History. Although primary HCMV infection in the immunocompetent patient is usually asymptomatic, some can present with an infectious mononucleosis-like picture.[157] Approximately 10% of infectious mononucleosis cases are caused by HCMV. Symptoms and signs are indistinguishable from EBV-induced mononucleosis, including fever, malaise, splenomegaly, hepatitis, peripheral, and atypical lymphocytosis. Unlike EBV mononucleosis, HCMV-induced mononucleosis patients do not typically have pharyngitis and lymphadenopathy.[158] Given the lack of heterophile antibodies, HCMV mononucleosis is also known as heterophile-negative mononucleosis. Postperfusion syndrome is the term used when HCMV mononucleosis occurs between 3 and 6 weeks after exposure to blood products.[159]

Reactivation of various herpesviruses including HCMV, EBV, HHV6, and HHV7 has been reported in the setting of drug induced hypersensitivity syndrome (DIHS), which, in some cases, might lead to multiorgan failure after the offensive drug is discontinued.[160]

Cutaneous Lesions. A few patients with HCMV mononucleosis develop a rubelliform or morbilliform eruption; if given ampicillin, 80%–100% develop a

morbilliform rash within 1 week (see eFig. 192-10.1 in online edition).[161] There have been reports of erythema nodosum[162] and urticaria[83] associated with acute HCMV mononucleosis. Cutaneous ulcers due to CMV have been reported in patients with severe cases of DIHS.[163]

HUMAN CYTOMEGALOVIRUS AND THE IMMUNOCOMPROMISED

History. Immunocompromised patients are at risk for HCMV primary infection as well as reactivation resulting in persistent viremia and disseminated systemic disease.[164] Immunosuppressive agents such as azathioprine and cyclophosphamide alone can reactivate HCMV disease, as can systemic corticosteroids in conjunction with other immunosuppressive agents.

Solid Organ Transplant Recipients. SOT recipients not infected with HCMV receive an organ from an HCMV-positive individual are at highest risk of developing HCMV disease posttransplantation. Other risk factors include therapy with anti-T-cell antibody (OKT3)[165] and those who undergo HHV-6 seroconversion.[166] Initial infection of the transplanted organ is followed by pneumonitis, enteritis, hepatitis, retinitis, and central nervous system disease.[167]

Bone Marrow Transplant Patients. The risk of HCMV disease in BMT patients is lower with the use of seronegative donors and use of leukocyte-depleted blood products.[168] Risk factors for reactivation include a seropositive recipient, graft-versus-host disease (GVHD), and T-cell depletion of allograft. Pneumonitis has a 60%–80% mortality without treatment and 50 % mortality with antiviral treatment and cytomegalovirus immune globulin.

Human Immunodeficiency Virus-Infected Patients. HCMV retinitis was seen in up to 25% of HIV-infected patients before the use of highly active antiretroviral therapy (HAART).[169] Now, immune recovery vitreitis with posterior segment inflammation is seen as CD4 counts recover after initiation of HAART.[170] Encephalopathy, peripheral polyradiculopathy, pneumonitis,[167] and colitis[171] may occur.

Cutaneous Lesions. Cutaneous manifestations of HCMV disease in immunocompromised patients are rare compared with involvement of other organs. Perianal and rectal ulceration are most common (Fig. 192-11).[172] Also seen are indurated hyperpigmented nodules or plaques,[173] papular and purpuric eruptions,[172] vesiculobullous lesions,[174] purpura, petechiae,[175] indurated plaques, and nodules (see eFig. 192-11.1 in online edition). Verrucous and necrotic nodules have been reported in HIV-infected patients.[164] Some of these cutaneous manifestations may be caused by infection of the endothelium of cutaneous blood vessels.[176]

Figure 192-11 Infant with AIDS and diaper dermatitis-like disseminated HCMV. (From Thiboutot DM et al: Cytomegalovirus diaper dermatitis. *Arch Dermatol* **127**:396,1991, with permission.)

LABORATORY TESTS

The gold standard for diagnosis of HCMV infection is viral culture from blood using human fibroblasts. Infection is determined by cytopathic effect. However, it takes days to several weeks to see the cytopathic effect in culture. The diagnosis of congenital HCMV infection can be made by detection of virus in urine or saliva via culture or PCR (Fig. 192-12).[177]

The characteristic histologic feature of cytomegalovirus (CMV) infection is cytomegalic cells with nuclear inclusions. In the skin, enlarged endothelial cells with large intranuclear inclusions and a clear halo (owl's eye cells) are seen in small dermal vessels.[178] Cytopathic changes seen in the vascular lumen vary according to the stage of infection of each cell, including intranuclear and intracytoplasmic inclusions (Figure 192-13). Histologic diagnosis is specific but sensitivity is low.[179]

Various fast and reliable methods for detection of HCMV antigens and nucleic acids in cells and tissue are available. These include HCMV antigenemia assay (detects pp65 in peripheral blood neutrophils), hybrid capture assay (detects HCMV DNA in leukocytes), and quantitative and qualitative PCR. In immunocompetent individuals, IgM is usually positive during primary infection. The reported sensitivity of commercially available ELISA for HCMV IgM varies. Rheumatoid factor and EBVIgM may yield false-positive results.[180] IgG may be negative during active infection, but subsequent fourfold rise in IgG titer is indicative of infection.

The diagnosis of invasive CMV disease can be challenging because the presence of the virus does not mean causality given that the virus establishes latency after primary infection.

DIFFERENTIAL DIAGNOSIS

(Boxes 192-9 and 192-10)

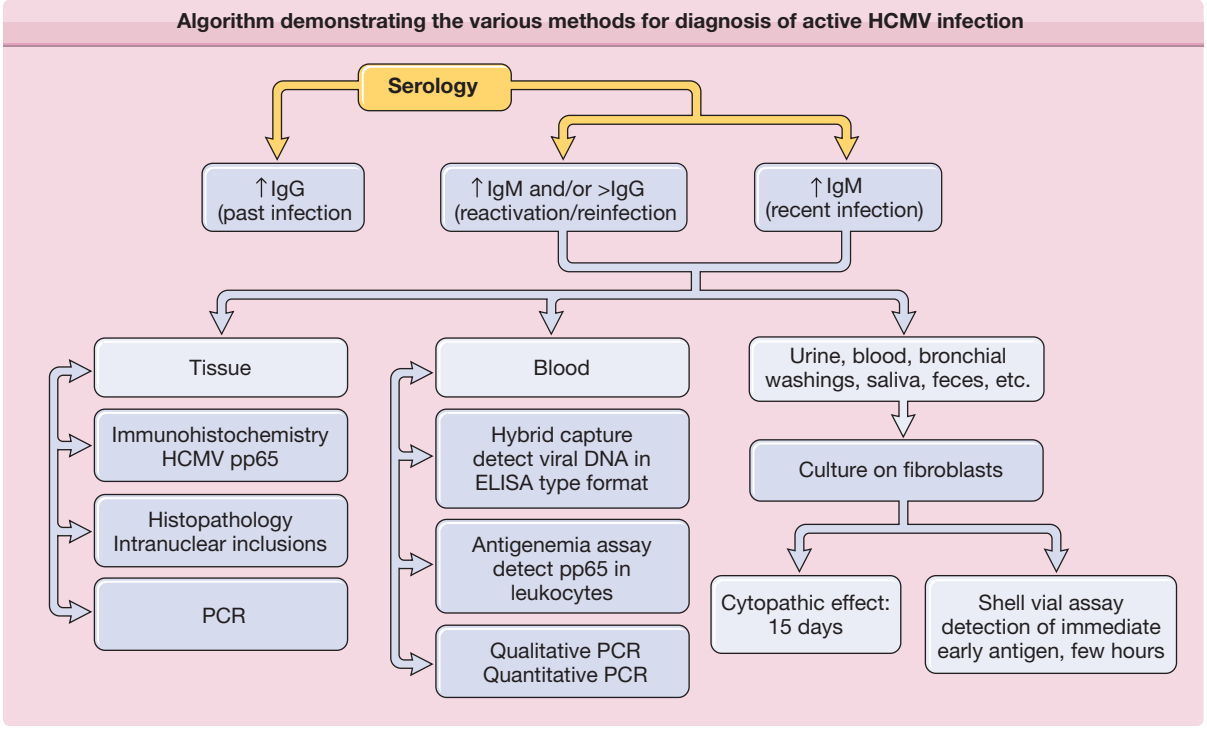

Figure 192-12 Algorithm demonstrating the various methods for diagnosis of active HCMV infection.

COMPLICATIONS

Possible complications of postnatal HCMV infection include interstitial pneumonia, hemolytic anemia, splenic infarction, thrombocytopenia and hemolytic anemia, hepatitis, Guillain–Barré syndrome, meningoencephalitis, myocarditis, arthritis, and gastrointestinal/genitourinary syndromes (i.e., colitis, esophagitis, cervicitis, and urethral syndromes).[143,149]

PROGNOSIS AND CLINICAL COURSE

HCMV disease in immunocompetent individuals is usually self-limited. In immunocompromised patients with systemic HCMV disease, the prognosis is poor and mortality 85%.[181]

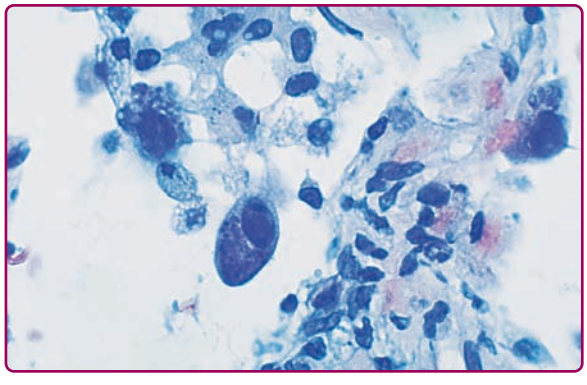

Figure 192-13 Intracellular inclusions in a cell infected by human cytomegalovirus. (From Konstadt JW et al: Disseminated cytomegalovirus infection with cutaneous involvement in a heart transplant patient. *Clin Cases Dermatol* **2**:2,1990, with permission.)

TREATMENT

HCMV infection in immunocompetent hosts is usually asymptomatic or self-limited, not requiring

treatment with antiviral drugs. Ganciclovir, valacyclovir, foscarnet, and cidofovir have been approved for systemic treatment of HCMV disease.[182] HAART is effective in suppressing HCMV viremia and preventing CMV retinitis in acquired immunodeficiency syndrome patients without end-organ disease.[183] Ganciclovir and valacyclovir are also used for HCMV prophylaxis.[143,182] None of these drugs is recommended for treatment of symptomatic congenital HCMV infection.

PREVENTION

Prevention of HCMV infection in transplanted patients can be achieved with use of blood and tissues from HCMV-negative donors.[168] Preemptive (at time of high risk for disease but before symptoms) or prophylactic treatment can be used for immunocompromised individuals at risk of infection from blood transfusions or organ transplantation with ganciclovir.[149] Risk factors evaluated for preemptive therapy include CMV viremia and GVHD. The use of prophylactic versus preemptive therapy remains controversial.[184–186]

HUMAN HERPESVIRUS 6

HUMAN HERPESVIRUS 6 AT A GLANCE

- Causes exanthema subitum (roseola infantum, sixth disease).
- Febrile seizures often without rash in children.
- High seroprevalence in general population by 1 year of age.
- Reactivation in immunocompromised individuals is cause of morbidity.

EPIDEMIOLOGY

HHV-6 has been identified as a causative agent for exanthem subitum (ES), also known as roseola infantum and sixth disease.[187] ES is usually seen in children ages 6 months to 4 years.[188–190] The seroprevalence of HHV-6 in the adult population is greater than 95%.[189] Seroprevalence is high in the first few weeks of life and subsequently declines as maternal antibodies wane. It rises again by 1 year of age, with its peak between 3 and 5 years of age, and declines with advancing age.[190,192–194] There is a discrepancy between the seroprevalence of HHV-6 and the incidence of ES, mainly thought to be due to the varied clinical manifestations of HHV-6 infection and subclinical HHV-6 infection.[195] Primary HHV-6 infection in children can result in a subclinical infection or an acute febrile illness without cutaneous manifestations.[196–197] There is seasonal variation of HHV-6 infection with highest incidence in spring; summer and fall epidemics have also been reported.[191]

ETIOLOGY AND PATHOGENESIS

HHV-6 is a member of the β-Herpesviridae subfamily. There are two distinct variants by restriction enzyme analysis, HHV-6a and -6b.[198] They are different in their immunologic, biologic,[199] and genetic[198] characteristics. HHV-6b causes ES, but it is unclear what diseases, if any, are caused by HHV-6a.[200]

The cellular receptor for HHV-6 is CD46.[201] The mode of transmission is proposed to be via nasopharyngeal viral shedding from healthy individuals.[202] Airborne transmission is likely via saliva.[203] HHV-6 has been isolated from the saliva of healthy individuals[188–190] and viral shedding is intermittent, not associated with changes in antibody titers.[188] HHV-6 DNA is found in the cervix of infected women,[204] raising the question of possible perinatal infection, although children of mothers with positive swabs do not acquire early HHV-6 infection. HHV-6 DNA has also been found in fetal tissue from spontaneous abortions.[205,206] HHV-6 is not transmitted through breast milk.[191] Transmission in transplant patients can occur via the grafted organ.[207,208] The incubation period for HHV-6 infection is 5–15 days, with an average of 10 days. Viremia in immunocompetent children lasts 3–4 days in ES, whereas viremia from HHV-6 reactivation in allogeneic BMT patients lasts weeks.[209]

HHV-6 replicates in salivary glands,[210] where it can establish a persistent infection.[191] It is tropic for $CD4^+$ T lymphocytes in vitro[211,212] and establishes latency in human peripheral blood monocytes/macrophages[213] and early bone marrow progenitors.[214] HHV-6 genome is able to integrate into the host cell DNA at the ends of chromosomes 1, 17, and 22.[191]

HHV-6 can reactivate from latency in immunosuppressed individuals.[191,206,215] A synergistic effect on disease of HHV-6 and CMV has been described in renal transplant recipients.[216,217] HIV and HHV-6 also appear

to be synergistic. The clinical importance of this finding remains to be elucidated. Unlike in transplant patients, there does not seem to be one specific clinical syndrome of HHV-6 infection in HIV-infected patients.[191]

CLINICAL FINDINGS

HISTORY. Primary infection with HHV-6 results in an acute febrile illness typically in children 6 months to 1 year of age.[191] The fever lasts approximately 3–7 days[191] and can be followed by the characteristic rash of roseola in a minority of children.[197,218,219]

HHV-6 infection is seen in 40%–50% of transplant recipients (BMT more than SOT) and peaks at 2–4 weeks posttransplantation. Approximately one-half of these infections result in symptomatic disease with bone marrow suppression.[220]

CUTANEOUS LESIONS

Exanthem Subitum. Palpebral edema can be evident from the first to third day of fever, resulting in a "sleepy" appearance, and resolves after a day of the exanthema.[221] Erythematous papules on the soft palate (Nagayama spots) may precede the viral exanthema.[221] The exanthem is seen from 1 day before to 1–2 days after the fever fades and lasts for 3–5 days.[221] It is characterized by rose red macules or papules 2–5 mm in diameter, surrounded by a white halo. These are distributed mainly on the neck and trunk and sometimes on the face and proximal extremities (Fig. 192-14). Desquamation is not usually seen.

Transplant Recipients. A rash similar to acute GVHD has been described in pediatric patients undergoing BMT who have HHV-6 reactivation.[222,223] Fever and/or rash are the most common manifestations of HHV-6 infections in SOT recipients.[191]

Human Immunodeficiency Virus Patients. HHV-6 can be an opportunistic pathogen in HIV patients, causing encephalitis and pneumonitis in some cases.[191] But most case reports do not show one consistent clinical syndrome in HIV patients.[191]

PITYRIASIS ROSEA. (See Chapter 42 and Section "Human Herpesvirus 7").

Rosai–Dorfman Disease
(See Chapter 148). HHV-6 genome has been detected in tissue from patients with sinus histiocytosis with massive lymphadenopathy or Rosai–Dorfman disease,[224] and immunohistochemical studies suggest a possible pathogenic involvement.[225]

RELATED PHYSICAL FINDINGS. Patients with ES may have high fever, malaise, inflamed tympanic membranes, conjunctival injection, gastrointestinal and respiratory tract symptoms, cervical lymphadenopathy, and bulging fontanelle.[221,226] A mononucleosis-like infection, which is EBV- and CMV-negative, has been attributed to HHV-6 in children and adults.

LABORATORY TESTS

Although laboratory results may be variable in HHV-6 primary infection, one can see leukopenia (between 3,000 and 6,000 cells/mm^3) with an increased percentage of lymphocytes between days 3 and 6 of the illness. White blood cell count elevation can be seen at

Figure 192-14 **A** and **B.** Exanthem subitum in an infant showing truncal pink macules and some papules that appeared one day after defervescence.

the beginning of the febrile phase. HHV-6 infection is usually benign and self-limited; however, in atypical cases, serologic studies may be valuable. This can be done by ELISA or by indirect immunofluorescence. Anti-HHV-6 IgM antibodies are a marker of recent infection or reactivation, but 5% of adults may be IgM seropositive at any time. IgM develops after 5–7 days of infection, peaks at 2–3 weeks, and disappears in 2 months. IgM alone is not reliable.[227] A fourfold IgG increase between acute and convalescent sera IgG indicates active infection.

Laboratory tests vary in their ability to distinguish latent virus from actively replicating virus. PCR detection of HHV-6 DNA in cell-free serum, plasma, or CSF indicates active replication, whereas a positive PCR from cellular material does not indicate active replication because the virus can be found latent in cells. Viral culture is not used routinely because it is technically difficult and may take more than 1 week. A combination of a positive serum IgM with positive PCR of whole blood DNA in patients older than 3 months of age has excellent specificity and sensitivity, and positive and negative predictive value for primary infection.[196,228] Although not routinely available, quantitative PCR allows fast, sensitive, and absolute quantitation of viral load, making it a method of choice.

COMPLICATIONS

Febrile seizures are thought to occur in 10% of children with primary HHV-6 infection.[191] Rarely, encephalitis has been reported in children with fatal or severe sequelae such as hemiparesis.[196] Although usually a benign infection, rare complications include hepatitis, hemophagocytic syndrome, pneumonitis, and thrombocytopenia.[191,195] Hemophagocytic syndrome has been reported on reactivation of HHV-6 in an immunocompetent adult.[229]

HHV-6 infection or reactivation in the immunocompromised can also result in hepatitis,[208] pneumonitis,[230,231] bone marrow suppression,[232,233] and graft dysfunction or rejection.[215] Reactivation of HHV-6 in the immunocompromised host can result in encephalitis and/or encephalopathy.[191] There have been reports of fulminant multifocal demyelinating disease in both immunocompetent and immunocompromised patients. The contribution of HHV-6 infection to progressive multifocal leukoencephalopathy or multiple sclerosis is being studied.[191]

PROGNOSIS AND CLINICAL COURSE

ES is benign and self-limiting. Treatment may be necessary for atypical cases with complications and in immunosuppressed patients. Primary infection can be fatal in the immunocompromised host.

TREATMENT

There are no controlled clinical trials, and no compounds have been formally approved for treatment of HHV-6 infection. The same drugs used for HCMV treatment and prophylaxis have been used for HHV-6. The activities of various antiviral compounds against HHV-6 have been tested in vitro.[234,235] Several case reports support the clinical effectiveness of ganciclovir in HHV-6 treatment and prophylaxis.[191] Foscarnet and cidofovir might also prove to be useful.[189] New antiherpesvirus drugs are being developed, although most are not active against HHV-6.[191] Further studies are needed before treatment and prophylaxis can be recommended.

PREVENTION

Prophylaxis with ganciclovir may prevent HHV-6 reactivation in BMT and stem cell transplant recipients,[236] but low-dose prophylaxis may facilitate the development of resistance. Preemptive therapy (treatment after systemic detection of virus but before clinical symptoms of disease) has been proposed instead.[191]

HUMAN HERPESVIRUS 7

HUMAN HERPESVIRUS 7 AT A GLANCE

- Causes a small subset of cases of exanthem subitum.
- Primary infection typically occurs later in life than human herpesvirus 6 infection.

EPIDEMIOLOGY

In seroconversion studies, 10% of ES cases are caused by HHV-7.[237] Primary infection occurs during childhood, but later than[238] and at a slower rate than infection with HHV-6[239]; both viruses are ubiquitous in adulthood. HHV-7 can be isolated from saliva samples of healthy seropositive adults.[240]

ETIOLOGY AND PATHOGENESIS

HHV-7 is a member of the β-Herpesviridae family. It has significant homology to HHV-6; however, it is serologically and biologically distinct. It was initially isolated from $CD4^+$ T lymphocytes from a healthy adult [241] has been identified as the cellular receptor for HHV-7.[242]

HHV-7 establishes persistent infection in salivary glands,[243] transmission might be through saliva.[195] Latent virus can be activated in vitro from peripheral blood mononuclear cells[244] and its DNA can be found in $CD4^+$ T cells. Similar to many other herpesviruses,[245,246] HHV-7 can downregulate expression of CD4[247] and major histocompatibility complex class I,[248] which may play a role in establishment of latency or pathogenesis.

Reactivation of HHV-7 occurs more often than reactivation of HHV-6.[239]

CLINICAL FINDINGS

EXANTHEM SUBITUM. HHV-7 causes a small subset of ES cases. When HHV-7 is associated, ES tends to occur later in life than when HHV-6 is associated.[196] The rash associated with HHV-7 is lighter in color and occurs later in the course of the disease than HHV-6-associated ES.[249]

PITYRIASIS ROSEA. (See Chapter 42). HHV-7 DNA has been isolated from skin biopsy specimens, peripheral blood mononuclear cell, and plasma of patients with pityriasis rosea and not controls.[250] However, these findings have not been confirmed by other studies.[251–254] It is possible that the inflammatory milieu in pityriasis rosea activates HHV-7 and HHV-6 within the lesions, but there is no evidence for causality.

LICHEN PLANUS. HHV-7 DNA and virion-like structures have been found in lesional lichen planus skin samples compared to nonlesional skin and psoriatic skin samples.[255] Although suggestive, further studies are needed to establish a causal relationship. HHV-7 has also been found to be the associated with febrile seizures in children.[256]

LABORATORY TESTS

There is limited cross reactivity between HHV-7 and HHV-6 in serologic studies.[257] Due to high prevalence, a single positive IgG is not sufficient to establish a diagnosis. Culture from peripheral blood mononuclear cells takes 1–3 weeks, and it is not widely available. PCR is more widely available and is useful for timely diagnosis. Diagnosis of active infection by PCR can only be made from acellular material such as CSF, serum, or plasma, because the virus is latent in peripheral blood mononuclear cells and tissue. Immunohistochemical studies for viral antigens in biopsy specimens can be performed.[258]

DIFFERENTIAL DIAGNOSIS

(Box 192-11)

BOX 192-11 DIFFERENTIAL DIAGNOSIS FOR HUMAN HERPESVIRUS 6 AND HUMAN HERPESVIRUS 7 ASSOCIATED EXANTHEM SUBITUM

Most Likely
- Human herpesvirus-associated exanthem subitum
- Drug hypersensitivity reaction
- Enterovirus (including coxsackie, echovirus)

Consider
- Rubella (German measles)
- Measles/rubeola
- Adenovirus
- Epstein–Barr virus
- Fifth disease (erythema infectiosum, parvovirus)

Always Rule Out
- Scarlet fever
- Kawasaki disease

COMPLICATIONS

Complications of HHV-7-associated ES include acute hemiplegia and febrile seizures with CSF findings consistent with encephalitis[259] and hepatitis.

PROGNOSIS AND CLINICAL COURSE

ES is a self-limiting disease, which does not require specific antiviral treatment. Disease in immunocompromised can be more serious and require treatment.

TREATMENT

Treatment for HHV-7 has not been evaluated in clinical trials but could be guided by treatment recommendations for HHV-6.

ENTEROVIRUSES

Human enteroviruses may cause a variety of exanthems and clinical syndromes. They are small, single-stranded RNA picornaviruses and include echovirus, coxsackievirus A and B, enterovirus, and poliovirus.[260] Most enteroviral infections are benign. However, nonpolio enteroviruses are the most common cause of aseptic (viral) meningitis.[261] Enteroviruses can also cause life-threatening infections with encephalitis, myocarditis, and sepsis.[261] These are more common in neonates and immunocompromised individuals. Enteroviral infections are seen throughout the year, but many epidemics occur in the summer and fall. The viruses are primarily spread via the fecal–oral route or more rarely oral–oral or respiratory routes. Common source water exposures may also be responsible. Typical incubation period is 3–6 days.

The exanthems seen with enteroviruses are often nonspecific and not very dramatic, with small pink macules and papules that resolve in a few days. Petechiae and purpura are frequently present (Figs. 192-15A and 192-15B). When a petechial rash due to an enterovirus accompanies high fever and meningeal signs and symptoms, the clinical picture may mimic meningococcemia.

Figure 192-15 **A** and **B.** Purpuric macules and papules in a 4-year-old girl with enteroviral infection.

HAND-FOOT-MOUTH DISEASE

HAND-FOOT-MOUTH DISEASE AT A GLANCE

- Viral exanthem seen mostly commonly in children in summer and fall.
- Erosions in the mouth and papulovesicles on the palms and soles.
- Caused by enteroviruses including coxsackievirus A16 and enterovirus 71.
- Self-resolving without serious sequelae in the majority of cases but may have serious complications when caused by enterovirus 71.

EPIDEMIOLOGY. Hand-foot-mouth disease (HFMD) is the best-recognized enteroviral exanthem with worldwide distribution that is usually self-limited. There is a slight male predominance. Children less then 10 years of age are most frequently affected and infected adults rarely show signs of infection. Similar to exanthems caused by other enteroviruses, HFMD occurs more during summer and fall in temperate climates and throughout the year in the tropics.[170,262–268] Outbreaks may be sporadic or in epidemics. The largest recorded epidemic was in Taiwan in 1998. This epidemic was caused by enterovirus 71 and affected over 120,000 people and caused 78 deaths.[269] Children under the age of 5 years were the most severely affected and the majority of deaths were secondary to pulmonary edema and hemorrhage.

Transmission is via the fecal–oral route and, less commonly, respiratory inhalation. There is a high transmission rate among household contacts as has been documented with studies of epidemics.[268] Once inhaled or ingested, virus replication ensues in the oropharynx and/or gastrointestinal tract with subsequent viremia. The incubation period of HFMD is believed to be short, lasting 3–6 days, with viral shedding lasting up to 5 weeks.[270]

ETIOLOGY AND PATHOGENESIS. HFMD is caused by a number of nonpolio enteroviruses, including coxsackieviruses A5, A7, A9, A10, A16, B1, B2, B3, B5, echoviruses, and other enteroviruses. The most common causes are coxsackie A16 and enterovirus 71. Enteroviruses belong to the Picornaviridae family, which are single-stranded RNA viruses.

CLINICAL FINDINGS

History. After an incubation phase of 3–6 days, affected individuals may complain of a low-grade fever, malaise, abdominal pain, and upper respiratory tract symptoms.

Cutaneous Lesions. Nearly all cases of HFMD have painful oral lesions. These are generally few in number and are found on the tongue (Figs. 192-16A and 192-17A), buccal mucosa, hard palate, and, less frequently, the oropharynx. The lesions start as bright pink macules and papules that progress to small 4–8 mm vesicles with surrounding erythema. These quickly erode and form yellow to gray erosions surrounded by an erythematous halo. The time between

Figure 192-16 **A.** Toddler with vesicles and surrounding erythema on the tongue from hand-foot-mouth disease. **B** and **C.** Elliptical, "football-shaped" vesicles with halo of erythema on the palms and soles in the same patient.

Figure 192-17 **A.** Hand-foot-mouth disease is clinically identical in adults. Shallow ulcerations on the tongue that are part of the oral lesions of hand-foot-mouth disease caused by coxsackievirus A16 infection. **B** and **C.** Vesicular lesions on the fingers and feet.

vesicle and erosion is short, and most patients have erosions by the time they visit their physician.

Cutaneous peripheral lesions are present in two-thirds of patients and appear soon after the oral lesions.[271] The lesions are most common on the palms, soles (see Figs. 192-16B and 192-16C and 192-17B and 192-17C), sides of hands and feet, buttocks (see eFig. 192-17.1 in online edition) and, occasionally, external genitalia, and on the face and legs. They evolve similarly to the oral lesions, starting as red macules that become clear oval, elliptical (football shaped), or triangular vesicles with surrounding red halos (see Figs. 192-16 and 192-17) The number of lesions ranges from few to numerous and run parallel to the skin lines on fingers and toes. After crusting, they heal in 7–10 days.

Related Physical Findings. HFMD usually begins with a nonspecific prodrome, including low-grade fever [38°C–39°C (100.4°F–102.2°F)] that lasts 1–2 days, malaise, and, occasionally, abdominal pain or upper respiratory tract symptoms. Sore throat or sore mouth is common and may lead to poor oral intake and dehydration. Cervical and submandibular lymphadenopathy may be present.

LABORATORY TESTS.

No laboratory tests are indicated. If an epidemic is suspected, stool and throat cultures may be helpful in determining the strain and, therefore, possible complications.

SPECIAL TESTS.

Historically, enteroviral infection was verified by viral culture, which lacked sensitivity, and suckling mouse inoculation, which detected neutralizing antibodies. Confirmation of enteroviral infection can be done by using viral culture or PCR-based assays. Virus can be recovered from skin vesicles as well as throat and stool swabs. PCR is most widely employed for CSF samples and can help to identify serotypes in severe enteroviral infection.

Skin biopsies are not typically performed. Nonspecific findings such as intraepidermal blister formation from vacuolar and reticular degeneration of keratinocytes is seen as in other viral blisters.

DIFFERENTIAL DIAGNOSIS.

(Box 192-12)

BOX 192-12 DIFFERENTIAL DIAGNOSIS OF HAND-FOOT-MOUTH DISEASE

Most Likely
- Herpangina

Consider
- Varicella
- Aphthous stomatitis
- Drug eruption
- Erythema multiforme

Always Rule Out
- Herpes gingivostomatitis

COMPLICATIONS.

Patients rarely experience complications from HFMD. One rare complication, called eczema coxsackium, occurs in individuals with eczema. These patients develop disseminated cutaneous viral infection similar to that seen in eczema herpeticum.[272] The most common serious complication associated with HFMD is aseptic meningitis. Aseptic meningitis is rarely life threatening, and patients do not develop permanent sequelae. Epidemics in Taiwan of enterovirus 71 have resulted in severe disease with encephalitis, encephalomyelitis, polio-like syndromes, myocarditis, pulmonary edema, pulmonary hemorrhage, and death.[266,267,273] Serious complications are less frequent in cases associated with coxsackievirus A16 than with enterovirus 71.[266]

PROGNOSIS AND CLINICAL COURSE.

HFMD is usually a benign, self-limited illness that resolves within 7–10 days. Occasionally, cases associated with more prolonged fever, systemic symptoms, diarrhea, and joint pains have been reported.[274]

TREATMENT.

Treatment is typically supportive with attempts to reduce discomfort. Early treatment with milrinone, a cyclic phosphodiesterase inhibitor, has the potential to significantly reduce mortality in the management the enterovirus 71-induced illness.[275] Intravenous administration of human IgG has been used in China since 2000, with some success, to treat severe cases of enterovirus 71 infection.[276]

PREVENTION.

During epidemics, public health measures should be instituted to decrease morbidity. Measures such as universal precautions, dissuading attendance at childcare centers or kindergarten, and isolating affected individuals have been suggested.[277] Vaccine development is underway.[276]

HERPANGINA

HERPANGINA AT A GLANCE

- A viral enanthem seen in small children in summer and fall in temperate climates.
- Papulovesicles on the tonsillar pillars, uvula, and soft palate that progress to erosions.
- Caused by enteroviruses, including coxsackievirus and echoviruses.
- Self-resolving over several days without serious sequelae in the majority of cases.

EPIDEMIOLOGY.

Herpangina is a self-limited exanthem seen in children around the world. There is no ethnic or sexual predilection. Children are affected most commonly between 3 and 10 years of age. Most outbreaks in temperate climates are seen in the

summer and fall. Herpangina is caused by multiple types of coxsackie viruses (most frequently subtypes A8, A10, and A16), echoviruses, and enteroviruses.[278] Transmission is via fecal–oral, respiratory inhalation, or oral–oral spread in the majority of cases.

ETIOLOGY AND PATHOGENESIS. Enteroviruses belong to the family of Picornaviridae, which are single-stranded RNA viruses. Herpangina may occur sporadically or in epidemics. Epidemics have been traced to coxsackievirus A types 1, 2, 3, 4, 5, 6, 8, 10, 22, and B1 as well as echovirus types 16 and 25 and enterovirus 71. Replication ensues in the pharynx and gastrointestinal tract, with subsequent viremia. The incubation period is about 4 days,[279] and viral shedding may continue for days to months.

CLINICAL FINDINGS

History. The presenting signs and symptoms of herpangina are sudden onset of fever, chills, sore throat, headache, dysphagia, and body aches. The fever ranges from 37.5°C to 41.5°C (99.5°F–106.7°F). There may be a prodrome of listlessness, irritability, and anorexia a few hours before the onset of fever.

Cutaneous Lesions. Lesions are 1–2 mm, yellow–white papulovesicles with surrounding erythema that progress to erosions (Fig. 192-18). They are seen most frequently on the anterior pillars of the tonsillar fauces (or tonsillar pillars), followed by the uvula, tonsils and soft palate. They are less frequently seen on the tongue and buccal mucosa. The number of lesions may vary from very few to numerous. They can occur in small clusters and later coalesce and ulcerate leaving a shallow, punched out grayish–yellow crater 2–4 mm in diameter. Resolution occurs over 5–10 days.

LABORATORY TESTS. No laboratory tests are indicated.

SPECIAL TESTS. Historically, enteroviral infection has been verified by viral culture that lacked sensitivity and suckling mouse inoculation looking for neutralizing antibodies. Recently, PCR has been found to be very effective in detection and identification of enterovirus serotypes. PCR could be very useful if it were to become widely available.[280]

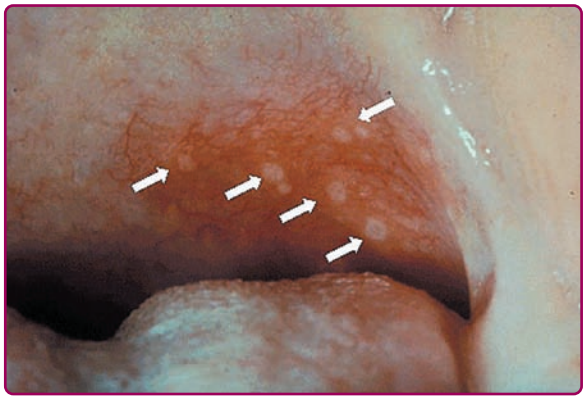

Figure 192-18 Typical appearance of the oropharyngeal lesions of herpangina. Acute, multiple papulovesicular lesions quickly progress to from shallow ulcerations with brisk marginal erythema.

BOX 192-13 DIFFERENTIAL DIAGNOSIS OF HERPANGINA

Most Likely
- Hand-foot-mouth disease

Consider
- Infectious mononucleosis
- Lymphonodular pharyngitis
- Aphthous stomatitis
- Oral candidiasis
- Varicella
- Diphtheria
- Nutritional deficiency
- Hematologic disorders

Always Rule Out
- Herpetic gingivostomatitis

DIFFERENTIAL DIAGNOSIS. (Box 192-13). Herpangina is located in the posterior oropharynx. Herpetic gingivostomatitis more commonly presents with labial and skin involvement.

COMPLICATIONS. Occasionally, patients suffer febrile seizures associated with the fever that is present in the first few days of infection. There have been rare case reports of serious complications, including myocarditis, encephalitis, meningitis, and pulmonary edema.

TREATMENT. The main goal of treatment is pain management. Viscous lidocaine, antihistamine mouthwashes and allopurinol mouthwash may be of benefit in relieving symptoms. Adequate fluid intake is encouraged to prevent dehydration.

PROGNOSIS AND CLINICAL COURSE. The fever rarely lasts longer then 4 days, whereas oral lesions spontaneously resolve several days after their eruption. The prognosis is good, and the course is most often benign.

PREVENTION. Once infected, a person has lifelong immunity to that particular strain. Recurrence of herpangina may occur but would be from one of the other strains.

ERUPTIVE PSEUDOANGIOMATOSIS

Cherry et al first described a syndrome in 1969 in which four children with acute echovirus infection (two with echovirus 25 and two with echovirus 32) developed small 2–4 mm red papules that resembled angiomas on the face and extremities.[281] The papules blanched on pressure and were surrounded by a small 1–2 mm halo. The eruption was short lived and typically resolved

within 10 days. Patients often had associated fever, malaise, headache, diarrhea, and respiratory complaints.

Other children and adults have been described with similar outbreaks. Although a virus is likely to cause eruptive pseudoangiomatosis, echoviruses have not been consistently confirmed as the causative agent.[282–284]

BOSTON EXANTHEM DISEASE

Named for its occurrence as an epidemic in Boston, this exanthem was found to be caused by echovirus 16. Clinical manifestations ranged from a light pink "roseola-like" exanthem to morbilliform or vesicular exanthems in more severe cases. Lesions were mostly localized to the face, chest and back and rarely the extremities. Small ulcerations were also found on the soft palate and tonsils.[285,286]

ROTAVIRUS

ROTAVIRUS AT A GLANCE

- Occurs worldwide; peak occurs in the winter.
- Transmission occurs primarily by fecal–oral route; major cause of diarrhea in children under age 2 years of age.
- Belongs to the Reovirus family.
- Skin manifestations may include exanthems, Gianotti–Crosti syndrome, and acute hemorrhagic edema of infancy.

EPIDEMIOLOGY

Rotavirus is a major cause of diarrheal illness in children under 2 years of age.[287] Rotaviral infections occur worldwide, affecting children in both developing and developed countries.[288] In the United States, the peak of rotaviral infections occurs in the winter. Typically, rotavirus appears in the Southwestern United States in November and reaches the Northeast by March.

Rotavirus is transmitted primarily by the fecal–oral route.[289] It has also been postulated that transmission via respiratory droplets and contaminated water is possible. The virus may survive on hands for at least 4 hours, and, in addition, ten infectious rotaviral particles may be all that is needed to transmit the infection. Once transmitted, viral shedding may commence as early as 48 hours before the development of symptoms and continue for 4–7 days thereafter. Asymptomatic shedding is also common.[290] Because of frequent diaper changing and contact between infected toddlers, day care centers often have outbreaks.[289] The fact that soap and water alone are relatively ineffective in removing virus from contaminated hands allows easier transmissibility.[291]

Children between the ages of 6 months and 2 years are most often affected. There is a male predominance that is poorly understood.[292] Adults can also become infected; they are often household members of infected children.[293]

CLINICAL FINDINGS

HISTORY. After an incubation period of 1–3 days, symptoms of rotaviral infection commence.[289] Typically, fever and vomiting are followed by nonbloody diarrhea (often 10–12 episodes per day), which occasionally results in moderate to severe dehydration.[292,297,298] Respiratory symptoms and otitis media may be present. In general, illness is less severe in adults.[294] Vomiting and diarrhea are usually present; however, fever and respiratory symptoms are absent.[293]

CUTANEOUS LESIONS. Rotaviral infections are not associated with specific dermatologic manifestations; however, several clinical pictures have been reported.[300] A generalized exanthem possibly related to rotavirus has been described.[299–301] Pink–red macules and papules appear 3–6 days after the onset of the diarrhea and as defervescence occurs. The asymptomatic rash progresses from the trunk to the extremities and, finally, to the face within hours. The exanthem then fades over approximately 3 days in the same order as it appeared.

Other dermatologic manifestations have been described. GCS occurs in response to a number of different viruses. Two toddlers had GCS with diarrhea 4 and 7 days before the eruption, and rotavirus was isolated from the stool cultures.[302] A third case of Gianotti–Crosti was reported without gastrointestinal symptoms.[303] Rotavirus was isolated from the stool culture, and all other suspected viruses yielded negative results. A child with acute hemorrhagic edema of infancy was found to be associated with a rotaviral infection.[303]

RELATED PHYSICAL FINDINGS. It has been noted that rotavirus is associated with respiratory symptoms and otitis media in up to 50% of cases.[289]

LABORATORY TESTS

Laboratory values may be unremarkable; however, it is not unusual to find a mild hyperchloremic metabolic acidosis.[304] Occasionally, liver transaminases may be mildly elevated. Hypernatremia, elevated albumin, and elevated uric acid, when detected, are likely the result of dehydration. Fecal leukocytes may be detected; however, they are usually not significant.[304]

COMPLICATIONS

Rotaviral infections may lead to persistent gastrointestinal symptoms, including diarrhea, gastroparesis, and lactose deficiency. Immunosuppressed patients and malnourished patients in developing countries are most at risk for protracted disease.[309] In addition, there have

been many associated conditions/syndromes reported, including seizures,[310] encephalopathy,[311] aseptic meningitis,[312] hepatic abscess,[313] acute myositis,[314] pneumonia,[315] sudden infant death syndrome,[316] Reye syndrome,[317] biliary atresia,[318] and Kawasaki disease.[319] It has also been suggested that rotaviruses have been associated with necrotizing enterocolitis[320] and intussusception.[321]

PROGNOSIS AND CLINICAL COURSE

Rotaviral infection in the United States resolves, on average, within 5–7 days, without any sequelae.[297,304] In developing countries, where poverty and malnutrition are common, children are most likely to experience chronic symptoms.[309] Death from rotaviral infection is not uncommon in developing countries due to dehydration.[295]

TREATMENT

Because there are no specific antiviral agents directed against the rotavirus, therapy is aimed at correcting dehydration and electrolyte imbalance. Oral rehydration is necessary. The World Health Organization recommends the oral rehydration solution, which consists of an isotonic salt solution with glucose supplementation or oral rehydration solution light, which has reduced osmolarity.[322] Intravenous fluids may be necessary if the patient is unable to rehydrate orally or if there is severe dehydration and should ideally consist of lactated Ringer or normal saline. Antibiotics are ineffective, and antimotility agents are not recommended for young children.

PREVENTION

Infection control is an important means of preventing rotaviral infections.[322] It is important to disinfect contaminated surfaces with quaternary ammonium compounds that contain 40% alcohol[273,305] or chlorhexidine gluconate in 70% ethanol.[289] Currently, two orally administered live rotavirus vaccines are available in the United States.[323]

UNILATERAL LATEROTHORACIC EXANTHEM

UNILATERAL LATEROTHORACIC EXANTHEM AT A GLANCE

- Asymmetric periflexural exanthem of childhood.
- Children 1–5 years of age.
- Pink papules that start in a large flexural region, become bilateral, but remain asymmetric.
- Probably viral etiology.

EPIDEMIOLOGY

Unilateral laterothoracic exanthem (ULE), also known as asymmetric periflexural exanthem of childhood (APEC), has a seasonal variation and occurs most frequently in late winter and early spring.[307] It typically occurs in children from 1 to 5 years of age but may be seen from 8 months to 10 years.[324] Rare cases in adults have been reported.[325] There is a slight female predominance and it is more common in Caucasians.

ETIOLOGY AND PATHOGENESIS

The etiology is unknown, but because of its seasonality and associated viral symptoms and lack of response to antibiotics, a viral trigger is suspected. The distinct clinical presentation may be a manifestation of a variety of infectious agents. The pathogenesis is also unknown.

CLINICAL FINDINGS

HISTORY. Mild upper respiratory tract, low-grade fever, or gastrointestinal tract symptoms precede the eruption in a majority of patients.

Conjunctivitis and fatigue may be present.

CUTANEOUS LESIONS. The lesions are usually 1–2-mm pinpoint, pruritic, pink papules that begin in a large flexural region like the axillae or groin and spread centrifugally (Fig. 192-19 and eFig. 192-19.1 in online edition). A variety of morphologies have been described, including macules, papules, morbilliform, annular, scarlatiniform, and annular. The initial lesion is often a pink papule with a surrounding pale halo.[307] The eruption typically becomes bilateral and more widespread within 5–15 days, but a unilateral and asymmetric distribution remains. The eruption is often quite pruritic.

RELATED PHYSICAL FINDINGS. Lymphadenopathy is seen in 70% of patients. This often manifests

Figure 192-19 Rough pink papules in the right axilla characteristic of unilateral laterothoracic exanthem. (Used with permission from Antonio Torrelo, MD.)

BOX 192-14 DIFFERENTIAL DIAGNOSIS OF UNILATERAL LATEROTHORACIC EXANTHEM

Most Likely
- Allergic or irritant contact dermatitis
- Scarlet fever

Consider
- Other viral exanthems

Always Rule Out
- Herpes zoster
- Atopic dermatitis

as a large (1–3 cm) mobile lymph node at the site where the rash starts.

LABORATORY TESTS

No laboratory tests are indicated.

DIFFERENTIAL DIAGNOSIS

(Box 192-14)

COMPLICATIONS

There has not been documentation of complications after ULE.

PROGNOSIS AND CLINICAL COURSE

The rash typically lasts from 2 to 6 weeks but may last as long as 2 months. Resolution is spontaneous and without scarring. During the healing stage, desquamation and postinflammtory pigment change may also be present as the exanthem resolves.

TREATMENT

Treatment for ULE is typically focused on controlling pruritus. This can be done with topical corticosteroids, antiitch lotions, and oral antihistamines.

PREVENTION

There is no known way to prevent ULE.

Chapter 193 :: Herpes Simplex

:: Adriana R. Marques & Jeffrey I. Cohen

HERPES SIMPLEX AT A GLANCE

- Herpes simplex viruses (HSVs) are common human DNA viral pathogens that intermittently reactivate. After replication in the skin or mucosa, the virus infects the local nerve endings and ascends to the ganglia where it becomes latent until reactivation.
- There are two types of HSV: HSV-1 and HSV-2. HSV-1 is mostly associated with orofacial disease, whereas HSV-2 usually causes genital infection, but both can infect oral and genital areas and cause acute and recurrent infections.
- Most of the adult population is seropositive for HSV-1, and the majority of infections are acquired in childhood. About one-fourth of adults are infected with HSV-2 in the United States. Acquisition of HSV-2 correlates with sexual behavior.
- Most primary HSV infections are asymptomatic or not recognized, but they can also cause severe disease. Most recurrences are not symptomatic (asymptomatic shedding), with most transmissions occurring by asymptomatic shedding.
- Genital herpes is the most prevalent sexually transmitted disease worldwide and is the most common cause of ulcerative genital disease, and it is an important risk factor for acquisition and transmission of human immunodeficiency virus.
- HSV can cause diseases involving the eye, central nervous system, and neonatal infection. Cellular immunity defects are a risk factor for severe and disseminated disease.
- Diagnosis is made by polymerase chain reaction, viral culture, or serology, depending on the clinical presentation.
- Treatment is with acyclovir, valacyclovir, or famciclovir. Regimens and dosages vary with the clinical setting. Resistance is rare in other than immunocompromised patients.

EPIDEMIOLOGY

Herpes simplex virus (HSV) infections are common worldwide and are caused by two closely related types of HSV. Their main clinical manifestations are mucocutaneous infections, with HSV type 1 (HSV-1) being mostly associated with orofacial disease, whereas HSV type 2 (HSV-2) is usually associated with genital and perigenital infection.

The incidence of primary infection with HSV-1, which is responsible for the vast majority of recurring labial herpes, is greatest during childhood, when 30%–60% of children are exposed to the virus. Rates of infection with HSV-1 increase with age and reduced socioeconomic status, the majority of persons age 30 or older are seropositive for HSV-1.[1,2] From 20% to 40% of the population have had episodes of herpes labialis.[3] The frequency of recurrent episodes is extremely variable, and, in some studies, averages about once per year,[4] but there is evidence that the frequency and severity of recurrent HSV-1 disease decrease over time.

Acquisition of HSV-2 correlates with sexual behavior and the prevalence of the infection in the pool of one's potential sexual partners. Antibodies to HSV-2 are rare in people before the onset of intimate sexual activity and rise steadily thereafter. HSV-2 seroprevalence in the United States is 22% in persons 12 years of age or older.[5] The rate of HSV-2 seropositivity declined in the United States from 21% in 1988–1994 to 17% in 1999–2004, and rate of HSV-1 seropositivity declined from 62% to 58% during the same period.[6]

Although most patients infected with HSV-1 or HSV-2 are asymptomatic, they still can transmit the virus. Studies using DNA polymerase chain reaction (PCR) assays show that rates of detecting HSV-2 DNA in genital secretions of people who have never recognized herpes outbreaks (asymptomatic persons) are similar to the rates of shedding viral DNA in people who have experienced symptomatic genital herpes but who are not symptomatic at the moment of testing (subclinical shedding).[7] In one study, 21% of genital swabs were positive for HSV-2 by PCR and 12% of oral swabs were positive for HSV-1 PCR in HSV-2 and HSV-1 seropositive persons, respectively.[8] It is estimated that more than 70% of transmission of HSV-2 is associated with asymptomatic and subclinical reactivation and shedding. The rate of transmission is no higher is persons with frequent symptomatic recurrences than those with infrequent recurrences.[9] The average risk of transmission for couples discordant for genital herpes (i.e., one partner has genital herpes and the other does not) varies from 5% to 10% per year.[10,11] As with other sexually transmitted infections, the rate of acquisition of HSV-2 infection is higher for women than for men (6.8 vs. 4.4 cases per 100 person-years;

relative risk, 1.55). Asymptomatic HSV-2 infection is more common among men and persons who are also seropositive for HSV-1, suggesting that prior infection with HSV-1 reduces one's likelihood of experiencing symptomatic HSV-2 infection.[12] Studies have shown that genital HSV infections significantly increase the risk for acquisition and transmission of human immunodeficiency virus (HIV). Randomized trials with acyclovir reduced the frequency of genital ulcers and slightly reduced HIV viral loads, but did not reduce transmission of HIV.[13,14]

ETIOLOGY AND PATHOGENESIS

THE VIRUS

HSV-1 and HSV-2 are members of the Herpesviridae family, a group of lipid-enveloped double-stranded DNA viruses. Both serotypes of HSV are members of the α-Herpesviridae virus subfamily. α-Herpesviruses infect multiple cell types in culture, grow rapidly, and efficiently destroy the host cells. Infection in the natural host is characterized by lesions in the epidermis, often involving mucosal surfaces, with spread of virus to the nervous system and establishment of latent infections in neurons, from which virus periodically reactivates. HSV-1 and HSV-2 have a high degree of genetic and antigenic homology. An analysis of herpesvirus phylogeny estimated that the two HSV types diverged from an ancestral protoherpesvirus approximately 8 million years ago.[15]

Herpesvirus replication is a carefully regulated process. Shortly after infection, immediate-early genes are transcribed whose proteins upregulate expression of early proteins that are required for genome replication. The late [HSV-2→HSV] genes encode virion structural components including the glycoproteins.

In vivo, HSV infections can be divided into three stages: (1) acute infection, (2) establishment and maintenance of the latency, and (3) reactivation of virus. During acute infection, virus replicates at the site of inoculation on mucocutaneous surfaces, resulting in primary lesions from which virus rapidly spreads to infect sensory nerve terminals, where it travels by retrograde axonal transport to neuronal nuclei in regional sensory ganglia. In a subset of infected neurons, a latent infection is established in which viral DNA is maintained as an episome and HSV gene expression is severely restricted: of all of the viral genes, only one is abundantly transcribed during latency. In the last stage, replication reactivates with concomitant anterograde axonal transport of newly assembled virus to a peripheral site, at or near the original portal of entry (see eFig. 193-0.1 in online edition).

HSV-1 reactivates most efficiently and frequently from trigeminal ganglia, whereas HSV-2 reactivates primarily from sacral ganglia. The rate of reactivation of HSV appears to be influenced by the quantity of latent viral DNA in the ganglia.[16] Reactivation is induced in experimentally infected animals by exposure to ultraviolet irradiation, by hyperthermia, by local trauma, and by other physiologic stressors.

IMMUNE RESPONSE

Host immunity to HSV clearly influences the risk of acquiring the infection, the severity of disease, and the frequency of recurrences. The risk of severe HSV disease and the recurrence rate correlates with the level of cellular immune competence of the host. Patients with mild decreases in cellular immunity may experience only an increased number of recurrences and a slower resolution of lesions, whereas severely compromised patients are more likely to develop disseminated, chronic, or drug-resistant infections.

