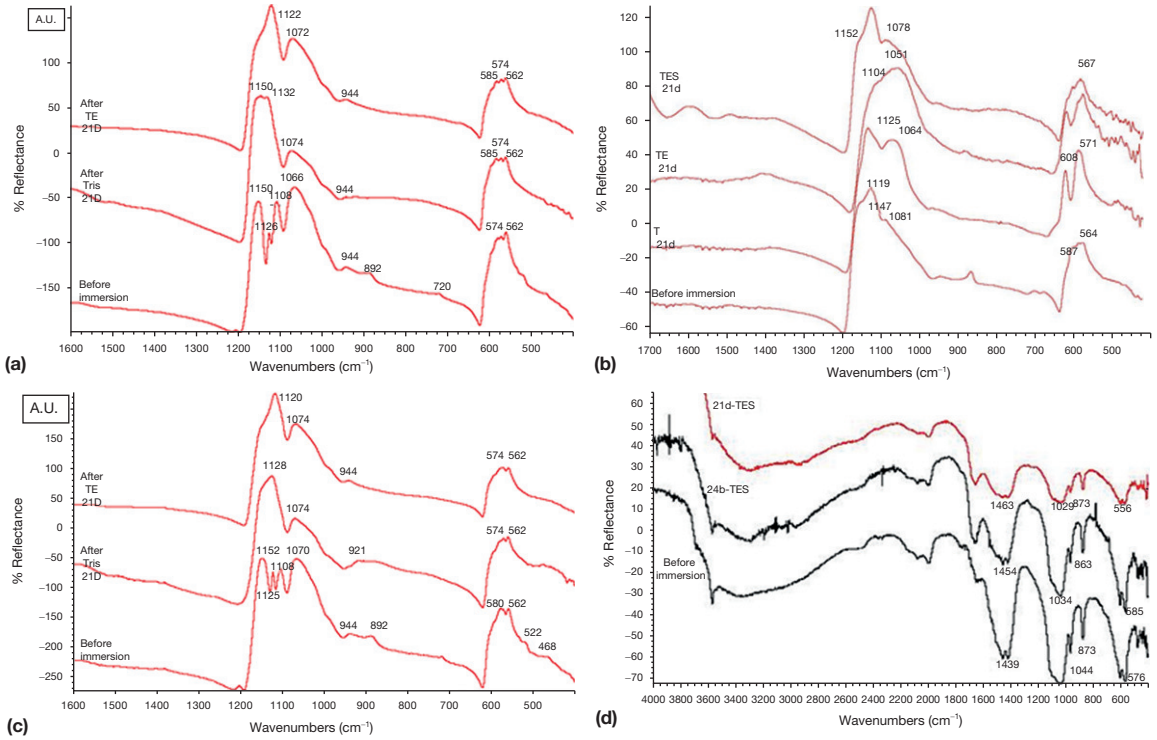

Figure 5 Fourier transform infrared sprectroscopy (FTIR) spectra of the pre- and postimmersion surface analysis after 21 days of immersion in 0.05 M Tris buffer (T), T supplemented with physiological electrolytes (TE), and TE supplemented with 10% fetal calf serum (TES): (a) GB14, (b) GB9, (c) GB9/25, and (d) BioOss®. FTIR spectra of GB14 and GB9 before and after showed that bioactive surface transformations occurred both in TE and in TES, whereas GB9/25 showed detectable phase transformation that were not associated with hydroxyapatite formation. A crystalline apatitic phase was also observed on BioOss®.

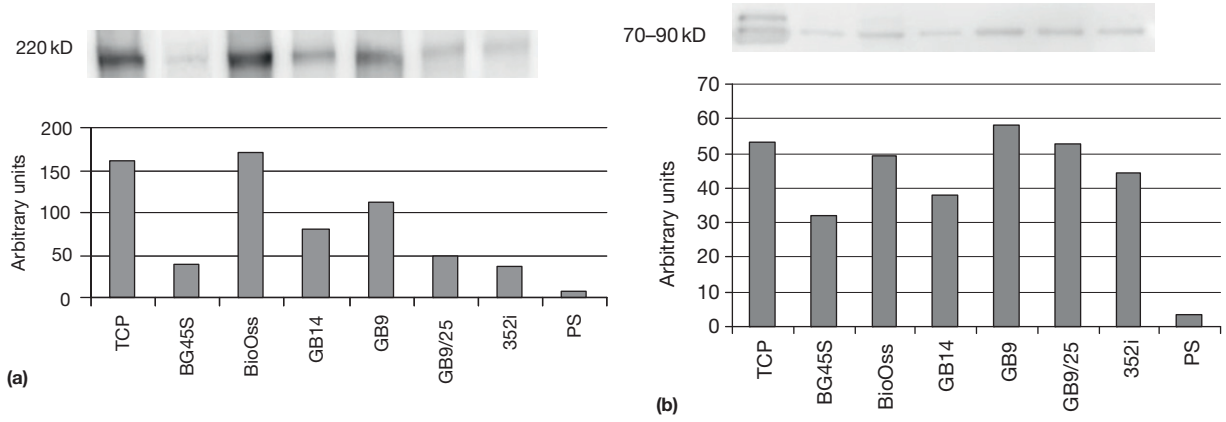

Figure 6 (a) Results of Western blot analysis for serum protein adsorption. Relative amount of Fn adsorbed to various calcium phosphate test materials after 24 h of immersion in serum-containing tissue culture medium (PS: tissue culture polystyrene control surface). (b) Relative amount of type I collagen adsorbed to various calcium phosphate test materials after 1 h of immersion in serum-containing tissue culture medium as determined by Western blot analysis.

experiments in comparison to the expression of the various markers *in vitro*.

To this end, a study was performed, in which the effect of the same selection of bioactive ceramics on the expression of osteogenic markers was studied *in vitro* as well as *in vivo*.[43,46,135] This required the development of an adequate hard tissue histology technique that facilitates immunohistochemical analysis of osteogenic markers on undecalcified sawed resin-embedded sections of bone that contain ceramic implant materials. This rendered it possible to study the effect of ceramic bone substitute materials on osteoblast differentiation and tissue maturation on *ex vivo* specimens by visualizing active osteoblasts in their different stages of differentiation at the bone–biomaterials interface.[136]

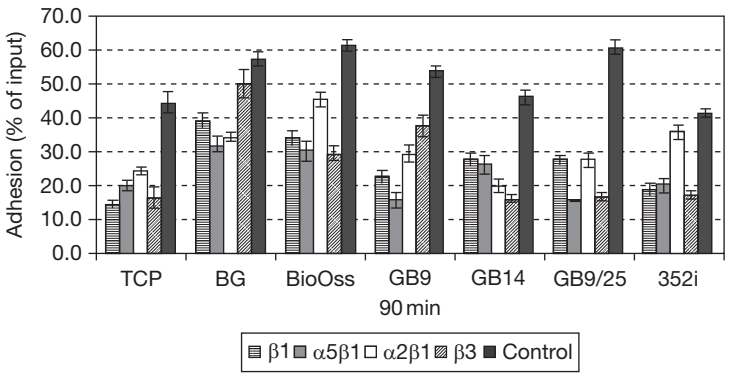

Figure 7 Results of the 90 min adhesion assay for the various calcium phosphate bone grafting materials utilizing functional blocking antibodies against β_1, $\alpha_2\beta_1$, $\alpha_5\beta_1$, and β_3 integrin receptors.

This was in addition to visualizing the expression of various osteogenic markers in the mineralized and unmineralized extracellular-matrix components.[32,43,44,135] Utilizing this novel hard tissue technology rendered it possible to study the effect of identical bioactive ceramics on the expression of osteogenic markers *in vitro* and *in vivo* and to test the above-stated hypothesis.[41–43] In this study, four calcium-alkali orthophosphate ceramic bone substitute materials (**Table 1**) were implanted in the sheep mandible and compared to currently clinically used synthetic bone substitute materials (β-TCP and BG45S5).[41,43,46,135] These materials were selected because previous *in vitro* studies demonstrated that they stimulated greater differentiation of osteoblasts compared to cells grown on TCP ceramic.[42,87,88] (for details, see **Chapter 6.620, Dental Graft Materials**). The various calcium phosphate materials (particle size 300–355 μm) were implanted in the sheep mandible for 1, 4, 12, and 24 weeks to regenerate critical size membrane-protected defects as described by von Arx *et al.*[10] Autogenous bone chips and empty defects, which were filled with collagen sponges, served as controls.[41,43,46,135] This study included examining the above-mentioned calcium-alkali orthophosphate material GB9. As outlined above, *in vitro* GB9 displayed a significantly greater stimulatory effect on osteoblast proliferation and differentiation compared to TCP, BG45S5, and other calcium-alkali orthophosphates.[41,42,46,135] These findings correlated with enhanced bone formation and bone–particle contact (i.e., bone-bonding behavior) *in vivo*, which was accompanied by enhanced expression of type I collagen, osteopontin, osteocalcin, osteonectin, and bone sialoprotein *in vivo*.[41,43,46] This was associated with a significantly greater decrease in particle area fraction over time, that is, a significantly greater biodegradation.[41,43,46] Staining for tartrate-resistant acid phosphatase (TRAP) showed that biodegradation for the various calcium-alkali orthophosphates as well as TCP occurred by dissolution rather than osteoclastic activity.[41,43,46,135] Furthermore, it is noteworthy that with GB9 already after 4 weeks, a significantly greater bone–particle contact was noted compared to all other calcium phosphates. By 12 weeks, defects which were augmented using GB9 displayed greater bone formation compared to defects that were augmented with autogenous bone chips.[41,43,46] These findings are clinically very significant as autogenous bone is considered to be the gold standard. BG45S5 and TCP displayed good bone regenerative capacities and bone-bonding behavior; however, the biodegradability was lower when compared to GB9.[41,43,46] Hence, correlating *in vivo* results with the data from the *in vitro* studies that elucidate the mechanisms by which bioactive ceramics materials induce enhanced osteoblastic differentiation is of great value, because taken together these studies facilitate characterizing the tissue response at the bone–biomaterial interface *in vitro* and *in vivo* at a molecular level and, thus, can contribute significantly to obtaining a fundamental understanding of the processes involved in tissue integration of bioactive implant materials.

1.114.3. Mechanisms of Biodegradation of Bioactive Ceramics

Biodegradation of bioactive ceramics used for bone regeneration can occur either by physicochemical dissolution or by cellular, that is, osteoclastic activity, or by a combination of both. For TCP[24,35] and BG45S5,[30] histological findings from animal studies and human biopsies showed that these materials degrade mainly by physicochemical dissolution and that the role played by osteoclasts was only minor. These results are in agreement with own findings when examining human biopsies[32] and specimens from the sheep study outline above.[41,43,46,135] In these studies, undecalcified histological sections were stained for TRAP activity to identify cells with osteoclastic activity in the vicinity of the various calcium phosphate bone substitute materials. In these sections stained for TRAP activity, no multinucleate TRAP-positive osteoclasts were found in fibrous mesenchym infiltrating the degrading TCP, BG45S5, and calcium-alkali orthophosphate particles or in the mineralized bone tissue in contact with the various calcium phosphate particles, while in the positive controls (experimental fracture-healing sites), numerous multinucleate TRAP positive cells were present. These findings are in agreement with observations by Müller-Mai *et al.*[137] who also noted that degradation of calium-alkali-orthophosphate materials occurred mainly by physicochemical dissolution rather than by osteoclastic activity.[137] With regard to HA-based calcium phosphate materials, however, it has been reported that biodegradation occurs mainly by osteoclastic activity.[77] It has been speculated that these differences in degradation behavior between HA and TCP or BG45S5 are related to the pH, which increases during

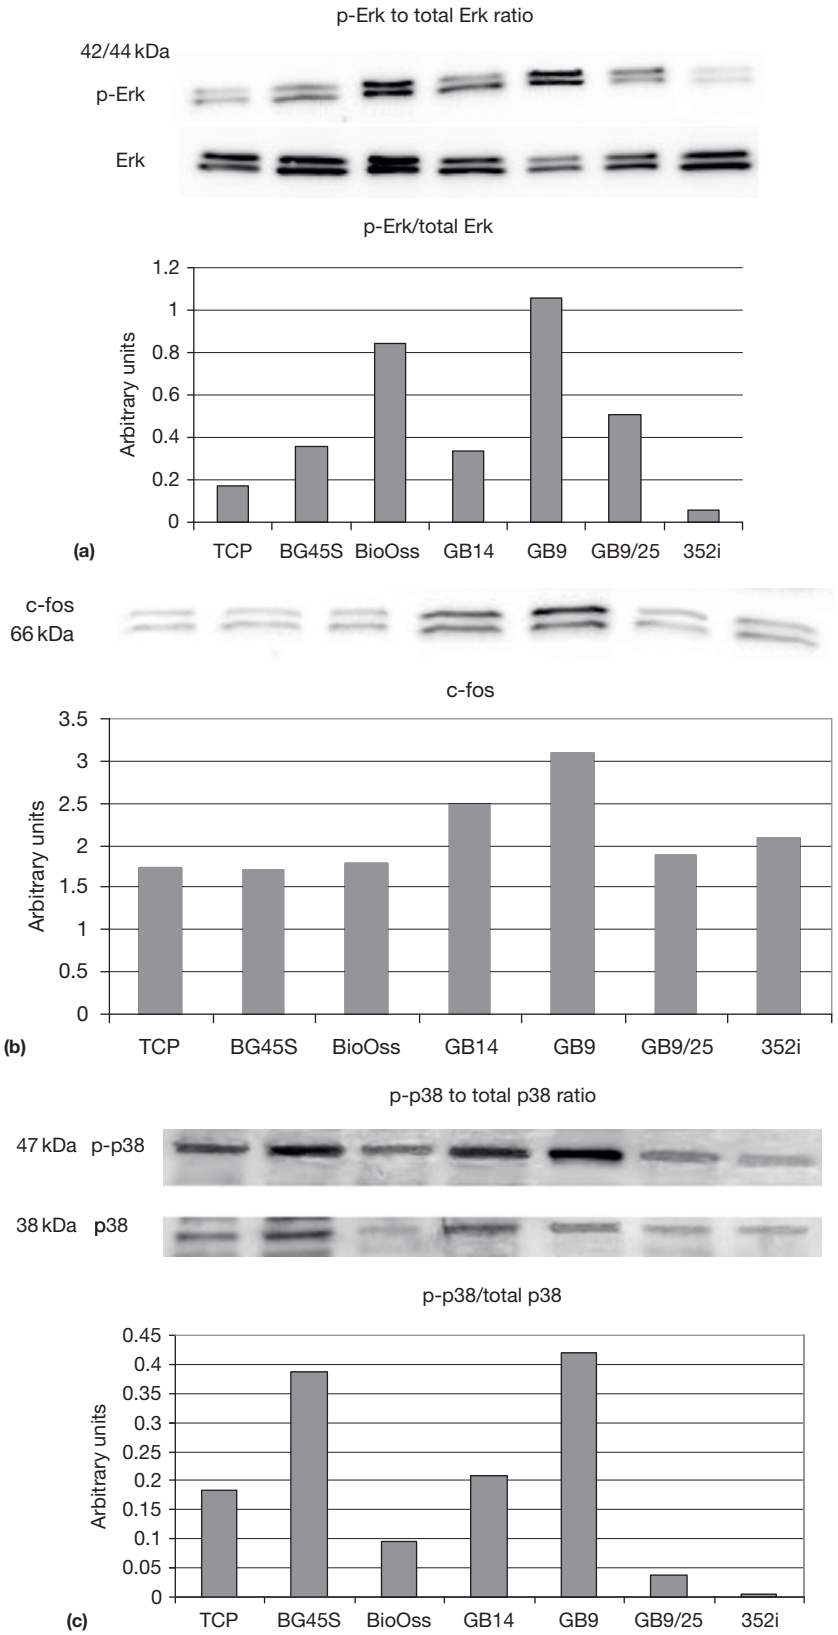

Figure 8 (Continued)

(a) Phospho-Erk to total Erk protein expression ratio after 3 h of cultivation of MC3T3-E1 osteoblasts on various bioceramics. (b) c-fos expression after 24 h of cultivation of osteoblasts on various calcium phosphates ceramics and glasses. (c) Phospho-p38 to total p38 protein expression ratio after 1 h of cultivation of osteoblasts on various calcium phosphates. (d) Phospho-Akt to total Akt protein expression ratio after 24 h of cultivation of MC3T3-E1 bone cells on various bioactive bone substitutes. (e) Protein expression of the antiapoptotic factor Bcl-x_L after 3 h of cultivation of osteoblastic cells on various bioactive calcium phosphates.

the dissolution process.[31] Dissolution of TCP, BG45S5, and calcium-alkali orthophosphates leads to a more alkaline milieu at the material surface, whereas dissolution of HA is associated with a lower pH.[77] This certainly is an interesting issue requiring further investigation.

1.114.4. Summary

Bioactive calcium phosphate ceramics and glasses are known to bond directly to bone and to stimulate bone tissue formation. This has led to their constantly increasing clinical use. Numerous studies have contributed to enhancing our understanding regarding the stimulatory effect of bioactive ceramics on osteoblast function and bone tissue formation. Significant progress has been made in revealing solution-mediated surface reactions that take place close to the surface of bioactive ceramics. Advanced surface analysis methods have been combined with molecular techniques in order to facilitate a better understanding of the surface transformations of bioactive, resorbable ceramics and glasses, and the serum protein adsorption events that are associated with the immersion in biological fluids. A considerable body of knowledge has been generated regarding the effect of various bioactive calcium phosphate ceramics and glasses on osteoblast differentiation *in vitro*. Recent studies provided insight into the effect of various bioactive ceramics on bone cell differentiation and tissue maturation *in vivo*, thereby allowing for correlation of *in vitro* and *in vivo* events. Moreover, techniques have become available to study integrin-mediated cell adhesion and the subsequently activated intracellular signaling pathways that regulate cell function including cellular differentiation and cell survival. As a result, very recent research efforts combined two powerful analytical methodologies (advanced surface

analysis methods and techniques to examine integrin-mediated cell adhesion and signaling mechanisms) to elucidate the mechanisms by which bioactive ceramics and glasses induce enhanced osteoblastic differentiation. Once reaction pathways are clearly identified, the means have become available to alter biomaterial molecular components and surface characteristics in ways that promote optimal cell adhesion, proliferation and differentiation, as well as depression of apoptosis. Thus, new bioactive materials can be created whose surface chemistry and morphology preferentially boosts the osteogenic cascade, thereby leading to more and more expeditious and copious bone formation, which facilitates the creation of bioactive calcium ceramics and glasses that are optimally tailored toward their clinical application.

Abbreviations

APC	Antigen presenting cell
BMP	Bone morphogenic protein
DC	Dendritic cells
HA	Hydroxylapatite
HLA-DR	Major histocompatibilty complex (class II) cell surface receptor whose function is to present peptide antigens, potentially foreign in origin, to the immune system for the purpose of eliciting or suppressing T-(helper)-cell
IL-12	Interleukin 12
Lac-Z	Bacterial enzyme β-galactosidase
MHC	Major histocompatibility complex
MSC	Mesenchymal stem cells
PBS	Phosphate buffered saline
pDNA	Plasmid DNA
TLR4	Toll-like receptor 4
TNF	Tumor necrosis factor

1.115.1. Introduction

Transfection is the process of introducing nucleic acids into cells by nonviral methods, whereas transduction is a term generally used to describe virus-mediated DNA transfer. Naked DNA is not able to significantly transfect cells *ex vivo*, although some limited gene transfer can be detected when injected into muscles.[1] This is the reason why materials and protocols have been developed in order to increase the efficiency of transfection for therapeutic use.

Today, any gene can be artificially synthesized and made readily available for gene therapy. Thus, the challenge is to get a good vector to deliver this gene in the right cell type. Since the first protocol of gene therapy used in humans was approved in September 1990, the number of available vectors has dramatically increased while the ideal vector is still to be found.

Viral vectors have been widely used for clinical trials due to the natural ability of viruses to deliver genetic material into the cell nucleus.[2] They represent the most effective way to deliver DNA, but show limitations regarding cell type targeting, size of carried DNA, production and packaging problems. Furthermore, immunological reactions, cytotoxicity, and hazardous integration events (when using retroviruses as vectors) led to secondary effects and even the death of several patients in clinical trials making viral vectors difficult to use for large-scale clinical research[3] (**Table 1**).

Besides gene delivery methods based on recombinant viruses, there are various alternative methods of introducing foreign DNA into eukaryotic cells. Physical methods have been developed since the permeability of cellular membranes is increased by electric or heat shocks, magnetic force or ultrasounds.[4] Although efficient *in vitro*, these physical methods are difficult to adapt for *in vivo*. Finally, many materials have been used as carriers for DNA transfection, including hydrogel polymers, polycationic lipids, polylysine, polyornithine, dendrimers, histones, and other chromosomal proteins, and precipitated calcium phosphate.[5–7] These different carriers apply the theory and methods of advanced particulate drug delivery to introduce DNA in selective somatic cells.[8] In these systems, DNA is condensed to form nanoparticles which are up taken in the endocytic pathway. Functional molecules can be incorporated in these DNA nanoparticles in order to target a

Table 1 Biological characteristics of viral and nonviral vectors

Viral	*Nonviral*
Cell specificity	No limit on plasmid size
High transfection efficiency	Toxicity predictible
Transportation mechanism of DNA into nucleus	Low immunity
Immune reaction against viral proteins	No integration
Virus infectiosity	Low transfection efficacy
Limitation on gene size	Not always efficient *in vivo*
Random chromosomal insertion: possibility of proto-oncogene activation	Unclear nuclear transport

Table 2 Barriers in gene delivery

Extracellular	*Intracellular*
Plasma nuclease	Endosomal escape
Uptake by reticuloendothelial system	Lysosomal degradation
Opsonization	Cytoplasmic nuclease
Complement activation	Translocation to nucleus

cell type and/or the nucleus. Once in the endosome, the plasmid DNA must be released in the cytosol and escape processing by the cytosolic nucleases.[9] Then, it may enter, through nuclear pores, into the nucleus where gene transcription occurs (Table 2).

Among these transfection agents, liposomes are particularly interesting. Liposomes are spherical vesicles with a diameter ranging from 20 nm to a few thousands nm. These vesicles consist of one or several lipid bilayers that separate an intravesicular space from an external medium. Within these lipid bilayers, like in the biological membrane, motion of phospholipids is observed.[10] Liposomes are easy to prepare. However, liposomes are phagocytosed by macrophages and are rapidly trapped in the liver, spleen, and lung.[11] In addition, liposomes must exhibit membrane-fusion promoting molecules at their surface to enhance the cytoplasmic delivery of pDNA. They can also carry different kinds of surface molecules such as viral glycoproteins, giving them some specificity for an organ or a defined tissue.[12,13]

The synthetic vectors are applicable *in vitro* with isolated cells, but *in vivo* applications are greatly limited by their toxicity or because physicochemical conditions necessary for the transfection are difficult to reach in an open medium. Transfection agents are much less efficient than viral vectors with regard to the transfection yield but they can be used with almost all gene size at the opposite of virus.[14]

1.115.2. Applications of Bioceramic Cell Transfection

Many clinical assays have been carried out in order to correct gene expression deficiencies.[15] However, transfection protocols based on bioceramics could be more useful for two particular applications, DNA vaccination and bone tissue engineering that do not require the integration and long-term expression of the transgene (Table 3).

Table 3 Diseases and conditions of the musculoskeletal system that may be amenable to gene therapy

Inherited	*Acquired*
Osteogenesis imperfecta	Arthritis
Familial osteoarthrosis	Arthrosis
	Delayed unions (pseudarthrosis)
Osteopetrosis	
Certain crystal-deposition arthropathis	Osteosarcomas, chondrosarcomas, bone metastasis
Certain form of osteoporosis	Osteoporosis
Inherited abnomalies of the growth plate	Rheumatic disease
Ehler–Danlos syndrome and other connective-tissue diseases	

DNA vaccination consists in transfection of subcutaneous or muscular cells with a gene coding for a viral or a bacterial protein that will be recognized by the adaptive immune system as a foreign antigen. When transiently expressed by transfected cells, this foreign antigen will trigger an antibody response that provides long term immunity against the corresponding pathogen. Furthermore, the mechanical properties of powdered bioceramics also allow their spray with a gene gun.

Maybe the most important argument for using this material would be to obtain a DNA vaccine that recruits and activates dendritic cells (DC)[16] (Figure 1). In this field, preliminary results suggest that HA particles could both mediate DC transfection and induce their maturation[17] as particulate bioceramics were proven to act as a vaccine adjuvant. DNA vaccination has been highly effective in mice, while less immunogenic in different primates including humans.[18] The efficiency of DNA vaccination depends on appropriate interactions between the foreign antigen, lymphocytes, and antigen presenting cells (APCs). B lymphocytes need helper signals from T lymphocytes to produce antigen-specific antibodies, but the efficient activation of antigen-specific T lymphocytes critically relies on three kinds of biological signals provided by APCs.[19] The APCs must (1) express MHC molecules to present antigen-derived peptidic fragments to T lymphocytes, (2) express suitable costimulatory molecules at their surface like CD80 and CD86, and (3) secrete costimulatory cytokines in their microenvironment such as IL-12. Only DC that have received a maturation signal can express these different signals at optimal levels to mediate T lymphocyte activation.

We have demonstrated that when human immature dendritic cells were grown *in vitro* with hydroxylapatite particles, they maturated within 48 h. The presence of the particles induced the expression of cd 40, 83, 86, and HLA-DR by the cells. It means that the HA bioceramic particles trigger in the APCs a series of events necessary for the priming of T lymphocytes. Interestingly, HA-induced activation of APCs critically relies on TLR4, a membrane receptor well-characterized for its role in the detection of pathogen-associated molecular patterns like bacterial lipopolysaccharides and viral glycoproteins.[20] Associated to the recruitment of APCs in the foreign body reaction, bioceramics can thus be used in combination with

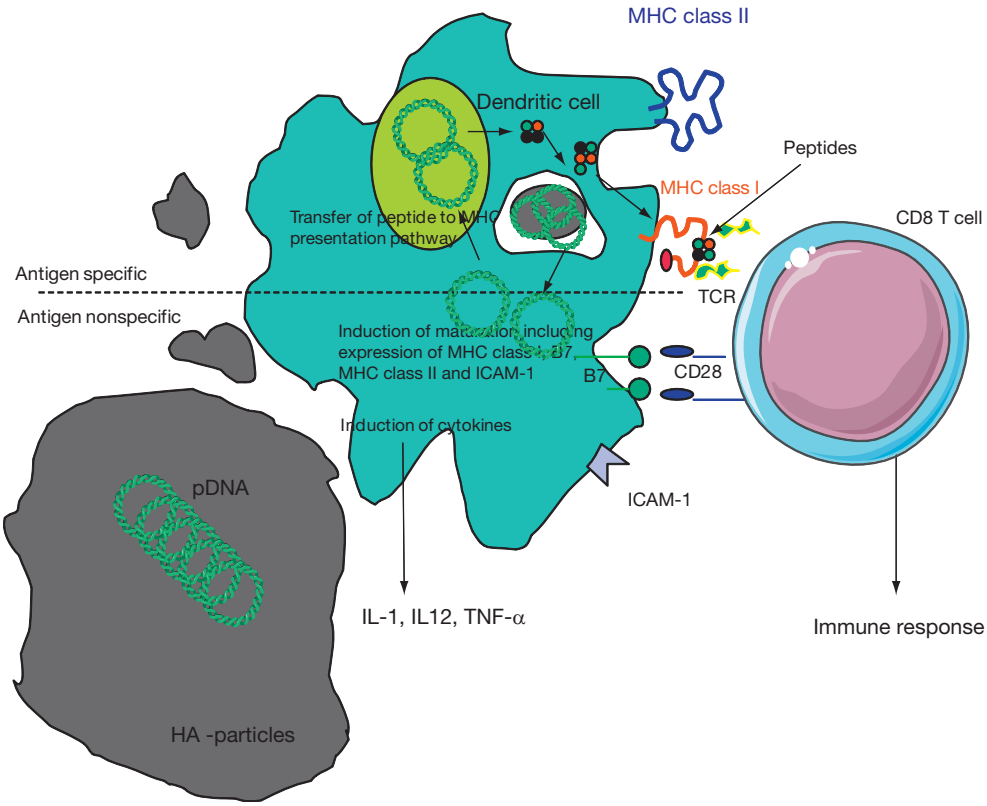

Figure 1 HA particles when in contact with APCs can transfect them with pDNA coding for an antigen which will be expressed and processed at the surface of the MHC class I proteins. The presence of the antigen at the surface of the APC cells will cross prime the CD8 cells. The phagocytosis of HA-fragments triggers the synthesis of costimulation molecules, interleukins, and cytokines like IL-12 necessary for the cross priming.

pDNA to make efficient vaccine in human beings without the need to bring additional signals to trigger the adaptive immune response.

Calcium phosphate bioceramics were used for decades for bone reconstruction and for vectorization of bone cell progenitors.[21,22] In this field, this technology can be used to induce the differentiation of cells grown at the material surface. Differentiation of Mesenchymal Stem Cells (MSCs) in osteoblasts for example using pDNA bearing BMPs genes could be achieved using porous ceramics with high surface area on which the pDNA is immobilized. MSCs are generally dedifferentiated after a culture period even when they are phosphatase alkaline positive, and the presence of morphogenetic proteins at the surface of the material would permit to induce osteoprogenitor cell differentiation and maintain cells in this differentiated state in culture. This type of material would also be useful for direct implantation into connective tissue such as pseudarthrosis fibrous tissue in order to transfect the cells of the surrounding tissue in order to modify their differentiation by transfection.[23]

1.115.3. The Role of Bioceramic Characteristics for their Applications

Bioceramics show biological and physicochemical characteristics, which make possible their use in special applications.

1.115.3.1. Bioactivity

Bioceramics are bioactive materials interacting with bone tissue when implanted inside bone to be totally integrated in several stages and replaced by the neoformed bone.[24] This property makes these materials particularly adapted to the transient transfection of bone cells, in particular osteoblasts and/or osteoclasts which are functionally deficient in some genetic diseases like osteogenesis imperfecta[25] or aging diseases like osteoporosis.[26] There is a number of genetic and acquired bone diseases clearly identified which could benefit from bioceramic transient transfection (**Table 3**).

1.115.3.2. Degradability

Bioceramics are degradable and get replaced by bone following a process of resorption/reconstruction identical to that of natural bone.[24] The ceramic grain boundaries are first resorbed. This degradation of the material allows the release of micro- or even nanoparticles that trigger biological reactions which can be useful for special applications. A good example of this is the transient induction of a foreign body reaction around the microparticles released by the calcium phosphate ceramics (**Figure 2**). The foreign body reaction is constituted by cells of monocytic origin involved in the immune response and in particular antigen presentation to the lymphocytes. Antigen expression

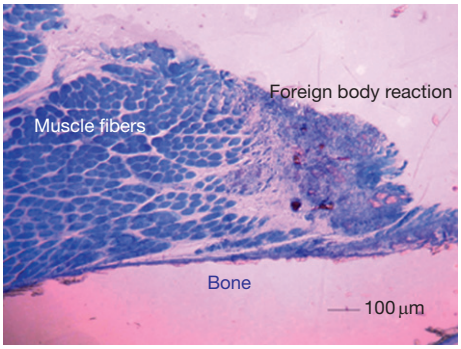

Figure 2 Histological section of the injection site of HA particles in a mice muscle showing the formation of a transient foreign body reaction around the particles.

in antigen presenting cells might enhance immune response.[16] The degradability can thus amplify the foreign body and innate immune reaction.

1.115.3.3. Physicochemical Properties

The biological activity of bioceramics is linked to their physical characteristics, and in particular properties of their surface. We have demonstrated that the toxicity and the inflammatory power of hydroxylapatite (HA) – particles were related to their physical properties, while their chemical composition was the same.[27–29] In the field of vaccination for example, the physical properties of ceramic HA particles, in particular their size and structure of their surface, show a major influence on the synthesis of interleukins and TNF that determine the adjuvant properties of the particles.[30]

Bioceramics can be powdered, porous, or under a bulk material form. Compared to the other transfection tools, the solid state of bioceramics which are implanted in a specific site allows a kind of cell specificity as the transfected cells must come into contact with the material surface. For example, it is of interest for tumor cell transfection since the material can be implanted directly in the tumor.

1.115.4. Traditional Use of Calcium Phosphate for Cell Transfection

Calcium phosphate has been one of the earliest transfection agent under the form of nanoparticles coprecipitated with pDNA. These nanoparticles are obtained by precipitation, through the incubation of pDNA in a supersaturated calcium and phosphate solution. The particles precipitated are nanosized and formed by a coprecipitate of DNA and a poorly characterized calcium phosphate.[31,32] Transfection is achieved when this coprecipitate is contacting a cell monolayer.

This method has a poor transfection yield,[33] with only a few percents of transfected cells being obtained. Above all, this method is only tractable *in vitro* in a closed environment as *in vivo* in an open medium the supersaturation cannot be reached. For this reason, the use of this method for *in vivo* cell transfection must be made in two times. The cells must be first transfected in culture and then injected in the tissue. It is also possible to isolate the nanoparticles from the solution after their formation *in vitro* and inject it in the tissue to be tranfected. However, the migration risk is very high.

Higher transfection yields (60%) can be obtained when the precipitation factors are better controlled.[34] Temperature, DNA concentration, and reaction time were shown to be crucial for better results over standard procedure. Almost 100 000 plasmid molecules could be delivered into individual cells.

Cell cycle is also a key factor for transfection efficiency, and the percentage of cells in S phase when adding the transfection agent correlates with the percentage of transfected cells.[35] The nuclear membrane is dismantled during mitosis, and this probably increases the number of pDNA molecules accessing the nuclear environment.

However, the transfection mechanism is unclear. It seems that the entrapped DNA in the nanoparticles is protected at least partially from the degradation by cellular nucleases, and released by the calcium phosphate degradation in the low pH environment of the endosomes and lysosomes. The way of migration from these cellular compartments into the nucleus is highly speculative.[36]

1.115.5. Hydroxylapatite Ceramics for Cell Transfection

We have developed new hydroxylapatite ceramics for transfection. They have different characteristics from the traditional calcium phosphate nanoparticles obtained by precipitation.

1.115.5.1. Physicochemistry

The calcium phosphate ceramics are different from the nanoparticles obtained by coprecipitation. The ceramics are made of calcium phosphate grains joined by grain boundaries due to the sintering process, with a porosity between the grains that depends on the sintering temperature. This structure makes the material surface area much lower than that of coprecipitates and less reactive. The degradation of the calcium phosphate ceramic is well documented. The degradation of the grain boundaries triggers the release of grains or grain aggregates that are endo- or phagocytosed depending on their size.[37] The internalized particles are then solved inside the low pH cell compartments.[38] Interestingly, we have shown the presence of multinucleated giant cells that contribute actively to the dissolution of the material at the cell–material interface.

DNA is a negatively charged molecule. Calcium phosphate ceramics used in our experiments also show a negatively charged surface. However, we have been able to immobilize pDNA at the surface of calcium ceramics, suggesting that pDNA binding to HA particles is not electrostatic. Numerous theories have been published to describe the interaction between organic molecules and HA. None of them however takes into account the linked water or the modification of surface occurring at the surface when the ceramics are immersed into a saline solution. The epitaxial growth of carbonated apatite at the surface of HA ceramics has been widely described.[39] It is suggested that DNA could be coprecipitated at the surface of the ceramic with the carbonated apatite. The protocol to immobilize pDNA at the ceramic

surface includes the maceration of the powder in a saline solution containing the DNA. Precipitation is then visible at the ceramic surface.[40]

1.115.5.2. Transfection of Isolated Cells

Isolated cells, established or primary cell lines grown in monolayer, were transfected using pDNA loaded ceramic powder. The powder must be introduced into the culture flask and let in contact with the cell layer to transfect for various periods of time. Transfection is generally time dependent. With a constant amount of powder, the percentage of cells expressing the reporter gene is dependent on the time of incubation. The yield of transfection is also dependent on the mass of powder used for the transfection (**Figures 3** and **4**).

1.115.5.3. Transfection of Tissue Culture

Different tissues can be maintained in culture and used to test their behavior in contact with some biomaterials. The interactions between the different cell types is relatively conserved on such biopsies and their differentiated functions maintained, allowing a better understanding of their relationships with the transfection material than when working with isolated cells.

We grew small fragments of bone tissue from rats in contact with HA-beads loaded with pDNA containing a galactosidase reporter gene for two periods of time, 8 and 21 days. The grown bone was made of calvaria, cancellous bone, and growth plate cartilage. The histology of the bone fragments showed that almost no cells were positive at 8 days while all cells expressed the *LacZ* reporter gene at 21 days. It was significantly different from the control made of pDNA in PBS.

The calvaria histology demonstrated that the HA beads were covered by layers of proliferating cells coming from the periosteum of the immature bone formed by a direct ossification process. Some multinucleated cells from monocytic origin were also present at the contact of the HA particles. The cells clearly expressed the *LacZ* gene whatever their distance from the beads (**Figure 5**).

The same results were observed with other types of bone. The cells were stained in blue whether they are proliferating like the mesenchymal cells located inside the pores of the cancellous bone or not as it was shown for the chondrocytes.

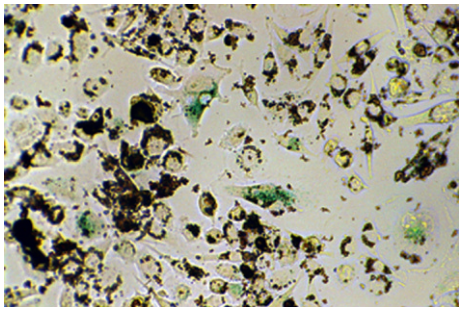

Figure 3 Established murine gliosarcoma cell line grown a few hours in the presence of HA particles showing that many particles were phagocytosed.

1.115.5.4. *In Vivo* Transfection

The same HA particles implanted in a connective tissue such as rabbit bone tissue trigger a foreign body reaction before integration within newly formed bone. Within 3 weeks, the most of the cells of the foreign body reaction at the particle contact expressed the *LacZ* gene (**Figures 6** and **7**). Other cells of monocytic origin were found positive for galactosidase staining. Osteoclasts in Howship's lacunae in the cancellous bone at remote location from the implantation zone were found to express the transgene. Some of these cells were found among the connective tissue present inside the bone pores. Other cells were labeled in this region, including some perivascular and mesenchymal cells, but also some cells of the dental ligament.

The cells labeled at 3 months are different. Fibroblasts of connective tissue and even odontoblasts expressed the galactosidase reporter gene.

1.115.6. Perspectives and Material Evolution

At the opposite of other transfection agents, bioceramics can be shaped. They can even be put in suspension to make solutions of bioceramic powder that can be injected or delivered by spray. Some interesting results were obtained using carboxymethyl cellulose without altering the powder transfection properties. The shaping of the bioceramics will allow their use in the various applications evoked in this chapter.

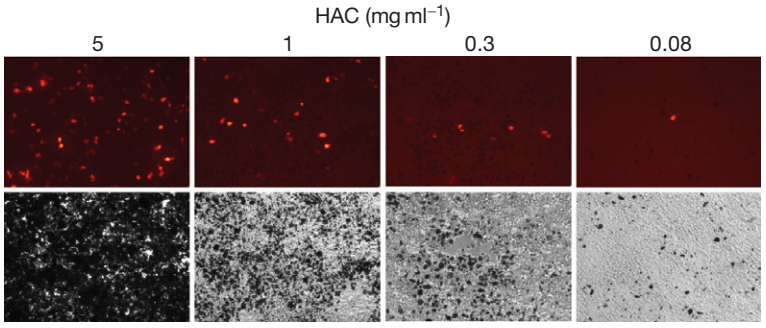

Figure 4 Transfection of a HEK293T cell line with different concentration of HA particles at 24 h. The particles were suspended at different concentrations in 1 ml of culture medium. The percentage of the transfected cells increases with the powder concentration.

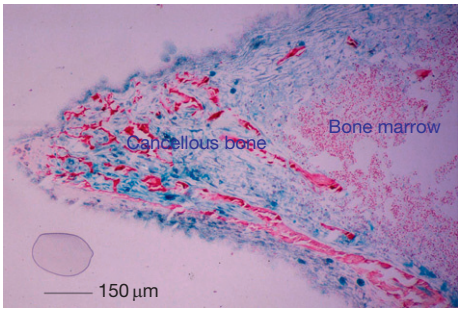

Figure 5 Calvaria tissue grown in the presence of HA particles loaded with a LacZ plasmid. After 3 weeks of culture the histological sections shows that all the cells express the *LacZ* gene.

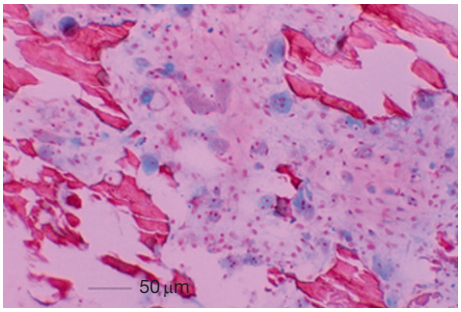

Figure 6 Three weeks after implantation in rabbit jaw, the histological sections shows that the monocytes and the plurinuclear cells of monocytic origin in bone expressed the *LacZ* gene.

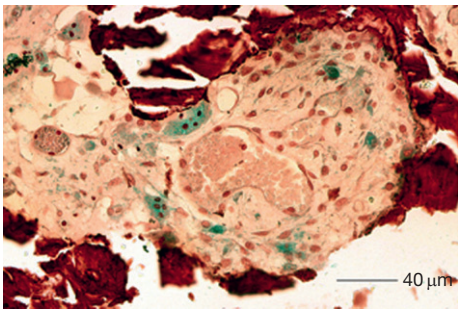

Figure 7 Histological section of a rabbit jaw bone after 3 weeks after implantation of HA particles loaded with pDNA (LacZ). The osteoclasts at the bone surface express the foreign gene.

Highly reactive material able to immobilize more pDNA than the ceramics used in our experiments could be available either by improving the surface area and/or by obtaining a better epitaxial growth at the material surface. This could be reached by associating other phases that are more soluble at physiological pH in the bioceramics.

Ceramic microparticles are not able to circulate in the blood stream for biocompatibility and physical reasons. The size of the particles must be submicronic or even nanometric in order to circulate inside the capillaries of the normal or tumoral tissues. Their density should also be modified in order to keep them in suspension in the blood.

Two other characteristics need to be improved in order to use such particles for *in vivo* transfection. First, particles injected in the blood stream are recognized by the innate immune system and are rapidly cleared by the spleen, the liver, and to a lower extent by the lungs. Thus, it is very important to minimize their recognition by macrophages so that the material is able to reach and enter targeted organs or tissues. Second, in spite of many works that have been published in the last 30 years, it is impossible to achieve transfection of a specific cell type by addressing particles into a specific tissue. This needs to be improved. Associated to a better biocompatibility of the material, humanized antibodies immobilized at the material surface should provide a way to target specific cells. In contrast to their nonhumanized counterparts, these molecules have proved to be able to target specific cells before they get eliminated by the immune system. The chemical molecules bridging these molecules to the material surface should also be eliminated or hidden in the body to minimize that their recognition by the immune system.

Glossary

Crystal A solid material whose constituent atoms, molecules, or ions are arranged in an orderly repeating pattern extending in all three spatial dimensions.

Cytotoxicity The quality of being toxic to cells.

Osteoblasts Mononuclear cells that are responsible for bone formation.

Periodontal In tissue around tooth.

Porogen An inorganic salt such as sodium chloride, crystals of saccharose, gelatin spheres or paraffin spheres used to create pores in a polymer.

Abbreviations

DDS	Drug delivery system
DFDBA	Demineralized freeze-dried bone allograft
ePTFE	Expanded polytetrafluoroethylene
EBA	Ethoxy benzoic acid
GTR	Guided tissue regeneration
HPMC	Hydroxypropyl methyl cellulose
MMA	Methyl methacrylate
MTA	Mineral trioxide aggregate
PMMA	Polymethyl methacrylate
POP	Plaster of Paris

1.116.1. Introduction

1.116.1.1. Bioactive Cement

The word 'bioactive' is defined in the dictionary as 'having a capacity to interact with a living tissue or system.' It has not been defined yet by any biomaterial related academic societies and, therefore, has been used with different meanings in history. Earlier, the term 'bioactive' was used for materials that are resorbed in the body. After the introduction of Bioglass®,[1] the meaning became synoymous with 'osteoconductive.' In this chapter, bioactive cement is defined as cement that shows osteoconductivity.

'Cement' also has different definitions; however, they are much clearer compared to the definition of 'bioactive.' In general, cement is defined as a fine inorganic powder mixture that sets and hardens independently. In this definition, cement is classified into two categories. One is air-setting cement or nonhydraulic cement and the other is hydraulic cement. In a narrow sense, cement indicates Portland cement, which is a hydraulic cement. A general definition of cement excludes organic materials as there are so many polymeric materials. However, combinations of methyl methacrylate (MMA) and polymethyl methacrylate (PMMA) have been used extensively in medical and dental clinics and thus, the broader definition of cement includes not only inorganic materials, but also organic materials that have hardening ability. Therefore, bioactive cements can be defined as inorganic or organic materials that set and harden independently and whose set mass exhibits osteoconductivity.

1.116.1.2. History of Bioactive Cement

Due to its important self-setting property, cement has been used clinically for a long time. Industrial cements were also used in medical and dental fields. Therefore, the history of bioactive cement runs close to the history of industrial cement. In other words, calcium sulfate or plaster has the oldest history as bioactive cement even though its bioactivity is limited. Portland cement is also used as medical cement for the reconstruction of bone defects. Interestingly, its use as a mineral trioxide aggregate (MTA) for dental treatment is one of the hottest topics in dentistry.

In 1976, Monma and Kanazawa[2] found that α-tricalcium phosphate (α-TCP; α-$Ca_3(PO_4)_2$) set and hardened to form calcium-deficient apatite ($Ca_9(HPO_4)(PO_4)_5(OH)$). LeGeros *et al.* reported calcium phosphate cement as a possible dental restorative material. In 1986, Brown and Chow[3,4] reported that a mixture of tetracalcium phosphate (TTCP: $Ca_4(PO_4)_2O$), and dicalcium phosphate anhydrous (DCPA: $CaHPO_4$) set to form hydroxyapatite (HAp: $Ca_{10}(PO_4)_6(OH)_2$). In 1987, Lemaitre and coworkers[5–7] found that a mixture of β-tricalcium phosphate (β-TCP: β-$Ca_3(PO_4)_2$) and monocalcium phosphate monohydrate (MCPM: $Ca(H_2PO_4)_2{\cdot}H_2O$) or phosphoric acid (H_3PO_4) set to form brushite or dicalcium phosphate dihydrate (DCPD: $CaHPO_4{\cdot}2H_2O$). These findings gave birth to the new history of bioactive cement.

1.116.1.3. Advantages of Bioactive Cement

The advantages of bioactive cements are apparently due to their self-setting property at low temperature or physiological temperature. First, the paste can set and harden, for example, at the bone defect. Therefore, the bone defect can be filled with the cement without leaving a gap between the cement and surrounding bone. In other words, the set cement and surrounding bone have a continuity between them, as shown in Figure 1.

This is extremely important as bone originates from cells, such as osteoblasts, and the migration of osteoblasts should not be prevented by discontinuity between the bone substitute and surrounding bone. Osteoblasts do not migrate if there is a gap between the surrounding bone and bone substitutes. In the case of sintered bioactive block-type ceramics, it is important to shape the ceramic so that it fits snugly into the bone defect to give good clinical results. However, this is very difficult to achieve (Figure 2).

Of course, bioactive cement can fit and follow the contour of the bone defect as the cement paste can be filled into the bone defect to set.

With respect to the continuity, it may be easier to fill the bone defect with granular type ceramics than with the block type. However, micromovement of the granules may prevent

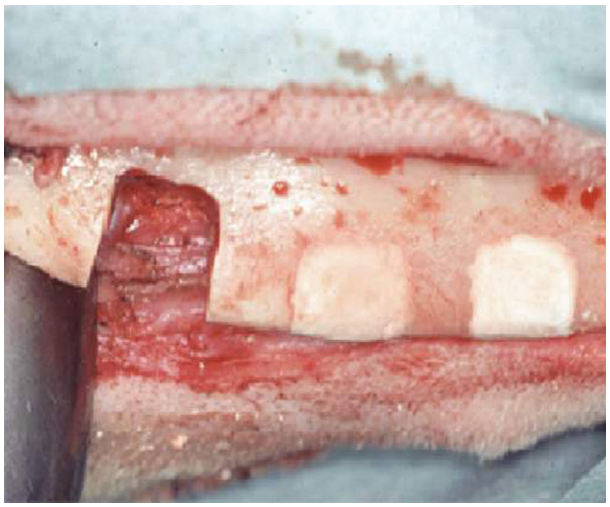

Figure 1 Example of bone defect reconstruction using bioactive cement. Bone defect can be filled with bioactive cement without leaving a gap between the bone and cement due to the cement's self-setting ability.

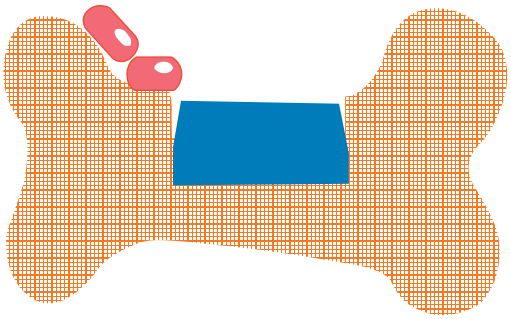

Figure 2 Illustrative view of bone defect reconstruction using the block form of bioactive ceramics. The block should fit into the bone defect to minimize the gap between the bone and the block.

the migration of bone cells. In addition, washout of the granules from the bone defect is a problem. In the case of cement, cement paste sets in the bone defect. Therefore, there is no need to worry about the micromovement or the washout of the set cement (Figure 3). Continuity of the cement and existing bone is presumed to be one of the reasons for the higher osteoconductivity of bioactive cement.

Second, the self-setting property of cement allows of minimum invasive surgery. As shown in Figure 4, the cement can be injected using a syringe.

Minimal invasive surgery has attracted much attention as it provides a better cosmetic result, less blood loss, less infection, a shorter hospital stay, and more effective rehabilitation.[8] However, it should be noted that filling the cement paste using a syringe has some drawbacks, at least with respect to the physical property of cement, including the washout of the paste (except for anti-washout-type cement), and lower mechanical strength of the set mass. Therefore, it is imperative that bioactive cement be used with a good understanding of its advantages and disadvantages and its underlying mechanism.

The third advantage of bioactive cement is that the setting reaction occurs at physiological temperature. As a result, apatite formed by the setting reaction of bioactive cement shows a low crystallinity similar to that of bone apatite. It is known that apatite with lower crystallinity shows higher osteoconductivity even though its mechanism has not been clearly understood till date.[9–11]

A fourth advantage of bioactive cement is that it can be used as a drug delivery system (DDS). Bioactive cement exhibits self-setting properties. Therefore, drug loading can be done by simply mixing the drug into the components of bioactive cement. Release of drug from the bioactive cement is skeleton type even though bioactive cements are known to exhibit adsorption abilities. The mechanical strength of the hardened cement could decrease slightly due to the increase in the porosity of the cement.[12] DDS can be also achieved by the incorporation of resorbable polymer that contains the drug for delivery.[13–15]

Yet another advantage is that bioactive cement can be used as a barrier membrane in guided tissue regeneration (GTR) or guided bone regeneration (GBR). In the case of GBR, bone is regenerated at the bone defect from the existing bone even though the bone defect is larger than critical size, the barrier membrane physically preventing connective tissue ingrowth into the bone defect. In the GBR, 'space making' and complete 'barrier' from the connective tissue are important so that the new bone can be formed at the space without invasion from the connective tissue. These can be achieved by the combination of bone substitute/grafted bone and bioactive cement, as shown in Figure 5. Also, connective tissue integration with the surface of the barrier membrane is important to prevent the separation of connective tissue from the defect. Due to the bioactive nature of bioactive cement, this requirement can also be achieved. Indeed, bone formation inside the bone defect as well as on the bioactive cement layer is facilitated due to the bioactive nature of the cement.

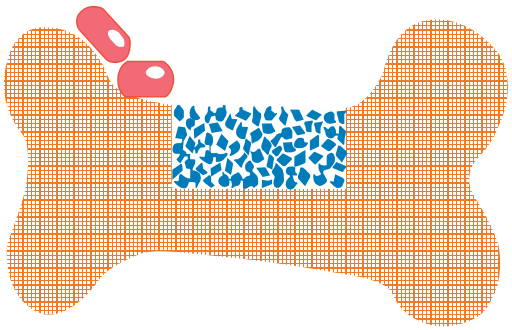

Figure 3 Illustrative view of a bone defect reconstruction using the granular form of bioactive ceramics.

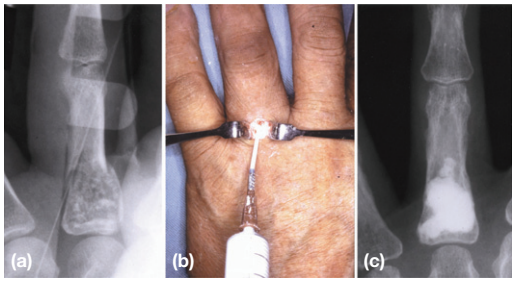

Figure 4 Example of the minimum invasive surgery using bioactive cement.

1.116.1.4. Drawbacks of Bioactive Cement

The main drawback of bioactive cement arises from the fact that the cement is not block but powder before setting. Unfortunately, calcium phosphate powders, including apatite, are known to cause an inflammatory response known as crystalline inflammatory response when they are exposed to soft tissue. Therefore, the setting reaction should be guaranteed for satisfactory clinical results. One of the causes for the disintegration of powder is the external stress before the setting reaction. Bioactive cement shows its inherent mechanical strength upon the setting reaction. As a result, the cement would not free the powder once it set. However, cement paste shows virtually no mechanical strength against external force. It should be pointed out that the cement should be free from external stress before its setting reaction.

Also, exposure of the paste to body fluid causes washout of the cement paste, except for the antiwashout-type or putty-type cement, which can also be used for haemostatic purposes. Washout becomes more problematic when the cement is injected using a syringe. When cement is injected with a syringe, a larger amount of liquid is usually employed than in

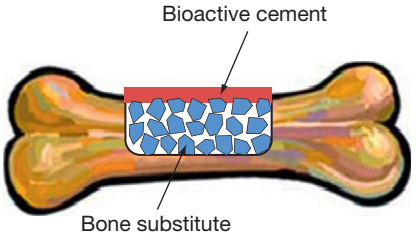

Figure 5 Schematic diagram of guided bone regeneration using bioactive cement instead of barrier membrane.

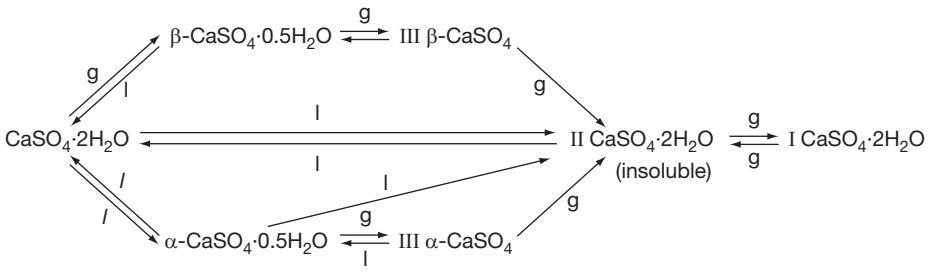

Figure 6 Polymorphism of calcium sulfate.

the packing method. This results in the cement being more sensitive to washout. Also, injected paste from the syringe has a larger area exposed to the body fluid. It should be emphasized that cement shows good tissue response only when it has set.

Another drawback is the lower mechanical strength. At present, the mechanical strength of bioactive cement is much lower compared with that of the sintered bioactive ceramics. Therefore, the cement can be used only in nonload-bearing areas.

1.116.2. Calcium Sulfate

1.116.2.1. History of Calcium Sulfate

Calcium sulfate has the longest history not only for its industrial use but also for its clinical use. The oldest use of calcium sulfate may have been for the hard-setting bandage.[16,17] Later in 1814, Hendrksz used calcium sulfate in the treatment of bone fractures.[16–18] Till date, many clinical *in vivo* and *in vitro* studies have been conducted and their results summarized in review papers.[18–22]

1.116.2.2. Setting Reaction of Calcium Sulfate

Gypsum is the name given to a mineral categorized as calcium sulfate mineral, and its chemical formula is calcium sulfate dihydrate, $CaSO_4 \cdot 2H_2O$. However, a broader definition includes all the calcium sulfates, including calcium sulfate hemihydrate, $CaSO_4 \cdot 0.5H_2O$, which is known as plaster or plaster of Paris (POP). **Figure 6** summarizes the polymorphism of calcium sulfate; 'g' indicates that the transformation reaction occurs in the gaseous phase, while 'l' indicates that the reaction occurs in the liquid phase.[23]

Calcium sulfate dihydrate and II-type calcium sulfate anhydrous, which has no solubility in water, can be taken as ore. When calcium sulfate dihydrate is heated, β- or α-form calcium sulfate hemihydrates are formed, as shown in eqn [I].

$$CaSO_4 \cdot 2H_2O \rightarrow CaSO_4 \cdot 0.5H_2O + 1.5H_2O \qquad [I]$$

The β-form calcium sulfate hemihydrates, whose density is 2.64 g cm^{-3}, are formed when $CaSO_4 \cdot 2H_2O$ is heated dry at round 120–130 °C. In contrast, the α-form, whose density is 2.76 g cm^{-3}, are formed when $CaSO_4 \cdot 2H_2O$ is heated hydrothermally at round 130 °C. At 190 °C, $CaSO_4 \cdot 0.5H_2O$ loses water and becomes calcium sulfate anhydrous, III-type α-$CaSO_4$ and β-$CaSO_4$. Calcium sulfate anhydrous taken as natural ore is stable. However, the calcium sulfate anhydrous formed by heating at 190 °C transforms to its hemihydrates easily by reacting with the humidity in the atmosphere. Further heating to 400 °C results in nonsoluble calcium sulfate anhydrous.

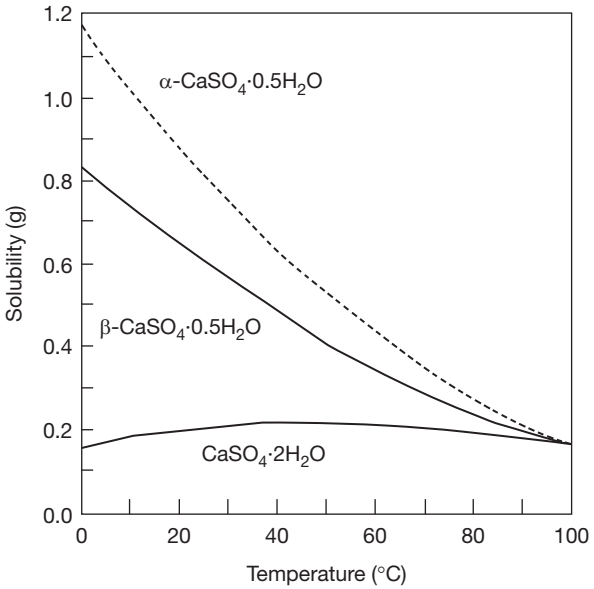

Figure 7 Solubility of α- and β-calcium sulfate hemihydrate and calcium sulfate dihydrate against temperature.

The setting and hardening reaction of calcium sulfate hemihydrate is a phase transformation from calcium sulfate hemihydrates to calcium sulfate dihydrate, and is known as a dissolution–precipitation reaction, as shown in eqns [II] and [III].

$$\alpha CaSO_4 \cdot 0.5H_2O + 1.5H_2O \rightarrow CaSO_4 \cdot 2H_2O + 17.2\,J\,mol^{-1} \qquad [II]$$

$$\beta CaSO_4 \cdot 0.5H_2O + 1.5H_2O \rightarrow CaSO_4 \cdot 2H_2O + 19.3\,J\,mol^{-1} \qquad [III]$$

In this exothermal dissolution–precipitation reaction, the solubility of $CaSO_4 \cdot 0.5H_2O$ and $CaSO_4 \cdot 2H_2O$ plays a very important role (**Figure 7**).

For example, the solubility of α-form calcium sulfate hemihydrate, $CaSO_4 \cdot 0.5H_2O$, and calcium sulfate dihydrate, $CaSO_4 \cdot 2H_2O$, is 0.92 g/100 ml and 0.2 g/100 ml at 20 °C as shown in eqns [IV] and [V], respectively. Therefore, when $CaSO_4 \cdot 0.5H_2O$ is mixed with water, Ca^{2+} and SO_4^{2-} ions, which are equivalent to 0.92 g $CaSO_4 \cdot 0.5H_2O$, are formed in 100 ml solution. If $CaSO_4 \cdot 2H_2O$ does not exist, the solution will be stable, that is, at equilibrium with $CaSO_4 \cdot 0.5H_2O$, and

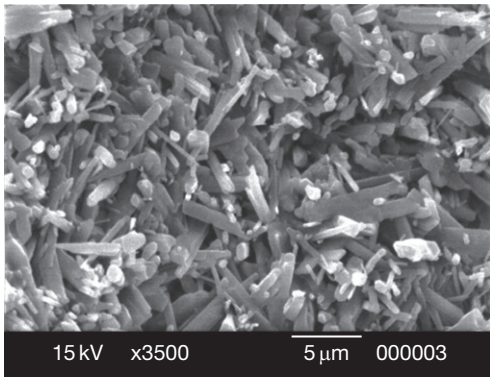

Figure 8 Scanning electron microscopic image of set calcium sulfate hemihydrate.

no further reaction occurs. However, $CaSO_4 \cdot 2H_2O$ exists, and its solubility is 0.2 g/100 ml at 20 °C, as shown in Figure 7.

$$CaSO_4 \cdot 0.5H_2O \rightleftarrows Ca^{2+} + SO_4^{2-} + 0.5H_2O \quad [IV]$$

$$CaSO_4 \cdot 2H_2O \rightleftarrows Ca^{2+} + SO_4^{2-} + 2H_2O \quad [V]$$

This means that the solution that is at equilibrium with $CaSO_4 \cdot 0.5H_2O$ is supersaturated with respect to $CaSO_4 \cdot 2H_2O$. Therefore, Ca^{2+} and SO_4^{2-}, which are equivalent to ~0.72 g $CaSO_4 \cdot 2H_2O$, will precipitate as $CaSO_4 \cdot 2H_2O$ crystals. The precipitation of Ca^{2+} and SO_4^{2-} ions from the liquid results in the undersaturation of the solution to $CaSO_4 \cdot 0.5H_2O$, thus leading to a further dissolution of $CaSO_4 \cdot 0.5H_2O$. In the actual reaction, the concentration of Ca^{2+} and SO_4^{2-} ions does not vary with time and is relatively constant. Anyway, this dissolution–precipitation reaction forms rod-like $CaSO_4 \cdot 2H_2O$ crystals, and the interlocking of these rod-like $CaSO_4 \cdot 2H_2O$ crystals forms the set mass, as shown in Figure 8.