Studies of humans and mice have implicated a role for both $CD8^+$ and $CD4^+$ T lymphocyte subsets, natural killer cells, and inflammatory cytokines like interferon-γ in mediating protection against HSV. However, the contribution of each cell subset and cytokine in the control of HSV infection has not been clearly defined. Innate immunity is also important and polymorphisms in *TLR2* are associated with increased rates of genital lesions in seropositive persons.[17]

Patients with defects in humoral immunity have no increase in HSV disease severity, but the humoral immune response is important in reducing virus titers at the site of inoculation and in regional neural tissues during primary infection. Animals are effectively protected from disseminated and neurologic disease by passive transfer of polyclonal or monoclonal antibodies and by antibody responses elicited actively through vaccination. Moreover, the transfer of HSV-specific antibodies from the mother to the child is a key factor in protecting against neonatal herpes.

The mechanisms of immunity required to sustain latency and limit reactivation of HSV are less clear. There is evidence that constant immune surveillance and engagement are required to maintain latency, mainly by HSV-specific $CD8^+$ lymphocytes and low levels of viral proteins produced in neurons.[18] T cells reactive to HSV-1 are clustered around latently infected neurons in ganglia from HSV-1 seropositive persons.[19] HSV-specific $CD8^+$ lymphocytes localize to site of reactivation and persist in the skin for weeks after lesions are cleared.[20]

CLINICAL FINDINGS

The clinical manifestations of HSV infection depend on the site of infection and, as indicated in Immune Response (above), the immune status of the host. Primary infections with HSV, namely those that develop in persons without preexisting immunity to either HSV-1 or HSV-2, are usually more severe, frequently with systemic signs and symptoms, and they have a higher rate of complications, than recurrent episodes.

OROFACIAL INFECTIONS

Herpetic gingivostomatitis (Fig. 193-1) and pharyngitis are most commonly associated with a primary HSV-1 infection. The symptoms of primary oral herpes may resemble those of aphthous stomatitis and include

Figure 193-1 Primary herpetic gingivostomatitis. (Used with permission from Clyde S. Crumpacker, MD.)

ulcerative lesions involving the hard and soft palate, tongue, and buccal mucosa, as well as neighboring facial areas. Patients with pharyngitis exhibit ulcerative and exudative lesions of the posterior pharynx that can be difficult to differentiate from streptococcal pharyngitis. Other common symptoms are fever, malaise, salivation, myalgias, pain on swallowing, irritability, and cervical adenopathy.

Reactivation of virus from these primary infections involves the perioral facial area, mainly the lips, with the outer one-third of the lower lip being the most commonly affected (Fig. 193-2 and see eFig. 193-2.1 in online edition). Other facial locations include the nose, chin, and cheek, and account for less than 10% of the cases (Fig. 193-3). Two-thirds of labial lesions involve the vermilion border, whereas the rest occur at the junction of the border with the skin. In patients with frequent recurrences, lesions may differ slightly in location with each episode. Immunocompetent patients tend not to experience recurrent intraoral lesions, but can present with clusters of tiny vesicles and ulcers, or linear fissures on the gingivae and anterior hard palate that are mildly symptomatic. Prodromal symptoms precede herpes labialis in 45%–60% of

Figure 193-2 Herpes simplex virus infection: recurrent herpes labialis.

Figure 193-3 Recurrent facial herpes simplex with grouped vesicles and crusting. (Used with permission from Clyde S. Crumpacker, MD.)

episodes. Patients experience pain, burning, or itching at the site of the subsequent eruption. Even in the immunocompetent patient, the severity of recurrent herpes labialis is extremely variable and may vary from that of prodromal symptoms alone without the subsequent development of lesions (aborted episodes) to extensive disease induced by severe local sunburn.

The progression of the classical herpes lesions has been divided according to the following stages based on their features: prodromal, erythema, and papule (the developmental stages); vesicle, ulcer, and hard crust (disease stages); followed by dry flaking and residual swelling (resolution stages). The lesions usually resolve within 5–15 days.

Trigger factors for oral herpes recurrences include emotional stress, illness, exposure to sun, trauma, fatigue, menses, chapped lips, and the season of the year.[21] Other well-documented triggers include exposure to ultraviolet irradiation, trigeminal nerve surgery, oral trauma, epidural administration of morphine, and abrasive, laser, and chemical facial cosmetic procedures. The exact mechanism by which these diverse factors trigger HSV reactivation is unknown.

HSV-2 causes a primary orofacial infection that is indistinguishable from that associated with HSV-1 except that it is usually in adolescents and young adults and following genital–oral contact. Moreover, HSV-2 orolabial infections are 120 times less likely to reactivate than is orolabial HSV-1 disease. For the differential diagnosis of orofacial herpes see Box 193-1.

GENITAL INFECTION

Genital herpes is the major clinical presentation of HSV-2 infection, but it may also result from HSV-1 in 10%–40% of the cases, primarily following oral–genital contact.[22] Because of their epidemiology,

BOX 193-1 DIFFERENTIAL DIAGNOSIS OF OROLABIAL AND GENITAL HERPES

Disease	Differences from Orolabial Herpes
Aphthous ulcers	Not preceded by vesicles, only on mucosa
Syphilis	Painless, not preceded by vesicles
Herpangina	Posterior portion of mouth (soft palate, tonsils)
Stevens Johnson syndrome	Disseminated lesions

Disease	Differences from Genital Herpes
Chancroid	Deep ulceration with exudate
Syphilis	Painless, not preceded by vesicles
Lymphogranuloma venereum	Painless ulcer, unimpressive primary lesions
Granuloma inguinale	Painless ulcer, exuberant lesions

acquisition of HSV-1 in a person with prior HSV-2 infection is unusual, but HSV-2 acquisition in the presence of previous HSV-1 infection is common, and infection of the genital tract with both HSV-1 and HSV-2 has been described. Patients with previously known HSV-1 genital infection who develop frequent genital herpes recurrences should be tested for HSV-2 infection.[23] Viremia occurs in about 25% of persons during primary genital herpes.[24]

The clinical course of acute first-episode genital herpes among patients with HSV-1 and HSV-2 infections is similar. These infections are associated with extensive genital lesions in different stages of evolution, including vesicles, pustules, and erythematous ulcers that may require 2–3 weeks to resolve (Fig. 193-4). In males, lesions commonly occur on the glans penis or the penile shaft; in females, lesions may involve the vulva, perineum, buttocks, vagina, or cervix. There is accompanying pain, itching, dysuria, vaginal and urethral discharge, and tender inguinal lymphadenopathy. Systemic signs and symptoms are common and include fever, headache, malaise, and myalgias. Herpetic sacral radiculomyelitis, with urinary retention, neuralgias, and constipation, can occur. HSV cervicitis occurs in more than 80% of women with primary infection. It can present as purulent or bloody vaginal discharge, and examination reveals areas of diffuse or focal friability and redness, extensive ulcerative lesions of the exocervix, or, rarely, necrotic cervicitis. Cervical discharge is usually mucoid, but it is occasionally mucopurulent.

The rates of recurrence for genital HSV-2 infections vary greatly among individuals and over time within the same individual. Infections caused by HSV-2 reactivate approximately 16 times more frequently than HSV-1 genital infections, and average 3–4 times per year, but may appear virtually weekly.[3] Recurrences tend to be more frequent in the first months to years after first infection. The classical clinical manifestations

Figure 193-4 **A.** Primary genital herpes with vesicles. (Used with permission from Clyde S. Crumpacker, MD.) **B.** Primary herpetic vulvitis.

Figure 193-5 **A.** Genital herpes: recurrent infection of the penis. Group of vesicles with early central crusting on a red base arising on the shaft of the penis. This "textbook" presentation, however, is much less common than small asymptomatic erosions or fissures. **B.** Genital herpes: recurrent vulvar infection. Large, painful erosions on the labia. Extensive lesions such as these are uncommon in recurrent genital herpes in an otherwise healthy individual.

of recurrent HSV-2 infection include multiple small but grouped vesicular lesions in the genital area (Fig. 193-5), but it can occur anywhere in the perigenital region, including the abdomen, groin, buttocks, and thighs (Fig. 193-6), and the lesions may recur at the same site or change location. The recurrence of genital lesions may be heralded by a prodrome of tenderness, itching, burning, or tingling, and the outbreaks are less severe than primary infection. Without treatment, the lesions usually heal in 6–10 days. Herpetic cervicitis is less common in recurrent disease, occurring in 12% of patients. It may present without external lesions. Signs and symptoms that are less classical for genital HSV infection, and which may divert one from the correct diagnosis include small erythematous lesions, fissures, pruritus, and urinary symptoms. HSV can cause urethritis, usually manifested only as a clear mucoid discharge, dysuria, and frequency. Occasionally, HSV can be associated with endometritis, salpingitis, or prostatitis. Symptomatic or asymptomatic rectal and perianal infections are common. Herpetic proctitis presents with anorectal pain, anorectal discharge, tenesmus, and constipation, with ulcerative lesions of the distal rectal mucosa. Genital herpes can recur at nongenital sites as well. For the differential diagnosis of genital herpes, see Box 193-1.

Figure 193-6 Recurrent genital herpes on the abdomen (zosteriform herpes simplex).

OTHER CUTANEOUS INFECTIONS

HSV can infect any skin site (Fig. 193-6). The common theme among virtually all of these cutaneous presentations is the requirement that virus has penetrated otherwise normal and well-keratinized tissues. Herpetic whitlow (Fig. 193-7) is infection of the fingers by HSV acquired by direct inoculation or by direct spread from mucosal sites at the time of primary infection. Thus, a typical presentation of whitlow would be in children who suck their fingers during a primary gingivostomatitis outbreak. It is also a well-documented occupational hazard for medical personnel. It is usually caused by HSV-1, but HSV-2 whitlow may develop as a manifestation of primary inoculation following manual–genital contact with an infected partner. The infected region becomes erythematous and edematous. Lesions are usually present at the fingertip and can be pustular and very painful. Fever and local lymphadenopathy are common. Whitlow is often misdiagnosed as a bacterial paronychial infection, but the surgical drainage, often needed for a bacterial infection, is unnecessary and potentially harmful, while antiviral therapy speeds healing. Whitlow may recur.

Figure 193-7 Herpes simplex virus infection: herpetic whitlow. Painful, grouped, confluent vesicles on an erythematous edematous base on the distal finger were the first (and presumed primary) symptomatic infection.

Cutaneous herpes can be transmitted between athletes involved in contact sports, such as wrestling (herpes gladiatorum) and rugby (herpes rugbiaforum or scrum pox), and may occur as outbreaks or small epidemics among team members. In these instances, multiple herpetic lesions may appear across the thorax, ears, face, arms, and hands, in which infection is facilitated by trauma to the normally keratinized skin during sport activities (Fig. 193-8A). Concomitant ocular herpes can occur.

Eczema herpeticum (Kaposi varicelliform eruption; Fig. 193-8B and eFig. 193-8.1 in online edition) results from widespread infection following inoculation of virus to skin damaged by eczema. It is usually a manifestation of primary HSV-1 infection in a child with atopic dermatitis, and the expression of cathelicidins in the skin may be a factor in controlling susceptibility to eczema herpeticum in these patients.[25] Mycosis fungoides, Sèzary syndrome, Darier disease, various bullous diseases of the skin (particularly if patients are receiving immunosuppressive therapy), and burns of second or third degree can also be complicated by cutaneous dissemination of HSV. The severity of eczema herpeticum ranges from mild to fatal, with mortality rates of up to 10% being reported before antiviral therapy was available. Mortality was usually primarily caused by bacterial superinfection and bacteremia. Common pathogens include *Staphylococcus aureus*, *Streptococcus*, and *Pseudomonas*. In a typical severe primary attack, several days after exposure vesicles develop in large numbers over areas of active or recently healed atopic dermatitis, particularly the face, and continue to appear in crops for several more days. The vesicles become pustular and markedly umbilicated. Patients commonly have high fever and adenopathy. Viremia with infection of internal organs can be fatal. Recurrences are usually far milder than these first infections. Arriving at the correct diagnosis can be delayed because of secondary impetigo involving the lesions, but it always should be considered in children with infected eczema, particularly if the child is more systemically ill than one might anticipate with impetigo. Eczema herpeticum of the young infant is a medical emergency, and early treatment with acyclovir can prove lifesaving.

Recurrent HSV infection is the most common precipitating event in cases of recurrent erythema multiforme (see Chapter 39). HSV-associated erythema multiforme is usually an acute, self-limited, recurrent disease. The duration of the disease is usually about

Figure 193-8 **A.** Herpes simplex gladiatorum with lesions on the neck. **B.** Herpes simplex virus infection: eczema herpeticum on face. Confluent and discrete crusted erosions associated with erythema and edema of the face of a man with atopic dermatitis.

3 weeks. The lesions are usually disseminated and symmetric, occurring on acral extremities and the face, and there is grouping of the lesions over the elbow and knees, as well as nail fold involvement. Mucosal involvement is usually mild and restricted to the mouth. Constitutional symptoms are rare, and the skin lesions heal without scarring.

LABORATORY TESTS

The method of choice for diagnosis of HSV infection depends on the clinical presentation. In many instances, the history and clinical findings may be sufficient, but the social, emotional, and therapeutic implications of a diagnosis dictate that it be confirmed by laboratory testing when possible. For patients with lesions, virus can be isolated in cell culture. In culture, HSV causes typical cytopathic effects, and most specimens will prove positive within 48–96 hours after inoculation. The sensitivity of the culture depends on the quantity of the virus in the specimen. Even in the most experienced centers, only approximately 60%–70% of fresh genital lesions are culture-positive. Isolation of the virus is most successful when lesions are cultured during their vesicular stage and when specimens are taken from immunocompromised patients or from patients suffering from a primary infection.

PCR is more sensitive than viral isolation and has become the preferred method for diagnosis. PCR has been extensively used for the diagnosis of central nervous system infections and in neonatal herpes. It is also useful for the detection of HSV in late-stage ulcerative lesions. Both viral culture and PCR assays enable typing of the isolate as HSV-1 or HSV-2. This information helps to predict the frequency of reactivation after a first-episode of HSV infection.

Direct fluorescent antibody staining of lesion scrapings and antigen detection assays can also be used but sensitivity is lower than viral culture.[26] The Tzanck smear can be helpful in the rapid diagnosis of herpesvirus infections, but it is less sensitive than culture and staining with fluorescent antibody, with positive results in fewer than 40% of culture-proven cases. It is performed by scraping the base of a freshly ruptured vesicle and staining the slides with Giemsa or Wright stain (the Papanicolaou staining method can also be used), followed by examination for the multinucleated giant cells that are diagnostic of herpetic infection (Fig. 193-9). Both HSV and varicella-zoster virus (VZV) will cause these changes. In skin biopsy specimens, epithelial cells are enlarged, swollen, and often separated. Multinucleated cells with intranuclear eosinophilic inclusion bodies (Cowdry type A inclusions) can be seen.

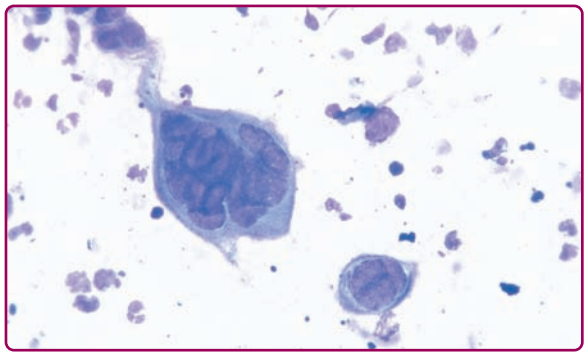

Figure 193-9 Herpes simplex virus: positive Tzanck smear. A giant, multinucleated keratinocyte on a Giemsa-stained smear obtained from a vesicle base. Compare size of the giant cell to that of neutrophils also seen in this smear. Another smaller multinucleated acantholytic keratinocyte is seen as well as acantholytic keratinocytes. Identical findings are present in lesions caused by varicella-zoster virus.

Serologic detection of antibodies to HSV can be helpful in certain settings, but the results are often misinterpreted. Its main function is in differentiating a primary episode from a recurrent infection (Table 193-1). A positive serologic test result can be useful in patients with

TABLE 193-1
Classification of Herpes Simplex Infections According to Viral Isolation and Paired Serologic Test Results

Classification	Virus Isolated	Serology (Acute)		Serology (Convalescent)	
		HSV-1	HSV-2	HSV-1	HSV-2
Primary HSV-1	HSV-1	–	–	+	–
Primary HSV-2	HSV-2	–	–	–	+
Primary HSV-1 plus previous HSV-2 infection[a]	HSV-1	–	+	+	+
Primary HSV-2 plus previous HSV-1 infection	HSV-2	+	–	+	+
Recurrent HSV-1	HSV-1	+	– or +	+	– or +
Recurrent HSV-2	HSV-2	– or +	+	– or +	+

HSV = herpes simplex virus; – = negative; + = positive.
[a]Rare.

recurrent, genital lesions that are not present at times of examination and, therefore, a positive culture cannot be obtained. Serologic testing can also be helpful for counseling patients with initial episodes of disease and their partners, especially during pregnancy, and in counseling partners of patients with genital herpes about their risk of acquiring HSV.

Type-specific serologic assays based on antigenic differences between HSV-1 and HSV-2 glycoprotein G, are available.[27] These tests should be used by practitioners who are prepared to counsel patients about the meaning of the test results in terms of the natural history of the disease, available treatment regimens, disease transmission, and the emotional and social implications of the diagnosis.[28]

COMPLICATIONS

IMMUNOCOMPROMISED HOST

All manifestations of HSV infection seen in the immunocompetent host can also be seen in immunocompromised patients but they are usually more severe, more extensive, and difficult to treat; for many of them, recurrences are more frequent as well. Patients with defects of T cell immunity, such as those with AIDS or transplant recipients, are at particular risk for progressive mucocutaneous or visceral infections, but the degree of dissemination depends on the level of immunodeficiency of the host. Recurrent and persistent ulcerative HSV lesions are among the most common and defining opportunistic infections in patients with acquired immunodeficiency syndrome. Genital herpes is very common in patients with HIV and can be persistent and severe. Oropharyngeal HSV in immunocompromised patients can present with widespread involvement of skin (Fig. 193-10), the mucosa, and extremely painful, friable, hemorrhagic, and necrotic lesions, similar to mucositis caused by cytotoxic agents. The lesions can spread locally to involve the esophagus. Esophagitis presents with odynophagia, dysphagia, substernal pain, and multiple ulcerative lesions. Esophagitis can also arise directly by reactivation of HSV and its spread to the esophagus via the vagus nerve. Tracheobronchitis can also occur by spreading of the virus from oropharyngeal HSV.

HSV can reactivate from visceral ganglia of the autonomic nervous system or disseminate hematogenously to other visceral organs (causing pneumonitis, hepatitis, pancreatitis, or meningitis) and other portions of the gastrointestinal tract, as well as causing adrenal necrosis. Most of these severe infections are caused by HSV-1, but HSV-2 can do so as well. Few are ever diagnosed except at autopsy.

OCULAR INFECTIONS

HSV is a leading cause of recurrent keratoconjunctivitis and it is associated with corneal opacification and visual loss. It is usually caused by HSV-1, except in neonates in whom HSV-2 is more prevalent. The majority of HSV eye disease is caused by reactivation of the virus in the trigeminal ganglia, but primary infections of the eye can also occur. Usually, the initial manifestation of herpetic eye disease is a superficial infection of the eyelids and conjunctiva (blepharoconjunctivitis), or corneal surface (dendritic or geographic epithelial ulcer with pain and blurred vision). Deeper involvement of the cornea (stromal keratitis) or anterior uvea (iritis) represents more serious forms of the disease and can cause permanent visual loss. Acute retinal necrosis is a rare but rapidly progressive disease characterized by retinal arteriolar sheathing, uveitis, and peripheral retinal opacification with variable pain and visual loss. Bilateral involvement may occur, and retinal detachment is common. It is usually associated with HSV-1 infection, but HSV-2 retinitis has been described, and VZV causes a similar process.[29]

Figure 193-10 Herpes simplex virus infection: chronic ulcer in an immunocompromised host. Multiple, slowly spreading, deep ulcers with central necrosis and hemorrhagic crusts on the lips, cheeks, and nose of a woman with leukemia.

NEUROLOGIC DISORDERS

All HSV infections involve the nervous system, as neurons are the sole proven site of virus latency. Neurologic manifestations of HSV infections, however, are not universal, but highly variable in their presentation and severity. HSV meningitis is manifested by headache, fever, stiff neck, and mild photophobia, with lymphocytic pleocytosis in the cerebrospinal fluid (CSF). Most cases result from HSV-2 infection.[30] It resolves spontaneously in 2–7 days. It is usually seen in association with primary genital HSV-2 infection. Recurrent lymphocytic meningitis (Mollaret meningitis) is associated with HSV-2 reactivation, often without

symptomatic genital disease. Involvement of the sacral nerves with autonomic nervous system dysfunction, numbness, pelvic pain, tingling, urinary retention, constipation, and CSF pleocytosis have been reported in association with HSV infection. Symptoms usually resolve in a few days, but in some cases, the neurologic residua take weeks to months to disappear, occasionally becoming permanent. Rare cases of transverse myelitis and Guillain-Barrè syndrome after HSV infection have been reported. Bell palsy is an acute, peripheral facial paresis of unknown cause and is thought to result from inflammation and subsequent mechanical compression of the facial nerve in the temporal bone. Reactivation of HSV and VZV are implicated in the pathogenesis of the disease.[31]

HSV encephalitis is the most commonly identified acute, sporadic viral encephalitis in the United States, accounting for 10%–20% of all cases. Nearly all of the cases arising after the neonatal period (see Section "Neonatal Herpes") are caused by HSV-1. HSV encephalitis usually presents with acute onset of focal neurologic symptoms and fever. Involvement of the temporal lobe is a characteristic feature of this disease, but overall, it is difficult to differentiate HSV encephalitis clinically from other viral encephalitides. PCR of the CSF for HSV DNA is the most sensitive noninvasive technique to help in the diagnosis, but it can occasionally be negative very early in the course of the disease.[32] Patients with presumed HSV encephalitis should be treated empirically with intravenous acyclovir until the diagnosis is confirmed or an alternative diagnosis is made. However, even with therapy, neurologic sequelae are frequent.[33]

NEONATAL HERPES

The neonate is a special category of immunodeficient host. The incidence of neonatal herpes varies from 1 case per 12,500 to 1 per 1,700 live births.[34] The category of maternal infection plays a significant role in defining the risk of neonatal herpes. Primary genital herpes is associated with a risk of neonatal infection of 25%–50% for vaginally delivered babies, and accounts for 50%–80% of cases of neonatal HSV infection. In contrast, recurrent maternal infection is associated with a risk of transmission of less than 3%, and transplacental antibodies are likely to play a role in decreasing the risk of infection.[35] Other risk factors for development of neonatal herpes include vaginal delivery, presence of cervical HSV infection, use of invasive monitors, and isolation of HSV from the genital tract.[36] Prolonged rupture of the membranes is also a risk factor.

Neonatal herpes infections manifest in one of the three forms: (1) skin, eye, and mouth involvement; (2) encephalitis; or (3) disseminated disease (Fig. 193-11). The latter two forms account for more than 50% of cases of neonatal herpes. It is important to remember that more than 20% of neonates with neurologic and disseminated disease do not develop cutaneous vesicles. Without therapy, the overall mortality of neonatal herpes is 65%, and fewer than 10% of untreated neonates

Figure 193-11 Neonatal herpes simplex virus 2.

with central nervous system infection will develop normally. With current therapeutic modalities, most babies with skin, eye, and mouth disease survive and have normal development at 1 year. For treated babies with encephalitis, mortality is 6%, with about 30% developing normally after 1 year. For babies with disseminated disease, mortality is 30%, with about 80% of the survivors apparently developing normally after 1 year.[34]

TREATMENT

All sexually active persons should be educated regarding the nature and risks of acquiring and transmitting sexually transmitted infections, including HSV. Studies show that about one-half of the patients with asymptomatic HSV-2 infection have mild, unrecognized disease and can be taught to recognize their symptoms and signs of genital herpes. Also, patients should be counseled regarding safer sex practices. It must be emphasized that the majority of transmission occurs in asymptomatic phases and from people who have no classical lesions. Patients with genital herpes should be counseled to refrain from sexual intercourse during outbreaks and for 1–2 days after and to use condoms between outbreaks. Suppressive antiviral therapy is also an option for individuals concerned about transmission to a partner (see Section "Antiviral Therapy under Prevention").

Pregnant women who are known to have genital herpes should be reassured that the risk of transmitting herpes to the baby during childbirth is extremely low. Recommendations for the management of pregnant women with recurrent genital herpes include clinical evaluation at delivery, with

delivery by Cesarean section indicated if there are signs and symptoms of active infection (including prodrome). But Cesarean section delivery may not reliably prevent neonatal HSV infection when membranes are ruptured for long periods (≥24 hours). Women with primary HSV infection during pregnancy should be treated with antiviral therapy. For women at or beyond 36 weeks of gestation who are at risk for recurrent HSV infection, suppressive antiviral therapy has been recommended, (1) as this decreases viral shedding, the incidence of active lesions near term, and the need of Cesarean delivery due to HSV.[37,38] Close follow-up, sequential[70] PCR or cultures for HSV of infants born to seropositive mothers who are shedding virus at the time of delivery, prophylactic therapy with intravenous acyclovir for infants born to mother with primary infection, and intravenous acyclovir if HSV is detected in infants of seropositive mothers have also been suggested.[34]

Women who are known by history and serologic tests not to have genital herpes should be counseled about signs and symptoms of HSV and how to avoid acquiring the infection during pregnancy. Serology is helpful in counseling a couple in which the male partner has recurrent genital herpes and the pregnant wife is susceptible.

ANTIVIRAL THERAPY

(See Chapter 231)

Many HSV infections require no specific treatment at all. Keeping the lesions clean and dry while they heal by themselves may be all that is required. Treatment is warranted for infections that are likely to prove protracted, highly symptomatic, or complicated. Acyclovir, an acyclic guanosine analogue, has a highly favorable therapeutic index because of its preferential activation in infected cells and preferential inhibition of the viral DNA polymerase. It must be phosphorylated to be active, and it requires the viral thymidine kinase (TK) for initial phosphorylation. Acyclovir inhibits HSV-1 and HSV-2 replication by 50% at a concentration of 0.1 and 0.3 μg/mL (range, 0.01–9.9 μg/mL), respectively, but is toxic at concentrations of >30 μg/mL. Any strain that requires more than 3 μg/mL of acyclovir to be inhibited is said to be relatively drug resistant.

Valacyclovir, the L-valyl ester of acyclovir, is an oral prodrug of acyclovir that achieves three- to fivefold higher bioavailability after oral administration, and it can be used in a more convenient dosage regimen. Famciclovir is the well-absorbed oral form of the related guanosine analogue penciclovir. Similar to acyclovir, famciclovir is converted by phosphorylation to its active metabolite penciclovir triphosphate. The efficacy and adverse effect profile of famciclovir is comparable to that of acyclovir. Penciclovir 1% cream is approved by the U.S. Food and Drug Administration (FDA) for the treatment of herpes simplex labialis. Docosanol 10% cream is approved by the FDA for over-the-counter treatment of recurrent herpes labialis. Docosanol is a long-chain saturated alcohol that inhibits entry of lipid-enveloped virus into the cell. It decreased the healing time by 18 hours when compared with placebo.[39]

The current recommendations for antiviral treatment depend on the clinical disease, on host immune status, and whether one is treating a primary or recurrent episode or considering suppressive therapy (Boxes 193-2, 193-3, 193-4, and 193-5).[84] For disseminated or severe herpes infections, the treatment of choice remains intravenous acyclovir 5–10 mg/kg every 8 hours. Some experts use acyclovir 15 mg/kg intravenously every 8 hours for life-threatening HSV infection, including encephalitis. The dose of intravenous acyclovir for neonatal herpes is 20 mg/kg per dose given every 8 hours.

For first episodes of genital HSV-2 infections, oral acyclovir, famciclovir, and valacyclovir all speed the healing and resolution of symptoms, and decrease viral shedding. When compared with placebo, acyclovir decreases time of healing from 16 to 12 days, the duration of pain from 7 to 5 days, and the duration of constitutional symptoms from 6 to 3 days.[51] Valacyclovir was compared with acyclovir in the treatment of primary episodes and shown to be equivalent.[52] Antiviral treatment of initial herpes episodes does not decrease subsequent recurrences, probably because HSV establishes latent infection within hours after inoculation and days before symptoms evolve.

Treatment of recurrent episodes of genital herpes with famciclovir, acyclovir, or valacyclovir has been shown to reduce the time of healing from about 7 to 5 days, time of cessation of viral shedding from 4 to 2 days, and duration of symptoms from 4 to 3 days when compared with placebo. Valacyclovir and acyclovir are equivalent[54,56]; valacyclovir was similar to famciclovir in one study,[57] but slightly superior to famciclovir to suppress genital herpes in another study.[67] A regimen of patient-initiated, 1-day famciclovir 1,000 mg twice daily was not different from placebo in immunocompetent black adults in a recent study, but this finding warrants further investigation.[85] For persons with frequent or complicated genital recurrences, long-term suppressive therapy with acyclovir or its analogues is the most effective management strategy.[71,86,87] Suppressive therapy was effective during the first year after acquisition of genital herpes.[69,70] Suppressive therapy reduces the rate of shedding in healthy persons and those with HIV.[60,70,88,89] Suppressive therapy with valacyclovir was more effective to reduce the burden of genital herpes disease than episodic therapy.[90] Because genital herpes is not progressive in the normal host and because the rate of recurrences varies over time and may decrease after some years, it is wise to recommend a "holiday" from treatment every year or so to reassess the person's continuing need for treatment.

The use of antiviral suppressive therapy during the late phase of pregnancy to avoid neonatal herpes has also been advocated, but a formal study of the approach would require a very large number of participants because of the rare incidence of neonatal herpes. A more achievable goal is to decrease the

BOX 193-2 RECOMMENDED REGIMENS FOR THE TREATMENT OF OROFACIAL HERPES SIMPLEX INFECTIONS

	ACCEPTABLE REGIMEN ALTERNATIVES[a]			
Disease	**Adults**	**Pediatric[b]**	**Duration**	**Comments**
Primary infection	Acyclovir, 200 mg orally five times a day. Acyclovir, 400 mg orally three times a day. Valacyclovir, 1,000 mg orally two times a day. Famciclovir, 250 mg orally three times a day.	15 mg/kg of acyclovir orally five times a day.[40]	7–10 days or until resolution of symptoms.	IV acyclovir for severely ill individuals. No studies have been done in adults: regimens are extrapolated from their effectiveness in primary genital herpes.
Recurrent infection: episodic treatment	Topical penciclovir, 1% cream q2h while awake.[41] Topical docosanol 10% cream five times a day.[39] Acyclovir, 400 mg orally five times a day.[42] Famciclovir, 500 mg orally two or three times a day.[43,44] Valacyclovir, 2,000 mg orally twice a day for 1 day.[45] Famciclovir, 1,500 mg single dose or 750 mg twice a day for 1 day.[46]	4–5 days or until lesions are healed. Valacyclovir and famciclovir were used for only 1 day.		Generally not warranted.
Recurrent infection: prophylaxis	Acyclovir, 400 mg orally twice a day.[47]			Start just before and during precipitating event, such as intensive ultraviolet exposure.
Recurrent infection: suppression of confirmed frequent recurrences	Acyclovir, 400 mg orally twice a day.[48] Valacyclovir 500 mg once a day.[49] Valacyclovir 1,000 mg once a day.[50]	There are no pediatric studies, but children with confirmed frequent recurrences may benefit from suppressive oral acyclovir therapy.		

[a]The doses are for patients with normal renal function.
[b]Oral dosage of acyclovir in children should not exceed 80 mg/kg/day. Children 40 kg and above should receive the adult dose.
Note: Neither valacyclovir nor famciclovir is approved by the US Food and Drug Administration for use in children.

need for Cesarean deliveries caused by herpes recurrences during labor. Studies have shown that antiviral therapy in late pregnancy (beginning at 36 weeks) prevent clinical recurrences, Cesarean sections due to genital herpes, and the risk of HSV viral shedding at delivery.[91]

Orolabial HSV infections warrant antiviral treatment less often than do the genital infections. Primary HSV gingivostomatitis should be treated with oral acyclovir. The pediatric dose is 15 mg/kg of acyclovir suspension orally five times a day for 7 days. When it is started within 3 days of onset of the disease, this regimen decreases the duration of oral and extraoral lesions, fever, and eating and drinking difficulties. Valacyclovir and famciclovir may be equally effective, but they have not been studied in this setting and are not currently approved for use in children. Severely ill children may need to be hospitalized for hydration, and intravenous acyclovir may be necessary.

Treatment of recurrent herpes labialis with antiviral drugs in immunocompetent hosts has shown

BOX 193-3 RECOMMENDED REGIMENS FOR THE TREATMENT OF GENITAL HERPES SIMPLEX INFECTIONS

	ACCEPTABLE REGIMEN ALTERNATIVES[a]			
Disease	**Adults**	**Pediatric[b]**	**Duration**	**Comments**
Primary infection	Acyclovir, 200 mg orally five times a day.[51] Acyclovir, 400 mg orally three times a day.[52] Valacyclovir, 1,000 mg orally twice a day.[52] Famciclovir, 250 mg orally three times a day.	Acyclovir, 40–80 mg/kg/ day orally divided in three to four doses (maximum 1 g/d).[53]	7–10 days or clinical resolution occurs.	
Recurrent infection	Acyclovir, 400 mg orally three times a day. Acyclovir, 200 mg orally five times a day.[54] Acyclovir, 800 mg orally twice a day.[55] Valacyclovir, 500 mg orally twice a day.[56,57,58,59] Valacyclovir, 1,000 mg orally once a day.[58] Valacyclovir, 1,000 mg orally twice a day.[60,61,c] Famciclovir, 500,[c] 250, 125 mg orally twice a day.[44,62–63] Famciclovir, 1,000 mg orally twice a day for 1 day (patient initiated).[57,59,64] Famciclovir, 500 mg, then 250 mg twice daily for 2 days.[63]	For children ≥12 years of age: acyclovir, 200 mg orally five times a day.[53] Acyclovir 800 mg orally twice a day.[53] Acyclovir 800 mg three times a day for 2 days.[53]	5–10 days or until clinical resolution occurs.	
Suppression of recurrences	Acyclovir, 400 mg orally twice a day.[65] Acyclovir, 800 mg orally once a day.[66] Valacyclovir, 500, 1,000 orally once a day.[67,68,d] Valacyclovir, 250 mg orally twice a day.[65,d] Valacyclovir, 500 mg twice a day or 1,000 mg orally once a day.[60,61,69,70,c;] Famciclovir, 250 orally twice a day.[71,72,73] Famciclovir, 125 mg, 250 mg orally three times a day.[74]	For children ≥12 years of age: acyclovir, 400 mg orally twice a day.[53]		Duration of the therapy is controversial. Some authorities will offer treatment for 1 year and then reassess the need to resume it.
Suppression of recurrences in pregnant women	Acyclovir, 400 mg orally three times a day from 36 weeks of gestation until delivery.[75,76] Valacyclovir 500 mg twice a day from 36 weeks of gestation until delivery.[77,78]			
Reduction of transmission	Valacyclovir, 500 mg orally once a day.[11]			Safer sex practices should continue to be used.

[a]The doses are for patients with normal renal function.
[b]Oral dosage of acyclovir in children should not exceed 80 mg/kg/day. Children 40 kg and above should receive the adult dose.
[c]Human immunodeficiency virus patients.
[d]The high once-a-day and twice-daily doses of valacyclovir are more effective in patients who present with more than 10 recurrences per year.
Note: Neither valacyclovir nor famciclovir is approved by the US Food and Drug Administration for use in children.

BOX 193-4 RECOMMENDED REGIMENS FOR THE TREATMENT OF OCULAR AND OTHER CUTANEOUS HERPES SIMPLEX INFECTIONS

		ACCEPTABLE REGIMEN ALTERNATIVES[a]			
Disease		**Adults**	**Pediatric[b]**	**Duration**	**Comments**
Ocular herpes	Therapy	1% trifluridine drop—1 drop q2h during day (maximum, 9 drops/day). until corneal ulcer has healed, followed by 1 drop every 4 h while awake (minimum 5 drops/day) for an additional 7 days (to not exceed 21 days) 3% vidarabine ointment—q3h during day (five times daily); after reepithelialization, treat for an additional 7 days at a reduced dose (such as twice daily) Acyclovir 3% ophthalmic ointment five times daily for 7–10 days Ganciclovir ophthalmic gel 0.15% 1 drop into affected eye five times daily until healed; then 1 drop three times daily for 7 days Acyclovir, 400 mg orally five times a day. Valacyclovir, 1,000 mg orally two times a day.[79]			Undertake in consultation with an ophthalmologist. The combination of interferon and an antiviral may speed healing.[80]
	Suppression of recurrences	Acyclovir, 400 mg orally twice a day.[81,82] Valacyclovir 500 mg daily[81]	For children ≥12 years of age: acyclovir, 400 mg orally twice a day.[53]		Undertake in consultation with an ophthalmologist.
Other cutaneous herpes (herpes gladiatorum, herpetic whitlow, etc.)	Treatment	Acyclovir, 200 mg orally five times per day. Acyclovir, 400 mg orally three times a day. Valacyclovir, 1,000 mg orally twice a day. Famciclovir, 250 mg orally three times a day.	Acyclovir, 4–80 mg/kg/day orally divided into three to four doses (maximum 1 g/day)[53]	7–10 days or until resolution of symptoms.	No studies have been done. Regimens are extrapolated from the treatment of genital herpes. Consider suppressive antiviral therapy for patients with frequent recurrences.

[a]The doses are for patients with normal renal function.
[b]Oral dosage of acyclovir in children should not exceed 80 mg/kg/day. Children 40 kg and above should receive the adult dose.
[c]Human immunodeficiency virus patients.
[d]The high once-a-day and twice-daily doses of valacyclovir are more effective in patients who present with more than 10 recurrences per year.
Note: Neither valacyclovir nor famciclovir is approved by the U.S. Food and Drug Administration for use in children.

BOX 193-5 RECOMMENDED REGIMENS FOR THE TREATMENT OF NEONATAL HERPES, DISSEMINATED INFECTION, ENCEPHALITIS AND ECZEMA HERPETICUM

	ACCEPTABLE REGIMEN ALTERNATIVES[a]			
Disease	**Adults**	**Pediatric[b]**	**Duration**	**Comments**
Neonatal herpes		IV acyclovir, 20 mg/kg every 8 hours.[83]	14–21 days.	The value of long-term suppression after initial treatment is being evaluated.
Disseminated infection	IV acyclovir, 10–15 mg/kg three times a day.	IV acyclovir, 10 mg/kg three times daily.[53]	14–21 days.	
Encephalitis	IV acyclovir, 10–15 mg/kg three times a day.	IV acyclovir, 15–20 mg/kg three times daily.[53]	14–21 days.	
Eczema herpeticum	Acyclovir, 200 mg orally five times a day. Acyclovir, 400 mg orally three times a day. Valacyclovir, 1,000 mg orally twice a day. IV acyclovir, 10–15 mg/kg three times a day.	Acyclovir, 40–80 mg/kg/ day orally divided in three to four doses (maximum, 1.2 g/d). IV acyclovir, 10 mg/kg three times daily.[53]	14–21 days.	No studies have been done. Use IV acyclovir in severely ill individuals. Consider suppressive antiviral therapy for patients with recurrences. Ocular involvement should be treated in consultation with an ophthalmologist.

[a]The doses are for patients with normal renal function.
[b]Oral dosage of acyclovir in children should not exceed 80 mg/kg/day. Children 40 kg and above should receive the adult dose.
Note: Neither valacyclovir nor famciclovir is approved by the U.S. Food and Drug Administration for use in children.

only modest benefits so far. The infections are inherently briefer and less symptomatic than genital herpes. Treatment is only effective if used very early in the disease, especially in the prodromal or erythema lesion stages. Patients who wish treatment should have the medication available and be vigilant for the earliest signs and symptoms of recurrence. When treatment is felt to be required, the therapy of choice is penciclovir 1% cream every 2 hours while awake, for 4 days.[41] Treatment should be initiated as early as possible. When initiated within 1 hour of first symptoms of recurrence, penciclovir sped the healing of lesions (4.8 days vs. 5.5 days) and decreased the duration of pain (3.5 days vs. 4.1 days). This regimen is approved by the FDA. Docosanol 10% cream is approved by the FDA for over-the-counter treatment of herpes simplex labialis. It is to be applied five times a day at the first sign of recurrence of herpes simplex labialis. There has been no direct comparison with topical penciclovir. Oral acyclovir, 400 mg five times a day for 5 days, affords marginal benefit if begun in the earliest hour or two of the outbreak. Famciclovir, 500 mg three times a day for 5 days, when started within 48 hours after experimental ultraviolet radiation, decreased the median time of healing from 6 to 4 days[43] but is not useful for the more usual sporadic cases of herpes labialis. A 1-day regimen of valacyclovir (2 g twice daily for 1 day) decreased the mean duration of cold sore episodes by 1 day when compared with placebo, if started in the prodrome period. Similarly, a single dose of famciclovir reduced time of healing of herpes labialis lesions by approximately 2 days compared with placebo.[46] Creams and ointments containing 5% and 10% acyclovir are not beneficial in recurrent herpes labialis.

The use of suppressive acyclovir for herpes labialis is controversial. In one small study, oral acyclovir, 400 mg twice a day, was effective in decreasing recurrences of herpes labialis.[48] In another study, suppressive therapy with valacyclovir was more effective than episodic therapy with valacyclovir for herpes labialis.[50] In studies with skiers (who have significant sun exposures), acyclovir 400 mg twice a day, was shown to reduce recurrences in one study,[47] whereas acyclovir, 800 mg bid, failed to prevent recurrences in another study.[92] Both perioperative famciclovir (125 or 250 mg orally twice daily given 1–2 days before to 5 days after the procedure) and valacyclovir (500 mg twice daily

for 14 days, starting either a day before or the day of the procedure) appeared to reduce the recurrence of orofacial HSV in patients undergoing facial laser resurfacing.[93,94] Valacyclovir has also been shown to suppress recurrences of herpes gladiatorum.[95]

Herpetic eye disease should always be treated in consultation with an ophthalmologist. Options usually involve topical antivirals, including vidarabine, trifluridine, acyclovir, or ganciclovir. Topical antivirals are effective in shortening the duration of dendritic and geographic keratitis, and are used to prevent corneal epithelial disease in patients with blepharitis and conjunctivitis, as well as patients on topical steroid therapy for corneal stromal inflammation and iridocyclitis.[80] Oral acyclovir is also effective for dendritic and geographical epithelial keratitis. Suppressive antiviral therapy reduces the rates of all types of recurrent ocular HSV disease, and it is most important for patients with a history of HSV stromal keratitis because it can prevent additional episodes and potential loss of vision.[81,82]

ANTIVIRAL RESISTANCE

Virtually all clinically relevant drug resistance has been seen in immunocompromised patients. The primary mechanism of acyclovir resistance is selection of viral mutants defective or deficient in TK expression. Most mutants that are TK deficient are somewhat attenuated for virulence in vivo.

The treatment of resistant HSV infection is complicated. First, one must make the diagnosis. Very few people who claim to be "resistant" to one of the antiviral drugs actually harbor resistant virus. There is a common misconception that treatment prevents all recurrences. One should suspect resistance only in people who continue to have culture-proven outbreaks of unaltered frequency and severity, especially if the lesions do not heal by themselves. When resistance is suspected, virus should be recovered and tested specifically for sensitivity to acyclovir. These tests are expensive but are available through commercial reference laboratories. Second, the options for patients with true resistance are few and far from ideal due to the lack of alternatives that are safe and easy to administer. Foscarnet inhibits replication of all known herpesviruses in vitro and does not require activation by TK or other kinases, and therefore can be effective in the treatment of acyclovir-resistant HSV. Foscarnet requires intravenous therapy and can cause numerous adverse reactions including nephrotoxicity, electrolyte disturbances, anemia, and seizures. Also, foscarnet-resistant HSV strains have been described.

Cidofovir does not require the viral TK for its intracellular phosphorylation to the active form. Cidofovir has been tested in cases of acyclovir-resistant HSV and topical cidofovir has been used with success to treat progressive herpetic lesions.[96] Intravenous cidofovir is associated with considerable nephrotoxicity and requires the coadministration of saline hydration and probenecid. A few patients with acyclovir-resistant genital herpes have responded to imiquimod 5% cream.[97] Imiquimod caused severe inflammation in some patients with recurrent herpes labialis.[98] Resiquimod reduced the rate of new lesions in one study of persons without drug-resistant virus,[99] but had no effect on genital herpes in another study.[100] Long-term suppressive acyclovir therapy reduced the rate of drug-resistant HSV disease in hematopoietic stem cell transplant recipients.[101]

PREVENTION

Strategies to prevent HSV infection have proved inadequate. HSV infection can be prevented by total abstinence, as indicated by very low seroprevalence rates in cloistered nuns. Condoms reduce rates of transmission if used routinely.[102,103] Male circumcision reduced the rate of HSV-2 infection from 10% in the control group to 7.8% in the circumcised group.[103] Other than these public health approaches, most efforts involve antiviral therapy and vaccines directed at genital herpes.

ANTIVIRAL THERAPY

Acyclovir, famciclovir, and valacyclovir decrease both symptomatic and subclinical shedding of HSV-2, from about 8% of the days in the placebo group to 0.3%–0.6% of the days in the treatment group, when assessed by culture.[67,74,88,104,105] Once daily valacyclovir reduced shedding by PCR from 14% to 3% in patients with newly diagnosed genital herpes.[106] Valacyclovir 500 mg once daily was shown to be effective in reducing the transmission of HSV-2 between partners by 48%, and reduced clinical disease in the susceptible partner by 75% in a randomized, placebo-controlled trial involving immunocompetent, heterosexual couples in stable relationships.[11] This therapy can be recommended for individuals concerned about transmission to a partner, in conjunction with the use of condoms. Regarding other groups (e.g., homosexual couples, nonmonogamous individuals, immunocompromised, and persons with asymptomatic HSV-2 infection), it is uncertain if the use of antiviral therapy (and which regimen) would be adequate to decrease transmission.

Vaginal microbicides are also being studied, mostly focusing on decreasing HIV transmission, but some of the compounds also have anti-HSV activity and may also affect HSV transmission.[107]

VACCINES

The best public health strategy to reduce infection and morbidity associated with HSV infection is development of effective vaccines. Unfortunately, no vaccine has proved to protect adequately against acquisition of HSV (prophylactic) or to reduce the number of recurrent episodes (therapeutic), although there are hopeful developments in these directions.

Recombinant glycoprotein vaccines containing immunogenic HSV proteins have been developed and

tested by multiple pharmaceutical and biotechnological companies. In a preliminary study, a recombinant HSV-2 glycoprotein D vaccine with alum adjuvant decreased the frequency of symptomatic outbreaks in patients with genital herpes. A modified form of the vaccine (with added glycoprotein B and a lipid emulsion adjuvant known as MF59) did not decrease the number of recurrences in patients with genital herpes, but did decrease the duration and severity of a subsequent study outbreak of genital herpes.[108] Two phase III studies of the effect of this vaccine (one in monogamous seronegative partners of individuals with genital herpes, and the other in seronegative persons attending clinics for sexually transmitted diseases) failed to prevent acquisition of genital herpes infection or disease.[109] A recombinant gD2 vaccine that uses monophosphoryl lipid-A as adjuvant was protective against HSV-2 genital disease (but had limited protection against infection) in HSV-1 and HSV-2 seronegative women but not in males or HSV-1 seropositive females.[110] A double-blind, randomized controlled study in HSV-1 and HSV-2 seronegative women found that the vaccine was not effective in preventing genital herpes disease.

A major theoretical limitation of recombinant HSV vaccines is their inability to induce broad and protective cellular immune responses, and therefore genetically engineered live vaccines have been developed. Replication-defective viruses are capable of only a single round of replication, and therefore have no pathogenic potential while potentially inducing the full spectrum of immune responses. The use of replication-defective HSV mutants has been tested with success as a candidate vaccine in animal models. A glycoprotein H-deficient virus had no effect on reducing HSV reactivation and clinical disease among individuals with recurrent genital HSV-2 infection.[111] Another replication-defective mutant, defective in ICP8 (a single-stranded DNA binding protein) and part of the helicase/primase complex, has demonstrated to be immunogenic and protective in animals but has not been tested in humans yet. DNA vaccines for HSV have also shown promising results in animal models, but resulted in very limited induction of HSV-specific cellular immune responses in a phase I human study.[112]

Chapter 194 :: Varicella and Herpes Zoster

:: Kenneth E. Schmader & Michael N. Oxman

VARICELLA AND HERPES ZOSTER AT A GLANCE

- Varicella (chickenpox) and herpes zoster (shingles) are distinct clinical entities caused by a single member of the herpesvirus family, varicella-zoster virus (VZV).
- Varicella, an acute, highly contagious exanthem that occurs most often in childhood, is the result of primary VZV infection of a susceptible individual.
- The rash usually begins on the face and scalp and spreads rapidly to the trunk, with relative sparing of the extremities. Lesions are scattered rather than clustered, and progress from rose-colored macules to papules, vesicles, pustules, and crusts. In varicella, in contrast to smallpox, lesions in all stages are usually present on the body at the same time.
- In normal children, systemic symptoms are usually mild and serious complications are rare. In adults and immunologically compromised persons of any age, varicella is more likely to be associated with life-threatening complications.
- Where use of varicella vaccine in susceptible children and adults is widespread, the incidence of varicella is markedly reduced, although breakthrough varicella may occur.
- Herpes zoster is characterized by unilateral, dermatomal pain, and rash that results from reactivation and multiplication of endogenous VZV that had persisted in latent form within sensory ganglia following an earlier attack of varicella.
- The erythematous, maculopapular, and vesicular lesions of herpes zoster are clustered rather than scattered because virus reaches the skin via sensory nerves rather than viremia.
- Herpes zoster is most common in older adults and immunosuppressed individuals.
- Pain is an important clinical manifestation of herpes zoster, and the most common debilitating complication is chronic pain or postherpetic neuralgia (PHN).
- Antiviral therapy and analgesics reduce acute pain; lidocaine patch (5%), high dose capsaicin patch, gabapentin, pregabalin, opioids, and tricyclic antidepressants may reduce the pain of PHN.
- A live attenuated zoster vaccine reduces the incidence of herpes zoster by one-half and the incidence of PHN by two-thirds.

EPIDEMIOLOGY

EPIDEMIOLOGY OF VARICELLA

Varicella is distributed worldwide, but its age-specific incidence differs in temperate versus tropical climates, and in populations that have received varicella vaccine. In temperate climates in the absence of varicella vaccination, varicella is endemic, with a regularly recurring seasonal prevalence in winter and spring, and periodic epidemics that depend upon the accumulation of susceptible persons. In Europe and North America in the prevaccination era, 90% of cases occurred in children younger than 10 years of age and fewer than 5% in individuals older than the age of 15.[1] From 1988 to 1995, there were approximately 11,000 hospitalizations and 100 deaths caused by varicella each year in the United States.[2–4] The risk of hospitalization and death was much higher in infants and adults than in children, and most varicella-related deaths occurred in previously healthy people.[5] In tropical and semitropical countries, the mean age of varicella is higher and susceptibility among adults to primary VZV infection is significantly greater than in temperate climates. High levels of susceptibility to varicella among adult immigrants from tropical climates are well documented in the US military, where many recruits from Puerto Rico and the Philippines have been seronegative. This is important for hospitals, where susceptible healthcare workers may pose a significant risk of nosocomial varicella.