As shown in Figure 7, the difference between the solubility of $CaSO_4 \cdot 0.5H_2O$ and $CaSO_4 \cdot 2H_2O$ becomes smaller with the increase in temperature. As a result of the smaller difference, $CaSO_4 \cdot 0.5H_2O$ does not set at high temperatures of around 100 °C.

Due to the crystal growth of calcium sulfate dihydrate, shown in Figure 8, the plaster exhibits setting expansion, as shown in Figure 9, where setting expansion and absorption expansion are plotted against time after the mixing. Setting expansion is caused by the crystal growth of calcium sulfate dihydrate, as explained earlier. On the other hand, absorption expansion or hygroscopic expansion is observed when the plaster is immersed in aqueous solution during its setting process. The different expansion is explained by the surface tension of water on the crystal surface. When the plaster is allowed to set in the atmosphere, the surrounding water is reduced, and the growing gypsum crystals impinge on the surface of the remaining water, whose surface tension inhibits outward crystal growth. When the water needed for the reaction is used up and the reaction is virtually complete, the growth of gypsum crystals stops, even in its inhibited form.

In contrast, if water is supplied during the setting process, the gypsum crystals can grow further. For absorption expansion, the additional water provided must be presented to the

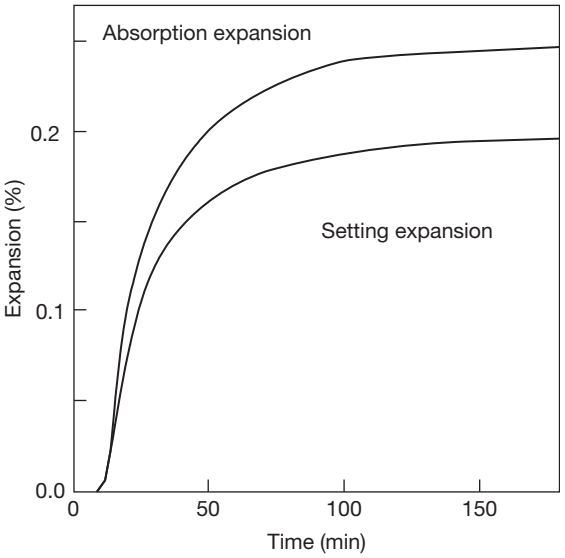

Figure 9 Example of setting and absorption expansion of plaster.

plaster during the setting. This is significantly different than the addition of more water to the premixed plaster.

The setting reaction of the plaster is affected by the additives or by contamination. Some proteins and biological macromolecules are known to retard the setting reaction by preventing full hydration of the hemihydrate, inhibiting seed crystal formation, and forming complexes with the seed crystals.[20,22,24] Contamination of the calcium sulfate with proteins may increase the setting time to 200 min.[25] Also, the set plaster dissolves more quickly in the presence of blood. To minimize the setting retardation and accelerated dissolution, setting accelerators such as NaCl, Na_2SO_4, KCl, and K_2SO_4 are used. However, preset calcium sulfate should be used if the setting cannot be guaranteed.

1.116.2.3. Tissue Response to Calcium Sulfate

Key properties of calcium sulfate are its rapid and complete resorption with minimal inflammatory response.[26–29] Of course, this is due to the high solubility of calcium sulfate dihydrate. Exposure of calcium sulfate paste to blood or body fluids results in significant extension of setting time along with lowered mechanical strength. In addition, washout and heat generation could cause clinical problems and therefore preset calcium sulfate is also used as a calcium sulfate bone substitute.

Replacement of calcium sulfate in bone occurs by the prevention of downgrowth of fibrous connective tissue and resorption of set calcium sulfate, which is followed by formation of bone.

Prevention of downgrowth of fibrous connective tissue or the sealing ability of calcium sulfate may be a common characteristic of cement, but it is an important characteristic, as proved by GTR.[30] The calcium sulfate then disappears from the bone defect. Although the length of resorption varies based on many factors, including the volume, location, accompanying diseases, and setting conditions, it takes ~5–8 weeks.[17,31,32]

Most of the resorption of calcium sulfate is caused by the physicochemical dissolution. However, resorption is accelerated in osteoporosis, indicating that other factors too are involved in the resorption of calcium sulfate.[33,34]

After the resorption of calcium sulfate, new bone is formed from adjacent host bone. The mechanism of bone formation after resorption of calcium sulfate has not been fully elucidated. It may be a complex of many factors. As stated, gradual resorption is thought to contribute to the similar system in GTR. In other words, resorbed calcium sulfate provides space for bone formation. Calcium sulfate also provides a surface to which osteoblasts can attach.[35] The Ca^{2+} that is released upon the dissolution of calcium sulfate can be used as a source of inorganic ions in the formation of new bone.[36,37] Elevated Ca^{2+} concentrations activate osteoblast genesis and function, and they may act as a stimulus in osteoblast differentiation.[20,22] Elevated calcium ion concentrations also exert a mitogenic effect on mesenchymal cells, mediated by the parathyroid/kidney/brain calcium-sensing receptor, PCaR. Similarly, osteoblast proliferation and differentiation, and nodulation of osteoid synthesis are stimulated by elevated calcium ion concentrations.[38]

It has also been found that granular HAp-like calcium phosphate mineral or resorbing calcium sulfate is deposited on the surface.[25,30] The thus-formed HAp-like calcium phosphate mineral may act as an osteoconductive 'trellis.'

1.116.2.4. Clinical Application of Calcium Sulfate

Pure calcium sulfate and its composites with calcium phosphates in the form of preset and cement are available. Many products are available, including Osteoset (Wright Medical Technology, Inc.), BoneGen (Bio-Lok Intl., Inc.), BonePlast (Biomet Inc.), and OsteoCure™ (Tomier Inc.).

Calcium sulfate can be used for the reconstruction of bone defects, to generate bone formation as a GTR membrane, for sinus augmentation, and for ridge preservation. For example, Aichelmann-Reidy evaluated the clinical efficacy of a combination of calcium sulfate as a binder and barrier, and demineralized freeze-dried bone allograft (DFDBA) to polytetrafluoroethylene (ePTFE) and DFDBA for the treatment of human periodontal intrabony defects in each of 19 patients with chronic periodontitis. It was found that calcium sulfate, when used as a binder and barrier in combination with DFDBA, supports significant clinical improvement in intrabony defects, evidenced in the form of reductions in probing depth, gains in clinical attachment level, and defect fill and resolution. The result was slightly better than the ePTTE group, but there was no significant difference.[39]

1.116.3. Portland Cement and MTA

1.116.3.1. History of Portland Cement and MTA

Cement made by heating lime stone and clay was used for large-scale construction of houses at Dadiwan, China around 5800–5400 BC. Many efforts were made to improve the properties of cement that consisted basically of calcined product of lime stone and clay. In 1824, Joseph Aspdin, a British bricklayer, named Portland cement and was granted a patent for the process of making this cement. Portland is derived from Portland stone, a type of building stone that was quarried on the Isle of Portland in Dorset, southern England in the eighteenth century. Due to the self-setting ability of Portland cement, it was used in the past in Egypt to fill bone defects.

MTA, on the other hand, was introduced in 1993 by Mahmoud Torabinejad at Loma Linda University as a dental endodontic cement.[40] The composition of MTA is basically the same as that of Portland cement, except that it has bismuth oxide (Bi_2O_3), which is used as a radiopaque agent. Its clinical application in dentistry has increased rapidly, and several products are available nowadays.

1.116.3.2. Composition of Portland Cement and MTA

There are many types of Portland cement and their compositions are different, depending on the types. However, the European Standard EN197.1 definition goes thus: "Portland cement clinker is a hydraulic material which shall consist of at least two-thirds by mass of calcium silicates ($3CaO{\cdot}SiO_2$ and $2CaO{\cdot}SiO_2$), the remainder consisting of aluminium- and iron-containing clinker phases and other compounds. The ratio of CaO to SiO_2 shall not be < 2.0. The magnesium content (MgO) shall not exceed 5.0% by mass." Tables 1 and 2 show the typical chemical composition of Portland cement and the key components in the Portland cement clinker, respectively. After the raw materials are mixed, they are heated in a cement kiln. The cement kiln rotates slowly with the temperature being

Table 1 Typical chemical composition of Portland cement

Oxide	*CaO*	*SiO_2*	*Al_2O_3*	*Fe_2O_3*	*MgO*	*SO_3*	*($Na_2O + K_2O$)*
Contents (%)	60–67	17–25	3–8	0.5–6	0.1–4	1–3	0.5–1.3

Table 2 Key component in Portland cement clinker

Name	*Composition*	*Code*	*Condition at clinker*	*Reaction rate*	*Heat of hydration ($J\ g^{-1}$)*
Tricalcium silicate	$3CaO{\cdot}SiO_2$	C_3S	Alite	Quick (h)	500
Dicalcium silicate	$2CaO{\cdot}SiO_2$	β-C_2S	Belite	Slow (day)	250
Tricalcium aluminate	$3CaO{\cdot}Al_2O_3$	C_3A	Aluminate	Immediate	850
Tetracalcium aluminoferrite	$4CaO{\cdot}Al_2O_3{\cdot}Fe_2O_3$	C_4AF	Ferrite	Quick (min)	420

increased gradually, to reach 1400–1450 °C in the end. Solid materials produced by the cement kiln stage are called clinker. The cement clinker is crushed, powdered, and added to calcium sulfate to retard the setting reaction, and this mixture is supplied as Portland cement.

The composition of MTA is the same, except for bismuth oxide (Bi_2O_3) which is used as a radiopaque agent. MTA-Angelus® contains 20 wt% bismuth oxide. ProRoot MTA contains 20 wt% bismuth oxide and 5% calcium sulfate.[41] The color of Portland cement is gray. Sometimes, however, gray is not preferred from the esthetic point of view. White MTA is available as ProRoot MTA (white), in which the amount of Fe_2O_3 is reduced.

1.116.3.3. Setting Reaction of Portland Cement and MTA

The setting and hardening reaction of Portland cement is caused by the hydration reaction of the components of the cement, listed in Table 2, with water. MTA shows the same reaction as Portland cement as their compositions are basically the same. For example, the hydration reactions of alite and belite are shown in eqns [VI] and [VII], respectively.

$$2Ca_3SiO_5 + 6H_2O \rightarrow Ca_3Si_2{\cdot}3H_2O + 3Ca(OH)_2 \quad [VI]$$

$$2Ca_2SiO_4 + 4H_2O \rightarrow Ca_3Si_2{\cdot}3H_2O + Ca(OH)_2 \quad [VII]$$

Based on this hydration reaction, amorphous calcium silicate hydrate and calcium hydroxide are formed, as shown in Figure 10, which results in setting and hardening.

1.116.3.4. Tissue Response to Portland Cement and MTA

Portland cement was used in Egypt for the reconstruction of bone defects, and it was discovered that the cement shows osteoconductivity. During the last decade, more attention has been paid to Portland cement, as MTA, in dental fields.[42–44] The composition of Portland cement and MTA is basically the same even though the latter contains bismuth oxide to provide greater radiopacity than dentin.[45] Also, some MTA products contain ~50% gypsum, when compared with the typical Portland cement, to accelerate the setting reaction. The clinical use of MTA in the endodontic field was approved by FDA in 1993.[46]

The advantage of MTA when compared with other dental cements includes its setting expansion. In the case of endodontic treatment, sealing ability, antibacterial effects, and biocompatibility are all equally important. When the cement expands, it increases the sealing ability and is thus beneficial in reducing the bacterial leakage. *In vitro* dye/fluid filtration method leakage studies as well as *in vitro* bacterial leakage studies have demonstrated that MTA allows for less microleakage than traditional dental cements when used as an apical restoration, in fracture repair, and in the treatment of immature apices.

The cytotoxicity evaluation of both freshly mixed and 24-h set MTA extract in human periodontal ligament fibroblasts showed that their cytotoxicity was less when compared to that of amalgam and EBA (ethoxy benzoic acid) cement.[47] It was also found that high pH value of freshly mixed MTA induced cell lysis in L-929 mouse fibroblasts and macrophage cell lines in direct contact with the MTA. However, set MTA demonstrated favorable biocompatibility, with no observed effect on cell morphology, as well as limited impact on cell growth at 72 h.

When the Portland cement and MTA were implanted in bilateral bone cavities prepared at the mandible of pigs, both materials showed the same histological results. At 2 weeks, no noticeable accumulation of inflammatory cells were observed. New bone apposition was observed in direct contact with the materials in both case in the ratio of more than 50% possibility. The remaining case shows new bone apposition on the materials through thin layer of fibrous connective tissue.

Similar histological results are reasonable as the compositions of Portland cement and MTA are almost the same. Although further evaluation of the degree of osteoconductivity is awaited, the usefulness of Portland cement and the need to modify Portland cement-based bioactive cement should be noted.

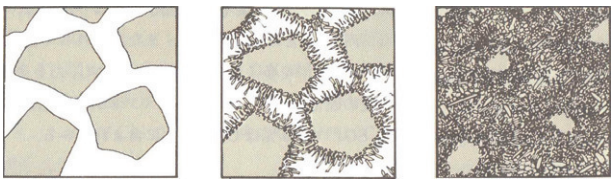

Figure 10 Schematic illustration of the setting and hardening reaction of Portland cement.

1.116.4. Apatite Cement

Although many names have been used so far, apatite cement or HAp cement is used for the calcium phosphate cements, which form apatite following the setting and hardening reaction.

Table 3 summarizes the calcium orthophosphates and their solubility product constants, and Figure 11 summarizes the phase diagram of calcium orthophosphate as a function of pH, using Ca concentration as the solubility index.

In neutral and alkaline regions, apatite is thermodynamically the most stable phase. Therefore, all calcium orthophosphates have the tendency to be precipitated as apatite when suitable conditions are applied. It should be noted that DCPD or brushite, $CaHPO_4{\cdot}2H_2O$ is the most stable phase thermodynamically in acidic regions when pH is 4.3 or lower. Under such conditions, the set cement would be brushite and not apatite.

In 1976, Monma and Kanazawa[2] reported that α-TCP set to form calcium-deficient HAp with Ca/P molar ratio of 1.5 when α-TCP was hydrated in water at 60–100 °C and pH between 8.1 and 11.4 as shown in eqns [VIII] and [IX].

$$3Ca_3(PO_4)_2 + H_2O \rightarrow 3Ca^{2+} + 2PO_4^{3-} + H_2O \quad [VIII]$$

$$3Ca^{2+} + 2PO_4^{3-} + H_2O \rightarrow Ca_9(HPO_4)(PO_4)_5(OH) \quad [IX]$$

Although this was the initial finding of apatite cement, long setting time prevented its clinical use for a long period. To accelerate the initial setting reaction, dicarboxylic acids, such as succinic acid or citric acids[48,49], were employed as liquid phase. In this method, the initial setting is not related to the formation of apatite but based on the formation of a chelate bonding between calcium compound and dicarboxylic acid. Unfortunately, dicarboxylic acid is known to inhibit apatite

Table 3 Calcium orthophosphates and their solubility product constants

Compound	*Abbreviation*	*Chemical formula*	*Ca/P*	*log*Ksp
Monocalcium phosphate monohydrate	MCPM	$Ca(H_2PO_4)_2{\cdot}H_2O$	0.5	Highly soluble
Monocalcium phosphate anhydrous	MCPA	$Ca(H_2PO_4)_2$	0.5	Highly soluble
Dicalcium phosphate dihydrate	DCPD	$CaHPO_4{\cdot}2H_2O$	1.0	6.59
Dicalcium phosphate anhydrous	DCPA	$CaHPO_4$	1.0	6.90
Octacalocium phosphate	OCP	$Ca_8H_2(PO_4)_6{\cdot}5H_2O$	1.33	96.6
α-tricalcium phosphate	α-TCP	$Ca_3(PO_4)_2$	1.5	
β-tricalcium phosphate	β-TCP	$Ca_3(PO_4)_2$	1.5	28.9
Hydroxyapatite	HAP	$Ca_{10}(PO_4)_6(OH)_2$	1.67	116.8
Fluoroapatite	FAP	$Ca_{10}(PO_4)_6F_2$	1.67	121
Tetracalcium phosphate	TTCP	$Ca_4(PO_4)_2O$	2.0	38–44

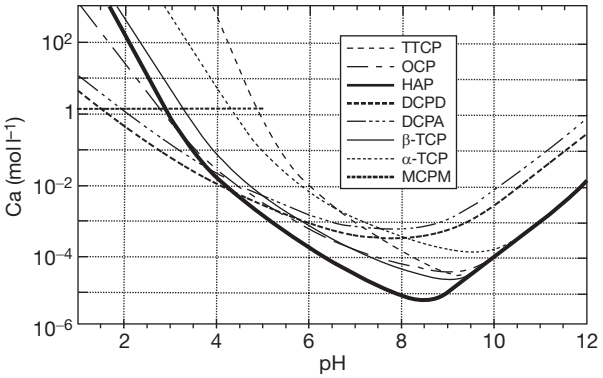

Figure 11 Solubility of Ca in various calcium phosphate compounds versus pH calculated from their solubility products.

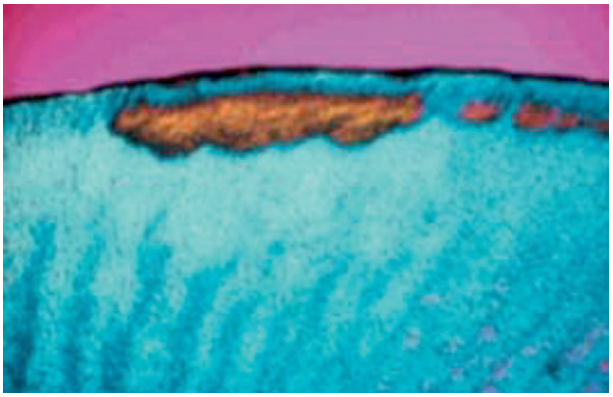

Figure 12 Typical example of subsurface decalcification.

formation. Therefore, compositional transformation from α-TCP to apatite is delayed even when compared to the apatite cement that employs distilled water. However, the amount of calcium phosphates is larger than that of dicarboxylic acid. In other words, dicarboxylic acid is required so that only the surface of the calcium phosphate salt reacts with the acid. Even after the chelate reaction, calcium phosphate under the surface of calcium phosphate particles continues to dissolve to supply Ca^{2+} and PO_4^{3-} ions. As all the dicarboxylic acid has already been used for the chelate reaction with the calcium phosphate salt surface, dissolved Ca^{2+} and PO_4^{3-} ions are supplied to the reaction medium, resulting in supersaturation with respect to Ca-deficient apatite, $Ca_9(HPO_4)(PO_4)_5(OH)$, and thus are precipitated as Ca-deficient apatite crystals. These crystals interlock with each other to harden. The setting reaction of α-TCP cement is exactly the same as that of gypsum when α-TCP cement is free from organic salts.

In 1982, LeGeros *et al.* reported calcium phosphate cement as possible dental restorative material. In 1986, Brown and Chow reported that a mixture of TTCP, and DCPA set within ~30–60 min at physiological temperature and formed apatitic products when mixed with aqueous solution.[3,4]

This apatite cement, which consisted of an equimolar mixture of TTCP and DCPA, was invented independent of the invention by Monma and Kanazawa. Brown and Chow studied the remineralization of decalcified enamel. In the early stage of dental caries, demineralization occurs not on the surface of enamel but below the enamel surface, as shown in Figure 12. At this stage, remineralization is possible if Ca^{2+} and PO_4^{3-} ions can be supplied properly. They chose a TTCP and DCPA mixture to supply Ca^{2+} and PO_4^{3-} ions and found that it set.

Commercially available apatite cements are summarized in Table 4.

1.116.4.1. Setting Reaction of TTCP–DCPA Type Apatite Cement

The setting reaction of apatite cement that consists of an equimolar TTCP and DCPA powder is also the same as that of apatite cement consisting of α-TCP or gypsum, that is, compositional transformation based on a dissolution–precipitation reaction, resulting in the interlocking of the formed apatite crystals. The main difference between the apatite cements consisting of α-TCP and TTCP–DCPA is that the former consist of single calcium phosphate powder whereas the latter consist of two calcium phosphate powders. The Ca/P ratio of TTCP is 2.0 and is higher than that of HAp, which has a Ca/P ratio of 1.67. On the contrary, Ca/P ratio of DCPA is 1.0 and is thus lower than that of HAp.

$$Ca_4(PO_4)_2O + H_2O \rightarrow 4Ca^{2+} + 2PO_4^{3-} + 2OH^- \quad [X]$$

$$CaHPO_4 \rightarrow Ca^{2+} + H^+ + PO_4^{3-} \quad [XI]$$

In the case of two-component apatite cements, Ca^{2+} and PO_4^{3-} ions have to be supplied so that the apatite can be

formed. Unfortunately, the dissolution rate of the calcium phosphate is different. When the dissolution rates of TTCP and DCPA are compared, TTCP dissolves quickly, while the dissolution rate of DCPA is slow. Table 5 summarizes the setting reaction of apatite cement consisting of TTCP and DCPA, with their different particle sizes.

As shown in this table, apatite cement that consists of small TTCP and large DCPA does not set. On the other hand, the mechanical strength of apatite cement increases in relation to the diameter ratio of TTCP/DCPA: apatite cement with the highest TTCP/DCPA diameter ratio or apatite cement with large TTCP and small DCPA affords the highest mechanical strength. The results clearly demonstrate that particle size regulation is very important. As stated above, TTCP dissolves faster than DCPA. Therefore, the combination of large TTCP and small DCPA, or TTCP with small specific surface area and DCPA with large specific area is necessary to minimize the dissolution rate of TTCP and DCPA. In the combination of small TTCP and large DCPA, TTCP dissolves quickly as it has a larger specific surface. Dissolution of TTCP supplies more Ca^{2+} ions and increased pH. At high pH, apatite is still the most stable phase themodynamically. Also the degree of supersaturation with respect to apatite is higher when compared to that at relatively lower pH. Too high a supersaturation results in the formation of amorphous calcium phosphate or small apatite crystals, which are too small to be interlocked with each other. The use of larger TTCP and smaller DCPA allows of proper supersaturation, and thus is the key to TTCP–DCPA type apatite cement.

In any case, the supply of Ca^{2+} and PO_4^{3-} by the dissolution of TTCP and DCPA (eqns [X] and [XI]) results in a supersaturated solution with respect to HAp. Therefore, Ca^{2+} and PO_4^{3-} are precipitated as HAp crystals. The precipitation reaction results in the decrease of the Ca^{2+} and PO_4^{3-} concentration, which elicits a further dissolution of the TTCP and DCPA. The dissolution–precipitation continues until all the TTCP and DCPA are consumed for the precipitation of HAp crystals. The precipitated HAp crystals interlock with each other to set and harden. As the mechanism of the setting and hardening reaction of apatite cement is exactly the same as that of gypsum, hardened apatite cement also shows similar morphology, as shown in Figure 13.

Table 5 Effects of particle size on the diametral tensile compressive strength of calcium phosphate cement consisting of tetracalcium phosphate and dicalcium phosphate anhydrous

Average particle diameter (μm)		*Ratio of the average particle diameter of TTCP/DCP*	*Compressive strength (MPa)*
TTCP	*DCPA*		
1.6	11.9	0.13	0 (no setting)
12.4	11.9	1.04	7.1 ± 1.0
1.6	0.9	1.78	21.8 ± 4.4
12.4	0.9	13.78	51.0 ± 4.5

1.116.4.2. Fast-Setting Apatite Cement

Apatite cement consisting of TTCP and DCPA has become clinically available. However, original apatite cement took

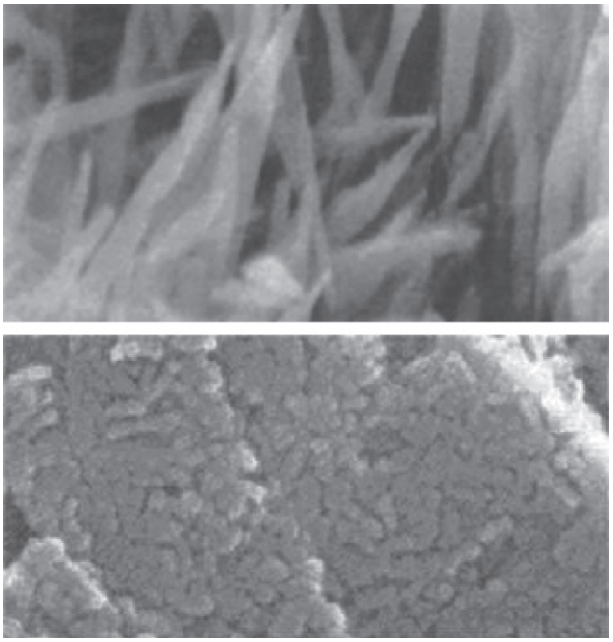

Figure 13 Typical scanning electron microscopic image of apatite cement consisting of tetracalcium phosphate and dicalcium phosphate anhydrous.

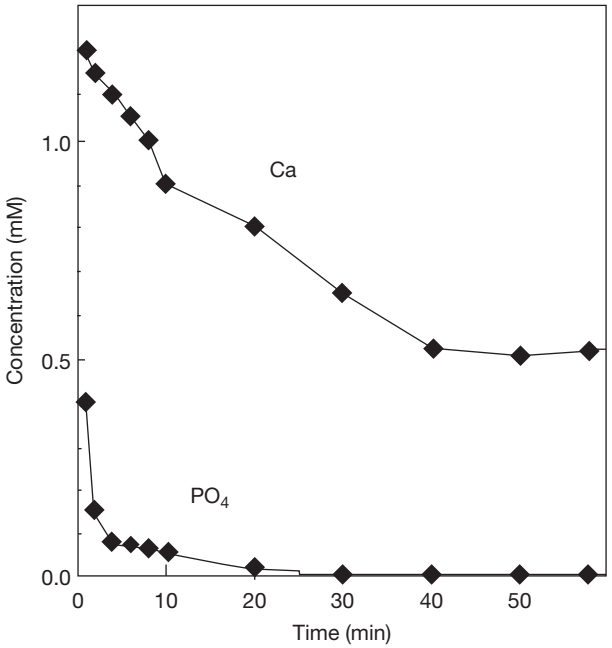

Figure 14 Example of the calcium and phosphate ion concentration in a suspension of apatite cement containing tetracalcium phosphate and dicalcium phosphate anhydrous. Calcium ion kept some concentration whereas phosphate concentration became less than the detection limit with time.

30–60 min to set even though the combination of large TTCP and small DCPA was employed. Setting time of 30–60 min is obviously too long for its clinical use. In addition, apatite cement shows excellent tissue response only when it sets, as stated in the tissue compatibility section. On the contrary, apatite cement causes an inflammatory response known as crystalline inflammatory response when the powders are released into soft tissue. Apatite cement paste can release powder when grazed with covering muscle. As the setting reaction of apatite cement is the same as the setting reaction of gypsum, a similar method can be applied to apatite cement to shorten the setting time. In the case of gypsum, for example, Na_2SO_4 is used as an accelerator. As stated earlier, rod-like crystals of $CaSO_4 \cdot 2H_2O$ are formed because the gypsum suspension is supersaturated with respect to $CaSO_4 \cdot 2H_2O$. Of course, Ca^{2+} and SO_4^{2-} ions have to be supplied for the solution to be supersaturated with respect to $CaSO_4 \cdot 2H_2O$. When Na_2SO_4 is introduced, it increases the ion product of $[Ca^{2+}][SO_4^{2-}]$ by increasing the concentration of SO_4^{2-} ions.

In the case of TTCP–DCPA apatite cement, a combination of large TTCP and small DCPA is employed to minimize the different dissolution rates. However, the dissolution of DCPA is still slower than the dissolution of TTCP, as shown in Figure 14.

In this figure, concentrations of Ca^{2+} and PO_4^{3-} ions in apatite cement suspension were plotted against time. As can be seen, concentration of PO_4^{3-} ions decreased significantly, while Ca^{2+} ion concentration showed a relatively stable value. In the case of cements with more than one component, addition of ions of less concentration is much more efficient. In the case of the TTCP–DCPA cement system, supply of PO_4^{3-} ions based on the dissolution of DCPA is the rate determining step. Note that further reduction of DCPA particle size is not practical as DCPA has already been ground to obtain the smallest particle size.

Table 6 Effects of liquid phase on the setting time of apatite cement that consists of TTCP and DCPA

Liquid	*Concentration (mol l^{-1})*	*Setting time[a] (min)*
Distilled water	–	30–60
$Na_{1.8}H_{1.2}PO_4$	0.2	5
$Na_{1.8}H_{1.2}PO_4$	0.6	5
$Na_{1.8}H_{1.2}PO_4$	1.0	5
$K_{1.8}H_{1.2}PO_4$	0.2	5
$K_{1.8}H_{1.2}PO_4$	0.6	5

[a]Setting time was measured using Vicat needle method at 37° and powder was mixed with liquid at the powder-to-liquid ratio of 4.

Table 6 summarizes the effect of neutral phosphate salt solution on the setting time of TTCP–DCPA apatite cement.[50]

For example, 0.2 mol l^{-1} $Na_{1.8}H_{1.2}PO_4$ aqueous solution was prepared by mixing 0.2 mol l^{-1} Na_2HPO_4 and 0.2 mol l^{-1} NaH_2PO_4 so that its pH became 7.4. Recently, Na_2HPO_4 salt has also been used instead of $Na_{1.8}H_{1.2}PO_4$, for simplicity. Na_2HPO_4 solution is slightly more alkaline than physiological pH, but there is no significant difference on its effect on setting time and the tissue response. As can be seen in Table 6, the setting time of TTCP–DCPA apatite cement shortened significantly from 30–60 to 5 min by employing neutral phosphate salt, regardless of the type and the concentration of neutral phosphate salts. Although the use of neutral phosphate salt solution is the principal method for the regulation of apatite cement, another approach based on the

dissolution– precipitation-based compositional transformation reaction is also possible to shorten the setting time. One such method is the introduction of apatite as seed crystals into the powder phase. Although the effect is limited when compared to the use of neutral phosphate salt solution in liquid phase, addition of the seed apatite into the powder phase allows of freedom for the regulation of liquid phase. Again, the shortening of the setting time, based on seed apatite addition, is the same as gypsum's setting reaction time. In the case of gypsum, the crystals formed by the dissolution–precipitation reaction are $CaSO_4 \cdot 2H_2O$. Therefore, $CaSO_4 \cdot 2H_2O$ is introduced in the powder phase to reduce the setting time. Of course, a shortened setting time is preferable for clinical use.

1.116.4.3. Antiwashout Apatite Cement

Upon the introduction of phosphate salts or dicarboxylic acid, apatite cement becomes less liable to be crumbled. Once apatite cement is hardened, it will not be crumbled. Therefore, apatite cements show excellent tissue response and good osteoconductivity. However, it should be noted that apatite cement takes time to set and the paste would be washed out if it came in contact with body fluid before its initial hardening reaction. Washout of the paste is a problem, especially when the paste is transferred into the bone defect using a syringe or tube as a larger specific surface is exposed to the body fluid.

Two reactions occur in the apatite cement placed in the bone defect, as shown in Figure 15.[51–54]

One is the compositional transformation to apatite based on the dissolution–precipitation reaction. This reaction is the key to the setting of apatite cement and can be accelerated by using neutral phosphate salt solution as the liquid phase. The other reaction is the penetration of the body fluid into the cement paste. This reaction is unavoidable and, unfortunately, induces the washout of the cement paste.

The overall reaction is decided as a result of the two reactions. Therefore, both acceleration of compositional transformation to apatite and inhibition of liquid penetration should be done for the apatite cement to acquire antiwashout property. As stated earlier, compositional transformation to apatite can be accerelated by employing a neutral phosphate salt. Therefore, the other method is the inhibition of body fluid penetration into the cement paste.

One of the effective methods to inhibit the penetration of body fluid into the cement paste is to employ a gelling agent.[51,53,55,56] Components of the cement powder have no bonding with the surrounding powder when the cement is free from the gelling agent. Therefore, body fluid can penetrate into the cement paste because of simple diffusion or osmotic pressure. On the contrary, when a gelling agent is introduced to the liquid phase, cement powder tends to have some bonding strength, even though the bonding strength is very weak. Second, body fluid cannot penetrate easily into the cement paste as the gelling agent that exists between the cement powder prevents such penetration.

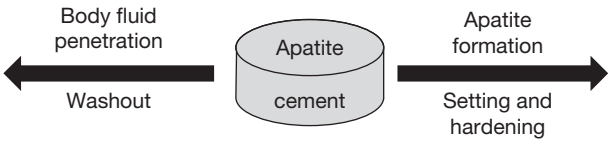

Figure 15 Illustration of the reaction of apatite cement paste when exposed to body fluid. Two different reactions proceeded. Right-hand side, setting and hardening reaction of the cement, which is closely related to cement conversion to apatite. Left-hand side, washout reaction induced by the penetration of body fluid into cement paste.

There are some requirements for the gelling agent to fabricate antiwashout-type apatite cement.

First, the gelling agent should have enough capability to prevent the body fluids from penetrating into the cement. Basically, all gelling agents prevent body fluid penetration into the cement. Therefore, concentration of the gelling agent is the factor.

Second, a gelling agent should enable some bonding between the calcium phosphate particles. For example, sodium alginate forms a weak bonding between the calcium phosphate particles by the formation of calcium alginate.

Third, the gelling agent should not show any toxic response, but instead should show good tissue compatibility. Tissue response depends on the concentration of the added gelling agent. Therefore, the effect of the added gelling agent on tissue response will be minimum when the amount of added gelling agent is small.

Fourth, the gelling agent should not decrease the mechanical strength. However, a slight decrease always occurs, at least with the gelling agents studied till date. Therefore, a slight decrease in mechanical strength should be accepted as acquired antiwashout property has higher priority.

Fifth, addition of gel should not decrease the handling property. With respect to this, the added gel seems to contribute to a better handling property.

Sixth, the gelling agent should not inhibit the conversion of cement to apatite. This is also difficult as basically all gelling agents inhibit the process of dissolution of the calcium phosphate powder as well as the diffusion of Ca^{2+} and PO_4^{3-}. Therefore, acceleration of apatite formation or the hardening process has to be employed at the same time.

Figure 16 summarizes the effect of the gelling agent (sodium alginate) on the antiwashout property of the paste, using the percentage of remaining cement as the index. As shown in this figure, fast-setting apatite cement or apatite cement using neutral sodium phosphate in its liquid phase acquires complete antiwashout property when the liquid phase contains 0.5% sodium alginate.

1.116.4.4. Injectability of Apatite Cement

As the names apatite cement or calcium phosphate cement indicate, the key advantage of the cement is its self-setting reaction. This enables the use of apatite cement with minimum invasive surgery, by using a syringe (Figures 4 and 17). In other words, bone defects can be filled with apatite cement using a syringe needle. In such case, injectability or how easily the cement paste can be injected from the syringe into the bone defect becomes an important factor.

Injectability is governed by many factors, including the syringe needle size. Surely, the use of a syringe with a larger needle diameter allows better injectability. However, the use of

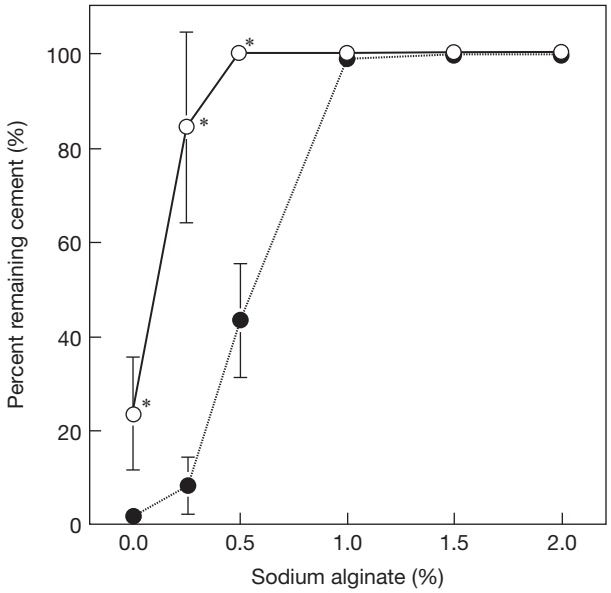

Figure 16 Effect of sodium alginate on the percentage of remaining cement paste after 24 h. The cement paste was immersed in serum at 37 °C immediately after mixing. Open circle employed fast-setting apatite cement as base cement. Closed circle employed conventional apatite cement as base cement.

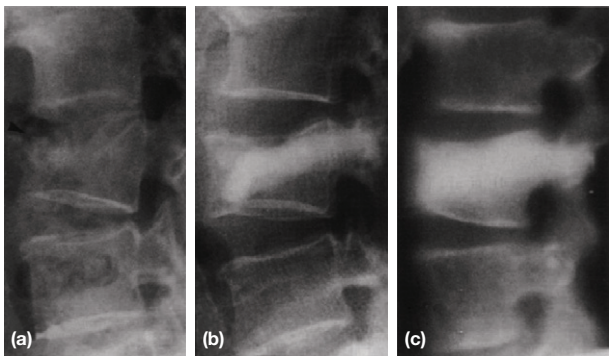

Figure 17 Clinical case of fixation of repositioned compression fracture with apatite cement. Osteoporotic compression fracture of the third lumbar vertebra shown in (a) was reconstructed with apatite cement paste as shown in (b) and (c). Photos courtesy of Kochi Medical University.

a syringe with too large a needle diameter results in less benefit for minimum invasive surgery.

Therefore, fabrication of apatite cement with better injectability is strongly desired. At first, viscosity of the paste should be regulated for the fabrication of injectable apatite cement. Apatite cement paste that is free from gelling agent or viscous additive is very difficult to be injected through a syringe with a small diameter. In such case, pushing the syringe piston results in the selective injection of the paste component from the syringe. In short, the liquid phase is selectively pushed out from the syringe, resulting in the apatite cement powder phase and a smaller liquid phase to remain. This selective injection happens because the syringe needle acts like a filter

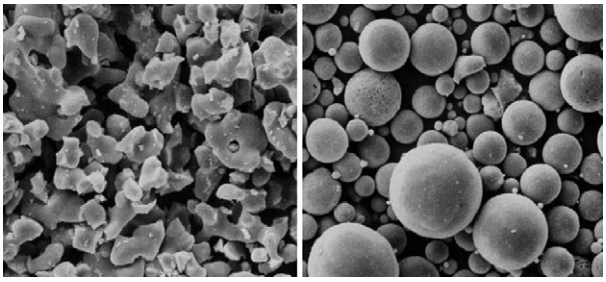

Figure 18 Irregular shape tetracalcium phosphate (left) and spherical tetracalcium phosphate (right) made using the plasma spherical method.

in the absence of a gelling agent. Basically, such a paste, that is, a paste with less liquid, is more difficult to be injected. Therefore, the cement powder phase remains uninjected in the syringe.

When gelling agent is added to the paste, less powder–liquid separation occurs and thus, cement paste is injected when some load is applied on the piston. As expected, the higher the viscosity, the less the powder–liquid separation, which results in higher injectability.

In the case of commercial products, concentration of the gelling agent cannot be regulated by the surgeon. On the other hand, the surgeon can change the liquid-to-powder mixing ratio. A higher liquid-to-powder mixing ratio results in a paste with higher injectability. It should be noted that higher liquid-to-powder mixing ratios result in lower mechanical strength and the paste becomes more sensitive to washout when exposed to body fluid. When apatite cement is injected into bone defect, the paste comes in contact with body fluid. Therefore, the liquid-to-powder mixing ratio should be minimum for better clinical results.

Injectability is also governed by the shape of the powder phase.[57,58] As can be expected, spherically shaped powder is easier to be injected when compared to powder of irregular shape. It is known that the mechanical strength is higher when using powder of irregular shape and the cement sets to form the core-matrix structure. However, the setting reaction of the apatite cement is a dissolution–precipitation reaction and thus, using a spherical powder has no drawback. Figure 18 shows the spherical TTCP, which is a component of TTCP–DCPA type apatite cement. The injectability of apatite cement containing spherical TTCP is known to be much easier when compared to that of apatite cement containing irregular shaped TTCP.

1.116.4.5. Mechanical Strength of Apatite Cement

The mechanical strength of apatite cement is governed by several factors, including powder size, powder-to-liquid mixing ratio, and the type of additives into the liquid and powder phases. Particle size may be the first factor to be regulated for a higher mechanical strength. As stated earlier in Section 1.116.4.2, combination of the particle size so that the supply of necessary ions for the precipitation of apatite is important. In the worst case, the combination of small TTCP and large DCPA would result in the cement not setting even when the Ca/P ratio of the powder was close enough to that of apatite, as shown in Table 6. Therefore, particle size should be regulated so that the particles can supply ions for apatite crystals to grow.

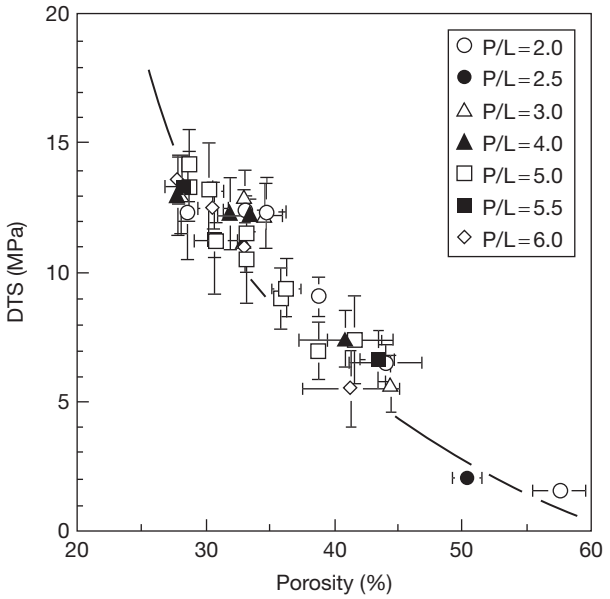

Figure 19 Relationship between wet DTS value and porosity of tetracalcium phosphate–dicalcium phosphate anhydrous type apatite cement specimen kept in an incubator at 37 °C and 100% relative humidity for 24 h.

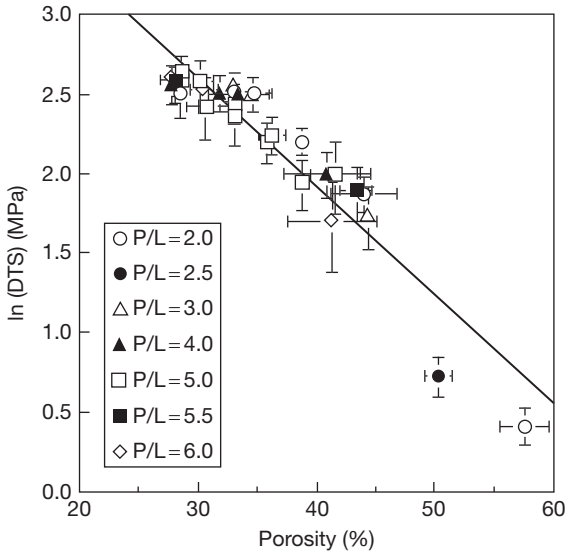

Figure 20 Relationship between logarithm of wet DTS value and porosity of tetracalcium phosphate–dicalcium phosphate anhydrous type apatite cement specimen kept in an incubator at 37 °C and 100% relative humidity for 24 h.

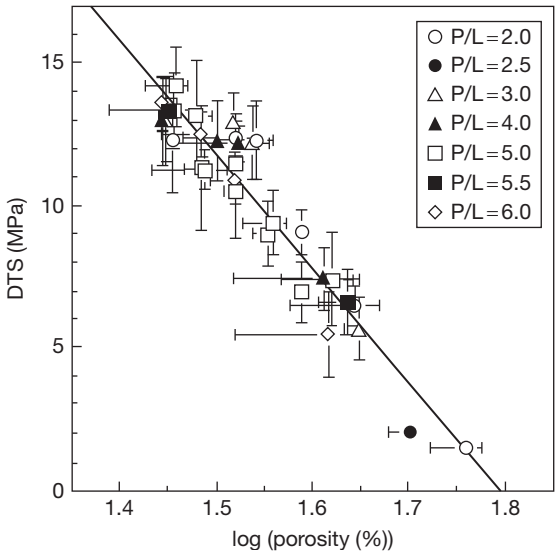

Figure 21 Relationship between wet diametral tensile strength value and the logarithm of the value for the porosity of the apatite cement specimen kept in an incubator at 37 °C and 100% relative humidity for 24 h.

Small particles are used for the component that has a limited dissolution rate. However, it should be noted that small particles result in low bulk density of the powder. In addition, small particles need more liquid to become wet and thus, a large liquid-to-powder mixing ratio becomes necessary to have good handling property. Unfortunately, a larger liquid-to-powder mixing ratio results in less interlocking of the precipitated crystals, which results in a lower mechanical strength.

It has been found that the mechanical strength of TTCP–DCPA type apatite cement is governed by the porosity of the set mass, as shown in **Figure 19**.[59]

An empirical equation for the relationship between the porosity and mechanical strength presented by Duckworth is shown in eqn [1].

$$S = S_0 \exp(-bP) \qquad [1]$$

where S is the observed mechanical strength of the porous material, S_0 is the ideal mechanical strength when there is no porosity, P is the porosity, and b is an empirical constant. By taking the natural logarithm of eqn. [1], eqn. [2] can be obtained:

$$\ln S = \ln S_0 - bP \qquad [2]$$

On the basis of the comparison of the equation obtained from **Figure 20** and eqn. [2], the ideal diametral tensile strength (DTS) value of the TTCP–DCPA type apatite cement is 103 MPa, which is approximately the same as the DTS value of sintered HAp.

Also, critical porosity can be calculated from eqn. [3].

$$S = Q \log (P_{cr}/P) = Q \log P_{cr} - Q \log P \qquad [3]$$

where S is the observed mechanical strength of the porous materials, Q is the strength of the skeleton (called the quality factor), P_{cr} is the critical porosity when S is equal to zero, and P is the porosity. Comparison of eqn [3] with the equation from **Figure 21** shows 62% as the critical porosity.

Addition of inorganic and/or organic materials into the components of apatite cement also affects the mechanical strength of apatite cement. For example, DTS increases when sodium hydrogen phosphate is added into the liquid phase as shown in **Figure 22**.[52]

Although the detailed mechanism of the increased mechanical strength has not been clarified, fast-setting calcium

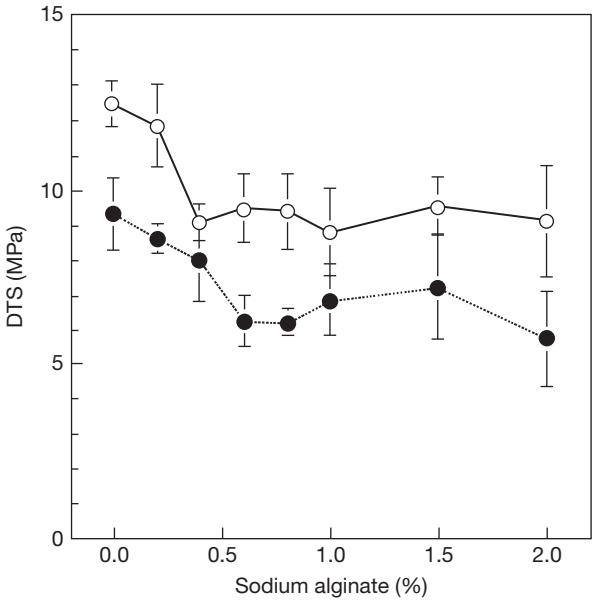

Figure 22 Effect of sodium alginate added to the liquid phase on the wet diametral tensile strength of tetracalcium phosphate–dicalcium phosphate anhydrous type apatite cement after being kept in an incubator at 37°C for 24 h. The powder-to-liquid mixing ratio is 4.0. Open circle: liquid contains 0.2 mol l^{-1} $Na_{1.8}H_{1.2}PO_4$. Close circle: distilled water.

phosphate cement or TTCP–DCPA type apatite cement containing sodium hydrogen phosphate in its liquid phase shows a higher mechanical strength than conventional apatite cement or apatite cement using distilled water as its liquid phase. Incorporation of additional phosphate may contribute to the increased mechanical strength.

On the other hand, organic component introduction usually decreases the mechanical strength. This may be due to the inhibitory effect of apatite crystal growth. For example, antiwashout-type apatite cement containing sodium alginate shows slightly decreased mechanical strength.

It should be emphasized that the addition of a gelling agent is required to obtain antiwashout properties. However, addition of a gelling agent prevents crystal growth and this results in a slight decrease in mechanical strength.

1.116.4.6. Porous Apatite Cement

The importance of macropores in HAp and other biomaterials to enhance bone ingrowth and implant fixation has been pointed out since the early 1970s.[60–63] Especially, macropores (>100 μm) allow ingrowth of bone tissue with Haversian systems and facilitate osteoconduction in the case of calcium phosphates.[64–70]

In the case of apatite cement, *in situ* macroporous fabrication is possible with the use of suitable porogens or macropore-forming materials. Key requirements of porogen are its complete dissolution after implantation and nontoxicity. Also, porogens are expected not to retard the setting reaction significantly. Several porogens have been studied to date, including sucrose, sodium hydrogen carbonate, disodium hydrogen phosphate, mannitol, polyglactin, poly(ε-caprolactone), poly (DL-lactic-*co*-glycolic acid), poly(L-lactic acid), and gelatin.[13–15,66–69,71–82] It should be noted that the mechanical strength of apatite cement decreases significantly with the introduction of macropores. For example, premixed apatite cement consisting of TTCP, DCPA, MCPM, glycerol, and hydroxypropyl methylcellulose (HPMC) shows 6.6 ± 1.8 MPa as flexural strength. However, the value decreases to 3.8 ± 0.3 and 0.7 ± 0.2 when 10% and 40% mannitol is added to the cement.[79] The introduction of bioresorbable fiber, however, contributes to increased mechanical strength. When 25% absorbable fiber (Vicryl) is introduced to the premixed cement, flexural strength increases to 11.7 ± 1.5 MPa. Mannitol-added cement also shows a higher value, 7.3 ± 1.8 MPa (10%) and 7.3 ± 1.8 (40%).[79] It should be noted that bioresorbable fiber acts not only as reinforcement for the cement but also as porogen.

As macropore is effective in tissue response, a balance should be achieved with mechanical strength for its clinical application.

Another aspect of porogen is the possibility that it can be used for drug delivery. So far, porogen has been introduced into the cement only to form macropores. As porogen dissolves at the implanted site, its use in drug delivery may increase the usefulness of porous apatite cement.

Porous apatite can also be made by gas foaming, using gases such as CO_2 and O_2 although problems of the excess gas, such as gas pocket formation and gas embolism need to be solved.[83] For the formation of CO_2, for example, NaH_2PO_4 and $NaHCO_3$ can be reacted.[84–86] For the formation of O_2, decomposition of hydrogen peroxide (H_2O_2) can be used.[87]

Also, surfactant such as sodium dodecyl sulphate[88] and albumen[89] can be used to form the pores in the paste. Because a relatively large amount of surfactant is necessary for the pore formation, tissue compatibility of the surfactant is the key requirement for this method.

1.116.4.7. Premixed Apatite Cement

Setting reactions of apatite cement are initiated when its powder phase is exposed to the liquid phase. Therefore, cement paste should be placed into the bone defect before the setting reaction. Homogeneous mixing and mixing methods that do not to introduce pores are required for a higher mechanical strength. Unfortunately, they are not so easy. Also, the mixing process is a problem for the clinician. In addition, as a ground rule, the powder should be kept out of the operation room to keep the room clean.

Therefore, premixed cement that sets only after the paste has been placed into the bone defect is desired. Premixed cement was initially introduced by Sugawara,[90] and improved later.[79,91,92] Basically, premixed cement consists of (a) calcium phosphate setting components, such as TTCP and DCPA; (b) nonaqueous, but water-miscible, liquid carriers, such as glycerol, poly(ethylene glycol), and poly(propylene glycol); (c) gelling agents, such as HPMC; and (d) hardening accelerators, such as sodium hydrogen phosphate.

Nonaqueous, but water-miscible, liquid is the main component in premixed apatite cement. Due to its nonaqueous property, cement powder is stable even when it is mixed with the liquid. Upon exposure to water, the nonaqueous

solution–water exchange occurs and the cement powder is then exposed to water. Once the cement powder is exposed to water, both TTCP and DCPA dissolve and supply Ca^{2+} and PO_4^{3-}; then, the setting and hardening reaction is initiated. Of course, the exchange of the nonaqueous solution and water cannot occur in the blink of an eye but takes some time. Also, most of the nonaqueous solution adsorbed on the surface of the TTCP and DCPA powder inhibits their dissolution and HAp formation. Therefore, an accelerator is required for premixed apatite cement. Usually, sodium hydrogen phosphate is used as the accelerator due to its neutral pH.[50–52] Also, MCPM is known to accelerate the setting reaction of TTCP–DCPA type apatite cement.[79]

1.116.5. Brushite Cement

1.116.5.1. Setting Reaction of Brushite Cement

Brushite or DCPD is the most thermodynamically stable phase when pH is 4.2 or lower (**Figure 1**). Therefore, a mixture of calcium phosphate powder that supplies Ca^{2+} and PO_4^{3-} ions, and in which the pH of the paste is 4.2 or lower could be brushite cement. One of the key components of brushite cement is β-TCP, and thus, sometimes, brushite cement is also called β-TCP cement. Brushite cement was invented by Lemaitre and coworkers.[5–7] Brushite cement basically consists of β-TCP and MCPM or H_3PO_4 and brushite is formed in the setting reaction, as shown in eqn [XIII].

$$\beta\text{-}Ca_3(PO_4)_2 + Ca(H_2PO_4)_2\cdot H_2O + 7H_2O \rightarrow 4CaHPO_4\cdot 2H_2O \quad [XIII]$$

MCPM is a very acidic calcium phosphate and supplies an acidic environment so that the pH of the cement paste becomes 4.2 or lower. Therefore, not apatite but brushite becomes the most thermodynamically stable phase, and thus brushite is formed. The setting reaction of brushite cement is also a compositional change based on a dissolution–precipitation reaction. Upon mixing with water, MCPM dissolves to supply Ca^{2+}, HPO_4^{3-}, and an acidic condition, as shown in eqn [XIV]. The dissolution occurs immediately after mixing as MCPM is a highly soluble salt. This is one of the main differences between apatite cement whose dissolution reaction takes some time and thus, its setting time is longer when compared to brushite cement. β-TCP does not dissolve immediately even when exposed to water, but β-TCP dissolves immediately in the acidic environment supplied by the dissolution of MCPM, as shown in eqn [XV]. The dissolution of β-TCP consumes protons resulting in the increase of pH, which induces precipitation of brushite, as shown in eqn [XVI],[93] and the precipitated brushite bridges the remaining β-TCP.

$$Ca(H_2PO_4)_2\cdot H_2O \rightarrow Ca^{2+} + 2H^+ + 2HPO_4^{3-} + H_2O \quad [XIV]$$

$$Ca_3(PO_4)_2 + 2H^+ \rightarrow 3Ca^{2+} + 2HPO_4^{3-} \quad [XV]$$

$$Ca(H_2PO_4)_2\cdot H_2O + Ca_3(PO_4)_2 + 7H_2O \rightarrow 4Ca^{2+} + 4HPO_4^{3-} + 8H_2O \rightarrow 4CaHPO_4\cdot 2H_2O \quad [XVI]$$

The use of phosphoric acid instead of MCPM shows asimilar but simpler setting reaction, as shown in eqn [XVII].

$$H_3PO_4 \rightarrow 2H^+ + HPO_4^{3-} \quad [XVII]$$

$$Ca_3(PO_4)_2 + 2H^+ \rightarrow 3Ca^{2+} + 2HPO_4^{3-} \quad [XVIII]$$

$$H_3PO_4 + Ca_3(PO_4)_2 + 6H_2O \rightarrow 3Ca^{2+} + 3HPO_4^{3-} \rightarrow 3CaHPO_4\cdot 2H_2O \quad [XIX]$$

In contrast to apatite cement, which showed a long setting time at the time of initial invention, brushite cement exhibited a rapid setting time even at the time of initial invention. The setting time was 30 s from the initiation of mixing.[6] This may have been due, at least in part, to the higher solubility of calcium phosphate under acidic conditions. Also, the mechanical strength of brushite cement was lower when compared to that of apatite cement. DTS of the brushite cement was low (<1 MPa) and decreased upon prolonged aging in 100% relative humidity at 37–40 °C.[6]

Commercially available brushite cements are summarized in **Table 7**.

1.116.5.2. Effect of Additive on Brushite Cement

Due to its rapid setting time, a retarder was added to the brushite cement. One of the additives is pyrophosphate, which is known to inhibit the nucleation and crystal growth of orthocalcium phosphate.[94] For example, 20 wt% addition of calcium pyrophosphate ($Ca_2P_2O_7$) results in a prolonged setting time: ~5 min. However, the addition of calcium pyrophosphate results in a slight decrease in mechanical strength. Calcium sulfate hemihydrate also prolongs the setting time to ~7 min when 20% of it is added. Interestingly, addition of calcium sulfate hemihydrate with 5 wt% calcium pyrophosphate results in a significant increase in mechanical strength. DTS of calcium sulfate hemihydrate with 5 wt% calcium pyrophosphate shows 3 MPa, which is three times larger when compared to DTS of additive free brushite cement.

Table 7 Example of the commercially available brushite cement and its composition

Registered name	*Powder*	*Liquid*	*Manufacturer*
ChronOS™ Inject	β-TCP(73%) + MCPM(21%) + $MgHPO_4\cdot 3H_2O$(5%) + $MgSO_4$(<1%) + $Na_2H_2P_2O_7$(<1%)	0.5% Sodium hyaluronate Sodium dextran sulfate sulfur 5	Norian
Eurobone®	β-TCP(98%) + $Na_4P_2O_7$(2%)	3 mol l^{-1} H_3PO_4 + 0.1 mol l^{-1} H_2SO_4	Kasios
VitalOs	Component 1: β-TCP(1.34 g) + $Na_2H_2P_2O_7$(0.025 g) 0.05 mol l^{-1} pH7.4 PBS Component 2: MCPM (0.78 g) + $CaSO_4\cdot 2H_2O$ + 0.05 mol l^{-1} H_3PO_4		CalciOs

Citrate and magnesium ions are also known to retard the fast-setting reaction.[95,96] The effect of a retarder was also confirmed by thermal analysis.[97]

When 15 wt% calcium sulfate hemihydrate and 5 wt% calcium pyrophosphate was added to brushite cement, small needle-like crystals were formed instead of rather large tabular brushite crystals. The small needle-like crystals interlocked with the larger β-TCP particles. Although the contribution of calcium sulfate hemihydrate, which is well known as POP, to mechanical strength has not been quantified yet, small brushite crystals are also thought to contribute to higher mechanical strength.

1.116.5.3. Tissue Response to Brushite Cement

The key tissue response of brushite cement is its rapid and complete resorption, which is similar to that of calcium sulfate. Initially, brushite cement attracted less attention than apatite cement because it is not brushite but apatite that is the inorganic component of the bone. Also, the weaker mechanical strength and rapid physicochemical dissolution of brushite are thought to be inferior to those of apatite cement. However, *in vitro* and *in vivo* studies have demonstrated that brushite cement was generally well tolerated by the bone and soft tissue environment.[98,99] When bone defect is reconstructed using brushite cement, the brushite dissolves slightly as the body fluid is undersaturated with respect to brushite or DCPD. Dissolution of brushite, which is the acidic calcium phosphate, reduces the pH, and this results in the activation of macrophage. Then, the phagocytic resorption of the hardened brushite cement is effected by mononuclear macrophage. After the phagocytic resorption, carbonate apatite is formed at the bone defect. In contrast to the phagocytic response to brushite, osteoclastic resorption becomes dominant after brushite is converted to carbonate apatite.[98]

It should be noted that the reaction of brushite cement is different up to the implant location. When brushite cement was used for the reconstruction of metaphyseal defects, part of the brushite cement was converted to carbonate apatite in 2 weeks. In contrast, brushite cement used for the reconstruction of diaphyseal defect begins to convert to another calcium phosphate phase only in 4 weeks. Although the mechanisms of these different reactions have not been understood to date, decreased vascular supply in the case of cements in the diaphysis compared with cements implanted in the metaphysis may be one of the reasons. It is assumed that a more active metabolic state, more blood flow, and a higher cement-specific area may be favorable for the higher conversion rate of brushite to carbonate apatite.

1.116.6. Future Direction

The invention of bioactive cements is one of the breakthroughs for biomaterials aimed at the reconstruction of bone defects. Although newly developed bioactive cement provides a number of benefits to patients, much remains to be studied. Future studies should be conducted with a full understanding of the clinical needs and of the findings from previous studies. Obviously, development and improvement of biomaterials should be the primary focus for the benefit and well-being of the patients. Clinicians have lots of information regarding the bioactive cements to be developed and how the current bioactive cements can be improved. MTA, one of the hottest topics in dentistry, may be a good example. In endodontic treatment, the cement's sealing ability and its antibacterial effects are important, as well as its biocompatibility. MTA, which has the same composition as Portland cement, except for the inclusion of radiopaque agent, was found to be ideal for endodontic cement. Initially, gray-colored Portland cement was used as it was. However, gray is not preferable for aesthetic reasons, so white MTA was developed by reducing the content of Fe_2O_3. This modification can be done easily as endodontic cement does not require high mechanical strength. However, this improvement cannot be made without an understanding of the needs of the clinician.

A number of improvements have also to be made in the properties of apatite cements. One of them may be increasing their mechanical strength for wider clinical applications. Some increase could be made possible by the introduction of the already established calcium sulfate technology. Further increase could also be possible by introducing the already established Portland cement technology. In other words, the core-matrix structure observed in Portland cement may be required as the mechanical strength of simple apatite cement is basically governed by the porosity. Not only higher mechanical strength but also flexibility may be preferable for apatite cement. To overcome the brittleness, a composite with collagen is being attempted. However, the current study level may still be far from inventing the ideal cement. Introduction of the concept of 'itacolumite,' which is known as flexible or bendable stone, may be interesting. In such a scenario, future bioactive cement study should be based not only on the harmonious collaboration of material scientists and clinicians, but also on an understanding of the way of nature.

1.117.1. Phosphate Glasses: Physical Properties and Processing

1.117.1.1. Introduction

Phosphate-based glasses are a unique glass system with properties that are not found in other glass systems. They possess, in general, a low dispersity and a high refractive index, and these properties have driven the development of phosphate glasses for optical use. Early work led to their development as achromatic optical components. As the use of optics diverged, it became apparent that phosphate-based glasses also had excellent UV transmission properties. Additionally, fluoride-containing phosphate glasses, doped with rare earth ions, were found to possess considerable applicability in optical and laser use due to their low absorption at particular frequencies.[1–3] However, for all of this work, one of the factors that

limited the widespread uptake of optical phosphate-based glasses was their poor chemical durability.[4] In particular, they can undergo complete breakdown of their structure and thus are completely degradable. However, this fact coupled with the simplicity with which these glasses can be synthesized (having generally, relatively low melting temperatures) has driven their use in a wide variety of other applications, particularly where this reactivity could be utilized. These areas include agriculture and water treatment.

More specialized optical applications have utilized phosphate-based glasses and these include lasers, and in particular, high-powered lasers. More recently, these glasses have also extended their use to more unusual areas such as glass to metal seals, where their high thermal expansion coefficients may be exploited[5]; as discussed in an excellent review by Brow.[6] Zinc phosphates, with unusually low processing temperatures, and iron phosphates, which have excellent chemical durability and low processing temperatures, lend themselves to utilization in the encapsulation of nuclear waste. Interestingly, various compositions of phosphate glasses have been investigated with the goal of vitrifying nuclear waste. Recently, iron-phosphate glass has come to the forefront of this application as a possible solution. Currently, only borosilicate glass has been approved by the US Department of Energy to vitrify high-level nuclear waste. Related to this, iron-phosphate glass with good chemical durability is able to accept more types of nuclear waste and up to 6 times more nuclear waste per unit volume, compared to borosilicate glasses.[7,8]

It is the combination of degradability and control over the rate of the degradation of these materials that makes them so attractive and is driving their development for biomedical use. In this chapter, we focus on their biomedical applications.

1.117.1.2. Glass Synthesis

1.117.1.2.1. Melt-derived glasses

Phosphate-based glasses produced by the conventional melting route are extremely simple to synthesize. The components used are low cost, even for high purity, and the melting temperature required is relatively low. As with most glasses, when melting, rather than using the pure oxides themselves (e.g., sodium oxide (Na_2O) or calcium (CaO)), they tend to be utilized in a different form, such as the carbonate. The starting point is the network-forming oxide (in this case phosphorous pentoxide) which, due to its extreme reactivity, is not usually added in pure form as it absorbs water very rapidly. It is also extremely volatile and can result in significant losses during melting and an altered composition. It is usual to add the phosphate combined with one of the other oxides, for example, NaH_2PO_4. This may be simply thought of as giving:

$$2NaH_2PO_4 \rightarrow Na_2O + P_2O_5 + 2H_2O$$

Thus it contributes to both the addition of Na_2O and P_2O_5. Any residual P_2O_5 that may be required can be added, as the pure oxide and should be added quickly and into a sealed container, in order to minimize water absorption which can be rapid and very exothermic. Once all the components have been thoroughly mixed and added to a suitable refractory container, (e.g., a platinum crucible) the crucible can be placed into the furnace. It is usual to place the crucible directly inside a hot furnace that has already been set to the appropriate melting temperature. This will result in rapid degassing (see equation above) and melting of the components. In general, the melt needs no more than an hour at the melting temperature to produce a homogeneous melt. The degassing that occurs either from loss of water as above or from other sources, for example,

$$CaCO_3 \rightarrow CaO + CO_2$$

can be significantly beneficial to the melt as the loss of gas helps to mix the glass melt and ensure homogeneity. It should be noted that some care should be taken when choosing precursors, as the production of large amounts of gaseous products can cause the melt to extrude over the crucible lip. The melt can now be poured into a preheated split mould constructed of graphite or steel (with a graphite release spray), the mould is then returned to a furnace to anneal and slowly cool the cast glass to produce the desired object in a stress-free form. Alternatively, the glass can be poured directly onto a cold steel plate to give the glass in a cullet form for further processing or measurement.

1.117.1.2.2. Sol–gel derived methods

The sol–gel method offers some significant advantages compared to the melt-derived route in the preparation of phosphate-based glasses and other sol–gel systems as covered in **Chapter 4.428, Sol–Gel Processed Oxide Controlled Release Materials**. However, the chemistry of sol–gel-derived phosphate-based glasses appears to be much more complex compared to the equivalent silicate-based glasses produced by the sol–gel route. While both the silicate- and phosphate-based glasses are based on tetrahedral units, they exhibit significantly different behavior in solution. The monophosphate unit $(PO_4)^{3-}$ is a good glass former but unlike the $(SiO^4)^{4-}$ unit, is not a good gel former. There are a number of possible precursors that may be considered, for example, phosphoric acid (H_3PO_4), but it is highly reactive with water and precipitates, as opposed to the required gelation. Phosphate esters ($PO(OR)_3$), where R = Methyl, Ethyl, or Butyl, can also be considered, but their rate of hydrolysis being extremely slow they are impractical. Alkyl phosphates $(OP(OR)_x(OH)_{3-x}$ where $x = 1, 2$), or phosphoryl chloride ($POCl_3$) could also be used.[9]

To prepare a mixture of mono- and diethyl phosphates, phosphorous pentoxide should be dissolved in ethanol via the following reaction:

$$P_2O_5 + 3EtOH \rightarrow OP(OEt)(OH)_2 + OP(OEt)_2(OH)$$

Using anhydrous inert conditions and dry glassware, ethanol is added dropwise to P_2O_5. This reaction is exothermic and so needs cooling to prevent the loss of ethanol. Refluxing at 78.5 °C for 24 h gives the required precursors. From this point, the phosphate sol may be prepared by adding the appropriate amounts of sodium ethoxide and/or calcium methoxide dissolved in ethylene glycol. Once dissolved, the mixture is then gelled (and this can take up to 2 weeks) followed by drying and a final calcination stage.

More recently,[10] a much more satisfactory reaction has been developed based on the utilization of *n*-butyl phosphate

in conjunction with titanium isopropoxide, and this was specifically used to synthesize glasses with very high TiO_2 content in the $TiO_2 - P_2O_5$ binary system. This particular system is of great interest as it allows compositions to be synthesized that are not normally achievable via the melt-derived route as TiO_2 is very refractory and difficult to get into solution even at high melting temperatures.

The initial step is to react titanium isopropoxide with 2-methoxyethanol. To this, *n*-butyl phosphate is added, very slowly. Once these have been allowed to react, an H_2O/HCl mixture in a solvent is added as an acid catalyst. This reaction may also be carried out as a base catalyzed reaction with *n*-butyl phosphate dissolved in *n*-butanol followed by addition of the titanium isopropoxide. The base catalyst used is ammonia in water with a solvent. These reaction routes are much more satisfactory, with gelation times of <5 min.

This methodology has also been successfully applied to the more complex ternary systems described initially in this section.[11] Using a mixture of mono- and di-substituted *n*-butyl phosphate $(OP(OH)_2(Bu^n)$ and $OP(OH)OBu^n)_2$, this is added to the sodium methoxide and allowed to react and then the calcium methoxide is added. This sol is then allowed to gel for 2 h. It is then aged at 60 °C for a week and dried at 120 °C for a further 2 weeks. It should be noted that the final calcination temperature is extremely low at 250 °C.

1.117.1.3. Phosphate Glass Structure and Q Speciation

As with all conventional glasses, the structural starting point is the network-forming oxide, which in this case, is a network built up of regular orthophosphate tetrahedra. However, in pure phosphate-based glasses, the tetrahedra have three bridging oxygens and a double-bonded nonbridging oxygen. This limits the speciation to a maximum of 3, compared to silica, which has a maximum of 4. Using the Q^i annotation, this maximum of Q^3 thus limits the degree of cross-linking possible within the glass structure and thus contributes to the relatively low resistance of phosphate glasses to water attack. Unlike silica, while of significant fundamental research interest, pure P_2O_5 has little use as a commercial glass due to its extreme reactivity in the presence of moisture. Much of the development work carried out is focused on reducing this reactivity and limiting or controlling the degradation rate.

Thus at the starting point, pure vitreous P_2O_5 consists almost entirely of Q^3 units. To aid in the understanding of the structural changes, initially, the focus will be on simple binary systems and the effects that the addition of modifying oxides and in particular the role of oxides of alkali metals or R_2O type oxides (i.e., oxides of metals from Group I in the Periodic Table), have on glass structure. The addition of R_2O gives rise to depolymerization of the phosphate network and initially the formation of Q^2 units and the loss of Q^3. The formation (and associated loss) follows simple predictions[6] which have also been proven experimentally.[12,13] The region of the compositional range, wherein the R_2O constitutes 50% or less of the total is deemed an ultraphosphate. At the point where the R_2O content is equal to 50%, this glass is deemed a metaphosphate and consists of a phosphorous-oxygen network that is based entirely on Q^2 units. As the incorporation of more R_2O into the glass melt is continued, further depolymerization occurs and the Q^2 chains are now terminated by Q^1 tetrahedra. With further increase in the R_2O content, the ratio of Q^2 units within a chain and the Q^1 termination units change as more and more Q^1 units are formed. When the amount of R_2O constitutes two-thirds of the total glass, the network consists of phosphate dimers, that is, two linked Q^1 tetrahedra. Further addition now results in complete depolymerization and the breakdown of the dimers into individual Q^0 orthophosphate units.

It should be noted that there is no simple linear relationship between composition and dissolution rate in a simple binary system such as $Na_2O-P_2O_5$. Gao *et al.*[14,15] showed that, in this system, the initial dissolution rate for glass in the metaphosphate region, that is, $0.5Na_2O-0.5P_2O_5$ is extremely high and is of the order of $20\,g\,cm^{-2}day^{-1}$. It should be remembered that the metaphosphate composition should consist almost entirely of Q^2 tetrahedra and hence will have infinitely long chains.[12] Increasing the P_2O_5 content by 10 mol% $(0.4Na_2O-0.6P_2O_5)$ into the ultraphosphate region should show the development of Q^3 tetrahedra at the expense of the Q^2 units and the dissolution rate decreases by over four orders of magnitude to $2\,mg\,cm^{-2}day^{-1}$. However, a continued increase in P_2O_5 content $(0.3Na_2O-0.7P_2O_5)$, at the expense of Na_2O, shows an increase in dissolution rate. The initial decrease in dissolution rate may be explained by the increasing numbers of bridging oxygens and branches that occur in the structure and this increasing complexity decreases the aqueous diffusion velocity and hence the reduction in dissolution. This does not explain why, with further additions of P_2O_5 an increase in dissolution rate is seen, and this has been explained by consideration of the resonance stability and its lack thereof.[16]

The complexity increases when considering the role of adding the oxides of alkaline earth metals (i.e., oxides of metals from Group 2 of the Periodic Table) which is due to the 2+ charge associated with them. Generally, it can be seen that replacing R_2O with RO results in an increase in durability of the glass or a decrease in the dissolution rate.[14,15] A recent detailed study by Walter *et al.*[17] investigated the short, medium, and submicroscopic structural features of the $MgO-P_2O_5$ glass system using a combination of X-ray and neutron scattering, in conjunction with ^{31}P magic angle spinning nuclear magnetic resonance (MAS-NMR) as well as the more conventional techniques of differential thermal analysis, to measure bulk properties such as glass transition temperatures. The glass transition temperature shows a clear linear relationship with composition, within the range studied. There is little change seen in both the $P-O_t$ and $P-O_b$ bond lengths with increasing MgO content, but the coordination number increases for the $P-O_t$ bond and decreases for the $P-O_b$ bond. According to van Wazer,[18] phosphate structural units can react according to:

$$2Q^2 \leftrightarrow Q^3 + Q^1$$

$$2Q^1 \leftrightarrow Q^2 + Q^0$$

Excellent agreement was seen by van Wazer between the metaphosphate composition and up to an $MgO:P_2O_5$ ratio of 1.5. However, above this ratio, when a decrease in Q^2 and a concomitant increase in Q^1 were expected, the presence of Q^0 is also actually seen and this is explained by the disproportionation, which is in accordance with the second reaction above.

The change in coordination number was confirmed by MAS-NMR, which shows a decrease in the proportion of Q^2.

1.117.1.4. Ternary Glass Systems

The binary systems described above give us a simple and controlled insight into the effect of additions on the overall phosphate network. Both the $Na_2O-P_2O_5$ and $CaO-P_2O_5$ systems are limited in the compositional variation that can be applied and also show either excessive dissolution rates or are difficult to process due to high thermal expansion coefficients, respectively. To move to more practical systems, it is necessary to increase the complexity and utilize ternary systems. Obviously, the number of systems now available increases significantly and it is our intention to focus on one ternary system that is of biomedical interest, namely that based on the $Na_2O-CaO-P_2O_5$ system.

The immediate logic in utilizing this system for biomedical use can be seen in the composition, as it contains elements that are present throughout the body at relatively high levels and so should be biocompatible. The majority of the work in literature has concentrated on glasses with P_2O_5 contents in the 40–60 mol% range. With contents <40 mol%, there are difficulties in obtaining a homogeneous melt as there is insufficient network former present and contents higher than 60 mol% do not allow sufficient modifying oxides to be added to give the required dissolution (and hence biological) properties. Substitution of the monovalent metal oxide (Na_2O) with the divalent metal oxide (CaO) gives rise to a significant decrease in the dissolution rate of the glass.[14] Examining the compositions around the metaphosphate region[19,20] showed expected relationships in terms of Q speciation and phosphate content. At the metaphosphate composition (i.e., 50 mol% P_2O_5), the glass consists almost entirely of Q^2 tetrahedra. However, there are some small amounts of Q^1 tetrahedra present and this would be expected as the theory states the chains are infinitely long; but in practice they must be terminated, and hence the presence of the small amounts of Q^1. In the ultraphosphate region, that is, at P_2O_5 contents of 55 mol%, again the structure is dominated by Q^2 speciation. Below the metaphosphate composition (45 mol% P_2O_5), the development of significant amounts of Q^1 tetrahedra is seen. However, within the glasses investigated, it can also be seen that the variation in the amounts of CaO and Na_2O also affects the Q speciation with increasing CaO content giving rise to increasing Q^2.

1.117.1.5. Phosphate Glass Degradation: General Concepts

The chemical durability of phosphate-based glasses is dependent on a number of factors, including the thermal history of the glass, the degradation medium in which the glass is placed and environmental conditions such as temperature. However, the most dominant factor is the composition of the glass. There are two well-known interdependent steps that take place during the degradation of phosphate-based glasses and they are analogous to the processes seen in silicate-based glasses[21] Figure 1).

The first of these reactions is a hydration reaction and involves the exchange of Na^+ with H^+ ions. This also leaves

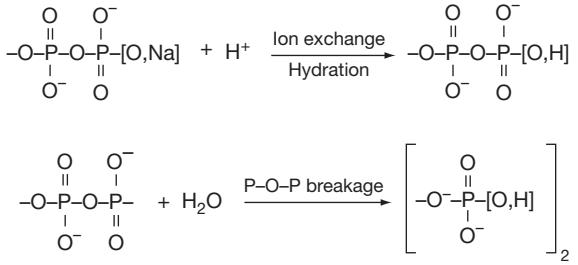

Figure 1 The two interdependent steps in the hydration process in phosphate-based glasses.

an excess of OH^- ions in solution and may account for any initial increases seen in pH.[22] The second stage is concerned with breakage of the phosphorous-oxygen network by hydrogen ions and water molecules. This causes the release of the phosphate chains and molecules into solution. It was proposed by Bunker *et al.*[23] that the dominating reaction was the first one and that the dissolution rate had two kinetic periods. One was proportional to the square root of time and in the second, the mass loss was proportional to time. Bunker also proposed that the dissolution was such that all components in the glass were released at the same time, that is, the solution composition would represent the bulk glass composition at any point in time. However, Gao and coworkers[14,15] indicated that the dominant reaction was the breakdown of the phosphate network and supported the theory of Bunker that dissolution was congruent. However, their work did not measure actual ion release and so this cannot be concluded.

1.117.1.5.1. Ternary glass degradation

Significant work has been carried out to understand the relationship between composition and degradation. In particular, with the advent of new measurement methodologies, not only has it become possible to measure the simple ionic species released but it has also become possible to measure, at least, the more simple mono and polyphosphates released from the glass with time. Recent work investigating glasses with the metaphosphate composition showed clear relationships between glass composition and degradation properties. For glasses in the range $50P_2O_5-(50-x)CaO-xNa_2O$, where x varies from 0 to 50 mol%, with increasing CaO content, the dissolution rate decreased significantly (by over three orders of magnitude). The sodium and calcium ion release also showed a decrease in release rate with increasing CaO content.

The work by Ahmed and coworkers[19,20] gives useful comparative data on the degradation phenomena for compositions on either side of the metaphosphate composition. Glasses below the metaphosphate composition (i.e., <50 mol% P_2O_5 content) showed an initial pH increase and then a slow decrease with time when measured in ultrapure water. Metaphosphate and higher compositions, however, showed a decrease in pH with time.

1.117.1.5.2. Phosphate glass dopants: Control of dissolution rate

A significant amount of work has been carried out to determine the role of dopants on the structure and properties of

phosphate-based glasses and, in particular, to reduce the dissolution rate, as will be discussed later. Three main dopants have been investigated, Al_2O_3, Fe_2O_3, and TiO_2. These are oxides of metals with high valency and this high valency has a significant effect on the glass structure and subsequent physical properties. The utilization of X-ray absorption near edge structure (XANES) analysis gives significant information concerning the structural environment of the titanium ions,[24] and allows elucidation as to whether the titanium is in four, five, or sixfold coordination.

A more detailed study of the role of Fe_2O_3 on the structure of glass was carried out by Qiu *et al.*[25] and they utilized a combination of extended X-ray absorption fine structure (EXAFS) and XANES, with XANES providing coordination and redox state information and EXAFS providing an insight into the local atomic information such as the Fe−O bond length.[26] For glasses in the metaphosphate region with Fe_2O_3 additions up to 5 mol%, the iron is in the Fe(III) oxidation state and has a distorted octahedral coordination geometry.[25] Looking in more detail at the structural information obtained, and in particular the Fe. . .P bond distance, it was inferred that the Fe atoms are incorporated as cross-links into the phosphate network between the phosphate tetrahedra of neighboring metaphosphate-like chains. This translates into a strengthening of the glass network and manifests itself as a significant decrease in the dissolution rate of the glasses.

1.117.1.5.3. Phosphate glass dopants: Additives for antibacterial use

While a number of elements are known to be antibacterial, some are relatively weak in their action. Probably the best known are silver and copper (which has also been discussed in detail in **Chapter 1.118, Calcium Phosphate Ceramics with Inorganic Additives**) and (to a lesser extent) gallium. The exact mechanisms of action for silver and copper have not been elucidated,[27] but it has been suggested that they block an enzyme involved in bacterial respiration. Silver can also bind to DNA. Copper-containing phosphate glasses were originally developed for trace element supplementation in ruminants[28] and also as molluscicides.[29] More recent work has attempted to investigate copper in more complex bacterial biofilm systems that contain single species cultures of *Streptococcus sanguis*.[30] A significant reduction in the number of colony forming units (CFU) can be seen and this improves with increasing copper content up to 24 h. However, if the experiment is extended, this becomes less significant with time and this is a direct reflection of the more complex experiment that was carried out in a constant depth film fermentor designed for conducting biofilm type experiments. This work was extended to investigate the role of silver on single species biofilms.[31] It showed that silver is a much more potent antibacterial ion compared to copper for *S. sanguis*, with only 5 mol% silver causing a 1−1.5 log reduction in CFUs at 6 h. Again, however, when the long-term biofilm experiments were carried out, a significant reduction in CFUs to almost zero was seen at 48 h. After 48 h, however, and for glass containing 10 mol% silver, there was a significant regrowth of bacteria, similar to almost the same level as for the control samples. This regrowth was explained and subsequently imaged (see **Figure 2**) using confocal laser scanning microscopy and quantified[32] as being due to the formation of a dead bacterial layer through which further ion diffusion was hindered, allowing bacteria to continue to grow.

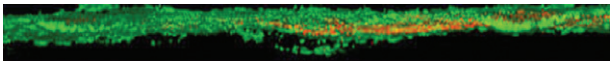

Figure 2 A cross-sectional view of the *S. aureus* biofilm on 20 mol% silver-doped PBGs. Viable (green) and nonviable (red) bacteria.

Further work[32,33] confirmed the effect of silver ions on a host of organisms including methicillin-resistant *Staphylococcus aureus* (MRSA) and the common yeast, *Candida albicans*, as well as the highly resistant *S. aureus*.

Gallium, as an antibacterial agent, functions in a very different way and offers some intriguing possibilities as an antibacterial ion. Infecting bacteria require Fe for growth and proper functioning of key enzymes. Gallium has an ionic radius almost identical to Fe and a similar charge, and thus, bacteria cannot distinguish between Fe^{3+} and Ga^{3+} and so Ga is actively taken up. However, Ga^{3+} cannot be reduced under the same conditions and so the Fe^{3+}-dependent processes are disrupted.[34] Addition of Ga does not change the Q speciation with the expected presence of Q^2 and some Q^1 for glasses with 45 mol% P_2O_5. The utilization of a Ga k-edge XANES coupled with the more unusual ^{71}Ga NMR[35,36] yielded information about the coordination compared to reference spectra for octahedrally coordinated Ga.

1.117.1.6. Processing of Phosphate Glass Fibers

Phosphate-based glasses readily lend themselves to melting and subsequent processing into a variety of forms and this is due to their low melting point, as already mentioned. They also have a relatively large processing window and do not readily crystallize, and thus, further heat treatments may be easily applied. In particular, they have been developed as glass fibers and this has been driven by an interest from the optoelectronics field. Microstructured optical fibers have been developed[37] that have utilized phosphate-based glasses due to their ability to solubilize rare earth components such as ytterbium, which give the fibers their high light absorption and amplification per unit length.[38] The processing of fibers for biomedical use would seem to be an interesting area for development. Fibers with controllable degradation can be utilized to suit the end application, a property not readily achievable with polymeric materials. Initial work utilized data from the glasses and from the structural studies[19] to develop ternary Na_2O−CaO−P_2O_5-based fibers. It is immediately apparent (and obviously so) that the glass structure and, in particular, the Q speciation exert significant control as to whether the glass will form fibers or otherwise.[20] Glasses with compositions below the metaphosphate region could not be converted into fibers. Glasses at the metaphosphate region and above could be readily converted to fibers due to the more polymeric nature of these glasses. Fibers were readily drawn with diameters ranging from ∼40 μm down to 10−12 μm, with both fiber diameter and composition exerting a significant control over the dissolution rate. For example, fibers with a $0.2Na_2O$−$0.3CaO$−$0.5P_2O_5$ composition and ∼37 μm diameter had a dissolution rate of ∼2 mg g^{-1} day^{-1}, but those with ∼17 μm had dissolution

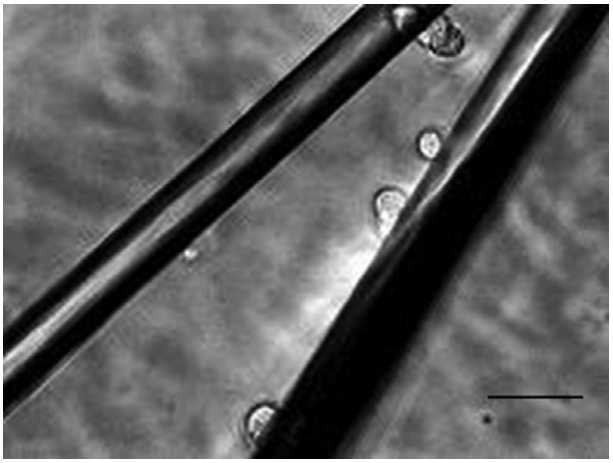

Figure 3 Bovine articular chondrocytes attached after 24 h to glass fibers containing 3% Fe (scale bar = 50 μm).

rate of 7 mg $g^{-1}day^{-1}$. From a biological perspective, these fibers are too soluble as work carried out to investigate the *in vitro* biological properties of the bulk glasses showed that only glasses with very high CaO content did not inhibit cell proliferation. Thus the further development of these fibers centered around the inclusion of dopants that can reduce their dissolution rate.

Phosphate-based fibers of the generic composition $(CaO)_{0.46}-(Na_2O)_n-(Fe_2O_3)_y-(P_2O_5)_{0.50}$ have been evaluated *in vitro* as three-dimensional scaffolds for tissue engineering at the hard–soft tissue interface by assessing fiber solubility and growth and functional gene expression of human cells.[39] Primary human osteoblasts and fibroblasts were seeded onto scaffolds and maintained in culture for up to 21 days. Fluorescent immunolabeling revealed the spread cell morphology and significant proliferation pattern on these fibers, particularly on the 3 mol% Fe_2O_3-containing formulation. Real-time quantitative polymerase chain reaction (rtQ-PCR) analysis of gene expression using TaqMan Probes was preformed and it has been established that committed cell differentiation was maintained by both cell types and was strongly related to the 3 mol% Fe_2O_3 glass composition. These novel, readily manufactured, soluble glass fibers offer a biocompatible and biochemically favorable alternative in the search for suitable degradable materials that can be used in tissue engineering and may offer promising potential for the growth of a variety of different tissue types, including chondrocytes (see Figure 3).

1.117.2. Biological Properties of Phosphate Glasses

1.117.2.1. *In Vitro* Biological Properties

1.117.2.1.1. Introduction

Over the last 50–60 years, biomaterials research has seen a paradigm shift from simply replacing nonfunctioning tissue to one that utilizes application-specific materials. The current ethos is to foster, in three dimensions, normal functionality and structurally compatible tissue. The basic need to replace a functioning joint with a metal prosthesis during the pioneering days of the 1950s has been strikingly enhanced. Nowadays, researchers are actively engaged in developing the biological as well as chemico-physical characteristics of the newer biomaterials in order to enhance the repair, or preferably the regeneration, of diseased or damaged tissues. The phosphate-based glass system represents one such class of innovative materials. Traditionally there has been a very naive belief that materials were typically 'inert' and it has quite correctly been suggested that this is a misleading interpretation, as it became clear that materials could indeed change, both physically and chemically, following implantation.[40] It has become evident that the choice of material is fundamental in enabling the cells to function in an opposite manner to produce the required extracellular matrix; and thus tissue of a desired geometry and normal functional capability. We have previously seen the variety of phosphate glass systems that are currently available in the previous section and here, their *in vitro* evaluations will be highlighted. The discussion will centre on hard tissue applications, although the section on fibers highlights their potential utilization even in soft-tissue applications. The unique solubility profiles of the glasses (from a few hours to several months) make them ideal candidates for a variety of tissue engineering approaches, and their doping with numerous metal oxides can suitably modify their physical properties or even induce specific cellular functions. Specifically, the pool of released ionic products provides an *in vitro* environment which can direct and modulate the biological response of the cells, thereby improving and achieving the desired result. The dissolution of the glass thus provides an environment for direct 'tissue engineering.'

An important consideration to be noted here is that although biodegradability can be a useful property for fixation devices such as orthopaedic pins/screws or tissue scaffolds, *degradable* biomaterials cannot necessarily be considered as truly biocompatible biomaterials unless specific functions of surrounding cells and tissues are considered during the degradation process. To this end, the fact that the phosphate-based glasses can be transformed into biocompatible and active materials by controlling, for example, dimensionality and chemical composition of glass formulations, allows for the incorporation of bioactive substances and ionic species. The subsequent controlled degradation of these glasses would provide time-dependent release of the incorporated bioactive substance and physiological factors and, therefore, a controlled, time-dependent impact on cellular and, ultimately, tissue function. The polymeric network of the phosphate glass species is formed around the tetrahedral phosphate anion; and in the ternary form, $CaO-Na_2O-P_2O_5$, calcium, and sodium oxides are added as modifiers.[20] Clear phosphate glasses can be generated at relatively low melting points provided the phosphorous pentoxide (P_2O_5) content is above 40 mol% in the ternary composition.[41] Solubility measurements have indicated that the degradation trends of these glasses are predictably stable and, by individually modifying each precursor's contribution within the generic glass form, extremely controllable glasses may be synthesized.[42] This flexibility allows the creation of specific solubility profiles that may correspond to the scaffold degradation-tissue formation balance *in vivo*. Solubility rates of these glasses appeared to be primarily dependent on the inhibitory effect of the CaO content as, in several studies, increasing the CaO mol% resulted in reduced glass

solubility.[19,20,22] This phenomenon has been attributed to the saturation of the local environment with the ions released from the least soluble glass constituent, in this case, CaO. However, a more plausible explanation may be the fact that the Ca cations can form cross links between oxygen atoms in different molecular chains within the glass.[41]

Another advantage of the phosphate glass chemical structure is the ability to incorporate a variety of additional elements to produce more complex quaternary compositions, thus further enhancing their physical properties. For example, the introduction of iron oxides to the glass network may lead to more favorable solubility trends and mechanical strength.[43,44]

When the *in vivo* application is targeted, overcoming the mechanical limitations imposed by the brittle nature of the glass is achievable using phosphate-based glasses. With the low melting temperature as an aiding factor, and through reasonably uncomplicated processes, phosphate glasses can be drawn into fibers of considerable tensile strength with flexible physical features so that scaffold systems of suitable shapes and volumes can be constructed.[19,20,45] Hence, the use of soluble phosphate-based glass fibers, doped with various inorganic ions, has been highlighted in several reports as reinforcement for scaffold material for orthopaedic use.[46,47]

1.117.2.1.2. In vitro *properties of ternary glass systems*

The ternary phosphate system containing calcium and sodium is the most common phosphate glass series investigated using *in vitro* analysis.[39,41,48,49] Uo *et al.*, used human pulp cells in a direct contact cytotoxic assay, to assess glass powders, which was quantified with Alamar blue. It was found that increasing the calcium content decreased the cytotoxicity. These studies were accompanied by light microscopy but no attempt was made to investigate the long-term effect of the glass particles on the cells. Salih *et al.*[49] studied calcium/sodium phosphate glass using elution tests using the MG63 and human osteosarcoma (HOS) cells. Along with MTT (3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) cytotoxic testing, the effect of the glass upon the expression of bone sialoprotein (BSP), osteonectin (ON), and fibronectin (FN) was also studied using ELISA. The highly soluble glasses with lower calcium concentrations caused some inhibition of growth and bone antigen expression, while extracts from the more durable glasses with higher levels of calcium upregulated proliferation and expression of BSP, ON, and FN. Elsewhere, osteosarcoma cells were cultured on the surface of phosphate glass that contained calcium and sodium.[39] Morphology and cell number were studied using scanning electron microscopy (SEM) and the CyQuant cell proliferation assay kit, respectively. Fluorescence immunocytochemistry was employed to identify BSP, ON, and osteopontin (OP). The most durable compositions supported greater proliferation, and BSP, ON, and OP were also detected. No tests were conducted for longer than 7 days and a quantification of these proteins was not performed. Franks and coworkers[50] studied the effect of exchanging calcium for magnesium in sodium phosphate glass. Elution tests were performed using the MG63 osteosarcoma cells and quantified using the MTT cytotoxic assay. No real difference was observed over a 5-day period. However, no attempt was made to assess any morphological changes or the expression of osteoblastic markers.

All of the previous cell culture studies were short term, despite the fact that the final material applications were to be medium or long term. Some studies looked at the production of particular osteoblast phenotypic markers, but with the exception of OP, all of these are produced early in the osteoblast cell cycle.

Conversely work performed by Gough *et al.*[48] looked at the long-term culture (28 days) of craniofacial fibroblasts seeded on to monolith calcium/sodium phosphate glass surfaces. Along with investigations on cell morphology and proliferation, collagen, ALP, and calcium deposition were also determined. Results from these studies demonstrated how osteoblasts cultured on these glasses progress through all the temporal stages of the osteoblast differentiation cell cycle.

This series of studies highlighted the fact that the degradation and resultant ion species release from these glasses can clearly affect the biocompatibility of these glasses and their efficacy during long-term use. Thus, addition of particular metal oxides to the parent ternary composition has been attempted in order to produce a novel series of quaternary systems that are more stable and potentially useful for biomedical applications.

1.117.2.1.3. In vitro *properties of quaternary glass systems*

By simply substituting K_2O for Na_2O, a monovalent ion for another similar ion of different ionic radius, a quaternary series of glasses were developed.[42] Further partial substitutions of calcium for divalent ions such as Magnesium have also been proposed[50] in quaternary systems and these have emphasized the importance of calcium in the degradation process. Cell proliferation studies showed that such glasses had at least an equal, and sometimes greater effect, on cell proliferation compared to control cells grown in their absence.

Glasses containing Zinc as the dopant have been shown to promote osteoblast cell adhesion.[51] The compositions investigated were P(50)Ca((40−x))Na(10) where $x = 0$, 1, 2, 3, 4, and 5 mol% of zinc. The effect of varying the amounts of zinc was tested on osteoblast adhesion. Furthermore, the dissolution rate and the effect of the pH of glass discs were also investigated and ion release from the glass discs was examined in distilled water at 37 °C up to 7 days, *in vitro*. All the glasses showed a linear decrease in their percentage mass of the glass discs for all compositions for the entire duration of the study, and the dissolution rates were similar for all the compositions. The pH of the glass solutions were slightly reduced; although these experiments were performed in nonbuffered solutions, a normal plasma/blood environment may well act as a suitable buffer under *in vivo* conditions. Cells exhibited attachment to all compositions and cell proliferation increased with an increase in ZnO content.

Previously, glasses with 50% P_2O_5−(20−15%) Na_2O−30% CaO−(0−5 mol%) TiO_2 have been prepared by the conventional melt-quenching process.[52] This study highlighted the importance of the combined addition of titanium ions to calcium ions on the biological activity of human osteoblast-like cells. Indeed the results clearly indicated that addition of TiO_2 in small amounts, up to 5 mol%, enhanced the biocompatibility of these glasses with high levels of cell attachment at 5 mol% of TiO_2 (see **Figure 4**).

The metabolic activity of cells was comparable with control cells up to 21 days in culture and the gene expression study

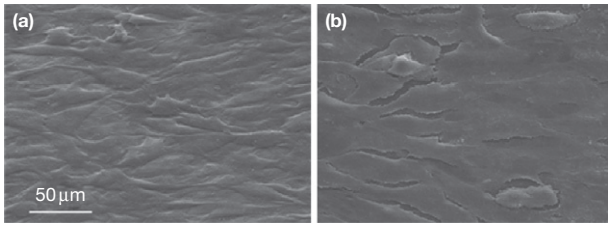

Figure 4 SEM shows MG63 cells after 4 days of culture on the surface of 5 mol% TiO_2-containing phosphate glass disc (a) and Thermanox as a positive control (b). Reproduced from Abou Neel, E. A.; Knowles, J. C. *J. Mater. Sci. Mater. Med.* **2008**, *19*, 377–386, with permission from Springer.

showed that by day 14 in culture, cells had significantly increased gene expression of important bone-associated proteins including alkaline phosphatase, collagen type I and ON. Even though such favorable cell response and gene upregulation were both abundantly evident, these glasses showed no evidence of an apatite layer formation even after incubation for 14 days in simulated body fluid.

Further studies examined the incorporation of strontium to the bulk Ti-based formulations.[53] This study focused on the effect of adding SrO to a Ti-containing quaternary phosphate glass system by incorporating 0, 1, 3, and 5% strontium, respectively. Structural characterization revealed glass transition temperatures in the range of 427–437 °C, and in all the glasses, sodium calcium phosphate was the dominant phase. Degradation and ion release studies conducted over a 15-day period revealed that the Sr-containing glasses showed significantly higher degradation and ion release rates than the Sr-free glass. This release profile was reflected in the cytocompatibility studies performed over a 7-day period using MG63 cells which showed that the addition of 5 mol% SrO yielded glasses with cell viability equivalent to that observed in quaternary TiO_2 glasses. Clearly, the manipulation of these glass compositions is relatively straightforward and the various formulations have profound, biologically relevant effects on human cells *in vitro*.

1.117.2.1.4. Phosphate glass fibers

As the conventional strategies aimed at replacing defective structures suffer many limitations, inductive tissue engineering may present the ideal solution by generating autogenic *de novo* tissue units with biological, histological, and biomechanical properties that match those of the recipient structure. Following injury or disease, clinical problems associated with tendons and ligaments are common and the cell–matrix tissue regeneration approach can potentially succeed in dealing with such problems. It is important to recognize, however, that this approach must be applied so that the structure is generated at the enthesis level as attempting to fuse hard and soft tissues by surgical means is often undermined by inferior integration, and in some cases, failure. Taking the anatomical architecture of the entheses into consideration, and in order to combine two histologically diverse entities so that an interface can be established, and evolved, the constituting cells must be seeded separately on one continuous, incorporating scaffolding system whereby this continuity will later guarantee the establishment of a functional bond between the two tissue elements. Current theories describe two conventional ways of using scaffold implant materials in the repair of bone defects; (1) via direct implantation of the material into the defect area which leads to subsequent repopulation of the scaffold by the surrounding tissues, or (2) via *in vitro* cell culture which involves seeding and incorporation to a porous, three-dimensional structure, followed by the hybrid cell/materials construct being implanted. Thus the *in vitro* conditions were optimized to allow the cells of interest, for example, bone to produce an immature osteoid, leaving the advanced maturation and bone remodeling to continue post implantation *in vivo*.[54,55] The events that occur at the interface of the glass and cells/tissues that lead to integral tissue formation have been previously elegantly described.[56] Essentially, dissolution and reprecipitation of the glass, exchange of ions and the solution-mediated effects on important cell functions, chemotactic events, attachment, proliferation, and differentiation leading to the formation of a functional extracellular matrix, in sequence, are the main processes that must occur to ensure a fully integrated and viable regenerated tissue. One could consider that the phosphate-based glasses, in the form of fibers and seeded with appropriate cell systems, may provide an ideal material which mirrors this concept of a cascade of cellular and material events leading to engineered tissues *in situ*.

Fiber-based matrices are therefore structurally suitable for providing a contiguous base for a coculture/cell transplantation strategy. Apart from the physical configuration, the scaffold structure must be generated from a biocompatible and biodegradable material in a manner that guarantees the survival and function of the seeded cells on one hand and its functional integration into the host tissue on the other. Owing to their biocompatibility and structural properties, phosphate-based glasses have been shown to be potentially excellent scaffold materials for tissue engineering. It is important, at this stage, that this potential is investigated further and developed as a primary, human cell-seeded, fiber-based scaffolding system.

The phosphate family of glasses has, therefore, recently emerged as a potential candidate to create high modulus, resorbable fibers. They possess unique characteristics that are desirable in several biomedical applications. They can be easily manufactured in the laboratory as fibers and they have been shown to exhibit excellent biocompatibility.[39,57] Moreover, they degrade to provide principally phosphate and calcium, which suggests that phosphate glasses in the form of fibers may be potentially osteo-conductive. To highlight this phenomenon, Shah *et al.*[58] utilized iron-based glasses in soft-tissue-engineering applications. They exhibited favorable *in vitro* characteristics, that is, they were nontoxic during degradation but retained their highly controllable degradation profiles.[19] These fibers have a high surface area to volume ratio, which can help increase the area available for the seeded cells to attach. They also have a narrow diameter of ~30 μm which allows for adequate delivery of nutrition and oxygen, and the dissolution products consist of ions that can be incorporated into other normal metabolic and physiological processes. Shah and coworkers[58] also investigated the use of these glass fibers as potential scaffold materials for the *in vitro* engineering of human craniofacial skeletal muscle. The authors concluded that the application of such glass fiber technology to the construction of a muscle organoid is highly suitable due to the structure of skeletal muscle; essentially bundles of fibers surrounded by

fibrous sheaths. This study demonstrated that the cell numbers on the fibers increased with time and that the scaffold mesh configuration as well as cell density aided the attachment of more cells to the fiber construct. Furthermore, the growth conditions were altered to encourage differentiation of the cells which may also have been affected by the glass composition.

Bitar *et al.*[59] investigated the development of a well-characterized, yet contiguous, glass fiber system for regeneration of the hard–soft tissue interface. This latter study evaluated the effect of fiber diameter on the attachment of human osteoblasts and fibroblasts using ternary glass fibers of the composition $0.48CaO-0.02Na_2O-0.50P_2O_5$. Fiber diameter significantly influenced cell attachment and survival, and fibers drawn at 800 revolutions per minute (diameter range of 20–25 μm) were found to be optimal. Using a known composition of iron-phosphate glass fibers (composition $0.46CaO-0.01Na_2O-0.03Fe_2O_3-0.50P_2O_5$), scaffolds were produced. These scaffolds were incorporated within an open laminar flow culture system to provide nutrients, oxygen, and waste removal throughout the culture. The design of the chamber ensured that laminar flow was present; both osteoblast and fibroblast differentiation was neither affected nor enhanced by laminar flow compared to static culture conditions. This system could potentially, therefore, be adapted to construct larger, more complex, three-dimensional iron-phosphate fiber scaffolds for tissue engineering and their performance evaluated *in vitro* with a variety of cells types under varying culture conditions.

A serendipitous finding of the iron oxide-doped phosphate-based glass fiber system was that capillary-like tubules were formed *in vitro* quite simply during their degradation in water.[52] This phenomenon has a unique and potentially important application in several areas including drug delivery, cell transportation, angiogenesis, or even as a conduit for nerve regeneration. These tubes would have great potential for the transportation of nutrients to and waste materials from the sites of tissue regeneration.

More recently, Ahmed *et al.*[60] have compared four more durable phosphate-based formulations for use as reinforcing components of biodegradable polymers like polylactic acid and polycaprolactone. Four invert phosphate-based glasses (PBG) formulations were produced with fixed phosphate and calcium contents at 40 and 25 mol%, respectively. MgO was added at 10–30 mol%, in place of Na_2O. *In vitro* investigations showed that the degradation rates of the glasses decreased by almost two orders of magnitude with an increase in MgO content. In addition, tests on the cytocompatibility of the fibers showed excellent osteoblast responses in terms of metabolic activity and production of alkaline phosphatase for up to 14 days when compared to control cell cultures grown on tissue culture plastic. Glasses containing 20 and 30 mol% MgO displayed optimal protein expression and cell coverage compared to control cells, revealing that the formulations investigated gave a response comparable to tissue cultured on plastic as control.

1.117.2.2. *In Vivo* Biological Properties

1.117.2.2.1. Introduction

Normally, a wide range of *in vitro* studies, including surface, physical, mechanical, and biological testing, are carried out prior to proceeding to *in vivo* experimentation, in order to assess the relevance of a material for clinical applications. Performing *in vitro* studies provides a wealth of information that is necessary to design a material with appropriate function and also to explore the potential toxicity of such a material. These *in vitro* methods, therefore, help to avoid costly and time-consuming *in vivo* procedures on a material that may not progress towards commercialization and eventual clinical use. It is often, however, difficult to extrapolate the *in vitro* behavior of a biomaterial to its *in vivo* performance as the environment that surrounds the material is very different in both the conditions.

Performing *in vivo* experiments, which are regarded as a link between *in vitro* studies and clinical trials, using animal models, is considered as a step towards a better understanding of biomaterial or implant behavior in both the short and long term. The choice of the animal model varies according to the estimated cost and the application of a biomaterial. Generally, small animal models will be employed initially, and then a progression to a higher animal model that has a closer relationship to the actual clinical situation will be performed prior to complex human clinical trials[61] and eventual clinical use. Even though these *in vivo* experiments are important for evaluation of a new material some argue about the use of animals in experimental work and they advocate the use of cell culture studies as a replacement for animal testing instead of supplementing it. They also claim that such animal testing may not be an accurate reflection of what could be expected from the same material in human body due to the expected variations between species.

1.117.2.2.2. Phosphate glasses as bone substitutes

Bone loss resulting from congenital abnormalities, traumatic injury, or disease is a major health care problem worldwide. When this occurs in the craniofacial region, it can also be highly emotive with serious physiological and psychological consequences. The extent of bone loss, commonly requiring reconstruction in the oral and maxillofacial region, varies considerably from small alveolar clefts to large mandibular defects.

As bone substitutes, various types of bone grafts (e.g., autograft, allograft, and xenograft) are regularly used to promote bone healing when insufficient bone is present at the desired surgical site. The limitations associated with them (e.g., limited supply, donor site infection and morbidity, pain, and cost of operation), however, led to the evolution and development of different approaches for the design of new types of synthetic materials as alternatives (see **Chapter 5.521, Calcium Phosphates and Bone Induction** for further reading on alternative types of calcium phosphates for bone induction). There is always a requirement for a biomaterial that can be easily shaped/handled, immunologically safe, and for the degradable materials to be safely eliminated from the body. Phosphate-based glasses provide a wide range of compositions, properties, and forms (e.g., granules, fibers, cloth, tubes, and monoliths of different shapes) for the applications detailed above. Being degradable, a key issue in choosing a biomaterial, this eliminates any concern about any long-term implantation effect. The degradation products, however, dissolve in the surrounding body fluid. When they are doped with oxides with known therapeutic actions, they could enhance new bone formation and reduce the chance of inflammation in the surrounding

tissue, as will be discussed below. Moreover, when they degrade, they provide microroughness and surface irregularities into which the new bone can be deposited and micromechanically bind to them.[62]

1.117.2.2.3. In vivo *response to phosphate glasses*

Although phosphate glasses have been extensively studied *in vitro*, as mentioned in the previous section, there are a limited number of publications that report the *in vivo* performance of this interesting class of materials. From the little information available, it is clear that the ability of these glasses to allow and promote new bone formation is dependent upon glass composition, particularly in the early stages of implantation (see **Figure 5**).[52,63] Some compositions[64] showed early bone formation within a week of implantation while others required several weeks for new bone formation to be detected.[52,63,65] Glasses doped with 1 and 3 mol% TiO_2 showed only soft-tissue formation, presumably due to their relatively higher solubility rate. However, at 5 mol%, bone growth directly on to the glass surface was observed (see **Figure 5**).

With longer implantation times, however, most of the variations between the glass formulations (e.g., solubility variation) could be masked by the physiological environment.[63,66]

Important issues that need to be considered during the selection of appropriate glass composition are when and how the glass is going to resorb and how this will affect the pattern and distribution of bone formation that proceeds to fill the spaces left by the degraded glass. In general, there were no signs of any inflammation or foreign body reaction surrounding the implanted glasses[67] or any soft-tissue intervention observed at the interface between the newly formed bone and the defect margin.[52,63] This newly formed bone also progressed, with time, to show some evidence of calcification and remodeling, as is the case with natural bone.[63,65,66,68] Sometimes, it was also comparable to or had even greater area, length, and density compared to that found on the control side.[63,64]

When these glasses were implanted subcutaneously, they showed a mild nonspecific inflammation, but actually, this mild inflammatory response was attributed to the suture material that was used at that time and not to the glass *per se*.[69,70] Most interestingly, when employed in porous form, they allowed penetration of vascularized tissue throughout the porous implant. These results were considered promising in terms of potential use of these glasses in clinical applications.[69]

1.117.2.2.4. *Human clinical trials on phosphate glasses*

Having materials that can be easily shaped into different forms which also show a potential use in clinical applications led to the development of metacarpophalangeal prostheses of different sizes. These glass prostheses were used in preliminary clinical trials that were carried out on one female patient, aged 44 and suffering from Rheumatoid arthritis. These prostheses were employed as a replacement for the metacarpophalangeal joint of the patient. Rheumatoid arthritis is a chronic, systemic inflammatory condition that may affect many tissues and organs but mainly joints; it can be a painful, disabling condition and can lead to substantial loss of mobility and function. The use of metacarpophalangeal prostheses made from phosphate glasses proved to be successful in pain relief and improved functional capacity with no adverse reactions. It also proved that phosphate glasses could be used without the need for a coating of perichondrium, a layer of dense irregular connective tissue which surrounds the cartilage of a developing bone, which is to be taken from the patient's rib to improve cartilage repair. Using these glass prostheses also eliminated the need for a second revision surgery for implant removal which is the case with conventional Silastic (medical grade silicon) prostheses and hence protected the patient from further complications associated with multiple surgical procedures.[69]

In general and as highlighted above, a lot more effort is still required to cover this area of experimentation. That is, to come up with compositions that could offer effective, safe, lower cost, less demanding, and easy-to-use bone substitutes that could serve a wide sector of population that suffers from bone diseases.

1.117.3. Therapeutic Actions of Phosphate Glasses

1.117.3.1. Introduction

The high temperatures used in the fabrication of these glasses through the conventional melt quench process makes the incorporation of bioactive organic molecules/materials (e.g., proteins, growth factors, genes, and hormones), which are necessary for imparting specific therapeutic action, into the glass structure, impossible. Using the sol–gel route (low-temperature fabrication process),[10,11,71] on the other hand, may make such incorporation possible, but there is still a limitation with the number of organic molecules/materials that can actually be incorporated into the glass network.

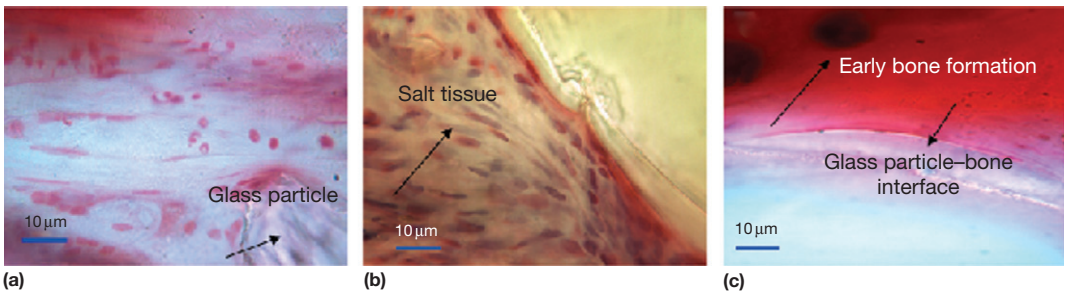

Figure 5 Histology images of glass particles doped with 1, 3, and 5 mol% TiO_2 after implantation in rat calvarium bone defects for 5 weeks (a, b, and c) respectively at ×20 magnification. (Stain: Cole's haematoxylin eosin). Reproduced from Abou Neel, E. A.; Mizoguchi, T.; Ito, M.; Bitar, M.; Salih, V.; Knowles, J. C. *Biomaterials* **2007**, *28*, 2967–2977, with permission from Elsevier.

However, given their dissolution properties, these glasses could be used as a vehicle for controlled delivery of inorganic ions, which may have the same or similar action as organic molecules/materials, as long as they are in contact with the biological environment.

Having this advantage, Standard Telecommunication Laboratories (STL) managed to develop the first phosphate glass releasing inorganic ions with known therapeutic action in the early 1970s.[72] This idea was further adopted, and currently, some of these glasses are under development or are being used for a variety of therapeutic applications, according to the ions being released. This section will deal with the currently commercially available phosphate glasses and then discuss the development of new systems that can potentially treat disease, reduce the risk of infection or help in hastening the healing process.

1.117.3.2. Therapeutic Phosphate Glasses

One of the commercially available therapeutic phosphate glasses is called coseCURE®. It is a soluble glass bolus containing cobalt, selenium, and copper and is used for the treatment of trace element deficiency in animals. This bolus is prepared for oral administration and when it reaches the reticulum, it starts to dissolve continuously over a period of 6 months, leaving no residues behind.[73–75] This bolus provides the animal with the required mineral supplement and guarantees a sustained dose to the animal for the lifetime of the device. These glasses also help in maintaining their offspring by absorbing the toxic molecules that could impair the fertility of the animals.[76–78]

Another example of therapeutic phosphate glasses is that used for treating natural or artificial bodies of water that have been infected with waterborne parasites. These glasses act as a molluscicide and kill the snail which is the intermediate host of the schistosoma parasite. Therefore, they help to reduce the risk of transmission of schistosomiasis, which is the second most socioeconomically devastating parasitic disease affecting humans via human–water contact sites. Thus, these glasses serve a high proportion of the population who are prone to get infected, particularly in developing countries, or those working in endemic areas such as the armed forces.[79–81]

Such an application of these glasses, as well as the metacarpophalangeal joint implant described previously, has also enabled its extension to other clinical areas in humans. Phosphate glasses have been used as a tissue bulking agent to prevent the abnormal flow of urine from the bladder to the kidney, which is essential for the treatment of vesicoureteral reflux.[82] They have also been used to control infection in patients suffering from urinary incontinence, particularly in those who require the use of long-term indwelling catheters. The long-term use of catheters has a significant risk of bacterial colonization and hence bladder infection; a condition that requires the catheter to be regularly changed and hence may impose trauma and additional cost to the patient. For the control of infection, a cartridge with silver containing glass is designed to be inserted, in line, between the catheter and urine collection bag. When in position, the insert is bathed with urine as it flows from the bladder into the collection bag. Then it releases silver ions that kill most of the bacteria that are commonly associated with catheter infection.[82–84] This device has an additional benefit in that it acts as a barrier that prevents bacteria tracking back up the catheter and causing bladder infections.

1.117.3.3. Other Potential Therapeutic Phosphate Glasses

Phosphate glasses could also have enormous potential in other therapeutic applications. They can be effectively used in controlling infections that are resistant to antibiotics (e.g., bone infection) by releasing ions known for their antibacterial actions such as zinc,[85] silver,[33,86] and gallium,[36] since there is no reported bacterial resistance against these ions. They could also be used to prevent bone fracture in osteoporotic patients by releasing ions that are known to strengthen and increase the existing bone mass and density (e.g., strontium),[87–89] or to help in bone healing by enhancing the bone forming ability of bone cells (e.g., zinc).[90]

Incorporation of radioactive ions known to be very effective at killing cancerous cells, for example, $^{90}Sr^{91}$ or $^{191}Pt^{92}$ or $^{90}Y^{93–95}$ into these glasses could also open another avenue for their use in the treatment of localized discrete cancer. Glass microspheres carrying the radioactive isotopes can be easily introduced into a specific organ to treat the cancer.[95] For such an application, they may provide a suitable means of directing these radioactive ions to a specific site and hence reduce the chance of these ions being lost systemically and thus having undesirable side effects on the neighboring healthy tissues. Furthermore, the capacity of these glasses to be X-rayed would be of a considerable asset in monitoring the precise location and degradation of the implant noninvasively.[69]

These therapeutic glasses may also be good candidates for restoring the blood levels of certain ions to their correct levels. They could be designed to correct zinc levels in patients suffering from Crohn's disease, an inflammatory condition of the intestines that can affect any other part of the gastrointestinal tract from the mouth to the anus. They could be also designed to maintain the necessary sodium–potassium balance for carrying out normal body functions in patients on diuretics (drugs that remove water from the body by increasing the amount of urine). In such cases, these glasses could controllably release sodium and potassium ions at the correct ratio and could easily be incorporated with a drip feed in order to avoid any periodic intervention and its subsequent risk of infection.[69]

Glasses releasing ions such as strontium could also be used in dentistry to reduce the prevalence of tooth decay when they are included within cements or in filling materials as these glasses can act as a matrix for the continuous supply of ions that help in remineralization of defective tooth structure.[96] Devices have also been tested to release therapeutic ions directly into the oral cavity to inhibit demineralization and promote remineralization, and this includes strontium mentioned above and also fluoride.

The development of phosphate-based glasses as composite materials for use in endodontic surgery also shows some promise. The rapid release of ions followed by reprecipitation of a calcium phosphate phase at the margin between the tooth and the filling material has been shown to provide an excellent marginal seal around endodontic filling materials by closing

the microgaps that normally exist around endodontic root-filling materials and the surrounding tooth structure. Providing this marginal seal helps to seal the route of ingress of microorganisms at the tooth/restoration interface and hence reduce the incidence of tooth decay.[97,98]

Glossary

Adipogenic Relating to or derived from the tissue from which fat is developed.
Allograft Graft taken from another individual of the same species as the recipient.
Autograft Graft taken from a source in the individual who receives it; that is, the donor and recipient are the same.
Bioactivity Phenomenon by which a biomaterial elicits or modulates biological activity.
Ceramic Type of material chemically derived from the combination of one or more metallic elements with one or more nonmetallic elements, usually ionically bound, but with a contribution from covalent bonding, characterized in the solid state by extreme brittleness.
Ectopic Located away from normal position.
In vitro Pertaining to a situation that involves the experimental reproduction of biological processes in a more easily defined environment such as a culture vessel.
In vivo Pertaining to a biological process occurring within a living organism or cell.
Orthotopic Occurring at a normal place.
Osteoblast Bone forming cell.
Osteoclast Large, multinuclear cell associated with absorption and removal of bone.
Osteogenic Relating to or derived from the tissue from which bone is developed.
Tissue engineering The application of the principles and methods of engineering and life sciences toward the fundamental understanding of structure/function relationships in normal and pathological mammalian tissues and the development of biological substitutes to restore, maintain, or improve functions.
Trace element Any metal or nonmetal found in minute quantities in the human body which are essential components of the diet, but are harmful if taken in excess.

Abbreviations

ALP	Alkaline phosphatase
BCP	Biphasic calcium phosphate
BMP	Bone morphogenetic protein
CaP	Calcium phosphate
FGF	Fibroblast growth factor
FTIR	Fourier transform infrared spectroscopy
HA	Hydroxyapatite
IGF	Insulin-derived growth factor
MSC	Mesenchymal stromal cell
PDGF	Platelet-derived growth factor
SBF	Simulated body fluid
TCP	Tricalcium phosphate
TGF-β	Transforming growth factor beta
XRD	X-ray diffraction

1.118.1. Introduction

Regenerative medicine, a field that is aimed at restoring rather than replacing the function of damaged and degraded organs and tissues, is becoming increasingly important in our society with aging population. In the areas of orthopedic and craniomaxillofacial surgery, for example, there exists a great demand for bone regeneration strategies. Restoration of bone defects caused by tumor removal, infections, traumas, as well as spinal fusion are frequently performed surgeries in the clinic. Currently, treatments of bone defects include the use of natural bone grafts, synthetic bone graft substitutes, and tissue-engineered constructs (Figure 1).

The goals of these different strategies are to provide an environment that is similar to natural bone and to facilitate bone regeneration in the defect area as optimally as possible. Approaches to bone regeneration are therefore developed on the basis of the properties of bone tissue, which are summarized in the next section.

1.118.2. Bone

Bone is a highly specialized form of connective tissue that is nature's provision for an internal support system in most higher vertebrates. Bone provides for the attachment of the muscles and tendons essential for movement, protects the vital organs of the cranial and thoracic cavities, and encloses the blood-forming elements of the bone marrow. In addition to these mechanical functions, bone plays an important metabolic role as a mobilizable store of calcium and phosphate, which can be drawn upon when needed in the homeostatic regulation of calcium and phosphate in blood and other fluids of the body.[1]

Morphologically, there are two forms of bone: cortical (compact) bone and cancellous (trabecular) bone. Compact bone, which is rigid with little porosity, is found mainly in long bones or shells of other bones. Found predominantly in the epiphyses, ribs, and spine, cancellous bone has a highly porous structure ($>75\%$), with numerous small bone trusses or trabeculae interconnected with each other, and tends to orient along the principal directions in adaptation to the external loading environment.

Bone comprises several cell types. Osteoblasts, osteoclasts, and bone lining cells are present on bone surfaces, whereas osteocytes are present within the mineralized interior. Osteoblasts and bone lining cells originate from local osteoprogenitor cells, whereas osteoclasts arise from the fusion of mononuclear precursors, which originate in the various hemapoietic tissues. Osteoblasts are the fully differentiated cells responsible for the production of the bone matrix and regulation of its mineralization. The osteocyte is a mature osteoblast within the bone matrix and is responsible for the matrix maintenance. Bone lining cells are flat, elongated cells that cover bone surfaces that are undergoing neither bone formation nor resorption. Little is known regarding the function of these cells; however, it has been speculated that bone lining cells can be precursors for osteoblasts. Osteoclasts are large, multinucleated cells, which can resorb bone and its mineral.

By weight, bone contains ~60% mineral, 10% water, and about 30% organic matrix. Type I collagen constitutes ~90% of the organic matrix; the remaining 10% is composed of proteoglycans and numerous noncallogeneous proteins, such as osteocalcin, osteopontin, osteonectin, bone sialoprotein, decorin, and biglycan.[2,3]

The inorganic component of bone mineral consists of nonstoichiometric hydroxyapatite, the exact composition of which varies depending on the location and function in the body,

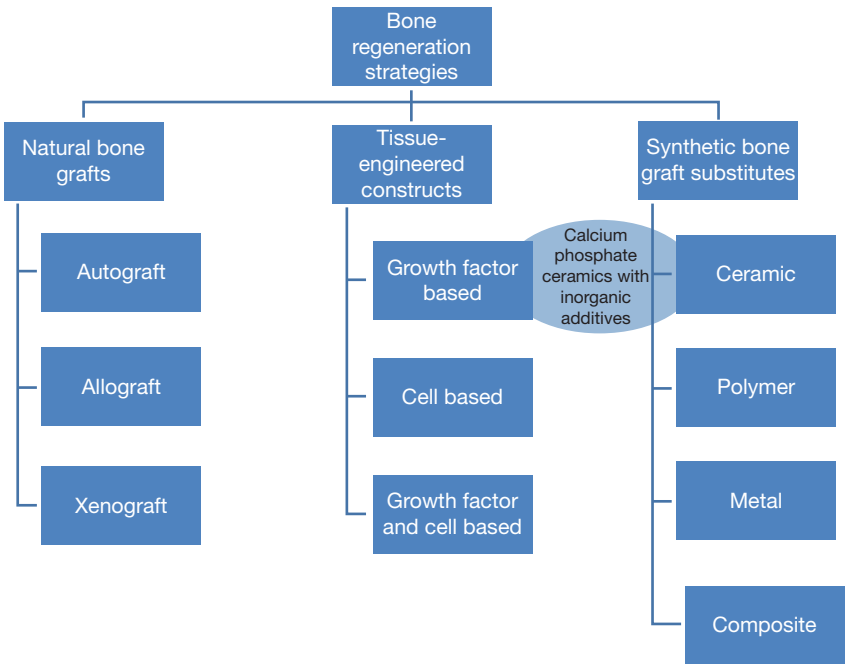

Figure 1 An overview of current strategies in bone repair and regeneration.

species, and age. Carbonate is the most abundant substitute in biological apatite crystal lattice, accounting for 2–8 wt% of total bone mineral in most mammals.[4] Apart from calcium, phosphate, and carbonate, bone mineral contains a great number of other inorganic compounds in varying quantities.