Widespread use of the varicella vaccine has markedly altered the epidemiology of varicella. In the United States, vaccine coverage rates among susceptible children increased from 0% in 1995, when varicella vaccine was licensed, to 88% in 2004.[6] This has resulted in a marked decline in varicella cases

and varicella-related hospitalizations. From 1995 through 2000, varicella cases reported to the Centers for Disease Control (CDC) declined by 71%–84%, depending upon surveillance area; by 2005 the incidence of varicella had decreased by 90%, with a comparable decline in varicella-related hospitalizations.[7–11] The decline was greatest among children aged 1–4 years, but cases declined in all age groups, including unvaccinated infants and adults, reflecting herd immunity. Varicella-related mortality has also declined substantially after introduction of the varicella vaccine. From 1990 to 1994, mortality from varicella decreased by 66% in all age groups under 50 years, with the greatest reduction (92%) among children 1–4 years of age.[4]

Varicella is highly contagious. Attack rates of 87% among susceptible siblings in households and nearly 70% among susceptible patients on hospital wards have been reported. More than 95% of cases of varicella are clinically apparent, although occasionally the exanthem may be so sparse and transient as to pass unnoticed. A typical patient is infectious for 1–2 days (rarely, 3–4 days) before the exanthem appears, and for 4 or 5 days thereafter, that is, until the last crop of vesicles has crusted. The immunocompromised patient, who may experience many successive crops of lesions for a week or more, is infectious for a longer period of time. The mean incubation period of varicella is 14 or 15 days, with a range of 10–23 days. It is often prolonged in patients who develop varicella after passive immunization with varicella-zoster immune globulin (VZIG) or zoster immune plasma (ZIP), or after postexposure immunization with live attenuated Oka strain varicella vaccine.[11]

The major route by which varicella is acquired and transmitted is thought to be the respiratory tract, but infection may also be spread by direct contact. Varicella crusts are not infectious, and the duration of infectivity of droplets containing virus is probably quite limited. Although the infectiousness of patients with varicella is thought to depend largely upon virus shed from the mucous membranes of the upper respiratory tract, VZV has only rarely been cultured from pharyngeal secretions; however, VZV DNA can be detected in the oropharynx of the majority of patients using polymerase chain reaction (PCR)-based assays.[12]

Natural varicella (i.e., varicella caused by wild-type VZV) generally confers life-long immunity to the disease. Re-exposure to the virus boosts humoral and cell-mediated immune responses, but rarely leads to clinical illness. Most reported second attacks of varicella involve incorrect diagnoses; others may represent cutaneous dissemination in patients with herpes zoster (see below). With severe immunocompromise, reinfections manifested as varicella have been observed. In addition, persons who develop modified varicella (e.g., because they are infected early in infancy in the presence of maternal antibody or have been immunized with live attenuated varicella vaccine) may respond to exogenous exposure by developing a second, usually mild, episode of "breakthrough" varicella.

EPIDEMIOLOGY OF HERPES ZOSTER

Herpes zoster occurs sporadically throughout the year without seasonal prevalence. The occurrence of herpes zoster is independent of the prevalence of varicella, and there is no convincing evidence that herpes zoster can be acquired by contact with other persons with varicella or herpes zoster. Rather, the incidence of herpes zoster is determined by factors that influence the host-virus relationship.

One strong risk factor is older age (Fig. 194-1A). The incidence of herpes zoster is 1.5–3.0 per 1,000 person-years in all ages and 7–11 per 1,000 per year in persons over 60 years of age in European and North American studies.[13–22] It is estimated that there are more than a million new cases of herpes zoster in the United States each year, more than half of which occur in persons ≥60 years of age, and this number will increase as the population ages.[14,17,21,23]

Another major risk factor is cellular immune dysfunction. Immunosuppressed patients have a 20–100 times greater risk of herpes zoster than immunocompetent individuals of the same age. Immunosuppressive conditions associated with high risk of herpes zoster include HIV infection, bone marrow transplant, leukemia and lymphoma, use of cancer chemotherapy, and use of corticosteroids. Herpes zoster is a prominent and early "opportunistic infection" in persons infected with HIV, in whom it is often the first sign of immune deficiency. Thus, HIV infection should be considered in individuals who develop herpes zoster.

Other factors reported to increase the risk of herpes zoster include female sex,[20] physical trauma in the affected dermatome,[24] IL-10 gene polymorphisms,[25] and white race.[19,20] Exposure to children and contact with cases of varicella have been reported to increase levels of VZV-CMI and confer protection against herpes zoster.[20,26]

Second episodes of herpes zoster are uncommon in immunocompetent persons, and third attacks are very rare. Persons suffering more than one episode may be immunocompromised. Immunocompetent patients suffering multiple episodes of herpes zoster-like disease are likely to be suffering from recurrent zosteriform herpes simplex virus infections.[27]

Patients with herpes zoster are less contagious than patients with varicella. The rate at which susceptible household contacts develop varicella after exposure to herpes zoster appears to be about one-third of the rate observed following exposure to varicella.[14] Virus can be isolated from vesicles and pustules in uncomplicated herpes zoster for up to 7 days after the appearance of the rash, and for much longer periods in immunocompromised individuals. Patients with uncomplicated dermatomal zoster appear to spread the infection by means of direct contact with their lesions. Airborne transmission has also been documented.[28] Patients with disseminated herpes zoster may also transmit the infection via aerosols, so that airborne precautions, as well as contact precautions, are required for such patients.

The effect of the marked reduction in the incidence of varicella, due to widespread varicella vaccination of

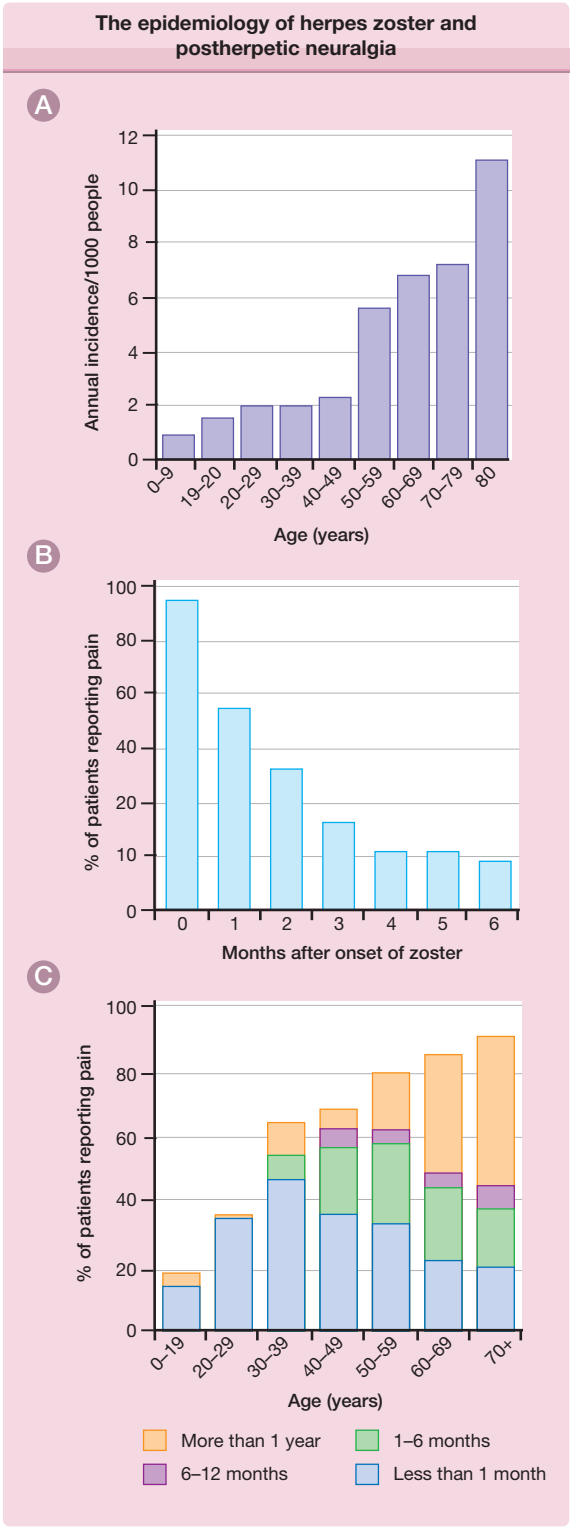

Figure 194-1 **A.** The epidemiology of herpes zoster and postherpetic neuralgia. The annual incidence of herpes zoster per 1,000 persons in a general medical practice. **B.** The percentage of patients with pain persisting after the onset of the herpes zoster rash. These data are from the placebo recipients in one large, double-blind treatment study. **C.** The proportion of patients with postherpetic neuralgia according to age. (From Kost RG, Straus SE: Postherpetic neuralgia: Pathogenesis, treatment, and prevention. *N Engl J Med* **335**:32, 1996 with permission.)

children, on the epidemiology of herpes zoster is unclear. In the long term, the incidence of herpes zoster is likely to decline as the cohorts of children now receiving varicella vaccine become adults; vaccine virus-associated herpes zoster will probably be less frequent and less severe in older adults than wild-type virus-associated herpes zoster because the vaccine virus is highly attenuated. In the short term, the incidence of herpes zoster could increase because a decline in the incidence of varicella will reduce the adult population's exposure to VZV thereby reducing immune boosting, hastening the age-related decline in immunity to VZV, and thus increasing the age-specific risk of herpes zoster. However, recent studies of herpes zoster in populations with high rates of varicella vaccination have shown little or no increase in the incidence of herpes zoster.[8,15,29,30]

ETIOLOGY AND PATHOGENESIS

VZV is a member of the herpesvirus family.[31] Other members pathogenic for humans include herpes simplex viruses type 1 (HSV-1) and type 2 (HSV-2); cytomegalovirus (CMV); Epstein–Barr virus (EBV); human herpesvirus-6 (HHV-6) and human herpesvirus-7 (HHV-7), which cause roseola; and Kaposi's sarcoma-associated herpesvirus, also called human herpesvirus type 8. All herpesviruses are morphologically indistinguishable and share a number of properties, including the capacity to establish latent infections that persist for life.

The VZV genome encodes about 70 unique genes, most of which have DNA sequence and functional homology to genes of the other herpesviruses.[32] Immediate early (IE) gene products regulate VZV replication. Early gene products, such as the virus-specific thymidine kinase and the viral DNA polymerase, support viral replication. Late genes encode virus structural proteins that serve as targets for neutralizing antibodies and cellular immune responses.

There is only one VZV serotype. However, there are multiple VZV genotypes that display geographic segregation and recombination, and minor variations in their nucleotide sequences allow one to distinguish wild type from vaccine virus strains, and to "fingerprint" viruses isolated from individual patients.[32,33]

PATHOGENESIS OF VARICELLA

Entry of VZV is through the mucosa of the upper respiratory tract and oropharynx. Initial multiplication occurs at this portal of entry, where VZV infects tonsillar T cells, which disseminate virus via the blood and lymphatics (the primary viremia). Infected T cells carry virus to the reticuloendothelial system, the major site of virus replication during the remainder of the incubation period, and to the skin, where innate immune responses delay VZV replication and rash formation.[32,34–36]

The incubating infection is partially contained by innate host defenses [e.g., interferon, natural killer (NK) cells] and by developing VZV-specific immune responses. In most individuals, virus replication eventually overwhelms these developing host defenses, so

that about 2 weeks after infection, a much larger (secondary) viremia and associated symptoms and lesions occur. Skin lesions appear in successive crops, reflecting a cyclic viremia, which in the normal host is terminated after about 3 days by VZV-specific humoral and cellular immune responses. Virus circulates in mononuclear leukocytes, primarily lymphocytes. Even in uncomplicated varicella, the secondary viremia results in the subclinical infection of many organs in addition to the skin. Effective host immune responses terminate viremia and limit the progression of varicella lesions in the skin and other organs. Humeral immunity to VZV protects against varicella. People with detectable serum antibody resulting from wild-type VZV infection do not usually become ill after exogenous exposure. Cell-mediated immunity to VZV also develops during the course of varicella, persists for many years, and protects against severe infections.[37,38]

PATHOGENESIS OF HERPES ZOSTER

During the course of varicella, VZV passes from lesions in the skin and mucosal surfaces into the contiguous endings of sensory nerves and is transported centripetally up the sensory fibers to the sensory ganglia. Infected T cells may also carry virus to sensory ganglia hematogenously. In the ganglia, the virus establishes a latent infection that persists for life. Herpes zoster occurs most often in dermatomes in which the rash of varicella achieves the highest density—those innervated by the first (ophthalmic) division of the trigeminal nerve and by spinal sensory ganglia from T1 to L2.[39]

Although the latent virus in the ganglia retains its potential for full infectivity, reactivation is sporadic and infrequent, and infectious virus does not appear to be present during latency. The mechanisms involved in reactivation of latent VZV are unclear, but reactivation has been associated with immunosuppression; emotional stress; irradiation of the spinal column; tumor involvement of the cord, dorsal root ganglion, or adjacent structures; local trauma; surgical manipulation of the spine; and frontal sinusitis (as a precipitant of ophthalmic zoster). Most important, though, is the decline in VZV-specific cellular immunity that occurs with increasing age.[40]

VZV may also reactivate without producing overt disease. The small quantity of viral antigens released during such contained reactivations would be expected to stimulate and sustain host immunity to VZV.[14,41]

When VZV-specific cellular immunity falls below some critical level, reactivated virus can no longer be contained.[14] Virus multiplies and spreads within the ganglion, causing neuronal necrosis and intense inflammation, a process that is often accompanied by severe neuralgia.[42,43] Infectious VZV then spreads antidromically down the sensory nerve, causing intense neuritis, and is released from the sensory nerve endings in the skin, where it produces the characteristic cluster of zoster vesicles. Spread of the ganglionic infection proximally along the posterior nerve root to the meninges and cord may result in local leptomeningitis, cerebrospinal fluid pleocytosis, and segmental myelitis. Infection of motor neurons in the anterior horn and inflammation of the anterior nerve root account for the local palsies that may accompany the cutaneous eruption, and extension of infection within the central nervous system (CNS) may result in rare complications of herpes zoster (e.g., meningoencephalitis, transverse myelitis). Viremia also occurs during herpes zoster.[44]

PATHOGENESIS OF PAIN IN HERPES ZOSTER AND POSTHERPETIC NEURALGIA

Pain is a major symptom of herpes zoster. It often precedes and generally accompanies the rash, and it frequently persists after the rash has healed—a complication known as postherpetic neuralgia (PHN). A number of different but overlapping mechanisms appear to be involved in the pathogenesis of pain in herpes zoster and PHN (Fig. 194-2).[45,46]

Injury to the peripheral nerve and to neurons in the ganglion triggers afferent pain signals. Inflammation in the skin triggers nociceptive signals that further amplify cutaneous pain. The abundant release of excitatory amino acids and neuropeptides induced by the sustained barrage of afferent impulses during the prodrome and acute phase of herpes zoster may cause excitotoxic injury and the loss of inhibitory interneurons in the spinal dorsal horn. Damage to neurons in the spinal cord and ganglion, and to the peripheral nerve, is important in the pathogenesis of PHN. Damaged primary afferent nerves may become spontaneously active and hypersensitive to peripheral stimuli, and also to sympathetic stimulation. Excessive nociceptor activity and ectopic impulse generation may, in turn, sensitize CNS neurons, augmenting and prolonging central responses to innocuous as well as noxious stimuli. Clinically, these mechanisms result in allodynia (pain and/or unpleasant sensations elicited by stimuli that are normally not painful, e.g., light touch) with little or no sensory loss.

The anatomic and functional changes responsible for PHN appear to be established early in the course of herpes zoster. This would explain the correlation of initial pain severity and the presence of prodromal pain with the subsequent development of PHN, and the failure of antiviral therapy to fully prevent PHN (see below).

CLINICAL FINDINGS

CLINICAL FINDINGS OF VARICELLA

PRODROME OF VARICELLA. In young children, prodromal symptoms are uncommon. In older children and adults, the rash is often preceded by 2–3 days of fever, chills, malaise, headache, anorexia, severe backache, and, in some patients, sore throat and dry cough.

RASH OF VARICELLA. In unvaccinated persons, the rash begins on the face and scalp and spreads rapidly to the trunk, with relative sparing of the extremities (Fig. 194-3). New lesions appear in successive crops, but their distribution remains central. The rash tends

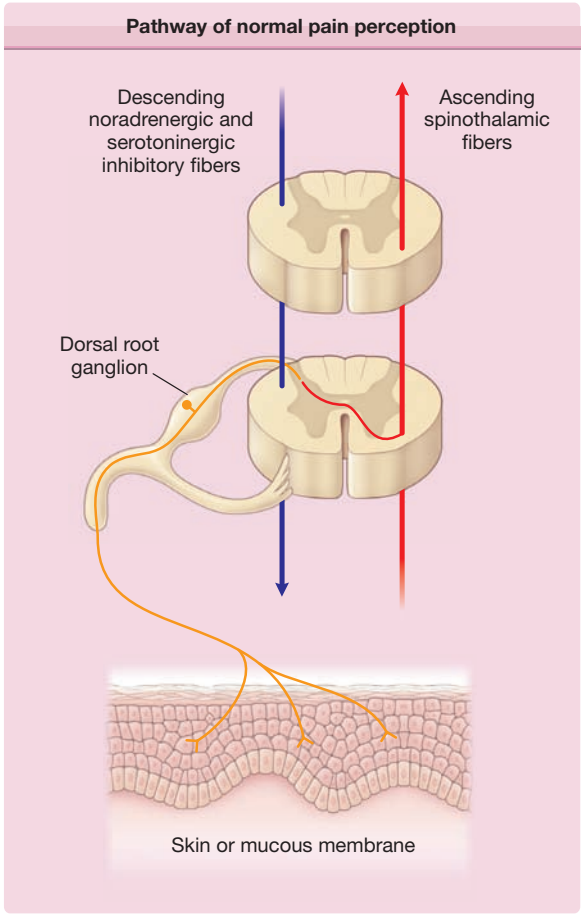

Figure 194-2 Pathway of normal pain perception. Noxious stimuli activate free nerve endings in the skin to generate signals that are conveyed through unmyelinated C fibers (*red*) and small Aδ fibers to the neuronal bodies in the segmental dorsal root ganglia, then proximally to the dorsal horn of the spinal cord, where they form synapses with second-order neurons. Spinal cord neurons are subject to powerful descending inhibitory signals from the brain (*green*), mediated by the biogenic amines serotonin and norepinephrine. Drugs that potentiate the central effects of biogenic amines, such as tricyclic antidepressant drugs, may act by enhancing these descending pathways. Endogenous opiates also contribute to descending inhibitory input. The net result of peripheral afferent input and descending inhibitory input is projected cephalad, joining other ascending fibers in the contralateral spinothalamic tract (*orange*). Information from the spinothalamic tract is integrated with input from brainstem and cortical areas for the perception of specific aspects of pain as well as more general affective components of pain perception.

to be denser in the small of the back and between the shoulder blades than on the scapulae and buttocks and more profuse on the medial than on the lateral aspects of the limbs. It is not uncommon to have a few lesions on the palms and soles, and vesicles often appear earlier and in larger numbers in areas of inflammation, such as diaper rash or sunburn.

A striking feature of varicella lesions is their rapid progression, over as little as 12 hours, from rose-colored macules to papules, vesicles (Fig. 194-3A), pustules, and crusts. The typical vesicle of varicella is 2–3 mm in diameter and elliptical, with its long axis parallel to the folds of the skin. The early vesicle is superficial and thin-walled, and it is surrounded by an irregular area of erythema, which gives the lesions the appearance of a "dewdrop on a rose petal." The vesicular fluid soon becomes cloudy with the influx of inflammatory cells, which convert the vesicle to a pustule (Fig. 194-3B). The lesion then dries, beginning in the center, first producing an umbilicated pustule and then a crust. Crusts fall off spontaneously in 1–3 weeks, leaving shallow pink depressions that gradually disappear. Scarring is rare unless the lesions were traumatized by the patient or superinfected with bacteria. Healing lesions may leave hypopigmented spots that persist for weeks to months; if scars occur they are depressed, pox-like.

Vesicles also develop in the mucous membranes of the mouth, nose, pharynx, larynx, trachea, gastrointestinal tract, urinary tract, and vagina. These mucosal vesicles rupture so rapidly that the vesicular stage may be missed. Instead, one sees shallow ulcers 2–3 mm in diameter.

A distinctive feature of varicella is the simultaneous presence, in any one area of the skin, of lesions in all stages of development. Careful prospective studies have shown that the average number of lesions in healthy children ranges from 250 to 500; secondary cases resulting from household exposure are more severe than primary cases resulting from exposure at school, presumably because more intense and prolonged exposure at home results in a higher virus inoculum.

Fever usually persists as long as new lesions continue to appear, and its height is generally proportional to the severity of the rash. It may be absent in mild cases or rise to 40.5°C (105°F) in severe cases with extensive rash. Prolonged fever or recurrence of fever after defervescence may signify a secondary bacterial infection or another complication. The most distressing symptom is pruritus, which is usually present throughout the vesicular stage.

The varicella vaccine alters the natural history of the rash. A small percentage of vaccinees develop "breakthrough" varicella after exposure to people with active VZV infections. The usual breakthrough rash is predominately maculopapular with fewer lesions (i.e., less than 60) and fewer vesicles than the rash of natural varicella. The incidence and severity of fever is also less than that in natural varicella.[47]

CLINICAL MANIFESTATIONS OF HERPES ZOSTER

PRODROME OF HERPES ZOSTER. Pain and paresthesia in the involved dermatome often precede the eruption by several days and vary from superficial itching, tingling, or burning to severe, deep, boring, or lancinating pain. The pain may be constant or intermittent and it is often accompanied by tenderness and hyperesthesia of the skin in the involved dermatome. The preeruptive pain of herpes zoster may simulate pleurisy, myocardial infarction, duodenal ulcer, cholecystitis, biliary or renal colic, appendicitis, prolapsed intervertebral disk, or early glaucoma, and this may lead to serious misdiagnosis and misdirected interventions. Prodromal pain is uncommon in

Figure 194-3 Varicella. **A.** A full spectrum of lesions—that is, erythematous papules, vesicles ("dewdrops on rose petals"), crusts, and erosions at sites of excoriation—is seen in a child with a typical case of varicella. **B.** A wider range of lesions, including many large pustules, is seen in a 21-year-old female who was febrile as well as "toxic" and had varicella pneumonitis.

immunocompetent persons under 30 years of age, but it occurs in the majority of persons with herpes zoster over the age of 60 years. A few patients experience acute segmental neuralgia without ever developing a cutaneous eruption—a condition known as *zoster sine herpete*.[48]

RASH OF HERPES ZOSTER. The most distinctive feature of herpes zoster is the localization and distribution of the rash, which is nearly always unilateral and is generally limited to the area of skin innervated by a single sensory ganglion (Fig. 194-4A). The area supplied by the trigeminal nerve, particularly the ophthalmic division, and the trunk from T3 to L2 are most frequently affected; the thoracic region alone accounts for more than half of all reported cases, and lesions rarely occur distal to the elbows or knees.[14,18,39]

Although the individual lesions of herpes zoster and varicella are indistinguishable, those of herpes zoster tend to evolve more slowly and usually consist of closely grouped vesicles on an erythematous base, rather than the more discrete, randomly distributed vesicles of varicella. This difference reflects intraneural spread of virus to the skin in herpes zoster, as opposed to viremic spread in varicella. Herpes zoster lesions begin as erythematous macules and papules that often first appear where superficial branches of the affected sensory nerve are given off, for example, the posterior primary division and the lateral and anterior branches of the anterior primary division of spinal nerves.[39] Vesicles form within 12–24 hours and evolve into pustules by the third day. These dry and crust in 7–10 days. The crusts generally persist for 2–3 weeks (Fig. 194-4B). In normal individuals, new lesions continue to appear for 1–4 days (occasionally for as long as 7 days). The rash is most severe and lasts longest in older people, and is least severe and of shortest duration in children.

Between 10% and 15% of reported cases of herpes zoster involve the ophthalmic division of the trigeminal nerve (Fig. 194-4C).[49] The rash of ophthalmic zoster may extend from the level of the eye to the vertex of the skull, but it terminates sharply at the midline of the forehead. When only the supratrochlear and supraorbital branches are involved, the eye is usually spared. Involvement of the nasociliary branch, which innervates the eye as well

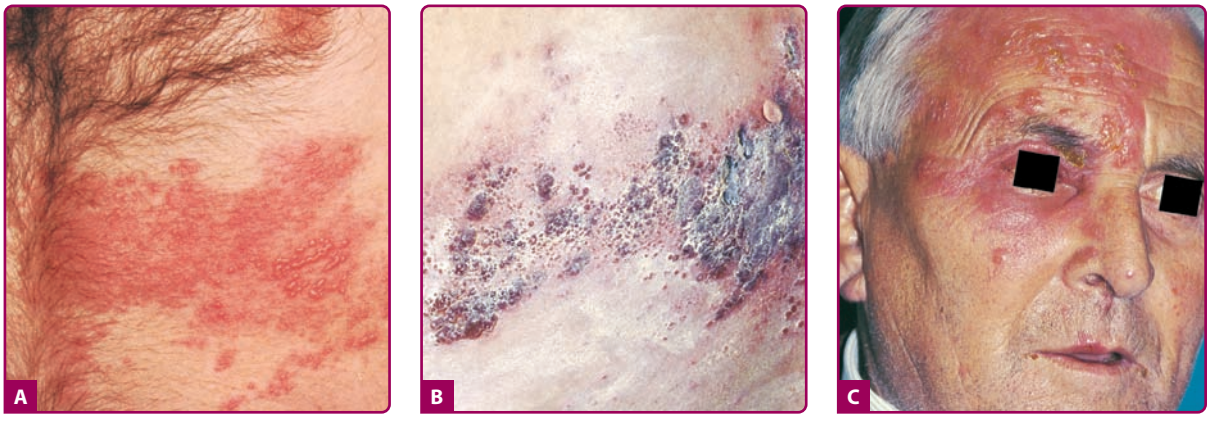

Figure 194-4 Herpes zoster. **A.** Early involvement of a thoracic dermatome with erythema within the dermatome and areas of grouped vesicle formation. **B.** Later involvement with crusted sites on the back, where the eruption first appeared, and many confluent hemorrhagic vesicles and bullae on the lateral chest wall, where the eruption appeared more recently; some vesicles are also seen outside the involved dermatome, representing hematogenous dissemination, a not uncommon occurrence. **C.** Ophthalmic zoster. Note the involvement of the tip of the nose, which frequently signals involvement of the eye.

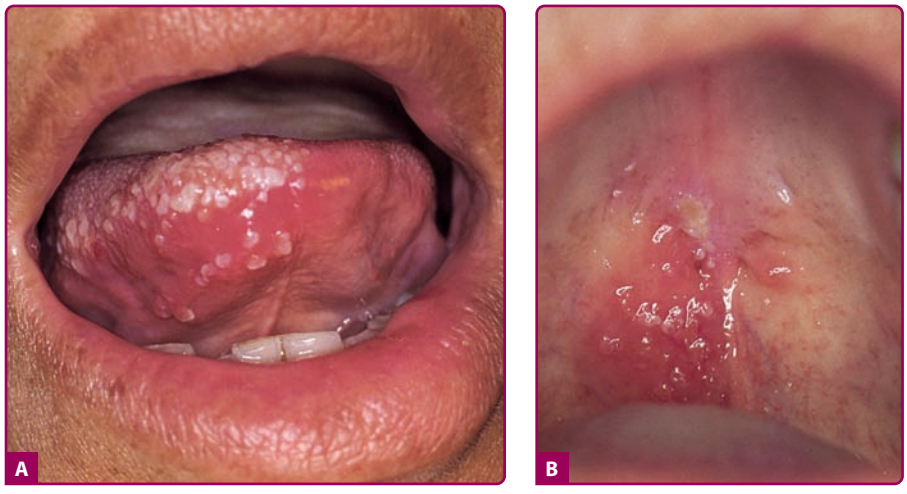

Figure 194-5 Cephalic herpes zoster with facial palsy (Hunt syndrome). A 60-year-old female with right-sided facial palsy and vesicles on her (**A**) *tongue* and (**B**) *soft palate.*

as the tip and side of the nose, provides VZV with direct access to intraocular structures. Thus, when ophthalmic zoster involves the tip and the side of the nose, careful attention must be given to the condition of the eye. The eye is involved in 20%–70% of patients with ophthalmic zoster. Corneal sensation is generally impaired and when impairment is severe, it may lead to neurotrophic keratitis and chronic ulceration.

Herpes zoster affecting the second and third divisions of the trigeminal nerve as well as other cranial nerves may produce symptoms and lesions in the mouth (Fig. 194-5), ears, pharynx, or larynx. The so-called Ramsay Hunt syndrome (facial palsy in combination with herpes zoster of the external ear or tympanic membrane, with or without tinnitus, vertigo, and deafness), results from involvement of the facial and auditory nerves.

PAIN OF HERPES ZOSTER. Although the rash is important, pain is the cardinal problem posed by herpes zoster, especially in the elderly. Most patients experience dermatomal pain or discomfort during the acute phase (The first 30 days following rash onset) that ranges from mild to severe. Patients describe their pain or discomfort as burning, deep aching, tingling, itching, or stabbing. For some patients, the pain intensity is so great that words like horrible or excruciating are used to describe the experience. Acute herpes zoster pain is associated with decreased physical functioning, emotional distress, and decreased social functioning.[50,51]

HERPES ZOSTER IN THE IMMUNOCOMPROMISED HOST. Except for PHN, most serious complications of herpes zoster occur in immunocompromised persons. These complications include necrosis of skin and scarring (Fig. 194-6) and cutaneous dissemination (Fig. 194-7) with an incidence as high as 25%–50%. Patients with cutaneous dissemination also manifest widespread, often fatal, visceral

dissemination, particularly to the lungs, liver, and brain.

HIV-infected patients are fairly unique in their tendency to suffer multiple recurrences of herpes zoster as their HIV infection progresses; herpes zoster may recur in the same or different dermatomes or in several contiguous or noncontiguous dermatomes. Herpes zoster in patients with AIDS may be severe, with cutaneous and visceral dissemination. Patients with AIDS may also develop chronic verrucous, hyperkeratotic, or ecthymatous cutaneous lesions caused by acyclovir-resistant VZV (Fig. 194-8) (see also Chapter 198).

DIFFERENTIAL DIAGNOSIS

(See Box 194-1)

Figure 194-8 Chronic verrucous lesions of herpes zoster despite long-term acyclovir treatment in a patient with advanced AIDS. (Used with permission from David Paar, MD.)

BOX 194-1 DIFFERENTIAL DIAGNOSIS OF VARICELLA AND HERPES ZOSTER

VARICELLA

Most Likely
- Vesicular exanthems of coxsackieviruses and echoviruses
- Impetigo
- Insect bites
- Contact dermatitis
- Rickettsialpox

Consider
- Papular urticaria
- Erythema multiforme
- Drug eruptions
- Disseminated herpes simplex
- Scabies

Always Rule Out
- Secondary syphilis
- Disseminated herpes zoster
- Dermatitis herpetiformis
- Smallpox and other poxviruses

HERPES ZOSTER

Most Likely
- Zosteriform herpes simplex
- Contact dermatitis
- Insect bites
- Burns

Consider
- Papular urticaria
- Erythema multiforme
- Drug eruptions
- Scabies

Always Rule Out
- Bullous pemphigoid
- Pemphigus vulgaris
- Dermatitis herpetiformis
- Epidermolysis bullosa herpetiformis

CLINICAL DIAGNOSIS OF VARICELLA

Varicella can usually be diagnosed readily on the basis of the appearance and evolution of its characteristic rash (see Fig. 194-3), particularly when there is a history of exposure within the preceding 2–3 weeks.

Disseminated herpes zoster may be mistaken for varicella when there is widespread dissemination of VZV from a small, painless area of herpes zoster or from the affected sensory ganglion in the absence of an obvious dermatomal eruption. This is not infrequent in profoundly immunosuppressed, seropositive persons (Fig. 194-7).

Disseminated HSV infections may resemble varicella; however, there is often an obvious concentration of lesions at and surrounding the site of the primary or recurrent infection (e.g., the mouth or external genitalia) and there may be marked toxicity and encephalitis.

The remaining differential diagnoses of varicelliform rashes are listed in Box 194-1. The character, distribution, and evolution of the lesions, together with a careful epidemiologic history, usually differentiate these diseases from varicella. When any doubt exists, the clinical impression should receive laboratory confirmation.

CLINICAL DIAGNOSIS OF HERPES ZOSTER

In the preeruptive stage, the prodromal pain of herpes zoster is often confused with other causes of localized pain. Once the eruption appears, the character and dermatomal location of the rash, coupled with dermatomal pain or other sensory abnormalities, usually makes the diagnosis obvious (Figs. 194-4 and 194-5).

A cluster of vesicles, particularly near the mouth or genitals, may represent herpes zoster, but it may also be recurrent HSV infection.[27] Zosteriform herpes simplex is often impossible to distinguish from herpes zoster on clinical grounds. A history of multiple recurrences at the same site is common in herpes simplex but does not occur in herpes zoster in the absence of profound and clinically obvious immune deficiency.

Box 194-1 lists other considerations in the differential diagnosis of herpes zoster.

LABORATORY DIAGNOSIS

The lesions of varicella and herpes zoster are indistinguishable by histopathology (Fig. 194-9). The presence of multinucleated giant cells and epithelial cells containing acidophilic intranuclear inclusion bodies (Fig. 194-9B) distinguishes the cutaneous lesions produced by VZV from all other vesicular eruptions (e.g., those caused by variola and other poxviruses, and by coxsackieviruses and echoviruses) except those produced by HSV. These cells can be demonstrated in Tzanck smears prepared at the bedside; material is scraped from the base of an early vesicle, spread on a glass slide, fixed in acetone or methanol, and stained with hematoxylin-eosin, Giemsa, Papanicolaou, or Paragon multiple stain.

Punch biopsies provide more reliable material for histologic examination than Tzanck smears and facilitate diagnosis in the prevesicular stage and in atypical lesions such as the chronic verrucous lesions produced by acyclovir-resistant VZV in patients with AIDS (Fig. 194-8).

The definitive diagnosis of VZV infection, as well as the differentiation of VZV from HSV, is accomplished by the isolation of virus in cell cultures inoculated with vesicle fluid, blood, cerebrospinal fluid or infected tissue, or by the direct identification of VZV antigens or nucleic acids in these specimens. Virus isolation is the only technique that yields infectious VZV for further analysis, such as determination of its sensitivity to antiviral drugs; however, VZV is extremely labile, and only 30%–60% of cultures from proven cases are generally positive. To maximize virus recovery, specimens should be inoculated into cell culture immediately. It is important to select new vesicles containing clear fluid for aspiration, because the probability of isolating VZV diminishes rapidly as lesions become pustular. VZV is almost never isolated from crusts.

VZV can be isolated and propagated in vitro in monolayer cultures of a variety of human (and certain simian) cells. The cytopathic effects induced by the replicating virus in such cell cultures are characterized by the formation of acidophilic intranuclear inclusion bodies and multinucleated giant cells similar to those seen in the cutaneous lesions of the disease. These changes are indistinguishable from those produced by HSV, but whereas HSV rapidly spreads to infect the remaining cells in the culture, the cytopathic effect of VZV remains focal. Cytopathic effects of VZV are generally not apparent until several days after specimen inoculation. Modifications of the cell culture assay in which vesicle fluid or lesion scrapings are centrifuged onto cells growing on coverslips at the bottom of thin glass-walled "shell" vials followed 24–72 hours later by fixation and staining with fluorescein- or enzyme-labeled monoclonal antibodies to VZV proteins, can confirm the presence of VZV relatively quickly, well before cytopathic effects are evident in conventional cell cultures.[52]

Immunofluorescent or immunoperoxidase staining of cellular material from fresh vesicles or prevesicular lesions has become the diagnostic method of choice

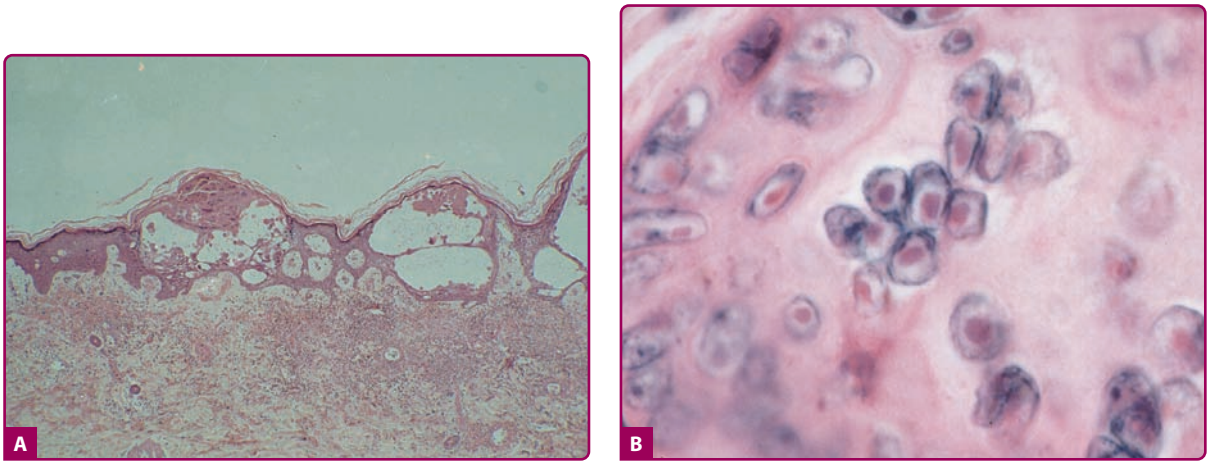

Figure 194-9 Herpes zoster, histopathology. **A.** Intraepidermal vesicle, acantholysis, reticular degeneration; underlying dermis shows edema and vasculitis. **B.** Multinucleated giant cells with characteristic nuclear changes.

in many centers; it can detect VZV significantly more often and faster than virus culture, even relatively late in the disease when cultures are no longer positive.[52] Enzyme immunoassays provide another rapid and sensitive method for antigen detection.

Detection of VZV DNA in clinical specimens following amplifications by PCR provides the greatest assay sensitivity, very high specificity and rapid turnaround time. It has revolutionized the diagnosis of VZV infections, and can distinguish among wild type and Oka vaccine strains of VZV and HSV.[52,53]

Serologic tests permit the retrospective diagnosis of varicella and herpes zoster when acute and convalescent sera are available for comparison.[52] These assays can also identify susceptible individuals who may be candidates for isolation or prophylaxis. The technique most commonly used is a solid-phase enzyme-linked immunosorbent assay (ELISA). However, this assay often lacks sensitivity and specificity, failing to detect antibody in people who are immune and sometimes yielding false-positive results in susceptible individuals. Several more sensitive techniques have been developed to measure humoral responses to VZV. These include an immunofluorescence assay for antibody to VZV-induced membrane antigens [fluorescent antibody to membrane antigen (FAMA)] that reliably distinguishes immune from susceptible adults and a latex agglutination test that is comparable in sensitivity and specificity to FAMA assays, but is much simpler to perform.[54]

COMPLICATIONS

COMPLICATIONS OF VARICELLA

In the normal child, varicella is rarely complicated. The most common complication is the secondary bacterial infection of skin lesions, usually by *Staphylococci* or *Streptococci*, which may produce impetigo, furuncles, cellulitis, erysipelas, and, rarely, gangrene.[55] These local infections often lead to scarring and, rarely, to septicemia with metastatic infection of other organs. Bullous lesions may develop when vesicles are superinfected by *Staphylococci* that produce exfoliative toxins. Invasive group A streptococcal infections are particularly virulent. In the absence of varicella vaccination, up to one-third of varicella is associated with invasive group A streptococcal infections; they usually occur within 2 weeks of the onset of the varicella rash.[56] Widespread varicella vaccination appears to have markedly reduced the percentage of invasive group A streptococcal hospitalizations associated with varicella in the United States.[57]

Secondary bacterial pneumonia, otitis media, and suppurative meningitis are rare complications and typically respond to appropriate antibiotic therapy. However, bacterial superinfection is common and potentially life threatening in leukopenic patients. Other complications reflect a basic defect in the capacity of the host to limit VZV replication and dissemination.

In adults, fever and constitutional symptoms are more prominent and prolonged, the rash of varicella is more profuse, and complications are more frequent. High rates of complications have been reported in adults not born in the United States (i.e., adults born in Mexico).[58] Primary varicella pneumonia is the major complication of adult varicella. Some patients are virtually asymptomatic, but others develop severe respiratory embarrassment, with cough, dyspnea, tachypnea, high fever, pleuritic chest pain, cyanosis, and hemoptysis 1–6 days after onset of the rash. The severity of the symptoms usually exceeds the physical findings, but the roentgenogram typically reveals diffuse, peribronchial nodular densities throughout both lung fields with a tendency to concentrate in the perihilar regions and at the bases. The mortality in adults with frank varicella pneumonia has been estimated to be between 10% and 30%, but it is less than 10% if immunocompromised patients are excluded.[59]

Varicella during pregnancy is a threat to both mother and fetus.[60] Disseminated infection and varicella pneumonia may result in maternal death, but neither the incidence nor the severity of varicella pneumonia appear to be significantly increased by pregnancy. The fetus may die as a consequence of premature labor or maternal death caused by severe varicella pneumonia, but varicella during pregnancy does not, otherwise, substantially increase fetal mortality. Nevertheless, even in uncomplicated varicella, maternal viremia can result in intrauterine (congenital) VZV infection, and a characteristic constellation of congenital abnormalities.[60] Perinatal varicella (i.e., varicella occurring within 10 days of birth) is more serious than varicella in infants infected even a few weeks later.

The morbidity and mortality of varicella are markedly increased in immunocompromised patients. In these patients, continued virus replication and dissemination result in a prolonged high-level viremia, a more extensive rash, a longer period of new vesicle formation, and clinically significant visceral dissemination. Immunosuppressed and glucocorticoid-treated patients may develop pneumonia, hepatitis, encephalitis, and hemorrhagic complications of varicella, which range in severity from mild febrile purpura to severe and often fatal purpura fulminans and "malignant" varicella.

CNS complications of varicella occur in fewer than 1 in 1,000 cases; they include several distinct syndromes. Varicella-associated Reye syndrome (acute encephalopathy with fatty degeneration of the liver) typically occurs 2–7 days after the appearance of the rash. In the past, from 15% to 40% of all cases of Reye syndrome occurred in association with varicella, with mortality as high as 40%, particularly when aspirin was administered for fever.[61] Acute cerebellar ataxia is more common than the other neurologic complications of varicella, occurring in 1 in 4,000 cases, and is more benign.[62] Encephalitis is much less common, occurring in 1 in 33,000 cases, but it frequently causes death or permanent neurologic sequelae. The pathogenesis of cerebellar ataxia and encephalitis remains obscure, but in many cases it is possible to detect VZV antigens, VZV antibodies, and VZV DNA in the cere-

brospinal fluid of patients, suggesting direct infection of the CNS.

Although elevated aminotransferase levels are common, clinical hepatitis is rare except as a complication of progressive varicella. Other rare complications of varicella include myocarditis, glomerulonephritis, orchitis, pancreatitis, gastritis and ulcerative lesions of the bowel, arthritis, Henoch-Schönlein vasculitis, optic neuritis, keratitis, and iritis. The pathogenesis of many of these complications has not been delineated, but direct parenchymal or endovascular VZV infection, or vasculitis induced by VZV antigen-antibody complexes, appear to be responsible in most cases.

COMPLICATIONS OF HERPES ZOSTER

(See Table 194-1)

The sequelae of herpes zoster include cutaneous, ocular, neurologic, and visceral complications.[39] Most complications of herpes zoster are associated with the spread of VZV from the initially involved sensory ganglion, nerve, or skin, either via the bloodstream or by direct neural extension. The rash may disseminate after the initial dermatomal eruption has become apparent. When immunocompetent patients are carefully examined, it is not uncommon to have at least a few vesicles in areas distant from the involved and immediately adjacent dermatomes. The disseminated lesions usually appear within a week of the onset of the segmental eruption and, if few in number, are easily overlooked. More extensive dissemination (with 25–50 lesions or more), producing a varicella-like eruption (generalized herpes zoster; Fig. 194-7), occurs in 2%–10% of unselected patients with localized herpes zoster, most of whom have immunologic defects as a result of acquired immunodeficiency, as seen with HIV infection, underlying malignancy (particularly lymphomas), or immunosuppressive therapy. If the rash spreads widely from a small, painless area of herpes zoster, the initial dermatomal presentation may go unnoticed, and the ensuing disseminated eruption may be mistaken for varicella.

When the dermatomal rash is particularly extensive, as it often is in severely immunocompromised patients, there may be superficial gangrene with delayed healing and subsequent scarring (Fig. 194-6). Secondary bacterial infection may also delay healing and cause scarring.

The eye is involved in 20%–70% of patients with ophthalmic zoster, with a wide range of possible complications.[49] VZV is also the principal cause of acute retinal necrosis (ARN), a fulminant sight-threatening disease observed primarily in otherwise healthy individuals.[46,63,64]

Herpes zoster may be attended by a variety of neurologic complications (Table 191-1), of which PHN is the most common and important.[65] PHN has been variably defined as any pain after rash healing or any pain 1 month, 3 months, 4 months, or 6 months after rash onset.[66,67] In clinic and community studies, the overall incidence of PHN is 8%–15% depending on the definition (Fig. 194-1A).[21,68,69] Age is the most significant risk factor for PHN (Fig. 194-1C). Clinically significant pain lasting 3 months or more is rare in immunocompetent persons younger than 50 years of age, but complicates 12%–15% of cases of herpes zoster in persons 60 years of age and older.[17] Other risk factors for PHN include the presence of prodromal pain, severe pain during the acute phase of herpes zoster, greater rash severity, more extensive sensory abnormalities in the affected dermatome and, possibly, ophthalmic (as opposed to thoracic or abdominal) herpes zoster.[70] Increasing age, greater acute pain severity, presence of prodromal pain, and greater rash severity have each been reported to be independent predictors of PHN.[67] The positive predictive value of each factor alone was low, but, together, the positive predictive value was almost 50%. PHN usually remits spontaneously over several months but, as with PHN itself, the risk of long-lasting PHN increases with increasing age.

Patients with PHN may suffer from constant pain (described as "*burning, aching, throbbing*"), intermittent pain ("*stabbing, shooting*"), and/or stimulus-evoked pain, including allodynia ("*tender, burning, stabbing*"). Allodynia (pain elicited by stimuli that are normally not painful) is a particularly disabling component of the disease that is present in approximately 90% of patients with PHN. Patients with allodynia may suffer severe pain after even the lightest touch of the

TABLE 194-1
Complications of Herpes Zoster

Cutaneous	Visceral	Neurologic

affected skin by things as trivial as a breeze or a piece of clothing. These subtypes of pain may produce disordered sleep, depression, anorexia, weight loss, chronic fatigue, and social isolation, and they often interfere with dressing, bathing, general activity, traveling, shopping, cooking, and housework.

TREATMENT

ANTIVIRAL AGENTS. (See also Chapter 231). The nucleoside analogues acyclovir, famciclovir, valacyclovir, and brivudin and the pyrophosphate analog foscarnet show efficacy in treating VZV infections. Acyclovir is a guanosine analogue that is selectively phosphorylated by VZV thymidine kinases (it is a poor substrate for cellular thymidine kinase) and thus is concentrated in infected cells. Cellular enzymes then convert acyclovir monophosphate to acyclovir triphosphate, which interferes with viral DNA synthesis by inhibiting viral DNA polymerase. VZV is approximately tenfold less sensitive to acyclovir than herpes simplex virus.

Two prodrugs, valacyclovir and famciclovir, are better and more reliably absorbed than acyclovir following oral administration. Thus, they produce much higher blood levels of antiviral activity and permit less frequent dosing than acyclovir. Valacyclovir is a valine ester of acyclovir that is converted enzymatically to acyclovir after absorption. Famciclovir is a prodrug of penciclovir, a nucleoside analogue similar to acyclovir in mechanism of action and antiviral activity against VZV and HSV. Famciclovir is converted enzymatically to penciclovir after absorption.

Brivudin is a uracil analogue with very high activity against VZV. Although effective in the treatment of herpes zoster, and licensed for such use outside the United States, it is not licensed in the United States, in part because of a potentially lethal interaction with 5-fluorouracil.

Foscarnet is an analogue of inorganic pyrophosphate that inhibits the replication of all known herpesviruses in vitro. It exerts its antiviral activity by selective inhibition at the pyrophosphate-binding site of virus-specific DNA polymerases and reverse transcriptases at concentrations that do not affect cellular DNA polymerases. Foscarnet does not require phosphorylation by thymidine kinase to be activated and is therefore active against acyclovir-resistant VZV mutants that have reduced or altered thymidine kinase activity.

Topical antiviral therapy lacks efficacy in patients with varicella and herpes zoster and is not recommended. Systemic therapy, either oral or parenteral, is required. Because of their superior pharmacokinetics, the lower sensitivity of VZV compared to HSV, and the existence of barriers to the entry of antiviral agents into tissues that are sites of VZV replication, famciclovir or valacyclovir are preferred to acyclovir for oral therapy of VZV infections. Acyclovir-resistant VZV has been documented in varicella and herpes zoster in patients with advanced AIDS (Fig. 194-8). Because of the mechanism of acyclovir resistance (mutations in the viral thymidine kinase gene), these acyclovir-resistant mutants are cross-resistant to ganciclovir, valacyclovir, famciclovir, and penciclovir. They usually respond to foscarnet, 40 mg IV every 8 hours; however, the infections commonly recur after treatment has ended.

TREATMENT OF VARICELLA

TOPICAL THERAPY. In normal children, varicella is generally benign and self-limited. Cool compresses or calamine lotion locally, tepid baths with baking soda or colloidal oatmeal (three cups per tub of water) and oral antihistamines may relieve itching. Creams and lotions containing glucocorticoids and occlusive ointments should not be used. Antipyretics may be needed, but salicylates must be avoided because of their association with Reye syndrome. Minor bacterial infections are treated with warm soaks. Bacterial cellulitis requires systemic antimicrobial therapy that is effective against *Staphylococcus aureus* and group A β-hemolytic streptococcus.

ANTIVIRAL THERAPY

Normal Children. (See Table 194-2). A large randomized, controlled trial of acyclovir treatment of healthy children 2–12 years of age found that early treatment (within 24 hours of the appearance of rash) with oral acyclovir (20 mg/kg four times a day for 5 days) modestly reduced the maximum number of lesions, the time to cessation of new lesion formation, and the duration of the rash, fever, and constitutional symptoms when compared to placebo.[71] Treatment initiated more than 24 hours after rash onset was not effective. Because varicella is a relatively benign infection in children and the clinical benefits of treatment are modest, routine antiviral treatment is not recommended in otherwise normal children[30,72,73]; however, many have favored its use where cost is not a concern, where it can be begun in time to benefit the patient (within 24 hours of rash onset), and where there is a perceived need to speed resolution of the infection so that parents can comfortably return to work. Because secondary cases among susceptible children in the household are generally more severe than the index cases, and because early initiation of treatment is more readily accomplished in secondary cases, treatment with acyclovir seems reasonable for such secondary cases.

The American Academy of Pediatrics recommends oral acyclovir for persons aged >12 years, persons with chronic cutaneous or pulmonary disorders, persons receiving long-term salicylate therapy, and persons receiving short, intermittent, or aerosolized courses of corticosteroids because these individuals are at increased risk for moderate-to-severe varicella.[73]

Normal Adolescents and Adults. A randomized, controlled trial of acyclovir treatment of healthy adolescents 13–18 years of age found that early treatment with oral acyclovir (800 mg five times a day for 5 days) reduced the maximum number of lesions and time to cessation of new lesion formation compared to placebo.[74] A randomized, placebo-controlled trial of

TABLE 194-2
Antiviral Treatment of Varicella in the Normal and Immunocompromised Host

Patient Group	Regimen
Normal[a]	
Neonate	Acyclovir 10 mg/kg or 500 mg/m^2 every 8 h for 10 days
Child (2 to <18 years of age)	Symptomatic treatment alone, or Valacyclovir 20 mg/kg every 8 h for 5 days[b] (not to exceed 3 g/day) or Acyclovir 20 mg/kg po four times a day × 5 days (not to exceed 3200 mg/day)
Adolescent (≥40 kg) or adult, especially with mild immune compromise (e.g., use of inhaled glucocorticoids)	Valacyclovir 1 g po every 8 h for 7 days or Famciclovir 500 mg po every 8 h for 7 days or Acyclovir 800 mg po five times a day for 7 days
Pneumonia	Acyclovir 10 mg/kg IV every 8 h × 7–10 days[b]
Pregnancy	Routine use of acyclovir is not recommended. If there are complication (e.g., pneumonia) treat pneumonia as per recommendation above.
Immunocompromised	
Mild varicella or mild compromise	Valacyclovir 1 g po every 8 h for 7–10 days or Famciclovir 500 mg po every 8 h for 7–10 days or Acyclovir 800 mg po five times a day for 7–10 days
Severe varicella or severe compromise	Acyclovir 10 mg/kg IV every 8 h for 7–10 days
Acyclovir resistant (advanced AIDS)	Foscarnet 40 mg/kg IV every 8 h until healed

[a]Oral acyclovir or preferably, famciclovir or valacyclovir, should be considered for otherwise healthy persons at increased risk for moderate-to-severe varicella (e.g., persons aged >12 years, persons with chronic cutaneous or pulmonary disorders, persons receiving long-term salicylate therapy, and persons receiving short, intermittent, or aerosolized courses of corticosteroids). (From Marin M et al: Prevention of varicella: Recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR Recomm Rep* **56**:1-40, 2007.)
[b]Must prepare suspension by grinding 500-mg valacyclovir caplets and suspending in cherry-flavored Suspension Structural Vehical USP-NF (SSV) at 25 mg/mL or 50 mg/mL in lots of 100 mL at time of dispensing.

oral acyclovir in healthy young adults with varicella showed that early treatment (within 24 hours of rash onset) with oral acyclovir (800 mg five times a day for 7 days) significantly reduced the time to crusting of lesions, the extent of disease, and duration of symptoms and fever.[59] Thus, routine treatment of varicella in adults seems reasonable. Although not tested, it is likely that famciclovir 500 mg PO q8h or valacyclovir 1,000 mg PO q8h would be convenient and appropriate substitutes for acyclovir in normal adolescents and adults. Many physicians do not prescribe oral acyclovir in uncomplicated varicella during pregnancy because the risk to the fetus of treatment is unknown. Other physicians recommend oral antiviral therapy for infections in the third trimester when organogenesis is complete, when there may be a heightened risk of varicella pneumonia, and when infection can be spread to the newborn. Intravenous acyclovir is often considered for pregnant women with varicella who have extensive cutaneous and/or systemic disease.