1.118.3. Current Methods in Bone Regeneration

1.118.3.1. Natural Bone Grafts

Patient's own bone meets all the requirements for successful bone regeneration, and it is therefore little surprising that autologous bone is still considered the gold standard in most applications. By its very nature, autologous bone grafts do not cause an immunogenic reaction upon use. Furthermore, they possess a great biological performance in terms of osteogenicity (supply of bone forming cells by the bone marrow),[5] osteoinductivity (initiation of the differentiation of mesenchymal stem cells toward the osteogenic lineage by, e.g., bone morphogenetic proteins (BMPs) present in the graft),[5–8] and osteoconductivity (facilitation of cell and nutrient infiltration through the 3D porous structure).[5,7,9] Several drawbacks are, however, associated with harvesting autologous bone grafts: an additional surgery is required; it is occasionally the cause of donor site morbidity,[5–7,10] chronic postoperative pain,[7,11–13] hypersensitivity,[7] and infections.[8,11,14] In addition to these drawbacks, limited availability of autologous bone is also an important reason why alternative bone regeneration strategies are needed. Other natural bone grafts, allografts and xenografts, are less limited in available quantity, but their performance is often inferior to that of autografts[5,13,15–17] because they need to undergo a number of treatments in order not to cause an immunogenic reaction.[18,19]

1.118.3.2. Synthetic Bone Graft Substitutes

Synthetic bone graft substitutes present an attractive alternative to natural bone grafts, in the first place because of their unlimited and off-the-shelf availability. Second, the fact that they do not cause an immunogenic response and that they can easily be tailored to meet requirements of a specific application explains a great number of substitutes developed in the past few decades. Although all three material types, metals, polymers, and ceramics, and combinations thereof have been used to develop bone graft substitutes, the use of calcium phosphate (CaP)-based biomaterials, mostly ceramics, has garnered the largest interest. The fact that the inorganic component of bone is basically a CaP mineral is the main reason for this interest and emphasizes the fact that the rationale behind a tissue regeneration strategy is often an attempt to create an optimal environment for regeneration.

1.118.3.2.1. Calcium phosphate ceramics

CaP ceramics possess chemical composition similar to that of bone and tooth mineral. In addition to an excellent biocompatibility, their bioactivity is remarkable.

As reviewed by Damien and Parsons,[7] various CaP biomaterials have shown some distinct clinical successes. Hydroxyapatites (HA), for example, both of natural (coral- and bovine bone-derived) and synthetic origin, have widely been tested and successfully used for clinical applications. Owing to its low resorption rate, HA has proven to be a good material for alveolar ridge augmentation, pulp capping, and filling of periodontal defects, where the use of autologous bone, which is resorbable, has been found to be less than optimal. In orthopedics, porous HA blocks have been used for filling defects remaining after tumor excision, as well as in spinal fusion of vertebral bodies. Tricalcium phosphate (TCP) is another widely used ceramic, particularly in applications where degradation of the material is required. Dental applications of TCP ceramics include the filling of defects due to periodontal loss, as well as repairing cleft palates. In orthopedics, TCP has been used in spinal fusion. A ceramic receiving much attention is biphasic calcium phosphate (BCP), consisting of HA and TCP. By altering the ratio of HA to TCP, variable rates of degradation can be achieved, an example of adaptability of synthetic bone graft substitutes to an intended application. Clinically, BCP has been tested for treatment of patient with scoliosis and for filling defects after tumor removal. Currently, CaP ceramics can be made in the form of particles, dense and porous scaffolds,[20,21] and even in more defined shapes using free form fabrication techniques.[22] Their microstructure can be modified by controlling production process, in order to control their bioactivity *in vivo*.[23] **Figure 2** shows an example of CaP ceramic particles (a), macro- (b) and microstructure (c) of porous CaP ceramic, and its bonding to bone (d), which is a sign of bioactivity.

It should be noted that ceramics are intrinsically brittle. This is an important limitation, because restoring the function of bone tissue includes restoration of mechanical properties of bone. However, brittle materials cannot be used in load-bearing applications, where mechanical load needs to be (temporarily) taken over by the implant. In order to overcome this limitation, ceramics are often combined with other materials, such as metals and polymers in the form of coatings[24–28] or composite materials.[29–31]

1.118.3.3. Tissue Engineering

Despite intensive research and continuous improvements of synthetic biomaterials, so far these materials by themselves have not shown a biological performance that is equal to that of autologous bone grafts. Bone conduction over the material surface and the replacement by bone as well as their mechanical properties are usually inferior to autologous bone grafts.[7,15,32–34] Tissue engineering is a relatively recent development, which was, in 1993, defined as an 'interdisciplinary field that applies principles of engineering and life sciences toward the development of biological substitutes that restore, maintain, or improve tissue function' by Langer and Vacanti.[35] In practice, in tissue engineering, attempts are made to create constructs with properties and function similar to that of natural tissue. In other words, rather than using a bioactive CaP ceramic that resembles bone mineral, an additional step is made to add cells and/or growth factors to the ceramic, creating thereby a construct that resembles both mineral and organic component of bone. Bone tissue-engineering construct

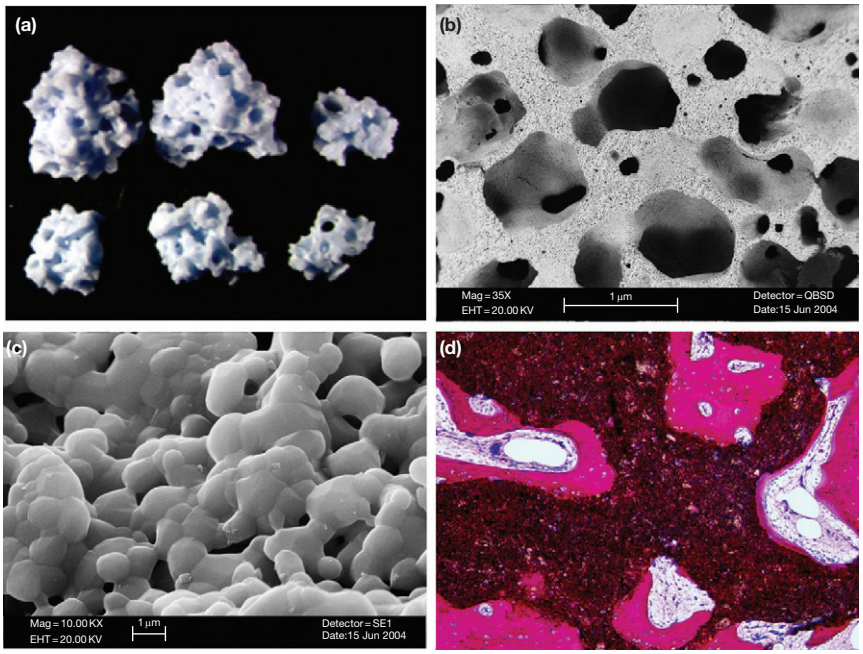

Figure 2 Calcium phosphate ceramic: (a) digital micrograph showing ceramic particles, (b) low magnification scanning electron microscopy micrograph of an open porous macrostructure, (c) high magnification scanning electron microscopy micrograph showing microstructure with ceramic grains among which micropores are found, and (d) light microscopy micrograph of a histological slide showing bone that has formed inside the ceramic pores and is in close contact with ceramic surface.

most often consists of a (synthetic) carrier loaded with bone-inducing substances (chemical stimulation of bone formation-growth factor based tissue engineering), osteogenic cells/tissue (cell-based tissue engineering), or both.[35]

To date, numerous growth factors have been identified and subsequently produced by recombinant gene technology, such as bone morphogenetic proteins (BMPs) and other members of the transforming growth factor β (TGFs-β) family, fibroblast growth factors (FGFs), platelet-derived growth factors (PDGFs), and insulin-derived growth factors (IGFs). Various studies have shown that bone growth factors have several regulating effects on cells from the osteoblastic lineage and *in vivo* studies have demonstrated that some factors can induce bone formation and/or stimulate bone healing. Kirker-Head has reviewed the application of BMPs in a number of animal models at various orthotopic sites, such as in spinal fusion, long bone defects, mandibular and cranial bone defects, fracture healing, as well as periodontal regeneration, alveolar ridge augmentation, and osteointegration of dental implants.[36] In addition, various preclinical and clinical studies have shown positive effects of BMP in nonunions and segmental defects, such as traumatic tibial defects[37,38] and femoral defects.[39]

The combination of autologous cells with carriers is another way to produce tissue-engineered hybrids. Various cell types such as calvarial[40,41] and periostal[42,43] cells, osteoblasts of trabecular bone,[44,45] chondrocytes,[46] and vascular pericytes[47] have been tested as potential sources of bone-forming cells. Nevertheless, the most widely used source of osteogenic cells is bone marrow. Bone marrow has been recognized as a source of osteoprogenitor cells that can differentiate toward bone-forming cells when cultured under adequate conditions.[48–51] In addition, bone marrow has been shown to be the most abundant source of osteoprogenitors, which possess high proliferative ability and great capacity for differentiation.[52,53] Studies in rodents have shown the feasibility of the tissue-engineered hybrids, consisting of a carrier and bone marrow stromal cells, after ectopic[54,55] and orthotopic implantation.[54–58] In larger animals, there are a few studies showing the biological performance of the TE hybrids, in ectopic[59–61] and orthotopic sites.[62–64] In a small number of studies in which cell-based tissue-engineered constructs have been tested in humans, the results obtained showed varying degrees of success.[65]

Although both growth factors-based and cell-based tissue-engineered constructs have shown the capability to enhance bone formation when implanted orthotopically, their biological performance is largely dependent on the construct carrier. For example, when BMPs are implanted without a carrier, they are reported to diffuse too rapidly to be able to induce or to enhance new bone formation. Further, the amount of BMP necessary to achieve a certain dose *in vivo* is also carrier dependent.[66–68] Similarly, a suitable carrier is a prerequisite for the success of a cell-based tissue-engineered construct. For instance, recent studies have shown that bone formation in tissue-engineered constructs is restricted to confined areas of the scaffold. Further, bone bridging between individual tissue-engineered material granules is exceptional. In addition, the findings of the clinically relevant studies suggest that the effect of tissue engineering is moderate and may be irrelevant at long-term implantation intervals.[69] The tissue-engineering technique is also associated with some drawbacks.

The production of recombinant growth factors, collection and transport of the biopsies, and culture of autologous cells are some of the factors that make tissue-engineering time, money, and labor consuming.

1.118.4. Improvement of Synthetic Bone Graft Substitutes

From this overview of the current status of bone regeneration strategies, the following summary can be made: (1) autologous bone is the gold standard with regard to biological performance, but its limited availability creates a need for comprehensive alternatives; (2) synthetic bone graft substitutes have a great advantage of being available in large quantities off-the-shelf and relatively inexpensive, but their biological performance by itself does not position them as an alternative to autograft; and (3) tissue engineering is a strategy with great possibilities, but owing to its complexity, extensive research is needed before tissue engineering will be widely applied in the clinic.

For material scientists, a real challenge lies in the improvement of the biological performance of the existing bone graft substitutes, while retaining their synthetic character. In this chapter, the potential use of inorganic additives to bone graft substitutes will be discussed as 'synthetic growth factors' (Figure 1). These inorganic additives are compounds found in bone mineral as trace elements. As mentioned in the section on bone composition, the inorganic component of bone is nonstoichiometric HA, mainly consisting of calcium (36.6 wt%), phosphorus (17.1 wt%), and carbonate (4.8 wt%). In addition, a number of other components are also found in bone minerals, such as sodium (1 wt%), potassium (0.07 wt%), fluorine (0.1 wt%), chlorine (0.1 wt%), magnesium (0.6 wt%), and strontium (0.05 wt%).[70] In an early work by Becker and coworkers, presence of alumunium, copper, iron, manganese, lead, silicon, tin, vanadium, and zinc has also been determined in human bone.[71] In 1997, El-Amri and El-Kabroun used neutron activation analysis and showed that also barium and bromine are present in human bone.[72] Most of these elements have an effect on properties of bone mineral, such as its mechanical and degradation properties. In addition, a number of them can influence processes of angiogenesis, bone formation, and remodeling, all of which are of importance in the field of bone regeneration. Probably, the best example of use of trace elements in bone regeneration and bone-related diseases is the clinical use of strontium ranelate in patients with osteoporosis. But there is also evidence that other elements can influence processes related to bone formation and remodeling. We have chosen three metallic components (cations), namely, zinc, copper, and strontium, and two nonmetallic components (anions) of bone, namely, fluoride and carbonate, to discuss their potential use in bone regeneration. The occurrence of these five ions in bone is summarized in Table 1. First, their importance will be discussed in bone metabolism and a literature review will be given on their effect on processes related to bone formation and remodeling. Then, a number of methods will be discussed to incorporate these elements in CaP-based ceramics and an overview of studies in which the ceramics with additives were tested with regard to bone formation and resorption will be given. Finally, some future perspectives in the search for and investigations of 'synthetic growth factors' will be given.

Table 1 Occurrence of zinc, copper, strontium, fluoride, and carbonate in bone

Element	*Content*
Zinc	60–85 ppm (in ash of human cortical bone)[71]
	153–266 ppm (in ash of various human bones)[73]
	54–315 ppm (in lyophilized human bone)[72]
Copper	5 ppm (in ash of human cortical bone)[71]
Strontium	62–130 ppm (in ash of human cortical bone)[71]
	11–418 ppm (in lyophilized human bone)[72]
Fluoride	0.1 wt% (in mineral of bovine cortical bone)[70,74]
	0.08–0.69 wt% (in ash of human iliac crest bone)[5]
Carbonate	4.8 wt% (in mineral of bovine cortical bone)[70,74]
	5.1–5.8 wt% (ash of human iliac crest bone)[75]

1.118.5. Trace Elements in Bone Metabolism and Processes Related to Bone Formation

1.118.5.1. Zinc

The amount of zinc in the human body is relatively low, between 1.4 and 2.3 g, on biochemical level; however, its importance has been proven in a number of physiological processes.[73] Zinc is required for the activity of over 300 metalloenzymes, including those involved in nucleic acid and protein synthesis, cellular replication, immune function, and antioxidant systems.[76] It is a constituent of various enzymes and proteins such as alkaline phosphatase (ALP), lactate dehydrogenase (LDH) and carbonic anhydrase, steroid hormone receptors, and transcription factors.[77,78] There exist about 1400 zinc-finger proteins that participate in the genetic expression of a range of proteins.[79] The amount of zinc in bone is relatively high as compared to that in other tissues. As reviewed by Colhoun and coworkers, human bone ash contains between 150 and 250 $\mu g\,g^{-1}$ zinc, depending on the location in body. Zinc deficiency is associated with a number of skeletal anomalies in fetal and postnatal development, such as depressed bone age, which can be treated with zinc supplementation. It was demonstrated that nutritional zinc deficiency results in a decrease of zinc concentrations in bone. Early studies indicated an increase in the uptake of zinc in the areas of bone healing, in particular, in the areas in close proximity to the sites of calcification, as well as during ectopic bone formation, suggesting the influence of zinc in osteogenesis.[73] The role of zinc in the bone has been shown to be twofold: (1) zinc plays a structural role in the bone matrix that consist of HA crystals, which contain zinc complexed with fluoride and (2) zinc is involved in the stimulation of bone formation by osteoblasts and inhibition of bone resorption by osteoclasts.[80]

Yamaguchi and coworkers, for example, showed an increase in Runx-2, osteoprotegerin, and regucalcin mRNA expression by MC3T3-E1 osteoblast-like cells in the presence

of zinc sulfate, at concentrations of 10^{-6}–10^{-4} M.[81] More recently, Kwun and colleagues showed that zinc deficiency reduced osteogenic activity of MC3T3-E1 cells *in vitro* by decreasing bone marker gene transcription through reduced and delayed Runx-2 expression and by reduction of extracellular matrix mineralization through a decrease in alkaline phosphatase (ALP) activity.[82] The effect of zinc on human osteoblast-like cell line SaOS-2 was also investigated, and it was observed that both ALP expression and the formation of mineral nodules were stimulated in presence of zinc at concentrations of 1 and 10 μM but inhibited at concentrations higher than 25 μM.[83] When primary murine bone marrow stromal cells and osteoblast were treated with zinc at concentrations of 10^{-9} M and lower, no effect was observed on proliferation, and inhibitory effect was proven on both osteogenic and adipogenic differentiation.[84]

As recently reviewed by Yamaguchi, zinc has been shown to have an inhibitory effect on bone resorption in tissue culture systems *in vitro* and to suppress osteoclastogenesis of osteoclastic cells derived from bone marrow.[85]

1.118.5.2. Copper

Copper deficiency is generally associated with syndromes of anemia and pancytopenia, as well as with neuro-degeneration in humans and other mammals. In the metabolism of the skeleton, copper performs a key catalytic function in the first step of the maturation of collagen to form stable fibrils.[86,87] This effect can be attributed primarily to the copper-dependent enzyme lysys oxidase, for which copper acts as cofactor. Lysyl oxidase is required for the formation of lysine-derived cross-links in collagen and elastin.[88] Several reports suggested that mild copper deficiency may contribute to bone defects such as osteoporotic-like lesions and bone fragility in humans and animals,[89,90] as well as to a variety of bone developmental defects in preterm infants.[91,92] Oral supplementation with copper, however, resulted in complete healing of fractures and improvement in other bone defects.[91,92]

Copper was shown to affect both the proliferation and differentiation behavior of mesenchymal stem cells (MSCs) *in vitro*. It decreased the proliferation rate of MSCs and induced an increase in their differentiation toward the osteogenic and adipogenic lineage.[93] Copper was also reported to affect the timing of expression of ALP activity, which reached its maximum earlier than in the controls in absence of copper.

Copper also plays a role in the inhibition of bone resorption through its action as a cofactor for superoxidase dismutase, an antioxidant enzyme containing a zinc and a copper atom, which acts as a free radical scavenger, neutralizing the superoxide radicals produced by osteoclasts during bone resorption.[80] While an inhibition in osteoclast function was observed in copper-deficient animals,[94] Wilson suggested that higher concentrations of copper in cell culture medium (10^{-5} M copper sulfate) reduced bone resorption and inhibited hydroxyproline, protein, and DNA synthesis *in vitro*.[95]

In a number of studies, copper was also shown to have an effect on angiogenesis, a process which is of great importance in bone regeneration. Angiogenesis is essential for the survival of osteoblasts, as well as for the regulation of fracture healing and bone remodeling.[96,97] Previous reports showed that copper can enhance growth of endothelial cells *in vivo*,[98–100] and copper found in wound tissues is known to be involved in generation of free radicals during tissue regeneration.[101]

1.118.5.3. Strontium

Strontium is, similar to calcium, a group IIa element and, from a chemical point of view, they behave similarly. Although strontium is not an essential trace element, a substantial amount of research has been performed on its properties and effects due to its chemical analogy to calcium. Strontium is a bone-seeking element, of which 98% in the human body can be found in the skeleton.[102] It is therefore not surprising that among the trace metals present in human bone, strontium was the only one that was correlated with bone compressive strength.[103] Strontium was shown to have dose-dependent effects on bone formation, which was further affected by presence or absence of renal failure. While low doses (0.19–0.34% in drinking water during 9 weeks) were reported to improve the vertebral bone density and stimulate bone formation in rats with normal renal function,[104–106] high doses (> 0.4% in drinking water) were shown to have deleterious effects on bone mineralization.[104,105] However, in animals with chronic renal failure, 0.34% of strontium (as chloride compound) in drinking water induced a bone lesion histologically characterized as osteomalacia.[107] This and further studies on a similar model showed the effect of strontium to be complex and dose dependent.

Similar, dose-dependent effect of strontium was also observed in cell culture experiments. Studies with primary osteoblasts isolated from fetal rat calvaria showed that at low doses (1 μg ml^{-1} strontium in the culture medium) reduced nodule formation occurred in the presence of intact mineralization; at an intermediate concentration (5 μg ml^{-1}), no effect was observed, while at high concentrations (20–100 μg ml^{-1}), intact nodule formation was accompanied by reduced mineralization.[108]

Strontium was also shown to reduce excessive bone resorption in rats with osteopenia, which was associated with a decrease in the number of osteoclasts.[109] Baron and Tsouderos further showed that a distrontium salt, S12911, dissolved into the culture medium inhibited osteoclast differentiation and osteoclast activity in a dose-dependent manner, without affecting the attachment of the osteoclast.[110]

As mentioned before, current clinical use of strontium ranelate for treatment of osteoporosis is an excellent example of application of inorganic trace elements in bone-related conditions. The dual anabolic and antiresorptive role of strontium ranelate has been described *in vitro*.[111] As recently reviewed by O'Donnell and coworkers, there is evidence that supports the efficacy of strontium ranelate in reducing vertebral and, to a lesser extent, nonvertebral fractures in postmenopausal osteoporotic women and in increasing bone matrix density in postmenopausal women with and without osteoporosis.[112,113]

1.118.5.4. Fluoride

Fluoride has been recognized as an important element in mineralized tissues, such as teeth and bone, for over a century.

Initial attention was paid to environmental overexposure to this element as a cause of crippling bone disease. However, research that followed led to some major clinical successes, in particular, in dentistry with eradication of endemic dental fluorosis worldwide and a successful water and topical fluoridation program that has reduced prevalence of dental caries.[114] The role of fluoride in the prevention and control of dental caries in both humans and animals has been shown to be predominant in the maturation stage of enamel formation.[115–119] Fluoride was also found to be the single most effective agent for increasing bone volume in the osteoporotic skeleton[120] and an effective anabolic agent to increase spinal bone density by increasing bone formation and mineralization.[121,122] Similar to strontium, fluoride was shown to have a dose related effect on bone formation: low doses of fluoride (50 mg sodium fluoride daily) increased the trabecular bone density of osteoporotic patients,[123–125] whereas a dose of 75 mg day^{-1} had no beneficial effects on bone mineral density in postmenopausal women.[126] Fluoride intake of 0.8 mg kg^{-1} also stimulated bone formation in rats.[106] Complex and dose-dependent effects of fluoride, together with reports showing an increase in occurrence of osteoporotic hip fractures related to regular fluoride intake, were important reasons for the lack of major achievements of fluoride treatment in orthopedics.

Also *in vitro*, dose-dependent effects of fluoride were observed. Bellows *et al*. demonstrated an increase in proliferation of fetal rat calvarial osteoblasts with increasing dose of sodium fluoride in cell culture medium in concentrations between 10 and 500 μM, with higher concentrations being cytotoxic.[127] A positive effect of 10 μM sodium fluoride on proliferation in culture medium was also observed on embryonic chick calvarial cells, while no effect was found in human osteoblast cultures.[114] Recently, dose-dependent effect of sodium fluoride was found on proliferation and differentiation of caprine osteoblasts: at concentrations below 10^{-5} M of sodium fluoride in cell culture medium, cell proliferation and ALP expression were enhanced, whereas above this dose, apoptosis occurred and a decrease in ALP expression was observed.[128] Burgener and coworkers suggested that fluoride enhances protein tyrosine phosphorylation in osteoblast-like cells UMR-106, by enhancing tyrosine kinase activity, postulating that this signal transduction pathway is involved in the osteogenic effect of fluoride.[129]

The effect of fluoride on the behavior of osteoclasts has been reported in a study where rabbit primary osteoclasts were cultured on thin slices of bovine bone. Sodium fluoride in concentrations of 0.5–1.0 mM in medium decreased the number of resorption lacunae made by individual osteoclasts as well as the resorbed area per osteoclast.[130] It was further shown that the suppression of the resorption was enhanced by increasing the sodium fluoride concentration of the cell culture medium.[131]

1.118.5.5. Carbonate

Carbonate, together with calcium and phosphate, is a major constituent of bone mineral, which makes it, potentially, an interesting compound for the treatment of damaged and degraded bone tissue. Bone mineral of most mammals contains between about 2 and 8 wt% carbonate,[4,70,132] depending on the age of the individual.[133] Type B carbonated apatite (CO_3^{2-} for PO_4^{3-} substitution, coupled with Na^+ for Ca^{2+} substitution) prevails in biological apatites.[132] A small amount CO_3^{2-} is believed to be a substituent for OH^- groups, known as type A substitution.[134] Type A to type B ratio in biological apatites is between 0.7 and 0.9.[135] Introducing carbonate groups in the structure of hydroxyapatite mineral, in general, results in a decrease of crystallinity and increase of solubility *in vitro* and *in vivo*.[136] Direct addition of carbonate to the cell culture medium will mainly affect its pH, which is of relatively little interest. Carbonate will therefore be discussed in more detail in the section on CaP ceramics with inorganic additives.

1.118.6. Inorganic Additives in Calcium Phosphate Ceramics

1.118.6.1. Methods of Preparation

A great advantage of inorganic additives, in comparison with organic compounds such as growth factors, is their thermal stability; that is, inorganic additives do not require physiological conditions to retain their stability and functionality. However, although standard methods of preparation can often be used, processes sometimes need adaptations for various additives to be efficiently incorporated into a CaP ceramic. Method of incorporation determines the way an element is a part of the ceramic and therewith also the release profile and the efficiency of the element upon release.

Powder preparation is often a first step in the process of ceramic production. Depending on the desired ceramic type, the produced powder then undergoes a number of subsequent processes. For sintered, porous, or dense ceramics, for example, calcination, slurry preparation, drying, and sintering are frequently the steps following powder preparation. In the case of nonsintered ceramics or cements, powder is often mixed with a liquid phase to initiate setting of cement. A great number of different coating techniques also exist, which are used to provide surfaces of, for example metallic, implants with a CaP ceramic layer. The most widely used coating method is plasma-spraying,[137,138] but alternative methods such as double decomposition,[139] biomimetic,[140–142] electrolytic deposition,[143,144] sol–gel,[145–147] laser,[148–152] magnetic sputtering,[137] and hydrothermal coating[153–156] have garnered interest in the past few decades. For a number of these methods, powder is a starting point; for others, precipitation of the coating directly from a solution is a part of the process.

Inorganic additives are frequently incorporated into a ceramic (coating) during the process of powder production, either by addition of a salt into the solution from which CaP phase is precipitated or by adding a precursor containing the additive of choice into a sol–gel process. Another way of additive incorporation is in the later stage of ceramic processing, by a solid-state reaction. In this case, a ceramic powder, such as HA or β-TCP, is mixed with a salt of choice, followed by heating at high temperatures, which allows incorporation of the inorganic additive into the ceramic powder.

Metallic ion additives can be doped into the crystal lattice, which is one of the most widely used methods of

incorporation. A maximum exists for the amount of dopant that can be added, above which impurities are formed.

Zinc, for example, is often incorporated into β-TCP ceramics.[157] Incorporation of zinc into β-TCP stabilizes the crystal lattice, preventing conversion to α-tricalcium phosphate,[158] thus increasing the thermal stability of the β-TCP. To manufacture a zinc TCP (ZnTCP) powder, an adapted coprecipitation process as used for the preparation of β-TCP and HA production can be applied. First, to a solution of calcium oxide, zinc nitrate is added with a final molar ratio of 10% in Zn:(Ca+Zn). Up to 12 mol% zinc can be taken up, as at higher concentrations, an impurity appears in the form of $Zn_2Ca(PO_4)_2$. Then, phosphoric acid is added as a source of phosphate, resulting in the precipitation of a zinc-containing powder, which is then used for further ceramic preparation.[157,159] Also sol–gel reactions with, for example, zinc nitrite as a precursor,[160] and solid-state reactions, wherein β-TCP powder was mixed with zinc phosphate powder and heated,[158] were used to produce zinc-containing ceramic.

Incorporation of zinc into HA results in instability of the crystal lattice, because of the lack of adequate atomic sites. Zinc exhibits an inhibitory effect on crystallization of HA, and heat treatment of HA in presence of zinc resulted in conversion into β-TCP, with a reduced lattice constant in comparison to pure β-TCP.[161]

A way to obtain strontium-doped β-TCP is by mixing tristrontium phosphate (α-TSrP/$Sr_3(PO_4)_2$), obtained by solid-state reaction of strontium carbonate and ammonium phosphate at a ratio of 3:2, with β-TCP powders, followed by heat treatment.[158] Strontium has also been added to HA powders, either by a coprecipitation process or sol–gel method. In the coprecipitation process, strontium substitution occurred by the replacement of a part of calcium nitrate with strontium nitrate in the reaction with ammonium phosphate. The overall molar ratio was kept at 10:6 with $(NH_4)_2HPO_4$:(Ca$(NO_3)_2 + Sr(NO_3)_2$), which is the desired Ca/P ratio for HA.[162]

To create a single-phase strontium HA, a sol–gel route was followed. A solution of sodium diphosphate was added to a strontium nitrate solution, with a molar ratio for Sr:P of 2:1. Then, sodium alginate (Na-Alg) was added to the aqueous solution-containing $Sr(NO_3)_2$ and $Na_4P_2O_7$ according to the molar ratio of Sr:P:Na-Alg = 2/1/2.5, followed by drying and calcination of the sol. The phase composition appeared highly dependent on the amount of Na-Alg added. When other ratios were used, phases such as $Sr_2P_2O_7$ and/or $Sr_3(PO_4)_2$ also formed.[163]

In contrast to zinc and strontium doping, a relatively limited amount of work has been done on copper doping of CaP ceramics. In a paper by Belik and coworkers, it was reported that $Ca_{10.5-x}Cu_x(PO_4)_7$ with $x = 0$, 1/6, 1/3, 1/2, 2/3, 5/6, 1, 7/6, 4/3, and 1.5 can be synthesized after the substitution of calcium by copper within the structure of β-TCP through a solid-state reaction.[164]

Fluoridated apatite powders can be readily made by adding a fluoride donor during CaP precipitation process, whereby F^- substitutes the OH^-,[165–167] leading to a reduction in crystal size and an increase in structure stability.[74,75]

Synthetic carbonated apatite type A (CO_3^{2-} for OH^- substitution) has been successfully produced by using a time-consuming process of sintering HA powder under CO_2 supply or by soaking HA powder in an aqueous solution saturated with CO_2.[70,168] Preparation of type B (CO_3^{2-} for PO_4^{3-} substitution, coupled with Na^+ for Ca^{2+} substitution) or type AB is more complex and occurs predominantly via closely controlled aqueous precipitation reactions.[169–173] However, when carbonated apatite powders are sintered to produce highly crystalline, porous ceramics, excessive loss of carbonate may occur[172,174,175] due to thermal instability of carbonated apatites.[176,177]

1.118.6.2. Effect of Inorganic Additives on Ceramic Properties

Effects of incorporation of inorganic additives on the physicochemical and structural properties of CaP ceramics, and consequently their biological behavior, are largely dependent on the way an additive is incorporated into the crystal lattice. HA crystals possess a hexagonal structure with a $P6_3/m$ space group (a space group with a sixfold symmetry axis with a threefold helix and a mirrorplane) and with cell dimensions $a = b = 9.42$ Å and $c = 6.88$ Å, but it can also occur in a similar pseudohexagonal monoclinic form with space group $P2_1/b$ (a space group with a twofold rotation axis and an axial translation of width $b/2$ along (010)). HA consists of a skeleton of PO_4^{3-} tetrahedra, with two oxygen atoms in a horizontal plane, and the other two in the plane parallel to the c-axis. In a crystal unit cell, the PO_4^{3-} tetrahedra are divided into two layers, at ¼ and ¾ of crystal, respectively, in such a way that two columns, perpendicular to the basal plane, exist.[178] Cations at site I, Ca I, are coordinated by nine oxygen atoms belonging to six PO_4^{3-} anions, forming triangles and displaying a columnar arrangement. Cations at site II are heptacoordinated by six oxygen atoms belonging to five PO_4^{3-} anions and one OH^- anion. The smallest distance between a cation and a coordinated oxygen is found at site II, while the smallest Ca–Ca distances are observed between Ca^{2+} ions at site I. Small ions (such as Cd^{2+}, Zn^{2+}, and Mg^{2+}) are incorporated preferentially in the HA structure at Ca I. In contrast, large cations (such as Sr^{2+}, Ba^{2+}, and Pb^{2+}) would first replace Ca^{2+} at Ca II.[162] Small monovalent anions occur in the sixfold symmetry axis, in the center of the Ca(II) triangles. F^- substitution has been shown to include interactions with neighboring OH^- ions via hydrogen bonding.[178] Carbonate ion incorporation into the apatite lattice predominantly occurs through phosphate group substitution (type B), whereas particularly in biological apatites, a small amount of carbonate replaces the OH^- ions (type A substitution).[162] Although the structural location of carbonate ions in the lattice is still incompletely understood, it has been shown that A CO_3^{2-} group is centered on the c-axis, whereas the B CO_3^{2-} group is located at the oblique face of the PO_4 tetrahedron.[178]

Incorporation of zinc into the CaP crystal lattice occurs by substitution of calcium ions. It has been shown that zinc incorporation decreases the lattice parameters a and c because of the Zn^{2+} ionic radius, which is smaller than Ca^{2+} ionic radius; however, there have also been reports suggesting an increase in the size of the a and c axes, at higher zinc contents.[179,180] Zinc generally destabilizes the crystal structure, except for that of β-TCP, which has an atomic site, known as a Mg site, that can incorporate divalent cations with an ionic radius ranging from 0.060 to 0.080 nm, where the ionic radius of zinc belongs to.[181] By heating the zinc-doped β-TCP at

temperatures above 800 °C, the zinc-doped β-TCP started to transform into zinc-doped α-TCP, which had higher solubility than β-TCP.[182] The highest content of zinc in the zinc-doped β-TCP was 6 wt%, which was higher than maximum zinc content of 1.26 wt% in zinc-doped α-TCP at 1450 °C.[183] While the zinc content increases, the solubility of TCP decreases. The negative logarithm of the K_{sp} is expressed as $pK_{sp} = 28.686 + 1.7414C - 0.42239C^2 + 0.063911C^3 - 0.0051037C^4 + 0.0001595C^5$, where C is the zinc content in TCP in mol%.[184] XRD results showed that TCP structure did not undergo great changes after substitution.[157,185,186] Rietveld refinement of the XRD data confirmed that the lattice parameters a and c decreased with an increase of the zinc content in β-TCP from 2 to 9 mol%, leading to contraction in the unit cell volume.[187] This effect on the unit cell volume was consistent with the reports on the effect of magnesium and copper and is probably caused by the lower ionic radius of zinc compared to that of calcium.[188,189] Reports also revealed that the replacement of M(5) site of calcium ions in the β-TCP structure was favored, consistent with reports on copper,[164,187] which can be explained by the fact that the Ca–O bond at M(5) site is the shortest mean distance in the β-TCP structure.[190]

Although substitution of zinc into HA is more difficult than substitution into β-TCP, Chung *et al.* successfully synthesized the ZnHA powders by a sol–gel method through addition of zinc ranging from 200 to 20 000 ppm by atomic ratio versus calcium atoms.[191] The TGA analyses, however, implied that the amount incorporated was relatively small. X-ray diffraction (XRD) results, supported by the Fourier transform infrared spectroscopy (FTIR) analysis showed that the only phase present was that of HA.[186,191,192]

HA was also doped with zinc using a hydrothermal method.[179,192] In this study, it was shown that the crystallinity of HA decreased with an increase in the zinc content from 10 to 20 mol%. Dissolution behavior of HA ceramic was affected in the presence of zinc: while Mayer and Featherstone observed a decrease in dissolution, in another study an increase in solubility was observed, possibly due to differences in production methods.[192–194]

In a study, in which copper-substituted β-TCP was prepared through a solid-state reaction, it was shown that the maximum copper content was 8.5 wt%. XRD data showed that the calcium cations on the M(4) and M(5) sites in the β-TCP structure can be replaced by copper cations and also confirmed the dependence of unit cell parameters on the copper concentration.[164] Replacement of Ca^{2+} with Cu^{2+} reduces the bond lengths between calcium and oxygen atoms in the crystalline lattice mainly because of the lower ionic radius of Cu^{2+} as compared with that of the Ca^{2+}.[188,195] From an energy point of view, the total molecular energy decreases with the replacement of Ca^{2+} with Cu^{2+},[188] meaning that copper ions are theoretically preferred to calcium ions.

In a study wherein single-phase strontium-doped β-TCP was produced by preparing a calcium-deficient apatite through aqueous precipitation and consequent heat treatment at a temperature above 700 °C, substitution of calcium by strontium was shown to have an effect on the lattice constant of the resulting β-TCP.[196] Substitution of calcium by strontium led to a significant expansion in both the *a*- and *c*-axes, which were increased with an increasing strontium content because of the larger ionic radius of strontium of 1.13 Å compared with that of calcium (0.96 Å). β-TCP showed the ability to host up to 80 at.% of strontium without provoking a remarkable rearrangement of the unit cell.[158,196,197] These findings were consistent with studies on strontium-substituted α-TCP.[198]

The substitution of calcium by strontium in the HA was proven possible to an extent of Sr/Ca atomic ratio of 30%. Also here, substitution resulted in larger crystal lattice and increased solubility of the ceramic.[199,200] These findings were consistent with other reports where the XRD and FTIR analyses in strontium-containing HA indicated a substantial expansion of the crystal lattice dimensions as compared to pure HA.[201,202]

Replacement of OH^- with F^- in an apatite lattice can bring about a reduction in the volume of the unit cell and a concomitant increase in structure stability.[70,203] FHA nanopowders with the composition of $Ca_{10}(PO_4)_6OH_{2-x}F_x$ (x in the range of 0–2) were successfully synthesized by mechanical alloying method whereby XRD and FTIR analyses revealed only the presence of apatite.[204] XRD patterns showed that some peaks gradually shifted to the right with the fluoride content increasing in FHA, because of the decrease in *a*-axis of the unit cell, caused by lower ionic radius of F^- compared with that of OH^-.[205–207] Dissolution tests showed that solubility decreased with the increase in fluoride content. The minimum solubility was observed at x values of 0.8–1.1, because the substitution of OH^- by F^- resulted in a stronger hydrogen bond between F^- and nearby OH^-, resulting in a more stable structure with lower solubility.[205,208–210]

An increase of carbonate content in a carbonated apatite by both A and B substitution, resulted in contraction of *a*-axis and expansion of *c*-axis of the unit cell, and therefore, in a decrease in crystal size and an increase in crystal strain, which in turn resulted in a higher solubility.[211,212] **Figure 3** shows microstructure of an HA and a carbonated apatite ceramic, produced using a similar method, from which it is obvious that even a carbonate content of about 5 wt% leads to a great decrease of grain size of the ceramic.

1.118.6.3. Biological Performance of Ceramics Containing Inorganic Additives

In this section, release profiles of the inorganic additives from the ceramics are discussed in physiological conditions as well as their effect in *in vitro* and *in vivo* systems related to bone formation and remodeling.

Studies on the *in vitro* release profiles of zinc for the ZnTCP in simulated body fluid (SBF) showed an initial burst release of zinc, followed by a sustained release over a longer period of time. The amount of zinc released increased with the increasing zinc content of the ceramic ranging from 0.6 to 6 wt%.[185] The rate of zinc release was shown to increase when the calcium content of the release medium was decreased.[185]

In a study by Tas *et al.* it was demonstrated that presence of zinc in β-TCP in concentrations 2900 and 4100 ppm increased viability of murine osteoblast-like cells, whereas further increase in zinc content had an opposite effect. ALP activity of these cells was found to reach its maximum on ceramics containing 4100 ppm zinc.[213] Dose-dependent effects on

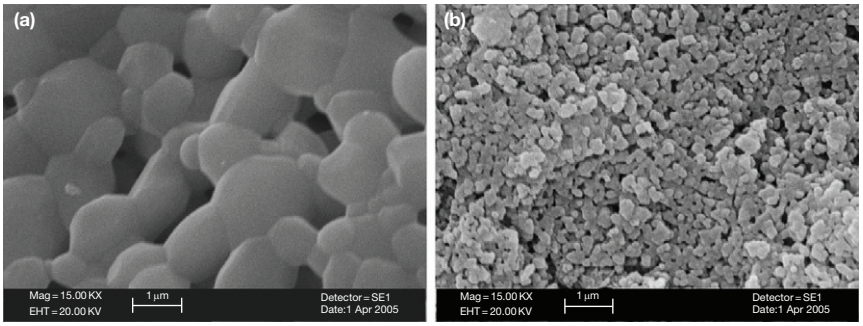

Figure 3 High magnification scanning electron microscopy micrographs showing microstructure of (a) hydroxyapatite and (b) type B carbonated apatite ceramic containing about 4 wt% carbonate, produced using a similar process. Note a significant decrease in crystal size in presence of carbonate.

osteoblastic cell attachment and growth were observed in both zinc-containing HA and β-TCP, with a positive effect up to 1.5 wt% and a negative effect above this level, possibly due to the toxic effects on cells.[186,214] Ito and colleagues also reported a more pronounced MC3T3-E1 osteoblasts proliferation *in vitro* for ZnTCP/HA ceramics with zinc content ranging from 0.6 and 1.2 wt% as compared to the control,[157] which was consistent with other *in vitro* reports.[215,216]

Resorption by mature osteoclasts of ZnTCP with zinc concentrations of 0.316 wt% and especially 0.633 wt%, was lower than resorption of pure TCP, possibly due to an increase in the apoptosis of osteoclasts.[184,217] At a zinc level of 0.633 wt%, the number of apoptotic osteoclasts was 2.8 times higher than on pure TCP after 24 h of culture. These findings were consistent with the laser microscopic measurement experiments on osteoclastic resorption pits, which showed that ZnTCP slightly reduced the resorption area by 15.5%, remarkably reduced the depth of resorption pits by 25.4%, and therewith the volume of resorption pits by 53.9% compared to pure TCP.[218]

In vivo studies in rabbit femora showed that 0.316 wt% of zinc was the optimum concentration at which the largest area of new bone was formed, in both ZnTCP and ZnTCP/HA, whereas zinc content of 0.633 wt% was too high, enlarging the medullary cavity area by stimulated bone resorption.[219] Interestingly, the optimum zinc content *in vivo* was much lower than the zinc amount needed to exert a positive effect of osteoblast proliferation *in vitro*.[157]

Copper-containing CaP ceramics have not been extensively investigated with regard to their bioactivity in bone regeneration; however, simple adsorption of copper ions on a CaP ceramic prepared at room temperature showed a positive effect on angiogenesis *in vitro* and *in vivo*.[220,221] This is an interesting finding because poor vascularization is considered an important reason for failure in timely and complete regeneration of large critically sized bone defects.

In vitro bioactivity studies in SBF showed that Sr-HA, with a strontium content below 10 mol%, showed a more pronounced apatite layer formation on the surface than pure HA, which can be attributed to a higher dissolution rate of strontium-containing ceramic.[200,222] A similar observation was made in strontium-containing TCP.[198] Experiments with osteoprecursor cells (OPC1) showed that both the attachment and proliferation were increased in HA-containing 20 mol% strontium as compared to the control without strontium. Increases in ALP and osteopontin were also seen, suggesting that strontium stimulated osteogenic differentiation of OPC1 cells.[222] Similar findings were also obtained in a study where osteoblast-like cells were cultured on strontium-substituted biphasic CaP ceramic.[223] Pulsed-laser deposition was successfully used to apply a coating of strontium-doped HA, prepared by an aqueous precipitation method, on metallic substrates. Osteogenic differentiation of human osteosarcoma cell line MG-63 was stimulated by strontium (3–7 at.% in the coating), whereas proliferation of osteoclasts was negatively affected.[224]

Injection of strontium-containing CaP cement into rabbit iliac crest cancellous bone revealed that Sr-HA stimulated the formation of osteoblast and osteoid layers, and hence new bone formation.[225]

Fluorinated HA showed a positive effect on proliferation and osteogenic differentiation of cells. In a study by Wang and coworkers, MG-63 cells were cultured on fluorinated HA coatings produced by a sol–gel dipping method. Positive effect of fluoride on cell attachment, as well as ALP and osteocalcin production, was observed in a certain concentration range,[208] at which the ceramic coating had the lowest solubility. A positive effect of fluoride on cell proliferation and osteogenic differentiation was also observed when SaOS-3 rat osteosarcoma cells were cultured on fluorinated HA disks in comparison to fluoride-free controls.[226] In a study by Inoue and coworkers, fluorinated apatite ceramics were tested in a short-term implantation model in rat tibia. A more pronounced bone formation was observed in fluoride-containing ceramic compared to that in an unsintered calcium-deficient apatite ceramic.[227]

Redey and coworkers showed a poor attachment and low collagen production of human primary osteoblasts on carbonated apatite ceramic as compared to that on HA ceramic, possibly caused by the difference in wettability between the two ceramics,[228] which is in agreement with other reports showing a positive correlation between surface energy and attachment of cells.[229–231] After initial cell attachment, however, no significant difference was found in further proliferation of the cells between carbonated and pure HA ceramic. Similar to osteoblast attachment, osteoclast attachment was more pronounced on carbonate-free ceramics compared to the carbonated one, while no difference was observed on the spreading of cells after initial attachment.[232] Doi *et al.* showed that CA was resorbed by osteoclasts in 2-day cultures, while

HA remained unresorbed, suggesting that the presence of carbonate may play a crucial role in osteoclastic resorption,[233] which was in accordance with the results obtained in an *in vivo* experiment in rats.[234] A possible reason could be the released carbonate that stimulates carbonic anhydrase activity and hence promotes acid secretion by osteoclasts.[235] Also Spence and coworkers recently observed an increase in osteoclastic resorption with an increase of carbonate content in an HA ceramic.[236] In an *in vivo* study in rabbits by Landi and coworkers, higher amount of new bone formation was found in sintered carbonated apatite ceramic compared to the pure HA ceramic.[237] An increase in the amount of newly formed bone with increasing carbonate content in an apatite ceramic was also observed in a rat femur model.[238] In a recent study in a critical-size iliac wing model in goats, it was shown that an increase in carbonate content of a ceramic does not necessarily lead to more bone formation if other ceramic properties are not controlled.[177]

Simultaneous incorporation of fluoride and carbonate into apatites led to inhibition of osteoclast proliferation and pit formation *in vitro* as compared to that in pure HA and carbonated apatites, whereas *in vivo*, faster bone remodeling was observed.[239]

1.118.7. Future Perspectives

Incorporation of inorganic additives to improve the biological performance of the existing bone graft substitutes is a complex matter, as we tried to demonstrate in the previous sections, in which we summarized some of the work performed in preparation, characterization, and biological activity assessment of ceramics-containing zinc, copper, strontium, fluoride, and carbonate, respectively. Incorporation of these additives into CaP bone graft substitutes not only adds an additional element into the structure that can exert a certain function but also changes intrinsic properties of the recipient material. The way and the efficiency of incorporation are dependent on the method used. These in turn affect the release profile of the incorporated additive and also the solubility of the recipient itself, and all these affect the behavior of osteoblasts and osteoclasts *in vitro*, as well as the *in vivo* bone formation and remodeling.

Zinc incorporation into β-TCP is responsible for a reduction in cell unit and a decrease in solubility of the ceramic. Zinc has shown positive effects on proliferation and osteogenic differentiation of bone forming cells and decreased osteoclastic resorption *in vitro*, but this effect was dose dependent. Some promising results were observed with regard to bone forming capacity in *in vivo* preclinical models with zinc-doped β-TCP. Copper was shown to have a similar effect on crystal properties as zinc, and although copper-doped ceramics have not been thoroughly tested, there is evidence that copper can stimulate angiogenesis. Strontium replaces calcium in the crystal lattice and increases the size of the unit cell as well as the solubility of the ceramic. Proliferation and osteogenic differentiation of osteoblastic cells were shown to increase in strontium-substituted ceramics, whereas the effect on osteoclast growth was negative. Replacement of OH^- with F^- in an apatite lattice can bring about a reduction in the volume of the unit cell and a concomitant increase in structural stability. Fluorinated apatites can stimulate osteoblast proliferation and osteogenic differentiation, but in a dose-dependent manner. Finally, carbonate is responsible for a decrease in size of an apatitic crystal and an increase in ceramic solubility. Attachment of osteoblastic cells on carbonated ceramics was poorer than on the hydroxyapatite ones, but proliferation was not affected. Osteoclast proliferation and resorption potential were higher on the carbonate-containing CaP ceramics compared to that on the control ceramics without carbonate.

As already mentioned, these are some general remarks about the effects of various additives on properties and efficiency of the existing bone graft substitutes. But due to variations in the preparation and characterization methods and assessment of biological performance of these materials, a comparison among the studies and the results obtained is difficult, and hence general conclusions cannot be drawn. Thus, it behooves the field of biomaterials research to utilize generally accepted, standard methods of study, such that *in vitro* behavior and *in vivo* performance can be correlated. We also suggest that high-throughput study concepts have their place in biomaterials research, such as in the context of quantifying the effect of ionic substitutions with the apatite lattice.

1.120.1. Introduction

Bone tissue has a remarkable ability for regeneration and repair. However, in some situations, bone repair cannot occur spontaneously because the bone defect has reached a critical size. These so-called *critical defects*, defined as defects of a size that will not heal during the lifetime of the patient/animal, are encountered in various conditions, including trauma, infection, congenital disease or surgical resection for tumor, or in association with failed joint replacements. Various procedures have been described to solve these often complex issues. Most of them imply the use of a bone graft, either natural or synthetic. Natural bone graft can be obtained from a genetically nonidentical donor of the same species as the recipient (allograft or homograft or allogenic bone transplant) or from the patient himself (autograft). Allografts circumvent some of the issues relative to autograft, such as donor site morbidity and limited supply. However, there are concerns associated with their use, including the risk of transmission of infectious disease, immunological reactions in the recipient, loss of biologic and mechanical properties due to their processing, increased costs, and availability. The gold standard of bone grafts remains autogenous bone graft or autograft. The latter is usually harvested from the iliac crest, but other donor sites are possible. Properties of autogenous bone graft include *osteointegration*, *osteoconduction*, *osteoinduction*, and *osteogenesis*. *Osteointegration* is considered the ability of achieving a bone-implant interface without an intervening fibrous layer. *Osteoconduction* refers to the ability of supporting the growth of bone over the surface of the graft. The graft supports the proliferation of new osteoblasts and osteoprogenitor cells, providing a matrix through which new cells can migrate and new vessels can form. When materials are porous, the requisite pore size for bone ingrowth into porous implants is 100–500 μm, and the interconnections typically exceed 100 μm. *Osteoinduction* refers to the ability of a graft to induce differentiation of pluripotential stem cells or osteoprogenitor cells to an osteoblastic phenotype. Finally, *osteogenesis* is defined as the property of a graft to form new bone from osteoblastic cells present within the material (Figure 1).

Only autogenous bone graft satisfies all these requirements. However, the limited quantity of bone autograft considerably limits its clinical use. Moreover, bone autografting implies the need for an additional surgical site, limited quantity, inappropriate form, and donor site morbidity (hematoma, infection, nerve damage, and chronic pain). In addition, the mechanical properties of the iliac bone are often poor, especially in postmenopausal women.

The disadvantages and potential complications related to the use of allo- and autograft have dictated the progress toward synthetic bone grafts and/or a biologic alternative, because

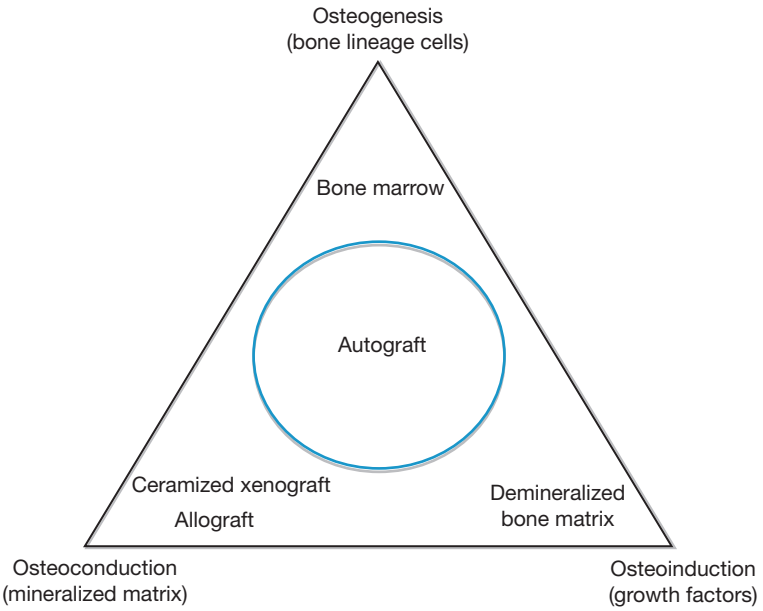

Figure 1 Bone autograft still represents the gold standard for bone grafting. As shown in the diagram, it combines the three most desirable properties of a bone graft material, namely ostoconduction, osteoinduction, and osteogenesis. Main families of bone substitutes are presented in the diagram with regard to their respective biological activity.

they circumvent all the risks related to the substitute procured from living tissue. There is no consensus definition of a synthetic bone graft substitute. One should consider a synthetic bone grafting material as a synthetically derived device, intended to fill, augment, or reconstruct bone defects of the skeleton. Also, recent generations of bone substitutes have introduced and increased the potential of synthetic bone grafts to promote biologic repair, to provide support for treatment, that is, antibiotics or bone morphogenetic proteins (BMPs), and to enhance osseointegration of orthopedic implants.

Today, current indications for bone substitutes are in spinal fusion, bone defects, osteoporotic fractures, revision prosthetic surgery, and vertebroplasty. Theoretically, a given synthetic bone graft should be biocompatible and well tolerated by the recipient, bioresorbable in the mid-term, easy to handle and store, and available at a reasonable cost; it should enhance bone repair and provide satisfying mechanical support. This chapter focuses on conventional synthetic bone grafts, with the exclusion of growth factors and gene- and cell-based strategies, proposed in the orthopedic field.

1.120.2. A Brief History of Bone Grafts

Original attempts at bone reconstruction were made using allogafts or xenografts. Cosmas and Damian, twin physiotherapists and surgeons, described a limb reconstruction with an heterologous graft in the fourth century AD. Hence, their most famous, miraculous, and legendary exploit was the grafting of a leg from a recently deceased Ethiopian to replace the leg of a patient who suffered from a bone tumor. Surgical repair of deformities or defects of the skull with varied materials (such as precious metals and gourds), a procedure currently named cranioplasty, was performed by many ancient civilizations, and a number of these procedures date back to 3000 BC, especially to the Inca period in Peru. There is strong evidence that this practice continued all around the world during the following centuries until the introduction of modern medicine by Hippocrates in Ancient Greece. Interestingly, it was not until the late sixteenth century, in 1565, that true cranioplasty in the form of a gold plate was described by the Italian anatomist and physiotherapist Fallopius (1523–1562) and Petronius. Later, the first bone graft was officially recorded by Job Janszoon van Meekeren (1611–1666), a Dutch surgeon, who reported (not performed!), in a posthumous publication in 1668, the repair of a cranial defect in a Russian soldier with a piece of bone from a dog's skull. Although healing was obtained, the Church ordered the removal of the graft. Recent researches have revealed that the description of the technique of cranioplasty could be attributed to a Turkish surgeon, Ibrahim bin Abdullah, who originally reported repair of skull defects with xenograft in AD 1505.[1] In the twentieth century, polymeric materials have largely replaced metallic bone substitutes in this indication. Polymethyl metacrylate (PMMA) was introduced in 1940 and is currently the most common material used in cranial bone defects, although its nature does not make it a true bone substitute.

In the nineteenth century, techniques of bone replacement became more common after the original publication of autologous bone graft by Van Merren d'Amsterdam in 1810. The safe use of materials of human or synthetic origin to replace bony segments did not come into practice until the advance of aseptic surgical techniques at the end of the nineteenth century. Thus, Ollier established the basic science of bone banking. During the same period, the first attempts to reconstruct long bone defects by nonosseous materials were reported. Among several materials, such as ivory, gold, or wood, only plaster of Paris, which is still employed, fulfilled some of the requirements of a true bone substitute. In 1892, Dressman from the Trendelenburg Clinic[2] first reported on the

clinical results of eight cases of bone filling with plaster of Paris. Subsequently, L.F. Peltier of the United States regularly reported clinical experience from the 1950s to the 1970s.[3–5]

The use of ceramic calcium phosphate materials to promote bone formation was reported close to a century ago. In 1920, Albee and Morrison[6] described the use of 'triple calcium phosphate' to promote bone ingrowth. Their results indicated that bone fractures associated with a bone defect, showed a more rapid bone ingrowth and healing when triple calcium phosphate was injected into the gap between the bone ends than did controls. In 1952, Ray and Ward[7] evaluated the effectiveness of synthetic hydroxyapatite (HA) granules in the reconstruction of experimental defects in the long bones and iliac wings of dogs and bur holes in cats' crania. They observed that synthetic hydroxyapatite graft could be replaced by new bone, but they concluded that HA was not as effective as autologous bone graft. Self-hardening calcium phosphate (CP) cements were developed in the late 1980s. Marshall Urist found in the early 1960s that the demineralized bone matrix (DBM) had the capability of inducing bone formation in an ectopic site.[8] This property was named osteoinductivity several years later, and the agent responsible for it was found to be a protein named BMP.

1.120.3. Synthetic Bone Graft Substitutes

Approximately, 60% of the synthetic bone graft substitutes currently available involve ceramics, either alone or in combination with another material. Ceramic bone substitutes include by calcium sulfate, CPs, and bioactive glasses and glass ceramics.

1.120.3.1. Calcium Sulfate (Plaster of Paris) (Table 1)

Plaster of Paris is a mineral bone substitute, composed of dihydrated calcium sulfate ($CaSO_4 + 2H_2O$), that has been employed since the end of the nineteenth century. Currently, calcium sulfate is obtained either by chemical synthesis or by a gypsum calcinating process. Sterilization is obtained by γ-radiation (min 25 kGy). Calcium sulfate is characterized by an absence of macroporosity, as a result of its industrial production process employing powder compression. Therefore, no osteoconduction can be allowed with this material. Compressive strength of calcium sulfate appears greater than cancellous bone, although tensile strength appears slightly inferior. It is noteworthy that plaster of Paris tends to soften and fragment if exposed to moisture, which results in a significant loss of mechanical properties upon its degradation in bony environment. Compression stress has been evaluated to 23 028 KPa in a dry sample, as compared to 10 342 KPa in a wet sample.

Calcium sulfate is biocompatible and bioactive, and biodegrades experimentally after 2–5 weeks. In clinical applications, a complete resorption of the material is usually observed 4–8 weeks after implantation. In a bone tissue environment, calcium sulfate degrades progressively in a centripetal pattern following a process of dissolution, in parallel with bone ingrowth. In an experimental model, it has been reported that the osteoblastic repair process was enhanced in the presence of calcium sulfate in critical bone defects without evidence of a foreign body reaction.[9–11]

Calcium sulfate has been used for over a century in clinical practice, mainly as a bone void filler. Current applications concern spine fusion, used alone or in combination with bone autograft, packing of benign tumors or cysts after resection or curettage, and trauma. It is noteworthy that indications for plaster of Paris should be limited to non-load-bearing bony voids or gaps, or should always be employed in association with a rigid internal fixation. Calcium sulfate appears as a viable option in filling bone cavities, and is not contraindicated in the presence of infection. Osteoset™ with or without DBM was used in 23 patients with bone cysts or benign bone tumors. Healing was observed in all patients and the rate and amount of bone regeneration was not dependent on the addition of DBM to the calcium sulfate granules. Osseous repair of the lesions was considered complete by 6 months, and all but one patient resumed normal functional activities in 12 months.[12] In a multicenter trial, Osteoset™ pellets were used in 46 patients with benign bone tumors. In 36 of 42 patients, a mixture of additional graft materials including DBM, bone marrow aspirate, and autograft were used. Results showed 100% pellet resorption and 96% bone ingrowth at 12 months, with no significant difference between patients receiving Osteoset alone or in combination with other graft material.[13]

Calcium sulfate is commercially available as small pellets ranging from 3 to 4.8 mm in diameter for implantation (Osteoset™, Wright Medical Technology, Arlington, TN). Calcium sulfate also comes impregnated with tobramycin (Osteoset™ T) (4% weight). Osteoset™ T comes in the form of 4.8 mm pellets and is indicated in the treatment of osteomyelitic bone defects, or during revision arthroplasties. Boneplast™ (Biomet Osteobiologics, Warsaw, IN) comes in the form of a mixing kit, composed of a calcium sulfate powder and saline. It is moldable to fit any shape defect up to 8 min after mixing. It begins hardening in 10 min. Calcium sulfate is also commercially presented as a carrier of DBM, which has been proved to stimulate osteoinduction (Allomatrix™ Injectable DBM Biocomposite, Wright Medical Technology).

1.120.3.2. Calcium Phosphate Ceramics (Table 1)

CP materials account for most of the ceramic-based bone graft substitutes currently available. They have been employed in clinical practice for over 20 years. The most desirable property of CPCs is their ability to form a direct bond with host bone, resulting in a strong interface as compared to bioinert or biotolerant materials, which form a fibrous interface. Numerous experimental and clinical reports since the 1970s have shown their applicability in filling bone defects in various fields such as periodontics, oral and maxillofacial surgeries, neurosurgery, and orthopedics.

The primary inorganic component of bone is a nonstoichiometric carbonated apatite, namely calcium HA. CPCs are characterized by their chemical composition similar to that of the mineral phase of calcified tissue.

The CP family includes numerous members, characterized by their chemical formula, and their calcium to phosphate ratio (Ca/P). It is possible to control the composition of the untreated product by adjusting the Ca/P ratio of the starting material to obtain a product as desired. This procedure allows the production of the four main CPCs, designed as

calcium tetraphosphate ($Ca_4P_2O_9$), characterized by a Ca/P ratio equal to 2, hydroxyapatite or hydroxylapatite (HA) [$Ca_{10}(PO_4)_6(OH_2)$] (Ca/P = 1.67), tricalcium phosphate (TCP) [$Ca_3(PO_4)_2$] (Ca/P = 1.5), and dicalcium phosphate dihydrate (DCPD or brushite) [$CaHPO_4 \cdot 2(H_2O)$] (Ca/P = 1). Among these compounds, HA and β-TCP are the most widely used (**Table 1**), mainly in combination in variable proportion in so-called biphasic calcium phosphate (BCP) ceramic. Of note is the fact that β-TCP ceramics are much more soluble and biodegradable compared to HA.[14,15] In addition, Becker *et al.*[16] showed that Chronos used in combination with autologous bone marrow (Chronos Perfusion Concept) could be almost entirely replaced by host bone 12 weeks after implantation. There is no report of systemic toxicity or immunologic or foreign body reaction, nor infectious disease transmission with these materials.

CPC biocompatibility has been shown to be excellent in *in vitro* and *in vivo* settings. For a given chemical composition, ceramics with lower Ca/P ratios resorb more rapidly, giving rise to unpredictable biodegradation profiles, which may result in undesirable loss of strength. On the other side, those with greater Ca/P ratios degrade more slowly but may give rise to remnants that may induce inflammation. Lower degradation rates usually result in less new bone formation around the scaffold. For instance, when dense HA ceramics are used as bone implants, they are almost nonresorbable and remain bioinert. The combination of different CP compounds can be used as a manufacturing strategy to control bioresorption rates of the ceramics. Under physiological conditions, material characteristics such as crystallinity, crystal size, particle size and size distribution, porosity and surface roughness also have been reported to influence biological performance.[15,17] Among these parameters, pore interconnectivity seems to be one of the most important parameters for bone ingrowth.[18–20]

CPCs may be prepared by several synthetic routes, which include hydrolysis, hydrothermal synthesis, hydrothermal exchange (coral-derived ceramics), solid process from bovine bone (ceramized xenograft), sol–gel processes, spray pyrolysis from natural coralline, and wet chemical methods. Conventional CPCs are usually prepared from highly purified precursor powders. The powders are calcined at temperatures below 900 °C. The mono- or multiphasic powders are then compacted at high pressure, and fired to high temperatures (1100–1300 °C), this step being termed 'sintering.' Once recrystallization and grain growth of the original powder has occurred after cooling, a material characterized by a mosaic pattern of aggregated crystals is obtained. These procedures result in a dense ceramic material. Its porosity is in the micrometric range, with the pore size always <100 μm in diameter. However, to favor bone ingrowth, a ceramic material should have an open macropore structure that enables cell migration. This is obtained at the step of sintering with the addition of pores and canal structure-forming agents in the form of porogen particles, such as naphthalene. The porogen compound is finally eliminated during the sintering phase. Another method relies on the decomposition of hydrogen peroxide to generate the desired porous structure. This manufacturing process should be stringently controlled as it dictates the mechanical, physical, chemical, and biological properties of the final ceramic product. Hence, the macrostructure of the material is determined by the particles size of the porogen compound. Macroporosity is defined by a pore size higher than 100 μm. Experimental studies have shown that optimal bone tissue ingrowth was observed in porous ceramics with macropores diameter ranging from 100 to 500 μm, combined with high interconnectivity. The overall porosity of the material corresponds to all pores and connective canals between pores in the material, which is equivalent to the ratio of the volume of void in the ceramic to the volume of the whole. It averages 30–45% in commercially available products.

These synthetic ceramic products differ substantially from ceramics produced from coral. Hence, HA can be manufactured from natural reef building coral skeleton by a hydrothermal exchange reaction. This procedure drives the conversion of the calcium carbonate skeleton to CP, the main component of hydroxyapatite. This concept is based on the finding that the structure of certain reef-building coral species resembles the trabecular structure of bone. Specifically, with pore diameters ranging from 140 to 160 μm, *Porites* and *Goniopora* coralline species meet satisfying criteria for bone substitution, and are employed in commercialized bone substitutes.[21–24]

Studies have shown that porous CPCs were osteoconductive, biocompatible, and bioactive.[16,18,19] Porosity of the ceramic promotes biological and cellular events, leading to bone tissue ingrowth. Schematically, chemical events take place in micropores within the hours following implantation of the bone substitute. They include the recruitment of Ca^{2+} and PO_4^{2-} ions from both implant and surrounding bony environment, to form a biological apatite layer, similar to the crystalline phase of bone. Apatite crystals unite with local proteins, such as growth factors and collagen. In parallel, cell attachment, proliferation and differentiation, and also vascular invasion, occur in the macropores. These steps result in a direct contact between host bone tissue and the ceramic, without interposition of a fibrous layer, and, further on, in osteointegration.

Pure HA resorbs with time but its degradation rate is very low, as a result of its limited solubility in biological fluids. Solubility is increased in biphasic materials, which combine hydroxyapatite and TCP in variable proportion. Currently, most of the biphasic ceramics are composed of 60–65% HA and 35–40% β-TCP. The replacement of β-TCP by bone does not occur in an equitable way. There is always less bone volume produced than the volume of β-TCP reabsorbed. Bioresorption of the bone graft ceramic depends on different parameters, including chemical structure, shape, overall porosity, interconnectivity, pore size, crystallinity, and specific surface. *In vivo* resorption of porous CP ceramics begins with the dissolution of ionic precursors in the extracellular environment. Chemotactic agents included in the apatite HA layer stimulate giant cells and macrophages which participate in the resorption of the material. Also, the material is resorbed as part of the physiological Haversian remodeling process, driven by osteoclasts. Then, new lamellar bone produced by osteoblasts forms in place of the artificial material.

There is a growing interest in developing HA/β-TCP BCP ceramics as scaffold materials because they are more effective in bone repair or regeneration than each of its components taken separately, and their degradation rate is controllable to a certain degree.[25,26]

CPCs are brittle and weak under tension and shear, and resistant to compressive loads. Their mechanical resistance has been evaluated from 10 to 15 MPa for current products. The compressive and tensile strengths of β-TCP are very similar to those of cancellous bone, whereas dense ceramics such as HA can resist in compression up to 100 MPa and have a much higher modulus of elasticity than bone. Therefore, CPC are not indicated in constrained or load-bearing areas, and should be employed in conjunction with an osteosynthesis. Mechanical resistance improves in parallel with osseointegration and ceramic remodeling.

CPCs are considered as reference bone substitutes, provided that indications and handling are in line with their properties. They have been demonstrated to bond to bone tissue under optimal conditions, including close contact between synthetic graft and host, achievement of primary stability, and a well-vascularized environment. These ceramics are indicated in a wide variety of fields, specifically in orthopedics, including prosthetic hip revision surgery, spine surgery, trauma, benign bone tumor filling, and high tibial valgus osteotomy. A few studies reported the use of bone substitutes in hip replacement revision. Historically, CPCs were employed to fill cavitary defects in acetabular reconstructions during hip revision surgery. Oonishi *et al.*[27] presented encouraging results of impaction technique with HA granules applied to acetabular reconstruction during revision in total hip replacement. The series included 40 hips, with a follow-up ranging from 4 to 10 years. Postoperatively, load bearing was restricted for 10–12 weeks. Socket migration occurred in five hips with severe segmental and cavitary defects. The authors concluded that socket loosening and migration could be reduced when major peripheral segmental defects were stabilized by structural allografts, allowing firm packing of the HA granules. Furthermore, histological analysis of HA granules retrieved from filled-in acetabular bone defects 1–10 years after surgery suggested that bone ingrowth into spaces between HA could be expected.[28] In a series of 32 acetabular reconstructions with a mean follow up of 5 years, Schwartz and Bordel[29] showed that a BCP ceramic employed as granules or blocks could result in satisfying bone stock restoration in a vast majority of hips.

During the past years, authors have reported successful results of femoral reconstruction with a morsellised impacted bone allograft technique.[30–33] Limited aseptic failure rates have been observed in the mid- to long term,[34,35] with a 90.5% global survival rate at 10–11 years reported by the Exeter group.[36] However, initial stability of the stem–graft composite was still far from optimal. Subsidence of the stem is a common finding that is considered as a positive event.[30,31,37,38] In parallel, CPCs have been shown to exhibit both much greater mechanical stability and reproducibility than pure allograft in experimental tests.[39] This has led one of us to investigate the use of a macroporous CPC in femoral reconstruction in revision hip surgery.[40] The bone graft substitute was employed as porous granules of macroporous biphasic calcium phosphate (MBCP), consisting of 75% hydroxyapatite (HA) and 25% β-TCP (Biosel®, Depuy Bioland, France). HA granules were irregular in shape and size (2–3 mm). Macropores ranged from 200 to 500 µm in diameter, resulting in a 70% overall porosity of the material. We retrospectively reviewed 21 femoral reconstructions with impacted CPC in 20 patients, at a mean of 36 months. Femoral cavitary defects were reconstructed according to a firm impaction of ceramic granules, followed by a cementing of the stem. At follow-up, we observed a satisfying bone reconstruction in all femurs but two, which required rerevision (one septic recurrence and one aseptic failure), and a limited rate of subsidence. Functional improvement was noted in all non-rerevised cases. We concluded that femoral reconstruction with an impacted bone graft BCP substitute was safe and reliable (Figure 2). These results were

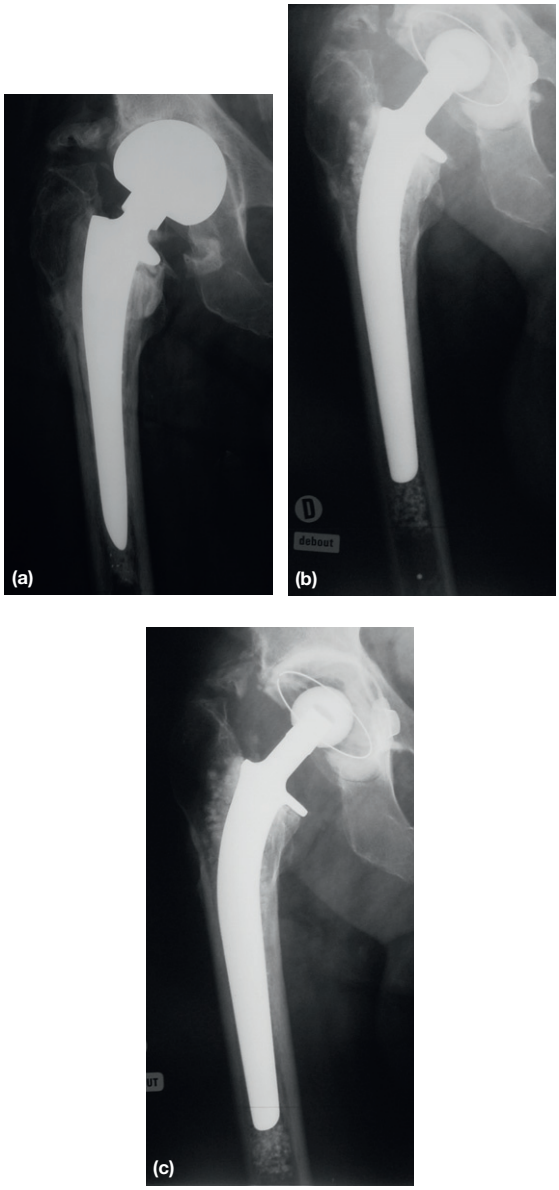

Figure 2 First hip revision in a 74-year-old active man. (a) Preoperative radiographs showing aseptic loosening of a bipolar hemiarthroplasty performed for femoral neck fracture. (b) Immediate postoperative anteroposterior view showing conversion to a total hip replacement and femoral reconstruction with hydroxyapatite/β-tricalcium phosphate granules. The graft–cement packing was considered complete and homogenous. (c) Radiographs taken 34 months postoperatively exhibit a good bone reconstruction and a satisfying synthetic graft incorporation. There is no evidence of stem subsidence and no radiolucent lines at the cement–bone interface. Functional score was rated excellent.

similar to those recently reported by Aulakh *et al.*[41] in terms of functional outcome and graft incorporation.

CPCs have also been proven to be an effective promoter of fusion in spine arthrodesis,[42,43] with radiological results similar to that obtained with autograft alone. A few studies reported on the use of CPCs in high tibial open-wedge osteotomy in the treatment of medial compartment osteoarthritis of varus knee.[44,45] These conditions are theoretically favorable, as the bone graft implantation is performed in a cancellous bone environment, well vascularized, and mechanically stable. Authors reported that signs of fusion and good integration of the implanted wedges were regularly observed, with no inflammatory reaction. Macroporous ceramics have been employed successfully in the treatment of acute fractures, including metaphyseal long bones fractures,[46] calcaneal fractures,[47] and in trauma sequelae.[48] Also, CPCs are indicated as void fillers after benign bone tumors curettage, either under the form of pure HA,[49,50] or as β-TCP,[51] but a combination of both is also a suitable option (**Figure 3**). Authors reported satisfying osseointegration of the graft substitute with no specific complication related to the bone substitute. Several authors have reported the lack of complete resorption of HA,[52] but it is probable that clinical implications of this phenomenon are moderate. An effort has been made to solve the problem of CP brittleness without reducing bone-bonding properties, by employing a hybrid composite of CP and a polysaccharide such as chitosan.[53–56] Ito *et al.*[55] demonstrated that subperiosteal implantation of HA/chitosan composite membranes over rat calvaria were biologically well tolerated, with occasional osteogenesis. Also, Zhang and Zhang[53] have shown that the addition of β-TCP to flexible chitosan resulted in an improvement in the compressive modulus and yield strength of the composite scaffolds. Recently, Ding[56] demonstrated that a CaP/chitosan ratio of 5% by mass to volume in the composite achieved the significantly higher bending strength, but a higher CaP content adversely affected mechanical properties of the hybrid composite.

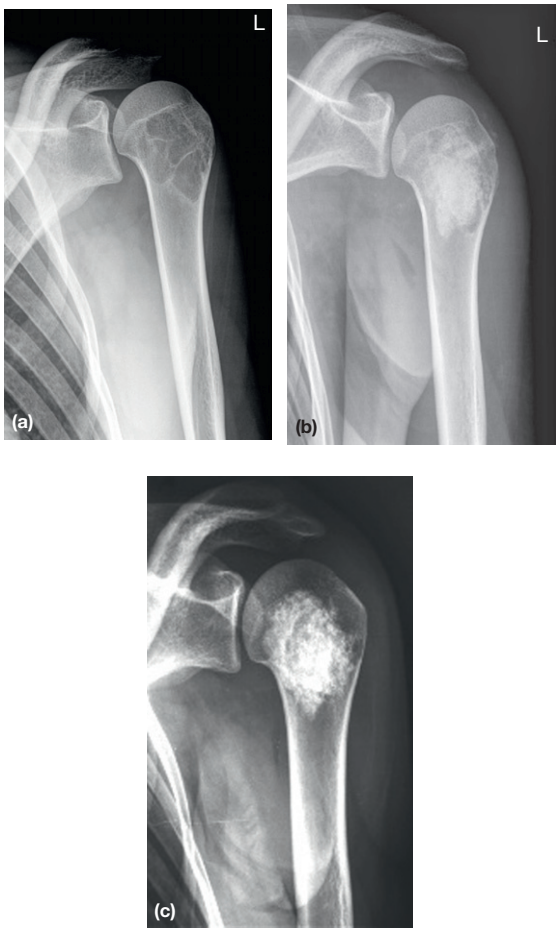

Figure 3 (a) A preoperative X-ray of left humerus shows a cavitary lesion (fibrous dysplasia) of proximal metaphysis in a 22-year-old woman. (b) A curettage followed by a filling of the cavity with hydroxyapatite/β-tricalcium phosphate (HA/β-TCP) (60/40) granules were performed. Immediate postoperative X-ray shows the cavity filled with granules of HA/β-TCP. (c) Eighteen months after surgery, the cavity has been remodeled and HA/β-TCP granules are considered osseointegrated.

1.120.3.3. Calcium Phosphate Cements

The first self-hardening calcium phosphate cements were introduced in the late 1980s by Brown and Chow.[57] The first CP composition received approval from the US FDA in 1996. The term *calcium phosphate cement* is synonymous with *apatitic cement, ionic cement, or hydraulic cement*. Despite the large number of formulations, CP cements can only have three different end products, namely apatite (PHA) (neutral), brushite (DCPD) (acid), and amorphous calcium phosphate (ACP) (basic). With the exception of several CP cements that form brushite as the product, most CaP cements form apatitic or carbonato-apatitic products, such as Norian™ SRS (Synthes USA, West Chester, PA). Apatitic CaP cements are viscous and easily moldable, but usually difficult to inject. In contrast, brushite CaP cements can be initially very liquid and still set within a short period of time. Data in the literature indicate that cementation can occur in mixtures containing a wide variety of CP compounds. The cement setting reaction determines the intermediate and the final products that will be formed in the CaP cement, and, consequently, its mechanical and biological properties. For brushite cements, setting time depends on the solubility of the basic phase (the higher the solubility of the basic phase, the faster the setting time), and ranges from a few seconds to several minutes.

Cement hardening is the result of three theoretical mechanisms, described as (1) reactions among calcium products in an aqueous environment (dissolution/reprecipitation reactions), (2) reaction between calcium and a carboxylic acid, and (3) reaction between CP and an aqueous polymer solution (acid–base reaction between the carboxyl groups of the polymer and the alkaline CP).[58] All brushite CaP cements are obtained by an acid–base reaction. Brushite can only precipitate at a pH value lower than 6. After setting, the pH of the cement paste slowly changes toward the equilibrium pH, and is dependent on the basic phase content.

The volume of CaP cements stays almost constant during the setting reaction. Unlike PMMA cements, CaP cements do not harden through a polymerization reaction and only a small amount of heat is released. CP cement is a microporous solid consisting of nanometer-sized HA or micrometer-sized DCPD

crystals. Therefore, the microporosity of the material, and its subsequent specific surface, are very high. Ionic exchanges between crystal surface and extracellular environment are very important. CaP cements can slowly degrade in a bony environment, without the need for a macroporous interconnected structure. Thus, CP cements degrade layer by layer, but this may be viewed as a drawback when compared to open macroporous CaP blocks. Sometimes, bone ingrowth is observed inside the cement, within a crack. However, the presence of macropores can facilitate ingrowth of bone and the overall process of cement replacement by newly formed bone.[58]

The biocompatibility of apatitic CaP cements is excellent, and their biodegradation is much larger than that of HA, but still very slow. HA-forming and DCPD-forming CP cements do not dissolve spontaneously in a normal physiological fluid environment, but are resorbable under cell-mediated acidic conditions. Being more soluble, the DCPD-forming CP cements resorb more rapidly than HA-forming CP cements. Frayssinet *et al.*[59] reported a 25% resoprtion of a brushite CP cement after 18 weeks implantation in a rabbit femur. This feature should help in making a choice between CP cements, in order to achieve optimum clinical results.

Once hardening has occurred, CP cements are brittle and have relatively low bending/flexural strengths. Mechanical properties of CaP cements depend on their composition, with brushite cements being slightly weaker than apatitic CaP cements. The main determining factor is the ratio of cement powder to the amount of mixing liquid: the higher the powder/liquid ratio, the lower the porosity of the cement. Hence, most CP cements have a tensile strength ranging from 1 to 10 MPa, whereas the compression strength varies in the range of 10–100 MPa. Therefore, CaP cements can only be used in combination with metal implants or in low or non-load-bearing applications as CPCs blocks. Significant increases in the mechanical properties of CaP cements have been achieved by incorporating biocompatible and bioresorbable reinforcement additives, such as Vicryl meshes,[60] or chitosan.[61] Moreover, the mechanical properties of the apatitic CaP cement may vary with implantation time. The mechanical properties of apatitic CaP cements tend to increase with time, in contrast to those of brushite CP cements, which decrease initially and increase after a few weeks of implantation when bone grows, explained by the higher solubility of DCPD compared with that of HA. Compression strengths and setting times have been evaluated for several CP cements[62]:

- Norian™ SRS (Synthes USA): 33 ± 5 MPa and 8.5 ± 5 min (= 50% porosity)
- Cementek™ LV (Teknimed SA, L'Union, France): 8 ± 2 MPa and 17 ± 1 min
- α-BSM™ (Etex Corporation, Cambridge, MA): 4 ± 1 MPa and 19 ± 1 min (= 80% porosity)
- ChronOS™ Inject (Synthes USA): 5–8 MPa and 11 ± 2 min (50% porosity)
- Bonesource™ BVF (Styker): 65 MPa and 7–10 min

In vivo, CP cements are injected as a liquid or as a paste. Injectability of CP cements is influenced by various intrinsic parameters including particle size and shape, particle size distribution, powder/liquid ratio, liquid viscosity and also by an extrinsic parameter, that is, the delay between mixing and implantation of the cement. Cement cohesion may be altered during this phase, resulting in a demixing of the cement: the liquid is expelled without the CaP particles. Decohesion of the cement during mixing can lead to inflammatory reactions.

Among the various products, Norian™ SRS has been widely studied. Its mechanical properties allow for rapid load bearing and/or provide good additional stabilization in unstable fractures of the distal radius,[63,64] tibial plateau,[65] and calcaneus.[66–68] CaP cements have also been proposed as bone void filler in acetabular defects in revision hip replacements.[69] Of note are the potential adverse effects of apatitic cements, described as soft-tissues reactions induced by cement.[70] CaP cement can be used as a delivery system for therapeutic peptides, antibiotics, anticancer drugs, anti-inflammatory drugs, or growth factors.[71]

1.120.3.4. Bioactive Glasses and Ceramics

Bioactive glasses and ceramics have been studied for almost four decades. They constitute a group of synthetic silicate-based materials, characterized by their bioactivity and their unique bone bonding properties, related to their surface reactivity, via hydroxylation and dissolution reactions.[72–75] In addition, most of these materials degrade naturally: similarly to other synthetic substitutes such as CP compounds, the degradation products are entirely metabolized by the body. Bioactive glasses consist of silica, that forms the main component, as well as sodium oxide (Na_2O), calcium oxide (CaO), and phosphorus pentoxide (P_2O_5). Conventional bioactive glass and glass ceramic are obtained by melting the glass phase at high temperatures followed by casting of bulk implants or quenching of powders. In 1991, Li *et al.*[76] showed that a bioactive glass could be made by sol–gel processing. This finding offered a potential method for using this new generation of bioactive materials in porous scaffolds and coatings.[77]

By varying the content of sodium oxide, calcium oxide, and silicon dioxide in the glass, a full range of biological stability, from soluble to nonresorbable, can be produced. Bioactivity is dependent on chemical composition, with a maximal content of SiO_2 in the cast glass being equal to 60% in weight. Compositions for most rapid bonding not only to bone tissue, but also to soft tissues, range from 45% to 52% in weight of SiO_2. Glasses with a SiO_2 content ranging from 55% to 60% in weight react more slowly, and do not bind soft tissues. Compositions with >60% SiO_2 do not bond bone and are considered as bioinert. One of the most studied bioactive glasses is glass 45S5, which was developed at the University of Florida in the late 1960s.[78] The key composition features of 45S5 are that it contains <60% SiO_2, high Na_2O and CaO contents, and a high CaO/P_2O_5 ratio, which make it highly reactive to aqueous medium and bioactive. Thus, bone bonding occurs as a result of a rapid sequence of chemical, cellular, and tissue reactions on the surface of the implant after contact of the glass with the biological milieu. A rapid ions exchange of Na^+ and K^+ released from the glass with H^+ and H_3O^+ present in the extracellular fluids occurs. Bioactive glasses have been demonstrated to stimulate the growth and maturation of osteoblasts, and to promote the expression and maintenance of the osteoblastic phenotype through a direct control over genes that regulate cell cycle induction and progression.[79–85]

An important modification of bioactive glasses was the development of apatite/wollastonite (A/W) bioactive glass-ceramic at Kyoto University, Kyoto, Japan, in the mid 1980s.[86] A unique processing method produced a very fine-grained glass-ceramic composed of very small apatite (A) and wollastonite ($W = CaSiO_3$) crystals, bonded by a bioactive glass interface. This process resulted in a consistent improvement of the component with regard to mechanical strength, toughness, stability, and bone bonding.[87–89] Clinical success in spine surgery has been documented.[90]

The first bioactive glass device cleared for marketing used in the United States was a device used to treat conductive hearing loss by replacing the bones of the middle ear, in 1985. It was a solid, cast bioactive glass structure that acted to conduct sound from the tympanic membrane to the cochlea due to its unique property to bond to soft tissue as well as to bone tissue. More recently, particulate glass materials have been employed to restore bone loss resulting from periodontal disease.[91,92] It has been clinically used from 1993 onward. 45S5 bioactive glass was cleared for general orthopedic bone grafting in non-load-bearing sites in 2000 (Figure 4).

Some of the difficulties associated with the use of bioactive glasses in biomedical applications are related to their brittle behavior and weak mechanical properties. However, bioactive glass blocks resist drilling and shaping. As a consequence, they are difficult to fix to the skeleton. The bending strength of most bioactive glasses is in the range of 40–60 MPa, which is not enough for load-bearing applications, while their Young's modulus is 30–35 GPa, very close to that of cortical bone. To improve the mechanical properties of bioactive glasses, the authors have developed glass materials reinforced with stainless steel fibers (bioactive glass), or zirconia particles (A/W glass ceramic).[93]

The combination of biodegradable polymers with bioactive glasses has been proposed to produce biodegradable products that display high levels of bioactivity and also improved mechanical properties as compared to conventional glasses. Among the various polymers such as poly(lactic acid), poly (caprolactone), and natural polymers (collagen, starch, and chitosan), polysulfone has been demonstrated to yield mechanical characteristics that are comparable to cortical bone and represents, therefore, a promising material.[94]

1.120.3.5. Glass Ionomer Cements

In the early 1970s, glass ionomer cements (GICs) were suggested as materials of choice for tooth restoration because they bond chemically to dental hard tissues and release useful amounts of fluoride ions over a relatively long period. They have the additional advantage of being aesthetic in that they match the natural color of the tooth. Their properties have initiated their development in medical applications, mainly in the field of ear, nose, and throat surgery (bone cements, auditory ossicular reconstructions, and craniofacial implants).

Conventional GIC are derived from aqueous polyalkenoic acid such as polyacrylic acid and an ion-leachable silicate glass,

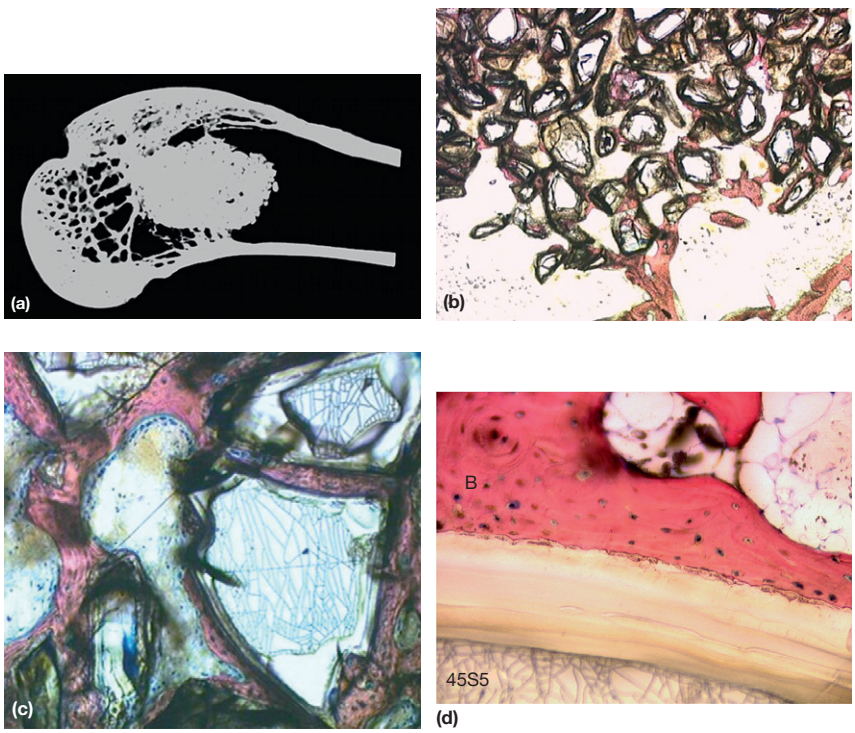

Figure 4 Bioactive glasses interact with surrounding bone tissue. (a) A figure shows a microradiograph of the distal femur of an adult rabbit 28 days after implantation of 45S5 Bioglass™ in particulate form: osseointegration is obtained, trabecular bone has reached the implant in a centripetal pattern. (b) Nondecalcified histology of the same implant showing that 45S5 particles are surrounded by newly formed bone (Magnification × 100, staining picrofuschine, Stevenel Blue). (c, d) Histological sections illustrating direct bone bonding to Bioglass™ particles, with no intermediate fibrous layer (Magnification × 200 and × 400 respectively, staining picrofuschine, Stevenel Blue). B = bone.

usually a fluoroaluminosilicate. When the powder and liquid are mixed together, an acid–base reaction occurs. As the metallic polyalkenoate salt begins to precipitate, gelation occurs and a porous cement paste is obtained.[95,96] Once the cement has hardened, maturation processes take place over several weeks. The final product is a rigid material with a porecelain-like appearance.

In the 1990s, several faster setting, high viscosity conventional GIC were developed.[97–99] Important modifications of GIC were developed to improve mechanical strength, such as the addition of silver-amalgam alloy powder to conventional GIC. Resin-modified GICs have been introduced more recently.[100] In these materials, the acid–base reaction is supplemented by a second resin polymerization usually initiated by a light-curing process, which requires the presence of photoinitiators within the formulation. Resin-modified GIC have been used in bone augmentation.[101] Advantages of GIC include their ability to bond directly to the surface of the tooth through an ionic exchange at the interface,[102] the progressive release of fluoride being potentially cariostatic, their color that is very close from that of tooth, and their biocompatibility. GIC have a number of advantages over acrylic bone cements, including lack of exothermic reaction during setting, and, therefore, absence of heat-labile protein damage, absence of monomer, and an improved release of therapeutic agents, such as antibiotics. One of the main drawbacks of GIC is their relative lack of flexural strength and low resistance to abrasion and wear. Although their compressive strength (180–220 MPa) and modulus of elasticity are comparable to cortical bone after 24 h, GIC remain very brittle and prone to bulk fracture,[103] and therefore should not be employed in load-bearing applications. In addition, early release of fluoride and aluminium ions and release of polyacids have been implicated in tissue compatibility, specifically neurotoxicity. Thus, GIC are contraindicated in contact with neural tissue or cerebrospinal fluid.

1.120.3.6. Biomimetic Nanocomposites and Nanopolymers

Conventional materials implanted today to regenerate tissues may be rough at the macro/microscale but are usually smooth at the nanoscale, and therefore, provide inadequate surface roughness value to cells. Since surface properties of a material vary with grain/particle size, there is a growing interest in nanomaterials in bone regeneration, as they enhance interaction of protein with implant surface, and subsequent cell function. Hence, bone tissue may be viewed as a nanocomposite system with a complex hierarchical structure, composed of biological entities such as collagen type I, and hydroxyapatite crystals. Cells are naturally accustomed to interact with nanostructured surface roughness in physiological environment. Such a roughness can be mimicked in polymers through the use of nanophase materials.

Cellular response to a biomaterial may be enhanced in synthetic polymer formulations by mimicking the surface roughness of natural bone tissue in the nanoscale range. Nanotechnology allows for the production of materials and systems whose structures and components exhibit novel and significantly changed properties that are controlled at the atomic, molecular, and supramolecular levels. HA nanocrystals are prepared by a wet chemical method that can control the fiber size, shape, and composition. A synthetic material characterized by a high surface area to volume ratio and an ultrafine structure, similar to biological apatite, is obtained. A nanocomposite includes a hydrogel and synthetic HA nanocrystals. They are characterized by their high specific surface, over $100\,m^2\,g^{-1}$, compared to that of CP sulfates, which is about $2\,m^2\,g^{-1}$.

It is now believed that cell responses might be more sensitive to changes in surface roughness in the nanometer scale (<100 nm) as compared with conventional regimes (>100 nm) and also that sensitivity may vary with cell type.[104] Recent studies have demonstrated that the adsorption and bioactivity of biomolecules (specifically, proteins such as fibronectin and vitronectin) were enhanced in terms of mediating osteoblast adhesion on nanophase materials.[105] Of note is the influence of the nanometer surface structure in controlling cell functions, as demonstrated by Dalby *et al.*[106]

Ramay and Zhang[107] first introduced the concept of nanocomposites to porous scaffolds for bone tissue engineering. Nanocomposites made of β-TCP as a matrix and HA nanofibers were used to produce porous scaffolds through a technique that integrated the gel casting with polymer sponge methods. These authors showed that inclusion of HA nanofibers as a second phase in β-TCP porous ceramic matrix significantly improved the mechanical properties of the porous scaffold. With a porosity of ≈73% and containing 5% in weight of HA nanofibers, the porous scaffold attained a compressive strength of 9.8 ± 0.3 MPa, which is comparable to the high-end value of the compressive strength of cancellous bone. The toughness, that is, the material's resistivity to crack propagation, of BCP ceramics correlated with HA fiber concentration in the scaffolds, and increased up to $1.72 \pm 0.02\,kN\,m^{-1}$ with the incorporation of 5 wt% HA nanofibers. The authors concluded that these porous scaffolds reinforced with nanofibers had better mechanical properties than the scaffolds of single-phase calcium prepared previously. In addition, it was shown that an electrospun nanocomposite containing amorphous TCP exhibited high *in vitro* bioactivity, cell proliferation, and osteogenic differentiation of human mesenchymal stem cells.[108]

The authors have also shown that some of the drawbacks of nano HA, such as bioresorption and particle migration in surrounding tissues, could be alleviated by using composites of HA nanocrystals in conjugation with polymers, such as the polysaccharides, chitosan,[56,109] polysulfone, polyhydroxybutyrate, collagen,[110] and polylactide acid. In parallel, Itoh *et al.*[111] reported that the use of a hydroxyapatite/collagen (HA/Col) nanocomposite as a carrier for the delivery of rhBMP-2 was effective in controlling both the mechanical strength and bioresorbability of the material, and was suitable for promoting anterior fusion of the cervical spine in a dog model. The beneficial use of ceramics in a nanoparticulate form as fillers in biopolymers has been demonstrated in numerous investigations. The bioactivity of nano biocomposite was evaluated in an *in vitro* and *in vivo* study by Jie *et al.*[112] A composite of nano HA and polyamide was evaluated after immersion in simulated body fluid (SBF) solution and after implantation in the muscles or femorae of rabbits. These authors confirmed that an apatite-like layer formed *in vitro* on the surface of the biocomposite and that a direct bonding between the composite and bone was present after implantation in a bony environment.

The conjunction of HA and collagen may be considered as an attempt to mimic composition and structure of the extracellular bone matrix (ECM), which mainly consists of collagen type I fibrils, mineralized with HA nanocrystals. Bernhardt *et al.*[110] observed an increased activity of alkaline phosphatase in human bone marrow-derived stromal cells (hBMSCs) cultured on membranes of biomimetically mineralized collagen. These results indicated a promoting effect of mineralized collagen on the osteogenic differentiation of hBMSC. Also, studies have suggested that osteoblast and osteoclast activity could be increased, while at the same time fibroblast function decreased on materials with nanostructured features, which may lead to improve osseointegrative potentials. Furthermore, these materials combine favorable properties such as ductility/flexibility of polymer fibers with the stability and bioactivity of CPC.

1.120.4. Conclusion

Considerable improvements have been realized with regard to synthetic bone grafting in recent years, due to a better understanding of biological events leading to bone repair. These recent developments are mainly due to the fusion of several research fields, such as chemistry, molecular and cell biology, medicine, and tissue/bioengineering. This has resulted in an exponential increase of graft materials that have to be tested and clinically validated. However, it implies that not all bone substitutes will perform the same way and that the orthopedic surgeon has therefore to face the dilemma of graft choice. The surgeon is asked to carefully match the clinical problem with the capabilities/properties of the graft material, having in mind that the gold standard remains the autograft. Although bone repair and bone regeneration are dependent on osteoblastic response, the development and/or preservation of an adequate vascular environment and the ability to maintain stability constitute crucial parameters in the technical choice.

With the exception of growth factors, that were not described here, most synthetic bone grafts available are osteointegrative and osteoconductive. They are currently employed as bone void fillers, and are indicated in non-load-bearing situations, with numerous clinical successes reported. Production of biodegradable and osteoconductive scaffolds with a 3D interconnected porous structure and adequate mechanical strength and toughness represent a formidable challenge. Further advances will result in new carrier constructs, characterized by the association of adequate biological scaffolds and growth factors and/or mesenchymal stem cells.

Glossary

Addition polymerization Rapid polymerization based on initiation, propagation, and termination of double bonded monomers and no small molecules are eliminated.

Anionic polymerization Polymerization initiated by a anion.

Cationic polymerization Polymerization initiated by cation and propagated by a carbonium ion.

Condensation polymerization Polymerization in which polyfunctional reactants produce larger units in a continuous, stepwise manner.

Coordination polymers Polymers based on coordination complexes.

Copolymer Polymers composed of chains containing more than one monomer unit.
Degree of polymerization Average number of repeating units in main chains.
Gel point Point at which cross-linking begins to produce polymer insolubility.
Glass transition temperature (T_g) Temperature at which a polymer gains local or segmental mobility.
Initiation Start of polymerization.
Kinetic chain length Average length of the polymer chain initiated by one free radical.
Propagation Continuous successive chain extension in a chain reaction.
Repeating unit Basic molecular unit that can represent a polymer backbone chain.
Tacticity Arrangement of the pendant groups in space; that is, isotactic, syndotactic, atactic.
Termination Destruction of active growing chains in a chain reaction.

1.121.1. Introduction to Polymer Science

A polymer is a macromolecule composed of a combination of many small units that repeat themselves along the long molecule. The small starting molecules are called monomers, and the unit which repeats itself along the chain is called the repeating unit. In general, polymer chains have several thousand repeat units. The length of the polymer chain is specified by the number of repeating units in the chains and this number is called the degree of polymerization. Most of the monomers are composed of carbon, hydrogen, oxygen, and nitrogen. Few other elements such as fluorine, chlorine, sulfur, etc. may also exist. Syntheses of polymers are carried out in vessels or large reactors, sometimes with application of heat and pressure, and the small monomeric units connect to each other through the chemical reactions. The chemical process used for the synthesis of polymers is called the polymerization process.

Polymers which have the ability to melt and flow are used in manufacturing and are generally identified with the common name, plastics. In general, plastic products contain other added ingredients such as antioxidants and lubricants to give the desired properties to the object produced.

Most of the macrochains obtained in polymerization reactions are linear polymers and are formed by the reactions of monomers containing either carbon–carbon double bonds or have two active functional groups or difunctionality. Many monomers have different active groups on the same molecule such as one end of the monomer contains a carboxylic acid and the other end contains an alcohol, and the reaction of the acid group of one molecule with the alcohol group of the other forms polyesters. Polymerization reactions also take place when one of the monomers contains two acid groups and the other contains two alcohol or two amine groups. If there are some monomers which have more than two functionalities (e.g., 3- or 4-functionality), their presence in the chain cause the formation of extra chains linked to the main backbone. In this case, branched polymers are obtained. If the extent of branching is very high and all the macrochains are connected to each other, then they form a highly cross-linked, three-dimensional structure which is called a network. These networks have infinite molecular weights since all chains are connected to each other. In a polymer structure, all chains are tangled around each other forming the bulk structure. At low temperatures they are solid, but in a good solvent, the chains start to separate from each other and for linear and branched polymers this separation leads to complete solubility. The cross-linked network polymers, however, cannot dissolve in a solvent; they swell, forming gels.

The process of creating macromolecules from monomers is called polymerization. If only one type of monomer is used in polymerization, there will be only one type of repeating unit in the chain. In this case, the macromolecule is a homopolymer. If the polymer is formed from two different monomers (have two different repeating units), it is known as a copolymer. If a chain is formed from only ethylene, the polymer is a homopolymer and named as polyethylene. On the other hand, the copolymer of ethylene and vinyl acetate has two monomers and, therefore, has two different repeating units. If three different monomers are used to produce a polymer, the product is a terpolymer. Biological polymers, such as enzymes, are formed from many different amino acids, and therefore, their structures contain a variety of repeating units.

Since a large number of combinations of these molecules are available, it becomes possible to design and synthesize polymers with the desired properties ranging from fibers to films, sponges to elastomers. This versatility makes them essential materials to be used in various applications ranging from macro-sized products used in the households to nanoscale devices used in nanotechnological and biomedical applications.

Polymers such as cellulose, silk, and chitin can be obtained from natural sources and polymers such as polyethylene, polystyrene, and polyurethanes can be synthesized in the laboratories and plants. The macrochains such as DNA, RNA, and enzymes have biological importance and are crucial for life. In general, the backbone of a polymer is formed mainly of carbon atoms. These are called the organic polymers. There are also a few inorganic polymers, and the atoms in their backbones are different than carbon. An example is silicone, the backbone of which is constituted of silicon and oxygen.

One very important property which strongly influences the mechanical strength of the polymer is its molecular weight. Hydrocarbon molecules with increasing number of carbons are methane, ethane, propane, etc. The ones containing up to five carbons are in the gaseous state. As the number of carbons, and therefore, the molecular weight increases, they become liquids, wax type solids, and eventually hard solids. The ones called polymers contain more than 100 carbons along the chain. Most polymers which are useful as plastics, rubbers,

fibers, etc. have at least 50 repeating units and have molecular weights between 10^4 and $10^6\,g\,mol^{-1}$. Most of the properties of the polymers (plastics) are dependent on the chain length. As it increases, the softening point, melting point, or mechanical strength of the polymers also increase. Molecular weights of polymers are defined with average molecular weight values since there is always a distribution in chain lengths and no constant length for chains during the polymerization process. Although there are various averaging approaches, the most commonly used ones are the number average molecular weight (M_n) and the weight average molecular weight (M_w). The equations for these parameters are given below:

$$M_n = \frac{\sum M_i N_i}{\sum N_i} \quad [1]$$

$$M_w = \frac{\sum M_i^2 N_i}{\sum M_i N_i} \quad [2]$$

where N_i is the number of moles of molecules with a molecular weight of M_i.

The simplest polymer is polyethylene which has the repeating unit of $(-CH_2-CH_2-)$. The repeating units of polyethylene have high regularity and the chains come close to each other and cause high intermolecular interactions. If one of the hydrogen atoms of polyethylene repeating unit is changed with a different atom or molecule such as a halogen atom or R group, the arrangement of the chain may have different possibilities. The arrangement of atoms or groups fixed by chemical bonding in a molecule is called the configuration. Some examples are cis and trans isomers, and D and L forms of molecules. Chains may have different orientations arising from rotation of the chain about single bonds. These types of arrangements which are continuously changing are called conformations. A chain can have many different conformations.

In vinyl polymers isomerism is also defined with head-to-tail configuration. If there is a substitute attached to one carbon atom of the double bond, this carbon side can be named as the head, and the other carbon will then be the tail. During polymerization, the carbon atoms containing a substitute come together in either head-to-tail configuration or head-to-head and tail-to-tail configurations.

Carbon atoms make four bonds in a tetrahedral geometry. If the –C–C– main backbone which forms a zigzag structure is assumed to be on a plane, the other two bonds of each carbon, linked to an atom or a group, are either on one side or the other side of this plane. Depending on the organization of the side groups linked to the adjacent chiral center carbons, a stereochemistry is created and this is named tacticity. If the polymer is isotactic, it means that all the substituted side groups on each successive chiral center are on the same side of the backbone plane and have the same stereochemical configuration. For syndiotactic polymers, the side groups take place alternatingly on opposite sides of the backbone plane, and each successive chiral center has the alternating stereochemical configuration. There is no regular arrangement of the subgroups in atactic polymers. The substituents are placed randomly along the chain. Different placements of substituent group R in vinyl polymers are shown in Figure 1. Since tacticity

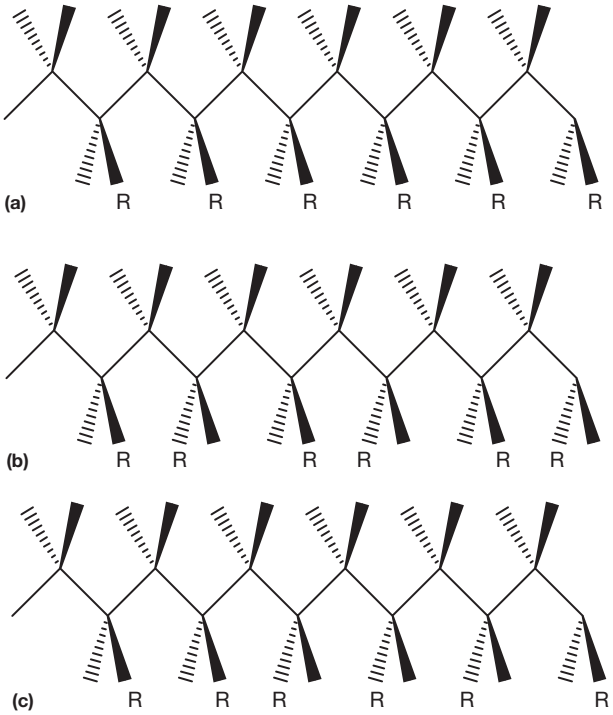

Figure 1 Tacticity of vinyl polymers: (a) isotactic, (b) syndiotactic, and (c) atactic.

creates highly ordered organization of repeating units along the chains, those polymers are more rigid with higher crystallinity and strength compared to atactic ones. Although this is the case in the industry for most of the processes, atactic polymers are preferred because of their ease of processing.

As defined previously, long chains are entangled with each other and stay together in a polymer structure forming a solid mass. This type of polymers have no ordered intermolecular arrangements and are called amorphous polymers. The vinyl polymers which contain bulky substitutes such as poly(methyl methacrylate) or polystyrene are amorphous polymers. On the other hand, in some polymers, intermolecular attractions are very strong and many backbone chains form closely packed structure as a result of these strong intermolecular forces. In these cases, they form crystalline polymers. Some polymers are partially crystalline, and some regions of the different or the same chains are closely packed and have strong attractions. These highly ordered domains are distributed in the amorphous matrix. In this case, the material is a semicrystalline polymer. Since crystallinity indicates highly ordered arrangement of macrochains with strong intermolecular forces, these polymers are stronger and have higher mechanical and thermal properties compared to their amorphous counterparts.

1.121.1.1. Classification of Polymers

During the early years of polymer science, two types of classifications have come into use. One was based on polymer structure (backbone) and divided polymers into Condensation and Addition polymers[1] and the other was based on

polymerization kinetics and mechanism and divided polymerizations into Step and Chain polymerizations.[2] Although these terms are often used interchangeably, because most condensation polymers are produced by step polymerizations and most addition polymers are produced by chain polymerizations, this is not always the case.

Polymers can be synthesized from hundreds of monomers in numerous combinations in very different forms ranging from solid elastomers to fibers, from films to sponges, from tubes to gels. Therefore, they are very important in our daily life. Polymers can be classified in many different ways depending on their various properties. Some of them are given below.

Polymer classification according to:

1. The origin
   a. *Natural polymers*: Proteins, starch, cellulose, natural rubber, etc. are of natural origin.
   b. *Synthetic polymers*: These are man-made polymers synthesized in the laboratories.
2. The polymerization process
   a. *Condensation polymers*: These polymers are formed when two di- or polyfunctional molecules react and condense forming macromolecules and with the possible elimination of a small molecule such as water in the case of polyester formation. All the natural polymers are condensation polymers.
   b. *Addition polymers*: These polymers are produced by chain reactions of double-bonded monomers in which the chain carrier can be a radical or an ion. Free radicals are usually formed by the decomposition of a relatively unstable compound, called the initiator.
3. The structural forms of the chains
   a. *Linear polymers*: These polymers are composed of long chains and their monomers have only two functional groups if the polymer is a condensation polymer or a single double bond if it is an addition polymer.
   b. *Branched polymers*: Similar to linear polymers, but they have long chains with shorter side chains (branches) caused by the presence of small amounts of trifunctional monomers for condensation or two unsaturations for addition polymers.
   c. *Network polymers*: These are cross-linked three-dimensional polymers. They consist of long chains connected to each other with multifunctional units and form a network.
4. The composition of the main backbone of the polymers
   a. *Homopolymers*: These polymers contain only carbon–carbon bonds in their backbone.
   b. *Heteropolymers*: These polymers contain atoms other than carbon in their main chain. The most common noncarbon atoms are oxygen and nitrogen.
5. The structure
   a. *Organic polymers*: These polymers contain mainly carbon atoms in their main chain.
   b. *Inorganic polymers*: The main chain of these polymers is not composed of carbon but mainly of inorganic atoms such as silicon in silicone rubbers.
   c. *Coordination (chelate) polymers*: In this type of polymers, a chelate ring is formed from an ion or metal and different organic ligands which have donor–acceptor bonds between.
6. The molecular weight
   a. *Oligomers*: These are the polymers with a molecular weight in the range of 500–5000 g mol^{-1}.
   b. *High polymers*: These are the polymers used in the industry in the production of materials and have a molecular weight in the range of 10^4–10^6 g mol^{-1}.
7. The thermal behavior
   a. *Thermoplastics*: These are linear or slightly branched chains containing polymers and they soften and flow when the temperature is increased. If they are loaded in a mold in this soft form and cooled, they solidify forming the product. Since there is no new chemical bond formation during the heating and cooling, they can be reshaped with further application of heat and pressure.
   b. *Thermoset polymers*: During the processing of these polymers, cross-linking reactions take place upon increase of temperature and they set in the shape of the mold they are in. Therefore, they cannot be melted and reshaped with the application of heat. At high temperatures, they decompose.
8. The arrangement of the repeating units
   a. *Homopolymers*: They are formed from single type of monomers.
   b. *Copolymers*: They are made of two or more types of monomers. The arrangements of the different repeating units in the chain can be different, and therefore, copolymers can be further divided into groups as given below.
      i. *Alternating copolymers*: the repeating groups of two different monomers alternatingly follow each other along the macrochain.
      ii. *Random copolymers*: there is no order in the positions of the repeating units of different monomers.
      iii. *Block copolymers*: in these polymers, one type of the monomer reacts and forms a long chain (a block) and then reacts with the other type of monomer forming a different block. These block copolymers can be diblock copolymers which are formed as AB type blocks, three-block copolymers which are formed as ABA type blocks, or graft copolymers in which the main chain is one type of block and the other type is attached to the main chain as side chains.
9. *The linkages repeating in the chains*: These polymers are classified according to the chemical linkages between the monomeric units which repeat along the chain. For example, polyethers have ether linkages, polyesters have ester linkages, polyurethanes have urethane linkages, etc.

1.121.1.2. Polymerization Systems

Polymerization reactions are carried out in vessels or reactors generally with application of heat and with the addition of different substituents. Depending on the phases that exist and the forms of the medium, the polymerization processes are classified as homogeneous and heterogeneous systems, which include different techniques as given below:

1. *Homogeneous polymerization systems*: All chemicals added into the reaction medium create a homogeneous mixture in which polymer formation occurs. These processes are either bulk or solution polymerization processes.

a. *Bulk polymerization*: In these polymerizations, there are only monomers and initiators in the reaction medium. These processes are generally used in the production of condensation polymers in which the reactions are mildly exothermic, less viscous, and therefore, mixing, heat transfer, and control of the process is easier compared to chain polymerization of vinyl polymers.
b. *Solution polymerization*: A monomer and a initiator are added in a solvent and the reaction takes place in this solution medium. This approach can be used for addition or condensation polymerizations since the medium does not get too viscous which makes mixing, heat transfer, and control of the process easy. On the other hand, it requires purification and removal of the solvent.

2. *Heterogeneous polymerization systems*: In these systems there are more than one phase creating heterogeneous media for the monomer, polymer, and initiator.
a. *Gas phase polymerization*: In these systems, the monomer is in gaseous form and the polymer formed is either in liquid or solid form. Ethylene polymerization is an example (Figure 2).
b. *Precipitation polymerization*: This is similar to bulk or solution polymerization, but the polymer formed precipitates as soon as it forms. This polymer is not soluble in its monomer and the solvent of the monomer is also not a solvent for the polymer (Figure 3).
c. *Solid phase polymerization*: Some solid crystalline olefins or cyclic monomers polymerize by solid state polymerization. In these systems, polymerization generally starts with radiation such as X-rays or γ-rays (Figure 4).
d. *Suspension polymerization*: In these systems, organic phase containing monomer and initiator is dispersed as droplets in the aqueous phase containing the stabilizers such as cellulose or polyvinyl alcohol. Initiator is soluble in the monomer phase, and therefore, in the droplet the mechanism is very similar to bulk polymerization. Size of the droplets is in the range of 0.01–0.50 cm and the polymer forms as dispersed solid particles of this size (Figure 5).
e. *Emulsion polymerization*: This system is similar to suspension system, but the initiator is soluble in the aqueous phase. As the polymerization starts in the aqueous phase, emulsifier molecules surround the growing chain forming micelles. As the polymerization proceeds, chains in the micelles elongate to get the monomer from the organic phase. Therefore, the monomer droplets get smaller and polymer micelles get larger. Still, these particles are very small (about 0.1 μm) (Figure 6).

There are numerous types of synthetic polymers or copolymers which are produced in the laboratories and every year new ones are added to the list. In addition, some new biological polymers are also added to the list obtained by some novel molecular techniques. These can be derived from renewable biomass sources, such as vegetable oil, corn starch, or microbiota. Some examples for these polymers are starch-based polymers (used for the production of drug capsules in the pharmaceutical sector), polylactic acid (PLA; produced from cane sugar or glucose, and used in the production of foil, molds, tins, cups, bottles, and as bone plates in the medical sector), poly(3-hydroxybutyrate) (PHB; is biodegradable and produced by certain bacteria), polyamide-11 (PA11; is derived from natural oil and not biodegradable), bioderived polyethylene (can be produced by fermentation of agricultural feed stocks such as sugar cane or corn, and is chemically and physically identical to traditional polyethylene), and bioplastics (produced by genetically modified organisms such as GM crops).

1.121.2. Polycondensation

1.121.2.1. Characteristics of Condensation Polymerization

Condensation polymerization is used for polymerization of monomers with functional groups and involves a series of

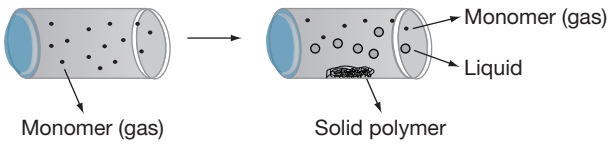

Figure 2 Gas phase polymerization.

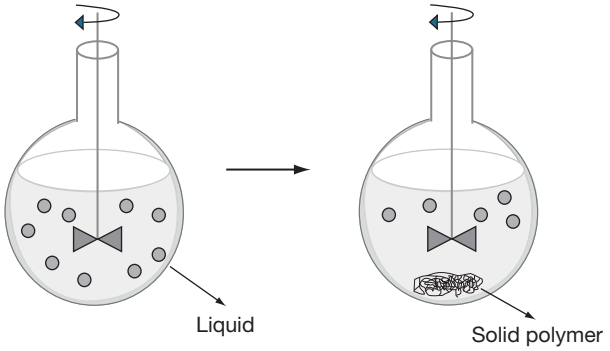

Figure 3 Precipitation polymerization.

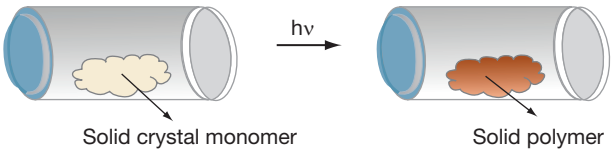

Figure 4 Solid phase polymerization.

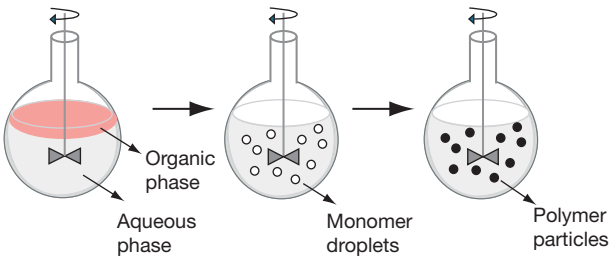

Figure 5 Suspension polymerization.

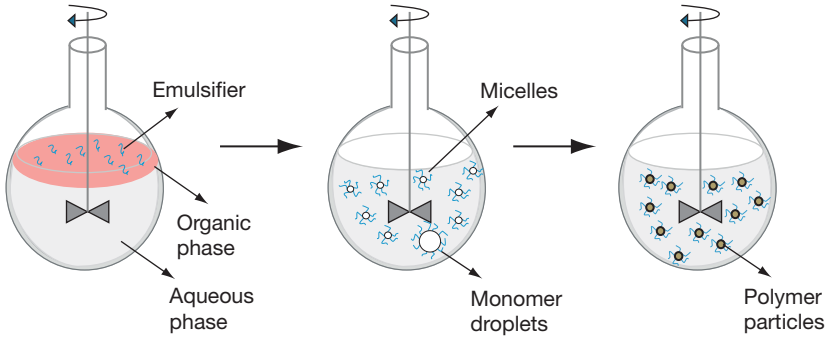

Figure 6 Emulsion polymerization.

chemical condensation reactions progressing generally with the elimination of side products with low molar weight, such as water, alcohol, or hydrogen.

In condensation polymers, the elemental composition of the repeating unit differs from that of the two monomers by the elements of the eliminated small molecule. Condensation polymers can, therefore, be degraded to their monomers upon the addition of the eliminated small molecules.

1.121.2.2. Kinetics of Linear Polycondensation

The type of product formed in a condensation reaction is determined by the functionality of the monomers, that is, by the number of reactive functional groups per monomer. Bifunctional monomers form long linear polymers but monofunctional monomers when used with bifunctional monomers form only low molecular weight products.

The monomers can have the same type or different type of functional groups, and in the former case, two different difunctional monomer types are necessary for product formation. Polyesters are formed by typical condensation reactions with the elimination of water. If a polyester is synthesized from a diol and a diacid, the first step is the reaction of the diol and diacid monomers to form a dimer:

$$\mathrm{HO{-}R{-}OH + HOOC{-}R^1{-}COOH \rightarrow}$$
$$\mathrm{HO{-}R{-}OCO{-}R^1{-}COOH + H_2O} \qquad [\mathrm{I}]$$

The dimer then might form a trimer by reaction with a diol monomer:

$$\mathrm{HO{-}R{-}OCO{-}R^1{-}COOH + HO{-}R{-}OH \rightarrow}$$
$$\mathrm{HO{-}R{-}OCO{-}R^1{-}COO{-}R{-}OH + H_2O} \qquad [\mathrm{II}]$$

or with a diacid monomer:

$$\mathrm{HO{-}R{-}OCO{-}R^1{-}COOH + HOOC{-}R^1{-}COOH \rightarrow}$$
$$\mathrm{HOOC{-}R^1{-}COO{-}R{-}OCO{-}R^1{-}COOH + H_2O} \qquad [\mathrm{III}]$$

Dimer could also react with itself to form a tetramer:

$$\mathrm{2HO{-}R{-}OCO{-}R^1{-}COOH \rightarrow HO{-}R{-}OCO{-}R^1{-}}$$
$$\mathrm{COO{-}R{-}OCO{-}R^1{-}COOH + H_2O} \qquad [\mathrm{IV}]$$

The tetramer and trimer proceed to react with themselves, with each other, with the monomer and the dimer.[3] The polymerization proceeds in this stepwise manner with the molecular weight of the polymer gradually increasing with time. Condensation polymerizations are characterized by the disappearance of monomer early in the reaction for before the production of any polymer of sufficiently high molecular weight to be of practical use.

The rate of a condensation polymerization is the sum of the rates of reactions between molecules of various sizes. The kinetics of such a situation with innumerable separate reactions is normally very difficult to analyze. However, it is generally assumed that the rate of reaction of a group is independent of the size of the molecule to which it is attached; in other words, the functional group reactivity is assumed to be independent of the molecular weight. These simplifying assumptions, often referred to as the concept of equal reactivity of functional groups, make the kinetics of condensation polymerization identical to those for the analogous small molecule reaction. There is both theoretical[4] and experimental[2] justification of these simplifying assumptions.

The kinetics of condensation polymerization can be explained by taking the formation of a polyester from a diol and a diacid as a model system. Condensation polymerization typically involves equilibrium reactions of the type

$$\mathrm{A + B} \underset{k_r}{\overset{k_f}{\rightleftarrows}} \mathrm{C + D} \qquad [\mathrm{V}]$$

and the rates of the forward and reverse reactions are $k_f[A][B]$ and $k_r[C][D]$, respectively. At equilibrium these rates are equal, therefore

$$K = \frac{k_f}{k_r} = \frac{[C][D]}{[A][B]} \qquad [3]$$

If the system is not at equilibrium, as in the initial stages of polymerization, the reverse reaction is negligibly slow and changes in the concentrations of the reactants may be considered to result from the forward reaction alone. This reaction is normally catalyzed by acids, however, in the absence of a strong acid, the diacid monomer acts as its own catalyst for the esterification reaction and the reaction is followed by measuring the rate of disappearance of carboxyl groups:

$$-\frac{d[COOH]}{dt} = k[COOH]^2[OH] \qquad [4]$$

where one of [COOH] represent the catalysis phenomenon.

If the starting concentrations of carboxyl and hydroxyl groups are equal

$$-\frac{d[COOH]}{dt} = k[COOH]^3 \quad [5]$$

rearrangement and integration gives:

$$2kt = \frac{1}{[COOH]_t^2} + \text{constant} \quad [6]$$

The extent of reaction, p, is defined as the fraction of functional groups that has reacted at time t. Therefore,

$$p = \frac{[COOH]_o - [COOH]_t}{[COOH]_o} \quad [7]$$

Substitution of p into eqn [6] and rearrangement gives:

$$\frac{1}{(1-p)^2} = 2k[COOH]_o^2 t + \text{constant} \quad [8]$$

or a plot of $1/(1-p)^2$ versus t should be linear with a slope of $2k[COOH]_o^2$ from which k can be determined (**Figure 7**).[3]

It was shown with experimentation that uncatalyzed esterifications require quite long times to reach high degrees of polymerization. Greater success is achieved by adding a small amount of acid catalyst to the system, whose concentration is constant throughout the reaction. In this case, the concentration of the catalyst has to be included in the rate constant (k'):

$$-\frac{d[COOH]}{dt} = k'[COOH][OH] \quad [9]$$

If the initial concentrations of carboxyl and hydroxyl groups are equal,

$$-\frac{d[COOH]}{dt} = k'[COOH]^2 \quad [10]$$

$$[COOH_o]k't = \frac{1}{(1-p)} + \text{constant} \quad [11]$$

If only bifunctional reactants are present in the reaction system and no side reactions occur, the number of unreacted carboxyl groups equals the total number of molecules (N) in the system. If acid or glycol groups separately (not in pairs) are defined as structural units, the initial number of carboxyls present is equal to the total number of structural units present N_0. The number average degree of polymerization, $\bar{X}_n$, is:

$$\bar{X}_n = \frac{\text{Number of original molecules}}{\text{Number of molecules at time } t} = \frac{N_0}{N} = \frac{[COOH]_o}{[COOH]_t} = \frac{1}{1-p} \quad [12]$$

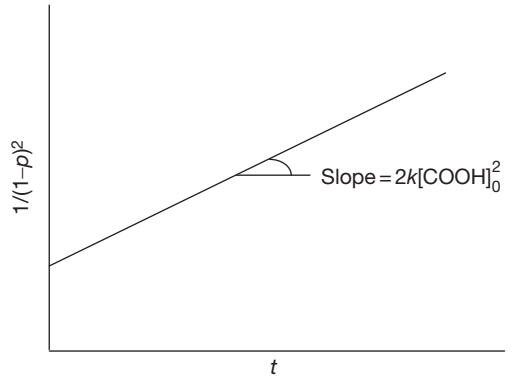

Figure 7 Plot of $1/(1-p)^2$ versus t in the determination of rate constant of linear polycondensation.