Complications of Varicella in Normal Persons. Uncontrolled trials in immunocompetent adults with varicella pneumonia suggest that early treatment (within 36 hours of hospitalization) with IV acyclovir (10 mg/kg q8h) may reduce fever and tachypnea and improve oxygenation.[75] Other serious complications of varicella in the immunocompetent host, such as encephalitis, meningoencephalitis, myelitis, and ocular complications, should be treated with IV acyclovir.

Immunocompromised Patients. Controlled trials in immunocompromised patients with varicella demonstrated that treatment with IV acyclovir decreased the incidence of life-threatening visceral complications when treatment was initiated within 72 hours of rash onset.[76] Immune compromise, however, is a continuum ranging from minimal to severe. Intravenous acyclovir has been the standard of care for varicella in patients with substantial immunodeficiency. Although oral therapy with famciclovir or valacyclovir might suffice for patients with mild degrees of immune impairment, there are no controlled clinical trials to guide the decision.

TREATMENT OF HERPES ZOSTER

TOPICAL THERAPY. During the acute phase of herpes zoster, the application of cool compresses, calamine lotion, cornstarch, or baking soda may help to alleviate local symptoms and hasten the drying of vesicular lesions. Occlusive ointments should be avoided, and creams or lotions containing glucocorticoids should not be used. Bacterial superinfection of local lesions is uncommon and should be treated with warm soaks; bacterial cellulitis requires systemic antibiotic therapy. Topical treatment with antiviral agents is not effective.

ANTIVIRAL THERAPY. The major goals of therapy in patients with herpes zoster are to (1) limit the extent, duration, and severity of pain and rash in the primary

TABLE 194-3
Antiviral Treatment of Herpes Zoster in the Normal and Immunocompromised Host

Patient Group	Regimen
Normal	
Age <50 years	Symptomatic treatment alone, or Famciclovir 500 mg PO every 8 h for 7 days or Valacyclovir 1 g PO every 8 h for 7 days or Acyclovir 800 mg PO 5 times a day for 7 days[a]
Age ≥50 years, and patients of any age with cranial nerve involvement (e.g., ophthalmic zoster)	Famciclovir 500 mg PO every 8 h for 7 days or Valacyclovir 1 g PO every 8 h for 7 days of Acyclovir 800 –mg PO 5 times a day for 7 days[a]
Immunocompromised	
Mild compromise, including HIV-1 infection	Famciclovir 500 mg PO every 8 h for 7–10 days or Valacyclovir 1 g PO every 8 h for 7–10 days or Acyclovir 800 mg PO 5 times a day for 7–10 days[a]
Severe compromise Acyclovir resistant (e.g., advanced AIDS)	Acyclovir 10 mg/kg IV every 8 h for 7–10 days Foscarnet 40 mg/kg IV every 8 h until healed

[a]Famciclovir or valacyclovir are preferred because their greater and more reliable oral bioavailability result in higher blood levels of antiviral activity, the lower susceptibility of VZV (compared to HSV), and the existence of barriers to the entry of antiviral agents into tissues that are sites of VZV replication.

dermatome; (2) prevent disease elsewhere; and (3) prevent PHN.

Normal Patients. Table 194-3 lists the current recommendations for treatment of herpes zoster. Randomized controlled trials indicate that oral acyclovir (800 mg five times a day for 7 days), famciclovir (500 mg q 8 hours for 7 days), and valacyclovir (1 g three times a day for 7 days) reduce time to rash healing, and the duration and severity of acute pain in older adults with herpes zoster who are treated within 72 hours of rash onset.[77] In some studies, the duration of chronic pain was also reduced, but the FDA has not approved these agents for the prevention of PHN.[78,79] Randomized controlled trials comparing acyclovir to valacyclovir, acyclovir to famciclovir, and valacyclovir to famciclovir demonstrated equivalent results in rash healing, acute pain, and the duration of chronic pain.[80–82] All three drugs are acceptable agents for older adults, with cost and dosing schedule determining the choice of agent. However, the reduced sensitivity of VZV compared with HSV, the existence of barriers to the entry of antiviral agents into tissues that are sites of VZV replication, and the higher and more reliable blood levels of antiviral activity achieved, make famciclovir or valacyclovir preferable to acyclovir for oral treatment of herpes zoster.

Because of the lower risk of PHN, antiviral therapy is less valuable or necessary for treatment of uncomplicated herpes zoster in healthy people younger than 50 years of age. The utility of antiviral agents is unproven if treatment is initiated more than 72 hours after rash onset. Nevertheless, we believe that it is prudent to initiate antiviral therapy even if more than 72 hours have elapsed after rash onset in patients who have herpes zoster involving cranial nerves (e.g., ophthalmic zoster) or who continue to have new vesicle formation.[77,79]

Ophthalmic zoster represents a special therapeutic challenge because of the risk of ocular complications. Examination by an ophthalmologist should be sought in most cases. Oral acyclovir has been shown in a randomized, controlled trial to be effective in preventing ocular complications of ophthalmic zoster.[83] Famciclovir and valacyclovir appear to have efficacy comparable to that of acyclovir in the treatment of ophthalmic zoster, and are preferred for the reasons cited above.[84,85]

Immunocompromised Patients. A randomized, double-blind, placebo-controlled trial in immunocompromised patients with herpes zoster showed that IV acyclovir (500 mg/m^2 q8h for 7 days) halted progression of the disease, both in patients with localized herpes zoster and in patients with cutaneous dissemination prior to treatment.[86] Acyclovir accelerated the rate of clearance of virus from vesicles and markedly reduced the incidence of visceral and progressive cutaneous dissemination. Pain subsided faster in acyclovir recipients, and fewer reported PHN, but these differences were not statistically significant. Clinical trials comparing IV acyclovir to IV vidarabine for the treatment of herpes zoster in immunocompromised patients showed that acyclovir was significantly more effective and less toxic.[86,87] In patients with mild immunocompromise and localized herpes zoster, oral acyclovir, valacyclovir, or famciclovir will usually suffice.[88,89] A randomized, controlled trial of oral famciclovir versus oral acyclovir in patients with localized herpes zoster following bone marrow or organ transplantation or cancer chemotherapy showed that the two treatments were equivalent in rash healing and loss of acute pain, and that both were well tolerated.[89]

ANTI-INFLAMMATORY THERAPY. The possibility that PHN might be caused by inflammation of the sensory ganglion and contiguous neural structures provided the rationale for the use of glucocorticoids during the acute phase of herpes zoster in an attempt to further reduce acute pain and prevent PHN.

Randomized controlled trials, however, showed that the addition of glucocorticoids to acyclovir did not change the incidence of chronic pain.[90–92] However, glucocorticoids did reduce acute pain in most trials, and in one trial of acyclovir and prednisone, the time to uninterrupted sleep, return to baseline daily activity, and cessation of analgesic therapy was reduced in patients who received glucocorticoids.[91] Consequently, some experts advocate oral glucocorticoids for otherwise healthy older adults whose rash is complicated by moderate-to-severe pain and who have no contraindications to glucocorticoids.[77] Others believe that the common adverse effects of glucocorticoids argue against their routine use in older patients with herpes zoster. We agree and do not recommend the use of glucocorticoids in this setting. Glucocorticoids, in combination with effective antiviral therapy, may improve motor outcomes and acute pain in VZV-induced facial paralysis and cranial polyneuritis, where compression of affected nerves may contribute to disability.

ANALGESICS. Greater severity of acute pain is a risk factor for PHN, and acute pain may contribute to central sensitization and the genesis of chronic pain. Therefore, aggressive pain control is both reasonable and humane.[77] The severity of acute herpes zoster pain should be determined using simple standardized pain scales. Clinicians should prescribe nonopiate or opiate analgesics with the goal of limiting the severity of pain to less than 3 or 4 on a 0-to-10 scale, and to a level that does not interfere with sleep. The choice, dosage, and schedule of drugs are governed by the patient's pain severity, underlying conditions, and response to specific drugs. A randomized controlled trial of oxycodone, gabapentin, or placebo in older adults with herpes zoster showed that oxycodone, but not gabapentin, provided significantly greater pain relief than placebo in patients with moderate-to-severe pain.[93] This trial was not powered to analyze PHN, and there are no other controlled trials of the effect of treatment with opioids or gabapentin during the acute phase of herpes zoster on the subsequent development of PHN. A crossover study of a single dose of 900 mg of gabapentin during the acute phase of herpes zoster showed greater pain relief than placebo.[94] If pain control remains inadequate, regional or local anesthetic nerve blocks should be considered for acute pain control.[77,95] A randomized controlled trial demonstrated that a single epidural injection of corticosteroids and local anesthetics in the acute phase of herpes zoster did not prevent the subsequent development of PHN.[95]

TREATMENT OF POSTHERPETIC NEURALGIA

Once established, PHN is difficult to treat. Fortunately, it resolves spontaneously in most patients, although this often requires several months (Fig. 194-1B). Clinicians have advocated a wide range of treatments, including many oral and topical medications, epidural injection of local anesthetic and glucocorticoids, acupuncture, biofeedback, subcutaneous injections of triamcinolone, trans-epidermal electric nerve stimulation (TENS), spinal cord stimulators, and systemic administration of a variety of compounds, but most have not been validated by controlled trials. The results of randomized controlled trials demonstrated efficacy for pain relief in PHN for the following drugs: gabapentin, pregabalin, tricyclic antidepressants (TCAs), opioid analgesics, tramadol, lidocaine patch 5%, and high-concentration capsaicin patch.[96–101] The choice of these medications should be guided by the adverse event profiles, potential for drug interactions, and patient comorbidities and treatment preferences. On average, these agents provide adequate pain relief (defined as reduction of pain to below 4 on a 0–10 point scale or by 50% on a visual analog or Likert scale) in 30%–60% of patients. These modalities are now recommended as evidence-based pharmacotherapy for PHN in practice management guidelines.[96–98]

TOPICAL THERAPY. Topical anesthesia delivered by means of a 5% lidocaine patch has been shown in controlled clinical trials to produce significant pain relief in patients with PHN. The 10 × 14-cm lidocaine patch contains 5% lidocaine base, adhesive, and other ingredients on a polyester backing. It is easy to use and is not associated with systemic lidocaine toxicity.[102] Up to three patches are applied over the affected area for 12 hours a day. The disadvantages of the patch are application site reactions, such as skin redness or rash, and substantial cost. Eutectic mixture of local anesthetics (EMLA) cream applied once a day over the affected area under an occlusive dressing is an alternative method of delivering topical anesthesia.

A single 1-hour application of a high-concentration capsaicin patch (8%) compared with a low-concentration control patch significantly reduced pain from PHN from the second week after the capsaicin application throughout a subsequent 12-week period.[99] The high-concentration patch was generally well tolerated. Adverse events include increases in pain associated with patch application (usually transient) and application-site reactions (e.g., erythema). The role of the high-concentration capsaicin patch in the treatment of PHN is yet to be clearly established, partly because its long-term benefits are not yet known. However, this intervention has promise because a single 1-hour application may yield several weeks of pain reduction.

ORAL AGENTS. Gabapentin has been shown to produce moderate or greater pain relief in 41%–43% of patients with PHN compared to 12%–23% in patients receiving placebo.[103,104] Frequent adverse effects of gabapentin include somnolence, dizziness, and peripheral edema. Pregabalin has been shown to produce 50% or greater pain relief in 50% of patients with PHN compared to 20% in placebo recipients.[105,106] Dizziness, somnolence, and peripheral edema were also the most common adverse effects reported for pregabalin.[105–107] Pregabalin has a less complicated dose titration schedule and a faster onset of action than gabapentin.

TCAs have been shown to produce moderate-to-good pain relief in 44%–67% of elderly patients with

PHN in several randomized, controlled trials.[96,97,100,108] Nortriptyline and desipramine are preferred alternatives to amitriptyline because they cause fewer cardiac adverse effects, sedation, cognitive impairment, orthostatic hypotension, and constipation in the elderly.[109]

Treatment with scheduled opioids may also reduce PHN. In a randomized, placebo-controlled crossover trial of sustained-release oxycodone in patients with PHN, patients reported significant pain relief when treated with opioid compared to placebo.[110] In a crossover study in patients with PHN, both controlled-release morphine and TCAs provided significant pain relief compared to placebo.[111] In this trial, patients preferred treatment with opioid analgesics to either TCAs or placebo, despite a greater incidence of adverse effects and more dropouts during opioid treatment.

The use of combinations of these drugs for PHN is common in clinical practice and undergoing increasing investigation. In a crossover trial, patients with diabetic polyneuropathy or PHN were randomized to daily active placebo (lorazepam), sustained-release morphine, gabapentin, and a combination of gabapentin and morphine.[112] Combination therapy with morphine and gabapentin produced greater pain relief than either agent alone or placebo, but with an increase in adverse effects (constipation, sedation, and dry mouth). In a crossover trial, patients with diabetic polyneuropathy or PHN were randomized to receive one of three sequences of daily oral gabapentin, nortriptyline, and a combination of the two.[113] Combination therapy with gabapentin and nortriptyline produced greater pain relief than either agent alone. The most common adverse event was dry mouth secondary to nortriptyline. These results suggest that combination therapy may benefit some individuals with PHN who have responded to one of the agents chosen, but at the risk of increased adverse effects than with either drug alone.

PREVENTION

PREVENTION OF VARICELLA

VARICELLA VACCINE. Several studies conducted in Europe, Japan, and the United States from the early 1970s through the early 1990s demonstrated that live attenuated (Oka strain) VZV vaccines were immunogenic and efficacious in protecting susceptible children against varicella. Although breakthrough cases of varicella were observed following subsequent exposure to wild-type VZV, they were relatively mild.[30] Similar results were obtained in adults when two doses were given 4–8 weeks apart. Vaccinated children and adults developed breakthrough varicella caused by wild-type VZV at a rate of 1%–3% per year compared to an attack rate of 8%–13% per year in unvaccinated children. On the basis of these data, the FDA licensed the Oka/Merck varicella vaccine in the United States in 1995. In 2005, the FDA approved a combined measles, mumps, rubella, and varicella vaccine (MMRV) for routine immunization of children 12 months to 12 years of age.

Because of the frequency of breakthrough varicella caused by wild-type VZV, the Advisory Committee on Immunization Practices (ACIP) now recommends two 0.5-mL doses of varicella vaccine for healthy children aged ≥12 months, adolescents, and adults without evidence of immunity.[30] For children aged 12 months—to 12 years, the recommended minimum interval between the two doses is 3 months, although the second dose may be administered as soon as 28 days after the first. For persons aged >13 years, the recommended minimum interval is 4 weeks. Single-antigen varicella vaccine is approved for use among healthy persons aged ≥12 months. Combination MMRV vaccine is approved for use among healthy children aged 12 months to 12 years. Because of the increased severity of varicella in adults, susceptible adults should be identified and vaccinated. High priority should be given to vaccinating adults who may be at increased risk for exposure or transmission and who do not have evidence of immunity, including (1) health care providers, (2) household contacts of immunocompromised persons, including susceptible pregnant women, (3) persons who live or work in environments in which transmission of VZV is likely (e.g., teachers, day care employees, residents, and staff in institutional settings), (4) persons who live or work in environments in which transmission has been reported (e.g., college students, inmates and staff members of correctional institutions, and military personnel), (5) nonpregnant women of childbearing age, (6) adolescents and adults living in households with children, and (7) international travelers. Second dose catch-up varicella vaccination is recommended for children, adolescents, and adults who previously received only one dose.[30,114]

The immunity to varicella induced by varicella vaccine is not as solid as that induced by wild-type VZV infection, and the duration of vaccine-induced immunity is not yet known. However, a high percentage of children followed long-term have remained seropositive.[115] Recent experience in clinical practice indicates that vaccine efficacy in children is modestly lower than that reported in clinical trials, and outbreaks of breakthrough varicella in schools and day care centers do occur.[114,116–118] In a prospective, population-based study, vaccine effectiveness for prevention of all disease was 78.9% (95% CI, 69.7%–85.3%); for prevention of moderate disease was 92% (50–500 lesions) and for prevention of severe disease and physician visits was 100%.[118] A CDC analysis of 10 years of surveillance data for varicella (1995–2004) showed that the annual rate of breakthrough varicella significantly increased with the time since vaccination, from 1.6 cases per 1,000 person-years (95% CI, 1.2–2.0) within 1 year after vaccination to 9.0 per 1,000 person-years (95% CI, 6.9–11.7) at 5 years and 58.2 per 1,000 person-years (95% CI, 36.0–94.0) at 9 years.[119] Although most breakthrough varicella in children are characterized by mild disease, more recent reports indicate that 25%–30% of breakthrough cases are not mild and are clinically similar to varicella in unvaccinated children.[120] Interestingly, cases of breakthrough varicella in household settings were half as contagious as cases of varicella in unvaccinated persons, although the minority of breakthrough cases

with 50 lesions or more were as contagious as cases in unvaccinated persons. In adults, approximately 20% of vaccinees lose detectable antibodies to VZV over time, but continue to be partially protected.[114,116–118] Of the 48 million doses of varicella vaccine distributed between 1995 and 2005, there were 25,306 adverse events reported (52.7/100,000 doses distributed) to the FDA's Vaccine Adverse Event Reporting System and the Centers for Disease Control and Prevention (CDC)[121] 95% of which were nonserious events, mainly minor rashes and injection site reactions.[121] Serious adverse events were rare (2.6/100,000 doses distributed) and, in the majority, a causal relationship between the serious adverse event and varicella vaccine could not be established.

Herpes zoster has been reported in vaccinees, but it occurs at a significantly lower frequency than herpes zoster in persons of similar age following varicella caused by wild-type VZV. Cases of laboratory-confirmed herpes zoster in vaccinees from several studies included some cases caused by reactivation of the vaccine virus and others caused by reactivation of wild-type virus acquired prior to vaccination as a consequence of unrecognized varicella.

POSTEXPOSURE PROPHYLAXIS AND INFECTION CONTROL. Patients with varicella and herpes zoster may transmit VZV to susceptible individuals. Preventive measures include the varicella vaccine, investigational high-titer zoster immune globulin (VariZIG), and postexposure chemoprophylaxis with acyclovir.

Active immunization with the live attenuated varicella vaccine is effective in preventing illness or modifying varicella severity in children if used within 3 days after exposure.[122] Whereas protection afforded by zoster immune globulin is transient, varicella vaccine induces long-lasting (active) immunity to VZV and protection against subsequent exposures. Therefore, the ACIP recommends varicella vaccine for postexposure prophylaxis in unvaccinated persons without evidence of immunity.[30]

Passive immunization with VZIG was an effective preventive strategy, but the production of VZIG has been discontinued in the United States. An investigational VZIG, VariZIG, is available under an investigational new drug application (IND).[123] The investigational VariZIG is a purified human immune globulin prepared from plasma containing high levels of antibody to VZV (immunoglobulin class G [IgG]). This product can be requested for patients who have been exposed to varicella and who are at increased risk for severe disease and complications.[123]

Chemoprophylaxis with acyclovir also has been studied in susceptible children following household exposure to varicella. Children who received postexposure treatment with acyclovir experienced fewer and less severe cases of varicella than children in the control group.[124] However, appropriate timing is critical, and immunity to varicella may not be achieved, especially with early postexposure treatment. In addition, there is concern that resistant strains of VZV may be selected by promiscuous application of this approach. Hence, postexposure antiviral chemotherapy is not recommended for routine use in children.

Infection control practices for VZV increase in importance with the age and compromised immune status of the exposed, susceptible individual. There is no need to prevent exposure of susceptible normal children to VZV, but careful isolation procedures should be enforced to prevent infection of susceptible immunocompromised patients, newborn infants, and adults, particularly women of childbearing age. Exposure of susceptible immunocompromised patients to VZV warrants reduction in the dosage of glucocorticoids and other immunosuppressive drugs, and administration of investigational VariZIG. Hospital and long-term care facility personnel without a clear history of varicella or herpes zoster should be tested for antibody to VZV, and susceptible personnel vaccinated against varicella. Appropriate leave from work should be instituted following VZV exposure of any susceptible personnel who are not vaccinated. In hospitals, airborne and contact precautions are recommended until all lesions are crusted for patients with varicella, immunocompromised patients with localized herpes zoster, and any patient with disseminated herpes zoster.[125,126] Contact precautions are recommended for immunocompetent patients with localized herpes zoster.

PREVENTION OF HERPES ZOSTER

ZOSTER VACCINE. Until universal varicella vaccination greatly reduces the number of people latently infected with wild-type VZV, prevention of herpes zoster must be aimed at preventing reactivation and spread of the latent wild-type VZV. Long-term suppressive acyclovir treatment is only practical in immunocompromised patients at proven risk of developing herpes zoster within a defined time period, for example, in the year following bone marrow or solid organ transplantation. Other strategies must be devised for the general population.

One approach to the prevention of herpes zoster is the stimulation of immunity to VZV, which wanes in the elderly and in other high-risk individuals.[40,127] Studies of healthy adults over 55 years of age with a history of varicella have demonstrated an increase in VZV-specific T lymphocytes and humoral immunity after vaccination with live attenuated VZV vaccine that is similar to the increase observed after an episode of herpes zoster.[128] These findings suggested that vaccination of older persons may be useful in preventing herpes zoster and its complications.[33,127] A recent VA Cooperative Study (the Shingles Prevention Study) tested the hypothesis that vaccination against VZV would decrease the incidence and/or severity of herpes zoster and PHN among older adults.[17] The study enrolled 38,546 adults 60 years of age or older in a randomized, double-blind, placebo-controlled trial of a live attenuated Oka/Merck VZV vaccine of much greater potency than the currently licensed varicella vaccine. A total of 957 confirmed cases of herpes zoster (315 among vaccine recipients and 642 among placebo recipients) and 107 cases of PHN (27 among

vaccine recipients and 80 among placebo recipients) were included in the efficacy analysis. The zoster vaccine reduced the burden of illness due to herpes zoster by 61.1% (P <0.001), reduced the incidence of PHN by 66.5% (P <0.001), and reduced the incidence of herpes zoster by 51.3% (P <0.001). Reactions at the injection site were more frequent among vaccine recipients but were generally mild. The proportion of subjects reporting serious adverse events, and rates of hospitalization and death were comparable in vaccine and placebo recipients.[129] Furthermore, the zoster vaccine neither caused nor induced herpes zoster in recipients. This landmark study showed that the zoster vaccine markedly reduced morbidity from herpes zoster and PHN among older adults. The FDA licensed the zoster vaccine for the prevention of herpes zoster in adults 60 years of age and older in 2006. The ACIP of the CDC unanimously recommended the vaccine for the prevention of herpes zoster and its complications, including PHN, in immunocompetent adults 60 years of age and older, irrespective of a history of herpes zoster.[23] Zoster vaccine has now been added to the US schedule of routinely recommended adult immunizations.[23]

The zoster vaccine may be administered without screening for a history of varicella or herpes zoster, nor should one conduct serologic testing for varicella immunity before vaccination.[23] Persons known to be VZV seronegative should be vaccinated against varicella according to current recommendations.[30] Older adults who have PHN or who have a current episode of herpes zoster may ask to be vaccinated, but zoster vaccination is not indicated to treat acute herpes zoster or PHN. Some patients may want to receive zoster vaccine after a recent episode of herpes zoster has resolved. The optimal time to immunize an individual after a recent episode of herpes zoster is unknown, and the clinical diagnosis of herpes zoster is not always correct. The authors believe that an interval of 3–5 years after the onset of a well-documented case of herpes zoster is reasonable.

A history of anaphylactic reaction to any of the vaccine components is a contraindication to the vaccine.[23] Neomycin is a vaccine component but contact dermatitis due to neomycin does not represent anaphylaxis and therefore is not a contraindication to zoster vaccination. The zoster vaccine should not be given to persons who have severe acute illness, including active untreated tuberculosis, until the illness has subsided. Persons with leukemia, lymphomas, or other malignant neoplasm affecting the bone marrow or lymphatic system, or with AIDS or other clinical manifestations of HIV infection, including those with $CD4^+$ T-lymphocyte counts ≤200 per mm^3 and/or ≤15% of total lymphocytes should not receive zoster vaccine.[23] Persons on immunosuppressive therapy, including high-dose corticosteroid therapy, should not receive the vaccine. The ACIP defines high-dose corticosteroids as 20 mg or more per day of oral prednisone or equivalent for 14 days or more.[130] Low doses of methotrexate (≤0.4 mg/kg/week), azathioprine (≤3.0 mg/kg/day), or 6-mercaptopurine (≤1.5 mg/kg/day) are not considered to have significant immunosuppression.[23]

When considering the zoster vaccine, older adults may express concerns about transmission of vaccine virus to other individuals. Transmission of VZV requires the development of a vesicular rash containing vaccine virus after vaccination. If there is no rash, there is no transmission. Zoster vaccine-associated vesicular rashes are very unusual. In the Shingles Prevention Study, vesicular lesions at the injection site were observed in 20 of 19,270 vaccine recipients a median of 3–4 days after vaccination and in 7 out of 19,276 placebo recipients. Neither vaccine virus nor wild-type VZV were detected by DNA PCR testing in the few specimens that were available for testing. Transmission of vaccine virus from recipients of zoster vaccine to susceptible household contacts has not been documented. Thus, immunocompetent older adults in contact with immunosuppressed patients should receive zoster vaccine to reduce the risk that they will develop herpes zoster and transmit wild-type VZV to their susceptible immunosuppressed contacts.[23,33] For the same reasons, adult contacts of susceptible pregnant women and infants should receive zoster vaccine. Zoster vaccine recipients with susceptible pregnant or immune compromised contacts need not take any special precautions following vaccination, except in the rare situation that a vesicular rash develops, in which case standard contact precautions are adequate. Eligible residents and personnel in nursing homes and other facilities housing older adults should also be vaccinated against herpes zoster. However, VZV-seronegative persons (e.g., health care workers from tropical countries who have not had varicella) should be vaccinated against varicella. These recommendations are consistent with those of the ACIP.[23] In the unlikely event that an immunocompromised contact develops a significant illness caused by vaccine virus, he/she may be treated with standard anti-VZV agents (acyclovir, valacyclovir, or famciclovir).

With the development of the varicella and zoster vaccines, antiviral therapy, and neuropathic pain treatments, clinicians now have multiple effective tools to reduce human suffering from varicella and herpes zoster.

Chapter 195 :: Poxvirus Infections

:: Caroline Piggott, Sheila Fallon Friedlander, & Wynnis Tom

POXVIRUSES

POXVIRUSES AT A GLANCE

- Poxviruses are the largest animal viruses; they can cause disease of varying severity in humans.
- Smallpox is the only poxvirus for which humans are the sole reservoir, which allowed its eradication.
- The smallpox vaccine virus, vaccinia, has its own adverse effects.
- Monkeypox is a zoonotic infection endemic in Africa, but it has recently appeared in the Western Hemisphere.
- Milker's nodule and orf mainly cause localized cutaneous infections.
- Molluscum contagiosum is generally a benign cutaneous disease most frequently seen in children and immunocompromised individuals.
- Histopathologic features of poxviral cutaneous lesions include the presence of intracytoplasmic eosinophilic inclusion bodies.

Poxviruses are double-stranded DNA viruses that replicate in the cytoplasm of host cells (Table 195-1). These "brick-shaped" viruses constitute the largest known animal viruses and can be seen with light microscopy.[1] The poxviruses that cause significant disease in humans are reviewed here. Their effects on the host range from systemic disease to localized infection to epithelial cell proliferation alone.

ORTHOPOXVIRUS INFECTIONS

SMALLPOX (VARIOLA)

Variola virus is the pathogen responsible for smallpox, a disease that devastated humankind in catastrophic epidemics for over 3,000 years. This poxvirus scarred and killed millions of people in both the Old and New Worlds, affecting entire populations on every continent.

SMALLPOX AT A GLANCE

- Smallpox is an illness with mortality rates of over 30% in its major form.
- It is transmitted mainly by the respiratory route; viremia leads to cutaneous and visceral involvement.
- The eruption consists of papules that progress simultaneously to vesicular and pustular lesions in a centrifugal pattern.
- The disease has not been seen since 1978, but the potential use of aerosolized variola virus for bioterrorism is of significant concern.
- Smallpox vaccination has been reinstituted on a selective basis for response in the case of an outbreak.

Edward Jenner altered the course of history in 1796 when he created the first vaccine by inoculating patients with cowpox virus in order to protect patients against the related smallpox virus. Utilizing this method of protection, smallpox could be prevented, and an intensive global effort at vaccination and tracking of cases led to its eradication in 1980.[2] It subsequently appeared an illness of merely historical interest until threats of bioterrorism in recent years renewed the need for knowledge about smallpox and its features, along with the development of improved vaccines and treatments for use should the disease arise again.

EPIDEMIOLOGY. Unlike other diseases caused by members of the family Poxviridae, smallpox affects only humans and thus cannot be acquired from another species. Transmission is generally via respiratory droplets and requires close contact. Outbreaks occur in the winter and early spring seasons when conditions of low humidity and low temperature favor survival of the aerosolized virus.[3] Smallpox is less infectious than other diseases spread by the respiratory route, including measles, varicella, and influenza. Secondary attack rates for unvaccinated contacts are estimated to range from 37% to 88%.[4] Secondary cases are often limited to family members or health care workers. Spread of smallpox is enhanced when there are large quantities of virus in the aerosolized droplets, an increased number and extent of exposures between infected individuals and contacts, and a higher population density. The very young, elderly, and pregnant women are more susceptible to infection.[5] Individuals

TABLE 195-1
Poxviruses with Humans as Hosts

Genus	Species	Hosts	Main Portal of Entry	Clinical Features
Orthopoxvirus	Variola virus	Humans	Respiratory tract	High fever and myalgias precede oropharyngeal enanthem and centrifugal exanthem. Simultaneous progression of skin lesions from macules to papulovesicles, pustules, and crusts, resulting in significant scars. Last reported case in 1978; concern for use in bioterrorism.
	Vaccinia virus	Humans	Skin	Used as vaccine for smallpox and monkeypox. Vaccination site progresses from papule to vesicle, pustule, and crust, leaving scar. Adverse events occur when virus spreads locally or in a generalized manner, more severe in individuals with disruption of the skin barrier or immunocompromise.
	Monkeypox virus	Rodents, humans, monkeys, anteaters	Skin	Clinical presentation similar to that of smallpox but more prominent lymphadenopathy and lower mortality.
	Cowpox virus	Rodents, cats, humans, cattle	Skin	Contact with infected animal host gives rise to papule that becomes vesicular, hemorrhagic, pustular, and ulcerative; resulting eschar heals over 3–4 weeks with scarring. Pustular stage: often umbilicated with surrounding zone of erythema and edema. Constitutional symptoms and lymphangitis common. Can be extensive or severe if skin barrier disrupted.
Parapoxvirus	Orf virus	Sheep, goats, humans	Skin	Contact with infected animal or fomite leads to papule(s) that forms pustules or nodules with central umbilication and surrounding gray-white or violaceous ring and outer zone of erythema; lesion usually occurs on hand. Lesions become weepy then dry and crust. Healing occurs over 4–8 weeks, usually without scarring. Constitutional symptoms/lymphangitis occur less commonly.
	Paravaccinia virus	Cattle, humans	Skin	Transmission by contact with infected teats/mouths of cattle. Clinical findings and course similar to those of orf; differentiated by their different animal hosts.
	Bovine papular stomatitis virus	Cattle, humans	Skin	Transmitted by contact with infected mouths of cattle. Clinical findings and course similar to those of orf and paravaccinia.
Molluscipox-virus	Molluscum contagiosum virus	Humans, chimpanzees (one report)	Skin	Discrete firm, dome-shaped papules; central umbilication. Can be extensive in individuals with atopic dermatitis or immunocompromise. Most cases self-resolve in 9–12 months but lesions often treated to speed resolution; can be persistent/refractory in immunocompromised individuals.
Yatapoxvirus	Tanapox virus	Humans, monkeys	Possibly skin	Uncertain mode of transmission, possible mosquito vector from infected monkeys to humans. Short fever precedes eruption of one to multiple pruritic, indurated papules with surrounding edema. Become necrotic and/or ulcerative then heal within 6 weeks with scarring.

with more severe clinical disease are reported to be more infectious, but these same people also tend to be toxemic and confined to bed.

Because no significant subclinical carrier state exists, eradication was possible and was accomplished in 1980. After its eradication, the responsible virus was presumed to be limited to two World Health Organization (WHO)-approved laboratories in the United States and the former Soviet Union (Russian Federation). A theoretical concern exists that these or other

unreported stocks of virus may be in the hands of countries or groups with terrorist relationships and could be aerosolized for use as a biologic weapon (see Chapter 213). The possibility of genetically altering variola or other similar viruses for increased virulence further heightens concerns regarding misuse.[6] The majority of the population would be susceptible to smallpox disease as routine vaccination of civilians was discontinued in the United States in 1972 and worldwide in the 1980s. Those vaccinated before 1972 have uncertain levels of immunity remaining. Until 2003, laboratory workers handling nonhighly attenuated orthopoxviruses were the only individuals recommended to receive routine vaccination. Since that time, military personnel and a small group of US civilians who would serve as first-line responders in a possible outbreak have been vaccinated.[7] The risk of untoward effects from the vaccine, particularly in immunocompromised patients and individuals with atopic dermatitis or other diseases where a skin barrier defect exists, caused health authorities to hesitate before implementing mass vaccination policies.

ETIOLOGY AND PATHOGENESIS.

Smallpox is caused by the variola virus, a linear, double-stranded DNA virus of the genus *Orthopoxvirus*. Variola virus measures approximately $300 \times 250 \times 200$ nm and has an oval- or brick-shaped appearance on electron microscopy (see eFig. 195-0.1 in online edition). Strains of the virus fall into two main groups: (1) variola major and (2) variola minor. Although their genomes share approximately 98% homology, their virulence is markedly different, with 30% or higher mortality associated with the major type and less than 1% mortality associated with the minor type.[2,8]

Humans are the only natural reservoir of the variola virus and the reason for this strict tropism is not fully understood.[9] The disease process begins following close, prolonged exposure to an infected individual. The usual portal of entry is the oropharyngeal or respiratory tract, either by inhalation of aerosolized droplets or direct contact with infected mucous membranes.[10] After entry, the virus attaches to respiratory epithelial cells, travels to regional lymph nodes, and replicates at these sites. Transient primary viremia with uptake of the virus by macrophages occurs, and the variola virus spreads to the reticuloendothelial organs, where asymptomatic replication continues. A massive secondary viremia follows and causes the onset of symptoms (the prodromal period). The virus spreads to the skin and mucosa, along with other organs and tissues such as the liver and kidneys.[11] Variola virus is transmissible beginning in the late prodromal phase through aerosolization of viral particles from the oropharynx. It is most infectious during the first 7–10 days after onset of the viral rash and remains transmissible until the scabs fall off of skin lesions.[11,12]

Variola virus is less commonly spread via accidental inoculation into the skin, through the conjunctiva, and through contact with infected body fluids or highly contaminated fomites. Rarely, it has been transmitted transplacentally and by long-range airborne or suspended viral particles in enclosed areas.[6]

CLINICAL FINDINGS

History. The infected individual remains asymptomatic during the incubation period of viral replication. A prodrome of high fever [39°C–41°C (102.2°F–105.8°F)], chills, myalgias, and severe headache develops within 7–17 days of exposure, with an average incubation of 12 days for variola major and a few days longer for variola minor. The person is usually severely ill and bedridden during the prodromal period, which lasts 2–4 days. Children may develop seizures.[4,10]

Cutaneous Lesions. Evanescent, nonspecific urticarial or morbilliform lesions can develop during the prodrome. These occur mainly in previously vaccinated individuals at the vaccination site and the axillae, popliteal, and groin areas.[2] Approximately 1 day after the onset of fever, an enanthem develops. The earliest viral lesions are red macules on the mouth, tongue, and oropharynx that subsequently vesiculate and ulcerate, releasing high concentrations of transmissible virus particles in respiratory secretions. A skin rash (exanthem) erupts two to several days after the onset of fever, at about the same time that the mucosal lesions ulcerate. The fever usually declines with appearance of the rash.[6,13] The exanthem varies depending on viral dose and strain, vaccination status, level of immunity, and nutritional status.[5] The outbreak is categorized into two clinical forms: (1) variola major and (2) variola minor.

Forms of variola major are more common than variola minor. One classification divides variola major into five clinical types.[14] Ordinary, common or classic smallpox is the most common type and accounts for over 90% of cases of smallpox in unvaccinated individuals. Skin lesions begin as macules on the face and upper extremities that then spread quickly to the trunk and lower extremities. Involvement of all parts of the body, including palms and soles, occurs within 24–48 hours. The macules become raised papules within 1 day and then form vesicles, often with central umbilication, after 4–5 days (see eFig. 195-0.2 in online edition). Fever recurs as the lesions become firm pustules around day 7 (Fig. 195-1) and persists until all lesions have crusted and scabbed at day 14 (Fig. 195-2). Scabs separate by 3–4 weeks after the onset of the rash. Key features of smallpox skin lesions are their prominence peripherally on the face and extremities and their simultaneous progression in a centrifugal pattern, with all lesions in any one area exhibiting the same morphology.[10,15] After their resolution, pitted scars ("pockmarks") often persist and can be disfiguring (Fig. 195-3). Scarring is most common on the face, where there are larger and more numerous sebaceous glands, which are particularly susceptible to infection and destruction by variola virus.[2]

Modified smallpox has as severe a prodromal illness as ordinary smallpox, but the clinical course of cutaneous lesions is accelerated. Lesions are fewer in number and tend not to progress to vesicles or pustules, crusting by day 10. This form occurs mainly in vaccinated individuals and does not cause death. Flat smallpox (also called *malignant smallpox*) is an uncommon form of variola major in which the macules barely raise. It

Figure 195-1 Pustular smallpox lesions with characteristic highest density on the face and extremities. [From the Centers for Disease Control and Prevention (CDC) Public Health Image Library, Atlanta, GA, USA.]

Figure 195-3 Scars and pockmarks remain after the crusts have fallen off. [From the Centers for Disease Control and Prevention (CDC) Public Health Image Library, Atlanta, GA, USA and contributed by J. Noble, Jr., MD.]

usually occurs in children and unvaccinated individuals lacking cellular immunity. Those affected become severely ill with toxic fever, and most die with hemorrhagic lesions and pneumonia.[4] The hemorrhagic, or fulminant, type of variola major is equally common in unvaccinated and vaccinated persons. It is divided into two forms: early and late. The early form consists of petechial hemorrhages into the skin or mucous membranes during the prodromal period. Massive hemorrhage from mucosal surfaces leads to death within 8 days of onset, before any appearance of the typical rash of smallpox, with a case fatality of 100%. Women, especially if pregnant, are more susceptible to this form. In the late form, hemorrhage appears after onset of the typical rash, death occurs by 12 days after onset, and men and women are equally affected.[16] The last type of variola major is variola sine eruptione, in which vaccinated individuals come in contact with affected individuals and develop fever and other symptoms (e.g., headache, conjunctivitis) but no rash. In this type, the illness lasts 48 hours or less. Serologic studies do show a rise in antibody titers against smallpox virus.[4,14]

Figure 195-2 Crusted lesions on the foot at day 21 of the rash of smallpox. [From the Centers for Disease Control and Prevention (CDC) Public Health Image Library, Atlanta, GA, USA and contributed by Paul B. Dean, MD.]

Variola minor is clinically indistinguishable from cases of modified smallpox and from cases of ordinary smallpox in which lesions are discrete rather than confluent. Occasionally, the lesions are nonumbilicated. In the pre-eradication period, the diagnosis of variola minor was given only after assessment of the severity of an outbreak, if the case fatality rate was low (1% or less).[8] Molecular virologic differentiation between major and minor viral strains is now available.

Related Physical Findings. Variola virus spreads via the blood to affect other noncutaneous systems. It can infect the metaphyses of growing bones and lead to arthritis in up to 2% of affected children. Osteomyelitis variolosa occurs less frequently than arthritis, but may also cause bone deformities.[17] Swelling of the eyelids and a mild conjunctivitis are common findings. Cough and bronchitis may be seen in some cases of smallpox. A degree of encephalopathy often occurs, with symptoms ranging from headache and hallucinations to delirium and psychosis.[2] Gross hematuria can occur with the hemorrhagic type of variola major.[16]

LABORATORY TESTS.

The white blood cell count may increase as the skin lesions of smallpox become pustular. Severe thrombocytopenia occurs in both early and late hemorrhagic smallpox. A marked decrease in the level of factor V (accelerator globulin) and increase in thrombin time are noted in the early form, likely from

disseminated intravascular coagulation. The late form has a smaller degree of these coagulation disturbances.[2]

Histopathology. Skin biopsy specimens from early papules show edema and dilation of the capillaries of the papillary dermis with a perivascular infiltrate of lymphocytes, histiocytes, and plasma cells. With progression, the cells of the epidermis become vacuolated and swollen and undergo ballooning degeneration. These vesicles have characteristic intracytoplasmic inclusion bodies called *Guarnieri bodies*. Pustules form with migration of polymorphonuclear cells into the vesicles. Eventually, the pustule becomes a crust, with new epithelium growing to repair the surface. Mucous membrane lesions show similar changes but also have extensive necrosis of the epithelial cells leading to rapid ulceration rather than vesiculation.[18]

Special Tests. For diagnosis, specimens (skin lesions, tonsillar swab, blood, skin biopsy) should be collected by someone recently vaccinated and sent to designated high-containment facilities.

Scrapings of skin lesions can be examined via electron microscopy to assess for the typical oval or brick shape of orthopoxviruses. Serologic testing for orthopoxviruses with paired samples can be performed; this identifies the presence of a member of the genus but is not specific for variola virus. Polymerase chain reaction (PCR) methods are used to definitively identify variola virus and can also characterize the viral strain. Variola virus can be cultured in several commonly used cell lines and can be identified by the formation of characteristic pocks on chorioallantoic membranes of chicken embryos.[6,19]

DIFFERENTIAL DIAGNOSIS.

(Box 195-1). The exanthem of smallpox is most often confused with that of varicella (chickenpox). Smallpox lesions are initially centrifugal with simultaneous progression of all lesions. In contrast, varicella lesions have a more truncal (centripetal) distribution, the vesicles are more superficial, and lesions are present at different stages. Varicella also has a shorter disease course, with only a 1–2-day prodrome and with all lesions crusting in 4–6 days from their initial appearance.[11] Human monkeypox clinically resembles smallpox but often manifests lymphadenopathy. It is a zoonotic disease and is not spread as easily between persons. The morbilliform prodromal rash of smallpox can be confused with measles or coxsackievirus infections. Secondary syphilis should be considered, especially when there are lesions on the palms and soles, but these lesions do not progress. Other eruptions in the differential diagnosis are listed in Box 195-1. The lesions of hemorrhagic smallpox can be similar to those of meningococcemia, viral hemorrhagic fevers such as Ebola, dengue or rift valley fever, severe acute leukemia, and other acute hemorrhagic eruptions such as those associated with coagulopathies.

COMPLICATIONS.

Secondary bacterial infection occurs commonly in skin lesions as well as at regional lymph nodes, affecting 5% of individuals. A temperature spike occurring 3–5 days after the start of the prodrome may indicate secondary infection.[13] Keratitis and corneal ulceration, common in malnourished individuals, result in blindness in 1% of cases. Either variola virus or bacterial superinfection can lead to respiratory complications, including pneumonia, at day 8–10 of illness. Both arthritis and osteomyelitis can lead to limb deformities, including bone shortening, subluxation, and flail joints. Orchitis is less common and usually unilateral. Encephalitis is reported in 0.2% of cases.[2]

PROGNOSIS AND CLINICAL COURSE.

The most common form of variola major, common smallpox, is associated with a mortality rate ranging from

BOX 195-1 DIFFERENTIAL DIAGNOSIS OF SMALLPOX AND MONKEYPOX

Most Likely

- Papulovesicular eruption
  - Varicella
  - Disseminated zoster
  - Generalized vaccinia
- Prodromal morbilliform eruption
  - Measles
  - Drug eruption
- Hemorrhagic lesions (smallpox only)
  - Meningococcemia
  - Disseminated intravascular coagulation
- Mucosal lesions
  - Hand-foot-and-mouth disease
  - Stevens-Johnson syndrome

Consider

- Papulovesicular eruption
  - Kaposi varicelliform eruption
  - Eczema vaccinatum
  - Extensive molluscum contagiosum (human immunodeficiency virus infection)
  - Drug eruption
  - Bullous impetigo
  - Pityriasis lichenoides et varioliformis acuta
  - Rickettsialpox
- Prodromal morbilliform eruption
  - Coxsackievirus infection
  - Other viral infections
- Hemorrhagic lesions (smallpox only)
  - Acute leukemia
  - Viral hemorrhagic fevers
- Mucosal lesions
  - Oral herpes simplex

Always Rule Out

- Papulovesicular eruption
  - Secondary syphilis
- Hemorrhagic lesions (smallpox only)
  - Acquired coagulopathy
- Mucosal lesions
  - Stevens–Johnson syndrome

less than 10% when lesions are discrete to 50%–75% when lesions are confluent. Death often occurs between days 10 and 16 of illness. Modified smallpox is associated with less than 10% mortality. In contrast, flat smallpox has a case fatality rate of over 90%, and hemorrhagic forms have nearly 100% mortality. The overall mortality rate for variola major is 30%, compared to less than 1% for variola minor.[14] Those who survive either disease have lifetime immunity. Death from smallpox is thought to be secondary to toxemia associated with immune complexes and variola antigens, which induce hypotension/shock and multiorgan failure. Encephalitis is an important factor in death from variola minor but not from variola major.[2,4]

TREATMENT. There is currently no specific treatment for smallpox. A patient suspected of having the disease should be isolated in a negative-pressure room and given supportive care. Precautions should be taken to prevent secondary infection and appropriate antibiotics administered should it occur. Research on antiviral agents is ongoing. Intravenous cidofovir, a nucleotide analog approved for treatment of cytomegalovirus infection, is available from the Centers for Disease Control and Prevention (CDC, Atlanta, GA, USA) through an Investigational New Drug protocol. It has been found to have activity against variola, vaccinia, and other orthopoxviruses in in vitro and animal studies, but lacks clinical trial data and does carry a risk of nephrotoxicity.[20] Lipid-soluble cidofovir-derivatives, such as CMX001, are under study.[21] In addition, the oral drug ST-246 (Tecovirimat, SIGA Technologies, Corvallis, OR, USA) appears to inhibit the function of a major envelope protein (p37) required for extracellular egress of orthopoxviruses and prevent viral spread. It has been used by Emergency Use Authorization since 2008, and has shown efficacy against variola, monkeypox, and other orthopoxviruses in animal studies, and is now in Phase II trials.[22] Topical idoxuridine may be used to treat corneal lesions, although its efficacy has not been proven.

PREVENTION. Because of the development of lifelong immunity after recovery from natural smallpox infection, the first efforts at prevention were to introduce crusts or fluid from lesions to unaffected individuals to induce mild disease. This process of variolation did reduce morbidity and mortality but also caused full infection and spread in some cases. In 1796, Dr. Edward Jenner developed vaccination, using the cowpox virus to introduce cross-immunity against the variola virus. Vaccinia virus later became the virus used. Vaccination is 90%–96% effective in preventing smallpox disease when given before exposure to variola virus. For postexposure prophylaxis, smallpox vaccination within 2–3 days of exposure can protect against severe disease. Vaccination within 4–5 days may protect against death.[2,23] However, vaccination does not give lifelong immunity. The duration and degree of protection over time are subjects of debate. Most estimates suggest that primary vaccination gives full protection for 3–5 years and some but declining immunity at 10 years and after. Revaccination may give significant protection for at least 30 years.[12,24]

VACCINIA AND SMALLPOX VACCINATION

The vaccinia virus is also of the genus *Orthopoxvirus*. Its origins are unknown, but it is most similar to the cowpox virus in this family. In the nineteenth century, it replaced cowpox as the agent used for smallpox vaccination. Discussion here focuses on its features as the smallpox vaccine, as vaccinia virus is not known to cause natural infection. Because of significant homology with other poxviruses, vaccination with vaccinia virus provides not only protection against smallpox, but also against closely related orthopoxviruses such as monkeypox, camelpox, and cowpox.[2]

EPIDEMIOLOGY. Eradication of smallpox was made possible by intensive tracking of cases of infection with ring vaccination of primary and secondary contacts. The last known case of natural infection was one of variola minor in Somalia in 1977. One final case of accidental laboratory infection occurred in 1978, and the WHO declared eradication in 1980. Routine vaccination of civilians was discontinued in the United States in 1972 and worldwide in the 1980s. Vaccination of US military personnel initially ceased in 1990 and laboratory workers handling nonhighly attenuated orthopoxviruses were the only group still recommended to receive periodic vaccination.[25] But with the postal anthrax and World Trade Center attacks in 2001 and other threats of bioterrorism, vaccination was reinitiated in the United States in late 2002 for the military and a small group of voluntary public health and health care workers who would be first-line responders in a possible outbreak.[26]

Vaccination made eradication of smallpox possible, but given that vaccinia is a live virus, it does carry its own set of adverse effects. Most adverse events can occur at any age, but infants and children younger than the age of 5 years tend to be particularly affected. Adverse reactions are ten times more common with primary vaccination than revaccination. Individuals with atopic dermatitis, or other diseases with skin barrier dysfunction can acquire a severe eruption, eczema vaccinatum, from secondary contact more often than from direct vaccination.[4,26]

ETIOLOGY AND PATHOGENESIS. Smallpox vaccination involves the introduction of vaccinia virus into the outer layers of the intact skin. There are many strains of the virus, with the less pathogenic New York City Board of Health (NYCBH) and Lister-Elstree strains being used during the global smallpox eradication campaign. The previous vaccine licensed and used in the United States was a lyophilized, calf-lymph vaccine (Dryvax, Wyeth Laboratories, Marietta, PA, USA) produced from the NYCBH vaccinia strain.[12] In 2007, the United States transitioned to the new ACAM2000 vaccine (Acambis, Cambridge, MA, USA), formulated using a clone of Dryvax and modern cell-culture technology.[27] ACAM2000 was developed for a number of reasons: the possibility of contamination of the Dryvax vaccine with bovine spongiform encephalopathy from

calves, expiration of available Dryvax vaccine, rising concerns of the use of variola for bioterrorism and having an adequate vaccine supply, and risk of hypersensitivity reactions with Dryvax.[27] ACAM2000 has thus far shown comparable safety and efficacy to its predecessor in clinical trials and is currently used by the US Department of Defense for military and laboratory worker immunizations.[28–30]

After injection of vaccine into the skin by a bifurcated needle (see eFig. 195-3.1 in online edition), the virus rapidly multiplies locally and occasionally at regional lymph nodes. Viable, transmissible vaccinia virus is present at the resulting skin lesion until the lesion scabs and separates. The area heals with scarring at the injection site. Infection is usually limited by the host response with the development of antibody- and cell-mediated immunity.[11] Adverse events and complications occur when the virus spreads outside of the local area, either by transfer or a host inability to contain the response.

CLINICAL FINDINGS

History. Soreness is almost universal at the vaccination site. Systemic symptoms can occur and are considered normal reactions. These include fever [greater than 37.7°C (99.9°F) and more common in children], chills, headache, myalgias, and malaise. They generally peak at days 8–10 and last 1–3 days. Approximately 30% of vaccinees feel too ill to carry out normal activities.[31]

Cutaneous Lesions. The normal local skin reaction to vaccination begins 3–5 days after administration, starting with a papule that then develops into a vesicle (Jennerian vesicle) followed by a pustule around day 7–9. It crusts and scabs over at day 10–14, with the scab detaching at day 17–21 and leaving a residual scar (Fig. 195-4). A robust take, in which the local reaction is 10 cm or larger in diameter, occurs in 2%–16% of first-time vaccinees (see eFig. 195-4.1 in online edition). This can be mistaken for bacterial cellulitis, but it occurs 8–10 days after vaccination and self-improves without antibiotic therapy in 24–72 hours.[32] In contrast, secondary bacterial infections usually occur within the first 5 days or 30 days after vaccination.