1.121.2.2.1. Molecular weight control in linear polycondensation

It is important to control the change in polymer molecular weight with reaction time since molecular weight determines the properties of the polymer. One method of stopping the reaction at the desired molecular weight is cooling. But, this is not preferable since the polymer could restart growing upon subsequent heating because the ends of the polymer molecules contain unused functional groups.

The easiest way to avoid this situation is to adjust the starting composition of the reaction mixture slightly away from stoichiometric equivalence, by adding either a slight excess of one bifunctional reactant or by introducing a small amount of a monofunctional reagent. Eventually, the monomer which is low in amount is completely used up and all chain ends consist of the excess group. If only bifunctional reactants are present and the two types of groups are initially present in numbers N_A and N_B with a ratio $r = N_A/N_B$, the total number of monomers present is

$$\frac{N_A + N_B}{2} = \frac{N_A(1 + 1/r)}{2} \quad [13]$$

At a given time, if p is the extent of reaction defining the fraction of reacted groups, $(1-p)$ will show the fraction of unreacted groups. Therefore, the total number of chain ends will be

$$N_A(1-p) + N_B(1-rp) = N_A\left[1 - p + \frac{1-rp}{r}\right] \quad [14]$$

Since each monomer is difunctional, the number of groups is twice the number of molecules present. Therefore, $\bar{X}_n$ will be

$$\overline{X}_n = \frac{N_A\frac{\left(1+\frac{1}{r}\right)}{2}}{N_A\frac{\left(1-p+\frac{1-rp}{r}\right)}{2}} = \frac{1+r}{1+r-2p} \quad [15]$$

This equation shows the variation of the degree of polymerization with the stoichiometric imbalance r and the extent of reaction p. When the two bifunctional monomers are present in equal amounts ($r = 1$), the equation reduces to

$$\overline{X}_n = \frac{1}{(1-p)} \quad [16]$$

On the other hand, for 100% conversion the $\bar{X}_n$ becomes

$$\overline{X}_n = \frac{1+r}{1+r-2} = \frac{1+r}{r-1} \quad [17]$$

In actual practice, p may approach but never becomes equal to unity. This means there are always some functional groups that are left unreacted.[5]

Stoichiometric balance should be precisely maintained in order to obtain high degrees of polymerization. Loss of one ingredient, side reactions, or the presence of monofunctional impurities may severely limit the degree of polymerization.[6]

1.121.2.3. Nonlinear Polycondensation and Its Kinetics

Polyfunctional monomers with more than two functional groups per molecule yield branched or hyperbranched condensation polymers. With certain monomers, cross-linking will also take place with the formation of network structures in which branches from one polymer molecule become attached to other molecules and eventually yield insoluble molecules.

The structures of these nonlinear condensation polymers are more complex than those of linear ones. Nonlinear polycondensation occurs with gelation, the formation of essentially infinitely large polymer networks. The sudden onset of gelation marks the division of the mixture into two parts: the gel, which is insoluble in all nondegrading solvents; and the sol, which remains soluble and can be extracted from the gel. As the polymerization proceeds beyond the gel point, the amount of gel increases at the expense of sol and the mixture rapidly transforms from a viscous liquid to an elastic material of infinite viscosity. An important feature of the onset of gelation is that the number average molecular weight stays very low while the weight average molecular weight becomes infinite.[7]

1.121.2.3.1. Prediction of the gel point

In order to calculate the point in the reaction at which gelation takes place, a branching coefficient (α) is defined as the probability that a given functional group on a branch unit to connect to another branch unit. In the case where polyfunctional A_f units are present with functionality f, the criterion for gel formation is that at least one of the $f-1$ segments radiating from the end of a segment is in turn connected to another branch unit. Therefore, the critical value of α for gelation (α_c) is given as:

$$\alpha_c = \frac{1}{f-1} \qquad [18]$$

The gel point can also be observed experimentally when the polymerizing mixture suddenly loses fluidity. If the extent of reaction is followed as a function of time by determining the number of functional groups present, the value of p (extent of reaction) at the gel point can be experimentally determined.[8]

1.121.2.4. Mechanisms of Polycondensation

As was stated earlier, all condensation polymerizations take place either by using a monomer with two unlike groups suitable for polycondensation (AB type, e.g., polycondensation of hydroxycarboxylic acids) or two different monomers, each possessing a pair of identical reactive groups that can react with each other (AA and BB type, e.g., polycondensation of diols with dicarboxylic acids).

These monomers polymerize following different routes such as carbonyl addition–elimination, carbonyl addition–substitution, nucleophilic substitution, double bond addition, or free radical coupling.[5]

1.121.2.4.1. Carbonyl addition–elimination mechanism

Carbonyl addition–elimination is the most important reaction which has been used for the preparation of polyamides, polyacetals, phenol–, urea–, and melamine–formaldehyde polymers. Some typical examples of this reaction include:

Direct reaction: The reaction of a dibasic acid and a glycol (to form a polyester) or a dibasic acid and a diamine (to form a polyamide) are some examples of direct reaction. A strong acid or acidic salt often serves as a catalyst. The reaction may be carried out by heating the reactants together and removing water (to draw the reaction toward product formation) usually by applying vacuum in the later stages.

Interchange: The reaction between a glycol and an ester yields polyesters and is preferred especially when the dibasic acid has low solubility. Frequently the methyl ester is used, as in the production of poly(ethylene terephthalate) from ethylene glycol and dimethyl terephthalate. The reaction between a carboxyl and an ester is much slower, but other interchange reactions, such as amine–amide, amine–ester, and acetal–alcohol are well known.

Acid chloride or anhydride: Either of these can be reacted with a glycol or an amine. Polyamides are prepared by the reaction of an acid chloride with a diamine.

Interfacial condensation: The reaction of an acid halide with a glycol or a diamine proceeds rapidly to high molecular weight polymer if carried out at the interface between two immiscible liquid phases each containing one of the reactants. Very high molecular weight polymers can be prepared. Typically, an aqueous phase containing the diamine or glycol and an acid acceptor is layered at room temperature over an organic phase containing the acid chloride. The polymer formed at the interface can be pulled off as a continuous film or filament. The method is applied to the formation of polyamides, polyurethanes, and polyureas. It is particularly useful for preparing polymers which are unstable at the higher temperatures.

Ring versus chain formation: Bifunctional monomers may react intramolecularly to produce a cyclic product. Thus, hydroxyacids may give either lactones or polymers on heating and amino acids may give lactams or linear polyamides. The type of the product is generally dependent on the size of the ring that can be formed.

1.121.2.4.2. Other mechanisms

Carbonyl addition–substitution reactions: The reaction of aldehydes with alcohols involving addition followed by substitution at the carbonyl group leads to the formation of polyacetals.

Nucleophilic substitution reactions: Nucleophilic substitution is the reaction of an electron pair donor (the nucleophile) with an electron pair acceptor (the electrophile). These reactions are used in the polymerization of epoxides. Nucleophiles attack the electrophilic C of the C–O bond causing it to break, resulting in ring opening. Opening the ring relieves the ring strain and epoxides can react with a large range of nucleophiles (such as H_2O, ROH, R–NH_2). Nucleophilic substitution reactions are also the basis for the formation of natural polysaccharides and polynucleotides.

Double bond addition reactions: Although addition reactions at double bonds are often associated with addition

polymerization, this is not always the case. The ionic addition of diols to diisocyanates in the production of polyurethanes is an example of condensation polymerization.

Free radical coupling: These reactions are used in the preparation of arylene ether polymers, polymers containing acetylene units, and arylenealkylidene polymers.

Aromatic electrophilic substitution reactions: This type of reactions including the use of Friedel–Crafts catalysts produces polymers by condensation polymerization.

1.121.2.5. Typical Condensation Polymers and Their Biomedical Applications

Polyesters, polyurethanes, polyamides, polyanhydrides, polycarbonates, and polyureas are among the condensation polymers that find broad use in medical applications in various forms. Some naturally occurring polymers such as proteins (collagen) and polysaccharides (hyaluronic acid) as well as bacterial polyesters (polyhydroxyalkanoates) are classified as condensation polymers, since their synthesis from their reactants are achieved by the elimination of water.[3,9] Some typical examples of condensation polymers and their biomedical applications are listed in Table 1.

1.121.3. Addition Polymerization

Polymerization in which the polymer forms by addition of monomeric unit to the growing chain is called as addition polymerization. Generally, a monomer containing double bond and an initiator creates the first active unit; they are needed to start the chain growth. The active group, which is the chain carrier group, may be a free radical, an anion, or a cation.

In addition polymerization reaction takes place by opening of the double bond and the created active group adds the monomer at a very high rate so that immediately high molecular-weight polymer chains form. Therefore, the reaction medium consists of large polymers and monomers unlike in condensation polymerization. Depending on the type of initiator a radical, anion, or cation is created and depending on the chemistry, adds monomers and eventually form a large molecule. The molecular weight of the polymer chains is practically unchanged during polymerization, but in time more of the monomer is converted into polymers and monomer concentration decreases.[3]

Monomers show varying degrees of selectivity with regard to the type of reactive center that will lead to polymerization. Most monomers are polymerized by free radicals, but they are more selective to the ionic mechanisms. For example, acrylamide polymerizes anionically but not cationically, whereas *N*-vinyl pyrrolidone polymerizes by cationic but not anionic route.[6] For both monomers, free radical polymerization is possible. Another type of polymerization is coordination polymerization in which special catalysts are used and highly ordered polymers with stereospecific properties are obtained.

Table 2 shows the types of initiation that polymerize various monomers. Although the polymerization of the monomers in Table 2 is thermodynamically feasible by having $\Delta G < 0$, practically polymerization is achieved only with a certain type of initiator.[3] The key to this phenomenon lies in the polarity of the monomer and the strength of the ion formed. Monomers with electron-donating groups (alkoxy, alkyl, alkenyl, and phenyl) attached the carbons of the unsaturation, increase the electron density on the carbon–carbon double bond and when these electrons react with a cationic initiator, a stable carbenium ion forms on the growing unit. In this case, chain polymerizes with cationic catalysts. On the other hand, monomers with electron-withdrawing substituents (aldehyde, ketone, acid, ester) decrease the electron density on the double bond and facilitate the attack of anionic catalysts leading to anionic polymerization. Free radical polymerization takes place in most cases but may be considered to be an intermediate case and a radical created on the growing chain leads to the formation of macromolecules. Many

Table 1 Typical condensation polymers and their biomedical applications

Type	*Characteristic linkage*	*Sample polymer*	*Biomedical application*
Polyacetal		Poly(ethyl glyoxylate)	Hard tissue replacement
Polyamide		Nylon	Intracardiac catheters, sutures, dialysis device components, heart mitral valves, hypodermic syringes
Polycarbonate		Bisphenol-A polycarbonate	Intraocular lenses, dialysis device components, heart/lung assist devices, blood collection, arterial tubules
Polyester		Poly(lactic acid-*co*-glycolic acid)	Grafts, sutures, implants, prosthetic devices, micro and nanoparticles
Polypeptides		Proteins, enzymes	Tissue engineering scaffolds, wound dressings
Polyurea		Polyisobutylene-based polyurea	Blood contacting surfaces
Polyurethane		Poly(ether urethane)	Aortic patches, heart assist devices, adhesives, dental materials, blood pumps, artificial heart and skin

monomers can polymerize by free radical mechanism in addition to an ionic mechanism.[3,5]

1.121.3.1. Free Radical Polymerization

Free radicals are unpaired electrons that are highly reactive and have short lifetimes. In free radical polymerizations, each polymer chain grows by addition of monomer to the free radical of the growing chain. Upon addition of the monomer, the free radical is transferred to the new chain end. Free radical polymerization has three stages: initiation, propagation, and termination.

1.121.3.1.1. Initiation

In the initiation step free radicals are formed from an initiator and then these free radicals bind to a monomer. Initiators can be peroxides or azo compounds in which scission of a single bond creates radicals, or a redox reaction in which radicals are created by an electron transfer to or from an ion or molecule.

Dissociation can be affected by the application of heat or electromagnetic radiation (e.g., UV, γ). Peroxides and hydroperoxides are frequently used as initiators because of the instability of the O–O bond. In the case of azo compounds, the process is driven by the release of N_2. Redox reactions are preferred especially when the polymerization is needed to be carried out at low temperatures.[6,10] Heat and electromagnetic radiations can also start polymerization by breaking the double bond of the monomeric units and creating two active radicals. In this case, the chain adds to monomeric units from both ends. Some of the most widely used initiator systems are given in Table 3.

The free radical initiation step can be shown as follows:

Dissociation of an initiator (I) such as benzoyl peroxide yields two radicals (R•) with a dissociation rate constant k_d:

$$I \xrightarrow{k_d} 2R\bullet \qquad [VI]$$

This radical then attacks to a monomer molecule to create the first radical M•.

$$R\bullet + M \xrightarrow{k_i} RM\bullet \qquad [VII]$$

where k_i is the rate constant of initiation.

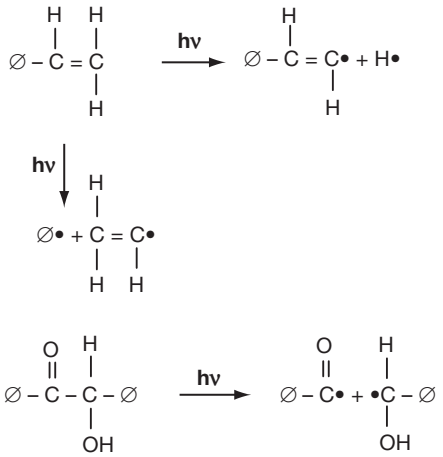
4. Electromagnetic radiation (photoinitiation)
Styrene, Benzoin:



1.121.3.1.2. Propagation

The free radicals formed are very active and immediately add on monomer molecules leading to growing macroradicals. Each addition creates a new radical that has the same identity as the previous one, except that it is larger by one monomer

unit. In the polymerization mechanism, it is assumed that all growing chains have the same propagation constant (k_p). The successive additions may be represented by:

$$M_n^{\bullet} + M \xrightarrow{k_p} M_{n+1}^{\bullet} \qquad [VIII]$$

Propagation with growth of the chain takes place in milliseconds and k_p for most monomers is in the range of 10^2–$10^4\,l\,mol^{-1}\,s^{-1}$.[3]

1.121.3.1.3. Termination

Termination usually occurs by combination or disproportionation reactions. Combination is coupling of two growing chains to form a single polymer molecule.

$$M_n^{\bullet} + M_m^{\bullet} \xrightarrow{k_{tc}} M_{n+m} \qquad [IX]$$

where k_{tc} is the rate constant for termination by combination.

In disproportionation reaction, a hydrogen atom is abstracted and exchanged between the growing chains leaving behind two terminated chains:

$$M_n^{\bullet} + M_m^{\bullet} \xrightarrow{k_{td}} M_n + M_m \qquad [X]$$

where k_{td} is the rate constant for termination by disproportionation.

Termination by disproportionation forms one polymer molecule with a saturated end-group and another with an unsaturated end-group. Type of termination affects the molecular weight. If it is through combination, average molecular weight will be two times higher than that of polymers terminated by disproportionation. In general, both types of termination reactions take place in different proportions depending upon the monomer and the polymerization condition. For example, polystyrene chains terminate by combination whereas poly(methyl methacrylate) chains terminate by disproportionation, especially at temperatures above 60 °C.[10]

1.121.3.1.4. Kinetics of radical polymerization

In radical polymerization reactions, decomposition of the initiator (such as peroxides and azo compounds) proceeds much more slowly than the reaction of the free radical with the monomer. This step is therefore the rate-determining step. The rate of initiation (R_i) is

$$R_i = \left(\frac{d[M^{\bullet}]}{dt}\right)_i = 2fk_d[I] \qquad [19]$$

where f is the initiator efficiency, the fraction of the radicals successful in initiating chains, k_d is the rate constant for initiator dissociation, and [I] is the concentration of the initiator. The constant 2 defines that two radicals are formed from one initiator molecule. The initiator efficiency is in the range of 0.3–0.8 due to side reactions. The initiator efficiency decreases when side reactions terminates the radicals.[6]

For a redox initiation system, rate of initiation is given as

$$R_i = \left(\frac{d[M^{\bullet}]}{dt}\right)_i = f\,k[Ox][Red] \qquad [20]$$

where [Ox] and [Red] are the concentrations of oxidizing and reducing agents and k is the rate constant.

For photochemical initiation, intensity of light affects the rate and equation is given as

$$R_i = \left(\frac{d[M^{\bullet}]}{dt}\right)_i = 2\Phi I_{abs} \qquad [21]$$

where I_{abs} is the intensity of the light absorbed and the constant Φ is called quantum yield.

The rate of termination is represented as

$$R_t = -\left(\frac{d[M^{\bullet}]}{dt}\right)_i = 2k_t[M^{\bullet}]^2 \qquad [22]$$

where k_t is the overall rate constant for termination. The constant 2 shows that the two growing chains are terminated by each termination reaction.

At the start of the polymerization, the rate of formation of radicals greatly exceeds the rate of termination. As the reaction proceeds, the rate of formation and the rate of loss of radicals by termination becomes equal and it can be stated that there is no change in the concentration of M•. This is the steady state ($d[M^{\bullet}]/dt = 0$). At steady state, the rates of initiation (R_i) and termination (R_t) are equal, leading to

$$[M^{\bullet}] = \left(\frac{f\,k_d[I]}{k_t}\right)^{1/2} \qquad [23]$$

The rate of propagation is represented as

$$R_p = -\left(\frac{d[M]}{dt}\right)_t = k_p[M][M^{\bullet}] \qquad [24]$$

so using eqn [23], R_p can be obtained as

$$R_p = k_p\left(\frac{f\,k_d[I]}{k_t}\right)^{1/2}[M] \qquad [25]$$

If the initiator efficiency is high (close to 1) and if f is independent of monomer, rate of polymerization is proportional to the first power of the monomer concentration.

In chain polymerization, one important phenomenon is 'gel effect' or 'Trommsdorff – Norrish effect' which is autoacceleration of the polymerization. In these cases, viscosity of the reaction medium increases and the mobility of the growing chains are restricted. Chains continue to grow with addition of monomers, but they cannot terminate. Therefore, the system is no longer in steady state. Fast polymerization causes heat evolution and local hot spots, leading to cross-linking and gel formation.[11]

1.121.3.1.5. Degree of polymerization

Kinetic chain length v is defined as the number of monomer molecules used per active center. It is, therefore, represented as $R_p/R_i = R_p/R_t$. Therefore,

$$v = \frac{k_p[M]}{2k_t[M^{\bullet}]} \qquad [26]$$

using eqn [24],

$$v = \frac{k_p^2[M]^2}{2k_tR_p} \qquad [27]$$

The number average degree of polymerization, $\bar{X}_n$, is the average number of monomer molecules added to the polymer

molecule. If the propagating radicals terminate by combination $\bar{X}_n = 2\nu$, and if termination is by disproportionation $\bar{X}_n = \nu$.

Chain transfer is the reaction of a growing chain with an inactive molecule to produce a dead polymer chain and a molecule with a radical. The transfer agent may be the initiator, monomer, polymer, solvent, or an impurity. When the transfer does not lead to new chain growth, it is called inhibition. If the newly formed radical is less reactive than the propagating radical, then it is called retardation.[3]

1.121.3.1.6. Thermodynamics of polymerization

Addition polymerizations of olefinic monomers have negative ΔH and ΔS. The exothermic nature of polymerization arises because the process involves the formation of new bonds and the negative ΔS arises from the decreased degree of freedom of the polymer compared to the monomer. ΔG depends on both parameters and is given by

$$\Delta G = \Delta H - T\Delta S \qquad [28]$$

The numerical value of ΔS is much smaller than ΔH. Therefore ΔG is negative under ambient T conditions since $|\Delta H| > |T\Delta S|$. Polymerization is thermodynamically favorable. However, thermodynamic feasibility does not mean that the reaction is practically feasible. For the polymerization reaction to take place at appreciable rates, it may require specific catalyst systems. This is the case with the α-olefins, which require Ziegler–Natta or coordination-type initiators.[3]

1.121.3.2. Ionic Polymerization

Addition polymerization of olefinic monomers can also be achieved with active centers possessing ionic charges. These can be either cationic polymerizations or anionic polymerizations depending on the type of the chain carrier ion. The ionic charge of the active center causes these polymerizations to be more selective unlike free radical polymerization. They proceed only with monomers that have appropriate substituent groups which can stabilize the active center. Since the required activation energy for ionic polymerization is small, these reactions may occur at very low temperatures. High rate of polymerization at low temperatures is a characteristic of ionic polymerizations. For cationic active centers, electron-donating substituent groups are needed. For anionic polymerization, the substituent group must be electron withdrawing to stabilize the negative charge. Thus, most monomers can be polymerized either by cationic or by anionic polymerization but not by both. Only when the substituent group has a weak inductive effect and is capable of delocalizing both positive and negative charges (e.g., styrene and 1,3-dienes) both cationic and anionic polymerization can be achieved.

Another important difference between free radicalic and ionic polymerizations is that many ionic polymerizations proceed at much higher rates than free radical polymerization, mainly because the concentration of propagating chains is much higher (by a factor of 10^4–10^6). Another difference is that an ionic active center is accompanied by a counter ion of opposite charge. Both the rate and stereochemistry of propagation are influenced by the counter ion and the strength of interaction with the active center. Finally, termination does not occur by a reaction between two ionic active centers because they are of similar charge.[10]

1.121.3.2.1. Cationic polymerization

Typical catalysts for cationic polymerization are strong electron acceptors and include Lewis acids, Friedel–Crafts halides, Brönsted acids, and stable carbenium-ion salts. Many of them require a cocatalyst, usually a proton donor, to initiate polymerization. Those monomers with electron donating 1-1-substituents that can form stable carbenium ions are polymerized by cationic mechanisms. For these systems, the polymerization rate is very high; for isobutylene initiated by $AlCl_3$ or BF_3, in few seconds at $-100\,^{\circ}C$, chains of several million daltons can form. Both the rate and the molecular weight decrease with temperature and are much lower at room temperature.[5]

In certain cationic polymerizations, a distinct termination step may not take place; therefore 'living' cationic polymers are formed. However, chain transfer to a monomer, polymer, solvent, or counterion can terminate the growth of chains. Cationic polymerizations are usually conducted in solution, at low temperature, typically -80 to $-100\,^{\circ}C$. The solvent is important because it determines the activity of the ion at the end of the growing chain. There is a linear increase in polymer chain length and an exponential increase in polymerization rate as the dielectric strength of the solvent increases.[12]

1.121.3.2.2. Anionic polymerization

The initiator in an anionic polymerization needs to be a strong nucleophile, including Grignard reagents and other organometallic compounds like *n*-butyl (n-C_4H_9) lithium. When the starting reagents are pure and the polymerization reactor is free of traces of oxygen and water, the chain can grow until all the monomer is consumed. For this reason, anionic polymerization is sometimes called 'living' polymerization. Termination occurs only by the deliberate introduction of oxygen, carbon dioxide, methanol, or water. In the absence of a termination mechanism, the number average degree of polymerization, $\bar{X}_n$, is

$$\bar{X}_n = \frac{[M]_o}{[I]_o} \qquad [29]$$

where $[M]_o$ and $[I]_o$ are the initial concentrations of the monomer and the initiator, respectively.

The absence of termination during a living polymerization leads to a very narrow molecular weight distribution with a heterogeneity index (HI) as low as 1.06, whereas for free radical polymerization polydispersities as high as 2 were reported.[12]

1.121.3.3. Coordination Polymerization

Use of some special catalysts may lead to the formation of very orderly structured polymers with high stereospecificity. For example, the processes used in the polymerization of both isotactic polypropylene (*i*-PP) and high density polyethylene (HDPE) employ transition-metal catalysts called Ziegler–Natta catalysts, which utilize a coordination type mechanism during polymerization. In general, a Ziegler–Natta catalyst is an

organometallic complex with the cation from Groups I to III in the Periodic Table, (e.g., $Al(C_2H_5)_3$), a hallide of transition metal from Groups IV to VIII, (e.g., $TiCl_4$). HDPE can be prepared by bubbling ethylene gas into a suspension of $Al(C_2H_5)_3$ and $TiCl_4$ in hexane at room temperature. Although the exact mechanism is still unclear, it is proposed that the growing polymer chain is bound to the metal atom of the catalyst and that monomer insertion involves a coordination of the monomer with the atom. It is this coordination of the monomer that results in the stereospecificity of the polymer. Coordination polymerizations can be terminated by introduction of water, hydrogen, aromatic alcohol, or metals.[12]

1.121.3.4. Typical Addition Polymers and Their Biomedical Applications

Addition polymers such as polyethylene, polypropylene, polystyrene, polyacrylates can be easily fabricated in many forms such as fibers, textiles, films, rods, and viscous liquids and they are used in a variety of biomedical applications. Some are given in Table 4.[13,14]

1.121.3.5. Comparison of Addition and Condensation Polymerization

The main characteristic of step polymerization that distinguishes it from chain polymerization is that the reaction occurs between any of the different sized species present in the reaction system. In step polymerization, the size of the polymer molecules increases at a relatively slow pace and the monomers disappear early in the reaction unlike chain polymerization where the monomer concentration decreases gradually (medium generally contains long and dead chains and monomers) and growth occurs very rapidly by addition of one unit at a time to the end of the growing chain. Longer polymerization durations are essential in obtaining high molecular weight condensation polymers whereas with chain polymers long reaction times give high yields but do not affect the molecular weight significantly.

The typical step and chain polymerizations differ significantly in the relationship between polymer molecular weight and the percent conversion of monomer. The chain polymerization will show the presence of high molecular weight polymer molecules at all percent of conversions. There are no intermediate sized molecules in the reaction mixture (only monomer and high polymer). The only change that occurs with conversion is the continuous increase in the number of polymer molecules. On the other hand, high molecular weight polymer is obtained in step polymerizations only near the very end of the reaction (at 98% conversion).[3,15,16]

1.121.3.6. New Polymerization Mechanisms

1.121.3.6.1. Atom transfer radical polymerization

Atom transfer radical polymerization (ATRP) is a controlled/living polymerization technique which is highly effective in obtaining well-defined polymers or copolymers with predetermined molecular weight, narrow molecular weight distribution, and a high degree of chain end functionality. ATRP has been used in the preparation of polymers with precisely controlled functionalities, topologies (linear, star/multiarmed,

Table 4 Some additional polymers used in biomedical applications

Synthetic polymers	*Monomeric unit*	*Applications*
Polyethylene (PE)	$\{CH_2–CH_2\}_n$	Pharmaceutical bottles, nonwoven fabrics, catheters, pouches, flexible containers, orthopedic implants (e.g., hip implants)
Poly(2-hydroxyethyl methacrylate) (PHEMA)	$\{CH_2–C(CH_3)(COOCH_2CH_2OH)\}_n$	Contact lenses, surface coatings, drug delivery systems
Poly(methyl 2-cyanoacrylate)	$\{CH_2–C(CN)(COOCH_3)\}_n$	Surgical adhesive
Poly(methyl methacrylate) (PMMA)	$\{CH_2–C(CH_3)(COOCH_3)\}_n$	Blood pumps and reservoirs, membranes for dialyzers, intraocular lenses, bone cement, drug delivery systems
Polypropylene (PP)	$\{CH_2–CH(CH_3)\}_n$	Disposable syringes, blood oxygenator membranes, sutures, nonwoven fabrics, artificial vascular grafts, reinforcing meshes, catheters
Polystyrene (PS)	$\{CH_2–CH(C_6H_5)\}_n$	Tissue culture flasks, roller bottles, filterwares
Poly(tetrafluoro ethylene) (PTFE)	$\{CF_2–CF_2\}_n$	Catheters, artificial vascular grafts, various separator sheets
Poly(vinyl chloride) (PVC)	$\{CH_2–CH(Cl)\}_n$	Blood bags, surgical packaging, i.v. sets, dialysis devices, catheter bottles, connectors, and cannulae

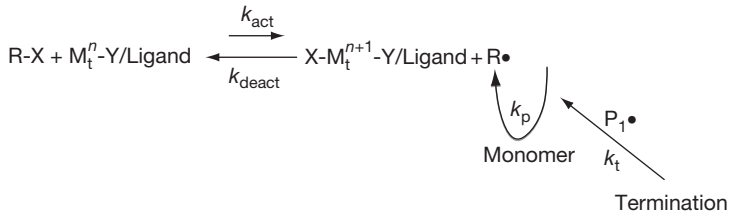


Figure 8 General mechanism of ATRP.

comb, hyperbranched, and network polymers), and compositions (homopolymers, block copolymers, statistical copolymers, gradient copolymers, graft copolymers).

Monomer, initiator with a transferable atom (halogen), and catalyst (transition metal with suitable ligands) are the main components of ATRP. In some cases, an additive (metal salt in a higher oxidation state) may be used. Type of solvent and level of temperature are important parameters for a successful ATRP. The most commonly used monomers are styrenes, methacrylates, methacrylamides, dienes, and acrylonitriles.

Atom transfer step is the key elementary reaction leading to the uniform growth of the polymeric chains. In ATRP, radicals are formed by a reversible redox reaction of a transition metal complex, M_t^n-Y/ligand, where M_t is transition metal and Y may be another ligand or a counterion. Transfer of an X atom (usually halogen) from a dormant species to the metal results in an oxidized metal complex (X-M_t^{n+1}-Y/ligand which is the persistent species) and a free radical (R•). Activation and deactivation processes occur with rate constants of k_{act} and k_{deact}, respectively (**Figure 8**).

Even when the same ATRP conditions (same catalyst and initiator) are used, each monomer has its own unique atom transfer equilibrium constants for its active and dormant species. The rate of polymerization depends on K_{eq} ($K_{eq} = k_{act}/k_{deact}$). If it is too small, polymerization reaction will occur slowly, and if it is too large, due to the high radical concentration, termination will occur and polymerization will be uncontrolled.

The new radical can initiate the polymerization by addition to a monomer with the rate constant of propagation k_p. Termination reactions (rate constant is k_t) also occur in ATRP, by combination or disproportionation, or the active species is reversibly deactivated by the higher oxidation state metal complex. In a well-controlled ATRP, no more than a few percent of the polymer chains undergo termination. During the initial, short, nonstationary stage of the polymerization, the concentration of radicals decays by the unavoidable irreversible self termination, whereas, the oxidized metal complexes increase steadily as the persistent species. As the reaction proceeds, the decreasing concentration of radicals causes a decrease in self-termination and cross-reaction with persistent species toward the dormant species. The decrease in the stationary concentration of growing radicals minimizes the rate of termination which has a key role in the first-order kinetic.

The stabilizing group (e.g., phenyl or carbonyl) on the monomers produces a sufficiently large atom transfer equilibrium constant. Typically, alkyl halides (RX) are used as the initiator. The halide group (X) must rapidly and selectively migrate between the growing chain and the transition-metal complex to form polymers with narrow molecular weight distributions. Catalyst is an important component of ATRP since it determines the position of the atom transfer equilibrium and the dynamics of exchange between the dormant and active species. A variety of transition metal complexes have been used as ATRP catalysts such as transition metal complexes of copper, ruthenium, palladium, nickel, and iron. Polymerization is conducted either in bulk or in solvents (benzene, water, etc.) at moderate temperatures (70–130 °C).[17–21]

1.121.3.6.2. Nitroxide-mediated polymerization

Nitroxide-mediated polymerization (NMP) is another controlled radical polymerization method. NMP allows the preparation of very well-defined polymers with controlled molecular weight and narrow molecular weight distribution and to extend chains with different monomers to obtain multiblock copolymers. Combination of a nitroxide and a free radical initiator or alkoxyamines serving as both initiators and controlling agents are used in this technique.

NMP is based on a reversible recombination between propagating species (P•) and nitroxide (R_2NO•, R = alkyl group) with the formation of alkoxyamine (R_2NOP), resulting in a low radical concentration and decreases the irreversible termination reactions. Polymer chains with equal chain lengths and reactive chain ends can be obtained because a majority of dormant living chains can grow until the monomer is fully consumed.

NMP is metal free and not colored, and polymer does not require any purification after synthesis. The main limitation of NMP is the range of monomers that can be effectively controlled. Some efficient alkoxyamines and nitroxides are able to control most of the conjugated vinyl monomers such as styrene and derivatives, acrylates (including some functional acrylates), acrylamides, acrylonitrile, and methacrylates (with some limitations) and also some dienes such as isoprene.[22,23]

1.121.3.6.3. Reversible addition–fragmentation chain transfer polymerization

Reversible addition–fragmentation chain transfer polymerization (RAFT) is one of the most versatile methods of controlled radical polymerization because it allows a wide range of functionalities in the monomers and solvents, including aqueous solutions. The method is relatively new for the synthesis of living radical polymers and may be more versatile than ATRP or NMP. RAFT polymerization uses thiocarbonylthio compounds, such as dithioesters, dithiocarbamates, trithiocarbonates, and xanthates in order to mediate the polymerization via a reversible chain-transfer process. The technique is applicable to a wide range of monomers including methacrylates, methacrylamides, acrylonitrile, styrene and derivatives, butadiene,

vinyl acetate, and *N*-vinyl pyrrolidone. As a result of its exceptional effectiveness and the wide range of monomers and solvents, RAFT polymerization has developed into an extremely versatile polymerization technique. Especially, the molecular weight of the polymer can be predetermined and the molecular weight distribution can be controlled fairly well.

Typically, a RAFT polymerization system consists of an initiator, monomer, chain transfer agent, and solvent. The control of temperature is crucial. It can be performed by simply adding a certain quantity of an appropriate RAFT agent (i.e., a thiocarbonylthio compound) to a conventional free radical polymerization medium. Radical initiators such as azobisisobutyronitrile (AIBN) and 4,4′-azobis(4-cyanovaleric acid) (ACVA) are widely used as initiators in RAFT polymerizations. RAFT agents (also called chain transfer agents) must be thiocarbonylthio compounds where the Z and R groups perform different functions (Figure 9). The Z group primarily controls the effectiveness with which radical species can add to the C=S bond. The R group must be a good homolytic leaving group which is able to initiate new polymer chains.

There are four steps in a typical RAFT polymerization: initiation, addition–fragmentation, reinitiation, and equilibration (Figure 10).

In the initiation step, the reaction is started using radical initators (I) such as AIBN. The initiator reacts with a monomer to create a radical species which starts an actively polymerizing chain. During addition–fragmentation step, the active chain (P_n) reacts with the dithioester, which releases the homolytic leaving group (R•). This is a reversible step, with an intermediate species capable of losing either the leaving group (R•) or the active species (P_n•). Reinitiation occurs with the reaction between the leaving group radical and another monomer species, starting another active polymer chain. This active chain (P_m•) then goes through the addition–fragmentation or equilibration steps. Equilibration is a fundamental step in the RAFT process which traps the majority of the active propagating species into the dormant thiocarbonyl compound. This limits the possibility of chain termination. Active polymer chains (P_m• and P_n•) are in an equilibrium between the active and dormant stages. While one polymer chain is in the dormant stage (bound to the thiocarbonyl compound), the other is active in polymerization.[24–28]

RAFT process allows the synthesis of polymers with specific macromolecular architectures such as block, gradient, statistical, linear block, comb/brush, star, hyperbranched, and network copolymers and dendrimers. Examples of architectures that can be synthesized by RAFT are given in Figure 11.

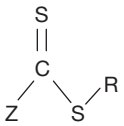

Figure 9 General structure of RAFT agents.

1.121.4. Polymer Reactions

1.121.4.1. Copolymerization

Copolymers are polymers formed from two or more monomeric units. The arrangement of repeating units can be in various ways along the chain. Some copolymers are very similar to homopolymers, because they have one type of repeating units. But proteins and some polysaccharides are copolymers of a number of different monomers.

Copolymers constitute the vast majority of commercially important polymers. Compositions of copolymers may vary from only a small percentage of one component to comparable proportions of both monomers. Such a wide variation in composition permits the production of polymer products with vastly different properties for a variety of end uses. The minor constituent of the copolymer may, for example, be a diene introduced into the polymer structure to provide sites for such polymerization reaction as vulcanization; it may also be a trifunctional monomer incorporated into the polymer to

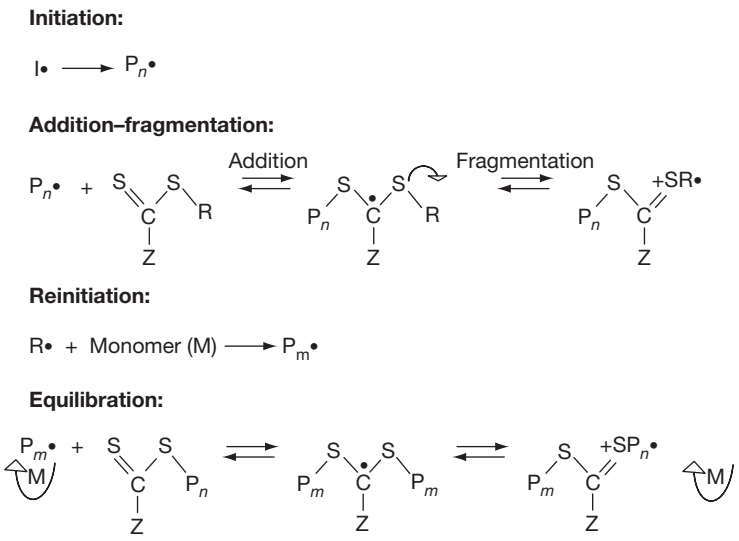

Figure 10 RAFT mechanism.

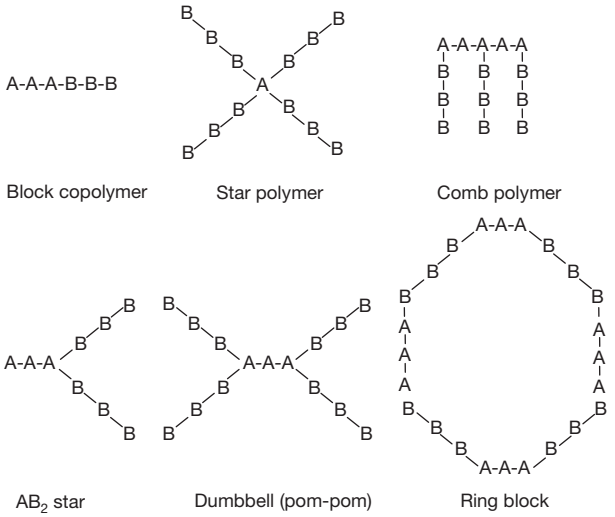

Figure 11 Examples of complex architectures prepared by RAFT.

ensure cross-linking, or possibly it may be a monomer containing carboxyl groups to enhance product solubility, dyeability, or some other desired properties.[12]

1.121.4.1.1. Types of copolymerization

In free radical polymerization, reactivity ratios of the monomers, r_1 and r_2, should be considered. Reactivity ratios represent the relative preference of a given radical that is adding its own monomer to the other monomer.

$$r_1 = \frac{k_{11}}{k_{12}} \qquad [30]$$

where k_{11} and k_{22} are the rate constants for radicals adding their own type of monomer and k_{12} and k_{21} are the rate constants for adding the opposite kind.

$$r_2 = \frac{k_{22}}{k_{21}} \qquad [31]$$

Depending on the r values, copolymerization reaction can form ideal, random, alternating, or block copolymers. Another type is graft copolymers.

In ideal copolymerization ($r_1 r_2 = 1$), the growing chain end reacts with one of the monomeric unit with a statistically possible preference. The multiplication of reactivity ratios should be equal to 1.

When $r_1 r_2 = 1$ then,

$$r_1 = \frac{1}{r_2} \quad \text{or} \quad \frac{k_{11}}{k_{12}} = \frac{k_{21}}{k_{22}} \qquad [32]$$

The relative amounts of the monomer units in the chain are determined by the reactivities of the monomer and the feed composition of the reaction medium.

$r_1 r_2 = 1$ occurs under two conditions:

1. $r_1 > 1$ and $r_2 < 1$ or $r_1 < 1$ and $r_2 > 1$.

   One of the monomers is more reactive than the other. The copolymer will contain a greater proportion of the more reactive monomer in the random sequence of monomer units. In this case, production of copolymers with significant quantities of both monomers will be more difficult as the difference in reactivities of the two monomers increases.
2. $r_1 = r_2 = 1$.

   Under these conditions, the growing radicals cannot distinguish between the two monomers. The composition of the copolymer is the same as that of the input concentrations and the monomers are arranged randomly along the chain. These copolymers show properties of both homopolymers of its constituents.

Random copolymers are formed when r values of both monomers are close to each other. A mixture of two or more monomers is polymerized in one process and where the arrangement of the monomers within the chains is determined by kinetic factors. If the reacting monomers are shown as A and B, the sequence will have no order in the chain, such as –AABBAAABABAA–.

Random copolymers tend to average the properties of the constituent monomers in the proportion to the relative abundance of the comonomers.

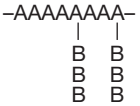
In the alternating copolymerization, r values of both monomers are equal to zero. When $r_1 = r_2 = 0$ (or $r_1 r_2 = 0$), each radical reacts exclusively with the other monomer; that is, neither radical can regenerate itself. Consequently, the monomer units are arranged alternately along the chain. These are called alternating copolymers and can be shown as –ABABAB–.

Polymerization continues until one of the monomers is used up and then it stops. Perfect alternation occurs when both r_1 and r_2 are zero. As the quantity $r_1 r_2$ approaches zero, there is an increasing tendency toward alternation. This has practical significance because it enhances the possibility of producing polymers with appreciable amounts of both monomers from a wider range of feed compositions.[12] Alternating copolymers, while relatively rare, are characterized by combining the properties of the two monomers along with structural regularity. Crystalline polymers can be obtained if a very high degree of regularity (stereoregularity extending along the all configuration of the repeat units) exists.

Block or segmented copolymers are usually prepared by multistep processes. The blocks may be a homopolymer or may themselves be copolymers. Diblock can be shown as –AAAABBB– and triblock can be shown as –AAABBBBAAAA–. In multiblock copolymers, the A and B segments repeat themselves many times along the chain.

Block copolymers are generally prepared by sequential addition of monomers to living polymers, rather than by depending on the improbable $r_1 r_2 > 1$ criterion in monomers.[6]

Graft copolymers and branched copolymers are formed by copolymerization of macromonomers and can form as a consequence of intramolecular rearrangement. In general, the backbone and the chain is formed from one type of monomer, and the chains of other type are attached as branches. This can be shown as



Special classes of branched copolymers are star polymers, dendrimers, hyperbranched copolymers, and microgels.[29]

1.121.4.1.2. Effects of copolymerization on properties

Copolymer synthesis offers the ability to alter the properties of homopolymer in the desired direction by the introduction of an appropriately chosen second repeating unit. Since the homopolymers are combined in the same molecule, copolymer demonstrates the properties of both homopolymers. Properties, such as crystallinity, flexibility, T_m, T_g can be altered by forming copolymers. The magnitudes and sometimes even the directions of the property alteration differ depending on whether random, alternating, or block copolymer is involved. The crystallinity of a random copolymer is lower than that of either of the respective homopolymers (i.e., the homopolymers corresponding to the two different units) because of the decrease in structural regularity. The melting temperature of any crystalline material formed is usually lower than that of either homopolymer. The T_g value will be in between those for the two homopolymers.

Alternating copolymers have a regular structure, and their crystallinity may not be significantly affected unless one of the repeating units contains rigid, bulky, or excessively flexible chain segments. The T_m and T_g values of an alternating copolymer are in between the corresponding values for the homopolymers. Block copolymers show the properties (e.g., crystallinity, T_m, T_g) present in the corresponding homopolymer as long as the block lengths are not too short. This behavior is typical since A blocks from different polymer molecules aggregate with each other and separately, B blocks from different polymer molecules aggregate with each other. This offers the ability to combine the properties of two very different polymers into the one block copolymer. The exception to this behavior occurs infrequently when the tendency for cross-aggregation between A and B blocks is the same as for self-aggregation of A blocks with A blocks and B blocks with B blocks.

Most commercial utilization of copolymerization falls into one of the two groups. One group consist of various random copolymers in which the two repeating units posses the same functional groups. The other groups of commercial copolymers consist of block copolymers in which two repeating units have different functional groups although only few commercial random copolymers in which the two repeating units have different functional groups exist. The reason for the situation probably lies in the difficulty of finding one set of reaction condition for simultaneously performing two different reactions.[30]

1.121.4.1.3. Kinetics of copolymerization

1.121.4.1.3.1. Kinetics of addition copolymerization

Kinetics of copolymerization reactions are very complicated. The copolymerization between two different monomers can be described using four reactions, two homopolymerizations and two cross-polymerization additions. Reaction mechanism is given in **Table 5**. The specific rate constants for the different reaction steps described are assumed to be independent of chain length.[11]

At steady state, the concentrations of $M_1^{\bullet}$ and $M_2^{\bullet}$ are assumed to remain constant. Therefore the rate of conversion of $M_1^{\bullet}$ to $M_2^{\bullet}$ necessarily equals that of conversion of $M_2^{\bullet}$ to $M_1^{\bullet}$. Thus,

Table 5 Reaction mechanism, rate constants, and rate equation or copolymerization

Reaction	*Rate constant*	*Rate equation*
$M_1^{\bullet} + M_1 \rightarrow M_1M_1^{\bullet}$	k_{11}	$k_{11}[M_1^{\bullet}][M_1]$
$M_1^{\bullet} + M_2 \rightarrow M_1M_2^{\bullet}$	k_{12}	$k_{12}[M_1^{\bullet}][M_2]$
$M_2^{\bullet} + M_2 \rightarrow M_2M_2^{\bullet}$	k_{22}	$k_{22}[M_2^{\bullet}][M_2]$
$M_2^{\bullet} + M_1 \rightarrow M_2M_1^{\bullet}$	k_{21}	$k_{21}[M_2^{\bullet}][M_1]$

$$k_{21}[M_2^{\bullet}][M_1] = k_{12}[M_1^{\bullet}][M_2] \quad [33]$$

The rate of polymerization can be given with the rates of disappearance of monomers M_1 and M_2 as shown below:

$$\frac{-d[M_1]}{dt} = k_{11}[M_1^{\bullet}][M_1] + k_{21}[M_2^{\bullet}][M_1] \quad [34]$$

$$\frac{-d[M_2]}{dt} = k_{11}[M_1^{\bullet}][M_2] + k_{22}[M_2^{\bullet}][M_1] \quad [35]$$

From the division of the two equations, the copolymer equation is obtained. The ratio of $d[M_1]/d[M_2]$ gives the monomer ratios present in the polymer chain.

$$\frac{d[M_1]}{d[M_2]} = \frac{[M_1]r_1[M_2] + [M_2]}{[M_2][M_1] + r_2[M_2]} \quad [36]$$

Here, r_1 and r_2 are monomer reactivity ratios and are defined by

$$r_1 = \frac{k_{11}}{k_{12}} \quad [37]$$

and,

$$r_2 = \frac{k_{22}}{k_{21}} \quad [38]$$

Monomer-radical reaction rates are also affected by steric hindrance. The role of steric hindrance in the reduction of the reactivity of 1,2-disubstituted vinyl monomers can be illustrated by the fact that while these monomers undergo copolymerization with other monomers (e.g., styrene), they do not tend to homopolymerize. Homopolymerization is prevented because of the steric effect of the 2-substituent on the attacking radical and the monomer. On the other hand, there is no 2- or β-substituent when the attacking radical is styrene; consequently, copolymerization is possible.[12]

The effect of steric hindrance in reducing reactivity may also be demonstrated by comparing the reactivities of 1,1- and 1,2 disubstituted olefins with reference radicals. The addition of a second 1-substituent usually increases reactivity three to ten-fold; however, the same substituent in the 2-position usually decreases reactivity 2- or 20-fold. The extent of reduction in reactivity also depends on the energy differences between *cis* and *trans* forms.[5]

1.121.4.1.3.2. Kinetics of condensation copolymerization:

- *Random copolymers:* The copolymerization of a mixture of monomers offers a route to random copolymers; for instance, a copolymer of overall composition XWYV is synthesized by copolymerizing a mixture of the four monomers.

(X) HOOC–R–COOH
(Y) HOOC–R_2–COOH
(W) H_2N–R_1–NH_2
(V) H_2N–R_3–NH_2

→ HOOC–CONH–R_1–NHCO–R_2–CONH–R_3–NH_2
Copolymer of XWYV

It is highly unlikely that the reactivities of the various monomers would be such that block or alternating copolymers are formed. The overall composition of the copolymer obtained in a step polymerization will almost always be the same as the composition of the monomer mixture since these reactions are carried out to essentially 100% conversion (a necessity for obtaining high molecular weight polymer). In the step copolymerization of monomer mixtures, one often observes the formation of random copolymers. This occurs either because there are no differences in the reactivities of the functional groups existing on different monomers or the polymerization under reaction conditions where there is extensive interchange. The use of only one diacid or diamine would produce a variation on the copolymer structure with either R=R_2 or R_1=R_3.[31]

Statistical copolymers containing repeating units each with a different functional group can be obtained using appropriate mixture of monomers. For example, a polyesteramide can be synthesized from a ternary mixture of a diol, diamine, and diacid or binary mixture of a diacid and amine–alcohol.

- *Alternating copolymers*: It is possible to synthesize an alternating copolymer in which R=R_2 by using a two-stage process. In the first stage, a diamine is reacted with an excess of diacid to form a trimer:

$$n\text{HOOC–R–COOH} + m\text{H}_2\text{N–R}_1\text{–NH}_2 \rightarrow m\text{HOOC–R–CONH–R}_1\text{–NHCO–R–COOH} \quad \text{[XI]}$$

The trimer is then reacted with an equamolar amount of a second diamine in the second stage:

$$n\text{HOOC–R–CONH–R}_1\text{–NHCO–R–COOH} + n\text{H}_2\text{N–R}_3\text{–NH}_2 \rightarrow \text{HO(–CO–R–CONH–R}_1\text{–NHCO–R–CONH–R}_3\text{–NH)}_n\text{–H} + (2n-1)\text{H}_2\text{O} \quad \text{[XII]}$$

Alternating copolymers with two different functional groups are similarly synthesized by using preformed reactants.[32–35]

$$n\text{OCN–R–CONH–R}_1\text{–OSi(CH}_3)_3 \xrightarrow[-(\text{CH}_3)_3\text{SiF}]{\text{HF}} \text{HF–(CH}_3)_3\text{SiF(CO–NH–R–CO–NH–R}_1\text{–O)}_n \quad \text{[XIII]}$$

$$n\text{OCN–R–CONH–R}_1\text{–NHCO–R–NCO} + \text{HO–R}_2\text{–OH} \xrightarrow{\text{HF}} \text{HF–(CONH–R–CONH–R}_1\text{–NHCO–R–NHCOO–R}_2\text{–O)}_n \quad \text{[XIV]}$$

The silyl ether derivative of the alcohol is used in reaction [XIII]. The corresponding alcohol OCN–R–CONH–R_1–OH cannot be isolated because of the high degree of reactivity of isocyanate and alcohol groups toward each other.

- *Block copolymers*: There are two general methods for synthesizing block copolymers. These two methods, the one prepolymer and the two prepolymer methods, are described below for block copolymers containing different functional groups in the repeating units. They are equally applicable to block copolymers containing the same functional groups in the two repeating units. The two prepolymer method involves the separate synthesis of two different prepolymers, each containing appropriate end groups, followed by the polymerization of two polymers via reaction of their end groups. Consider the synthesis of a polyester-block-polyurethane. A isocyanate-terminated polyester prepolymer is synthesized from HO–R_3–OH and HOOC–R_1–COOH using an excess of diol reactant. An isocyannate-terminated polyurethane prepolymer is synthesized from OCN–R_2–NCO and HO–R_3–OH using an excess of the diisocyanate reactant. The α,ω-dihydroxypolyester and α,ω-diisocyanatapolyurethane prepolymers, referred to as macrodiol and macrodiisocyanate, respectively, are subsequently polymerized with each other to form the block copolymer:

$$\text{H–(–O–R–OCC–R}_1\text{–CO–)}_n\text{–O–ROH} + \text{OCN–(–R}_2\text{–NHCOO–R}_3\text{–OOCNH)}_m\text{–R}_2\text{–NCO} \rightarrow \text{H–(–O–R–OOC–R}_1\text{–CO–)}_n\text{–O–RO–OCNH–R}_2\text{–(NHCOO–R}_3\text{–OOCNH–R}_2\text{–)}_m\text{–NCO} \quad \text{[XV]}$$

The block lengths n and m can be varied by adjusting the stoichiometric ratio r of reactants and conversion in each prepolymer synthesis. In typical systems, the prepolymers have molecular weights in the range of 500–6000 Da. A variation of the two-prepolymer method involves the use of a coupling agent to join the prepolymers. For example, a diacyl chloride could be used to join together two different macrodiols or two different macrodiamines or a two different macrodiamines or a macrodiol with a macrodiamine.

The one-prepolymer method involves one of the above prepolymers with two 'small' reactants. The macrodiol is reacted with a diol and diisocyanate

$$\text{H–(–O–R–OOC–R}_1\text{–CO)}_n\text{OR–OH} + (m+1)\text{OCN–R}_2\text{–NCO} + m\text{HO–R}_3\text{–OH} \rightarrow \text{H–(O–R–OOC–R}_1\text{–CO)}_n\text{OR–OOCNH–(–R}_2\text{–NHCOO–R}_3\text{–OOCNH)}_m\text{–R}_2\text{–NCO} \quad \text{[XVI]}$$

The block lengths and the final polymer molecular weights are again determined by the details of the prepolymer synthesis and its subsequent polymerization. An often-used variation of the one-prepolymer method is to react the macrodiol with excess diisocyanate to form an isocyanate-terminated prepolymer. The latter is then chain-extended (i.e., increased in molecular weight) by reaction with a diol.

The one- and two-prepolymer methods can in principle yield exactly by the same final block copolymer. However, the dispersity of the polyurethane block length is usually narrower when the two-prepolymer method is used.[32,35]

1.121.4.2. Cross-Linking Reactions

Cross-linking is the predominant reaction upon irradiation of many polymers. It involves attachment of polymeric chains to each other. When each molecule is bonded at least once, then the whole sample becomes insoluble. It is accompanied by the formation of a gel and ultimately by the insolubilization of the specimen. Cross-linking has a beneficial effect on the mechanical properties of polymers.

In commercial practice, cross-linking reactions take place during the fabrication of articles made with thermosetting resins. The cross-linked network is stable against heat and does not flow or melt. Most linear polymers are thermoplastic. They soften and take on new shapes upon the application of heat and pressure.[5]

Cross-linking can be achieved by the action of electromagnetic radiation, heat, or catalysts and results in opening of unsaturated groups on chains and reaction of multifunctional (>2) groups. Control of cross-linking is critical for processing. The period after the gel point, when all the chains are bonded at least to one other chain is usually referred to as the curing period.

1.121.4.2.1. Effect of cross-linking on properties

The change in properties is determined by the extent of cross-linking. Lightly cross-linked polymers swell extensively in solvents in which the uncross-linked material dissolves, but covalently (irreversibly) cross-linked polymers cannot dissolve but only swell in the solvent of the uncross-linked form. Upon extensive cross-linking, the sample may even not swell appreciably in any solvent.

Cross-linking has a significant effect on viscosity; it becomes essentially infinite at the onset of gelation. The effect of chain branching and cross-linking on T_g are explained in terms of free volume. A high amount of branches increase the free volume and lower the T_g, whereas cross-linking lowers the free volume and raises the T_g.

The addition of cross-links leads to stiffer, stronger, tougher products, usually with enhanced tear and abrasion resistance. However, extensive cross-linking of a crystalline polymer leads to a loss of crystallinity, and this might decrease mechanical properties. When this occurs, the initial trend of properties may be toward either enhancement or deterioration, depending on the degree of crystallinity of the unmodified polymer and the method of formation and location (crystalline or amorphous regions) of the cross-links.[5]

1.121.4.2.2. Cross-linking of biological polymers

1.121.4.2.2.1. Cross-linking of proteins

Proteins are found to be chemically (permanent) or physically (reversibly) cross-linked. These cross-links can be intra or intermolecular. For example the triple helix of collagen is intermolecularly cross-linked whereas many reversible cross-links are observed in the secondary and tertiary structure of the proteins. Proteins are also cross-linked for various applications (biotechnological, biomedical, etc.).

Physical cross-linking methods include drying, heating, or exposure to γ or UV radiation. The primary advantage of physical methods is that they do not cause harm. However, the limitation of such methods is that obtaining the desired amount of cross-linking is difficult. In chemical cross-linking methods, cross-linkers are generally used to bond the functional groups of amino acids. In recent years, there has been an increase in interest in physical cross-linking methods. The main reason is that use of cross-linking agents is avoided because most cause some toxic effects. However, the degree of cross-linking is considerably lower and cross-links are weaker than obtained by chemical methods.

Collagen is the major protein component of bone, cartilage, skin, and connective tissue and also the major constituent of all extracellular matrices in animals. Collagen can be chemically cross-linked by various compounds including glutaraldeyde, carbodiimide, genipin, and transglutaminase. 1-Ethyl-3-diaminopropyl carbodiimide (EDC) and *N*-hydroxysuccinimide (NHS) catalyze covalent bindings between carboxylic acid and amino groups; thus, cross-linking between collagen structures is possible (**Figure 12**). Furthermore, other extracellular matrix components containing carboxyl groups, such as glycosaminoglycans, can also be cross-linked with this approach.[36,37]

1.121.4.2.2.2. Cross-linking of polysaccharides

Chemical and physical methods are used for cross-linking of polysaccharides. Physical cross-linking is achieved by physical interaction between different polymer chains.

In physical cross-linking, polysaccharides form cross-linked networks with the counterions on the surface. High counterion concentration requires long exposure times to achieve complete cross-linking of the polysaccharides. Chemical cross-linking of polysaccharides leads to products with good mechanical stability. During cross-linking, counterions diffuse into the polymer and reacts with polysaccharides forming intermolecular or intramolecular linkages. Factors which affect chemical cross-linking are the concentration of the cross-linking agents and the cross-linking duration. High concentration of cross-linking agent induces rapid cross-linking. Like physical cross-linking, high counterion concentration require longer exposure times to achieve complete cross-linking of the polysaccharides.

Polysaccharides can be chemically cross-linked with either addition or condensation cross-linking mechanism. For addition polymerization, the network properties can be easily tailored by the concentration of the dissolved polysaccharide and the amount of cross-linking agent. These reactions are preferably carried out in organic solvents because water can also react with the cross-linking agent.

Polysaccharides can be cross-linked through condensation using 1,6-hexamethylene diisocyanate or 1,6-hexanedibromide or other reagents. Condensation cross-linking can also be done by carbodiimide which induces cross-links between carboxylic acid and amine groups without itself being incorporated. The commonly used carbodiimide is a water-soluble

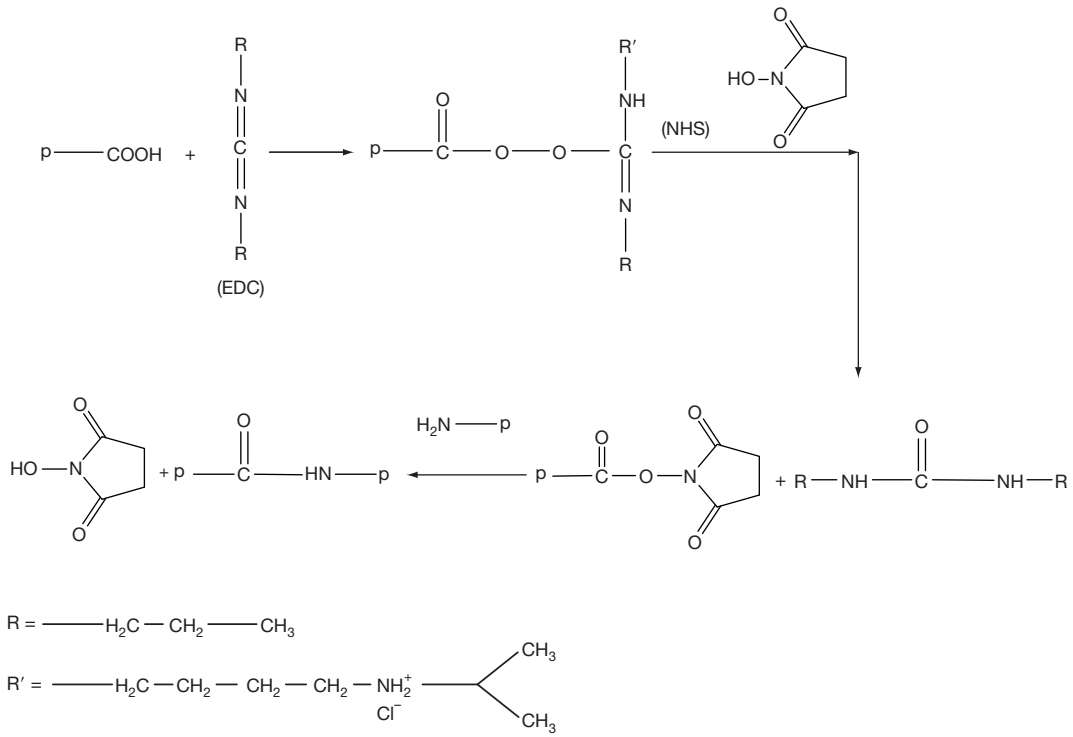


Figure 12 Mechanism of protein cross-linking using carbodiimide (EDC).

carbodiimide called 1-ethyl-3-(3-dimethyl aminopropyl) carbodiimide (EDC). EDC cross-linking involves the activation of the carboxylic acid groups of aspartic acid (Asp) or glutamic acid (Glu) residues by EDC to give *O*-acylisourea groups. Besides EDC, another reagent, *N*-hydroxysuccinimide (NHS) is used in the reaction for the purpose of suppressing side reactions of *O*-acylisourea groups such as hydrolysis and the *N*-acyl shift. NHS can convert the *O*-acylisourea group into a NHS activated carboxylic acid group, which is very reactive toward amine groups of hydroxy lysine, yielding a so called zero length cross-link. In this cross-linking process, neither EDC nor NHS is incorporated in the matrix.