Previously vaccinated individuals have a milder reaction with an accelerated time course. Those with substantial residual immunity may have only erythema with revaccination. Minor local reactions that can occur near the primary site include nearby satellite lesions that progress at the same rate, lymphadenopathy/lymphangitis, and intense surrounding erythema or edema.[12]

Adverse Reactions. Adverse cutaneous reactions associated with smallpox vaccination can be localized or generalized. Secondary bacterial infection, usually by *Staphylococci* or group A *Streptococci*, can occur at the primary site. Accidental vaccinia is the autoinoculation of vaccinia virus from the vaccination site to another area. It is the most common adverse event seen

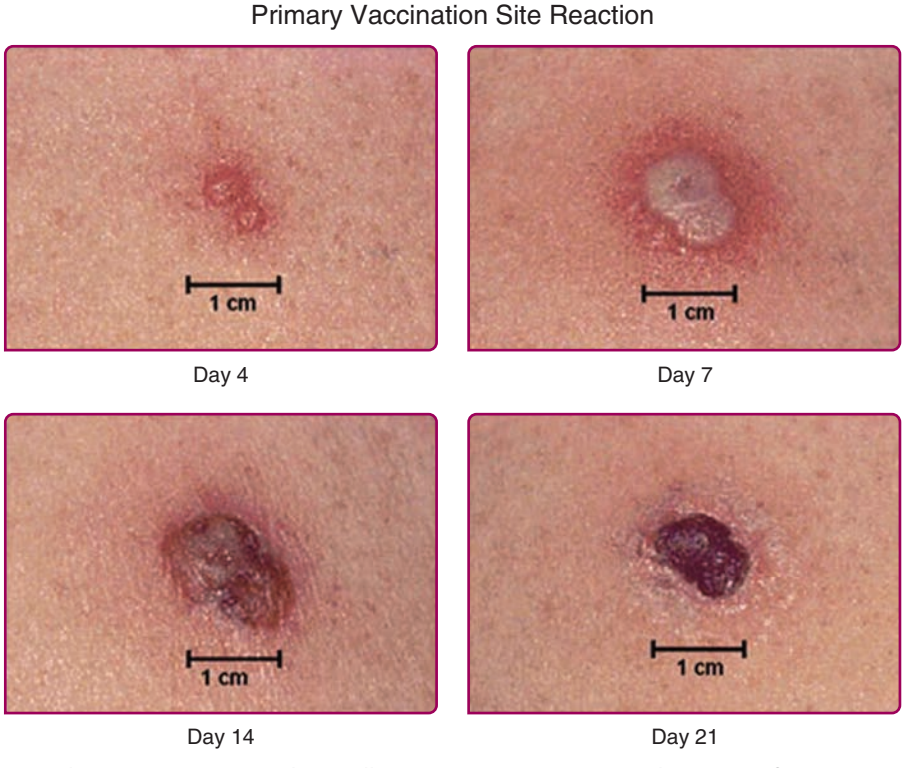

Figure 195-4 Normal progression seen at the smallpox vaccination site. [From the Centers for Disease Control and Prevention (CDC), Atlanta, GA, USA.]

and accounts for about half of all adverse events. The most common sites of transfer are the eyelids (see eFig. 195-4.2 in online edition), nose, mouth, and genitalia. Lesions are seen at these areas 7–10 days after vaccination, and they usually follow the time course of the original primary lesion. The lesions may be more attenuated if autoinoculation occurs more than 5 days after vaccination as the host immune response is developing.[33] Accidental inoculation to the eyes can lead to conjunctivitis, keratitis, or iritis.

Generalized adverse eruptions can be nonspecific, immune-mediated reactions, including morbilliform and roseola-like rashes. Hypersensitivity reactions such as erythema multiforme can also develop (see eFig. 195-4.3 in online edition). These rashes typically self-resolve over several days. In rare cases, Stevens–Johnson syndrome can develop and require hospitalization and supportive care. Vaccination can also lead to generalized vaccinia, in which macular, papular, or, less commonly, vesicular lesions can be disseminated to normal skin without evidence of autoinoculation. Generalized vaccinia can be limited or extensive and can occur anywhere on the body (Fig. 195-5). It is thought to be caused by spread of vaccinia virus via the bloodstream and usually occurs 6–9 days after primary vaccination. The lesions progress, as do other vaccinial lesions. The condition is self-limited in immunocompetent individuals but is often more severe in the setting of immunodeficiency.[34]

Eczema vaccinatum is the localized or generalized spread of vaccinia virus in individuals affected with atopic dermatitis or, less frequently, other chronic dermatoses such as Darier disease. The individual feels ill with fever, malaise, and lymphadenopathy. It can occur in the primary vaccinee with onset usually at the same time or soon after the appearance of lesions at the vaccination site. Papules, pustules, or vesicles can occur anywhere on the body but have a predilection for areas with prior lesions of atopic dermatitis (see Fig. 195-6). Lesions can range from several to hundreds; the most serious cases result in substantial loss of the skin barrier. The severity of eczema vaccinatum is independent of the severity or activity of the atopic dermatitis or other underlying skin disease. It can also be acquired by secondary transmission, usually by children in contact with a recently vaccinated family member.[10,35]

Figure 195-5 Generalized vaccinia in an 8-month-old infant. [From the Centers for Disease Control and Prevention (CDC) Public Health Image Library, Atlanta, GA, USA and contributed by Allen W. Mathies, MD of the California Emergency Preparedness Office, Immunization Branch.]

Figure 195-6 Eczema vaccinatum with lesions in areas of active dermatitis.

Vaccination of individuals with severe impairment of the immune system leads to progressive vaccinia, also called *vaccinia necrosa* and *vaccinia gangrenosa*. In these individuals, the primary lesion at the site of vaccination does not heal but instead enlarges and progresses to a painless ulcer with central necrosis (see eFig. 195-6.1 in online edition). Viral replication is not halted and viremia occurs, with similar metastatic lesions developing at distant sites in the skin, bone, and/or viscera. Most cases have occurred in individuals with defective cell-mediated immunity, but cases have also been described in those with humoral defects.[4] The degree of immune impairment may correlate with the risk for development of progressive vaccinia, but the precise protective level is unknown.[32]

Related Physical Findings. In addition to the skin, other organ systems can be affected by smallpox vaccination. Central nervous system complications can occur in previously healthy individuals. Postvaccinial encephalopathy most commonly affects children younger than 2 years of age, causing cerebral edema without inflammation. Symptoms develop abruptly 6–10 days after vaccination and can include fever, headache, seizures, hemiplegia, aphasia, and transient amnesia. Postvaccinial encephalitis and encephalomyelitis occur 11–15 days after vaccination, with fever, malaise, vomiting, and headache that progress

to confusion, seizures, amnesia, spinal cord signs, and coma.[36] These complications are thought to be autoimmune reactions, because vaccinia virus is not found in sampled cerebrospinal fluid or tissue. Higher rates of central nervous system complications are seen with non-NYCBH vaccinia strains. Other neurologic events reported to occur in temporal association with smallpox vaccination include transverse myelitis, paralysis, seizures, and polyneuritis, but causality has not been established.[2,37]

Cardiac events, including myopericarditis, can also occur with vaccination. With the Dryvax vaccine, the rate of myopericarditis among US military vaccinees was elevated 3.6-fold compared to the rate in unvaccinated personnel.[38] In clinical trials with ACAM2000, suspected cases of myopericarditis were noted at an approximate rate of 1 in every 175 primary vaccinees, with no cases in revaccinees.[28] Since reinitiation of smallpox vaccination in the United States in 2002, ischemic cardiac events as well as nonischemic dilated cardiomyopathy have been reported for the first time. Whether these events are caused by smallpox vaccination or are coincidental occurrences is not yet clear.[10]

LABORATORY TESTS. Recent studies suggest that IgM antibodies, detected as early as day 4, may play a role in preventing potentially deadly early viral spread.[39] Neutralizing IgG antibodies and cellular immunity start to become detectable around day 7 of vaccination and are responsible for maintaining the long-term host-immune response to the virus. Vaccinia virus can be detected at the primary vaccination site and sites of accidental vaccinia, generalized vaccinia, eczema vaccinatum, and progressive vaccinia.

COMPLICATIONS. Vaccinia keratitis can cause corneal ulceration with scarring and visual loss. Eczema vaccinatum can be so severe that the affected individual loses a substantial amount of the cutaneous barrier, much like a burn victim. Individuals with postvaccinial encephalopathy, encephalitis, or encephalomyelitis may recover in approximately 2 weeks, but one-fourth of survivors are left with residual sequelae (e.g., mental impairment, paralysis).[40]

Smallpox vaccination of a woman during pregnancy can rarely lead to fetal, or congenital, vaccinia, with about 50 cases reported in the literature. Transmission to the fetus can occur at any time during the pregnancy and results in lesions on the skin, mucous membranes, and placenta. The appearance can be similar to that of generalized vaccinia or progressive vaccinia, and lesions can be extensive (see eFig. 195-6.2 in online edition). It is unknown whether infection is through the blood or by direct contact with infected amniotic fluid. No reliable intrauterine diagnostic test exists to confirm fetal infection.[37]

PROGNOSIS AND CLINICAL COURSE. The potentially fatal adverse reactions from smallpox vaccination are eczema vaccinatum, progressive vaccinia, and postvaccinial central nervous system disease. Progressive vaccinia is universally fatal if untreated. Central nervous system complications have a 15%–25% case fatality rate. Most fatal cases from secondary transmission occur in infants younger than 1 year of age and are from contact eczema vaccinatum. Fetal vaccinia often results in fetal or neonatal death.[10,40]

Myopericarditis was reported in the pre-eradication era and was thought to cause the rare cases of cardiac-associated deaths after vaccination. Since reinstitution of vaccination in the United States in 2002, cases of myocarditis have been reported (as discussed above) but no deaths have occurred to date. Several ischemic cardiac deaths have occurred.[28,41]

TREATMENT. Symptomatic treatment alone is needed for the normal systemic symptoms and minor local events (robust take, lymphangitis, intense erythema, or edema) occurring after vaccination. Secondary infections should be treated with appropriate antimicrobial therapy. Uncomplicated cases of accidental vaccinia do not require therapy. Extensive cases can be treated by intravenous administration of vaccinia immune globulin (VIG) or cidofovir to speed recovery. VIG is a sterile solution of the immunoglobulin fraction of plasma from persons vaccinated with the smallpox (vaccinia) vaccine. Topical antiviral medications can be used in moderate-to-severe cases of ocular vaccinia. Vidarabine ointment has been effective in the past, but supplies are likely very limited because it is no longer manufactured. Trifluridine eyedrops can be tried, but there are no clinical data regarding successful treatment. It should not be administered for longer than 14 days, because it can cause a reversible superficial punctate keratopathy. VIG can exacerbate vaccinia keratitis and should not be used in cases of isolated keratitis.[32]

Generalized vaccinia usually requires only symptomatic treatment, but if severe, such as in those with immunodeficiency, VIG may be of benefit. With severe eczema vaccinatum in which there is significant loss of the skin barrier, meticulous skin care with volume and electrolyte repletion are needed. Early treatment with VIG has been shown to reduce mortality from eczema vaccinatum (from 30% to 40% down to 7%, based on pre-eradication era data).[32] VIG administration and care in an intensive care unit also reduces the case fatality rate of progressive vaccinia from 100% to 20%–30%.[40] In 2009, a US military vaccinee diagnosed with acute myelogenous leukemia several weeks after primary vaccination developed progressive vaccinia at the vaccination site; he was treated with VIG, CMX001, topical imiquimod, and oral and topical ST-246 during his course to achieve improvement.[42] Treatment for neurologic complications is supportive care; there is no evidence that VIG is effective in these cases. Given the rarity of fetal vaccinia, inadvertent vaccination during pregnancy is not ordinarily a reason for termination. There is also no indication for prophylactic administration of VIG to the pregnant woman, but it might be considered for a viable infant born with vaccinial lesions.[34,43]

PREVENTION. The vaccination site should be covered with gauze and an overlying semipermeable membrane bandage. Observing contact precautions

and washing the hands frequently when caring for the site should be emphasized.

A higher proportion of persons are at risk for adverse vaccine reactions today than during the era of routine smallpox vaccination. Atopic dermatitis as well as immunocompromise have increased in prevalence.[44] To reduce the incidence of adverse events, smallpox vaccination in the United States is currently limited to the select groups discussed earlier (see Section "Epidemiology"). There are no absolute contraindications to vaccination should an actual outbreak occur. Current recommendations and contraindications in the absence of a known exposure risk are listed in Box 195-2. More detailed guidelines are available from the CDC.

Safer vaccines remain under research and development to prevent the adverse effects and complications of smallpox vaccination. Tissue and cell-culture vaccines, including the new ACAM2000 and a different cell-cultured smallpox vaccine (DynPort, Frederick, MD, USA) under clinical trial, are the current generation of smallpox vaccines in the United States. Production involves the sterile growth of cell lines that host the vaccinia virus. By increasing purity and reducing contamination, these vaccines may help avoid the allergic and autoimmune reactions thought to stem from the nonvaccinia material in calf-lymph vaccines. These reactions include hypersensitivity reactions, erythema multiforme, and possibly the encephalitic and cardiac reactions. But because they are live viruses similar in immunogenicity to Dryvax, their safety profiles are not significantly different with regard to adverse events specifically associated with vaccinia exposure.[24,28,29] For other strategies, see online edition of this book.

Another strategy is the development of vaccines using strains of vaccinia attenuated by serial passage through nonhuman tissue. This leads to a reduced capacity for replication and potentially reduced adverse effects. The modified vaccinia Ankara strain is produced by passage through chick embryo fibroblasts. No significant complications were reported with its use in Germany and Turkey in the 1970s to help people at high risk for side effects (such as those with atopic dermatitis/eczema, etc.) tolerate the standard smallpox vaccine; efficacy against actual disease, however, was never proven. The LC16m8 vaccine also uses an attenuated vaccinia strain, with passage of the Lister vaccinia strain through rabbit kidney cells. Studies in Japan in the 1960s and 1970s found it to have less local and systemic reactogenicity but similar protective immunity to conventional smallpox vaccines. Further clinical study of the modified vaccinia Ankara-based and Lc16m8 vaccines is under way.[6,10,45] Finally, advances in modern molecular immunology have introduced the idea of subunit vaccines with genes or proteins from vaccinia virus. These are under laboratory investigation as future vaccine candidates.[11,46]

BOX 195-2 VACCINATION AGAINST SMALLPOX USING VACCINIA VIRUS

Indications

- Pre-exposure prevention of smallpox
- Postexposure prophylaxis against severe disease and death

Contraindications

- Contraindications in the pre-exposure setting
  - Presence of atopic dermatitis or other eruptions with disruption of the skin barrier
  - Immunosuppression, including human immunodeficiency virus infection/acquired immunodeficiency syndrome (HIV/AIDS), inherited and acquired cellular immunodeficiencies, and severe autoimmune disease
  - Known heart disease or significant cardiac risk factors
  - Serious allergy to components of the vaccine diluent (polymyxin, neomycin, streptomycin, chlortetracycline)
  - Age younger than 12 months
  - Pregnancy or breast-feeding
- Contraindications in the postexposure setting
  - No absolute contraindications in the case of an actual smallpox outbreak

MONKEYPOX

In contrast to smallpox, which was described in writings as far back as 340 AD, monkeypox is a relatively recently recognized disease. It was first identified in 1958 as an illness of cynomolgus monkeys, hence its name. Monkeypox was first documented to cause human illness in 1970 in Zaire (the present Democratic Republic of the Congo), when an illness similar to smallpox was noted after eradication of the latter.

EPIDEMIOLOGY. Human monkeypox is a disease acquired mainly from infected animals. It is endemic in the rain forest countries of Central and West Africa, occurring in sporadic outbreaks. The majority of cases are in children. Despite its recent recognition, monkeypox has presumably caused illness for thousands of years.[47] Transmission occurs mainly during handling of infected animals or contact with the animals' body fluids. Person-to-person spread via respiratory droplets and close contact can occur as with smallpox, but usually in a more limited manner. Outbreaks in the Democratic Republic of the Congo in 1996–1997 showed sustained human-to-human transmission for the first time. This may reflect decreased immunity secondary to the discontinuation of routine smallpox vaccination.[48] In spring 2003, the first cases of human monkeypox in the Western Hemisphere occurred in the Midwest region of the United States (72 reported cases, 37 laboratory confirmed). All cases are thought to be associated with contact with ill pet prairie dogs previously housed with African rodents imported from Ghana.[49]

The longest documented chain of person-to-person transmission is eight generations, which suggests that monkeypox has little potential for the type of

epidemic spread seen with smallpox.[48] However, possible genetic alteration to produce greater virulence or transmissibility is a concern.

ETIOLOGY AND PATHOGENESIS.

Monkeypox is caused by the monkeypox virus, a zoonotic virus. Like variola and vaccinia viruses, it is also of the genus *Orthopoxvirus* and has an oval or brick shape on electron microscopy. The monkeypox viral genome is 96% identical to that of the variola virus at the central region, which encodes essential enzymes and structural proteins. The end regions that encode virulence and host-range factors are substantially different, and the range of hosts for the monkeypox virus is much wider than that for variola virus.[49] In addition to humans, hosts for monkeypox include cynomolgus and other monkeys, other primates (apes, gorillas, chimpanzees, orangutans), and nonprimate animals such as rabbits, mice, guinea pigs, and giant anteaters. The natural reservoir is unknown but is thought to be wild rodents such as the squirrel.[1,50]

Monkeypox is mainly transmitted through abraded skin after a bite or scratch from an infected animal or by contact with their infected body fluids. The virus multiplies locally at the site of injury; then it is rapidly transported to regional lymph nodes, where multiplication continues. Invasion of the bloodstream disseminates the virus to distant sites. The monkeypox virus is also transmissible from person-to-person via aerosolization of the virus or contact with lesions or body fluids during the first week of the rash, although this transmissibility is significantly lower than that for smallpox.[49] Monkeypox may also rarely be transmitted by contaminated fomites.[51]

CLINICAL FINDINGS

History. Monkeypox is difficult to differentiate from smallpox based on clinical findings alone.[52] Subclinical cases of monkeypox can occur in individuals with and without prior smallpox vaccination. In those with illness, symptoms manifest after a 10–14-day incubation period. A prodrome of fever, chills, malaise, headache, myalgias, and back pain occurs, lasting 2–3 days. Some individuals experience sore throat, cough, or shortness of breath. Diarrhea and abdominal pain may also be reported.[2,48]

Cutaneous Lesions. A rash generally develops 1–3 days after the onset of fever, initially consisting of monomorphic macules and papules. Most commonly, the eruption begins on the face and/or trunk, with the lesions spreading in a centrifugal pattern to become generalized. They then progress over 14–21 days to vesicles and pustules that umbilicate, crust, and desquamate (see eFigs. 195-6.3 and 195-6.4 in online edition). Dyspigmented and pitted scars result. Monkeypox lesions can involve the oral and genital mucous membranes.[47] No hemorrhagic form of monkeypox like that of smallpox has been described in humans.

In the outbreak in the United States, only one patient (a child) had a generalized rash as extensive as that seen in cases in Africa. The other affected individuals had only localized lesions, mostly on the hands, associated with direct contact with the infected animals from Ghana (Fig. 195-7 and see eFig. 195-7.1 in online edition). This likely reflects the fact that West African strains of monkeypox virus are less virulent than those of Central Africa.[48,49]

Figure 195-7 The primary inoculation site of monkeypox virus in a 3-year-old child, 14 days after being bitten by a prairie dog. (Used with permission from the Marshfield Clinic, Marshfield, WI, USA.)

Related Physical Findings. Significant lymphadenopathy develops 1–2 days before the onset of the rash, usually in submandibular, cervical, or inguinal areas (Fig. 195-8). Conjunctivitis and keratitis may occur. Confusion and seizures are rare.[53,54]

Figure 195-8 Significant postauricular lymphadenopathy with pustular skin lesions in a 2-year-old female with monkeypox. (Used with permission from the Armed Forces Institute of Pathology, Washington, DC, USA, http://www.afip.org/Departments/infectious/mp/.)

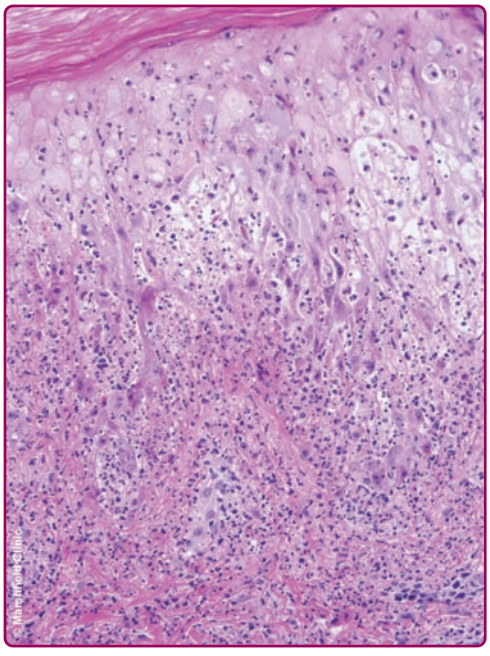

Figure 195-9 Histopathology of a monkeypox lesion with dermal papillary edema, acute inflammation, and ballooning degeneration of keratinocytes. (H&E; Used with permission from the Marshfield Clinic, Marshfield, WI, USA.)

LABORATORY TESTS. Leukocytosis, elevated transaminase levels, and low blood urea nitrogen levels are often seen. Lymphocytosis and thrombocytopenia occur with less frequency.[55]

Histopathology. On examination of skin biopsy specimens, the features are indistinguishable from those of smallpox. There is similar dermal papillary edema, acute inflammation, and ballooning degeneration of keratinocytes (Fig. 195-9). Cytoplasmic eosinophilic inclusion bodies (Guarnieri bodies) are also seen (see eFig. 195-9.1 in online edition). Focal necrosis may occur.[53]

Special Tests. Electron microscopy of material from scabs or fluid from skin lesions can be used to determine the presence of an orthopoxvirus, but it cannot distinguish among them. Assays for specific antibodies against monkeypox can differentiate it from other poxviruses. Monkeypox virus has good growth in RK13 cells and causes pocks on chorioallantoic membranes at 39°C (102.2°F). Isolation of the virus on mammalian cell culture and characterization by PCR and sequencing can definitively identify monkeypox virus and can differentiate Central African from West African monkeypox.[19,50,52]

DIFFERENTIAL DIAGNOSIS. (See Box 195-1). The features of monkeypox are clinically similar to but less severe than those of ordinary smallpox (variola major). Lymphadenopathy is a distinctive hallmark of monkeypox not usually seen in smallpox. It is observed in 90% of cases in which the individual has never received the smallpox vaccine and in approximately 53% of those who have been vaccinated.[2] Varicella has a milder and shorter viral prodrome, with pleomorphic lesions evolving in a centripetal distribution. Lymphadenopathy is also infrequent with varicella. Orf and bovine stomatitis, caused by poxviruses of family Parapoxviridae, can produce similar skin lesions but these are localized. Also in the differential diagnosis are drug eruptions, eczema herpeticum, and rickettsialpox (see Box 195-1). Persons with human immunodeficiency virus (HIV) infection may develop extensive molluscum lesions that can look similar.

COMPLICATIONS. Secondary skin and soft tissue infections may occur (approximately 20% of cases). Affected individuals may also develop pneumonitis (12%), encephalitis (fewer than 1%), and ocular complications, including scarring with corneal lesions.[47]

PROGNOSIS AND CLINICAL COURSE. The scars left by the rash may improve over time. In Africa, mortality ranges from 1% to 10% and mainly occurs in children. Death is generally in the second week of disease and is secondary to bacterial superinfection, gastrointestinal complications, or pulmonary complications. These are likely compounded by poor nutrition and inaccessibility of medical care.[2,49] All affected individuals recovered without any deaths during the outbreak in the United States in 2003.[56]

TREATMENT. Currently, there is no specific treatment for monkeypox. Symptomatic treatment should be instituted. Cidofovir may be considered in severe cases, but there is no available data on its clinical efficacy in humans. VIG administration can also be considered in severe cases, but its benefits are unknown. ST-246 has been shown to prevent disease and death from monkeypox virus in mice and nonhuman primate models and it is now in Phase II clinical trials.[22]

PREVENTION. Global eradication of monkeypox is more difficult than smallpox eradication, because the wide range of hosts for monkeypox virus allows it to maintain an animal reservoir while sporadically causing human disease. Vaccination with the calf-lymph-derived smallpox vaccines (vaccinia virus) was found to be effective in preventing human monkeypox. Observation of cases in Africa showed 85% protection against monkeypox; cases that do occur are milder and even subclinical when they occur in vaccinated individuals.[53] The newer ACAM2000 has similar immunogenicity to Dryvax and showed equal protective efficacy against monkeypox virus in a nonhuman primate model.[29,57]

The CDC currently recommends pre-exposure vaccination for investigators of animal or human monkeypox cases and health care providers who may care for or be in close contact with patients with monkeypox, provided they have no contraindication to smallpox vaccination (Box 195-3). The role of postexposure vaccination is less clear, but it is recommended for those within 4 days of direct exposure to monkeypox virus

BOX 195-3 VACCINATION AGAINST HUMAN MONKEYPOX USING VACCINIA VIRUS

Indications

- Pre-exposure vaccination for investigators of animal or human monkeypox cases and health care providers who may care for or be in close contact with patients with monkeypox
- Postexposure vaccination for those within 4 days of direct exposure to monkeypox virus, should be considered up to 14 days after exposure

Contraindications

- Contraindications in the pre-exposure setting
  - Presence of atopic dermatitis or other eruptions with disruption of the skin barrier
  - Immunosuppression, including human immunodeficiency virus infection/acquired immunodeficiency syndrome (HIV/AIDS), inherited and acquired cellular immunodeficiencies, and severe autoimmune disease
  - Known heart disease or significant cardiac risk factors
  - Serious allergy to components of the vaccine diluent (polymyxin, neomycin, streptomycin, chlortetracycline)
  - Age younger than 12 months
  - Pregnancy or breast-feeding
- Contraindications in the postexposure setting
  - Immunosuppression, including HIV/AIDS, inherited and acquired cellular immunodeficiencies, and severe autoimmune disease
  - Life-threatening allergy to components of the vaccine diluent (polymyxin, neomycin, streptomycin, chlortetracycline)

and should be considered up to 14 days after exposure, including in children under the age of 12 months, pregnant women, and people with skin conditions. Those with impaired immune systems or life-threatening allergy to latex or vaccine components should not receive the ACAM2000 vaccine even if exposed to monkeypox, but VIG can be considered for postexposure prophylaxis.[47,48]

The newer smallpox vaccines under research and development are also being studied for efficacy against monkeypox virus and may in the future allow prevention of human monkeypox with fewer adverse effects.

PARAPOXVIRUS INFECTIONS

Unlike the orthopoxviruses, members of family Parapoxviridae tend to cause localized rather than systemic disease in healthy individuals.

MILKER'S NODULE

EPIDEMIOLOGY.

Milker's nodule, also called *paravaccinia* and *pseudocowpox*, occurs worldwide but is prevalent only in individuals in close contact with cattle. It is an occupational disease of milkers, veterinarians, and workers in the meat industry. Most cases are in newly employed milkers who have not developed immunity.[1] Cases are mostly sporadic, but small epidemics have been reported. No natural cases of human-to-human transmission have been reported, only experimentally transmitted cases in the laboratory setting.[58]

ETIOLOGY AND PATHOGENESIS.

Milker's nodule is caused by the paravaccinia virus (also called *pseudocowpox virus*), a member of family Parapoxviridae. It is a 260 ×160-nm cylindrical virus with spirally arranged tubules. The virus typically is found at the teats and mouth of cattle but may also occur on the trunk and legs. Humans are accidental hosts following contact with infected animals or contaminated fresh meat. Paravaccinia virus is transferred by direct inoculation into the skin, often through a break in the skin barrier.[59] Cases of transmission from contaminated fomites to individuals with burn injury have been reported.[60] (see Fig. 195-10B).

CLINICAL FINDINGS

History. The incubation period for milker's nodule is 4–7 days. In a minority of cases, the infected individual develops mild systemic symptoms such as a transient low-grade fever.[61]

Cutaneous Lesions. The sites of inoculation of paravaccinia virus are usually the hands and, on occasion, the face. After the incubation period, skin lesions develop. One to several lesions usually appear, but they may occasionally be numerous. Lesions begin as red and occasionally pruritic macules that become raised papules (see eFig. 195-9.2 in online edition). They can then form papulovesicles with a target-like appearance—a red center surrounded by a white or gray ring and outer red halo. The lesions then develop into bluish or violaceous tender nodules. Some ulcerate or have a central depression (Fig. 195-10), which results in formation of eschars with crust. Lesions often take 4–8 weeks, and sometimes longer, to heal.[58,59]

Related Physical Findings. Lymphangitis is often present in the skin surrounding the primary lesion(s). Lymphadenopathy is not common.

LABORATORY TESTS

Histopathology. The histopathologic findings of milker's nodule depend on the stage of the lesion. Early lesions show vacuolization and ballooning of cells in the upper third of the epidermis, which sometimes leads to multilocular vesicles. Intracytoplasmic inclusion bodies may be seen, with rare intranuclear inclusions. Epidermal necrosis may be observed

Figure 195-10 **A.** Firm, eroded milker's nodule. **B.** Multiple lesions at the site of a second-degree scalding burn sustained in a milking barn.

focally with ulceration and crust as the lesion progresses. Neutrophils are seen in the epidermis and superficial papillary dermis with epidermal necrosis. Mature lesions have finger-like epidermal projections, papillary dermal edema, and a mixed inflammatory infiltrate that includes lymphocytes, histiocytes, and eosinophils. Regressing lesions have decreasing acanthosis and inflammation.[58,62]

Special Tests. Electron microscopy of blister fluid or crusts can identify the characteristic cylindrical shape of parapoxviruses. Paravaccinia virus is slow growing on tissue culture. Viral DNA hybridization or PCR procedures may be used to distinguish paravaccinia virus from other parapoxviruses.[63]

DIFFERENTIAL DIAGNOSIS.

Milker's nodules appear very similar to the lesions of orf, another parapoxvirus. Attention to clinical history usually allows differentiation, with cattle the source of infection for milker's nodules and sheep or goats for orf. Tissue cultures can aid in diagnosis if needed. Bovine papular stomatitis virus causes disease in cattle with lesions around the animal's mouth. Transmission to people produces lesions similar to milker's nodules, and some believe the etiology of both of these conditions may actually be the same virus.[64] Milker's nodules must also be differentiated from cowpox. Cowpox is very rare in humans. It has a longer incubation period, causes more pain and lymphadenopathy, and has led to death in persons with immunocompromise or atopic dermatitis. Large lesions of milker's nodule can be confused with anthrax, pyogenic granuloma, giant herpetic lesions, and keratoacanthoma (Box 195-4).

COMPLICATIONS.

Secondary bacterial infection can occur but is rare. Erythema multiforme, morbilliform eruptions, and erythema nodosum have been reported in cases of milker's nodule.

PROGNOSIS AND CLINICAL COURSE.

Milker's nodule is a self-limited illness. Most cases heal without scarring. Infection produces lifelong immunity.

TREATMENT.

Because the disease is self-limited, treatment, if needed, is symptomatic. Surgical curettage of large lesions may help speed healing.[61,65]

PREVENTION.

There is no cross-immunity between orthopoxviruses and parapoxviruses, and thus smallpox vaccination (vaccinia virus) has no effect on this illness. Prevention mainly consists of isolation of infected animals and contact precautions.[66]

BOX 195-4 DIFFERENTIAL DIAGNOSIS OF MILKER'S NODULE AND ORF

Most Likely
- Few to multiple lesions
  - Bovine papular stomatitis
  - Cowpox
  - Herpetic whitlow
- Solitary lesion
  - Pyogenic granuloma
  - Pyoderma

Consider
- Few to multiple lesions
  - Atypical mycobacterial infection
  - Sporotrichosis
- Solitary lesion
  - Tularemia
  - Giant herpetic lesion
  - Giant molluscum
  - Erysipeloid

Always Rule Out
- Few to multiple lesions
  - Anthrax
  - Primary inoculation tuberculosis
- Solitary lesion
  - Keratoacanthoma
  - Syphilitic chancre

ORF

Contagious pustular dermatosis, infectious pustular dermatitis, scabby mouth disease, and sore mouth disease are all synonyms for orf, a self-limited zoonotic viral infection that usually involves the hands of people handling infected animals. The offending Orf virus is a member of the *Parapoxvirus* genus. It is an endemic disease in sheep and goats that usually affects the area around the lips and nostrils of the animal, as well as the teats of ewes suckling young. It is transmitted to humans through contact with infected tissue or fomites, and human infections have been noted after vaccination of sheep herds.[67,68] Orf shares clinical characteristics with other infectious diseases and may be mistaken for more serious and life-threatening disorders such as tularemia, anthrax, and erysipeloid (Box 195-4). Although clinical appearance and history of ruminant exposure are usually diagnostic, real-time PCR testing, which is available through the CDC, is the most rapid and accurate way to make the diagnosis when clinical uncertainty exists.[68]

EPIDEMIOLOGY. Human disease is more commonly seen in farmers and shepherds, but anyone who has contact with small ruminants is at risk. Although sheep and goats are the more common sources of infection, the virus has also been found in camels, mountain goats, gazelles, and musk oxen. Disease can occur after contact with animals or fomites such as barn doors, feeding troughs, wire fencing, and bottles. The virus is quite hardy and can survive heating, drying, and certain solvents such as ether and chloroform. Vaccination of animals with unattenuated virus leads to milder disease in the animal, but can result in infection of humans exposed to the vaccinated animal.[67]

ETIOLOGY AND PATHOGENESIS. Orf virus is the prototypic species of the genetically heterogeneous *Parapoxvirus* genus.[69] It is an ovoid cross-hatched particle of approximately 250 × 160 nm with a twine-like structure. Electron microscopic analysis can distinguish this *Parapoxvirus* from *Orthopoxviruses* such as variola (smallpox). Virulence proteins elaborated by the virus aid in evading host immunity.

CLINICAL FINDINGS

Cutaneous Lesions. Five to six days after inoculation, a slightly elevated red papule appears, which subsequently vesiculates (Table 195-2). The lesions then evolves into a targetoid nodule with a red center, white ring, and peripheral rim of erythema (Fig. 195-11). A weeping stage (see eFig. 195-11.1 in online edition) is followed by a dry stage and finally a dry crust and scab, which generally resolves without scarring. Multiple lesions are sometimes present, and giant lesions occasionally occur.[70]

Related Physical Findings. Systemic findings are uncommon in immunocompetent individuals but can include lymphadenopathy and lymphangitis. Rarely fever and malaise may occur.

TABLE 195-2
Clinical Manifestation of Orf

Time After Exposure	Clinical Manifestations	Laboratory Analysis	Other Notes
3–7 days	One to four papules on hand (typically only one lesion): begin as a red maculopapular lesion ↓ Vesicle ↓	Can confirm by histology, viral culture, increase in serologic titers, or complement fixation. Electron microscopy of lesional skin shows brick-shaped viral particles (200–380 nm in length); intranuclear inclusions are occasionally seen.	Systemic symptoms are rare, but may include lymphadenopathy and lymphangitis, fever, rigors, drenching sweat, malaise, and urticaria.
10–14 days	Target lesion, with red center, white middle ring, and red halo ↓		
14–21 days	Acute weeping stage ↓		Lesions are relatively painless.
21–28 days	Regenerative dry stage with black dots ↓		
28–35 days	Papillomatous stage ↓		
35 days	Regressive stage with dry crust and eventual shedding of the scab		Typically no scarring occurs.

From Diven DG: Poxvirus. In: *Mucocutaneous Manifestations of Viral Disease*, edited by SK Tyring. New York, Infarma Healthcare, 2002, p. 39, with permission.

Figure 195-11 The target phase of orf shows a white circle with central and peripheral erythema.

LABORATORY TESTS

Histopathology. In the target stage, intranuclear and intracytoplasmic inclusions are present in vacuolated epidermal cells, with an accumulation of neutrophils, basophils, dendritic cells, and lymphocytes (see eFig. 195-11.2 in online edition). Papillomatosis and acanthosis subsequently develop, and marked finger-like downward projections of the epidermis may be seen (see eFig. 195-11.3 in online edition).

Special Tests. Electron microscopy may be helpful in distinguishing between *parapoxviruses* and other types of poxviruses but is not diagnostic for orf; similar limitations exist with serologic testing. Tissue culture is possible but time consuming. The most rapid and sensitive means of making the diagnosis is PCR testing, and real-time PCR procedures, in particular, appear extremely sensitive.[68]

DIFFERENTIAL DIAGNOSIS.

A variety of bacterial and infectious diseases can present with findings similar to those of orf (see Box 195-4). Exposure history is important, because many of these disorders (milker's nodules, cowpox, monkeypox, etc.) are associated with exposures to animals other than sheep or goats.[63] The lesion of anthrax is more hemorrhagic with rapid progression to an eschar. Tularemia and syphilis are associated with chancres. Sporotrichosis begins as a single necrotic nodule but is followed by multiple nodules arising in a linear fashion along the lymphatics. Primary innoculation tuberculosis and atypical mycobacterial infection can give rise to ulcerative lesions that may take months to years to heal.

COMPLICATIONS.

Secondary bacterial infection, swelling, lymphadenitis, and fever can occur. Erythema multiforme,[71] vesicular eruptions,[72] and secondary spread within active atopic dermatitis skin lesions have been reported.[72] Bullous pemphigoid has also rarely been reported after orf infection.[73]

PROGNOSIS AND CLINICAL COURSE.

Orf is usually a self-limited disease that resolves within 4–6 weeks. Typically scarring does not occur. Immunocompromised individuals can develop progressive destructive lesions that may require interventions such as débridement or antiviral therapy such as cidofovir cream.[65,74]

TREATMENT.

Supportive care is the most appropriate intervention for immunocompetent patients. Application of compresses, culture of lesion specimens, and antibiotic coverage may be appropriate if secondary bacterial infection is suspected. Immunocompromised patients may require medical intervention (see Section "Prognosis and Clinical Course").

PREVENTION.

Barrier precautions such as use of gloves and good hand hygiene are recommended. Patients with an impaired skin barrier from either abrasions or intrinsic skin disease (e.g., atopic dermatitis) should be particularly vigilant regarding avoidance of contact with infected animals or potential fomites.

MOLLUSCIPOXVIRUS INFECTION: MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum (MC) is a benign but nonetheless frequently troublesome viral infection that most often affects young children. It is characterized by smooth, dome-shaped, discrete, opalescent papules with a central core that occasionally develops surrounding areas of scale and erythema (molluscum dermatitis). Patients and families are bothered by this infection because of its often prolonged course, as it may persist for months to years. MC is a greater concern in immunocompromised individuals and those with atopic dermatitis, in whom the extent and duration of infection may be more extreme. Sexually transmitted disease occurs in adults but is extremely unlikely in children.

EPIDEMIOLOGY

MC virus (MCV) infection occurs worldwide and appears specific to humans. The prevalence of MCV infection has risen significantly in the past several decades, with an 11-fold increase noted in one US study of patient visits for this disorder over a two-decade span.[75] This rise appears to parallel the overall increase in sexually transmitted diseases. Although a prevalence rate of less than 5% in US children is often cited,[76] the rate varies by location, and it is thought that subclinical infection may be more common than overt disease. A representative Australian study documented an overall seropositivity rate of 23%, which supports the view that subclinical or mild

Figure 195-12 Molluscum contagiosum. **A.** Discrete, solid, skin-colored papules, 1–2 mm in diameter with central umbilication. **B.** Multiple, scattered, and discrete lesions, some of which are inflamed.

unrecognized disease exists in the population. HIV-infected individuals are at higher risk for extensive prolonged disease, and individuals with atopic conditions appear more likely to have increased numbers of lesions and experience a more prolonged disease course.[76]

Transmission may occur via direct skin or mucous membrane contact, or via fomites. Bath towels, swimming pools, and Turkish baths have all been reported as sources of infection, and individuals involved in close contact sports (e.g., wrestling) also appear at higher risk.[77,78] Autoinoculation and koebnerization also play a role in the spread of lesions. Recent reports also document the possibility of vertical transmission from mother to neonate during the intrapartum period.[79]

ETIOLOGY AND PATHOGENESIS

MCV is a large, brick-shaped poxvirus that replicates within the cytoplasm of cells. It shares a number of genomic similarities with other poxviruses, and approximately two-thirds of the viral genes are similar to those of vaccinia and variola virus.[80] There are four subtypes of MCV, but they all appear identical clinically. Ninety-eight percent of disease in the United States is caused by MCV genotype 1 and it is the main cause of MC in children.[80,81] MCV-2 is primarily seen in adults and immunocompromised individuals, with sexual contact being the most common mode of transmission. Serial transmission of the virus has not yet been achieved in culture. An incubation period of 2–7 weeks has been observed.

Virus replicates within the cytoplasm of epithelial cells, and infected cells replicate at twice the baseline rate. There are many MCV genes that may contribute to an impaired immune response to this virus, including (1) a homolog of a major histocompatibility class 1 heavy chain, which may interfere with antigen presentation; (2) a chemokine homolog that may inhibit inflammation; and (3) a glutathione peroxidase homolog that may protect the virus from oxidative damage by peroxides.[82,83]

CLINICAL FINDINGS

CUTANEOUS LESIONS. MC often presents with extremely small pink, pearly, or flesh-colored papules that then enlarge, occasionally reaching sizes of up to 3 cm ("giant molluscum"). As they enlarge, a dome-shaped, opalescent morphology may become more apparent. The lesions may have a central dell or umbilication (Fig. 195-12), within which a white curd-like substance can be seen that can be expressed with pressure. Most patients develop multiple papules, often in intertriginous sites, such as the axillae, popliteal fossae, and groin. Genital and perianal lesions can develop in children and are only rarely associated with sexual transmission in this population.[75]

Lesions may be grouped in clusters or appear in a linear array. The latter often results from koebnerization or development of lesions at sites of trauma. Erythema and eczematous changes may occur around lesions; this is termed *molluscum dermatitis*. Papules may become erythematous (Fig. 195-12B), which is believed to be an immune response to the infection. Patients with acquired immunodeficiency syndrome may develop large and extensive lesions involving both genital and extragenital sites.[82] (see Chapter 198)

SPECIAL TESTS

Diagnosis is usually straightforward. Evaluation of the central contents using a crush preparation and Giemsa staining can be carried out when necessary (eFig. 195-12.1 in online edition), and histopathologic evaluation can be performed as needed. Some clinicians recommend that an adult with new-onset MC infection

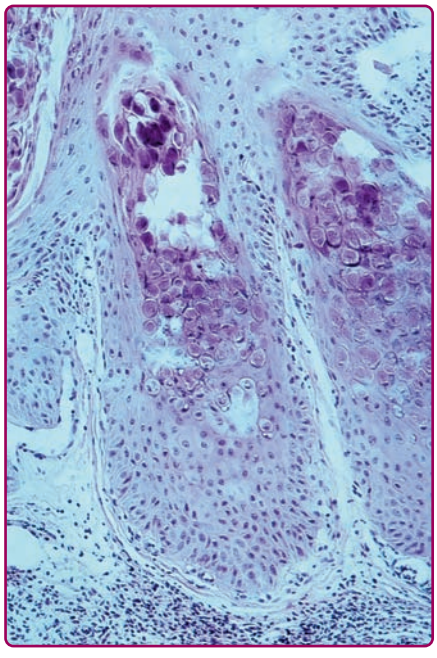

Figure 195-13 Molluscum contagiosum. Histopathology (skin biopsy, H&E) shows downgrowth of infected epidermal cells bearing large eosinophilic cytoplasmic inclusion bodies (Henderson-Paterson bodies).

undergo evaluation for HIV infection and/or other causes of an immunocompromised state.[84]

Histopathologic examination reveals a hypertrophied and hyperplastic epidermis. Above the basal layer, enlarged cells containing large intracytoplasmic inclusions (Henderson-Paterson bodies) can be seen (Fig. 195-13). These increase in size as the cells reach the horny layer.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes verrucae, pyogenic granulomas, amelanotic melanoma, basal cell carcinomas, and appendageal tumors. Fungal infections caused by *Cryptococcus*, histoplasmosis, and *Penicillium* must be considered in immunocompromised hosts (Box 195-5).

COMPLICATIONS

Although many patients are asymptomatic, pruritus is sometimes a significant problem, particularly in those patients with underlying atopic dermatitis. Chronic conjunctivitis and punctate keratitis may develop in patients with eyelid lesions. Secondary bacterial infection can occur, particularly if patients scratch their lesions.

PROGNOSIS AND CLINICAL COURSE

Spontaneous clearance occurs, but often over a prolonged period of months to years. Most families prefer treatment if lesions persist more than a month or two.

BOX 195-5 DIFFERENTIAL DIAGNOSIS OF MOLLUSCUM CONTAGIOSUM

Most Likely
- Verrucae

Consider
- Pyogenic granuloma
- Papular granuloma annulare
- Epidermal inclusion cyst
- Sebaceous hyperplasia

Always Rule Out
- Appendageal tumors
- Basal cell carcinoma
- Amelanotic melanoma
- Cryptococcosis/histoplasmosis/penicilliosis

In patients with HIV, MC infection is usually indicative of a more advanced state of HIV, with higher viral load and lower $CD4^+$ T-cell count.[84]

TREATMENT

It is important to discuss the risks and benefits of individual therapies with families before embarking on treatment for this essentially benign condition, which will generally resolve without complication in the immunocompetent individual (Table 195-3). For some children, no treatment is the best option as the child's native immune response may clear the MC without additional intervention. Many experts use cantharidin 0.7% or 0.9% liquid for treatment of MC. This extract of the blister beetle, *Cantharis vesicatoria*, induces vesiculation at the dermoepidermal junction when applied topically to the skin. It must be applied with care and washed off 2–6 hours later. Use on the face or genital areas is not recommended, and families must be counseled regarding the small risk of extreme reaction or scarring.

Other traditional therapies have included curettage and cryotherapy; however, both of these treatments are painful. The use of topical anesthetic agents may ameliorate some of the associated pain, but patients generally find topical cantharidin treatment the most efficient and least painful. Other topical therapeutic modalities include retinoid creams, imiquimod cream, salicylic acid, trichloroacetic acid, cidofovir, and silver nitrate paste and tape stripping. Oral cimetidine has also been used with some success.[85] However, a 2009 Cochrane Database analysis of treatments for MC, which identified only 11 therapeutic studies of high quality, found that no single intervention is convincingly effective for the treatment of MC.[86]

PREVENTION

Prevention of spread may be enhanced by avoiding trauma to the sites of involvement as well as avoiding

TABLE 195-3
Treatment of Molluscum Contagiosum

		Considerations	Level of Evidence[a]
Watchful waiting	Spontaneous resolution occurs over months to years in immunocompetent individuals.	Risk of autoinoculation, associated dermatitis, secondary bacterial infection	3
Topical therapies	Cantharidin (0.7% or 0.9%)	Rarely severe blistering and scarring of concern	2, 3
	Podophyllin (10%–25% resin) (0.3% or 0.5% cream)	Rarely severe blistering and scarring of concern	1, 2, 3
	Cryotherapy/liquid nitrogen	Rarely severe blistering and scarring of concern	3
	Curettage	Painful	3
	Imiquimod cream (5%)	Painful, scarring possible	1, 2, 3
	Topical retinoids	Irritation common	3
	Silver nitrate paste	Irritation common	2
	Trichloroacetic acid (25%–35%)	Rarely severe blistering and scarring of concern	2, 3
	Topical cidofovir (1%, 3% gel; 1%, 3% cream)	Expensive	2, 3
Systemic therapies	Oral cimetidine (40 mg/kg/day)	Recommended only for immunocompromised individuals, expensive	2, 3
	Oral cidofovir		3
	Subcutaneous interferon-α	Recommended only for immunocompromised individuals	3

Chapter 196 :: Human Papilloma Virus Infections

:: Elliot J. Androphy & Reinhard Kirnbauer

PAPILLOMAVIRUS INFECTIONS AT A GLANCE

- Very common infection of skin and mucosa of children and adults.
- Papules of variable size often with a rough scaly surface.
- Caused by human papillomaviruses (HPV), a subset of which are associated with cervical, penile, anal, and other epithelial malignancies.
- Treatment often requires physical or immune mediated destruction of infected epithelial cells.
- A prophylactic vaccine effectively protects from infection with HPVs most commonly identified in cervical cancer and genital warts.

Papillomaviruses (PVs) cause benign cutaneous and mucosal epithelial proliferations commonly called warts or verrucae. PV infections do not produce acute local or systemic signs or symptoms but induce slow, focal accumulations of keratinocytes. Lesions may remain subclinical for long periods or may enlarge into fulminating masses that persist for months or even years. Persistent lesions caused by certain types of human PV (HPV) can undergo neoplastic transformation.

ETIOLOGY AND PATHOGENESIS

(See Also Chapter 191)

PVs comprise a large family of small DNA viruses that infect humans and many other species.[1] PVs are highly host-specific, meaning that those from one species do not induce papillomas in heterologous species, so HPVs infect only humans. Rabbit, bovine, and canine PVs have been used in animal models of viral infection because biologic experiments cannot be performed in humans using HPVs due to their oncogenic potential.

The PV genome is present within the viral particle as a single, covalently closed circle of double-stranded DNA. Each genome is composed of approximately 8,000 nucleotide base pairs and is approximately one-twentieth the size of a herpesvirus genome. Based on their DNA sequences, most human and animal PVs share a similar genetic organization (Fig. 196-1) that encodes only eight to nine related proteins.[2] PV proteins are labeled as E (early) and L (late).[3] The E proteins are necessary for viral DNA replication and are not incorporated into the infectious virus particle. Because the E genes do not encode a DNA polymerase or thymidine kinase, PV replication is not selectively susceptible to inhibition by nucleoside analogues. Rather, PVs use host cell enzymes and factors to replicate their DNA genomes. The *L1* and *L2* genes encode the structural proteins that form the outer protein shell or capsid of the infectious viral particle, which is called the *virion*. The spherical virion measures approximately 55 nm in diameter and packages the viral DNA (Fig. 196-2).

More than 100 HPV genotypes have been isolated and sequenced; the actual number of HPV genotypes is even higher.[1,4] By convention, two HPV isolates are classified as the same type when a highly conserved sequence within their *L1* genes are at least 90% identical.[5] A new HPV genotype is recognized based on less than 90% homology to all other known HPVs within this DNA sequence.[4] A subtype has 91%–98% identity, whereas a natural variant has less than 2% divergence to a known type in this region of *L1*.

Often associated with distinct regional predilection, histopathology, and biology, HPVs are often categorized as cutaneous (nongenital) and include genotypes such as HPV-1, -2, -3, and -4, whereas HPV-6, -11, -16, and -18 predominate in genital and mucosal infections. A large variety of HPV types such as HPV-5 and -8 have been isolated in epidermodysplasia verruciformis (EV), immunosuppressed individuals, and are

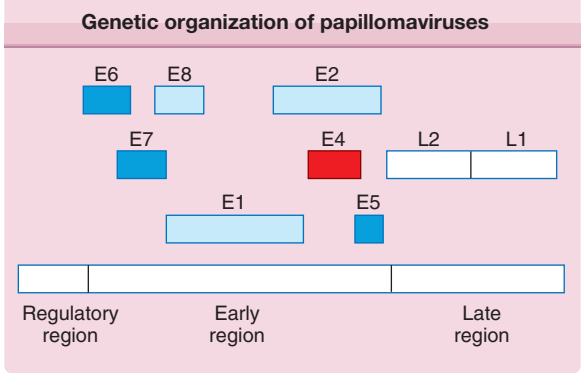

Figure 196-1 All papillomaviruses genomes are composed of approximately 8,000 nucleotide base pairs, represented as a linear sequence but actually a closed circle of double-stranded DNA. The boxes depict the viral genes, each of which encodes a protein. The regulatory region does not encode proteins but is a DNA segment that controls expression of viral genes and replication of the viral genome. *E6*, *E7*, and *E5* represent transforming genes; E1 and E2 coordinate replication and transcription of the viral genome; and the L1 and L2 proteins form the viral capsid. E4 encodes a protein that may be involved in the release of the virus from the cell's keratin framework.

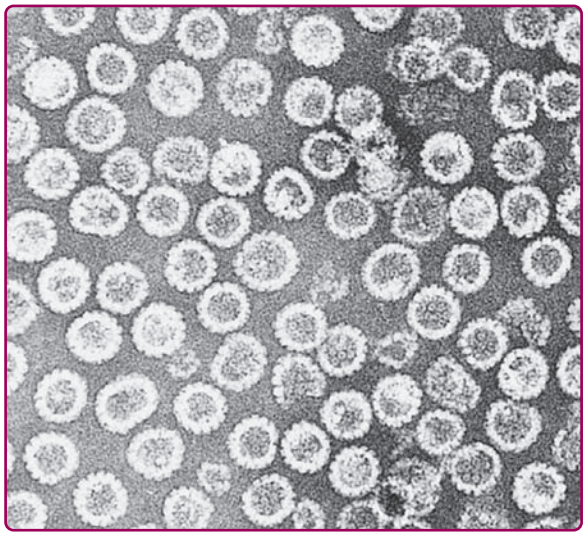

Figure 196-2 Transmission electron micrograph of human papillomavirus type 16 virus-like particles composed of the L1 and L2 proteins. These proteins were synthesized in cell culture and self-assembled into 55-nm particles that are morphologically similar to natural infectious virus except that they do not contain the viral DNA. The particles in the electron micrograph were purified from the cells. (Micrograph used with permission from Heather Greenstone.)

also found to be present in normal skin (Table 196-1). PVs have also been classified by phylogenetic organization based on their DNA sequence relationships.[6,7] The α genus includes a large set of cutaneous and genital-mucosal types and the β genus is primarily comprised of EV-types. Other genus classifications include more distantly related human and animal PV species. HPVs closely related by DNA sequence tend to induce similar lesions. Examples include highly related types such as 3 and 10, which induce flat warts; types 6 and 11, which cause genital–mucosal warts (condylomata acuminata); and types 5 and 8, which appear as scaly patches in EV.

Another important distinction is that specific HPV genotypes have malignant potential. This was first noted in EV. Warts that contain HPV types -5 and -8 undergo a high rate of malignant degeneration, whereas those induced by other HPV types, even in the same patient, tend to remain benign.[8] Similarly, approximately 50% of cervical carcinomas contain HPV-16, with HPV-18, -45, -31, -33, -52 and -58 accounting for an additional 35%.[9] Less frequent HPVs account for the remainder of cervical malignancies. This group is collectively referred to as *high-risk* types, whereas the *low-risk* types such as HPV-6 and -11 are isolated from benign cervical disease and genital warts, and identified in <1% of cervical malignancies.

HPV infection occurs through inoculation of virus into the viable epidermis through breaks in the epithelial barrier. Maceration of the skin is probably an important predisposing factor, as suggested by the increased incidence of plantar warts in swimmers who frequently use public pools. In rodent models of cervical HPV infection, mechanical disruption of the epithelium or inclusion of the mild detergent nonoxynol-9 dramatically increased the incidence of infection.[10] Animal models using HPV virions demonstrate that attachment to heparan sulfate proteoglycans on the basement membrane is a required initial step in natural infection. A furin protease then cleaves L2, inducing a conformation change that allows binding to an unidentified basal cell receptor.[11] This experimental model explains how PVs reserve infection for

TABLE 196-1
Clinical Associations of Human Papillomavirus (HPV) Types

HPV Type	Most Common Clinical Lesion	Less Frequent Lesion	Potential Oncogenicity
1	Deep plantar/palmar warts	Common warts	
2, 4, 27, 29	Common warts	Plantar, palmar, and mosaic warts	
3, 10, 28, 49	Flat warts	Flat warts in EV	HPV-10 rare in cervical and vulvar carcinomas
7	Butcher's warts		
13, 32	Oral focal epithelial hyperplasia		
5, 8, 9, 12, 14, 15, 17, 19–26, 36, 47, 50	EV, warts in immunosuppression	Normal skin (?)	HPV-5, -8, -9 isolated from SCCs
6, 11	Anogenital warts, cervical condylomata	Bowenoid papulosis, oral warts; respiratory papillomatosis	Buschke-Löwenstein tumor; rare in penile, vulvar, cervical, and other urogenital tumors; "low risk"
16, 18, 31, 33–35, 39, 40, 51–60	Cervical condylomata; anogenital warts; bowenoid papulosis	Common warts	Genital and cervical dysplasias and carcinomas; rare in SCC of the digit; "high risk"

EV = epidermodysplasia verruciformis; SSC = squamous cell carcinoma.

Figure 196-3 **A.** Common wart, periungual. Multiple, confluent, keratotic papules around the proximal periphery of the fingernails. **B.** Common wart, verruca plantaris with black dots of thrombosed capillaries. **C.** Common wart, mosaic plantar. A large hyperkeratotic plaque is seen on the heel, made up of multiple small coalescing warts.

and specifically target epithelial basal cells. To establish persistent infection, the virus presumably must enter a stem cell or convert the infected cells to one with stem-like properties. After entry, a single copy or at most a few copies of the viral genome are maintained as an extrachromosomal plasmid or episome within the infected epithelial basal cell's nucleus. When these cells divide, the viral genome also replicates and partitions to the progeny cell, which transports the viral infection into the differentiating layers of the epithelium. Viral RNA expression (transcription) is extremely low until the upper Malpighian layer, where viral DNA synthesis and genome amplification typically results in hundreds to thousands of copies per cell. The viral capsid proteins L1 and L2 (see Fig. 196-1) are synthesized in these upper epithelial strata and assemble into a tightly packed, very stable protein capsid. The newly synthesized viral DNA is packaged in the capsid, and mature virions accumulate in the nuclei of these upper level cells (see Fig. 196-2). The viral E1-E4 protein (the product of a spliced RNA from the *E1* and *E4* genes) may induce collapse of the cytoplasmic keratin filament network that surrounds the residual nucleus that contains assembled viruses.[12] This is postulated to facilitate release of the virions from the cross-linked cytoskeleton of keratinocytes/corneocytes so that virus can be inoculated into another site or desquamated into the environment.

PV virions exfoliate along with the residual epidermal cells. PVs do not bud from the nuclear or plasma membrane as do many viruses such as herpes simplex or human immunodeficiency virus (HIV). Therefore, HPVs do not possess a lipoprotein envelope that leads to susceptibility to environmental conditions such as freezing, heating, or dehydration with alcohol that inactivate enveloped viruses. In contrast, PV virions are resistant to desiccation and to the detergent nonoxynol-9, although exposure of virions to formalin, strong detergents such as sodium dodecyl sulfate or prolonged high temperature reduces their infectivity.[13,14] PVs can remain infectious for years when stored in glycerol at room temperature or in liquid nitrogen.

After experimental PV inoculation, a verruca usually appears within 2–9 months. This observation implies a relatively long period of subclinical infection that may act as an inapparent source of infectious virus. The rough surface of a wart can disrupt adjacent skin and enable inoculation of virus into adjacent sites, with the development of new warts over a period of weeks to months. Autoinoculation of virus into apposed skin is commonly seen on adjacent digits (see Fig. 196-3), mucosa (see Fig. 196-4), and in the anogenital region. Each new lesion results either from the initial exposure or spread from other warts. There is no convincing evidence for blood-borne dissemination.

The relative abundance of virus particles in a wart varies with the clinical setting and the HPV type. Newer lesions tend to contain more virions than do older verrucae. Plantar warts containing HPV-1 produce a high number of virions; anogenital verrucae typically have trace quantities of mature virus particles; common warts usually have intermediate numbers.

Because the viral episomes are at low copy and the L1 and L2 capsid proteins are not expressed in the lower epithelial levels in warts, the differentiation state of the infected epithelial cell influences viral transcription, signals initiation of viral DNA synthesis, and

Figure 196-4 Multiple mucosal warts extending to the vermillion border where they become highly keratinized.

permits virion assembly. Further support for the belief that the production of virus particles depends on the state of epithelial differentiation is the fact that virion production decreases as benign papillomas progress toward dysplasia. Capsid proteins are never observed in HPV-infected malignant cells. The propagation of limited amounts of HPVs in cultured cells results from the ability to reproduce the physiologic milieu required for differentiation.[15,16] Although it is possible to isolate infectious HPVs from cultured epithelial cells, the process is time-consuming, technically challenging, expensive, and limited to research laboratories. Therefore, laboratory culture for detection of HPV is not a practical diagnostic test.

EPIDEMIOLOGY

Acquisition of HPV depends on several factors, including the location of lesions, the quantity of infectious virus present, the degree and nature of the contact, and the general and HPV-specific immune status of the exposed individual. The roles of immunity and genetic susceptibility to PV infection are incompletely understood. The decrease in the frequency of warts with age implies that resistance to infection develops over time, and much of this resistance may be immunologic. In experimental PV infection in animals, resistance to virus challenge correlates with the presence of neutralizing anti-capsid antibodies. Serum or immunoglobulin G from resistant animals can provide protection through passive transfer.[17,18] It is therefore likely that neutralizing antibodies account for at least some of the resistance to reinfection. Serum antibodies to viral capsids are detectable in some patients with current warts or a history of warts. These antibodies, as well as other host factors, may help to limit the spread of warts to new sites. Although humoral immunity may contribute to resistance to acquisition of infection, host cellular immune reactivity plays a critical role in wart regression. Individuals with impaired cell-mediated immunity are particularly susceptible to persistent HPV infection, and their infections are notoriously resistant to treatment. Warts are common in renal and solid organ transplant patients on immunosuppressive therapy, which may contribute to their increased risk of cutaneous malignancy.[19,20] Although there are instances in which treatment of one or a few warts leads to resolution of many or all warts in nonimmunosuppressed patients, this outcome is the exception rather than the rule.

The reservoir of HPV is believed to be individuals with clinical and subclinical infection, as well as virus present in the environment. It is now apparent that HPV DNA is resident at very low levels on normal skin and in hair follicles. Using ultrasensitive polymerase chain reactions (PCR), a wide range of HPV, often of the β genus, is detected in the majority of individuals with both normal and suppressed host immunity.[21–23] Whether this HPV DNA represents a subclinical state rather than true "latency" (i.e., nonreplicating and transcriptionally inactive virus) is unknown. Whether HPV DNA persists in a latent state in the epithelium after successful treatment of immunocompetent individuals also remains an unresolved issue. However, the fact that HPV DNA becomes undetectable in the majority of cervical infections, even by exquisitely sensitive PCR techniques, implies that complete viral clearance is possible.

Nongenital warts occur most frequently in children and young adults, in whom the incidence may exceed 10%.[24,25] The age-specific incidence of nongenital warts differs from that of anogenital warts, which are uncommon in children. Anogenital warts behave as a sexually transmitted condition, and partners can transmit the virus with high efficiency.[26] Penile lesions occur frequently in sexual contacts of women with cervical intraepithelial neoplasia.[27,28]

Although genital warts in children may be a consequence of sexual abuse, such warts in infants and children commonly result from virus inoculation at birth or from incidental spread from cutaneous warts (see Chapter 106). In contrast to anogenital lesions in adults, a significant proportion of genital warts in children contain HPV types that are usually isolated from nongenital warts.[29–31]

In addition to causing lesions on the external genitalia, genital-mucosal HPV types also infect the uterine cervix.[32,33] This sexually transmitted infection, which may involve low- or high-risk HPV types, is especially common in sexually active women younger than 25 years of age. The majority of HPV DNA positive cervical infections are transient and remain histologically normal. Thus, even normal-appearing genital skin or mucosa may represent a reservoir for contagion. Studies of large populations throughout the world have documented the natural history of cervical infection and the association of high-risk HPV with cervical cancer. Persistence of HPV DNA strongly correlates with an increased risk for progression to cervical dysplasia and invasive cancer. High-risk HPV DNA has also been detected in clinically normal penile skin, although less is known of the epidemiology of genital HPV infection in men.[34]

The majority of respiratory (laryngeal) papillomas occur in infants and young children. The HPVs isolated from respiratory tract papillomas are often the same types as those of genital warts, especially HPV-6 and -11,[35] and respiratory papillomatosis in young children is thought to result from seeding of the larynx and oropharynx during parturition.[36] Although the epidemiologic correlation of condyloma in mothers of infants with respiratory papillomas has been documented,[37] cervical and genital warts are common in the childbearing age women and respiratory papillomatosis of infants is rare. Because Cesarean section has attendant risk and is not fully protective, this is not routinely recommended for expectant mothers. Instead, treatment efforts should be aimed at reducing HPV infection before delivery. Oral and respiratory warts in adults are usually the consequence of oral–genital contact and is a significant risk factor for development of HPV-associated oropharyngeal cancers, most commonly with HPV-16.[38]

Approximately 50% of EV cases are inherited, usually with an autosomal recessive pattern. Studies to identify the HPV genotype in EV wart lesions are limited to research laboratories. In contrast to the finding of β-HPV types on normal skin, large numbers of these

viruses are easily detected in EV lesions. Mutations in the *EVER* genes are reported to be present in a subset of EV individuals.[39,40]

CLINICAL FINDINGS

HISTORY

The typical history is of a newly acquired, slowly expanding, persistent, and often scaly papule of the skin. Over several weeks to months, the appearance of additional nearby lesions indicates local spread and infers the diagnosis of HPV infection.

CUTANEOUS WARTS

Warts are often classified by their anatomic location or morphology. As shown in Figs. 106-3 to 106-8, the physical appearance of warts varies. *Common warts* (verruca vulgaris) are scaly, rough, spiny papules or nodules (see Table 196-1). These may occur as single or grouped papules on the hands and fingers (see Figs. 196-3A and 196-5) or elsewhere (Fig. 196-7). Verrucae may be *filiform* and resemble cutaneous horns (Fig. 196-6). *Flat warts* (verruca plana) are 1–4 mm, slightly elevated, flat-topped papules that have minimal scale (see Fig. 196-8). These are most frequent on the face, hands, and lower legs. *Plantar and palmar warts* are thick, endophytic, and hyperkeratotic papules, which may be painful with pressure (see Figs. 196-3B and C). Punctate black dots ("seeds") that represent thrombosed capillaries become evident after shaving off the outer keratinous surface. *Mosaic warts* result from coalescence of plantar or palmar warts into large plaques (see Fig. 196-3C). Some individuals with an apparently normal immunologic state develop exuberant warts of the palms or soles that are refractory to treatment. *Butcher's warts* are verrucous papules, usually multiple, on the dorsal, palmar, or periungual hands and fingers of meat cutters, and may be infected with HPV-7.

Anogenital warts (also known as condylomata acuminata, genital warts, or venereal warts) consist of epidermal and dermal papules or nodules on the perineum, genitalia, crural folds, and anus (196-9A,B,C and E). They vary in size and can form large, exophytic, cauliflower-like masses, especially in the moist environment of the perineum. Discrete 1- to 3-mm sessile warts may occur on the penile shaft. Lesions that resemble common

Figure 196-5 Common wart. A giant wart on the dorsum of the hand in a renal transplant recipient; the lesions were resistant to treatment but resolved spontaneously when immunosuppressive therapy was discontinued.

Figure 196-7 The large, scaly, and horny warts contain human papillomavirus (HPV)-2. The smaller, flatter, less scaly papules are warts that contain HPV-3.

Figure 196-8 Plane warts, verruca plana. **A.** Multiple pink flat warts on the face of an 11-year-old girl. **B.** Many flat-topped papules occur in a linear configuration resulting from self-inoculation.

warts also occur in this region but are unusual. Warts may extend internally into the vagina, urethra, and perirectal epithelium.

Bowenoid papulosis and erythroplasia are clinicopathologic entities in which high-risk HPVs have been identified.[41] In bowenoid papulosis, papules, often multiple, appear as 2–3-mm lesions on the external male and female genitalia (see Chapters 77 and 78). Erythroplasia is characterized by a velvety, erythematous mucosal plaque with distinct borders (Fig. 196-9B). Histologically, there is cellular atypia resembling Bowen disease or squamous cell carcinoma (SCC) in situ. These lesions are usually infected with HPV-16, which suggests that bowenoid papulosis and erythroplasia may represent a precursor of penile and vulvar cancer. Erythroplasia can progress to invasive SCC (Fig. 196-9B). However, in bowenoid papulosis the rate of transition to frank malignancy is much lower for the external genitalia than for the cervix. These small papules should be treated also because they may represent a reservoir for the transmission of potentially oncogenic HPVs.

EPIDERMODYSPLASIA VERRUCIFORMIS

EV usually manifests in childhood with persistent and often widespread warts that do not regress due to unique susceptibility to specific HPV types. Individual lesions typically have either the appearance of flat warts (Fig. 196-10) or flat scaly red-brown macules that resemble pityriasis versicolor, particularly if the occur on the trunk. The presence of warts on large areas of the body is suggestive but not necessary to consider this diagnosis. Involvement of the cervix and oropharynx is rare. Failure to clear lesions despite adequate treatment is another indication of potential EV. Because warts in EV almost always recur after treatment, this implies a failure to mount an effective immune response to the HPV infection. Individuals with EV do not usually have frequent bacterial or other viral infections. Immunocompromised individuals, such as those with HIV infection, may have multiple warts that contain EV and other β-HPV types and are difficult to eradicate, but this susceptibility is acquired.[42,43] SCCs in EV and immunosuppression usually arise in pityriasis-like lesions on sun-exposed areas (Fig. 196-11). Regional and distant metastases may occur. Although pityriasis-like lesions caused by any EV type are at risk of becoming malignant, this is higher for those caused by HPV-5 and -8.

EXTRACUTANEOUS (MUCOSAL) INFECTIONS

Oral warts are usually small, slightly elevated, soft, often pink or white papules that may be found on the buccal, gingival, labial mucosa (Fig. 196-4), tongue or hard palate. Verrucous, horny papillomas may occur on the palate. Mucosal lesions of the oropharynx, termed focal epithelial hyperplasia, also contain HPVs. In oral florid papillomatosis, multiple large verrucae appear within the oral cavity (see Fig. 196-9D). Progression to verrucous carcinoma may occur. Oral warts may result from genital contact. Warts may also occur in the urethra, usually when meatal warts are present. They may spread to the urinary bladder.

In respiratory (laryngeal) papillomatosis, multiple warts usually involve the larynx and may extend to the oropharynx and bronchopulmonary epithelia. Presenting symptoms commonly include hoarseness and stridor. Cases typically occur in infants or young children in whom the lesions may block the airway, but the condition may develop at any age. These HPV-associated papillomas may spontaneously remit, especially at puberty, but recurrences are frequent.

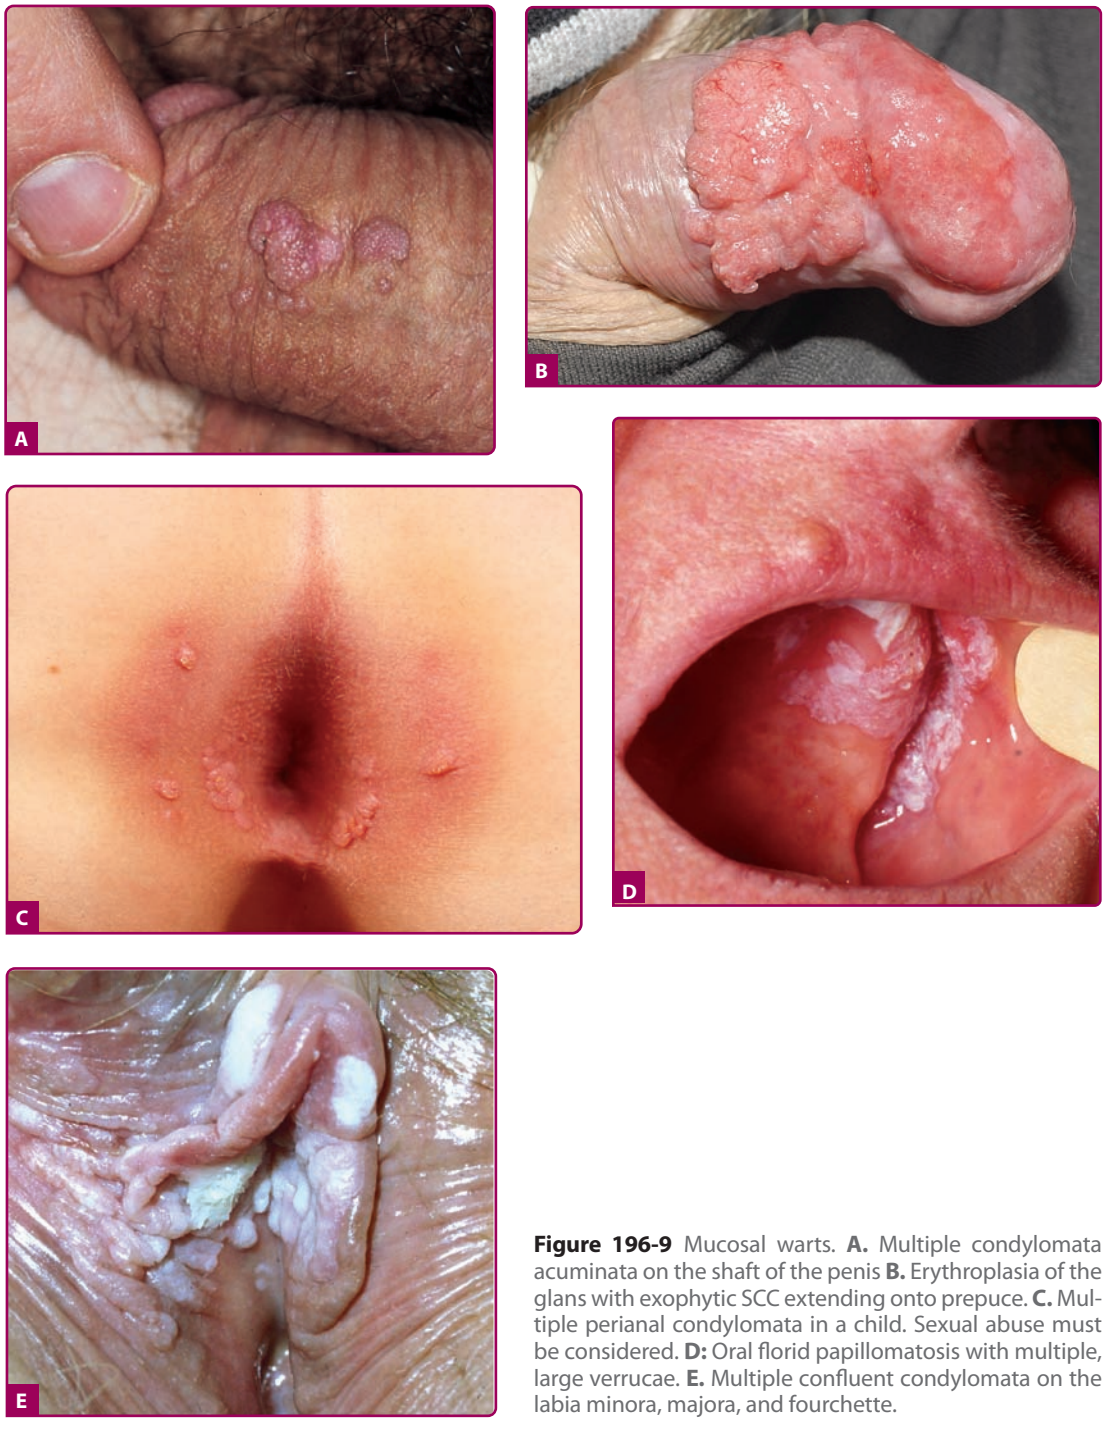

Figure 196-9 Mucosal warts. **A.** Multiple condylomata acuminata on the shaft of the penis **B.** Erythroplasia of the glans with exophytic SCC extending onto prepuce. **C.** Multiple perianal condylomata in a child. Sexual abuse must be considered. **D:** Oral florid papillomatosis with multiple, large verrucae. **E.** Multiple confluent condylomata on the labia minora, majora, and fourchette.

Cervical lesions are usually flat or slightly elevated and visualization may require colposcopy and enhancement after acetic acid application, which makes them appear as white patches (Fig. 196-12).

HISTOPATHOLOGY

Verrucae consist of an acanthotic epidermis with papillomatosis, hyperkeratosis, and parakeratosis (Fig. 196-13). The elongated rete ridges often point toward the center of a wart. The dermal capillary vessels are prominent and may be thrombosed. Mononuclear cells may be present. Large keratinocytes with an eccentric, pyknotic nucleus surrounded by a perinuclear halo (koilocytotic cells or koilocytes) are characteristic of HPV-associated papillomas. Koilocytes visualized in a Papanicolaou (Pap) smear represent a hallmark of HPV infection. PV-infected cells may have small, eosinophilic granules and dense clumps of basophilic keratohyaline granules. These granules may be composed of or associated with the PV E4 (E1-E4) protein

Figure 196-10 Epidermodysplasia verruciformis. Plane wart-like lesions on the dorsa of the hands and forearms, associated with human papillomavirus-5 and -8. The lesions are numerous, flat, reddish, and partly confluent.

and are not conglomerates of virus particles. Flat warts have less acanthosis and hyperkeratosis and do not display parakeratosis or papillomatosis. Koilocytotic cells are usually abundant, indicating the viral origin of the lesion. Anogenital warts may have slight or extensive acanthosis and parakeratosis: they lack a granular layer as they are within or adjacent to a mucosal surface. The rete ridges often form thick bands extending extensively into the underlying, highly vascular dermis.

Flat warts have a similar histologic appearance whether in the general population or in patients with EV (Fig. 196-14). The granular and upper spinous layers contain many cells with perinuclear vacuolization. In EV, lesions containing HPV-5 or -8 have a characteristic basket weave hyperkeratosis with many large clear cells in the granular and spinous layers (Fig. 196-15).

Figure 196-11 Invasive cancer in an epidermodysplasia verruciformis patient infected with numerous human papillomavirus (HPV) types, including HPV-5, -8, -9, -14, and others. In the tumor cells, HPV-5 DNA was detected in a high copy number. This large squamous cell carcinoma did not metastasize and did not recur after surgery. There are numerous actinic keratoses on the forehead.

DIFFERENTIAL DIAGNOSIS

The clinical appearance and history of acquired, slowly enlarging papules usually lead to the diagnosis of viral wart. Histologic examination can be used to confirm the diagnosis. Application of 3%–5% acetic acid to genital warts enhances visualization of these lesions, particularly with colposcopic magnification (Fig. 196-12), although the diagnosis should not rest only on the presence of white lesions as the test is nonspecific. Detergent-disrupted PV particles expose L1 and L2 antigens shared among most PVs. Immunohistochemistry using antibodies can detect these capsid proteins in clinical materials, including formalin-fixed tissue,

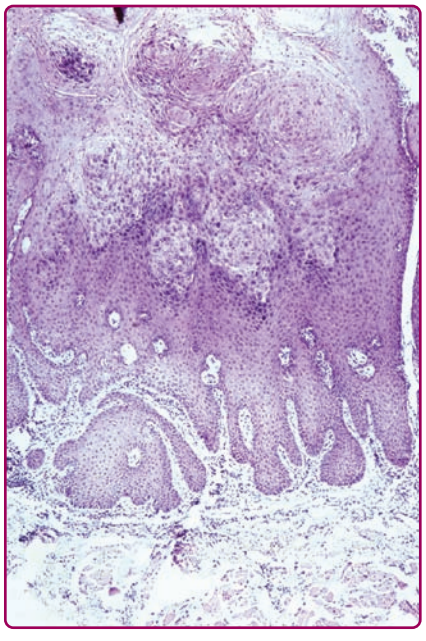

Figure 196-13 Verruca vulgaris. The process is one of extensive hyperplasia, and the hyperplastic cells contain both intranuclear and intracytoplasmic inclusion bodies.

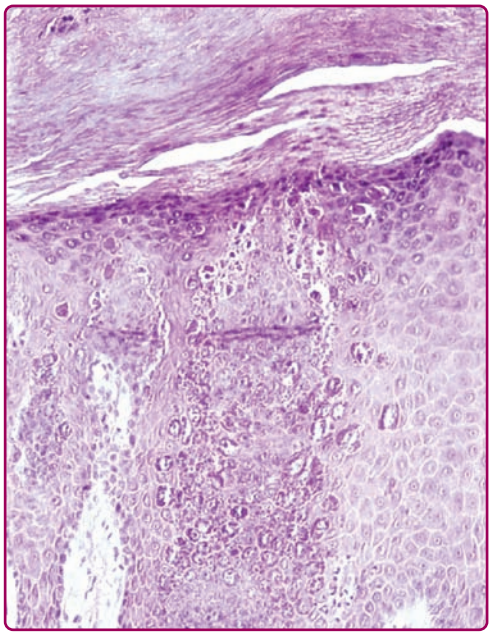

Figure 196-14 Human papillomavirus-3–associated plane wart-like lesion in patient with epidermodysplasia verruciformis. Numerous cells show perinuclear vacuolization in the granular and upper spinous layers.

but is insensitive and not routine. In situ hybridization using HPV specific probes is much more sensitive and can be used on pathologic specimens. PCR techniques detect cutaneous or EV type HPVs but are generally limited to research and diagnostic laboratories. Highly sensitive and specific diagnostic hybridization tests to identify genital–mucosal HPV types are commercially available (Digene Hybrid Capture 2; Roche Amplicor HPV and Linear Array HPV Genotyping Tests).[44,45]

Cutaneous warts are commonly found in all age groups. Multiple warts that do not spontaneously resolve, always recur after treatment, persist for years, or have an unusual morphology (especially if familial) suggest EV. HPV typing may be of benefit in confirming the diagnosis of EV and will disclose whether the patient is infected with a type that is associated with cutaneous malignancy. Immunocompromised patients, such as those with acquired immunodeficiency syndrome, lymphoproliferative disorders, or drugs to prevent transplant rejection, often have multiple warts.

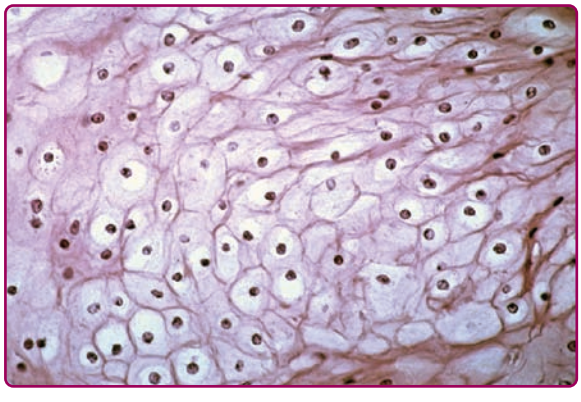

Figure 196-15 Characteristic cytopathic effect of epidermodysplasia verruciformis-specific human papillomavirus (HPV) in a patient found to be infected with HPV-5, -8, and -9. Very abundant clear large cells with small pyknotic nuclei replace almost the entire epidermis.

Common lesions such as seborrheic and solar keratoses, nevi, acrochordons, sebaceous hyperplasia, clavi, small pyogenic granuloma, or SCC may resemble a verruca. The differential diagnosis varies considerably with the type of lesions and the site of involvement (Box 196-1).

Papules of lichen planus may resemble flat warts; the former may be differentiated by their color, polygonal shape, Wickham's striae, and buccal involvement (Box 196-2). Acrokeratosis verruciformis is characterized by verrucous papules on the extremities. Warts in epidermodysplasia may resemble pityriasis versicolor but are not transient.

Nevi, benign keratoses, cysts, or ectopic sebaceous glands may resemble penile and vulvar warts (Box 196-3). A history of increasing number of acquired, grouped lesions is suggestive of warts. Syphilitic condylomata must be ruled out.

COMPLICATIONS

PAPILLOMAVIRUSES AND CANCER

Viral genome amplification occurs in upper levels of the epithelium composed of nondividing keratinocytes. Therefore, all PVs must block terminal differentiation and activate the cellular machinery necessary for synthesis of viral DNA. Most molecular studies of viral gene functions use the high-risk types, since these generally exert more pronounced phenotypes in cell culture models. In one assay, primary human keratinocytes or cervical cells proliferate and differentiate as a stratified epithelium at the air-media interface on a floating collagen raft.[46] Introduction of high-risk HPV-16 or -18 DNA into these organotypic keratinocyte cultures induces a disorganized pattern of differentiation with suprabasal mitotic figures resembling SCC in situ, whereas the keratinocytes expressing low-risk HPV-6 or -11 DNA retain a normal pattern of stratification.[47,48] In another model, the high-risk HPV-16 or -18, *E6* genes were found to induce resistance of keratinocytes to calcium-induced differentiation.[49] Expression of high-risk E6 and E7 together in primary keratinocytes, which have a limited lifespan in culture, efficiently blocks replicative senescence with the cells able to sustain serial passage and becoming "immortal."[50,51] Low-risk HPVs are much less effective in immortalization assays.[52,53] These experiments highlight the oncogenic properties of high-risk *E6* and *E7* genes and rationalize why these genes always retained and expressed in cervical cancers. Metastatic tumors in cervical cancer and EV express *E6* and *E7*, implying their retention is necessary for maintenance of the malignant phenotype. Thus, for the genital–mucosal HPVs, there is

an excellent correlation between their ability to induce cell transformation in vitro and their association with malignancy.[54]

The E6 and E7 proteins (see Fig. 196-1) have evolved multiple mechanisms to the cellular DNA replication program and inhibit apoptosis, which is the innate protective death response to cell stress and DNA damage.[55–57] Studies demonstrate that E6 and E7 each have distinct protein targets in the cell.[58,59] High-risk E7 binds to and induces degradation of the retinoblastoma family of tumor suppressors. These proteins restrict entry into cell cycle, and their inactivation by E7 allows infected cells to enter cell cycle and initiate DNA synthesis.[60] Low-risk E7 are less effective at retinoblastoma protein inactivation and also more restricted in their effects on certain members of this family.[61]

The best-known property of high-risk E6 proteins is their ability to bind to and induce ubiquitination of p53.[59,62] This results in degradation of this tumor suppressor and inhibition of p53 mediated growth arrest, apoptosis, and autophagy pathways in response to cell stresses such as DNA damage. However, the E6 proteins from low-risk HPV and those types associated with malignancies in EV and immunosuppression do not directly bind p53. These viruses may prolong the life span and restrict tumor suppressor pathways by alternate mechanisms.[59,63] Another remarkable activity of high-risk and several other E6 proteins is their ability to increase expression of hTERT, the catalytic subunit of telomerase.[64–66] Telomerase is expressed in immortal stem cells and many cancers. This enzyme protects chromosome ends from progressive deterioration during replication, which normally limits a cell's lifespan. In addition, high-risk E6 bind to several factors in the programmed cell death pathway, including tumor necrosis factor receptor (TNF-R), fas-associated death domain (FADD), and caspase-8, and in this manner interferes with apoptotic signaling.[62,67] Cutaneous β- and high-risk α-type HPV E6 proteins target Bak

for degradation, thereby abrogating its activity in the mitochondrial pathway of apoptosis.[68–71] The E5 oncoproteins activates growth factor receptors. For bovine PV, which induces fibropapillomas, E5 appears to preferentially activate the receptors for platelet-derived growth factor, whereas HPV-16 E5 may stimulate the epidermal growth factor receptor.[72,73]

Robust epidemiologic and molecular studies confirm that infection with high-risk HPVs is the cause of almost all cases of cervical cancer. Even with high-risk HPVs, most cervical infection have a benign outcome.[32,33] Persistent infection with high-risk or other HPV types is a major risk factor. The critical determinants of whether HPV infection of the cervix is transient or persistent and thus at high-risk for malignant progression are not known. Individuals with impaired cellular immune function, such as renal transplant recipients or HIV infection and acquired immunodeficiency syndrome, are at greater jeopardy for persistent HPV infection that can progress to dysplasia and to cancer.[74]

In the genital–mucosal HPVs, transcription of E6 and E7 is regulated by the viral E2 protein, which has been shown to repress their expression. Loss of E2 function may alleviate repression and lead to increased levels of the E6 and E7 oncoproteins and stochastic mutations of E2 are found in many cervical cancers.[75] Furthermore, E2 binds to the viral E1 protein, and this complex is necessary for viral genome replication as an episome or plasmid.[76] Loss of E2 would obligate HPV genome integration into the infected cells DNA, and this would also alter the viral transcription program. Furthermore, HPV integration assures persistence of the viral infection in the basal cell population, for as these cells divide, viral episomes could otherwise partition during mitosis to the progeny cells and be lost as these migrate up through the epithelium and ultimately exfoliate. While interruption of E2 and HPV integration is likely an important step in neoplastic transformation of the cervix, it is not absolutely required, for approximately 15% or more of cervical cancers contain only viral episomes.[77,78]

While E6 and E7 contribute to the malignant state, cervical cancers develop from benign or dysplastic precursor lesions over a span of years to perhaps a decade or more. Not all warts in EV become cancerous. These observations imply the requirement for oncogenic cofactors in addition to continued expression of E6 and E7. Skin cancers in EV usually appear in sun-exposed regions. The benign but locally obstructive verrucae in respiratory papillomatosis, if treated by X-rays, often progress to invasive SCC. In cervical cancer, chromosomal mutations and deletions have been reported, with the most common being on chromosomes 3 and 4.[79–82] Small doses of chemical carcinogens convert benign warts in rabbits induced by the Shope cottontail rabbit PV into invasive SCC. In cattle, esophageal papillomas induced by bovine PV type 4 become malignant if the infected animals graze on bracken fern, which contains a potential carcinogen. These phenomena indicate that oncogenic PVs do not induce malignant tumors directly but predispose the infected cell to tolerate genetic damage and select for mutations that promote cell survival and continuous cell division.

Epidemiologic and molecular evidence has clearly linked a subset of penile, vulvar, vaginal, anal, and oropharyngeal carcinomas with HPV infection.[83,84] As with cervical cancer, these tumors are associated primarily with high-risk HPV types. High-risk HPVs, especially HPV-16, have been identified in some periungual cutaneous tumors. The giant condyloma acuminatum, also called the Buschke–Lowenstein tumor, is a low-grade, locally invasive SCC. Low-risk HPVs, such as types 6 and 11, are usually found in these tumors. Epithelioma cuniculatum, another rare type of verrucous carcinoma, is found on the sole and is thought to arise from a plantar wart (see Chapter 114).

Many studies have detected low levels of HPV DNA, often of EV or β-HPV types, in actinic keratoses, basal cell carcinoma (BCC) and SCC, psoriasis, and other skin lesions.[85–89] These genomes are present at extremely low levels, usually much less than one copy per cell. RNA expression of HPV genes has been difficult to detect in these cutaneous lesions. It is possible that HPV genes induce an altered transitional state, and their presence and expression becomes unnecessary in cutaneous cancers ("hit and run"). In contrast, all cells within cervical tumors express E6 and E7, and continuous expression of these two viral genes is necessary for their continued proliferation. Furthermore, because PCR detects persistent HPV DNA in 50%–90% of normal skin and hair follicle samples,[23,90,91] contamination by incidental HPV from normal skin is possible.[92] For example, a broad spectrum of HPV types has been reported to be detected in cutaneous melanomas, but the evidence for HPV as causative is very weak.[93] Therefore, the causal role of HPV in the pathogenesis of these benign, premalignant, and malignant epithelial lesions remains unresolved.[85,94–96]

TREATMENT

The management of warts depends on the degree of physical and emotional discomfort, the extent and duration of lesions, the patient's immunologic status, the patient's desire for therapy, and the risk of contagion to other persons.[97,98] Recurrences are common with all treatment modalities.

Most treatments for verrucae involve physical destruction of the infected cells. The existence of multiple treatment modalities reflects the fact that none is uniformly effective or directly antiviral. In general, there are few adequately controlled studies of HPV treatment. The choice of treatment depends on the location, size, number and type of wart, as well as on the age and cooperation of the patient. Pain, inconvenience, risk of scarring, and the benefit to the patient should be considered. Children with common warts may not require treatment as spontaneous regression is frequent. However, new warts may appear and virus can be spread to other areas or susceptible individuals. In patients with anogenital warts (including bowenoid papulosis), sexual partners should be examined, the cervix should be evaluated and a Pap smear obtained; male contacts of women with cervical disease should also be examined. Anogenital warts in sexual contacts should be treated.

Cryotherapy using liquid nitrogen applied with a cotton tip or a spray canister to achieve a halo of ice in and around the lesion is a standard and effective treatment for most warts.[99,100] A single freeze is sufficient for most warts. Caution must be used near the nail matrix when treating periungual warts. Aggressive cryotherapy with a spray canister can injure underlying structures such as nerves and therefore its use on the lateral surfaces of the digits and genitalia mandates caution. Warts on the elbows and knees of children may be particularly susceptible to scarring with cryotherapy; although effective, this modality should be used in moderation in these patients.

Warts may be curetted or surgically excised, particularly large anogenital warts unresponsive to topical treatments. Electrodesiccation of condyloma acuminata requires local anesthesia but is also effective. Laser treatment in several different energy formats, including photodynamic therapies, can be useful for destroying warts that are treatment resistant or those that require careful control of width and depth, such as large periungual warts. Use of a surgical mask should be routine because infectious PV has been identified in the vapor plume with laser or with electrocoagulation of warts.[101] Mohs micrographic surgery has been useful in the treatment of verrucous carcinoma. X-irradiation of verrucae is contraindicated because of its association with the development of malignancy in respiratory papillomatosis and EV. Avoidance of and protection from sun exposure is critical in EV.

Chemotherapeutic agents are commonly used to treat warts. Although topical podophyllin resin has been widely used for anogenital warts, the potency of podophyllin preparations is variable. Podophyllin is contraindicated during pregnancy. Purified podophyllotoxin (Condylox) has activity that is uniform from batch to batch and is approved for treatment of genital and perianal warts.[102] Topical 5-fluorouracil has been used to treat cutaneous and genital warts, and has been reported to be highly effective with occlusion in the treatment of plantar warts.[103] Intralesional bleomycin may eradicate verrucae, but should be used cautiously because of the possibility of extensive tissue necrosis.[104] Anecdotal reports suggest topical application of the nucleotide analog cidofovir may be effective in the treatment of warts, however, pain and ulceration are significant side effects.[105,106]

Caustics and acids such as salicylic acid, lactic acid, and trichloroacetic acid, destroy and peel off infected skin. Home use of salicylic acid preparations can be particularly efficacious in young children who cannot tolerate other modalities. Retinoic acid has been used topically for flat warts and probably has a similar mechanism of action. Oral isotretinoin has also been used in the treatment of extensive cutaneous warts but carries the same cautions as its use for acne. Cantharidin is an extract of the green blister beetle that is painlessly applied and causes delayed blistering and focal destruction of epidermis.

Immunotherapies have been attempted in various forms. Induction of allergic contact dermatitis with diphenylcyclopropenone or squaric acid dibutylester allows localization of inflammation to warts on which the allergen is painted; it has been speculated that this treatment stimulates local immunity.[107,108] Cimetidine has been associated with the resolution of cutaneous warts, particularly in children. Although this regimen has its supporters, a double-blind controlled study failed to confirm a beneficial outcome.[109] Interferon has been effective in short-term studies, reducing warts in laryngeal papillomatosis and EV, but lesions return when therapy is stopped. Recombinant interferons have been used by intralesional injection of refractory genital warts.[110] Imiquimod, a potent stimulator of the release of several proinflammatory cytokines that acts at least in part by activation of Toll-like receptors 7 and 8,[111] is approved for patient-applied therapy treatment of genital warts, although some report cure rates are lower than treatments with physical modalities, other studies have found greater than 90% resolution.[112,113] Imiquimod is less effective for cutaneous warts. A small double-blind study of oral zinc sulfate for cutaneous warts reported a 78% response rate that was durable to 6 months.[114] Home application of 5% potassium hydroxide solution has induced regression of genital warts in men.[115] Anecdotal reports suggest that intralesional injections of candidal extracts induce wart regression.[116–118] Because yeast and viruses share no homologous proteins, the mechanism of action is obscure but thought to be due to induction of a localized immune response. Imiquimod and low-dose retinoids appear to reduce the development of cutaneous malignancies in transplant recipients.[119,120]

PREVENTION

For nongenital warts, direct exposure to lesions or to fomites that contain virus represent likely sources of infection. The risk for acquisition of new genital or cervical HPV infection correlates with the number of sexual partners. The risk of genital infection appears to be lower in circumcised males and in their sexual partners,[121] and there is evidence that regular use of condoms may partially protect against the acquisition of genital HPV infection.[122] Widespread Pap smear screening in the United States and other developed countries has greatly reduced the incidence of invasive cervical cancer.

The prophylactic HPV vaccine represents the newest approach to preventing genital HPV infection. The vaccine, which is noninfectious, is based on self-assembly of the L1 protein into virus-like particles (VLPs) that morphologically and antigenically resemble authentic capsids (see Fig. 196-2). VLP immunization induces high titers of type-specific neutralizing antibodies.[123] In human clinical trials, the L1 VLP vaccine, which is administered intramuscularly, induced seroconversion in more than 99% of vaccines and resulted in serum antibody titers 40 times or more than those that develop after natural infection, with nearly 100% protection against the development of cervical infections attributable to the HPV types in the vaccine.[124–127] A quadrivalent vaccine (Gardasil) composed of L1 VLPs from HPV-6, -11, -16, and -18, is approved by the US Food and Drug Administration for females and males ages 9–26 (in Europe in males only 9–15 years). A bivalent HPV-16 and -18 VLP vaccine (Cervarix) is also marketed as a vaccine to prevent cervical cancer. Both are administered as three intramuscular injections over a 6-month period. Headache, fever, and pain, itching, redness, swelling, and bruising at the injection site, were the most common side effects observed. Because the quadrivalent vaccine includes HPV-6 and -11 VLP, it offers reduction in the occurrence of genital warts. Despite nearly 100% efficacy in preventing HPV infection, these vaccines do not have therapeutic activity against established infection. Another limitation is that protection appears to be primarily type-specific, with limited cross-protection against very closely related types, so most infections caused by HPV types other than those in the vaccine will not be prevented. However, HPV-16 and -18 account for approximately 70% of cervical cancer worldwide. Thus, the prophylactic VLP vaccines should protect against the majority of HPV infections that lead to cervical cancer.

Chapter 197 :: Human T-Lymphotropic Viruses

:: Erwin Tschachler

HUMAN T-LYMPHOTROPIC VIRUS 1-INDUCED SKIN DISEASES AT A GLANCE

- An estimated 10–20 million people are infected by human T-cell lymphotropic virus type 1 (HTLV-1) worldwide, with endemic pockets of high prevalence in Southern Japan and the Caribbean islands.
- Infective dermatitis is a recalcitrant form of eczema occurring in HTLV-1-infected children in the Caribbean.
- Adult T-cell leukemia (ATL) shows monoclonal HTLV-1 provirus integration in tumor cells and occurs in four clinical variants, all of which tend to show skin involvement:
  - Smoldering ATL—5% of all cases.
  - Chronic ATL—15% of all cases.
  - Lymphoma-type ATL—20% of all cases.
  - Acute ATL—60% of all cases.
- The prognosis of lymphoma-type and acute ATL is very poor despite chemotherapy, with a projected 4-year survival of 5%.

The first known pathogenic human retrovirus was isolated in 1980 from the lymphocytes of a patient with cutaneous T-cell lymphoma (CTCL) by Poiesz and coworkers.[1] Independently, Miyoshi and co-workers later isolated an identical retrovirus from a Japanese leukemia patient.[1] The name *human T-cell leukemia virus type 1* (HTLV-1) is used now for all isolates previously called *adult T-cell leukemia virus* in Japan and *HTLV* in the United States.

EPIDEMIOLOGY

An estimated 10–20 million individuals are infected by HTLV-1 worldwide,[2–4] with an endemic pattern in Southern Japan, the Caribbean islands, and some countries in equatorial Africa. In some of these locations, most notably the Japanese islands Shikoku, Kyushu, and Okinawa, the seroprevalence reaches 36%.[2–4] Small clusters of HTLV-1/HTLV-2 seropositive populations have been reported in restricted areas in South America, among Australian aborigines, and in the Middle East.[2–4] In the United States and Europe, the incidence of HTLV-1 infection is below 0.1%, and clusters are found predominately among immigrants from endemic areas, especially those from the West Indies and Africa.[2–4]

Sexual intercourse is the main mode of horizontal transmission of HTLV-1.[2–4] In vertical transmission, breast-feeding plays a more important role than perinatal or intrauterine transmission.[2–4] Parenteral transmission of HTLV-1 is also possible, and approximately one-half of patients who received transfusions from an HTLV-1-infected donor seroconvert,[2–4] however, the transmission risk by blood transfusion in low prevalence countries is minimal.[4,5] Transfusion-mediated HTLV-1 infection in Japan has been virtually eliminated by mass screening of donated blood. In contrast to blood transfusions, cell-free, fresh, frozen plasma appears not to be infectious.[5] Parenteral transmission via needle sharing very likely accounts for clusters of HTLV-1/HTLV-2 seropositivity in intravenous drug users in certain areas of the United States and Europe.[6]

ETIOLOGY AND PATHOGENESIS

HTLV-1 together with HTLV-2, a virus that has not yet been clearly associated with any human disease, and bovine leukemia virus form their own genus within family Retroviridae.[2] Many strains of HTLV-1 have been isolated in different areas of the world, including the United States, the Caribbean islands, Africa, and Japan.[3] The overall nucleic acid sequence variation among different HTLV-1 strains does not exceed 7%. By comparison, the nucleotide sequence conservation between HTLV-1 and HTLV-2 is only approximately 55%. In addition to genes coding for viral structural proteins, both the HTLV-1 and HTLV-2 genomes contain an extra sequence of approximately 1.6 kilobases between the *env* and the 3′ LTR, which contains several regulatory genes. These include the transregulatory proteins Tax (transactivator in the region x) and Rex (regulator in the region x), whose functions have been elucidated, but the function of the other proteins of the pX region—p21Rex, $p12^{I}$, $p13^{II}$, and $p30^{II}$—still awaits full clarification.[2,7–9]

Infection of human, monkey, and rabbit T lymphocytes by HTLV-1 in vitro leads to their continuous growth in tissue culture and the development of cell lines with growth characteristics of transformed cells. In infected patients, HTLV-1 is present mainly in $CD4^{+}$ T cells.[10] The steps leading from virus infection to the development of the different HTLV-1-associated diseases are still only partly understood. Only a small percentage of patients infected with HTLV-1 ultimately develop adult T-cell leukemia (ATL), and the time from infection to the appearance of leukemia is usually several decades.[2,4]

Tax, the viral transactivator, is necessary for the transformation of T cells. It interferes with at least two inhibitors of cell cycle progression, including the tumor suppressor protein $p16^{ink}$ and p53.[2,8] In the transformed state, HTLV-1-infected T cells proliferate in the absence of exogenous growth factors. This event correlates with both the constitutive activation of the Janus kinase/signal transducer and activator of transcription (Jak/STAT) signaling pathway[8] and the constitutive activation of the cyclin E/cyclin-dependent kinase 2 complex. The in vitro model of T-cell transformation appears to mirror the event that leads to leukemogenesis. In most cases of ATL, genetic mutation or deletion of p53 or $p16^{ink}$ occurs,[8] and the leukemic cells of 70% of patients display constitutive activation of the Jak3 and STAT proteins.[8] An antisense transcript of HTLV-1 from the 3′ long terminal repeat and called HTLV-1 bZIP factor (HBZ) has been identified, its expression was documented HTLV-1-infected cells as well as in all ATL cases studied and its expression is correlated with proviral load.[11] HBZ mRNA promotes proliferation of ATL cells and is thought to play a critical role in leukemogenesis.

Although HTLV-2 has been less well studied than HTLV-1, most of the properties described for the latter, including the transformation of T cells in vitro and the presence and importance of transregulatory genes, are also true for the former.[2]As noted above, no disease has been associated with HTLV-2 infection, to date.