1.121.4.2.3. Cross-linking agents

Cross-linkers (CL) are either homo- or hetero-bifunctional reagents permitting the establishment of inter- as well as intramolecular cross-linkages. Homo-bifunctional reagents, specifically reacting with primary amine groups (i.e., ε-amino groups of lysine residues) have been used extensively as they are soluble in aqueous solvents and can form stable inter- and intrasubunit covalent bonds.

Genipin is a naturally occurring cross-linking agent that has significantly low toxicity. It can form stable cross-linked products with resistance against enzymatic degradation that is comparable to that of glutaraldehyde-fixed tissue. Genipin reacts in a similar manner to glutaraldehyde, but can only bind to one other genipin molecule.

Even though the definite cross-linking mechanism of genipin is not known some mechanisms are proposed as presented in Figure 13(a) and 13(b). In scheme (a) NH_2 group of the protein binds to the ester group (outside the ring structure) which then reorganizes by releasing a methanol group and achieves the binding. Then two protein-bound genipins interact to create the cross-linkage. In scheme (b), the reaction begins with an initial nucleophilic attack of a primary amine group of the protein on the C3 carbon atom of genipin to form an intermediate aldehyde group. Opening of the dihydropyran ring is then followed by an attack on the resulting aldehyde group by the secondary amine formed in the first step of the reaction.

The predominant chemical agent that has been investigated for the treatment of collageneous tissues is glutaraldehyde, which yields a high degree of cross-linking when compared to formaldehyde, epoxy compounds, cyanamide, and the acylazide method. Glutaraldehyde, a popular reagent, has been used in a variety of applications where maintenance of structural rigidity of protein is important. It covalently binds to amino groups, but can also bind to other glutaraldehyde molecules.

The glutaraldehyde cross-linking reactions have been extensively studied (Figure 14). In general, it is believed that aldehydes react with the amine groups of proteins, yielding a Schiff base. However, the exact cross-linking structure is still not clear because a mixture of free aldehyde and mono- and dehydrated glutaraldehyde and monomeric and polymeric hemiacetals is always present in a glutaraldehyde aqueous solution. However, depolymerization of polymeric glutaraldehyde cross-links has been reported. This depolymerization leads to the release monomeric glutaraldehyde and subsequent toxicity.

Calcium ions may also be used as a cross-linker for alginates which are water soluble polymers. When a sodium alginate

solution is dipped into a solution containing calcium ions, each calcium ion replaces two sodium ions. The alginate molecule contains plenty of hydroxyl groups that can be coordinated to cations (Figure 15).[3,11]

1.121.5. Conclusion

In brief, polymers are very complex molecules owing to the large variety of initiators, catalysts, monomers, and mechanisms

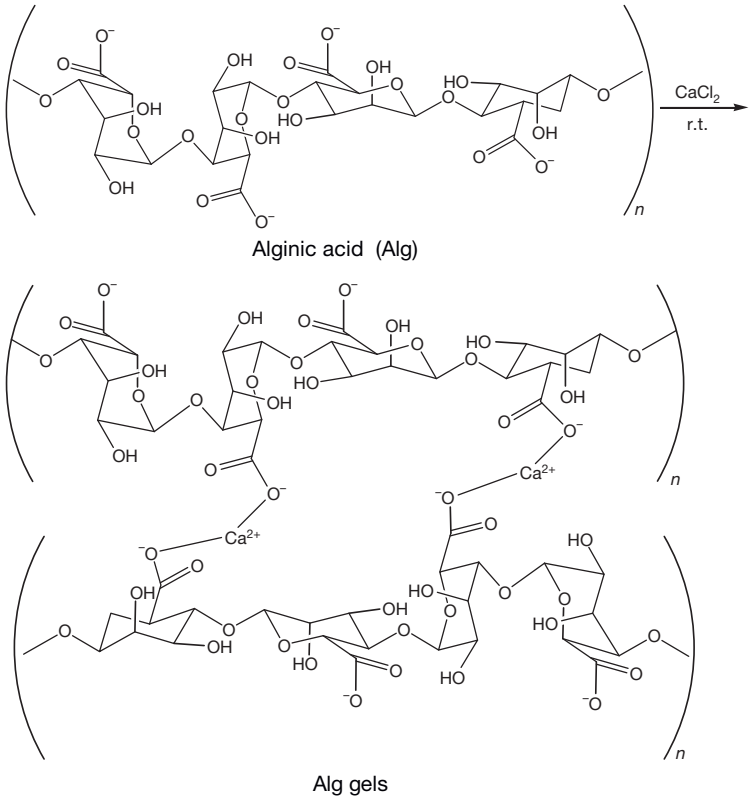

Figure 15 Cross-linking of alginic acid with calcium ions.

available. This enables us to produce very large numbers of different polymers with very diverse properties and this is precisely why polymers play a very important role as a source for materials needed to satisfy human needs. They can be made flame retardant, conductive, bio- or hemocompatible, inert or reactive, stable or degradable at a controlled rate, very tough or soft as gelly. The biomedical field benefits from this diversity immensely since the physical and chemical properties of polymers resemble that of the tissues of the human body more than any other material type such as metals or ceramics. With the developments in biotechnology, nanotechnology, and nanomedicine polymers will keep getting better and more useful for human well-being.

Glossary

Acetabulum The cup-shaped socket in the hip that receives the head of the thigh bone (femur).
Amorphous Unorganized or random arrangement of molecules (no long-range order).
Biocompatibility The ability of a material to function properly in the body without eliciting any undesirable local or systemic effects in the patient or beneficiary of the medical device/implant.
Biomimetic The ability to replicate something found in nature or the body.
Femoral Relating to the thigh bone or femur.
Glass transition temperature The temperature at which the amorphous phase of a polymer begins to show large segmental motion. It often represents the transition from glassy to rubbery behavior.
Mer The basic molecular unit that comprises a collection of atoms. This unit is continuously repeated in macromolecular structures.
Neovascularization Formation of new blood vessels.
Polymer Macromolecules that contain thousands of repeating mers bonded to form a long chain.
Stent A load-bearing tube, usually in mesh form, that restores blood flow to an occluded artery or other blood conduit in the body.
Young's modulus The material property that linearly relates stress and strain up until the point of permanent (plastic) deformation. The modulus is found by taking the slope of the stress versus strain plot in the linear elastic regime.

1.122.1. Historical Overview

Polymers have been utilized in medical implants for nearly 80 years. Polymethylmethacrylate (PMMA) was first used in the body in the 1930s and was initially chosen for its biocompatibility, stiffness, and optical properties. Today, PMMA is widely used as a medical implant in applications such as bone cement for dental and orthopedic applications.[1] For the next 20 years, polymers expanded their use in the body with a diverse range of applications including blood pumps, heart–lung machines, vascular grafts, angioplasty catheters, dental and orthopedic implants, and mammary prosthetics.[2] Materials such as rubbers, silicones, polyurethanes (PU), and cyanoacrylate adhesives were employed during this time; however, there were no stringent FDA regulations in place, and many of the earlier plastic components suffered from *in vivo* degradation and stress cracking. In the 1960s and 1970s, developments in heart valve technology, orthopedics, sutures, dental materials, and soft-tissue reconstruction prevailed. Early heart valve cages made of silicones fared poorly due to lipid adsorption; urethane foam surfaces and silicone mammary prosthetics were suspected of causing chronic inflammatory response; and Teflon utilized in the bearing surfaces of both dental and orthopedic implants was complicated by high wear rates and premature device failure.[3,4] By 1976, medical devices were subject to premarket approval by the FDA. Over the decades that followed, certain materials such as the original silicone breast implants and Teflon materials were removed from the market, while other polymers became the mainstay of certain device applications. During the past 20 years, attention has focused on the improvement of medical polymers known to fare well in the body.

Polymers are now widely used in biomaterial applications, with diverse applications in vascular grafts, balloon catheters, stent coatings, orthopedic bearings, screws, suture anchors,

bone cement, sutures, and soft-tissue reconstruction. One primary advantage of polymeric materials is that their macromolecular structure provides many biomimetic properties that can be utilized in the body. The elastic modulus and strength of a polymer can be tailored through chemistry and processing to provide values that are bounded by those of biological materials. A comparison of elastic modulus values for metals, ceramics, and polymers, as well as hard and soft tissues is given in Figure 1. The modulus can be extended to lower values by reducing the molecular weight or expanding the polymer so that it is porous. This controlled variability of polymer properties enables these medical materials to be utilized in a way that optimizes compliance match with structural tissues, ranging from blood vessels to bone. This is a great advantage of polymers over metals and ceramics, which are often much stiffer than adjacent tissues. A compliance mismatch can result in clinical complications such as stress shielding in bone; in total hip replacements, for example, if a femoral stem is too stiff, then the stress is not sufficiently carried by the neighboring bone and the tissue resorbs around the implant, resulting in loosening of the device.

One of the most important structural polymers used in the body is ultra-high-molecular-weight polyethylene (UHMWPE). This material has been employed in the body since the early 1960s and remains the gold standard as a bearing material in total joint replacements.[5] High-density polyethylene (HDPE) is used in tendon reconstruction and catheter tubes. Ligaments can be reconstructed with braided forms of expanded polytetrafluoroethylene (e-PTFE) that offer both strength and stability.[6–8] This same polymer, e-PTFE, is most successful not only in vascular applications,[9,10] where its porous structure offers tissue integration and opportunity for neovascularization (growth of new blood vessels), but also in facial reconstruction, where the open pore structure facilitates tissue ingrowth and fixation of the implant.[11–13] Nylon and polyester polymers have good tensile strength and are often employed in applications such as sutures[14] and in vascular devices such as balloon catheters.[15] PUs have shown excellent promise as bearing materials and are being utilized in orthopedic applications.[16] Bioresorbable polymers are used where structural properties are temporarily needed and where tissue integration and resorption are required in a medical device; degradable polymers are used in applications such as resorbable sutures,[17] suture anchors,[18] bone screws,[19] and drug delivery devices.[20] Polymeric coatings can also be used to obtain desired surface properties, such as the use of a fluorinated surface treatment for improved lubricity[21] of catheters or for improved biocompatibility of a device.[22] A summary of the primary medical polymers used today in orthopedics, dentistry, and cardiovascular and soft-tissue implants is given in Table 1.

1.122.2. Classifications of Medical Polymers and Their Applications

Medical polymers are used in a wide range of medical devices including restorative dentistry, soft-tissue reconstruction, orthopedic implants, and vascular structures. The most commonly used inert medical polymers include polyethylenes (low-density polyethylene (LDPE), HDPE, and UHMWPE), PMMA, fluoropolymers such as e-PTFE, polypropylenes (PP), polyesters, polyamides (nylons), PU, siloxanes (silicone), and polyetheretherketones (PEEK). Nondegradable polymers are used where long-term structural stability and biocompatibility are needed and are utilized in applications such as bearing surfaces in hip, knee, or shoulder implants; vascular grafts or

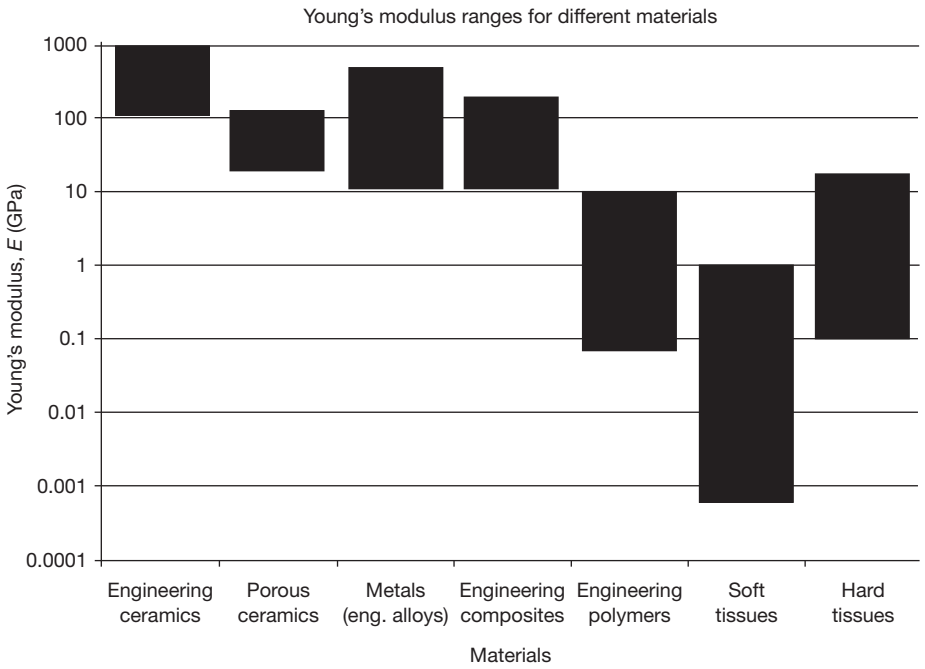

Figure 1 Elastic modulus values are compared for engineering materials and tissues. Polymers offer the greatest overlap with both hard and soft tissues.

Table 1 Examples of polymers used in load-bearing medical devices

Application	*Devices*	*Polymers*	*Performance requirements*
Vascular	Balloons/catheters	Nylon, polyester/LDPE, LLDPE, HDPE	Rupture, flexibility, friction
			Compliance, tissue integration
	Grafts	E-PTFE, polyester	Compliance, tissue integration
Soft tissues	Suture anchors	PEEK	Resilience, strength
	Sutures	Polyester, nylon	Tensile strength
	Breast implants	Silicone	Burst strength
Dental	Crown/filling	Acrylic resins	Wear, fatigue, thermal expansion
	Cements	PMMA	Adhesive strength, interface fracture
Orthopedics	Joint replacements	UHMWPE	Fracture, wear, fatigue, creep
	Spinal implants	Polyurethanes	Fatigue, creep, fracture, wear
	Tendons/ligaments	HDPE, e-PTFE	Strength, wear, creep
	Bone cement	PMMA/PS	Interface fracture
	Spinal fusion	PEEK	Fracture, wear, fatigue

Table 2 Summary of commonly used medical polymers with their structural properties

Polymer	*Linkage*	*Morphology*	T_g *(C)*	T_m *(C)*
Polyethylene (PE)	$-(C_2H_4)-$	Semicrystalline	−80	125–135

Table 3 Range of properties in polyethylene polymers

Polyethylene	*Molecular weight (g mol^{-1})*	*Crystallinity (%)*	*Density (g cm^{-3})*	*Applications*
LDPE	30 000–50 000	30–40	0.910–0.925	Medical packaging, catheters
MDPE	60 000–100 000	50–60	0.926–0.940	Facial implants
HDPE	200 000–500 000	70–90	0.941–0.980	Tendons, catheters
UHMWPE	4–6 million	45–60	0.925–0.935	Orthopedic bearings

catheters; fillings and resins for teeth; nose, chin, and cheek implants; and ocular implants. Polymers that are porous by design can facilitate tissue ingrowth and enable long-term stability. A summary of commonly used medical polymers along with their structural properties is provided in Table 2.

1.122.2.1. Polyethylene

Polyethylene polymers are commonly employed as biomaterials and, depending on the specific structure, they can be employed as catheter tubes, facial implants, artificial tendons, or bearing components in total joint replacements. Polyethylene is made through an addition polymerization reaction that utilizes an ethylene monomer ($-C_2H_4-$) repeated along the chain. Process time, temperature, and pressure conditions enable a broad range in degree of branching, molecular weight, crystallinity, entanglements, and cross-linking to be obtained in polyethylene polymers (Table 3). The molecular weight of polyethylene can vary from 30 000 to 6 000 000 g mol^{-1}, density can range from 0.91 to 0.98 g cm^{-3}, and crystallinity can span 30–90%. The melting temperature is typically in the range of 120–147 °C and the glass transition temperature is on the order of −80 °C. Additionally, the polymer can be cross-linked through either chemical or energetic means. This provides an enormous range of structural and mechanical properties within the category of polyethylene. For this reason, polyethylene is generally subcategorized as LDPE, medium-density polyethylene (MDPE), HDPE, or UHMWPE. Thus, it is imperative that the details of the processing, structure, and mechanical properties are well characterized when using polyethylene in medical implants.

The branched form of polyethylene (LDPE) minimizes the packing efficiency of chains, resulting in lower crystallinity and density. The linear form of polyethylene (HDPE) facilitates efficient packing of chains and concomitantly has high crystallinity (70–90%) and density (0.96–0.98 g cm^{-3}). If the polymerization is allowed to continue, the linear chains get very long and a UHMWPE is achieved (4–6 million g mol^{-1}). The very high molecular weight enhances the propensity for entanglement, limits the ability to crystallize (50%), and

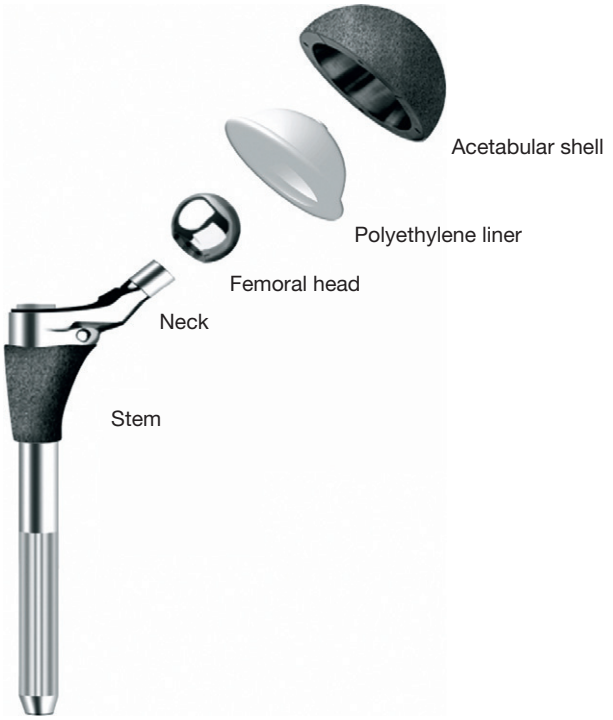

Figure 2 A typical total hip replacement utilizing a UHMWPE acetabular cup that articulates against a Co–Cr femoral head.

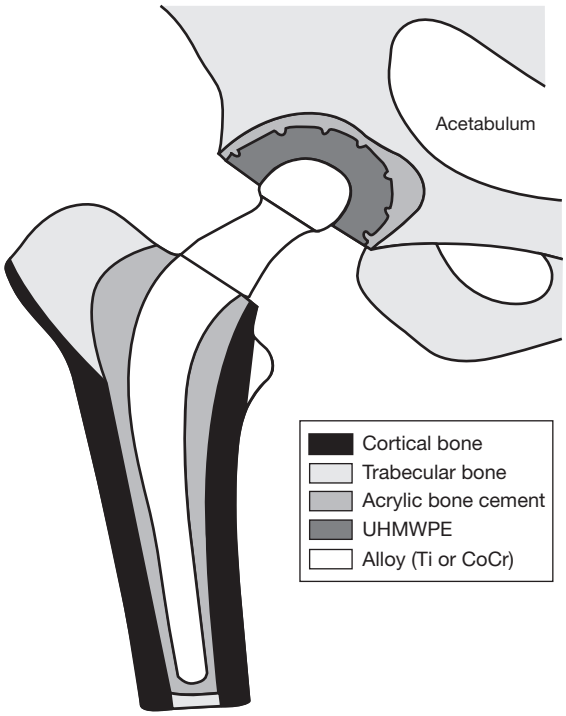

Figure 3 Illustration depicting the use of acrylic bone cement as a bonding agent between the implant and adjacent bone.

results in lower density (0.935 g cm^{-3}). The unique properties of UHMWPE provide it with exceptional energetic toughness, low coefficient of friction, and good wear resistance. UHMWPE can also be cross-linked to further minimize wear in this polymer.[23] UHMWPE is a widely studied medical polymer, especially in the domain of orthopedic bearings, and decades of research have been devoted to the characterization of microstructure, processing, sterilization, oxidation, mechanical behavior, fatigue behavior, and wear behavior of this material.[5,24] UHMWPE remains the gold standard as a bearing material in total joint replacements for hips, knees, shoulders, and elbows. A typical total hip replacement utilizing an UHMWPE acetabular cup that articulates against a Co–Cr femoral head is shown in Figure 2. Such implant designs can have survivorship rates of up to 90% after two decades of *in vivo* service.

1.122.2.2. Acrylates

Acrylate polymers are widely used in dentistry and in bone cements. PMMA polymers are also made through an addition polymerization reaction; the chemical formulation of PMMA is –($C_5O_2H_8$)–. The bulky side groups on this backbone chain limit its ability to crystallize and to have high ductility. In general, this PMMA is amorphous, with a relatively high elastic modulus (3–4 GPa) and glass transition temperature (118 °C). The molecular weight can vary widely (200 000–700 000 g mol^{-1}), depending on processing conditions. Without any additives, this material is known to have excellent transparency. For this reason, it can be used in ocular implants. With additive or copolymerization, this material is commonly used as a grouting agent to secure implants to bone, and it may be best known for its application as bone cement, used in orthopedics and dentistry. There is an abundance of literature devoted to the structure and properties of PMMA, and its use as a bone cement.[1] The greatest challenge for PMMA as a bone cement is that it is mixed at the time of surgery and is prone to porosity and void entrapment that can affect its mechanical performance *in vivo*.[25] One of its primary benefits is that, when it is first mixed, the bone cement is doughy for several minutes and is able to penetrate the pores and open spaces of the adjacent bone tissue. In fact, more cement penetration is achieved in porous bone; this bone cement serves as an excellent fixation medium for patients with osteoporotic bone.[26] The bone cement sets within about 10 min, and, from that point onward, it provides a secure interface and load transfer mechanism between the implant and the bone tissue. Figure 3 shows the use of bone cement as a bonding interface in a total hip replacement.

1.122.2.3. Fluorocarbon Polymers

Fluorocarbon polymers are addition-reacted polymers that are fully or partially fluorinated along the carbon backbone. Polytetrafluoroethylene, commonly known as Teflon®, is a fully fluorinated form with a chemical formulation –(CF_2–CF_2)–. These polyolefins (flexible polymer chains) possess exceptional properties such as chemical inertness, mechanical integrity, and lubricity that are due to the highly electronegative fluorine sheath that protects the carbon backbone from chemical attack and results in a hydrophobic polymer with low surface energy. Most fluorocarbon polymers are semicrystalline

and have a low glass transition temperature (−70 °C) that enables exceptional resilience. The primary fluoropolymer used in biomedical applications is based on e-PTFE. The success of this biomaterial has resulted from its microporous structure, which allows biointegration for fixation and provides structural integrity (Figure 4). The first successful medical applications of e-PTFE were initiated with vascular grafts and then evolved to soft-tissue reconstruction.[27] The mechanical properties of e-PTFE depend strongly on the porosity and microstructure of the polymer as well as strain rate.[11] However, the predominant success of e-PTFE as a biomaterial is due to its microporous structure, which allows biointegration for fixation and long-term stability *in vivo*.[12]

1.122.2.4. Polypropylene

PP polymers are also generated through addition polymerization and have structural properties similar to polyethylene due to their close chemical formulation, –(CH_2CHCH_3)–. This polymer has a methyl side group that can affect the crystallinity of the polymer, depending on its arrangement on the backbone. Typically, the molecular weight spans 200 000–700 000 g mol^{-1} and the density spans 0.85–0.98 g cm^{-3}. Its melting temperature spans 125–167 °C and its glass transition temperature is on the order of −10 °C. This material has exceptional fatigue life in flexion and is commonly used in finger joint prostheses, grafts, and nondegradable sutures (Figure 5).

1.122.2.5. Polyester

Polyester polymers are generated through condensation reactions. A polyester has a characteristic ester linkage, –(RC=OOR′)–, in its backbone chain and includes materials such as polyethylene terephthalate (PET) and Dacron® fibers. Polyesters typically have a high melting temperature (250–265 °C) and high crystallinity. PET is known to be hydrophobic and nonthrombogenic and is commonly employed as a vascular graft or as a suture material. The most widely known polyester is marketed under the trade name Dacron® and is utilized in fabric form as a graft material.

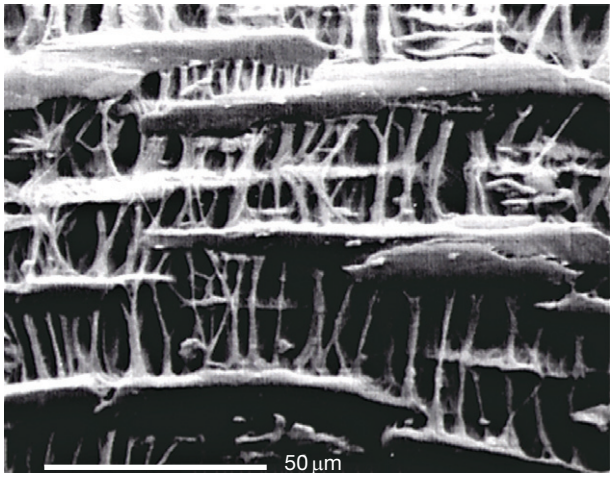

Figure 4 Microstructure of expanded polytetrafluoroethylene used in vascular grafts.

1.122.2.6. Polyamide

Another group of condensation polymers are the polyamides or nylons. These materials have a common amide linkage, –(RCONH–R′)–. Polyamides have a broad range of properties, depending on the specific chemistry and processing, and may be amorphous or semicrystalline. The melting temperature spans 190–350 °C, and the glass transition temperature is on the order of 45 °C. These polymers are susceptible to swelling in aqueous solutions but are often employed in short-term applications such as catheters and catheter balloons in angioplasty procedures or stent deployment. Nylons are a classification of polymer fibers within polyamides, and the most commonly used forms are nylon 6 and nylon 6,6. The general chemical form for the latter is –$(NHCO(CH_2)_4CONH(CH_2)_6)$–. Nylon is commonly used as the outer layer of balloon angioplasty catheters and also as the balloon used for deployment of a stent or the expansion of an occluded artery. Nylons offer strength and stiffness to balloon angioplasty systems; an example of a nylon balloon used in the deployment of a stent is illustrated in Figure 6.

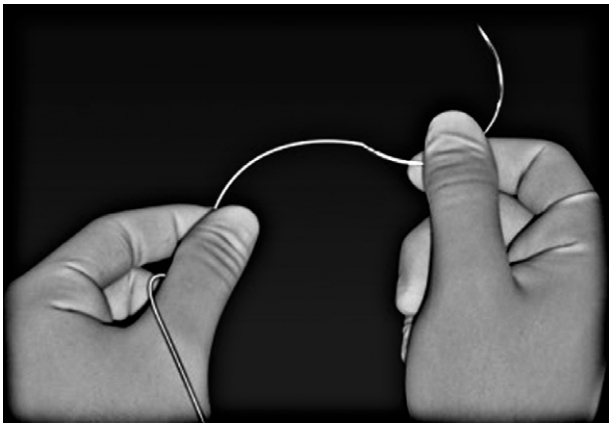

Figure 5 Polypropylene has good tensile strength and is commonly employed as a nondegradable suture.

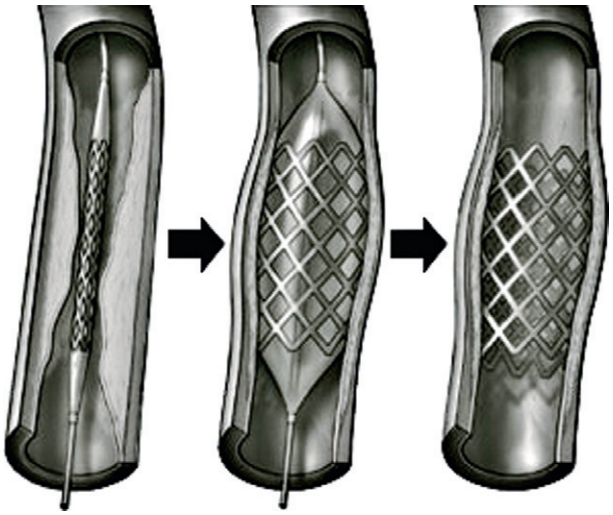

Figure 6 Schematic of nylon balloon that is expanded to deploy a stent in an artery.

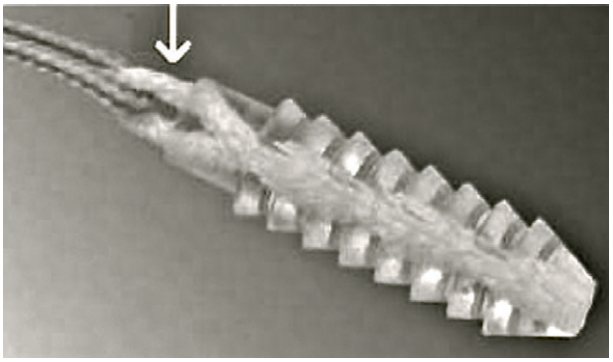

Figure 7 Illustration of a suture anchor and the anchoring point (arrow) used to securely fasten a suture in soft-tissue repair.

Figure 8 Early silicone breast implants were susceptible to rupture and leaking.

1.122.2.7. Polyurethane

PUs are generated through a step-growth polymerization that combines a monomer comprising at least two isocyanate functional groups with another mer containing at least two hydroxyl (alcohol) groups. The urethane links that build the polymer chains have the chemical formulation (R_1–O–C=ONR_2R_3). PUs can be processed to have hard and soft segments of varying glass transition temperatures and can span a full range of structural properties, ranging from elastomeric (rubber-like) to glassy. Thus, all its properties are highly dependent upon its backbone chemistry. As a biomaterial, PUs can be used as bearing materials in orthopedics or spinal implants, and, in elastomeric form, they can be used for soft-tissue reconstruction.

1.122.2.8. Polyetheretherketone

PEEK is a thermoplastic that offers exceptional mechanical properties. The backbone structure of PEEK is $(–C_6H_4–O–C_6H_4–O–C_6H_4–CO–)_n$, and this structure provides strength and resistance to deformation. PEEK is used in spinal cages and is also used in suture anchors in soft-tissue repair. Suture anchors must maintain an anchoring point to fasten a suture securely and are often employed in shoulder arthroplasty (Figure 7).

1.122.2.9. Silicone

Silicones are a broad class of polymers also known as siloxanes. These polymers comprise –($OSiR_2$)– on their backbones and are known best for their elastomeric–viscoelastic properties. A well-known subclassification of silicone is

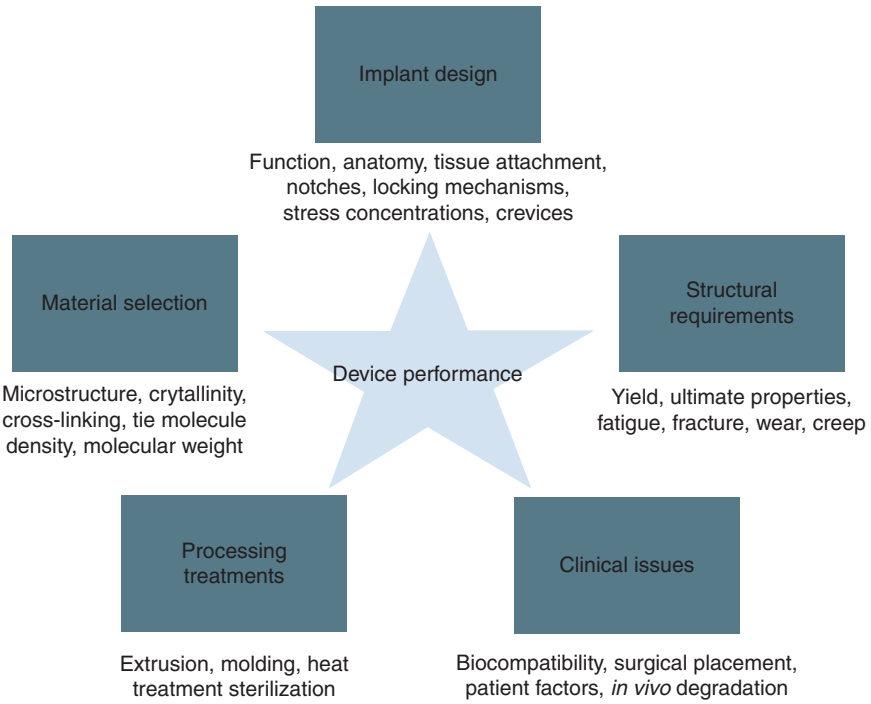

Figure 9 Schematic showing the factors that contribute to device performance.

polydimethylsiloxane (PDMS), which was once used as the fluid filler in silicone breast implants, but this technology was terminated due to concern about leaking (Figure 8); modern breast implants utilize a cross-linked form of silicone that is a soft solid and elastomeric in nature.

1.122.3. Designing Structural Implants with Polymers

Structural implants made with medical polymers are susceptible to failures *in vivo*. The functional demands placed on a polymer implant may result in damage that is sufficient to cause clinical failure of the implant. The performance of a medical device is quite complicated as there are several contributing and related factors, including the implant design, material selection, the structural requirements of the device, the processing or manufacturing modality of the implant, and clinical issues. Figure 9 schematically illustrates the contributing factors that affect device performance.

1.122.4. Summary

Polymeric materials provide a broad range of structural properties and offer numerous benefits as biomaterials. Polymers can be tailored to have high toughness, resilience, wear resistance, compliance match to tissue, and controlled resorption in the body. Medical polymers are commonly employed as bearing materials in total joint replacements, artificial tendons and ligaments, vascular grafts, catheter balloons, bone and device fixation, and soft-tissue repair.

Glossary

Critical aggregation temperature Refers to a change in hydrodynamic radius of a particle when subjected to temperature variations.
Drug-loading capacity (DLC) Weight of drug loaded in carrier/weight of drug-loaded carriers × 100%.
Drug-loading efficiency (DLE) Weight of drug loaded in carrier/weight of drug used for loading × 100%.
Drug-loading index A parameter used to quantify the overall effectiveness of drug carrier (DLC usually varies inversely with DLE). Calculated using the formula: DLC × DLE.
Glass transition Is the reversible transition (of amorphous materials) from a hard and relatively brittle state into a molten or rubber-like state.
IC_{50} Half maximal inhibitory concentration, usually in microgram per milliliter, a quantitative measure that indicates how much of a particular substance is needed to inhibit proliferation of cells by 50% relative to controls.
Length scale A term used to describe the physical size of biomaterials (length, width, or depth).
Macroscale Describes biomaterials with length scales above 1 mm.
Microscale Describes biomaterials with length scales between 1 μm to 1 mm.
Nanoscale Describes biomaterials with length scales below 1 μm.
Polymer backbone Refers to the longest continuous molecular sequence of a polymer molecule.

PVA Poly(vinyl alcohol)

1.123.1. Introduction

Degradable polymers find their biomedical applications mostly as devices that provide temporary structure support or deliver therapeutics.[1] They have also been intensively studied and developed for environmental applications as recyclable materials, the importance of which will undoubtedly grow with time. The focus of this review will, however, be on medical applications of biodegradable polymers. Biodegradable sutures composed of polyesters represent early examples of commercial success of biodegradable polymers in the 1960s. Advance of drug delivery in the 1970s saw the appeal of using biodegradable polymeric carriers to provide a local and sustained release of drugs. Controlled drug delivery can offer tremendous benefits including maximization of drug efficacy, minimization of side effects, and improvement of patient compliance.[2] The idea of a carrier breaking down into harmless products to be cleared from the body after release of the embedded drug has captured the imagination of the scientists and public alike. This stimulated the remarkable growth of biodegradable polymer research and development, sustained by emergence of the fields of gene therapy and tissue engineering two decades later. As an alternative to viral vectors, biodegradable and cationic polymers can condense nucleic acids into nanoparticles for intracellular delivery. Although highly inefficient compared to viral delivery, nonviral gene transfer compensates with potential long-term safety and less demanding manufacturing hurdles. Biodegradable gene carriers can play a significant role in advancing nonviral gene transfer by satisfying the conflicting requirements of binding the nucleic acid tightly in the extracellular space and releasing it intracellularly.[3] As scaffolding material to support tissue growth *in vitro* and *in vivo*, biodegradable polymers offer the advantage of gradual disappearance to free up space for cellular infiltration and tissue development. Many other medical devices, such as a stent for percutaneous transluminal angioplasty or bone cement for spinal fusion, can also benefit from a biodegradable polymeric design.

A vast array of biodegradable polymers, ranging from synthetic to natural and to hybrid, have been studied and developed. It would be impossible to provide a comprehensive review on these different types of polymers. Readers are referred to other reviews on this topic.[4–17] This review will instead focus on the poly(lactide-*co*-glycolide) (PLGA) copolymers and poly (phosphoester)s (PPEs). Enjoying the favorable status of the U.S. Food and Drug Administration (FDA) approval, PLGAs are the obvious choice for the development of many biodegradable medical devices. Since numerous reviews have already covered this class of polymers, we will concentrate on its degradation behavior, its influence of drug release kinetics, and its dependence on the length scale. As the

device shrinks from the macro- to micro- and then to the nanoscale, the structure–property relationship of PLGAs may differ, which may impact their applications. After a brief review of the PLGAs, we will discuss PPEs in comparison. PPEs were developed with the rationale of versatility and potential biocompatibility. Due to the pentavalency of phosphorous, the physicochemical properties of PPEs can be independently varied with respect to their backbone or side-chain structure. This affords a wealth of chemical structures that can be applied to drug and gene delivery and tissue engineering. We will again concentrate on the structure–property relationship of these polymers and their performance across different length scales. It is our hope that this focused review can offer a glimpse of the working principles and vast potential of biodegradable polymers in medicine.

1.123.2. Overview of PLGA Copolymers

Approved by the FDA for some human uses since the 1970s, PLGA polymers are being used in a growing array of applications. This chapter explores the degradation behavior of PLGA in applications in length scales from nano to macro. PLGA is a synthetic polymer made from monomers of lactide and glycolide. Poly(lactide) (PLA), poly(glycolide) (PGA), and their copolymer PLGA are aliphatic polyesters. PLGA is synthesized by ring-opening reactions of glycolic and lactic acid and linked linearly through ester bonds (**Figure 1**).[18] Polymers made of only L-lactide are crystalline, but generally both the D- and L-stereoisomers of lactide are used so that the polymer is more amorphous. To change the properties of the polymer, the molar ratio of lactide to glycolide and the molecular weight of the polymer can be varied; the molar ratio is the most important parameter influencing degradation rate.[19,20]

The polymer degrades by hydrolysis of the ester bonds. PLGA causes low levels of toxicity and immunogenicity when implanted in the body, which is why it is considered biocompatible. The FDA has approved the human use of PLGA for several applications, which makes it an attractive choice for future biodegradable polymer uses. This chapter focuses on the biodegradation of PLGA and highlights some of its applications from each length scale: nano, micro, and macro.

1.123.2.1. PLGA History and Uses

PGA was used in the first totally biodegradable sutures developed in the 1960s and marketed in the 1970s under the name Dexon. However, the tension in the sutures decreased by half 2 weeks post implantation because of PGA's hydrophobic nature and relatively fast degradation.[21] To lengthen the degradation time of these sutures, PLA/PGA copolymers were developed. The sutures, which had a lactide-to-glycolide ratio of 10:90, were marketed as Vicryl and Polyglactin 910.[21,22] The sutures had good mechanical properties and biocompatibility as well as predictable degradation rates, so the applications of PLA/PGA copolymers expanded to tissue engineering and drug delivery.[23]

Devices and therapies made with PLGA have garnered FDA approval over the last several decades, making the route to FDA approval transverse to attain by other proposed PLGA therapies. Some of the applications PLGA devices have been marketed for are sutures, bone fixatives, suturing reinforcements,

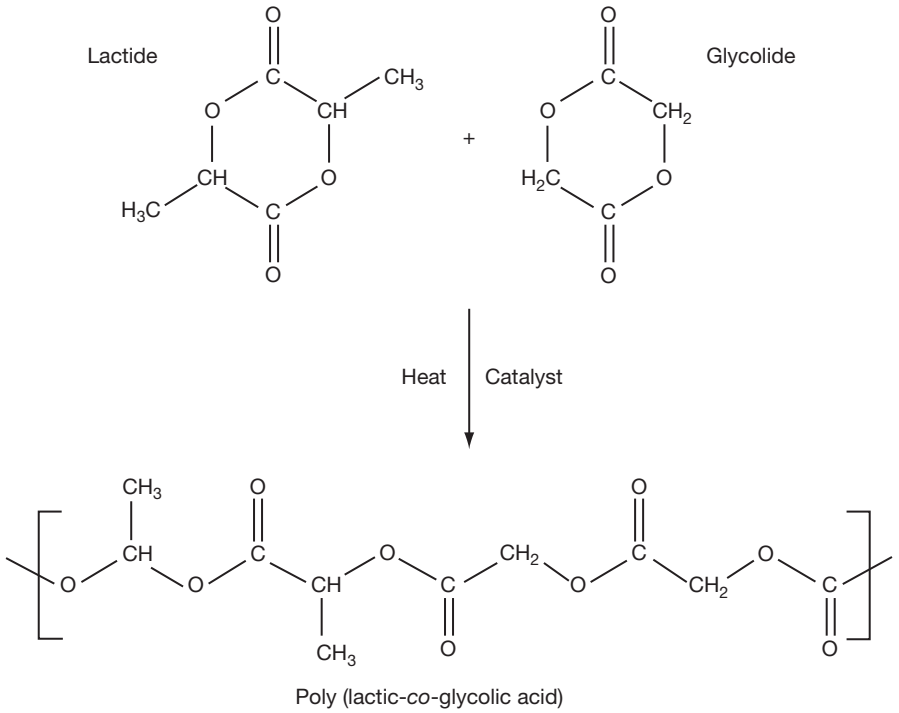

Figure 1 The basic structures of lactide, glycolide, and PLGA. Reproduced from Uchegbu, I. F.; Schatzlein, A. G. *Polymers in Drug Delivery*; CRC Press: Boca Raton, FL, 2006.

artificial skin, dental materials, bone regeneration, artificial blood vessels, as well as protein, nucleic acid, and small molecule delivery.[21] PLGA therapies of various types have been so successful that PLGA is often used as a standard for comparison with other polymers, both in efficacy and biocompatibility.

1.123.2.2. Common Manufacturing Techniques

One of the most common ways to generate PLGA micro- or nanoparticles is by the solvent evaporation method, either by a single or double emulsion. With a single emulsion (O/W), the polymer is dissolved in a volatile organic solvent (the oil phase), which is then dispersed into a large volume of aqueous solvent (the water phase) so that small droplets are formed. An emulsifier such as poly(vinyl alcohol) (PVA) is typically used in the water phase. Dispersion is generally accomplished by stirring, homogenization, or sonication. The mixture is placed under reduced pressure or is vigorously stirred at atmospheric pressure to evaporate the organic solvent. Another method of removing the oil phase is by extraction, where the emulsion is placed in a larger volume of water into which the organic solvent diffuses. The particles that remain are then washed, collected, and dried. Lipophilic drugs can be loaded into the particles by dissolving them with the polymer in the organic solvent (**Figure 2**).[23]

A double emulsion (W/O/W) is appropriate for loading micro- or nanoparticles with water-soluble drugs or genes. An aqueous solution of drug, possibly with a stabilizer such as gelatin, is dispersed into an organic phase with PLGA (W/O). This solution is added into a larger volume of the second aqueous phase with stirring. The solvent evaporation or solvent extraction method is employed, leaving PLGA particles encapsulating drugs.[23]

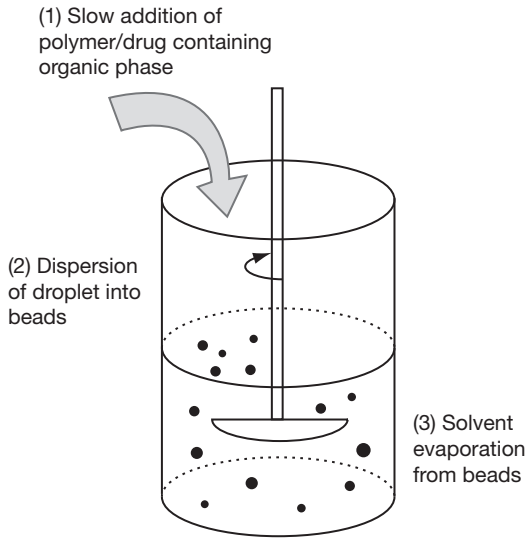

Figure 2 Oil-in-water solvent evaporation steps. The organic phase is dispersed in the aqueous phase, forming droplets. The solvent is evaporated from the organic phase under stirring or low pressure, leaving polymer beads, which are then collected, washed, and dried. Reproduced from Freiberg, S.; Zhu, X. X. *Int. J. Pharm.* **2004**, *282*, 1–18, with permission from Elsevier.

1.123.3. Parameters Affecting Degradation Rate of PLGA

The mechanism of degradation of PLGA is nearly always by simple hydrolysis of the ester bonds in the chain backbone. The degradation process occurs by random scission wherever water is able to penetrate into the polymer structure. The degradation rate of the PLGA structure depends on the monomer ratio, the molecular weight of the polymer, the crystallinity, the glass transition temperature, the size of the device, and environmental factors such as temperature and pH, among others.

1.123.3.1. Copolymer Ratio

The copolymer ratio (lactide-to-glycolide) determines the hydrophilicity of the polymer matrix; lactide is more hydrophobic and glycolide is more hydrophilic. There is more water penetration with an increased fraction of glycolide because glycolide–glycolide and glycolide–lactide bonds are preferentially hydrolyzed.[24] An increasing fraction of glycolide increases the weight loss from degradation.[19] The fastest-degrading PLGA polymers have a 50:50 lactide-to-glycolide ratio, with the degradation rate increasing with higher glycolide or lactide content.[23] However, it is not common to use polymers with more than 50% glycolide composition.

1.123.3.2. Molecular Weight

PLGA with a lower molecular weight degrades faster and has a larger burst release of its payload, when a burst release is present. Heya *et al.* created microspheres loaded with the thyrotropin-releasing hormone from a double emulsion method from PLGA with a lactide-to-glycolide ratio 75:25 and molecular weights of 6, 8, and 11 kDa. The observed drug release *in vitro* for all polymer molecular weights at low drug loading levels had two parts: an initial burst release followed by a slower release over a longer time. The initial burst was larger for microspheres made with lower molecular weight PLGA. The researchers measured the decrease in molecular weight and polymer weight over the long term and found that all the polymers' molecular weights decreased at about the same rate but the weight loss was much faster from the lower molecular weight polymers. Drug release rate and polymer erosion rate were correlated. The drug release rate was faster than the polymer weight loss, so the authors concluded that the drug diffuses out from the polymer matrix as the matrix degrades. The *in vivo* release rate results correlated with those of the *in vitro* release rate.[25]

1.123.3.3. Crystallinity and Glass Transition Temperature

The crystallinity of PLGA depends on the type of its component PLA and PGA, the molar ratio of the two, and the molecular weight of the polymer. The crystallinity affects the mechanical strength, swelling behavior, and capacity to undergo hydrolysis of the polymer, which influence the biodegradation rate.[23]

Lactic acid is a chiral molecule and exists in the D- and L-forms; L-lactic acid is the naturally occurring stereoisomer. D-PLA and L-PLA are both semicrystalline polymers but the

racemic mixture of the two with less than 85% PGA is amorphous.[20] L-PLA and D,L-PLA are much more commonly used than D-PLA.[22]

It has been reported that in some cases more crystalline PLGA degrades and releases drug faster than the less crystalline variety, and in some cases the opposite effect has been observed. The release rates may be affected by drug loading and drug portioning.[19] During the degradation of a semicrystalline device, the amorphous portions degrade first, so over time the crystallinity of the device increases.[26]

Because the glass transition temperature (T_g) of PLGA is above 37 °C, at physiological temperature the polymer has a rigid-chain structure and significant mechanical strength.[23] T_g increases with increasing molecular weight and increasing lactide content of the polymer. As water penetrates a PLGA device, the T_g decreases, which increases chain mobility and drug release.[20]

1.123.3.4. Heterogeneous Degradation

Though initially thought otherwise, careful study by several groups has shown that PLGA undergoes a heterogeneous degradation. By hydrolysis, PLGA ester bonds are broken throughout an initially homogenous macro- or microscale bulk device. A small amount of monomer is lost into solution from the outside of the device, but the monomers in the interior are unable to diffuse away, become trapped, and begin to accumulate. The carboxylic acid end groups of the degradation products lower the pH inside the device and catalyze further degradation in the interior. The device develops two speeds of degradation: a fast-hydrolyzing interior and a slow-hydrolyzing exterior that acts as a one-way membrane to allow water to penetrate the device while keeping the degradation products in the interior from escaping into solution. Vert *et al.*, speaking of macroscale PLGA devices, propose that the outer section finally becomes thin enough that it degrades and releases the degradation products from the interior, followed by slow degradation of the whole device. Park *et al.*, speaking of PLGA microparticles, propose that the osmotic pressure increases inside the microparticles due to the reduced pH until the capsule bursts.[24,27]

1.123.3.5. Degradation and Length Scale

The size of the PLGA device itself impacts the degradation rate of the polymer. Two studies by Lee *et al.* and Dunne *et al.* investigated the release mechanism of model drugs from PLGA nano- and microparticles. Both determined that diffusion plays the dominant role and the length scale influences the rate, at least until mass loss changes the porosity of the particles.

Lee *et al.* studied the *in vitro* cyclosporin A release rate of three particle size regimes ('nanoparticles,' 'small microparticles,' and 'large microparticles') made of PLA, PLGA 50:50, and PLGA 85:15. The authors found that the release mechanism was predominantly by diffusion over matrix erosion and that release occurred more quickly with smaller particles. They postulated that the faster release was due to the larger surface area to volume ratio and the smaller diffusion length of the nanoparticles.[28]

Dunne *et al.* studied *in vitro* the degradation of PLGA 50:50 nanoparticles and microparticles and found that the molecular weight of the larger particles decreased faster than that of the smaller particles (**Figure 3**). While molecular weight starts to decrease immediately, no mass loss is observed for some time, indicating that the degradation products must diffuse to the surface to escape, and that process is slower for larger particles. These trapped degradation products will begin to catalyze the remaining hydrolytic reactions to speed the PLGA degradation. Once mass loss begins, the particles become so porous that the differences due to length scale become negligible and the rate of degradation is similar among all of them.[29]

Another study considered how PVA may affect drug release rates for different sized particles. Panyam *et al.* found that for

120 kDa 50:50 PLGA, particles in the size range of 1 μm released bovine serum albumin (BSA) the fastest, followed by 100 nm particles, followed by 10 μm particles (Figure 4). Degradation for particles in all size ranges occurred in two distinct steps: a rapid degradation in the first 20–30 days and then a slower degradation over 60–70 days. The first stage of degradation involves fast molecular weight loss and autocatalytic acceleration of the degradation due to the slow escape of the degradation products. The second phase occurs when the particles have become more porous so that the degradation products can escape more easily. Degradation occurred fastest for the nanoparticles but there was no significant difference between the rates for the microparticles.[30]

The authors believe that PVA might be confounding the more straightforward relationship between drug release and particle size found by other researchers. The 100 nm particles had more PVA associated with them than did the larger particles. The authors hypothesize that, during the initial degradation phase, the relatively high amount of PVA on the 100 nm particles formed a barrier to outward diffusion of the degradation products, leading to faster degradation. In the second phase of degradation, the PVA had been mostly lost so it did not play a significant role.[30]

Siepmann *et al.* came to a conclusion opposite to those of Lee *et al.* and Dunne *et al.*, arguing that the drug release rate increased with the particle diameter. Microspheres were manufactured with 104 kDa 50:50 PLGA by the double emulsion solvent evaporation method and loaded with 5-fluorouracil. The microspheres were grouped into five size ranges between <36 and 125 μm for analysis with a mathematical model that took into account both diffusion and polymer degradation. The authors found that drug release rate increased with particle diameter and that there was no significant contribution from the polymer degradation due to trapped degradation products (Figure 5). Instead, they concluded for their system that the increased rate for larger microspheres was due to higher initial drug loading, which after leaching out would leave the larger microspheres more porous than the smaller microspheres.[31]

Berkland *et al.* went a step further to consider how the type of drug loaded into the PLGA particles might affect drug loading and therefore release. The authors made monodispersed, drug-loaded microparticles in a range of sizes to investigate the effect of particle diameter on drug release and polymer degradation. They used 15 kDa 50:50 PLGA to create microspheres with diameters 10, 20, 40, 50, 65, and 100 nm encapsulating rhodamine, and microparticles with diameters 10, 50, and 100 nm encapsulating prioxicam. Small microspheres rapidly released the drug while larger microspheres followed a sigmoidal drug release profile, and the type of drug loaded had an effect on the release profile. Rhodamine-loaded particles lost polymer molecular weight faster than piroxicam-loaded particles. Rhodamine is much more soluble in water than prioxicam at neutral pH, which likely facilitates water penetration into the microsphere for the rhodamine-loaded microparticles. Increasing rhodamine loading in microspheres sped up degradation, while increasing prioxicam loading decreased the degradation rate. Through SEM (scanning electron microscopy), the authors observed that in larger microparticles rhodamine preferentially distributes uniformly at the surface of the microparticles while piroxicam partitions to the interior of the particle and forms large crystals. In the smaller particles, the drug distributions were more uniform. Larger particles, particularly rhodamine-loaded particles, had faster degradation rates, likely due to trapping degradation particles within the matrix. Smaller microparticles had higher drug encapsulation efficiency and, as the diameter increased, the differences between rhodamine and piroxicam distributions became more evident. The authors concluded that this was due to the differences in polymer phase-inversion rate between the two drugs.[32]

It is apparent that there is a complex relationship between PLGA particle length scale and degradation and drug release. Most papers indirectly evaluate PLGA degradation by measuring drug release rates, which can be dominated by diffusion

instead of matrix erosion. The drug loading, drug type, and manufacturing parameters affect how the polymer matrix erodes.

1.123.3.6. Environmental Factors Affecting Degradation

Alexis reports, based on *in vitro* tests in the literature, that extreme pH environments can accelerate the degradation of PLGA. The ester bonds can be cleaved by acid- or base-catalyzed reactions.[19]

Dunne *et al.* charted the effect of temperature on the molecular weight of PLGA 50:50 for microspheres incubated *in vitro*. There was no observed loss of molecular weight or shape of the particles over 175 days for particles incubated at 5 °C. For microspheres incubated at 25, 37, and 45 °C, however, there was increasing molecular weight loss with increasing temperature, according to the Arrhenius equation (**Figure 6**).[29]

1.123.4. Biocompatibility of PLGA

The monomeric products of PLGA degradation are lactic acid and glycolic acid. Lactic acid is metabolized by the body and is expired as CO_2 and H_2O. Glycolic acid is excreted through the kidneys or metabolized as CO_2 and H_2O.[23] Because these monomeric products are naturally handled by the body, the biocompatibility of PLGA is very good, and this property has contributed to it becoming such a popular choice of polymer.

1.123.4.1. *In Vivo* Biocompatibility of Implants

Kou *et al.* examined the biocompatibility of PLGA implants in the rat brain for use in a future drug delivery application. They implanted 50:50 PLGA rods (no loaded drug) 1 cm long with diameter 300 μm into the right lateral ventricles of 24 rats. The rats were sacrificed on days 3, 7, 14, and 28 for histological analysis; direct comparison was made to the contralateral side of each animal's brain. The authors observed that the implants were well tolerated and that PLGA was a suitable material for brain implants. On days 3 and 7, the brain showed signs of a reaction typical after a foreign body invasion – mild gliosis and moderate inflammation with mineralized deposit. At day 14, the authors observed mild gliosis, mineralized debris attributed to bone fragments from the implantation, and minimal early neuronal degeneration. At day 28, the gliosis and inflammation were greatly reduced and there was no sign of neuronal degeneration, and the polymer was nearly completely eroded. The authors classified PLGA to be somewhere between 'nonreactive' and 'reactive' on the scale proposed by Stensaas *et al.*, similar to platinum and Teflon.[33]

1.123.4.2. *In Vivo* Biocompatibility of Microspheres

Visscher *et al.* completed a detailed study of the biocompatibility of 15.5 kDa 50:50 PLGA microspheres (average diameter 30 μm) injected intramuscularly into Sprague–Dawley rats. Tissues were examined using light microscopy, transmission electron microscopy (TEM), and SEM. On days 1 and 4 after injection, a slight inflammatory response was observed and the microspheres were thinly walled off. By day 12, fibroblasts, macrophages, and foreign body giant cells were present. After 35 days, the outer part of the microspheres appeared intact but the inner part had started eroding, and by day 42 the outer shells had eroded as well. By day 63, only fragments of the microspheres remained and the inflammatory response was almost completely resolved. The tissue response observed was consistent with previous observations of foreign bodies in muscle tissue and was considered minimal.[34]

1.123.4.3. *In Vivo* Biocompatibility of Nanoparticles

Kumar and colleagues studied the *in vivo* biocompatibility of estradiol-loaded PLGA nanoparticles in rats. PLGA nanoparticles were made using the solvent evaporation method from low- and high-molecular-weight PLGA with lactide-to-glycolide ratios of 50:50 and 65:35. The authors carried out histopathological analysis for the presence of inflammation of the liver, spleen, duodenum, jejunum, and ileum of the rats and compared them with untreated controls. In the liver, the

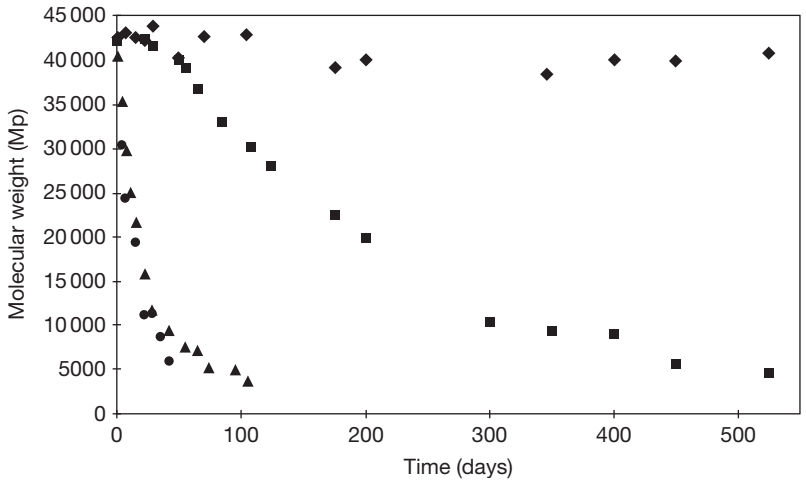

Figure 6 The molecular weight decrease of PLGA when incubated at various temperatures. Diamonds are 5 °C, squares are 25 °C, triangles are 37 °C, and circles are 45 °C. Reproduced from Dunne, M.; Corrigan, O. I.; Ramtoola, Z. *Biomaterials* **2000**, *21*, 1659–1668, with permission from Elsevier.

authors found no difference in the number, arrangement, and appearance of Kupffer's cells, hepatocytes, and sinusoids. The spleens of treated rats were no different from those of untreated controls in the lymphoid tissue mass, sinusoids, and number and appearance of red blood cells (RBCs). The treated animals' intestines showed no difference in the number or distribution of the lymphocytes in the lamina propria region of the intestinal mucosal layer, and the authors observed no evidence of inflammation in the mucosa, submucosa, and muscularis. The authors found no significant increase in white blood cell count during the study for the low-molecular-weight 50:50 PLGA (not reported for other PLGA formulations). It was concluded that the nanoparticles showed good biocompatibility and would be appropriate as an oral drug delivery system for estradiol.[35,36]

1.123.4.4. Bioavailability: Damage to Encapsulated Payload

The degradation of PLGA and particularly the drop in pH in the center of microspheres due to the presence of degradation products can damage the encapsulated payload. The drop in pH in the center of PLGA microspheres was studied by Fu *et al.* using pH-sensitive fluorescent dyes. The authors used a double emulsion technique with 25 kDa 50:50 PLGA to create dye-loaded microspheres of varying diameters. They used the emission ratio of carboxyl SNARF-1 to C1-NERF, both conjugated to dextran, to determine the pH inside the microspheres in the range of 1.5–3.5. The study was unique in that the distribution of the pH within the microspheres could be assessed, and not just the average. Pockets of extreme pH within a microsphere could damage encapsulated drugs even if the average pH would not. Microspheres were incubated in phosphate-buffered saline (PBS) for 15 days and imaged periodically. The pH inside the microsphere dropped over time, reaching 1.5 in the center of the microspheres, and there was a gradient of pH along the radius of the microsphere, with the lowest pH in the center and the higher pH near the outer edge. The diameter of the microspheres affected the pH gradient within the microspheres; the smaller diameter microspheres had smaller pockets of low pH. This is likely because clearance of the products of degradation from the microsphere interior is faster for smaller microparticles. (**Figure 7**).[37]

The low-pH interior of the microspheres should be taken into account when designing a delivery vehicle for proteins or nucleic acids that may be sensitive to low-pH environments, either by a different choice of agent to be delivered or by encapsulating additional compounds that can buffer the interior. It is possible that certain encapsulated proteins could buffer the interior of the microsphere so that the pH is partially neutralized.[37]

1.123.5. Applications of PLGA Across Length Scales

PLGA has been used in many different devices and therapies from nano- through macro-length scales. In this section, we highlight certain applications in each of the length regimes, from nanoparticles to tissue engineering scaffolds, focusing on the degradation kinetics of the applications.

1.123.5.1. Nanoscale Particles

PLGA nanoparticles have been widely applied and are being used in several clinical trials and products on the market. They are typically created by the double emulsion solvent evaporation method using PVA as the emulsifier.[15] The nanoparticles are most often used for cytoplasmic delivery of drugs, proteins, and nucleic acids because of their comparatively high efficiency of uptake into cells.[10] In this section, we will look at a few examples of loading and release studies for PLGA nanoparticles.