HUMAN T-LYMPHOTROPIC VIRUS 1 INFECTION AND CLINICAL DISEASES

ADULT T-CELL LEUKEMIA/LYMPHOMA

Uchiyama and co-workers first described ATL in 1977 as a distinct malignancy of mature T cells occurring primarily in patients born in Southwestern Japan.[1–4,12] At the beginning of the 1980s, HTLV-1 was linked to ATL by virus isolation from leukemic cells, by the demonstration of oligoclonal or monoclonal integrated HTLV-1 provirus in leukemic cells, and by extensive seroepidemiologic studies.[1,2,4,8] Besides Japan, the West Indies are a major region where HTLV-1 infection and ATL are endemic.[2–4]

Although the presence of HTLV-1 is a prerequisite for ATL development, infection with this virus does not necessarily lead to the occurrence of leukemia. More than 90% of infected individuals remain asymptomatic carriers.[2,12] The annual incidence rate of ATL among HTLV-1 carriers older than 40 years is approximately 0.6–1.7 in 1000.[13] The cumulative incidence rate of ATL in HTLV-1 carriers approximates 2–5%. The latent period from infection to outbreak of leukemia is 20 years or longer, as concluded from studies in migrants.[14] Interestingly, the average age of onset of ATL differs in patients in Japan (56 years) and in the Caribbean (43 years).[15]

According to the World Health Organization's lymphoma classification, ATL is a peripheral T-cell lymphoma. Based on the clinical course and laboratory parameters, ATL is classified into four subtypes—(1) smoldering (5% of cases), (2) chronic (15%), (3) lymphoma type (20%), and (4) acute or prototypic ATL (60%)—for which diagnostic criteria have been formulated (Box 197-1).[16,17]

Acute, prototypic ATL is a fatal malignancy of adult onset with a clinical presentation that appears to be identical in all endemic areas.[54,12,16,17] It is characterized by the variable combination of multiorgan involvement,

BOX 197-1 DIAGNOSTIC CRITERIA FOR ADULT T-CELL LEUKEMIA (ATL)

FEATURES COMMON TO ALL ATL SUBTYPES

- Positive results on serologic testing for HTLV-1
- Clonal integration of HTLV-1 in tumor cells
- Expression of CD25 and HLA class II antigens by tumor cells

DISTINGUISHING FEATURES OF ATL SUBTYPES

- Smoldering ATL
  - Normal lymphocyte counts with 1%–5% leukemic cells present
  - Skin lesions and/or lung lesions possible but not essential, no other visceral involvement
  - No lymphadenopathy, no hypercalcemia
  - Serum LDH level up to 1.5× the normal upper limit
- Chronic ATL
  - Lymphocytosis ($>4 \times 10^9$/L) with 5% or more leukemic cells present
  - Skin, liver, lung, or lymph node involvement possible but not essential; other viscera not involved
  - No hypercalcemia
  - Serum LDH level above 2× the normal upper limit
- Lymphoma-type ATL
  - Normal lymphocyte counts with <1% leukemic cells present
  - Possible involvement of multiple visceral organs, lymphadenopathy
  - Possible hypercalcemia
  - Serum LDH level strongly elevated
- Acute ATL
  - Lymphocytosis ($>4 \times 10^9$/L) Large numbers of leukemic cells present in peripheral blood
  - Involvement of multiple visceral organs with organomegaly
  - Frequently hypercalcemia with osteolytic lesions
  - Serum LDH level strongly elevated

HTLV-1 = human T-cell lymphotropic virus type 1; LDH = lactic acid dehydrogenase.

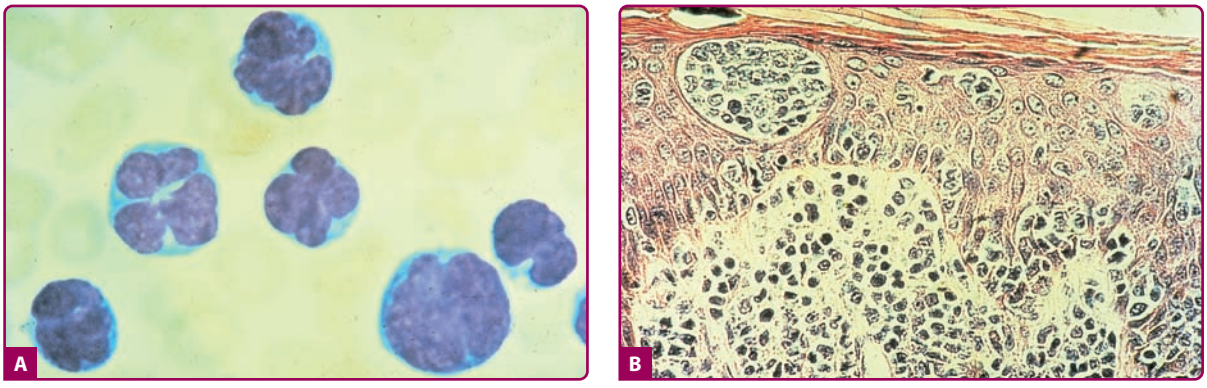

Figure 197-1 **A.** Abnormal lymphocyte with multilobated nucleus ("flower cell") from a patient with adult T-cell leukemia (ATL). (Used with permission from K. Takatsuki, MD, Kumamoto University, Japan.) **B.** ATL tumor cells infiltrate the epidermis, creating Pautrier's microabscesses. (Used with permission from B. Hanchard, MD, University of the West Indies, Kingston, Jamaica.)

including hepatosplenomegaly, systemic lymphadenopathy, central nervous system involvement, and skin lesions, with the massive presence of multilobated leukemic cells in the peripheral blood (Fig. 197-1A). The presence of leukemic infiltrates in different organs determines the clinical presentation and the morbidity: central nervous system involvement may alter the mental status of the patient; lymphoma within the liver may lead to abnormalities in liver function test results and jaundice; and lung involvement may lead to tachypnea, cyanosis, and dyspnea.

A striking feature in a high percentage of patients with acute ATL is refractory hypercalcemia, which may be the first sign of the disease and indicates an aggressive course.[4,12,16–18] Patients may have weakness, lethargy, polyuria, and polydipsia. Lytic bone lesions resembling those of multiple myeloma are often present at the time of diagnosis, and levels of alkaline phosphatase may be elevated.[4,18] Parathyroid hormone levels and 1,25-dihydroxyvitamin D levels are normal in ATL patients with hypercalcemia. Factors produced by leukemic cells themselves have been suggested to account for the hypercalcemia and bone resorption in ATL patients.

Lymphoma-type ATL also shows severe organ involvement and high serum levels of lactic acid dehydrogenase and may be associated with hypercalcemia. Unlike in acute ATL less than 1% leukemic cells are present in the peripheral blood. Both lymphoma-type and acute ATL have a poor prognosis, with a projected 4-year survival of no more than 5%.[4,12,17]

Smoldering and chronic ATL have more protracted courses; however, they may convert into acute ATL.[4,12,16,17]

The skin involvement in ATL varies considerably among patients and is present to a variable degree in all forms of ATL.[4,12,19–21] Skin lesions may appear as uncharacteristic erythematous patches, as papules and nodular tumors (Fig. 197-2), and as erythroderma. Nonspecific skin lesions may precede the onset of acute ATL by up to two decades.[21] Specific skin infiltrates may occur as the first manifestations of ATL, and monoclonality of skin-infiltrating cells may be evident by the criteria of both T-cell receptor rearrangement and integration of HTLV-1 DNA. This occurs at a time when circulating T cells of these patients still appear unaffected.[20] To designate this latter situation, the term *cutaneous-type ATL* has been proposed.[20] However, it is questionable whether this form represents an independent type of ATL or should be included in the smoldering form. Alternatively, it may reflect very early detection of prototypic or chronic ATL as a result of improved diagnostic methods.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS OF ADULT T-CELL LEUKEMIA.

Not only does prototypic ATL show a characteristic clinical course but examination of the leukemic cells yields a characteristic picture: numerous multilobated cells called *ATL cells* or *flower cells* (see Fig. 197-1A) are present in peripheral blood and can usually be readily distinguished from cells of other T-cell leukemias by light microscopy, although sometimes occasional cells indistinguishable from Sézary cells may be present.[4,12,16,17] In smoldering-type ATL and chronic-type ATL, multilobated cells are less frequent, and in lymphoma-type ATL they may comprise fewer than 1% of lymphocytes (see Box 197-1). Monoclonal integration of HTLV-1 DNA[4,12,16,17] in leukemic cells as well as in affected organs is a diagnostic criterion. Immunophenotyping shows that leukemic cells display predominantly a mature $CD2^+/CD3^+/CD4^+/CD8^-/CD25^+$ phenotype.[4,12,16,17] Although most of these T-cell markers can be found in other T-cell malignancies, the strong expression of the interleukin 2 receptor α chain (CD25) can be regarded as a distinguishing marker differentiating ATL and Sézary syndrome.[12,16,17,22]

The histopathologic features seen in affected organs and lymph nodes are more variable than the signs in peripheral blood, and ATL is associated with lymphomas of several histologic subtypes. Differentiation of ATL from other peripheral T-cell lymphomas, especially HTLV-1-positive and HTLV-1-negative cases, on morphologic grounds is not possible. No specific pathologic finding distinguishes ATL from other forms of non-Hodgkin lymphoma. Difficulties can also be encountered in differentiating the skin manifestations of ATL from mycosis fungoides (MF) and Sézary

Figure 197-2 Skin manifestations of adult T-cell leukemia (ATL). **A.** Generalized papular infiltrates in a patient from Jamaica with prototypic ATL. **B** and **C.** Nodular skin tumors in Japanese ATL patients. (Used with permission from K. Takatsuki, MD, Kumamoto University, Japan.)

syndrome, because focal epidermal infiltration by T cells or Pautrier's microabscesses (see Fig. 197-1B) can be present in skin lesions of ATL.[21,23,24] Indeed, the diseases of patients from whom the original US HTLV-1 isolates were obtained were originally classified as Sézary syndrome and CTCL.[1] Four diagnostic criteria have been put forward that must be fulfilled to unequivocally establish the diagnosis of HTLV-1-associated ATL[4,12,16,17]: (1) a histologically or cytologically proven lymphoid malignancy with T-cell surface antigens must be present; (2) abnormal T lymphocytes must be detected in peripheral blood, except in the lymphoma type; (3) anti-HTLV-1 serum antibodies must be present; and (4) the clonality of HTLV-1 proviral DNA must be demonstrated.

The fact that the first HTLV-1 isolates were obtained from patients misclassified as having MF and Sézary syndrome, together with the earlier reports regarding the presence of retroviral particles in the skin and lymph nodes of patients with these diseases, has prompted an intensive search for HTLV-1 in CTCL. Although several reports claimed that HTLV-1 DNA sequences were detectable in tumor tissue and in cell lines derived from MF patients, an overwhelming majority of investigators, studying patients from the same geographic regions with comparable methods, were unable to find HTLV-1 DNA in CTCL samples.[25] It is now well accepted by most that HTLV-1 is not involved in the pathogenesis of CTCL (see Chapter 145).

PROGNOSIS AND TREATMENT OF ADULT T-CELL LEUKEMIA.

The prognosis of ATL depends largely on the subtype. In the most extensive study on the course of ATL to date, 818 Japanese patients newly diagnosed with the disease were studied for a median follow-up time of 13.3 months.[12,15] Median survival time was 6.2 months for those with the acute type, 10.2 months for those with the lymphoma type, and 24.3 months for those with the chronic type. Projected 2- and 4-year survival rates were, respectively, 16.7% and 5.0% for the acute type, 21.3% and 5.7% for the lymphoma type, 52.4% and 26.9% for chronic type, and 77.7% and 62.8% for the smoldering type. The presence of hypercalcemia, high levels of lactic acid dehydrogenase, and an excessively high white blood cell count are prognostic factors[4,12,15–17,26] associated with poor survival.

Treatment of ATL remains disappointing. Combination cytotoxic therapy used to treat non-Hodgkin lymphoma has little effect on prototypic ATL and ATL lymphoma. Although complete remission can be achieved in up to 40% of patients with different combinations of conventional chemotherapy, most of the patients experience relapse within weeks or months, and the 4-year overall survival rate is below 10%.[4,12,15–17,26] Frequent complications of treatment include septicemia and opportunistic infections, which result from chemotherapeutic intensification of the immune suppression already present in ATL patients. Besides conventional chemotherapy, the combination of interferon-α and zidovudine, a nucleoside analog used against human immunodeficiency virus type 1 (see Chapter 231), has shown some effect in the treatment of acute and lymphoma-type ATL.[15–17,26] Allogeneic hematopoietic stem-cell transplantation that has been used in several clinical trials ATL,[26] holds some promise for the future. Other therapeutic approaches,[17,26] including the use of monoclonal antibodies against surface molecules of leukemic cells, arsenic trioxide, proteasome inhibitors, and angiogenesis inhibitors, have been under study; however, to date no breakthrough has been reported.

The course of smoldering and chronic ATL is less dramatic, internal organ involvement and hypercalcemia are observed less frequently than in ATL lymphoma and acute ATL, and the prognosis is better.[4,12,15–17,26] Because chemotherapy-associated immunosuppression increases the immunosuppression caused by the disease itself, early chemotherapy may be more harmful than beneficial for patients with smoldering and chronic ATL. Therefore, these patients should not be treated with chemotherapy unless they enter a more aggressive phase of their disease. The combination of zidovudine and interferon-α has been suggested as a possible treatment for these clinical variants.

NONMALIGNANT SEQUELAE OF HUMAN T-LYMPHOTROPIC VIRUS 1 INFECTION

NEUROLOGIC DISEASE. HTLV-1 infection is associated with chronic progressive myelopathy, which is referred to as *tropical spastic paraparesis* (TSP) in the Caribbean and *HTLV-1-associated myelopathy* (HAM) in Japan.[27] Patients with TSP/HAM are generally younger at disease onset than ATL patients. The latent period from infection to development of clinical neurologic symptoms has been described to be very short in individual cases. The lifetime risk for developing TSP/HAM has been estimated at 1%.[28] In contrast to ATL, which is associated with HTLV-1 infection very early in life, TSP/HAM frequently occurs in patients who became infected only in adolescence. In particular, the acquisition of HTLV-1 by blood transfusion has been reported to play an important role in the development of TSP/HAM.

INFECTIVE DERMATITIS. Infective dermatitis (Fig. 197-3) is a severe, chronic, relapsing eczema in Jamaican children[29] associated with infection by *Staphylococcus aureus* and β-hemolytic *Streptococci*.[29] An association between infective dermatitis and HTLV-1 infection has been reported. Bacterial infection in infective dermatitis is difficult to control, and although it responds to antibiotic treatment, prolonged therapy is necessary and relapses are common after discontinuation. The characteristic clinical picture, the recalcitrant course, and HTLV-1 seropositivity sets infective dermatitis apart from other forms of recurrent eczema, including atopic eczema.[29] Immunosuppression observed in HTLV-1 carriers, as well as in ATL patients,[30] may play a role in the pathogenesis of infective dermatitis. Although HTLV-1-infected individuals are overrepresented among patients hospitalized for infectious diseases in Japan, infective dermatitis has rarely been reported in regions outside the Caribbean. Regional, cultural, or genetic factors may play an additive role in the occurrence of infective dermatitis. Evidence that infective dermatitis in childhood might be associated with subsequent development of ATL comes from studies of HTLV-1 infection and infective dermatitis in Jamaica.[31,32] In addition to infective dermatitis, several other infectious and noninfectious skin disorders are frequently observed in HTLV-1-infected individuals.[33]

Figure 197-3 Dermatitis in a Jamaican girl infected with human T-cell lymphotropic virus type 1. (Used with permission from L. LaGrenade, MD, University of the West Indies, Kingston, Jamaica.)

OTHER DISORDERS. In addition to the diseases described in the previous sections, certain types of uveitis, polymyositis, chronic inflammatory arthropathy, and peripheral neuropathy have been suggested to be associated with HTLV-1 infection.[4] However, future epidemiologic and virologic studies will be necessary to establish the causative role of the virus in the pathogenesis of these diseases.

Chapter 198 :: Cutaneous Manifestations of Human Immunodeficiency Virus Disease

:: Lily Changchien Uihlein, Arturo P. Saavedra, & Richard Allen Johnson

HUMAN IMMUNODEFICIENCY VIRUS (HIV) INFECTION AND ACQUIRED IMMUNE-DEFICIENCY SYNDROME (AIDS) AT A GLANCE

- As of 2008, more than 30 million people were living with HIV infection/AIDS.
- HIV-1 and HIV-2 are human lymphotropic retroviruses that principally infect $CD4^+$ T lymphocytes and $CD4^+$ cells of monocytic lineage.
- An individual is deemed to have AIDS if he or she is HIV-seropositive with a $CD4^+$ T cell count <200/μL, a $CD4^+$ T cell percentage <14, or any of several diseases deemed to be indicative of a severe defect in cell-mediated immunity.
- The broad and diverse spectrum of dermatologic disease in HIV infection/AIDS includes inflammatory, infectious, neoplastic, and medication-related disorders.
- Specific stages of HIV disease (acute HIV syndrome, immune reconstitution, clinically latent disease, and advanced disease) tend to be associated with different dermatologic disorders.
- Dermatologic disease may help to estimate the level of immunosuppression in HIV infection/AIDS, particularly in resource-limited settings.
- As there are many dermatologic disorders that are seen in HIV infection/AIDS, this chapter focuses on those diseases that are the most closely associated.

The introduction of antiretroviral therapy (ART) has markedly altered the life expectancy and quality of life for many of the 33.4 million individuals worldwide infected with human immunodeficiency virus (HIV).[1] However, the number of newly diagnosed infections remains high, and many individuals in areas of high HIV prevalence remain unaware of their infection. Globally, 2.7 million new infections were estimated to have developed in 2008, while 56,300 new infections were estimated to have occurred in United States in 2006.[1, 2] It is estimated that 21% of the 1.1 million infected HIV individuals in the United States are currently undiagnosed.[2,3] This suggests that identification of HIV infection/acquired immune-deficiency syndrome (AIDS)-associated dermatoses has the potential to facilitate the diagnosis of HIV infection not only in resource-limited settings but in relatively resource-abundant ones.

Cutaneous disorders occur in nearly every patient during the course of HIV disease, either as a result of acquired immunodeficiency or from treatment. The spectrum of dermatologic manifestations of HIV disease is broad and diverse.[4] Individuals who have access to combination ART have a markedly altered course of disease if immune restoration is successfully achieved.[5] In most cases, there is a marked reduction in the incidence of opportunistic infections and neoplasms. Globally, however, the majority of HIV-infected individuals lack access to ART and, consequently, many of the cutaneous manifestations associated with HIV disease become chronic and progressive.

ETIOLOGY

HIV is a lymphotropic human retrovirus, which is predominantly transmitted through sexual contact. Other

important means of transmission include exposure to infected blood (including needles shared by injecting drug users and "skin popping") and transmission from an infected mother to her infant during pregnancy, delivery, or breastfeeding. HIV-1 is the most common cause of HIV infection globally, whereas HIV-2 infection has been detected mainly in West Africa. Although both HIV subtypes cause clinically similar disease, HIV-2 is associated with slower progression of immunosuppression, decreased infectivity, and resistance to non-nucleoside reverse transcriptase inhibitors.[6–8]

PATHOGENESIS

The profound immunosuppression that defines HIV disease results from progressive depletion of $CD4^+$ T lymphocytes. Efficient infection of a target cell by HIV requires not only expression of a CD4 molecule on that cell's surface, but also the presence of a co-receptor (such as CCR5 or CXCR4). Although HIV infects primarily $CD4^+$ T lymphocytes and $CD4^+$ cells of monocytic lineage, any cell that expresses CD4 and an appropriate co-receptor may be infected by HIV.[9] The depletion of $CD4^+$ T cells in HIV disease is believed to be multifactorial, and includes direct infection and destruction of $CD4^+$ T cells by HIV, as well immune exhaustion and apoptosis of T cells due to persistent and aberrant activation of the immune system.[9]

NATURAL HISTORY

HIV disease is a continuum that progresses from primary infection to death via a sequence of opportunistic infections and neoplasms that mark the gradual deterioration of the immune system (Table 198-1 and Fig. 198-1). Increased availability of ART has dramatically altered the course of HIV disease in many individuals—by delaying the development of symptomatic disease, reducing the burden of opportunistic disease, and prolonging life expectancy. The field of HIV medicine continues to rapidly evolve, and excellent Web resources that are frequently updated include http://www.aidsinfo.nih.gov and http://www.cdcnpin.org.

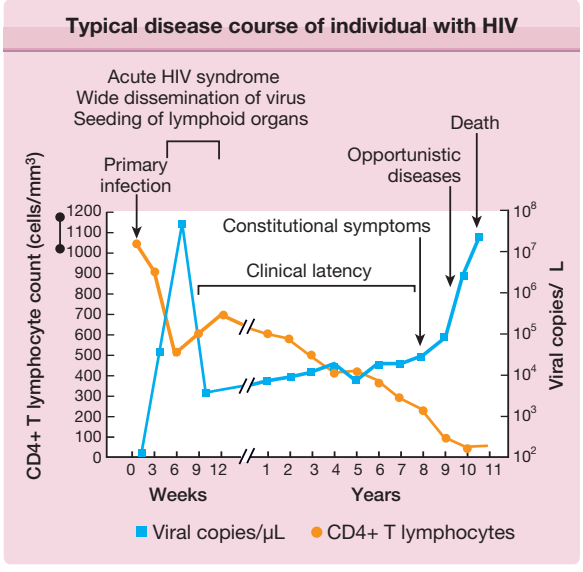

Figure 198-1 Typical disease course in an individual with human immunodeficiency virus (HIV) infection (From Fauci A et al: Immunopathogenic mechanisms of HIV infection. *Ann Intern Med* **124**:654, 1996.)

ACUTE HIV SYNDROME

About 3–6 weeks following primary infection, the majority of individuals infected with HIV develop an acute mononucleosis-like syndrome, which is referred to as *acute retroviral syndrome*. Clinical manifestations include fever, lethargy, rash (Fig. 198-2), myalgias/arthralgias, cervical and axillary lymphadenopathy, pharyngitis, night sweats, and nausea/vomiting/diarrhea. Less commonly reported findings include leukopenia, thrombocytopenia, weight loss, aseptic meningitis, anorexia, abnormal liver function tests, and oral and genital ulcers.[10] Symptoms generally

TABLE 198-1
Stages of Human Immunodeficiency Virus Disease

Stage and Clinical Features	Typical Duration	$CD4^+$ Cell Range (Cells/μL)
Acute retroviral syndrome (brief mononucleosis-like illness)	1–2 weeks	1000–500
Asymptomatic (no symptoms or signs other than lymphadenopathy)	>10 years	750–500
Early symptomatic (non–life-threatening infections, chronic or intermittent illness)	0–5 years	500–100
Late symptomatic (acquired immunodeficiency syndrome; increasingly severe symptoms, life-threatening infections and cancers)	0–3 years	200–50
Advanced (increasing risk of death, fewer transferable opportunistic infections)	1–2 year	50–0

Figure 198-2 Exanthem of acute retroviral syndrome: discrete, erythematous macules and papules on the trunk and arm. Associated findings were fever, scrotal ulcers, erythematous macules on the palate, and lymphadenopathy.

last an average of 2–3 weeks and resolve gradually as levels of plasma viremia decrease. It is important to maintain a high index of suspicion in individuals with a suggestive constellation of symptoms. Studies have documented that up to 25% of those with HIV infection are not tested, despite suggestive symptoms.[11] In fact, 2% of individuals thought to have Epstein–Barr virus were found to have HIV when tested retrospectively in one study, and roughly half of those had acute primary HIV infection.[12]

The laboratory diagnosis of HIV-1 infection is typically made by either identification of antibodies to HIV or direct detection of HIV antigens or nucleic acids (Table 198-2). A delay of 3–4 weeks typically occurs between newly acquired HIV-1 infection and development of antibodies, which is referred to as the "window period." However, core structural protein p24 antigen may be detected several weeks prior to seroconversion. The viral-RNA assay detects infection up to 5 days earlier than the p24 assay, and appears to be more sensitive.[11]

COURSE AFTER PRIMARY INFECTION

The length of time between initial infection and the development of symptomatic disease varies significantly, and is now augmented by ART in many cases. This period of clinical latency does not necessarily imply disease latency. Viral replication may persist, and $CD4^+$ T cell levels progressively decline (Fig. 198-1). The more severe and life-threatening complications of HIV disease typically occur when $CD4^+$ T cell counts fall below 200/μL. The World Health Organization published in 2006 criteria for clinical staging in individuals with confirmed HIV infection, while the US Centers for Disease Control and Prevention (CDC) published a revised classification system for HIV infection in 1993.[13,14] The AIDS is defined by the CDC as an HIV-seropositive individual with a $CD4^+$ T cell count <200/μL, a $CD4^+$ T cell percentage <14, or any of several diseases considered to be indicative of a severe defect in cell-mediated immunity.[14] Conditions deemed by the CDC to be AIDS-defining in a patient with a confirmed HIV infection are listed in Box 198-1.

CLINICAL FINDINGS IN HIV DISEASE

(See Table 198-3)

CUTANEOUS FINDINGS IN ACUTE HIV SYNDROME

The majority of individuals with acute retroviral syndrome develop a mucocutaneous eruption, typically consisting of distinct, well-demarcated, nonpruritic macules and papules favoring the upper chest and back (particularly the clavicular region), forehead,

TABLE 198-2
Laboratory Diagnosis of Human Immunodeficiency Virus (HIV) Infection[5]

Test	Component Tested	Window Period	Role in Diagnosis
Enzyme-linked immunosorbent assay[a]	Antibodies (IgM and IgG)	3–6 weeks	Screening
Antigen capture[b]	HIV p24 antigen	2–3 weeks	Screening
Western blotting	Antibody (IgG)	3 weeks	Confirmatory
Immunofluorescence	Antibody (IgG)	3 weeks	Confirmatory
Nucleic acid testing	HIV RNA or DNA	2 weeks	Confirmatory
Viral culture	Virus, usually from peripheral blood mononuclear cells, not serum or plasma	—	Confirmatory, research

Ig = immunoglobulin.
[a]Rapid tests as well as particle agglutination tests are also available.
[b]Detection can be increased with the use of immune complex dissociation techniques.

BOX 198-1 AIDS-DEFINING CONDITIONS IN HIV-INFECTED INDIVIDUALS >13-YEARS-OLD[14]

Candidiasis of bronchi, trachea, or lungs
Candidiasis, esophageal
Cervical cancer, invasive
Coccidioidomycosis, disseminated or extrapulmonary
Cryptococcosis, extrapulmonary
Cryptosporidiosis, chronic intestinal (>1 month's duration)
Cytomegalovirus, extrapulmonary
Cytomegalovirus disease (other than liver, spleen, or nodes)
Cytomegalovirus retinitis (with loss of vision)
Encephalopathy, HIV-related
Herpes simplex: chronic ulcers(s) (>1 month's duration); or bronchitis, pneumonia, or esophagitis
Histoplasmosis, disseminated or extrapulmonary
Isosporiasis, chronic intestinal (>1 month's duration)
Kaposi sarcoma
Lymphoma, Burkitt or immunoblastic (or equivalent term)
Lymphoma, primary, of brain
Mycobacterium tuberculosis, any site (pulmonary or extrapulmonary)
Mycobacterium, other species or unidentified species, disseminated or extrapulmonary
Pneumocystis jiroveci pneumonia
Pneumonia, recurrent
Progressive multifocal leukoencephalopathy
Salmonella septicemia, recurrent
Toxoplasmosis, brain
Wasting syndrome due to HIV

and scalp (Fig. 198-2).[23] Diffuse urticaria and pustular/vesicular eruptions have also been reported, though less commonly. Noninfectious ulcerations of the oral, genital, and anal mucosa are another common finding, and have been reported in up to 6%–28% of patients. Cutaneous symptoms are often accompanied by fever, lethargy, lymphadenopathy, and joint pain. The eruption of acute retroviral syndrome typically presents 3–6 weeks after initial infection, and persists for about 5–8 days. The differential diagnosis of acute retroviral syndrome includes Epstein–Barr virus infection, cytomegalovirus infection, primary herpes simplex infection, viral hepatitis, secondary syphilis, and systemic drug hypersensitivity. As acute infection with HIV-1 has been associated with a high degree of viremia within 2–6 weeks of infection, identification of individuals with acute retroviral syndrome provides the opportunity to prevent secondary transmission during a period of significant viremia prior to seroconversion.

CUTANEOUS FINDINGS IN IMMUNE RECONSTITUTION

Initiation of ART typically results in partial recovery of the immune system, as measured by an increase in $CD4^+$ T cell counts and decrease in plasma HIV viral load. In general, this leads to clinical improvement; however, in a small subset of individuals, a paradoxical clinical deterioration occurs. Termed immune restoration disease or immune reconstitution inflammatory syndrome (IRIS), this phenomenon typically presents within the first 3 months of ART initiation with either symptoms of a new infectious or inflammatory condition or clinical worsening of an existing infectious or inflammatory condition. It is believed that IRIS results from an exaggerated immune

TABLE 198-3
Correlation of Mucocutaneous Manifestations of Human Immunodeficiency Virus Infection with CD4 T Cell Counts[13,15–22]

CD4 T Cell Count >500/μL	500/μL >CD4 T Cell Count >250 μL	CD4 T Cell Count <200/μL
Acute retroviral syndrome	Dermatophyte infections, recurrent or persistent	Bacillary angiomatosis
Herpes zoster infection (nondisseminated)	Oral candidiasis	Hyperkeratotic scabies
Seborrheic dermatitis	Oral hairy leukoplakia Herpes zoster infection, disseminated	Cutaneous miliary tuberculosis Eosinophilic folliculitis
		Herpes simplex virus infection (>1 month's duration)
		Idiopathic pruritus
		Invasive fungal infections
		Kaposi's sarcoma
		Molluscum contagiosum, large facial lesions
		Papular pruritic eruption of HIV

BOX 198-2 DERMATOLOGIC MANIFESTATIONS OF IMMUNE RECONSTITUTION SYNDROME[27–32]

INFECTIOUS
- Mycobacterial infection
- Cytomegalovirus
- Viral hepatitis
- Varicella zoster virus
- Herpes simplex virus
- Human papillomavirus
- Cryptococcosis
- Histoplasmosis
- Leishmaniasis

INFLAMMATORY
- Sarcoidosis
- Rheumatoid arthritis
- Systemic lupus erythematosus
- Tumid lupus
- Dyshidrotic eczema
- Eosinophilic folliculitis

NEOPLASTIC
- Kaposi sarcoma
- Dermatofibroma

response to preexisting microbial, host, or other antigens at a time when $CD4^+$ T cell counts are rapidly increasing. IRIS has been reported in 15%–25% of individuals initiating ART, with an incidence of 15%–45% in individuals who also have a documented underlying opportunistic infection.[24] Risk factors associated with the development of IRIS include male gender, a shorter interval between initiating treatment of an opportunistic infection and starting ART, a rapid fall in HIV viral load after initiation of ART, a lower baseline $CD4^+$ T cell count, and a higher baseline viral load during ART.[25,26] IRIS has been reported in association with a broad range of infections, inflammatory disorders, and neoplasms (Box 198-2).[27,29] If a patient presents with paradoxical worsening of an existing disease in the setting of starting ART, it is important to consider the possibility of IRIS, in addition to treatment nonadherence, antimicrobial resistance, and tachyphylaxis. Although most cases of IRIS are self-limited and typically last weeks to months, IRIS can be associated with severe morbidity and, in rare cases, even mortality.

Management of IRIS consists of continuation of antiretroviral medications and initiation of appropriate therapy for the underlying infectious or inflammatory condition. In addition, systemic steroids have been reported to be beneficial in some cases.[33] In severe cases of IRIS, discontinuation of ART should be considered and weighed against the risk of development of viral resistance or HIV progression.

CUTANEOUS FINDINGS IN CLINICALLY LATENT HIV INFECTION

The introduction of ART has markedly altered the natural history of HIV infection by allowing for immune reconstitution, thereby significantly reducing the incidence of both opportunistic infections and neoplasms. As a result, many of the common skin manifestations of clinically latent HIV consist of cutaneous disorders normally seen in immunocompetent individuals, such as seborrheic dermatitis, psoriasis, drug hypersensitivity reactions, skin cancers, and human papillomavirus infections. In addition, increasing availability of ART has brought with it an increase in the prevalence of cutaneous side effects of antiretrovirals.

INFLAMMATORY DERMATOSES

Seborrheic Dermatitis. (See Chapter 22). Seborrheic dermatitis is one of the most common dermatologic manifestations of HIV disease, affecting as many as 83% of HIV-infected individuals during the course of their disease.[34] Seborrheic dermatitis may occur during all stages of HIV disease, and frequently occurs early in HIV-infection ($CD4^+$ T cell count >500/μL).[15] As is the case in immunocompetent adults, HIV-infected individuals with seborrheic dermatitis typically present with erythema and greasy scale involving the scalp, eyebrows, nasolabial folds, and posterior auricular regions. However, more disseminated forms of seborrheic dermatitis are often seen in advanced HIV disease. The forehead and malar areas, as well as the chest, back, axillae, and groin may be involved. In fact, erythroderma arising from seborrheic dermatitis may be an initial presenting sign of HIV infection in developing countries. Treatments commonly include low-potency topical steroids and topical antifungals, though more widespread forms tend to be more refractory to standard therapy.

Psoriasis Vulgaris. (See Chapter 18). Although psoriasis may develop at any stage of HIV infection, the severity of psoriasis tends to correlate with worsening immune function. For some individuals, psoriasis may be the initial presenting symptom of HIV infection, and new onset psoriasis in an individual at risk for HIV is an indication for HIV testing (Box 198-3). All clinical subtypes of psoriasis are observed in HIV-infected individuals, though guttate, inverse and erythrodermic psoriasis are the most common.[35] There are no randomized trials evaluating treatments for psoriasis in HIV-infected individuals. However, based on case reports and case series, topical therapies (such as calcipotriol, corticosteroids, and tazarotene) have been recommended as first-line therapy for mild to moderate psoriasis.[35] For moderate to severe psoriasis, phototherapy and ART have been recommended as first-line agents, whereas oral retinoids such as acitretin have been suggested as second-line treatment.[35,36] For severe and refractory disease, methotrexate, etanercept, and infliximab have been effective, but are associated with a higher risk of opportunistic infection.[35]

BOX 198-3 MUCOCUTANEOUS DISORDERS THAT ARE INDICATIONS FOR HIV SEROTESTING

Highly Indicative of HIV Infection (correlated with risk factors for HIV infection)

- Exanthem of acute retroviral syndrome
- Proximal subungual onychomycosis
- Herpetic ulcers of >1 month's duration
- Oral hairy leukoplakia
- Kaposi's sarcoma
- Eosinophilic folliculitis
- Multiple facial molluscum contagiosum in an adult
- Papular pruritic eruption of HIV

Strongly Associated with HIV Infection (correlated with risk factors for HIV infection)

- Any sexually transmitted disease (suggestive of "unsafe" sexual practices)
- Herpes zoster
- Signs of injecting drug use
- Candidiasis (oropharyngeal or recurrent vulvovaginal)

May be Associated with HIV Infection (correlated with risk factors for HIV infection)

- Generalized lymphadenopathy
- Seborrheic dermatitis (extensive, refractory to therapy)
- New Onset Psoriasis B

OPPORTUNISTIC INFECTIONS

Human Papillomavirus Infections. (See Chapter 196). Although the incidence of opportunistic infections in general has declined markedly since the introduction of ART, the incidence of human papillomavirus (HPV) infections has not significantly decreased and may actually have increased.[37–39] HPV infections are commonly seen at all stages of HIV disease, and anogenital and oral HPV infections have been reported to occur at a higher rate in HIV-infected individuals compared to that in the general population.[40,41]

Common Warts. As immunodeficiency progresses, common warts may become larger, more numerous, confluent, and more refractory to treatment. HPV-5 can cause an unusual pattern of extensive verruca plana and pityriasis (tinea) versicolor-like lesions, similar to that seen in epidermodysplasia verruciformis.[42]

Anogenital Warts. Clinically, anogenital warts appear similar to those seen in immunocompetent individuals; however, condyloma may be more numerous or extensive, and are often less responsive to therapy. As in immunocompetent individuals, anogenital warts in HIV-infected individuals most commonly result from infection by HPV-6 and HPV-11. Although anogenital warts are commonly considered to be benign lesions, anogenital warts in HIV-infected individuals are more likely to reflect infection with multiple HPV types, including high-risk oncogenic types -16, -18, -31, -51, -53, -56, and -58 as well as low-risk types -6 and -11.[43] One study found that the majority of anogenital warts in HIV-infected individuals represent coinfection by both low-risk and high-risk HPV types.[44] In another series, histologic evidence of low-grade anal intraepithelial neoplasia was found in about 50% of apparently benign anogenital warts in HIV-infected individuals.[45]

Management of external anogenital HPV infection in HIV-infected individuals is directed toward identifying high-grade dysplasia before progression to invasive squamous cell carcinoma (SCC). All HIV-infected individuals should be examined annually for evidence of HPV infection, especially those with a history of HPV infections. Application of 5% acetic acid may help to highlight subclinical dysplastic lesions. Based on the principles of cervical cytology, periodic anal cytology testing (via Papanicolaou smears) every 1–2 years has been proposed as a means of early detection of anal cancer.[46] The sensitivity of anal cytology has been reported to range from 69%–93%, while specificity ranges from 32% to 59%.[47] However, both sensitivity and specificity are reported to be higher for identification of disease within the anal canal compared to that of the external anogenital area, likely because of lower yield of cells from hyperkeratotic surfaces.[48] High-resolution anoscopy/coloposcopy with biopsy should be performed in all patients with abnormal cytology. Individuals with documented external anogenital dysplasia should be followed by periodic examinations every 4–6 months, with biopsy of any new lesions at those sites.

Oral HPV Infections. HPV-induced oropharyngeal lesions typically present as pink or white verrucous papules, resembling anogenital condyloma. If lesions are extensive, they may coalesce to form multiple large plaques, which may transform to verrucous carcinoma (oral florid papillomatosis). Oral HPV infection has also been associated with a subset of oropharyngeal SCC, which sometimes arises from the base of the tongue and tonsils.[49,50] Interestingly, advanced markers of HIV disease such as low $CD4^+$ T cell count have not been shown to be predictive of oral HPV infection.[51] Electrosurgery is effective for treatment of oral HPV-induced lesions.

HPV-Induced Dysplasia and Invasive SCC. The risk of HPV-induced dysplasia and malignancy is significantly higher in HIV-infected individuals compared to that in the general population. One large prospective cohort study estimated that the incidence of anal SCC in HIV-infected individuals was 42.9 times that in the general population, whereas the incidence of cervical cancer in HIV-infected women was 12.2 times that in the general population.[52] A low $CD4^+$ T cell count has been associated with a significantly increased risk of anal SCC in men, but not cervical or vulvar SCC in women.[53] The effect of ART on the incidence of HPV-induced in situ and invasive SCC varies. The introduction of ART has been associated with an increase in the incidence of anal cancer in HIV-infected individuals;

however, ART has also been associated with decreased incidence of cervical cancer.[52]

Anogenital dysplasia has been successfully treated with ablative therapies, such as surgery, electrocautery, laser, and infrared coagulation. Topical therapy is another approach, and options include imiquimod, podophyllotoxin, 80% trichloroacetic acid, and liquid nitrogen. In one small study of HIV-infected men with anal intraepithelial neoplasia, subjects were treated with imiquimod cream three times a week for 16 weeks. Nearly 80% of subjects showed complete clearance of lesions at the end of therapy.[54] However, 26% of individuals who had completely cleared after imiquimod therapy experienced a recurrence after a mean follow up of 30 months.[55] For minimally invasive SCC arising on the anal verge (nonkeratinized to keratinized epithelium) or on external anogenital sites (such as the penis, vulva, and perineum), surgical excision with adequate margins is recommended. Invasive SCC of the anus (transformation zone) is generally treated by radiation therapy and chemotherapy.

Staphylococcus Infections. *Staphylococcus aureus* is a common bacterial pathogen causing cutaneous and systemic infections at all stages of HIV disease. No unique staphylococcal infections occur in HIV disease. Rather, HIV-infected individuals tend to present a wide range of primary skin and soft tissue infections that are normally seen in immunocompetent individuals (see Chapters 176, 178, 179, 180, 181). Secondary infection of underlying dermatoses, particularly in those colonized with *S. aureus*, is frequently seen in individuals with atopic dermatitis. Secondary infection of herpetic ulcers and molluscum may occur (see Chapters 193, 195).

Risk factors for staphylococcal infection in HIV-infected individuals include nasal carriage of *S. aureus*, the presence of an indwelling vascular catheter, and a $CD4^+$ T cell count <100/μL.[56] Interestingly, a prevalence of *S. aureus* carriage in the nares of 30%–50% has been documented in both symptomatic and asymptomatic HIV-seropositive individuals.[56,57]

More recently, an increase in methicillin-resistant *S. aureus* (MRSA) strains has been noted in the United States and Europe, particularly those acquired from the community.[58,59] Risk factors associated with MRSA skin infections include recent hospitalization, receipt of systemic antibiotics within the past 6 months, history of injection drug use, high-risk sexual practices, and previous incarceration.[58,60] The prevalence of MRSA infections does not appear to be correlated with $CD4^+$ T cell count or viral load.[60]

Management of staphylococcal infections should be directed at treatment of the acute infection, treatment of any underlying dermatoses, eradication of nasal carriage of *S. aureus* with mupirocin ointment, and chronic oral prophylaxis for recurrent infections (See Chapter 176). Given the current prevalence of MRSA infection, culture and sensitivities of lesions and the nares are imperative.

Herpes Simplex Virus 1 and 2 Infections. (See Chapter 193). Herpes simplex virus (HSV) infection is commonly associated with HIV disease. Chronic herpetic ulcers of greater than 1 months' duration are an AIDS-defining condition. HSV infection in HIV disease may present with severe, painful ulcerations of the perioral region, anogenital region, and digits (Fig. 198-3). Atypical morphologies, such as hyperkeratotic, verrucous papules and nodules, are sometimes observed in advanced HIV disease.[61] In more advanced HIV disease, lesions typically respond less promptly to oral antiviral therapy and recur more frequently.

Figure 198-3 Herpes simplex virus infection. Chronic herpetic ulcers and ulcerated tumor on the penis, scrotum, and pubic area in a patient with human immunodeficiency virus infection. The herpes simplex virus was acyclovir resistant, and lesions resolved after treatment with topical cidofovir.

Foscarnet and cidofovir may be administered intravenously for infections caused by acyclovir-resistant HSV.[62] Cidofovir gel has been effective as a topical therapy of acyclovir-resistant HSV infections.[63] Imiquimod 5% cream is also an effective topical treatment for cutaneous herpetic infections, including those caused by acyclovir-resistant HSV strains.[64]

Varicella Zoster Virus Infections. (See Chapter 194). In HIV-infected individuals, varicella zoster virus infection (VZV) may present as severe varicella (primary VZV infection), persistent varicella, dermatomal herpes zoster (see eFig. 198-3.1 in online edition), disseminated herpes zoster, and chronic or recurrent herpes zoster.[65] In advanced HIV disease, herpes zoster may present atypically. Disseminated herpes zoster infection may manifest with scattered vesicles in the absence of dermatomal lesions. Persistent ecthymatous ulcerations and verrucous papules in the absence of a vesicular stage have also been described.[66,67] Management of HIV-infected individuals with primary VZV infection should include evaluation for visceral disease. If evidence of visceral involvement is present, treatment with intravenous acyclovir (10 mg/kg every 8 hours, renally adjusted) should be initiated.[68] Management of herpes zoster is based on extent of

disease and degree of immunocompromise of the patient. Individuals with early HIV disease and localized cutaneous involvement may be treated with oral acyclovir, valacyclovir, or famciclovir for 7–10 days.[68,69] Those with advanced HIV disease ($CD4^+$ T cell count <200/μL), disseminated disease, visceral disease, or ocular involvement should be treated with intravenous acyclovir.[68] Acyclovir-resistant VZV is rare.[70]

Sexually Transmitted Diseases. (See Chapters 200, 202, 203, 204.) Given that the vast majority of HIV infections are sexually transmitted, individuals with HIV infection should also be screened for other sexually transmitted diseases such as Chlamydia, gonorrhea, and genital ulcerative diseases (e.g., syphilis, herpes, and chancroid).

MEDICATION-RELATED EFFECTS

Adverse Cutaneous Drug Eruptions. (See Chapter 41.) The incidence of adverse cutaneous drug eruptions is estimated to be as much as 100 times more common in individuals with untreated HIV disease compared to that in the general population, and may become more frequent with advancing immunodeficiency.[71] Morbilliform eruptions are by far the most common manifestation, accounting for about 75%–95% of cases (see eFig. 198-3.2 in online edition).[72,73] Urticaria, erythema multiforme major, erythema multiforme minor, lichenoid eruption, vasculitis, and fixed drug eruption are also reported, though far less frequently.[72,73] About 20% of cases are associated with systemic symptoms, such as fever, headache, myalgias, and arthralgias.[72] Severe bullous eruptions appear to be more common in HIV disease. In one study of toxic epidermal necrosis (TEN) patients over a 6-year period, the incidence of TEN in HIV-infected individuals was found to be 375 times greater than that in the general population.[74] TEN was more common in patients with advanced HIV disease and was associated with a 21% mortality rate.[74]

Sulfonamide drugs and penicillins are common causative agents of cutaneous drug eruptions, accounting for 75% of cases in one study.[72] Factors that have been associated with increased risk of drug eruptions include female gender, $CD4^+$ T cell count <200/μL, $CD8^+$ T cell count >460/μL, and a history of having had drug eruptions in the past.[72,75,76] In addition, individuals who are sulfa-allergic are at increased risk of more severe reactions to sulfa drugs in the setting of immune reconstitution following initiation of ART.

Management of a cutaneous drug eruption should include discontinuation of all potentially causative drugs if possible. In the absence of mucosal involvement and systemic symptoms, a causative medication may be continued with close clinical monitoring. However, if early symptoms of urticaria/angioedema or Stevens–Johnson syndrome/TEN are present, the drug should be immediately discontinued. Oral corticosteroid therapy has been reported to be helpful in decreasing the risk of cutaneous drug eruptions, and short-term corticosteroid therapy appears to be safe in most HIV-infected individuals.[75,77] One placebo-controlled trial randomized 41 asymptomatic HIV-infected individuals (median $CD4^+$ T cell count 131/μL, all but one was undergoing treatment with ART) to 8 weeks of oral prednisolone (0.5 mg/kg) or placebo to examine the immunologic consequences of corticosteroid use in HIV disease. After 8 weeks of therapy, no major side effects or HIV disease-related events had occurred, and HIV RNA levels remained stable.[78] Desensitization is an option for individuals with a history of uncomplicated cutaneous drug eruptions, and has been successfully accomplished in individuals allergic to trimethoprim-sulfamethoxazole (TMP-SMZ).[79]

Adverse Effects of Antiretroviral Therapy. There are currently six classes of antiretroviral medications: (1) non-nucleoside reverse transcriptase inhibitors (NNRTIs), (2) protease inhibitors, (3) nucleoside reverse transcriptase inhibitors (NRTI), (4) integrase inhibitors, (5) chemokine receptor 5 antagonists, and (6) entry inhibitors (see also Chapter 231). These medications are associated with a variety of cutaneous adverse effects, including hypersensitivity reactions, lipodystrophy, retinoid-like effects, hyperpigmentation, nail changes, and injection site reactions (Table 198-4).

Lipodystrophy Syndrome and Metabolic Syndrome. (See also Chapter 71.) HIV-related lipodystrophy is characterized by abnormal fat distribution, which may include lipohypertrophy, lipoatrophy or both. Lipohypertrophy presents with central obesity, cushingoid habitus ("buffalo hump"), increased neck girth (Fig. 198-4), increased abdominal girth due to intraabdominal fat ("protease pouch" or "crix belly"),

Figure 198-4 Lipohypertrophy. The subcutaneous fatty tissue of the cervicothoracic region as well as the preauricular cheeks and neck are strikingly enlarged.

TABLE 198-4
Adverse Effects of Antiretroviral Drugs[9,80–84]

Drug	Mechanism	Nonmucocutaneous Side Effects	Mucocutaneous Side Effects
Nucleoside Reverse Transcriptase Inhibitors			
Abacavir (ABC) Didanosine (ddI) Emtricitabine (FTC) Lamivudine (3TC) Stavudine (d4T) Tenofovir (TDF) Zidovudine (AZT) Zalcitabine (ddC)	Nucleoside analogs that act by incorporating themselves into the growing viral DNA chain, which eventually induces termination of viral DNA elongation.	■ Pancreatitis, peripheral neuropathy, lactic acidosis, and hepatotoxicity with didanosine, stavudine, and zalcitabine ■ Hepatotoxicity with emtricitabine and lamivudine ■ Renal toxicity with tenofovir ■ Anemia, granulocytopenia, myopathy, lactic acidosis, hepatotoxicity, and nausea with zidovudine	■ Hypersensitivity, with rare instances of Stevens Johnson syndrome/toxic epidermal necrolysis (SJS/TEN) ■ Systemic hypersensitivity reactions in up to 5%–8% with abacavir, associated with HLA-B5701/HLA-DR7/HLA-DQ3; incidence reduced by prescreening for HLA-B5701 ■ Leukocytoclastic vasculitis, pancreatitis, and peripheral neuropathy with didanosine ■ Hyperpigmentation of the nail bed, palms, and soles with emtricitabine ■ Hyperpigmentation of the nails (including multiple longitudinal and transverse bands), diffuse hyperpigmentation of the skin and oral mucosa, leukocytoclastic vasculitis, and hypertrichosis with zidovudine ■ Lipohypotrophy with stavudine and zidovudine ■ Paronychia with nailfold pyogenic granuloma with lamivudine and zidovudine ■ Oropharyngeal and esophageal ulcerations with zalcitabine
Non-nucleoside Reverse Transcriptase Inhibitors			
Delavirdine Efavirenz Etravirine Nevirapine	Non-nucleosides that directly bind to reverse transcriptase to prevent conversion of viral RNA to DNA.	■ Hepatotoxicity ■ Somnolence and depression with efavirenz	■ Hypersensitivity reactions are common within the first 6 weeks of therapy, with rare progression to systemic hypersensitivity or SJS/TEN (highest incidence with nevirapine)
Protease Inhibitors			
Amprenavir Atazanavir Darunavir Fosamprenavir Indinavir Lopinavir Nelfinavir Ritonavir Saquinavir Tipranavir	Prevents cleavage of protein precursors essential for HIV maturation, infection of new cells and replication	■ Nausea, vomiting, diarrhea, headaches, lipid anomalies, and hyperglycemia ■ Oral paresthesias with amprenavir ■ PR prolongation and hyperbilirubinemia with atazanavir ■ Hepatotoxicity and intracranial hemorrhage with tipranavir ■ Nephrolithiasis and hyperbilirubinemia with indinavir ■ Ritonavir may affect levels of many other medications, including saquinavir	■ Hypersensitivity reactions with rare progression to SJS, particularly with amprenavir, fosamprenavir and tipranavir ■ Acute exanthematous pustulosis ■ Lipohypertrophy, most commonly with indinavir ■ Dose-dependent retinoid-like effects (xerosis, cheilitis, alopecia, lateral nailfold pyogenic granuloma, curly hair, and recurrent paronychia), acute porphyria, "frozen shoulder," and venous thrombosis with indinavir ■ Spontaneous bleeding and hematomas, particularly with ritonavir ■ Rare cases of fixed drug eruptions with saquinavir ■ Darunavir, tipranavir, fosamprenavir, and amprenavir contain sulfa moieties and should be used with caution in sulfa allergic patients
Fusion Inhibitors			
Enfuvirtide	Inhibits binding of HIV to CD4 cells by binding to and inhibiting the action of gp40, a HIV protein that induces structural changes needed for fusion of HIV to host CD4 cells	■ Increased frequency of bacterial pneumonia	■ Systemic hypersensitivity reactions in <1%
Integrase Inhibitors			
Raltegravir	Inhibits HIV integrase, a viral enzyme that catalyzes the integration of HIV DNA into host chromosomal DNA	■ Nausea	■ Pruritus
Chemokine Receptor 5 (CCR5) Antagonists			
Maraviroc	Binds to the CCR5 receptor, a HIV co-receptor on CD4 cells, and thereby blocks attachment of HIV envelope proteins and HIV entry into host cells	■ Hepatotoxicity, nasopharyngitis, cough, abdominal pain, dizziness, musculoskeletal symptoms	■ Injection site reactions in up to 98% of patients, requiring discontinuation in only 3%

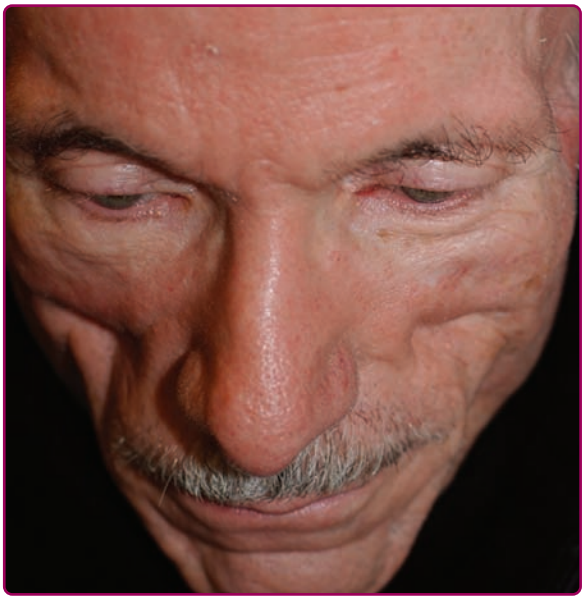

Figure 198-5 Lipoatrophy. The cheeks are hollowed, secondary to loss of subcutaneous fat. This caused significant cosmetic concern for this patient with human immunodeficiency virus infection who was on antiretroviral therapy. Lipohypertrophy was also present on the neck and upper central back.

and breast enlargement. Lipoatrophy of subcutaneous fat produces a pseudoathletic appearance, and often presents with a prominent venous pattern and musculature on the extremities, buttocks, and face (Fig. 198-5). Abnormal fat distribution is often accompanied by metabolic abnormalities, such as fasting glucose levels, fasting insulin levels, hypertriglyceridemia, hypercholesterolemia, and decreased high-density lipoprotein.[85] In a study of 581 HIV-infected individuals (of which 95% were currently treated with or had previously undergone treatment with ART), the overall prevalence of lipodystrophy was 38%, whereas the prevalence of lipoatrophy alone was 16% and lipohypertrophy alone was 12%. The prevalence of lipid anomalies was 49% and the prevalence of glucose disorders was 20%.[86]

Lipohypertrophy is most commonly associated with protease inhibitor therapy, whereas lipoatrophy is frequently associated with NRTIs, particularly the thymidine analogues stavudine and zidovudine. It should be noted, however, that HIV infection by itself may induce changes in fat distribution and metabolic anomalies such as insulin resistance.[87,88]

Management of lipodystrophy remains challenging. Substitution of regimens containing stavudine and zidovudine has been shown to be of partial benefit for lipoatrophy. For example, one study showed a significant increase in limb fat when stavudine or zidovudine was substituted with abacavir.[89] Although switching individuals to NRTI sparing regimens have produced modest results in lipoatrophy, the improvement in fat distribution may come at the expense of lipid anomalies if patients are switched to protease inhibitors.[90] Thiazolidinediones, such as rosiglitazone, have been shown to increase limb fat in small studies of individuals with HIV-associated lipodystrophy and insulin resistance.[91] However, concern about the risk of cardiovascular events, particularly with rosiglitazone, may limit the use of thiazolidinediones.[92] Facial lipoatrophy has been treated with soft tissue fillers, such as poly-L-lactic acid or calcium hydroxylapatite, with varying degrees of success.[93,94] Liposuction has been used to treat the dorsocervical lipomatosis, but results are often unsatisfactory.