1.123.5.1.1. Drug delivery

The detailed study by Mittal *et al.* demonstrates how the parameters of molecular weight and copolymer ratio affect particle size, loading efficiency, and release rates for estradiol. The authors used mathematical models to conclude which nanoparticles' release kinetics was dominated by diffusion of the drug out of the matrix and which was dominated by polymer degradation. The authors determined that the bioavailability of the drug was prolonged by using PLGA nanoparticles in comparison with administering the pure drug.[36]

Mittal *et al.* completed both *in vitro* and *in vivo* drug loading and release studies for estradiol delivery using PLGA nanoparticles of various molecular weights (14.5, 45, 85, 137, and 213 kDa) and copolymer ratios (50:50 with 85 kDa, 65:35 with

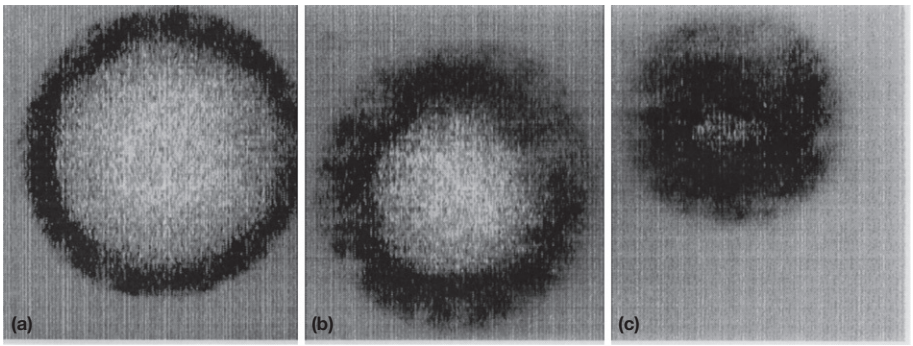

Figure 7 The pH difference in the centers of different sized microspheres. Microsphere diameters are (a) 38 μm, (b) 24 μm, and (c) 14 μm. Color scale: black pH 3.5 or higher, white pH 1.5. 97 kDa, 85:15 with 87 kDa) prepared by a double emulsion solvent evaporation method. Nanoparticle diameter increased with increasing molecular weight, probably due to the polymer solution's increased viscosity that makes larger emulsified droplets for the same stirring speed, but the diameter did not change significantly for different copolymer ratios.[36]

The *in vitro* drug release studies were performed by dispersing nanoparticles in pH 7.4 phosphate buffer in dialysis membranes and suspending the bags in pH 7.4 ionic strength 10 mM phosphate buffer; the release medium was replaced completely at 6 and 12 h on the first day and then sampled every 24 h. Increasing the molecular weight significantly decreased the release rate of estradiol from the PLGA nanoparticles (**Figure 8(a)**). The 14.5 kDa PLGA released 94.7% of the estradiol within 18 days, while the 213 kDa PLGA released 26.6% of the estradiol within 19 days. The authors fitted the release profiles and concluded that the two lower molecular weight polymers released the drug at zero order and the two higher molecular weight polymers released the drug consistent with Higuchi's square root relation. This indicates that for lower molecular weight polymers, drug release is dominated by degradation, which increases with time because of autocatalysis and lowering the glass transition temperature. For higher molecular weight polymers, drug release is mediated by diffusion with little contribution from degradation.[36]

The authors also examined release rate from nanoparticles made with different copolymer ratios but all with high-molecular-weight polymers. There was a decrease in release rate with increasing glycolide content (up to 50:50), but the release was still dominated by diffusion, not degradation (**Figure 8(b)**). The authors state that the decrease in release rate is due to the increase of hydrophobicity of the polymer which has increased affinity with the drug. The authors note that they did not observe a burst release of drug from the nanoparticles as is typical for most particle formulations, perhaps because there was no unbound drug associated with the particles.[36]

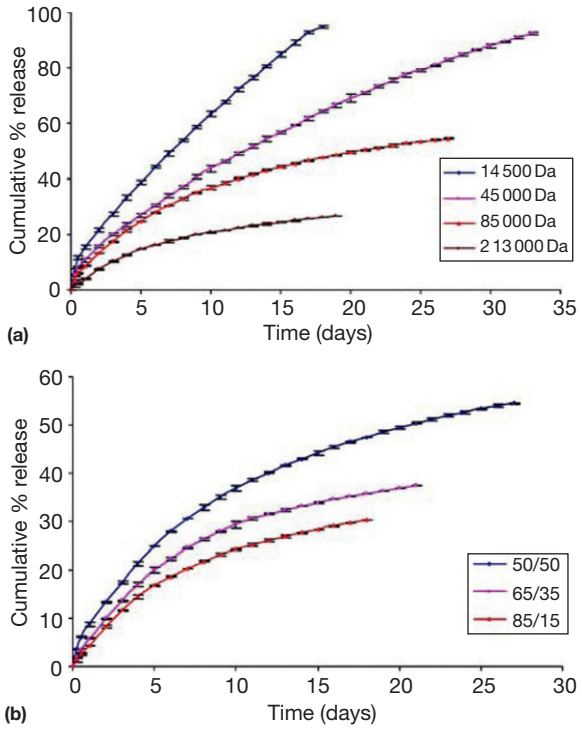

Figure 8 *In vitro* cumulative estradiol release from (a) PLGA nanoparticles with 50:50 copolymer ratio and varying molecular weights and (b) PLGA nanoparticles with average molecular weight 85–97 kDa with varying copolymer ratios. Reproduced from Mittal, G.; Sahana, D. K.; Bhardwaj, V.; Kumar, M. *J. Control. Release* **2007**, *119*, 77–85, with permission from Elsevier.

Mittal *et al.* administered estradiol-loaded nanoparticles orally to rats and included oral and intravenous delivery of pure estradiol and measured the resulting blood estradiol levels. The nanoparticles were made of 50:50 PLGA at molecular weights 14.5, 45, and 213 kDa and 65:35 PLGA at 97 kDa. The *in vivo* studies show that increasing the molecular weight of PLGA or increasing the lactide content decreases the drug release rate (**Figure 9**). Particle size was also found to strongly influence the release rate because the 65:35 97 kDa PLGA (diameter 126 nm) showed a much more sustained release than the 50:50 213 kDa PLGA (diameter 155 nm). The studies show improved bioavailability of estradiol loaded into nanoparticles versus delivered as pure drug.[36]

1.123.5.1.2. Gene delivery

Kang *et al.* compared the transfection, cytotoxicity, and efficacy *in vitro* and *in vivo* of DNA-loaded PLGA nanoparticles, DNA-loaded polyethyleneimine (PEI) nanoparticles, and naked DNA delivering the gene for the vascular endothelial growth factor (VEGF). PLGA nanoparticles were found to sustain VEGF transfection levels better than naked VEGF DNA and DNA-loaded PEI nanoparticles. VEGF will promote vascular growth in the mouse ischemic limb model.[38] Biocompatibility was tested *in vivo* with TUNEL (Terminal Deoxynucleotidyl Transferase Mediated dUTP Nick End Labeling) staining for apoptosis of skeletal muscle tissue in normal mice one day after injection of naked VEGF pDNA, PEI nanoparticles containing VEGF pDNA, and PLGA nanoparticles containing VEGF pDNA. The apoptosis level in tissue transplanted with PLGA nanoparticles was significantly less than for tissue injected with PEI nanoparticles. The naked VEGF pDNA produced the highest transfection levels six days after administration, but the PLGA nanoparticles with VEGF pDNA produced the highest levels 12 days after administration, and the VEGF level in the PLGA group increased with time while all other groups' VEGF levels decreased.[38]

The authors used the mouse ischemic limb model to determine the therapeutic potential of each delivery system, measuring neovascularization and capillary density (**Figure 10**). PLGA/VEGF pDNA nanoparticles produced the most extensive neovasuclarization, highest capillary density, and highest growing capillary density of the three groups. This is because the PLGA nanoparticles were able to sustain the VEGF pDNA delivery and were less cytotoxic in comparison with PEI.[38]

Prabha and Labhasetwar studied how the PLGA and PVA formulation parameters in a double emulsion solvent evaporation method could influence DNA delivery to human breast carcinoma and human prostate cancer cells. PVA was included in the study because it had been previously found that the hydrophobic segment of PVA anchors into the polymer matrix

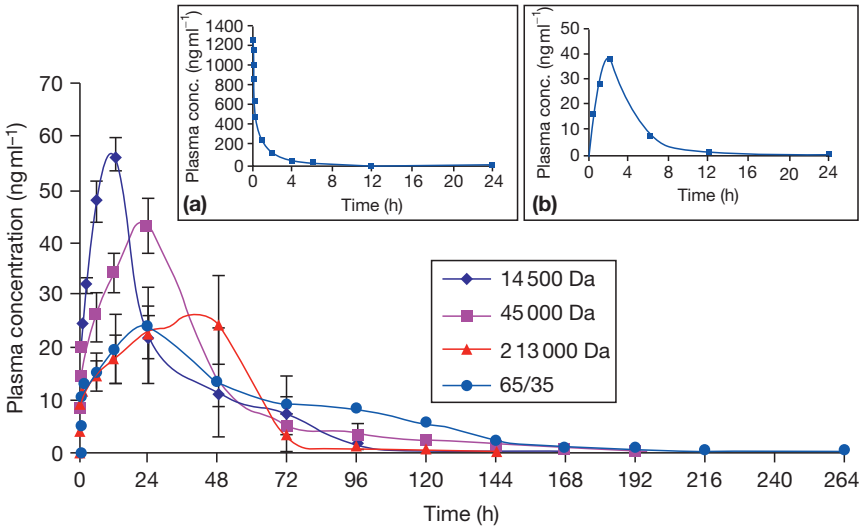

Figure 9 Blood plasma concentration following administration of PLGA nanoparticles of varying molecular weights for 50:50 PLGA as well as molecular weight 65:35 PLGA 97 kDa. Inset is plasma concentration of pure estradiol administered (a) intravenously and (b) orally. Reproduced from Mittal, G.; Sahana, D. K.; Bhardwaj, V.; Kumar, M. *J. Control. Release* **2007**, *119*, 77–85, with permission from Elsevier.

of the nanoparticle and remains associated with the surface. PLGA molecular weight was found to affect particle size; nanoparticles made with higher molecular weight PLGA (143 kDa) were smaller and more uniform in size than those made with lower molecular weight PLGA (12 and 53 kDa). The efficiency of encapsulation, the total amount of DNA released, and the transfection levels were also higher for higher molecular weight PLGA in both cell types.[39]

The authors also compared PLA to 75:25 and 50:50 PLGA (all 53 kDa) and found that DNA release and transfection were highest for 75:25 PLGA. PVA concentration, molecular weight, and the degree of hydrolysis were also studied for their effect on gene transfection. DNA loading was higher for nanoparticles made with 2 and 5% PVA than for those made with 0.5% PVA. The highest gene transfection levels were observed for 2% PVA, and 0.5% PVA had higher transfection than 5% PVA despite lower DNA loading. The authors propose that a higher amount of surface-associated PVA could shield the surface charge reversal necessary for nanoparticles to escape the acidic endolysosomes, based on previous studies and the observation that there are more nanoparticles in the cytoplasmic fraction formed with lower concentrations of PVA than those formed with higher concentrations of PVA. With increased PVA hydrolyzation (89 vs. 80%), DNA loading and release increased, surface-associated PVA decreased, and transfection increased. Nanoparticles made with lower molecular weight PVA were smaller and had higher DNA loading, but had lower transfection than those made with higher molecular weight PVA. Transfection was greater from nanoparticles with higher molecular weight PVA and higher hydrolyzation levels because those nanoparticles had less surface-associated PVA. All of these parameters were studied *in vitro*, but the authors believe that these parameters will have a similar influence over nanoparticles applied *in vivo*.[39] This study makes a valuable contribution to the body of knowledge on PLGA formulation parameters, as PVA is such a popular emulsifier in the creation of micro- and nanoparticles.

1.123.5.2. Nanoscale Fibers

Nanofibers are attractive candidates as scaffold components for tissue-engineering applications because of their porous nature, which facilitates mass transport, high surface area for attachment, and possibility of providing topographical cues. PLGA for these reasons has been used extensively in fiber fabrication. The degradation rate of fibers in these scaffolds needs to be optimized so that cells produce their own extracellular matrix (ECM) at approximately the same rate as scaffold degradation. Shin *et al.* studied how the copolymer ratio in PLGA nanofibers affected degradation time and the suitability of PLGA nanofibers as a scaffold for tissue-engineered cartilage (Figure 11). The PLGA tested had a lactide-to-glycolide ratio of 50:50, 75:25, and a 1:1 blend of the two. The authors made electrospun fibers that averaged 550 ± 150 nm for the 75:25 PLGA and with 80.68% porosity in the scaffolds.

The Young's modulus of the scaffolds was 66 MPa for 50:50 PLGA and 111 MPa for 75:25 with the blend intermediates; the ultimate tensile stress had a similar pattern and ranged from 1.8 to 4.7 MPa. The mechanical properties were greater for 30% PLGA solution than 25% PLGA solution and for aligned over nonaligned fibers architecture. By comparing their work with work from another group that measured the mechanical properties of 85:15 PLGA, the authors estimated that a polymer with a lactide-to-glycolide ratio of between 85:15 and 75:25 would be optimal to mimic the mechanical properties of cartilage. *In vitro* fiber degradation was also more rapid with higher glycolide content, as measured by mass, molecular weight, and pH changes, likely because of the greater hydrophilic character and lower crystallization rate of the polymer that would facilitate water absorption and diffusion.

The architecture of the scaffold also affects the degradation time. Shin *et al.* cited a study of 50:50 PLGA block-like scaffolds with similar molecular weight that degraded more slowly than the nanofiber scaffolds in their study. While a block-like scaffold would experience autocatalytic acceleration of

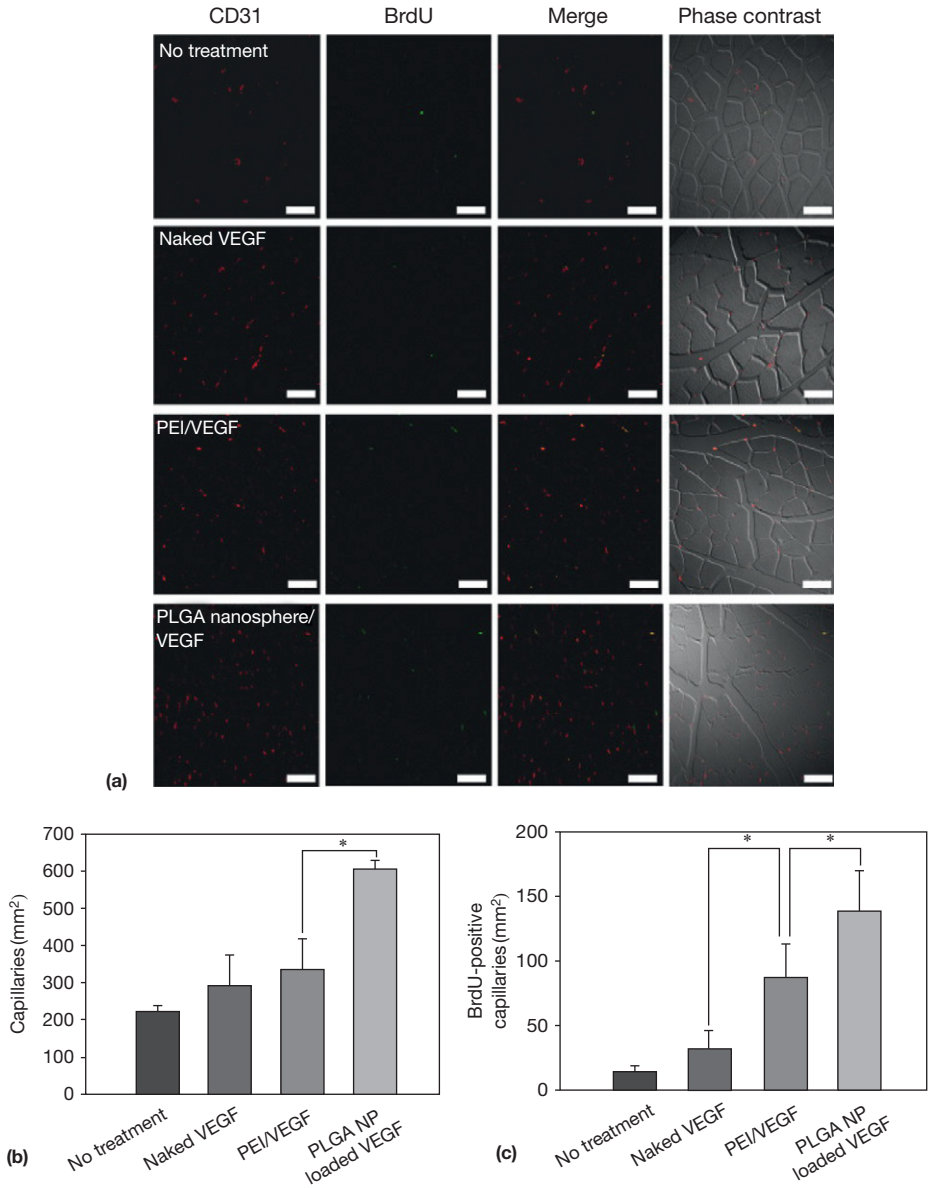

Figure 10 (a) Immunofluorescent staining of CD31 and BrdU of mouse ischemic limb model for PLGA nanoparticles delivering VEGF and controls. Scale bars are 50 μm. (b) Capillary density and (c) BrdU-positive capillary density in mouse ischemic limb model. BrdU-positive cells signify growing capillaries $*p < 0.05$. Reproduced from Kang, S. W.; Lim, H. W.; Seo, S. W.; Jeon, O.; Lee, M.; Kim, B. S. *Biomaterials* **2008**, *29*, 1109–1117, with permission from Elsevier.

degradation due to the lack of clearance of the degradation products, nanofibers are more susceptible to hydrolysis because of the high surface area to volume ratio of the fibers and scaffold. The PLGA nanofibers also had good biocompatibility with chondrocytes as measured by cell proliferation and morphology despite concerns about the solvents used in the electrospinning process.[40]

1.123.5.3. Microscale Particles

Microparticles are well sized to be taken up by antigen-presenting cells and are therefore ideal for delivering DNA vaccines.[13] Also discussed in this section are microparticles used for a contrast agent in ultrasound and to construct macroscale scaffolds for tissue engineering. Most microparticles are made by the emulsion solvent evaporation process or spray-drying.

1.123.5.3.1. Vaccines

In developing a single-administration human immunodeficiency virus (HIV) vaccine using the gp120 subunit, Cleland *et al.* capitalize on the presence of an initial burst release from their PLGA microspheres and design their delivery vehicle to produce a second delayed burst instead of a continuous release. Ideal for vaccination situations where a follow-up visit to a physician may not be possible, the initial burst release

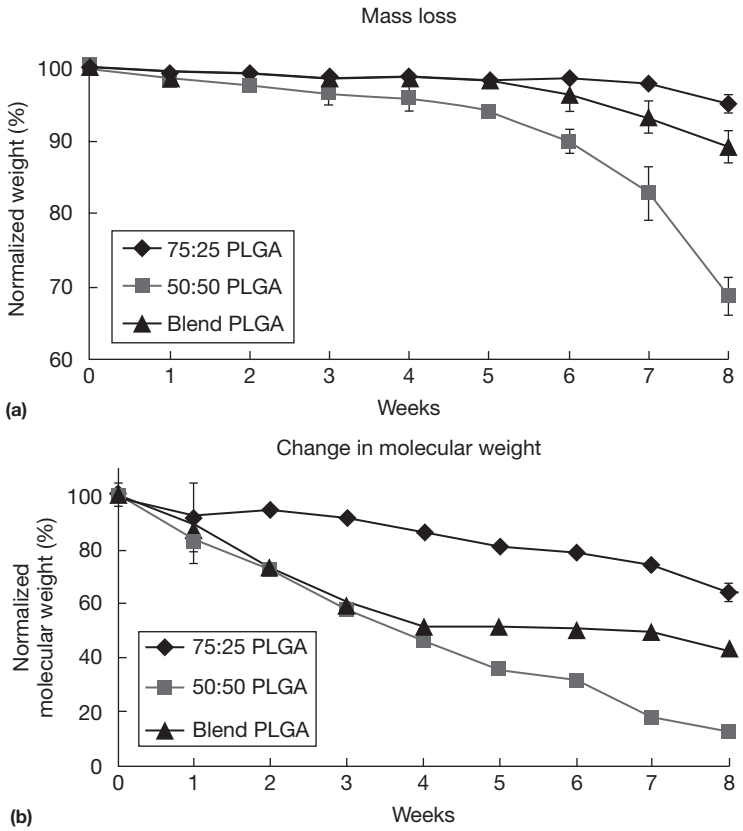

Figure 11 The degradation of nanoscale PLGA fibers in terms of (a) weight and (b) molecular weight. Reproduced from Shin, H. J.; Lee, C. H.; Cho, I. H.; *et al. J. Biomater. Sci. Polym. Ed.* **2006**, *17*, 103–119, with permission from Brill.

of gp120 serves as the priming vaccination and the second release serves as the booster. This is a more effective immunization strategy than a continuous release of gp120. The authors formed microspheres using a double emulsion method with low aqueous volume in comparison with the mass of polymer so that the pore structure in the microsphere would be discontinuous. This made for very low rates of release of gp120 until the matrix was nearly fully degraded, at which point the second burst release of gp120 occurred. The authors tuned the polymer properties to dictate when the second burst release occurred (1, 2, 3, or 4 months after the initial burst). To decrease the rate of degradation, the authors changed the lactide-to-glycolide ratio away from 50:50, increased the molecular weight of the polymer, and increased the degree of crystallinity.[41]

Jaganathan *et al.* developed and tested *in vitro* and *in vivo* a vaccine against hepatitis B virus (HBV) using PLGA microspheres modified with the natural biodegradable polymer chitosan. Vaccines available on the market at the time of publication were successful in generating humoral immune responses, but not the necessary cellular immune response. Mucosal immunization and the generation of secretory IgA were determined to be the most effective first line of defense as most HBV infections occur through the mucus membranes, so the authors studied the effectiveness of PLGA microparticles as a nasal vaccine. W/O/W microparticles 1–10 μm in diameter and with 80% loading efficiency were created with recombinant hepatitis B surface protein (HBsAg) in the inner aqueous phase, 50:50 PLGA (MW 30–70 kDa) in the oil phase, and chitosan and PVA in the outer aqueous phase. Chitosan was added to the surface of the PLGA microspheres to promote mucoadhesion. The particles were kept below 10 μm in diameter to more effectively target the antigen-presenting cells in the mucous membranes. Nasal clearance time of the microparticles in rabbits increased from 30 to 180 min. *In vitro* testing showed that $\geq$90% of loaded HBsAg had been released from the microspheres by day 42 and that the stability of the HBsAg in the PLGA microspheres was similar to the control, which was alum-absorbed HBsAg. The authors studied the antibody response in mice after intranasal administration of the modified PLGA microspheres and controls. They found that modified PLGA microspheres delivering HBsAg induced a mucosal immune response more effectively than unmodified PLGA microspheres and a control alum vaccine, particularly when a booster dose of the microspheres was administered.[42]

1.123.5.3.2. Contrast agent for ultrasound

AI-700 is a gas-filled PLGA microparticle technology used as an ultrasound contrast agent for echocardiography and has been taken through Phase III clinical trials. The biocompatibility of PLGA made it an attractive candidate for this application. The microparticles are prepared using an emulsion and spray-drying method. Ammonium bicarbonate is in the

inner aqueous phase to give the microparticles a porous, honeycomb-like structure. The polymer layer also contains 1,2-diarachidoyl-*sn*-glycero-3-phosphocholine (DAPC), which helps to trap the gas in the microparticle following reconstitution. The AI-700 microparticles were directly compared with Optison™, a commercially available contrast agent for ultrasound. In the functional assay, the backscatter generated at 2.25 MHz from the AI-700 was stable at around 60 dB for 10 min, while the backscatter from Optison dropped to less than 40 dB in the same period. The microparticles were not destroyed even under extreme ultrasound conditions, showing them to be more stable than many currently used ultrasound contrast agents.[43]

1.123.5.3.3. Tissue engineering

Jaklenec *et al.* fused PLGA microspheres to create a porous scaffold appropriate for cell seeding and flexible for many different tissue-engineering applications. The microspheres were less than 20 μm in diameter and had up to 4.3% BSA loading to add a drug delivery function to the scaffold. To make the scaffold, microspheres were added to a disk mold 6 mm in diameter and 1–2 mm high and placed in a chamber with dichloromethane. The dichloromethane diffused into the microspheres and lowered the T_g of the microspheres, softening the polymers and allowing them to fuse. The scaffolds were removed to air for 10 min, where the T_g rose and the scaffold hardened, and then taken out of the mold and dried under vacuum. During the fusion experiments, the authors found that higher BSA content and larger microsphere mass required increased time for fusion. The scaffolds and control loose microspheres were subjected to an *in vitro* BSA release study over 20 days. Two scaffolds, fused for 10 and 10.5 min, were found to have statistically identical release rates. The loose microspheres released BSA faster in the first week of incubation, but overall they released the same amount of BSA as the scaffolds. The authors proposed that the scaffolds have a slower BSA release rate because of their lower surface area in comparison with the loose microspheres.

The authors created two sizes of microspheres averaging 11 and 113 μm, which resulted in scaffolds with pore sizes of 20 and 200 μm (Figure 12). The scaffolds with the larger pore sizes were used in a cell attachment study. The authors were able to seed fibroblasts into their prewet scaffolds, and the cells attached to the surface and in the pores of the scaffold, demonstrating biocompatibility of their scaffolds.[44]

1.123.5.4. Macroscale Hydrogel

Thermosensitive hydrogels of poly(ethylene glycol) (PEG)–PLGA–PEG block copolymers have been developed and used for *in vivo* drug delivery applications. Jeong *et al.* characterized the sol–gel transition ranges of PEG–PLGA–PEG with molecular weights from 3.5 to 4.5 kDa and various PLGA lengths. The PLGA polymer block forms the hydrophobic core of a micelle, and the PEG block forms the corona. At room temperature, the solution is free-flowing, but with increasing temperature the PEG and PLGA partially phase-mix and the micelles become close-packed and overlapping, and at body temperature the polymer is a gel.[45]

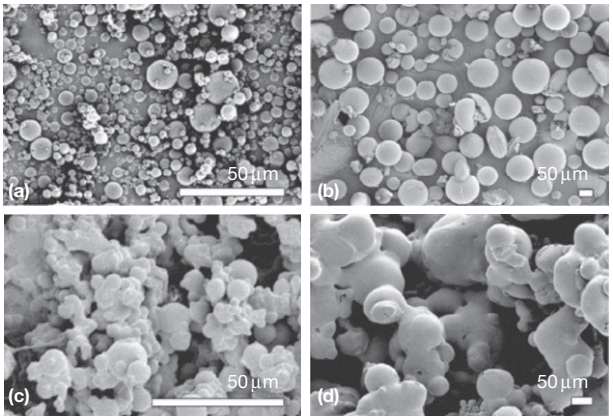

Figure 12 SEM images of (a and b) loose microspheres and (c and d) scaffolds made from (a and c) small and (b and d) large microspheres. Scale bars are 50 μm. Reproduced from Jaklenec, A.; Wan, E.; Murray, M. E.; Mathiowitz, E. *Biomaterials* **2008**, *29*, 185–192, with permission from Elsevier.

Jeong *et al.* tracked the *in vitro* release rates of ketoprofen and spironolactone from two PEG–PLGA–PEG copolymers, one with block lengths 550–2810–550 and molecular weight 4.27 kDa and the other with block lengths 550–2320–550 and molecular weight 3.56 kDa. Ketoprofen is more hydrophilic and spironolactone is more hydrophobic, so under the micelle model they should partition differently within the gel and exhibit different release profiles. Ketoprofen's release was almost complete after about 5 days and obeyed the Higuchi equation, showing it was diffusion-dominated. The authors concluded that ketoprofen partitions more in the PEG domain of the gel so that the continuous repartitioning of the drug between the polymer phases results in easier diffusion out of the gel. Spironolactone's drug release profile was S-shaped, indicating two mechanisms of release. The authors concluded that spironolactone partitions more in the hydrophobic PLGA core. The initial diffusion release is probably from the drug partitioned in the hydrophilic regions, and the later drug release is due to degradation of the PLGA. Increasing the hydrophobic PLGA domain lowers the water content in the gel, slowing PLGA degradation and spironolactone release.[46] Changing the lactide-to-glycolide ratio greatly changed drug release when controlled by degradation and diffusion but had little influence on the rate of diffusion-controlled release.[47]

Li *et al.* delivered pDNA from a thermosensitive 12.8 kDa PEG–PLGA–PEG copolymer. Incubating for 48 h with HEK293 cells showed that the hydrogel persisted for about 30 days and produced no change in cell morphology and 98% cell viability, with pDNA release occurring over about 15 days. The authors applied the luciferase pDNA-loaded hydrogel to a skin wound on mice, where it gelled in about 45 min. Biopsied tissue showed that luciferase expression peaked after about 24 h and was at 6.4% of the peak at 72 h.[48]

PLGA–PEG–PLGA thermosensitive hydrogels have been commercialized under the name ReGel®. *In vivo* paclitaxel release from ReGel was diffusion-controlled for about 2 weeks and then degradation- and diffusion-controlled for about 5 weeks. Subcutaneous injection of insulin in ReGel maintained insulin levels for 15 days.[47]

1.123.5.5. Macroscale Foams

Lu *et al.* studied the degradation processes of PLGA foams (diameter 13.45 mm, thickness 350–800 μm) and compared them with the degradation processes undergone by PLGA microparticles and films. Tailoring the degradation rate of these foams is crucial for tissue-engineering applications. The authors created six types of foams using the solvent-casting, particulate-leaching technique. One-half of the foams used 50:50 PLGA (MW 94.5 kDa) and the other half used 85:15 PLGA (MW 140.4 kDa), each with varying fabrication conditions such as NaCl crystal size and NaCl % weight. The degradation was studied *in vitro* and *in vivo*, where the *in vitro* system was a shaking, 37 °C PBS bath where the PBS was replaced once per week and the *in vivo* system was implantation into the mesentery of rats.

The *in vitro* and *in vivo* results for the PLGA 85:15 foams were similar; the weight remained relatively constant over 20 weeks and there was little change in the porosity, median pore diameter, and surface-to-volume ratio but the molecular weights decreased exponentially, with half-lives between 9.4 and 14.3 weeks. The 50:50 PLGA foams degraded faster *in vitro* than the 85:15 foams, with dramatic weight loss occurring after about 6 weeks. The pore distribution changed over time and the porosity and surface-to-volume ratio decreased and the pore size increased after about 8 weeks. Molecular weight also decreased exponentially but the half-lives were between 3.0 and 3.3 weeks *in vitro*. *In vivo* the degradation of the 50:50 PLGA foams was even faster, with half-lives of molecular weight degradation between 1.9 and 2.4 weeks. The longer degradation time of the 85:15 PLGA is consistent with previous research that showed decreased water penetration into the more hydrophobic 85:15 PLGA due to the higher lactide content. The authors determined that the shorter degradation time of the 50:50 PLGA foams *in vitro* was due to the autocatalytic acceleration of degradation inside the foams because of the accumulation of degradation products near the foams *in vivo*. The degradation times of these porous PLGA foams were similar to those previously reported for PLGA films and microparticles.[49]

1.123.6. Rationale for Development of PPEs

PPEs represent a class of biodegradable polymers having a phosphoester linkage in the backbone, which would include polyphosphates, polyphosphonates, and polyphosphites.[50] Much of the research into the basic science of these polymers has been pioneered by Penczek and his colleagues.[51–53] Here, we highlight the characteristics of PPEs that will repeatedly manifest in various biomedical applications discussed in this chapter. The pentavalency of phosphorus in the backbone of PPEs makes it possible to conjugate functional groups. Starting from the parent polyphosphite, the P–H bonds can be readily converted for conjugation of different chemical structures, including charged groups through a phosphate (P–O) or a phosphoramide (P–N) bond as side chains. These are tabulated on the basis of their applications in Table 1 (biodegradation (1-1 to 1-3), drug and gene carriers (2-1 to 2-5), and thermoresponsive PPEs (3-1 to 3-6)). The phosphorus-containing backbone confers versatility and tunability in PPE-based material design as the physicochemical and degradation properties can be adjusted by changing the backbone and the side-chain structures. Secondly, the flexible phosphoester bond in the backbone also provides the plasticizing effect to lower the glass transition temperature and improve solvent solubility and processibility of polymers with otherwise unfavorable physical and colligative properties. Thirdly, the intermediate and ultimate hydrolytic breakdown products of PPEs are innocuous, conferring PPEs excellent toxicity and biocompatibility profiles. This section will closely examine the structure–property relationships of PPEs by drawing upon data published in the last 10 years. Discussions will highlight the application of the unique characteristics of PPEs (mentioned above) over a wide range of biomedical applications.

1.123.7. Structure–Function Relationships of PPEs

1.123.7.1. Material Properties of PPE Films

Many biomedical applications involve the use of scaffold materials to provide mechanical support or to deliver therapeutic agents (drugs, cells, etc.). As different parts of the body experience different types, patterns, and ranges of mechanical stress, scaffold requirements inevitably depend on the site of application.

Dacron (poly(ethylene terephthalate), PET)) is a highly crystalline, nondegradable polymer ($T_m = 265$ °C, $T_g = 69$ °C). Introduction of the ethyl phosphate bond into the backbone not only introduces degradable characteristics but also significantly changes the bulk properties of the polymer. An initial attempt to synthesize a PPE P(BHET-EOP) by polycondensing 1,4-bis(hydroxyethyl) terephthalate (BHET) with ethyl phosphorodichloridate (EOP) at stoichiometric ratios resulted in a very viscous semisolid at room temperature ($T_g = 19$ °C, water-in-air contact angle = 8°), which was not suitable for tissue engineering. To raise the T_g and improve the mechanical properties of the polymer, a two-step polymerization scheme was applied to synthesize a series of poly(terephthalate-*co*-phosphate)s with different contents of the phosphoester component (EOP).[54] When the EOP/TC (terephthaloyl chloride) ratio is higher than 1 (i.e., 50:50), the PPEs are amorphous; no melting point (T_m) is observed in differential scanning calorimetry (DSC) analysis and the copolymers begin to soften at around 150 °C. As expected, the glass transition temperature (T_g) increases as the EOP/TC ratio decreases. Nevertheless, the T_g increment is minor until the EOP/TC ratio decreases to below 3 (i.e., 75: 25). There is a dramatic increase of T_g from P(BHET-EOP/TC, 80:20) ($T_g = 25$ °C) to P(BHET-EOP/TC, 50:50) ($T_g = 64$ °C). At the EOP/TC ratio of 1, DSC shows a melting peak at 201 °C, indicating the presence of a crystalline phase. The T_g values of a series of other P(BHET-EOP/TC) copolymers of differing EOP/TC ratios are shown in Table 2.

Introducing sterically hindered diol to the polymer backbone, by substituting ethylene glycol with 2-methylpropylene diol (MPD) or 2,2-dimethylpropylene diol (DMPD) residues, reduces its glass transition temperature (Table 2). The T_g values of the copolymers with DMPD and MPD residues are

lower than that of ethylene glycol EG residues. Results demonstrate that polymer chains with extra pendant methyl groups are not only more rigid but also more amorphous (packed less closely and orderly).

The solubility of the copolymers also decreases as the phosphate content decreases (Table 2). When the EOP/TC ratio is 1, the resulting copolymer P(BHET-EOP/TC, 50:50) becomes insoluble in chloroform. The relative hydrophobicity of the P(BHET-EOP/TC) series is also determined by measuring the water-in-air contact angle (Table 2). The contact angle decreases dramatically from 65° for P(BHET-EOP/TC, 80:20) to 8° for P(BHET-EOP/TC, 100:0). Substituting the ethoxy side chain with methoxy side chain (MOP) also markedly increases the hydrophilicity (Table 4). At the ratio of EOP/MOP/TC of 40:40:20, the contact angle decreases to a value close to that of P(BHET-EOP/TC:100:0). Furthermore, introducing negative charges to the phosphate side chains by converting the methoxy groups into sodium salt renders the polymer less soluble in chloroform and methylene chloride. The negatively charged P(BHET-ENaOP/TC)s become hydrophilic by gross observation. As expected, the methoxy group-substituted P(BHET-EOP/TC) and the negatively charged poly(terephthalate-*co*-phosphate)s have much higher T_g values than their parent polymers (Table 2). P(BHET-NaOP/TC, 80:20) has a clear, sharp melting peak at 180 °C as determined by DSC.[54] Poly(terephthalate-*co*-phosphate)s show typical tensile properties of amorphous or low-crystalline thermoplastics. At an EOP/TC ratio higher than 90:10, the film becomes weak and difficult to handle. The P(BHET-EOP/TC, 80:20) film yields at 86.6% elongation (Table 2), with a modulus of elasticity of 13.8 MPa. Substituting EOP with MOP partially (40:40 or 60:20) does not affect the film-forming property significantly, except that the film becomes more brittle and less ductile. P(BHET-EOP/MOP/TC)s have nearly 100% higher moduli of elasticity than P(BHET-EOP/TC, 80:20). In addition, fibers could be drawn from copolymer melts at 160–180 °C from all three copolymers (i.e., P(BHET-EOP/TC, 80:20), P(BHET-EOP/MOP/TC,60:20:20), and P(BHET-EOP/MOP/TC,40:40:20)).[54]

1.123.7.2. Degradation

PPEs can be degraded both enzymatically and chemically. Enzymatic degradation can be mediated by endogeneous phosphodiesterases and phosphotriesterases commonly involved in cellular metabolism.[55] Although enzymes are known to be highly specific, drug-loaded PPE coblock polymers are more rapidly degraded in the presence of phosphoesterases,[56,57] suggesting that enzymatic degradation is a valid mode of polymer degradation even when they are not endogeneous metabolic substrates. As phosphoesterases are not ubiquitous in the body, it is important from an application standpoint that degradable polymers can also be chemically broken down. Indeed, the hydrolysis of the phosphoester bond can occur,[58] and the rate of degradation increases with pH because of a higher concentration of hydroxide ions, which are strong nucleophiles.[59]

1.123.7.3. Structure–Degradation and Length Scale–Degradation Relationship

As degradation of PPEs is dependent on the presence of water, the rate of degradation can be controlled by controlling the rate of water penetration. Hydrophobic segments can be introduced into the PPE backbone in a controlled way to yield predictable degradation profiles.[54,60] These structures are shown in Table 1 (1-1 to 1-4). In the former,[60] PLU-4 contains no degradable linkage in the backbone and is expected to be stable (Figure 13). The modest weight loss is possibly caused by the cleavage of the disodium phosphate in the side chain. PLU-5 shows a mass loss because of the presence of the biodegradable BEP. PLU-2 shows a higher mass loss than PLU-5 because of the substitution of poly(tetramethylene oxide) (PTMO) with polycaprolactone (PCL) which is degradable by itself. Finally, when PTMO is replaced by a more hydrophilic poly(ethylene oxide) (PEO), an even higher mass loss is observed in PLU-1.

Similar structure-dependent degradation profile is observed in poly(terephthalate-*co*-phosphate) copolymer.[54] As mentioned in previous sections, changing the side chains of PPE can further modify its structure–function relationship. In the P(BHET-EOP/TC, 80:20) series, substituting the ethoxy with a methoxy group yields copolymers with increased hydrophilicity, which in turn accelerates the *in vitro* degradation as demonstrated in Figure 13. Furthermore, converting the methoxy group to a sodium salt dramatically increases the degradation rate. Taken together, these data demonstrate the feasibility of tuning the degradation rates of the phosphoester-based polymers by adjusting the backbone structure (e.g., EOP/TC ratio) and changing the side-chain structure (ethyl group vs. methyl group). The resultant copolymers become more hydrolytically labile as the phosphate component (EOP) is increased and as the side chains are switched from the ethoxy to the methoxy group, which allows a higher rate of water penetration.

Figure 14 shows the SEM images of the cross-sections of degrading samples of P(BHET-EOP/TC, 80:20) and P(BHET-EOP/TC, 85:15) disks immersed in 0.1 M PBS at 37 °C for 18 days. P(BHET-EOP/TC, 80:20) disks (Figure 14 left) swell much less than P(BHET-EOP/TC, 85:15) disks (Figure 14 right). The latter has a more porous and coarser texture at the edge compared to its interior, indicating a greater extent of degradation, while the texture of P(BHET-EOP/TC, 80:20) disks is still relatively uniform throughout the disks even when imaged at a higher magnification. P(BHET-EOP/TC, 80:20) degrades at a slower rate than P(BHET-EOP/TC, 85:15), reflecting the influence of the phosphoester backbone in accelerating the rate of degradation. The former shows a gradual decrease in mass over time, losing more than 20% in total mass after 18 days of incubation (75–80% mass remaining), while the latter has 57% (mass remaining) on day 18.

The length scale of degradable polymers is expected to affect the rate of degradation. Degradation profiles of PPEs in different length scales are collated in Figure 15.[61–63] Their molecular structures are shown in Table 1(1-2). As the degradation rate depends on the rate of water penetration, macro-scale constructs are expected to degrade at a lower rate due to lower surface to volume ratio. Consequently, degradation of micrometer-scale constructs takes weeks to reach 50% of their original mass, and the same takes significantly longer for macroscale constructs. However, on the nanoscale, measuring the percentage of mass remaining may not be practical because the amount of polymers applied on a nanoscale is usually very low (in micrograms) and difficult to recover. Therefore, rate of degradation on a nanoscale is usually monitored via the percentage reduction of

molecular weight (Figure 15, top and right axes) using sensitive analytical techniques such as gel permeation chromatography (GPC), nuclear magnetic resonance (NMR), or matrix-assisted laser desorption/ionization (MALDI).

Molecular weight also plays a role in the rate of degradation of macroscale constructs. The total surface area of the 6 mm OD disk (263 mm^2) is similar to that of 1.4 mm OD hollow cylinders (both cylinders are reported to be identical in size: 258 mm^2; wall thickness = 0.17 mm) and thus the rate of degradation is expected to be similar despite differences in geometry.[61,64] The molecular weight of P(BHET-EOP,TC, 80/20) disk is 7.9 K compared to those of the cylinders which are 14.9 and 18.9 K, respectively.[64] The rate of degradation correlates with the molecular weights: the 7.9 K disk degrades much faster than the cylinders, and the 14.9 K cylinder slightly faster than the 18.9 K cylinder (Figure 16). The reason for an increased rate of degradation can be attributed to a higher degree of water penetration in the lower molecular weight constructs as seen on the graph inset in Figure 16. At all time points, the percentage weight increase

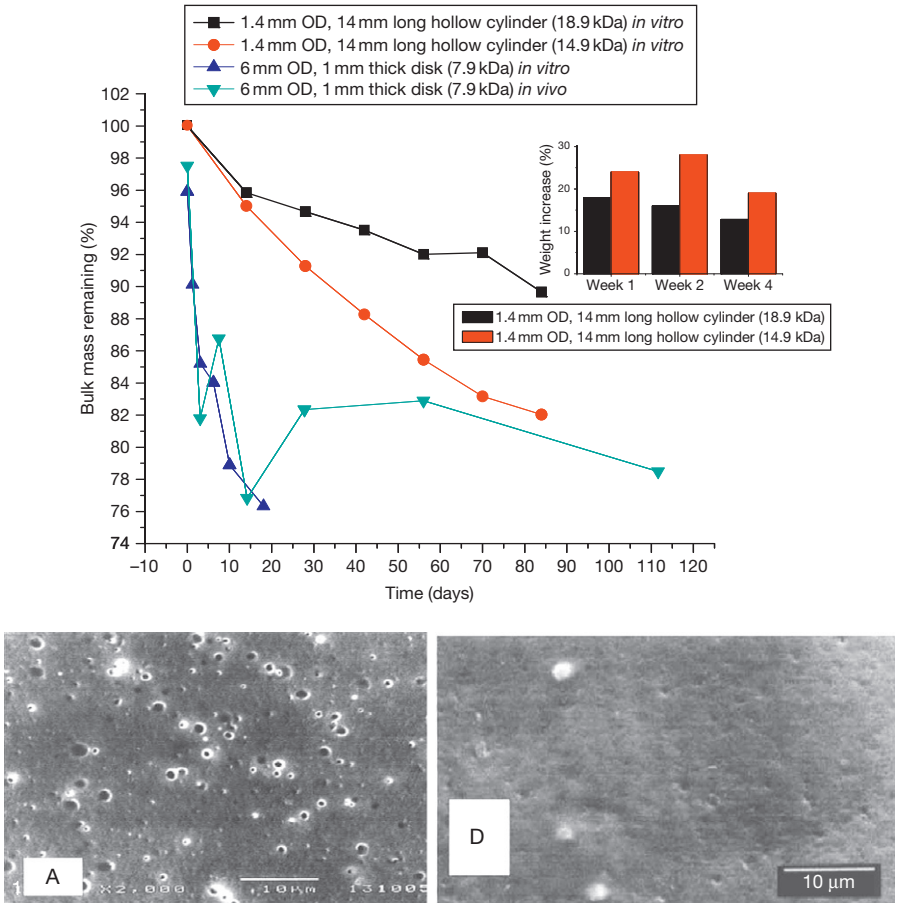

Figure 16 Rate of bulk degradation as a function of molecular weight. Bottom: SEM images of P(BHET-EOP/TC, 80:20) hollow cylinders (left: 14.9 kDa, right: 18.9 kDa). Reproduced from Wang, S.; Wan, A. C. A.; *et al*. *Biomaterials* **2001**, *22*(10), 1157–1169; Mao, H.; Leong, K. W.; Leaf Huang, M.-C. H.; Ernst, W. *Adv. Genet*. **2005**, *53*, 275–306, with permission from Elsevier.

of the 14.9 K cylinder is always higher than its 18.9 K counterpart. While one could attribute a higher degree of water penetration to a more amorphous morphology in the lower molecular weight construct, that may not be the critical factor. SEM images show that cylinders made of lower molecular weight P(BHET-EOP,TC, 80/20) (Figure 16, left) are more porous than their higher molecular weight counterparts (Figure 16, right). This might more likely be the explanation for the higher rate of water penetration and consequently the higher rate of degradation.

Figure 17 shows the correlation between the length scale and the rate of degradation measured in terms of molecular weight (MW) reduction under both *in vitro* and *in vivo* conditions. These data are collated from Mao *et al.*[64] and Chaubal *et al.*[63] There is better agreement between *in vitro* and *in vivo* results on a micrometer scale than on the macroscale. The rate of MW reduction is much faster on a micrometer scale than on the macroscale. Cylinders of 14.9 kDa P(BHET-EOP/TC, 80:20) correlate with a higher rate of MW reduction both *in vitro* and *in vivo*. Together with Figure 16, it can be inferred that lower MW leads to an increase in both the rate of bulk degradation as well as molecular weight reduction. Interestingly, as shown on Figure 18, the positive correlation between bulk degradation and molecular weight reduction differs across length scales. Bulk mass and MW losses on the macroscale correlates linearly, but not so on the micrometer scale, where initial degradation is characterized by a rapid decrease in MW (from 100 to 70%) while bulk mass remains relatively constant (100%).

In summary, the degradation behavior of PPEs is determined by the rate of water penetration into the polymer. Although the polymer can be enzymatically hydrolyzed, for practical applications the rate of degradation can be assumed to be a direct function of water penetration. The latter can be systematically controlled via the backbone structure by copolymerizing PPE with a hydrophobic residue, via the side-chain structure by substituting ethoxy groups with methoxy groups, and via length scale as well as the molecular weight of the polymer.

1.123.8. Toxicity and Biocompatibility of PPEs

The cytotoxicity of a biomaterial is important for practical reasons. Over time, biomaterials break down and release oligomers (partial breakdown) and monomers (complete breakdown). These degradation products are taken up by cells and exert a range of biological effects on them. The culmination of such effects may lead to cell death, which is undesirable in

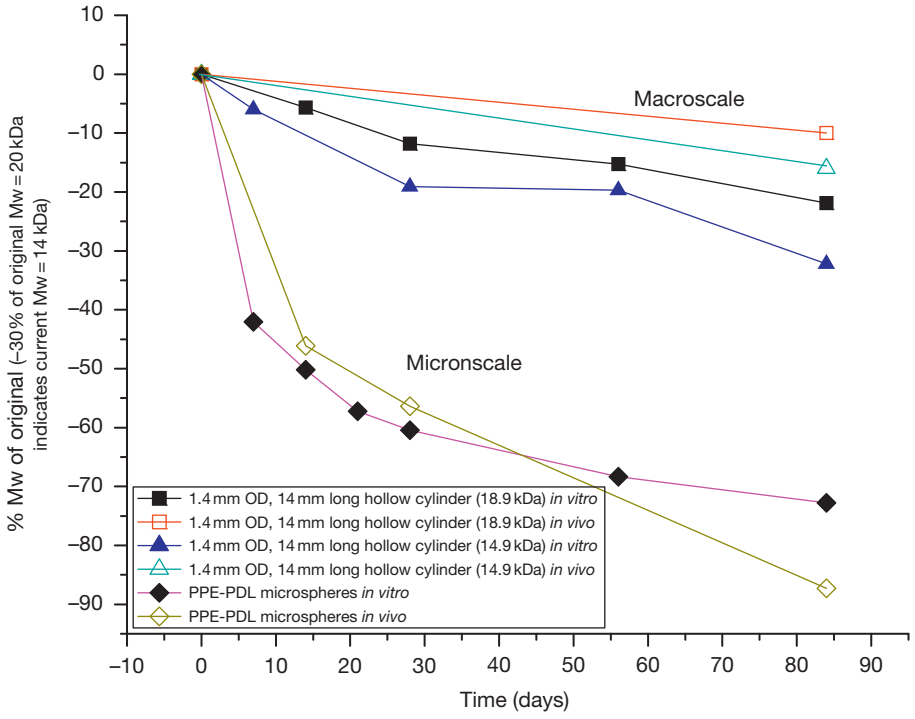

Figure 17 Rate of molecular weight reduction on macro and micro scales. Replotted from Wang, S.; Wan, A. C. A.; *et al*. *Biomaterials* **2001**, *22*(10), 1157–1169; Chaubal, M. V.; Su, G.; *et al*. *J. Biomater. Sci. Polymer Ed*. **2003**, *14*(1), 45–61.

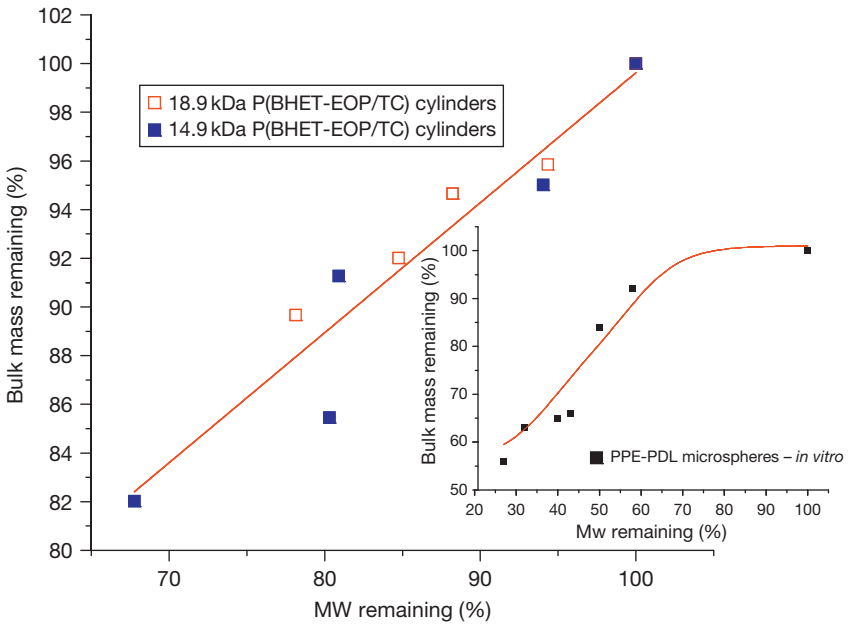

Figure 18 Correlation of mass loss and MW loss. Replotted from Wang, S.; Wan, A. C. A.; *et al*. *Biomaterials* **2001**, *22*(10), 1157–1169; Chaubal, M. V.; Su, G.; *et al*. *J. Biomater. Sci. Polymer Ed*. **2003**, *14*(1), 45–61.

biomedical applications. For PPEs, the major degradation products include aliphatic diols, phosphates, phosphoramides (PPAs), aliphatic amines, and alcohols. Thus by carefully choosing the building blocks of PPEs, the degradation products of PPEs can be biocompatible. The backbones of most PPEs contain α-propylene glycol, which has a favorable safety profile compared to other diols. When PPEs are applied in gene delivery applications, cationic moieties (which are necessary to complex with anionic DNA) are introduced by linking residues containing amino groups to the phosphoryl side chain via

either phosphorous–ester or phosphorous–amide bonds. These amines have also been carefully selected to minimize toxicity.[65]

Cytotoxicity assays for PPEs and PPAs have mostly been assessed using the 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyl-tetrazolium bromide (MTT) assay. A compendium of toxicity data of PPEs and PPAs is given in **Table 3**. As cytotoxicity is cell type dependent, we have also included the cell types in both tables. PPEs in general possess excellent toxicity and biocompatibility profiles and have been evaluated over a wide range of applications. The IC_{50} is commonly used as an indicator of *in vitro* toxicity, and materials with IC_{50} between 500 and 1000 $\mu g\,ml^{-1}$ can be considered excellent. All PPEs (except PPE-HA and PCEP) listed in **Table 3** are reported to have an IC_{50} far greater than 500 $\mu g\,ml^{-1}$. With recently reported PPEs having IC_{50} values greater than 10 $mg\,ml^{-1}$, the safety profile of PPE as a class of polymer is indeed encouraging.

Although the IC_{50} values of PPAs ($>100\,\mu g\,ml^{-1}$) are at least four times higher than that of PEI ($\sim 25\,\mu g\,ml^{-1}$), they are still significantly lower than those of PPEs. PPAs are mostly applied as gene carriers, as they mediate higher transfection efficiencies ($\sim$1 order of magnitude) than their PPE counterparts. Due to this reason, applications of PPA might be limited to gene delivery.

1.123.9. Design of PPE Drug Carriers

1.123.9.1. Amphiphilic PPE Copolymers as Drug Carriers

Biodegradable nanoparticles such as micelles and liposomes have been widely studied as chemotherapeutic drug carriers. The most basic characteristics of amphiphilic copolymers include the ability to self-assemble into a core–shell structure

where the hydrophobic core encapsulates lipophilic drugs and the hydrophilic shell stabilizes the particles and prevents the drug from precipitating out of water. The range of sizes in which these particles form allows passive accumulation via the enhanced permeation and retention (EPR) effect in tumor tissues. As these drug-loaded particles degrade, the hydrophobic drugs can be released in a controlled manner. This basic design has been greatly improved in the recent years to improve circulation time (via pegylation), drug targeting (via ligand conjugation), and environmental responsiveness for payload release (pH, heat, magnetic, light, electricity, etc.). Table 1 (2-1 to 2-5) shows the list of PPE-based drug carriers. The hydrophobic segments are provided by poly-L-lactide (PLLA) or PCL, while the hydrophilic segments are provided by poly(ethyl ethylene) phosphate (PEEP). Structures 2-1 to 2-3 are linear di- or triblock copolymers, while Structure 2-4 (ssPCL-PEEP) is a star-shaped copolymer synthesized starting with a branched polyalcohol. Structure 2-5 (PEG–TEGP), however, does not have any hydrophobic PCL or PLLA segments. Instead, it is synthesized starting with a PEG molecule (as macroinitiator) and extending it with difunctional phosphate monomers, which eventually forms a nanogel with a cross-linked core.

1.123.9.2. Drug-Loading Index

Drug carriers are also characterized by their ability to encapsulate drugs. This is commonly measured using two different parameters: drug-loading capacity (DLC) and drug-loading efficiency (DLE), as defined in Table 4. If a given amount of the drug carrier is unable to fully encapsulate a fixed quantity of the drugs, one would increase the amount of drug carrier to soak up the remainder. At such time, as DLE increases, DLC drops. This inverse relationship is well illustrated by paclitaxel-loaded PCL_x–$PEEP_y$ diblock copolymer (Table 4). For ease of discussion, we define a useful parameter: DLI defined in Table 4 to quantify the overall efficacy of drug loading while factoring in the inverse relationship between DLC and DLE. For example, the DLI of PCL_x–$PEEP_y$ diblock copolymer decreases by almost one-third when polymer/drug ratio is increased from 50 to 200. Even though DLE increases from 77 to 90%, DLC dives from 1.55 to 0.47%. At such time, DLI can be a good indicator of drug-loading characteristics.

Although one would expect a more hydrophobic copolymer to have a higher DLE, there seems to be no apparent structure–DLI relationship for PPE-based block copolymers. The highest DLI for a diblock copolymer is seen for both PCL_{67}–$PEEP_{36}$ and PCL_{150}–$PEEP_{30}$ at 195 and 192, respectively. The highest DLI for a star-shaped diblock copolymer is for $ssPCL_{33}$–$PEEP_{53}$, while that for a triblock copolymer is for $PEEP_{48}$–PCL_{94}–$PEEP_{48}$ without an apparent trend correlating hydrophobic/hydrophilic ratio. PEG–TEGP has the highest DLI due to a heavily cross-linked PEEP core. Moreover, each PEEP repeat unit contains a hydrophobic ethyl side chain, and the combination of both factors could have greatly increased the hydrophobicity and therefore the partition coefficient of doxorubicin into its nanogel interior.

1.123.9.3. Effect of Molecular Structure on Critical Micelle Concentration

Carrier properties can be tuned in a predictable manner by varying the chain lengths of the hydrophobic and/or hydrophilic segments. For triblock copolymers, the critical micelle concentration (CMC) can be systematically adjusted by varying the chain length (i.e., degree of polymerization, DP) of the hydrophilic segment (PEEP). Data obtained from two different triblock copolymers (PEEP–PLLA–PEEP by Yang *et al.*[66] and PEEP–PCL–PEEP[67]) are collated and analyzed.

Table 4 Drug-loading characteristics of polyphosphoester-based drug carriers

No.		x	y	*Carrier:drug ratio*	*DLC (%)*	*DLE (%)*	*DLI (%)*
1	PCL_x–$PEEP_y$ diblock copolymer (paclitaxel) micelles	67	36	10	4.42	44.2	195
				20	2.87	57.5	165
				50	1.55	77.4	120
				200	0.47	92.9	44
2	PCL_x–$PEEP_y$ (doxorubicin) micelles	150	30	10	4.38	43.8	192
3	$ssPCL_x$–$PEEP_y$ star-shaped diblock copolymer (paclitaxel) micelles	33	25	10	1.62	16.19	26
		33	35	10	2.64	26.38	70
		33	53	10	3.46	34.59	120
		33	69	10	2.09	20.88	44
		44	32	10	2.79	27.86	78
		69	35	10	2.52	25.08	63
		69	56	10	2.63	26.28	69
4	$PEEP_y$–PCL_x–$PEEP_y$ triblock copolymer (paclitaxel) micelles	27	44	10	0.56	5.6	3
		36	7	10	0.92	9.2	8
		36	21	10	1.56	15.6	24
		36	49	10	1.32	13.2	17
		63	45	10	2.46	24.6	61
		94	48	10	3.16	31.6	100
		186	49	10	1.81	18.1	33
5	$[PEG_{5kDa}]_x$–$[TEGP]_y$ nanogel	1	5	10	9.10	91.0	828

Drug-loading capacity (DLC) = Weight of drug loaded in carrier/weight of drug-loaded carriers × 100%; Drug-loading efficiency (DLE) = Weight of drug loaded in carrier/weight of drug used for loading × 100%; Drug-loading index (DLI) = DLC × DLE.

When DP is plotted against CMC, some results are highly consistent and collapsed into a straight line as shown in Figure 19. The empty symbols plotted for PEEP–PLLA–PEEP and PEEP–PCL–PEEP are obtained by varying the chain length (i.e., DP) of the PEEP segment while keeping, respectively, PLLA (DP = 29) and PCL (DP = 36) segments constant. Linearity is not observed when PLLA and PCL segments are varied while keeping PEEP segment constant. Instead, only a general trend is observed describing a decrease in CMC when PLLA and PCL segment lengths are increased. This is expected because the molecular structures of PLLA and PCL are inherently different. Figure 19 points to the possibility of varying the physicochemical properties of drug carriers in a predictable manner by adjusting the length of the PPE backbone. Also, an inverse relationship ($y = 1/x$) exists between the CMC and the hydrophobic/hydrophilic ratio (Figure 20). The CMC approaches asymptotically to about 0.6 mg l^{-1} while the hydrophobic/hydrophilic ratio approaches 0.25. As the final drug carrier design is almost always a compromise among various factors, from a rational design standpoint these values provide useful guidance in drug carrier design and optimization.

1.123.9.4. Drug Release Kinetics

As drug carriers degrade over time, hydrophobic drugs are released from its core. At such time, the rate of drug release is a function of rate of degradation of the drug-loaded carrier. As the rate of degradation for PPE is dependent on water penetration, a carrier with a longer hydrophobic segment is expected to have a slower rate of drug release as water penetration is impeded. The drug release characteristics of diblock copolymers are collated and replotted on Figure 21. The rate of doxorubicin release by PCL_{150}–$PEEP_{30}$[56] is much slower than that of paclitaxel by PCL_{67}–$PEEP_{36}$[68] even though doxorubicin itself is more soluble than paclitaxel. This can be attributed to a more hydrophobic core that impedes water penetration needed for the degradation of both phosphoester (in PEEP) and polyester bonds (in PCL). These structures are listed in Table 1 (2-2, 2-3).

The same phenomenon is observed in the star-shaped PCL–PEEP copolymer,[69] with $ssPCL_{33}$–$PEEP_{69}$ having the highest PEEP content and hence the highest drug release rates (Figure 21). This is followed by $ssPCL_{69}$–$PEEP_{56}$ (PCL:PEEP = 1.23) and $ssPCL_{44}$–$PEEP_{32}$ (PCL:PEEP = 1.38), respectively, with the former having a slightly higher rate of release due to a slightly lower PCL:PEEP content in the copolymer backbone. When seen over a time scale of days, it can be observed that all copolymers, despite differences in molecular structures and segment lengths, have similar burst release characteristic, diverging after about 20% of it payload is released. At such, the graph at the early time points are expanded (inset of Figure 21) and further analyzed. In time scales of hours, there are differences in rate of drug release; however, 20% of total payload is released after 18 h of incubation in PBS (experimental conditions used for various drug release studies). Therefore, it is also important to consider the time scale of the intended drug delivery application. If the time scale is in the order of days, one may assume a burst release characteristic of 20% for all copolymers and focus on the drug release rate after 18 h, using the molecular structure of the drug carrier to design a desired rate of release. On the other hand, if the intended application requires drug release rates over a short period of 18 h, direct infusion might be a simpler and more reliable alternative. Similar trends are observed in triblock copolymers[67] in Figure 22. As the PCL segment is increased, the rate of drug release drops correspondingly.

Structure 3-5 (PEG–TEGP) is a nanogel with PEG arm and a cross-linked PEEP core.[57] The PEG arm is expected to increase the circulation time of the nanogel in the body, while the heavily cross-linked PEEP core provides the

hydrophobic core needed for drug encapsulation. PEG–TEGP has a high DLI contributed by both a higher DLC (9.1%) and DLE (91%) (Table 4). However, the heavily cross-linked PEEP core might not have allowed sufficient water to penetrate into its interior. Therefore, the drug is released at a very slow rate after the initial burst.