OPPORTUNISTIC NEOPLASMS

Cutaneous Cancers. A 3–5 fold increased incidence of nonmelanoma skin cancer has been reported in HIV-infected individuals, as is the case with immunosuppressed solid organ transplant recipients.[95] However, the ratio of SCC to basal cell carcinoma (BCC) in HIV-infected individuals is 1:7, which is markedly different from a ratio of approximately 2:1 in transplant patients.[96] In HIV-infected individuals, SCCs tend to favor the head and neck, as they do in the general population.[97] However, they tend to appear at a younger age and may follow a more aggressive course with a higher risk of local recurrence, metastasis, and mortality (Fig. 198-6).[98] Superficial BCCs of the trunk have been reported to be the most common type of BCCs in HIV-infected individuals; however, an increased frequency of more aggressive subtypes of BCCs have been reported, including metastatic BCC and multiple infundibulocystic BCC.[99–101] As is the case for the general population, risk factors for the development of nonmelanoma skin cancer in HIV-infected individuals include sun exposure, blond hair, blue eyes, and a

Figure 198-6 Human papillomavirus-induced invasive squamous cell carcinoma in a 32-year-old man with human immunodeficiency virus infection. The perianal tumor had been present for several months, and histology was consistent with squamous carcinoma.

family history of skin cancer.[100] CD4+ T cell count and ART have not found to be significantly associated with the incidence of nonmelanoma skin cancer.[97]

The incidence of malignant melanoma in HIV-infected individuals has been reported to be 2.6 times that of the general population in one study.[52] However, neither CD4+ T cell count nor ART was significantly associated with the incidence of melanoma.[52] In fact, the incidence of melanoma has been reported to have significantly increased since the introduction of ART, suggesting the role of other factors, such as behavioral and lifestyle factors.[52] As in immune-suppressed solid organ transplant recipients, the incidence of Merkel cell carcinoma is higher in HIV-infected individuals.[102]

CUTANEOUS FINDINGS ASSOCIATED WITH SYMPTOMATIC AND ADVANCED HIV INFECTION

More than 90% of HIV-infected individuals will experience dermatologic symptoms of HIV during the course of their disease.[103] These symptoms tend to occur with greater frequency as immune function deteriorates. Specific cutaneous disorders that correlate with lower CD4+ T cell counts (<300/μL) include dermatoses (such as eosinophilic folliculitis and papular pruritic eruption of HIV), opportunistic malignancies (such as Kaposi sarcoma), and opportunistic infections (such as *Mycobacteria* infections, oropharyngeal candidiasis, molluscum contagiosum, and deep fungal infections).

INFLAMMATORY DERMATOSES

Pruritus and Pruritic Eruptions of HIV Disease. Pruritus is a common complaint in individuals with late symptomatic and advanced HIV disease.

In the majority of cases, primary or secondary dermatoses rather than metabolic disorders are the cause of pruritus.[104] The differential diagnosis of pruritus in an HIV-infected individual is listed in Box 198-4.

An atopic-like diathesis may become manifest in individuals with advanced HIV disease and pruritus, even in the absence of a prior history of atopy. Changes secondary to chronic rubbing and scratching are often seen, including excoriations, lichen simplex chronicus, and prurigo nodularis. Secondary *S. aureus* infection (impetiginization, furunculosis, or cellulitis) may also occur in traumatized lesions. Ichthyosis vulgaris and xerosis are common in advanced HIV disease and may be associated with mild pruritus. Protease inhibitors (particularly indinavir) may cause a retinoid dermatitis. These changes typically occur relatively soon after initiation of therapy. Idiopathic pruritus is associated with CD4+ T cell counts <200/μL and viral load >55,000 copies/mL, whereas ART has been associated with a decrease in idiopathic pruritus.[105]

Eosinophilic Folliculitis. Eosinophilic folliculitis is a chronic pruritic dermatosis occurring in persons with advanced HIV disease.[16] In one retrospective study of HIV-infected individuals, low CD4+ T cell counts (<200/μL) were associated with the development of eosinophilic folliculitis, independent of ART status.[16] Clinically, eosinophilic folliculitis presents with extremely pruritic small pink to red, edematous, folliculocentric papules, and less commonly pustules. Lesions tend to develop symmetrically above the nipple line on the chest, proximal arms, head, and neck (Fig. 198-7). Secondary changes are common, and include excoriations, lichen simplex chronicus, and prurigo nodularis, as well as secondary infection with *S. aureus*. In individuals with darker skin, postinflammatory hyperpigmentation often produces significant cosmetic disfigurement. The histologic findings of eosinophilic folliculitis are relatively specific, and demonstrate an inflammatory infiltrate of lymphocytes and eosinophils at the level of the isthmus and sebaceous glands.[106] Peripheral eosinophilia is seen in about 25%–50% of patients.[106,107]

The most effective therapy for eosinophilic folliculitis is prednisone (starting with an initial dose of 70 mg daily, and tapered by 5 or 10 mg over 7 or 14 days). However, in the majority of persons with successfully treated eosinophilic folliculitis, lesions recur within a few weeks of discontinuation of prednisone. In individuals with severe symptoms, prednisone may be given on alternate days or weekly. Itraconazole 200 mg daily has also been reported to be effective. If no response or only a partial response is seen after 2 weeks, the dose may be increased to 300 mg or 400 mg daily.[108] A third alternative is oral isotretinoin 40–80 mg daily.[109] When lesions and symptoms resolve, the dose

- Adverse cutaneous drug eruptions

Figure 198-7 Eosinophilic folliculitis. **A.** Multiple erythematous pruritic papules and a few pustules in an individual with a CD4 cell count of 50/μL. **B.** Close-up showing urticaria papules, pustules, and crusted erosions secondary to rubbing.

may then be tapered to 40 mg daily for several weeks, and then to 20 mg daily or 40 mg every other day. Isotretinoin can raise serum triglyceride levels, which are often high in HIV-infected individuals. As a result, serum lipids should be monitored regularly. Phototherapy with narrow-band ultraviolet B (UVB) and ultraviolet A with or without psoralen is considered to be a safe and effective treatment modality in HIV-infected persons, and does not have a significantly deleterious effect on viral load.[110–112] High-potency topical corticosteroid preparations may reduce the formation of new lesions as well as treat eczematous dermatitis, thus providing symptomatic relief. Topical preparations containing 4% hydroquinone are relatively ineffective in treating postinflammatory hyperpigmentation.

Papular Pruritic Eruption of HIV. Papular pruritic eruption (PPE) of HIV has been considered to be within the spectrum of pruritic papular disorders in HIV, which includes eosinophilic folliculitis and nonspecific pruritus. The primary lesion is a firm urticarial papule, though sterile pustules have been described as well. The eruption is usually symmetric and distributed primarily on the extremities, and less commonly on the trunk and face. Lesions are occasionally but not always folliculocentric. Because the eruption is intensely itchy, the eruption is typically associated with multiple excoriations, marked postinflammatory hyperpigmentation, and scarring (Fig. 198-8).

PPE is rarely reported in Europe and North America. However, the prevalence of PPE is estimated to be between 18%–46% in Africa and Haiti, where it is frequently the initial presenting sign of HIV disease.[113,114] In fact, PPE appears to be a marker of severe immunosuppression as more than 80% of HIV-infected individuals with PPE have been reported to have $CD4^+$ T cell counts <100/μL.[17] The etiopathogenesis of PPE is unclear, but it has been suggested that PPE may represent a hypersensitivity reaction to arthropod bites.[115] PPE is extremely difficult to treat effectively and is only moderately responsive to antihistamines and topical steroids. Immune reconstitution with ART is an effective treatment for PPE, though several months of therapy may be required for lesions to resolve. UVB is also an effective therapy, though its utility is limited by the lack of treatment centers in resource-limited settings where the prevalence of PPE is highest.

Photosensitivity. Photosensitivity in HIV-infected individuals has been reported in association with other diseases such as porphyria cutanea tarda, chronic actinic dermatitis, lichenoid photoeruption, and

Figure 198-8 Papular pruritic eruption of human immunodeficiency virus infection. There are multiple, disseminated excoriated papules, postinflammatory pigmentation, and small scars. (Used with permission of Anisa Mosam, MD.)

photosensitive granuloma. Idiopathic photosensitivity is an uncommon phenomenon in HIV disease but may be the presenting complaint of advanced disease.[116] Clinically, photosensitive eruptions tend to present with two distinct morphologies: (1) photodistributed lichenoid eruptions and (2) photodistributed eczematous eruptions.[117] Risk factors for development of photosensitivity include African American ethnicity (6.7-fold risk) and ART (2.8-fold risk).[117]

Erythroderma. (See Chapter 23). Erythroderma in HIV disease may be related to drug hypersensitivity, atopic dermatitis, psoriasis, seborrheic dermatitis, photosensitivity dermatitis, coexisting human T-cell lymphotrophic virus-1 infection, pityriasis rubra pilaris, or cutaneous T cell lymphoma.[118]

DISORDERS OF THE OROPHARYNX.

Nearly all untreated HIV-infected individuals experience disorders of the oropharynx during the course of their disease.[119] In about 10% of cases, oropharyngeal disorders have been reported to be the first sign of HIV disease.[120] Thus, the presence of persistent oropharyngeal disorders may be an indication for HIV testing (Box 198-3). In a study of oropharyngeal disorders in advanced HIV disease, candidiasis was the most common finding, diagnosed in more than 90% of subjects.[121] Other common oropharyngeal disorders included herpetic ulcers, xerostomia, exfoliative cheilitis, oral hairy leukoplakia, Kaposi sarcoma, patchy depapillation of the tongue, and ulcers of unclear etiology.[121] Individuals treated with ART have been found to have a decreased prevalence of oral disorders compared to individuals that are untreated.[122]

ORAL HAIRY LEUKOPLAKIA.

(See Chapter 76). Oral hairy leukoplakia is a benign infection of epithelial cells of oral mucosa with Epstein–Barr virus. A common oral manifestation of HIV disease, oral hairy leukoplakia is marker of moderate to advanced immunosuppression.[123] However, the incidence of oral hairy leukoplakia has been noted to have decreased with ART.[122] Clinically, oral hairy leukoplakia presents with asymptomatic hyperplastic, whitish plaques on the bilateral aspects of the lateral tongue. Lesions are typically asymmetric, and have corrugations accentuating the normal tongue ridges (Fig. 198-9). Treatment may not be necessary as the lesions are often asymptomatic. However, acyclovir and valacyclovir are sometimes effective. Podophyllin has also been reported to be helpful.[124]

Figure 198-9 Oral hairy leukoplakia. White plaques with vertical corrugations on the inferolateral aspect of the tongue. The lesions are fixed unlike those of oral candidiasis, which can be brushed off.

OPPORTUNISTIC INFECTIONS

Bartonella. (See Chapter 182). Bacillary angiomatosis, caused by *Bartonella henselae* and *Bartonella quintana,* occurs most commonly in the setting of advanced HIV disease ($CD4^+$ T cell count <200/μL).[18] Clinically, the cutaneous lesions of bacillary angiomatosis are red to violaceous, dome-shaped papules, nodules, or plaques that may resemble cherry angioma, pyogenic granuloma, or Kaposi sarcoma. Lesions may be tender to palpation, and range in size from a few millimeters up to 2–3 cm in diameter (Fig. 198-10). Less commonly, domed subcutaneous masses may develop without the characteristic red color of more superficial vascular lesions.[125] Lesions may be solitary or multiple—in rare cases, totaling more than 1,000 lesions. Nearly any cutaneous site may be involved, but the palms, soles, and oral cavity are usually spared. The spectrum of internal disease caused by *B. henselae* and *B. quintana,* following hematogenous or lymphatic dissemination, includes soft tissue masses, bone marrow involvement, lymphadenopathy, splenomegaly, and hepatomegaly. Hepatic infection, in the form of *Bartonella*-associated

Figure 198-10 Bacillary angiomatosis. Cherry hemangioma-like papules and a larger pyogenic granuloma-like nodule on the skin of a patient with advanced human immunodeficiency virus infection. Subcutaneous nodules were also present.

peliosis hepatitis, has been reported in a number of HIV-infected individuals.[126]

Currently, the prevalence of bacillary angiomatosis in North America and Western Europe is low because of widespread availability of ART and prophylaxis given for infections such as *Mycobacteria avium* complex. The antibiotics of choice for bacillary angiomatosis are erythromycin (250–500 mg PO qid) or doxycycline (100 mg bid), for at least 4 weeks or until the lesions resolve.[127] Secondary prophylaxis is indicated in patients with recurrent bacillary angiomatosis.

Cutaneous Tuberculosis. (See Chapter 184). Although tuberculosis infections are a common opportunistic infection in HIV disease particularly in developing countries, cutaneous tuberculosis is rare.[128] Tuberculosis of the skin is caused by *Mycobacterium tuberculosis*, *Mycobacterium bovis*, and the BCG vaccine. Various manifestations of cutaneous tuberculosis have been described in HIV-infected individuals, including scrofuloderma, lichen scrofulosorum, disseminated miliary tuberculosis, gummatous tuberculosis, and tuberculous abscess.[19,128,129] Cutaneous miliary tuberculosis—a previously rare form of cutaneous tuberculosis that arises from hematogenous spread of bacilli to the skin from an internal focus of infection—has been reported in multiple individuals with advanced HIV disease ($CD4^+$ T cell count <100/μL).[19,130] Clinically, cutaneous miliary tuberculosis may initially present with red–brown pinpoint macules, papules, and papulovesicles. Lesions often develop into small flat-topped papules that crust over centrally. The eruption tends to be asymmetrically distributed, and favors the buttocks, thighs, and extensor surfaces. The cutaneous findings of cutaneous miliary tuberculosis are nonspecific, and may resemble a bacterial folliculitis.[19] Pulmonary symptoms may be present, though radiographic findings may be nonspecific as well. Cutaneous military tuberculosis is treated with multidrug antituberculosis therapy; however mortality rates are high (>50%), particularly in the case of multidrug resistant organisms.[130]

Candidiasis. (See Chapter 189). *Candida* colonization of the oropharynx is common in HIV-infected individuals, and has been reported in up to 90% of individuals with advanced disease.[120] Oropharyngeal candidiasis typically presents in four different clinical patterns: (1) pseudomembranous (thrush), (2) hyperplastic, (3) erythematous (atrophic), and (4) angular cheilitis. Pseudomembranous candidiasis typically involves the tongue, and presents with yellow–white plaques that are removable by scraping. Hyperplastic candidiasis usually involves the buccal mucosa, and consists of white plaques that are not removable by scraping. Erythematous candidiasis commonly presents with erythematous patches of the palate and the dorsal tongue with associated depapillation. Angular cheilitis manifests as erythema with curdlike flecks or painful fissures at the angles of the lips.

A number of studies have documented a higher incidence of vulvovaginal candidiasis in HIV-infected women, particularly in those with advanced HIV disease. For instance, in one prospective study, women with $CD4^+$ T cell counts <200/μL had a fourfold increased risk of symptomatic vulvovaginal candidiasis compared to immunocompetent women.[131] In a study of 200 HIV-infected women in North America, recurrent vaginal candidiasis was the most common initial clinical manifestation of HIV infection in 37% of subjects.[132] Children with HIV infection often experience oral candidiasis, diaper area candidiasis, and intertrigo of the axillae and neck folds.[133]

Dermatophyte Infections. (See Chapter 188). As is the case for immunocompetent individuals, *Trichophyton rubrum* and *Trichophyton mentagrophytes* are the most common dermatophytes seen in HIV-infected individuals. In HIV disease, dermatophyte infections of the epidermis, commonly caused by *T. rubrum* may be more extensive, and are often asymptomatic. Disseminated disease may sometimes present atypically. For instance, disseminated *T. rubrum* has been reported to mimic Kaposi sarcoma.[134] Infections of the nails are also common. *T. rubrum* frequently causes distal and lateral subungual onychomycosis in both HIV-infected and immunocompetent individuals. However, *T. rubrum* also causes proximal subungual onychomycosis (infection of the undersurface of the proximal nail plate), which is seen almost exclusively in individuals infected with HIV.[135] As a result, the diagnosis of proximal subungual onychomycosis is an indication for HIV testing (Box 198-3). Unless immunocompetence is restored, dermatophyte infections are often chronic and recurrent. ART has markedly diminished the incidence of these infections, and adverse drug interactions between ART and antifungal medication appear to be less clinically significant than previously believed.[135]

Invasive Fungal Infections. (See Chapter 190). Disseminated fungal infections in advanced HIV disease may arise either by (1) local invasion of the skin or mucosa with secondary lymphatic or hematogenous dissemination or (2) reactivation of a latent pulmonary focus of infection. Cutaneous findings commonly resemble multiple molluscum contagiosum lesions, which tend to favor the face and upper trunk.

Cryptococcosis. Disseminated infection by the encapsulated yeast *Cryptococcus neoformans* is probably the most common life-threatening fungal infection associated with advanced HIV disease. Disseminated disease typically involves the brain, kidney, prostate, bone, and pericardium. Disseminated cryptococcus is more commonly seen in individuals with a $CD4^+$ T cell count <50/μL.[136,20] The most common clinical presentation of cutaneous cryptococcosis is umbilicated skin-colored or pink papules or nodules of the head and neck that mimic molluscum contagiosum. Less frequently seen are subcutaneous nodules, cellulitis, herpetiform ulcers, palpable purpura, violaceous plaques mimicking Kaposi sarcoma, and pyoderma gangrenosum–like lesions.[137,138] Skin lesions may develop many weeks or months prior to onset of systemic symptoms.

Coccidioidomycosis. *Coccidioides immitis* is dimorphic fungus endemic to the Southwestern United States, Mexico, and Central and South America. The cutaneous lesions of disseminated coccidioidomycosis are usually asymptomatic, and typically begin as papules that evolve to pustules, plaques, or nodules with minimal surrounding erythema. Lesions often resemble molluscum contagiosum lesions. In time, lesions may enlarge and become confluent with the formation of abscesses, multiple draining sinus tracts, ulcers, cellulitis, verrucous plaques, and granulomatous nodules.[139,140] Unlike histoplasmosis and cryptococcosis, the oral mucous membranes are typically spared.[140]

Histoplasmosis. *Histoplasma capsulatum* is a dimorphic soil fungus. Endemic areas include the river valleys of the Midwestern and Southeastern United States, Southeastern South America, and Southern and East Africa. Disseminated histoplasmosis is more commonly seen in individuals with advanced HIV disease ($CD4^+$ T cell count <50/μL) and presents with fevers, weight loss, pulmonary symptoms, lymphadenopathy, hepatosplenomegaly, and rash. The skin findings associated with disseminated histoplasmosis may consist of lesions of multiple morphologies, including erythematous papules, necrotic umbilicated papules and nodules mimicking molluscum, folliculitis, acneiform eruptions, rosacea-like eruptions, psoriasiform eruptions, ulcers, vegetative plaques, and pyoderma gangrenosum-like lesions (Fig. 198-11).[141,142] Lesions occur most commonly on the face, followed by the extremities and trunk. The oral mucosa may also be affected, and nodules and ulcerations of the soft palate, oropharynx, epiglottis, and nasal vestibule are sometimes seen. HIV-infected individuals already on systemic antifungal therapy may develop a subtle widespread exanthematous or psoriasiform eruption.

Figure 198-11 Histoplasmosis. A young woman from South Africa with advanced untreated HIV/AIDS presented with disseminated skin-colored umbilicated papules, papulopustules, and ulcerated nodules of varying sizes (Used with permission of Adam Lipworth, MD).

Aspergillosis. Invasive aspergillosis is rare in HIV disease, and is a complication primarily seen in individuals with $CD4^+$ T cell count <50/μL.[21] Primary cutaneous aspergillosis typically arises from direct inoculation and are sometimes seen at the site of intravenous catheters.[143] Secondary cutaneous aspergillosis is commonly the result of hematogenous spread or direct extension to the skin from a pulmonary focus. Risk factors for invasive aspergillosis in HIV disease include neutropenia, corticosteroid use, and intravenous drug use.[21,144] Skin lesions commonly consist of skin-colored to pink umbilicated papules and nodules resembling molluscum contagiosum, fluctuant papules, deep-seated pustules, vesiculopustular plaques, and nonhealing ulcers.[143] Mortality in invasive aspergillosis remains high even with appropriate treatment. Therapy with voriconazole has been reported to be associated with improved survival and fewer side effects, compared to amphotericin B.[145]

Penicilliosis. The dimorphic fungus *Penicillium marneffei* is the third most common HIV-associated opportunistic infection in South East Asia, and is endemic to Northeastern India, Vietnam, Thailand, Indonesia, and Southern China.[146] The clinical presentation of penicilliosis varies, though it often presents with fever, weight loss, anemia, and lymphadenopathy in patients with $CD4^+$ T cell count <50/μL. Skin lesions are present in about 70% of patients, and typically consist of umbilicated papules favoring the face, pinnae, upper trunk, and arms (Fig. 198-12).[147,148]

Figure 198-12 Penicilliosis. A 27-year-old Vietnamese man with advanced untreated HIV/AIDS presented with fever, weight loss, and hundreds of skin-colored umbilicated papules and nodules of varying sizes, many with central erosion and crust (Used with permission of Hoang Van Minh. From Wolff K, Johnson RA: *Fitzpatrick's Color Atlas and Synopsis of Clinical Dermatology*, 6th edition. New York, McGraw-Hill, 2009.)

Figure 198-13 Molluscum contagiosum infection. A patient with advanced HIV/AIDS presented with multiple large facial mollusca causing significant cosmetic disfigurement.

Pustules, subcutaneous nodules, and acne-like lesions have also been reported.[147] Treatment with amphotericin or itraconazole is often effective, though relapse is common. Secondary prophylaxis with itraconazole in patients is indicated until immune reconstitution with ART.[149]

Molluscum Contagiosum. (See Chapter 195). Molluscum contagiosum lesions are caused by poxvirus infection, and are a cutaneous marker for advanced HIV disease ($CD4^+$ T cell count <100/μL).[18,22] Commonly seen in children, molluscum infections in HIV-infected individuals may present with pearly skin-colored umbilicated papules characteristically seen in immunocompetent individuals. However, lesions that are large, confluent and predominantly facial are characteristic of advanced HIV disease (Fig. 198-13). Atypical lesions are also common, and may resemble folliculitis, abscesses, warts, furuncles, and cutaneous horns. The differential diagnosis of molluscum-like lesions in an HIV-infected individual is listed in Box 198-5. In a study conducted during the pre-ART area, molluscum lesions were detected in 30% of individuals with a $CD4^+$ T cell count of <100/μL.[22] After initiation of ART, molluscum infections often resolve completely.[150,151]

In HIV-infected individuals, molluscum infections tend to be progressive and recurrent. Electrofulguration with repeated curettage is effective for multiple large and confluent lesions. For cases refractory to standard therapies, imiquimod 5% cream may be effective in both children and adults.[152,153] Topical cidofovir, a nucleotide analogue with activity against several DNA viruses, is also reported to be efficacious.[154,155]

BOX 198-5 DIFFERENTIAL DIAGNOSIS OF UMBILICATED PAPULES IN A HIV-POSITIVE INDIVIDUAL

Varicella zoster infection
Basal cell carcinoma
Arthropod bites
Lymphomatoid papulosis

Human T Cell Lymphotrophic Virus. (See Chapter 197). Human T cell lymphotrophic virus-1 (HTLV-1) is a human retrovirus that is associated with adult T cell leukemia, a slowly progressive neurologic disorder (HTLV-1-associated myelopathy/tropical spastic paraparesis), uveitis, and a chronic eczematous dermatitis referred to as "infective dermatitis." The skin findings of HTLV-1 infection mimic chronic atopic dermatitis, typically presenting with erythematous, scaly, crusted plaques of the scalp, neck, and groin in children and adolescents. Periorbital papules with seborrheic scale may be seen near the eyebrows.[156] Retroauricular fissuring and generalized ichthyosis are seen in a minority of cases. The exudative nature of these lesions may help to differentiate HTLV-1 from atopic dermatitis.[156]

High rates of HTLV-1 seroprevalence are found in Japan, the Caribbean, Africa, and South America (particularly Brazil). The exact rate of HTLV-1 and HIV coinfection is not clear, though one study of HIV infected individuals in Brazil documented a HTLV-1 coinfection rate of 12.5%.[157] In HIV-infected adults, an increased incidence of inflammatory dermatoses including seborrheic dermatitis and prurigo has been reported with HTLV-1 coinfection.[157] In addition, HIV and HTLV-1 coinfection has been associated with higher $CD\text{-}4^+$ T cell counts as well as more advanced clinical disease than HIV infection alone, suggesting that the higher $CD4^+$ T cell counts may not offer immunologic benefit in the setting of HTLV-1 coinfection.[158]

Scabies. (See Chapter 208). Scabies, a parasitic infection caused by the mite *Sarcoptes scabiei* var. *hominis*, is included in the differential diagnosis of pruritus in HIV disease. In HIV-infected individuals, scabies may present with more typical symptoms but individuals with advanced HIV disease, who are not

able to control mite replication, are at risk for developing crusted scabies. Crusted scabies commonly presents with extensive thick hyperkeratotic plaques with dirty gray brown scale, involving atypical locations such as the scalp, beard area, palms, and soles. Lesions are often not pruritic, or only minimally pruritic. While an immunocompetent host is estimated to harbor 10–15 mites, a gram of crust from an individual with crusted scabies may harbor thousands of mites.[159,160] For this reason, crusted scabies is extremely contagious. *S. aureus* superinfection may occur, but is rarely complicated by bacteremia. For classic scabies, a topical scabicide or oral ivermectin (200 µg/kg weekly) ×2 doses is usually effective.[161] For crusted scabies, multiple doses of ivermectin (200 µg/kg weekly) may be necessary (3–7 doses, depending on the severity of the infection), and should be combined with a topical scabicide (every 2–3 days × 1–2 weeks) and a keratolytic cream to improve penetration of the agent.[161]

Leishmania. (See Chapter 206). The rate of HIV and leishmania coinfection varies; however, studies have reported rates ranging from 2% to as high as 30% in endemic areas.[162,163] HIV infection has been reported to increase the risk of developing visceral leishmaniasis by 100–2,320-fold in endemic areas, as well as the risk of recurrent disease[162] Conversely, leishmaniasis is believed to increase HIV infectivity and promote progression of HIV disease, likely through upregulation of HIV-1 replication.[162,163] HIV-infected individuals with leishmaniasis tend to have lower cure rates, higher recurrence rates, and higher mortality rates than those of immunocompetent individuals.[162,164] See Chapter 206 for a discussion of treatment of leishmaniasis.

OPPORTUNISTIC NEOPLASMS. Individuals with HIV disease have been reported to have a higher prevalence of the AIDS-defining malignancies, Kaposi sarcoma (see Chapter 128), in situ and invasive cervical SCC, and non-Hodgkin lymphoma.[52,97,165] However, HIV-infected individuals have also been noted to have an increased incidence of in situ and invasive anal SCC, vulvar/vaginal SCC, Hodgkin lymphoma, primary liver cancer, lung cancer, melanoma, nonmelanoma skin cancers, oropharyngeal cancer, and leukemia.[52] Since the introduction of ART, the incidence of some opportunistic neoplasms, such as Kaposi sarcoma and non-Hodgkin lymphoma, have declined dramatically.[52,97,165] However, the incidence of many non-AIDS defining cancers (such as anal SCC, nonmelanoma skin cancers, melanoma, and Hodgkin lymphoma) have not decreased despite the introduction of ART, and there is evidence that the incidence may have actually increased in some cases.[52,97] The etiology of the higher incidence of malignancy among HIV-infected individuals is likely multifactorial. Contributing factors may include diminished immune-mediated tumor surveillance, concomitant infection with oncogenic viruses (such as Epstein–Barr, HPV, and human herpesvirus-8), and associated behavior and lifestyle factors.

Chapter 199 :: The Rickettsioses, Ehrlichioses, and Anaplasmoses

:: Sandra A. Kopp, Analisa V. Halpern, Justin J. Green, & Warren R. Heymann

RICKETTSIAL, EHRLICHIAL, AND *ANAPLASMA* INFECTIONS AT A GLANCE

- Rickettsiae primarily target vascular endothelial cells, causing febrile illness and rash in the mammalian host.
- Transmission is predominantly via tick bites, with certain pathogens transmitted by human body lice and mites.
- Fever, headache, myalgia, and malaise are common to rickettsial, ehrlichial, and *Anaplasma* infections; rash is common in rickettsial disease, occasional in ehrlichial infection, and rare in anaplasmosis.
- The early signs and symptoms of infection are often nonspecific and can mimic self-limited viral illnesses or other life-threatening illnesses.
- Early empiric treatment with doxycycline should be considered in highly suspicious cases until rickettsial infection is definitively ruled out, as delayed treatment can lead to severe sequelae and high mortality rates.

Rickettsial diseases are curable infections that, if unrecognized, can be readily lethal. Early nonspecific symptoms can mimick benign viral illnesses and should be considered in any patient who presents with constitutional symptoms, fever, headache, and a characteristic petechial rash. The advent of modern molecular technologies, including genetic analysis, has allowed for significant taxonomic reclassification of the rickettsiae including moving the family *Bartonella* (see Chapter 192) and the genus *Coxiella* out of the order Rickettsiales to the orders Rhizobiales and Legionellales, respectively. "Rickettsiae" now includes a polyphyletic group of microorganisms in the class Proteobacteria, comprising species belonging to the genera *Rickettsia*, *Orientia*, *Ehrlichia*, *Anaplasma*, and *Neorickettsia*. Several non-rickettsial agents that were historically included in the group of infections loosely termed the *rickettsioses* remain incorporated in the discussion of rickettsial disease herein to reflect that precedent.[1]

Historically rickettsiae and *Rickettsia*-like organisms (e.g., *Coxiella burnetii*) were endemic pathogens, however the rise of international travel has allowed for the spread of rickettsial infections to nonendemic areas. *Rickettsia prowazekii and C. burnetii,* agents of epidemic typhus and Q fever, respectively have emerged as potential agents of bioterrorism.[2]

RICKETTSIAE

ETIOLOGY AND PATHOGENESIS OF SPOTTED FEVER AND TYPHUS GROUPS

Rickettsiae are obligate, intracellular, Gram-negative bacteria. They are pleomorphic 0.3–1 µm coccobacilli composed of DNA and RNA and reproduce through binary fission. Rickettsiae are propagated by arthropod vectors that use mammals (and sometimes the arthropods themselves) as reservoirs of infection. Rickettsiae are separated into the spotted fever group and the typhus group on the basis of common genetics, immunologic patterns, and intracellular growth characteristics. The typhus group lives entirely within the cell cytoplasm, whereas the spotted fever group can reside within the cytoplasm or nucleus. Rickettsiae are differentiated by unique antigenic structures on cell surface proteins. *Rickettsia rickettsii* has two major surface proteins, outer membrane protein A (OmpA) and B (OmpB), which are the main targets for serological testing.

Infection occurs through arthropod-induced breaks in the skin allowing access of the pathogen to the blood and lymph. Spotted fever rickettsiae are injected into the host through the saliva of the feeding tick, whereas typhus group rickettsiae enter through the feces of infected human body lice or fleas. Manipulation of the bite site, a long attachment of the arthropod, and exposure to arthropod hemolymph during tick removal aid in the transmission of pathogenic organisms. The rickettsial organisms then spread via the hematogenous and lymphatic systems, attach to endothelial cell membranes, and are phagocytosed. Spotted fever group rickettsiae stimulate host cells to produce reactive oxygen species and cause actin polymerization that aid in bacterial extrusion. In contrast, typhus group rickettsiae replicate intracellularly until the host cell bursts.[3] The severe clinical manifestations of rickettsial infection (e.g., hypovolemia, purpura, pulmonary and cerebral edema) are caused by proliferation of bacteria within the vascular endothelium resulting in a multifocal, systemic vasculitis and microvascular leakage.[4]

SPOTTED FEVER GROUP

ROCKY MOUNTAIN SPOTTED FEVER. Rocky Mountain Spotted Fever (RMSF) was first recognized in 1896 in the Snake River Valley of Idaho and was originally called *black measles* because of the characteristic appear-

ance of the rash. Caused by the tick-borne *R. rickettsii*, it is the most frequently reported rickettsial infection in the United States. Fatal outcomes have been reported in 5% of treated cases, and as high as 20% of untreated cases.[5]

Epidemiology. The vector largely responsible for RMSF in the eastern two-thirds of the United States is the American dog tick, *Dermacentor variabilis*, whereas the Rocky Mountain wood tick, *Dermacentor andersoni*, is prevalent in the Western United States (Fig. 199-1). RMSF is most prevalent in the Southeastern and South Central states, during spring and early summer. Historically, children younger than 10 years of age had the highest incidence of RMSF; however, surveillance data in the United States during 2003 demonstrate a higher age-specific incidence in persons aged 40–64 years.[6] The principal epidemiologic characteristics of RMSF are outlined in Table 199-1.

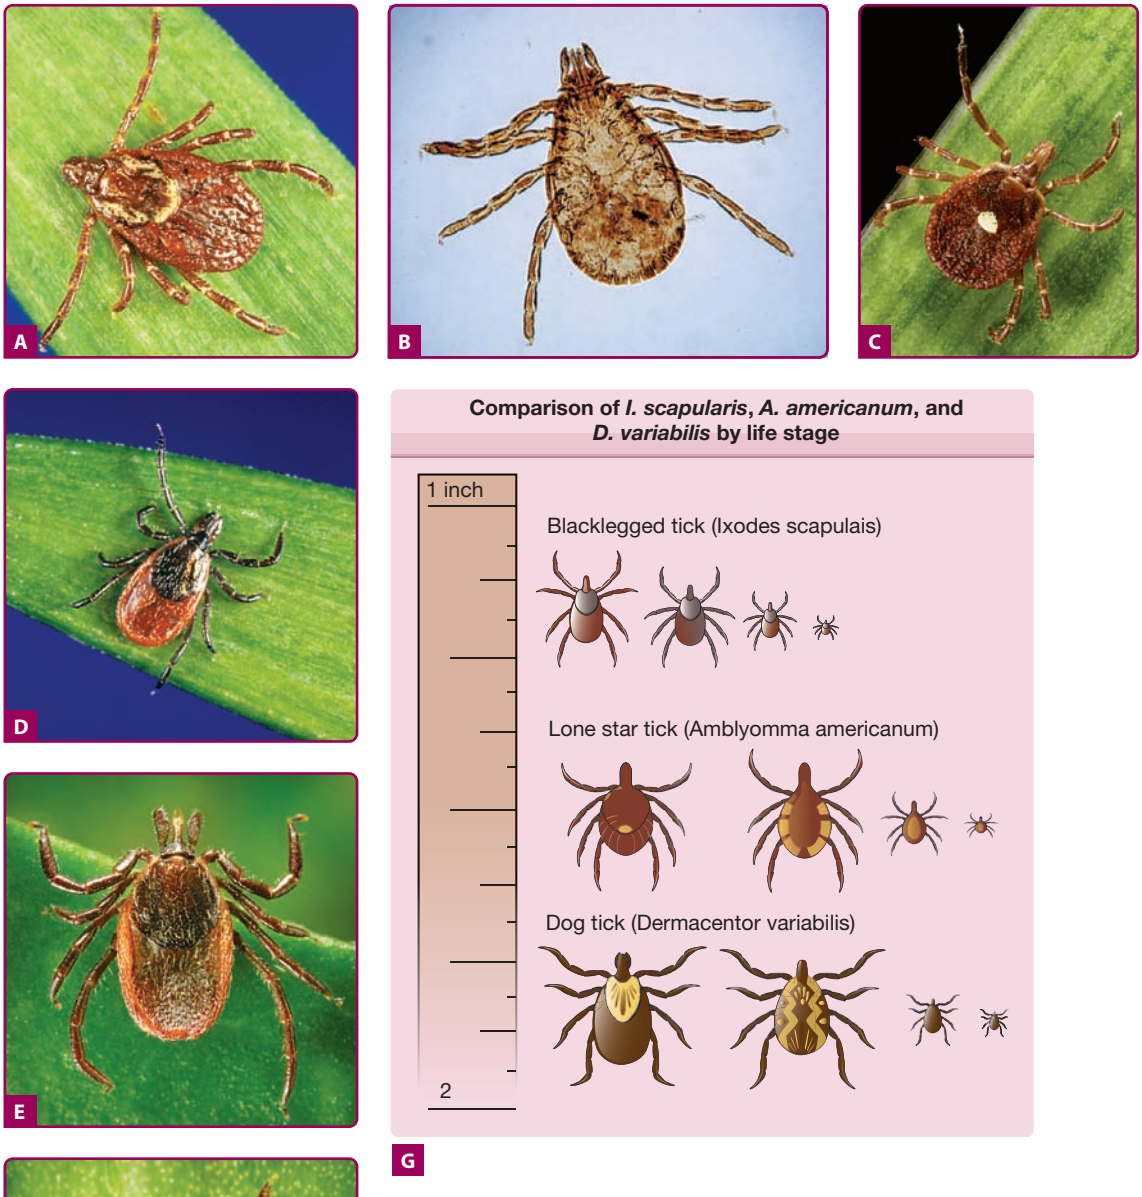

Figure 199-1 Tick species responsible for transmission of *Rickettsia*, *Ehrlichia*, and *Anaplasma*. **A.** *Dermacentor variabilis*. **B.** *Dermacentor andersoni*. **C.** *Amblyomma americanum*. **D.** *Ixodes scapularis*. **E.** *I. pacificus*. **F.** *Rhipicephalus sanguineus*. **G.** Comparison of *I. scapularis*, *A. americanum*, and *D. variabilis* by life stage. TABLE 199-1
Epidemiologic Features, Prognosis and Treatment of *Rickettsia*, *Ehrlichia* and *Anaplasma* Infection

Disease (Agent)	Primary Vector(s)	Epidemiology	Incubation Period	Risk Factors[a]	Prognosis	First Line Treatment	Second Line Treatments
Rocky Mountain spotted fever (*Rickettsia rickettsii*)	*Dermacentor variabilis* (American dog tick), *Dermacentoandersoni* (Rocky Mountain wood tick), *Amblyomma americanum* (lone star tick), *Rhipicephalus sanguineus* (brown dog tick), *Amblyomma cajennense* (Central and South America), *Haemaphysalis leporispalustris* ticks	Widespread in the United States, concentration in South Atlantic and South-Central states; Argentina, Brazil, Columbia, Costa Rica, Mexico, Panama, Canada Spring–Summer	>2–14 days	Males; adults 40–64 years, children <10 years; rural dwelling	Severe disease: G6PD deficiency (rapid decompensation, fulminant disease with higher incidence of necrosis), males, elderly, neurologic disease, hepatitis, jaundice, thrombocytopenia, acute renal failure, sulfa medications, delayed diagnosis and treatment.	Adults[b]: Doxycycline 100 mg po q12h × 5–10 days Children[c]: Doxycyline 2.2 mg/kg po q12h × 5–10 days Pregnancy[c]: Doxycycline 100 mg po q12h for 5–10 days	Adults: Chloramphenicol, 50–75 mg/kg po q6h × 5–10 days *or* Tetracycline 500 mg q6h po × 5–10 days Children: Chloramphenicol, 12.5–25 mg/kg po q6h × 5–10 days Pregnancy[d]: Chloramphenicol
Mediterranean spotted fever (*Rickettsia conorii*)	*R. sanguineus* (brown dog tick)	Endemic to Southern Europe, Middle East, Southwest Asia, India, and Africa Summer	5–7 days	Exposure to dogs	Mild disease (mainly in children) has good prognosis. Severe disease "malignant Mediterranean spotted fever": Alcoholics, elderly, G6PD deficiency, diabetes mellitus, heart disease, delayed diagnosis and treatment.	Adults: Doxycycline 200 mg po q12h × 1 day *or* 100 mg po q12h for 2–5 days Children[c]: Doxycyline 2.2 mg/kg po q12h × 5–10 days Pregnancy: Azithromycin 500 mg po daily × 3 days	Adults: Tetracycline 500 mg po q6h × 10 days *or* Ciprofloxacin 750 mg q12h for 8 days Children: Clarithromycin, 15 mg/kg/day divided q12h for 7 days *or* Azithromycin, 10 mg/kg/day daily × 3 days Pregnancy[d]: Chloramphenicol
Rickettsialpox (*Rickettsia akari*)	*Liponyssoides sanguineus (Allodermanyssus sanguineus)* (house mouse, *Mus musculus*, mite)	United States (mainly eastern seaboard), South Africa, Korea, Ukraine, Croatia Sporadic	~ 7 days (eschar), ~ 7–24 days (systemic symptoms and rash)	Males; urban dwellers (likely from mice exposure); intravenous drug users	Excellent.	Self-limiting	Doxycycline can be used for severe cases
Endemic typhus (*Rickettsia typhi; Rickettsia felis*)	*Xenopsylla cheopis* (rat flea), *Ctenocephalides felis* (cat flea)	Southeast United States, Gulf region, Southern California; worldwide most cases in Africa (reported on all continents except Antarctica) Summer	1–2 weeks (~12 days)	Exposure to fleas, poverty, poor hygiene	Excellent prognosis with treatment. Complicated disease occurs with alcoholism, elderly, hematologic disorders, and exposure to sulfa-containing drugs.	Adults: Doxycycline 100 mg po q12h for 7–14 days Children[c]: Doxycyline 2.2 mg/kg po q12h × 5–10 days Pregnancy[c,d]: Chloramphenicol *or* Doxycycline	Adults: Chloramphenicol, 80–100 mg/kg/day po divided q6h Children: Chloramphenicol, 12.5–25 mg/kg po q6h for 5–10 days Pregnancy: Azithromycin

Epidemic typhus (*Rickettsia prowazekii*)	*Pediculus humanus var. corporis* (human body louse), *Neohaematopinus sciuropteri* lice, *Orchopeas howardii* fleas	United States, Eastern Europe, Africa, Central and South America, China, Himalayan region Sporadic (increased in Winter)	~1–2 weeks (8 days, average)	Wartime, poor hygiene, natural disasters, cold weather	Good prognosis with treatment. Fever abates in 2 weeks (without treatment) and 48 hours (with treatment). Recovery of strength in 2–3 months	Adults[e]: Doxycycline 200 mg single dose (or until afebrile for 24 h) Children[c]: Doxycyline 2.2 mg/kg po q12h × 5–10 days Pregnancyc,[d]: Chloramphenicol *or* Doxycycline	Adults: Chloramphenicol, 80–100 mg/kg/day po divided q6h Children: Chloramphenicol, 12.5–25 mg/kg po q6h for 5–10 days Pregnancy: Azithromycin
Human monocytic ehrlichiosis (*Ehriichia chaffeensis*)	*A. americanum* (lone star tick), *D. variabilis* (American dog tick), *Ixodes pacificus* ticks	South and Mid-Atlantic, North/South-Central United States, isolated areas of New England[f] Spring and summer (peak in May–July	5–14 days	Males; adults >70 years	Poor prognosis: Immunosuppression (HIV, transplantation, glucocorticoids); cough, lymphadenopathy, diarrhea; use of trimethoprim-sulfamethoxazole.	Adults: Doxycycline 100 mg po q12h for 5–14 days Children[c]: Doxycyline 2.2 mg/kg po q12h × 5–14 days Pregnancy[c]: Doxycycline 100 mg po q12h for 5–14 days	Adults: Tetracycline 500 mg po q6h × 5–14 days *or* Rifampin 300 mg po q12h x7–10 days Children: Tetracycline 25–50 mg/kg/day po divided q6h × 5–14 days *or* Rifampin 10 mg/kg po q12h × 7–10 days Pregnancy: Rifampin 300 mg po q12h x7–10 days
Human granulocytic anaplasmosis *(Anaplasma phagocytophilum)*	*Ixodes scapularis* (Eastern United States) and *I Ixodes pacificus* (Western United States), *Ixodes ricinus* (Europe) (black-legged ticks)	New England, upper Midwest United States, Mid-Atlantic, Northern California and Europe[g] Spring and summer (peaks in July and November	5–21 days	Males; adults 60–69 years	Poor prognosis: Elderly, marked lymphopenia, anemia, immunosuppression (HIV, transplantation, glucocorticoids); development of opportunistic infections (e.g., *Aspergillosis,* disseminated candidiasis, etc.).	Adults[h]: Doxycycline 100 mg po q12h for 5–14 days Children[c,h]: Doxycyline 2.2 mg/kg po q12h × 5–14 days Pregnancy[c,h]: Doxycycline 100 mg po q12h for 5–14 days	Adults: Tetracycline 500 mg po q6h × 5–14 days *or* Rifampin 300 mg po q12h x7–10 days Children: Tetracycline 25—50 mg/kg/day po divided q6h × 5–14 days *or* Rifampin 10 mg/kg po q12h × 7–10 days Pregnancy: Rifampin 300 mg po q12h x7–10 days

G6PD = glucose-6-phosphate dehydrogenase; HIV = human immunodeficiency virus.
Children = <45 kg.
Tetracycline maximum daily dose = 2 grams.
Chloramphenicol maximum daily dose = 4 grams.
[a]Males appear to be at higher risk of all tick-borne rickettsial diseases, presumably because of greater recreational and occupational exposure. Disease occurs in all age groups; numbers reflect highest age-specific incidence.
[b]Treat for 3 days after fever subsides and until clinical improvement is noted, typically for a minimum of 5–7 days. More severe illness may require longer duration of therapy.
[c]In severe, life-threatening cases, or when rocky mountain spotted fever cannot be ruled out, doxycycline should be considered first line in any age and during pregnancy.
[d]Use with caution in the third trimester of pregnancy as chloramphenicol may cause gray baby syndrome in neonates (abdominal distention, pallor, cyanosis, vasomotor collapse). Doxycycline should be considered in near-term gravidas.
[e]For recrudescent disease (Brill-Zinsser), a second course of antibiotics is usually curative.
[f]In 2003, 70% of cases of human monocytic ehrlichiosis were reported from seven states: Arkansas, Georgia Missouri, Maryland, North Carolina, Oklahoma, and Tennessee.
[g]In 2003,71% of cases of human granulocytic anaplasmosis were reported from four states: Massachusetts, Minnesota, New York, and Rhode Island.
[h]Treatment is extended to treat potential coinfection with Lyme disease.
Data from Parola P, Paddock CD, Raoult D: Tick-borne rickettsioses around the World: Emerging diseases challenging old concepts. *Clin Microbiol Rev* **18**:719, 2005, and Dana AN: Diagnosis and treatment of tick infestation and tick-borne diseases with cutaneous manifestations. *Dermatol Ther* **22**:293-326, 2009.

Clinical and Laboratory Findings. A high index of suspicion is important to the diagnosis of RMSF. One or two classic symptoms, outlined in Table 199-2, may be seen at presentation, but only about 60% of patients will have the complete clinical triad of fever [>39.5°C (102°F)], headache, and rash. Fever usually presents within the first 3 days of the illness, followed by a characteristic rash 2–4 days after the onset of fever. The rash usually starts on the wrists and ankles, spreading centripetally over the next 6–18 hours. Palms and soles are typically involved with relative sparing of the face.[6] Cutaneous lesions are initially blanchable red macules that become papular and display evidence of petechiae or purpura (Fig. 199-2). Atypical "spotless" fever, seen in approximately 20% of cases does not imply milder disease, and is more common in the elderly and darker-skinned individuals.[4] Periorbital edema, confusion, abdominal pain mimicking an acute abdomen, conjunctival injection, palatal petechiae, edema of dorsal hands, and calf pain are sometimes appreciated. Necrosis from overwhelming vasculitis is rare and preferentially occurs in peripheral locations such as the digits, penis, and scrotum (Fig. 199-3).[7]

TABLE 199-2
Clinical and Diagnostic Findings in Rocky Mountain Spotted Fever (RMSF), Human Monocytic Ehrlichiosis (HME), and Human Granulocytic Anaplasmosis (HGA)

	RMSF	HME	HGA
Tropism	▪ Endothelial cells.	▪ Monocytes.	▪ Granulocytes.
Common initial signs and symptoms	▪ Fever to 38.9°C, chills, malaise, myalgia, nausea, vomiting, anorexia, headache. ▪ Periorbital edema, abdominal pain mimicking appendicitis (children >adults), conjunctival injection, palatal petechiae, edema of dorsal hands, calf pain.	▪ Fever, chills, headache, malaise, myalgia, nausea, vomiting, anorexia, photophobia. ▪ Abdominal pain mimicking appendicitis (children >adults), conjunctival injection, palatal petechiae, edema of dorsal hands, calf pain.	▪ Malaise, fever, myalgia, headache. ▪ Less common: Arthralgia, nausea, vomiting, diarrhea, cough.
Rash	▪ Erythematous blanching macules and/or papules 2–4 days after fever onset; starts at wrists/ankles and spreads centripetally; may involve palms, soles. Rash evolves over few days to petechial and purpuric lesions.	▪ Erythematous macules and/or papules, petechiae, or diffuse erythema approximately 5 days after onset of systemic symptoms	▪ Rare
Common laboratory abnormalities	▪ Common: Thrombocytopenia, anemia, mild hyponatremia. ▪ Variably elevated: Liver transaminases, lactate dehydrogenase, creatine kinase, bilirubin, alkaline phosphatase, blood urea nitrogen, creatinine. ▪ Cerebrospinal fluid: Leukocytosis, moderately elevated protein, and a normal glucose level.	▪ Leukopenia, lymphopenia, thrombocytopenia, transaminitis, and anemia	▪ Thrombocytopenia, transaminitis, leukopenia, anemia, elevated creatinine. ▪ Neutropenia is more common than lymphopenia.
Systemic sequelae	▪ Cardiovascular: Hypotension, hypovolemia, peripheral edema, inappropriate tachycardia, myocarditis, arrhythmias. ▪ Gastrointestinal: Bleeding, perforation, hepatomegaly, jaundice ▪ Neurologic: Confusion, delirium, stupor, meningismus, coma, motor deficits, cranial nerve palsy, deafness, photophobia, hallucinations, seizures, Guillain-Barré syndrome. ▪ Other: Conjunctivitis, acute renal failure, adult respiratory distress syndrome.	▪ Respiratory: Cough, dyspnea, respiratory insufficiency/ adult respiratory distress syndrome. ▪ Neurologic: Meningoencephalitis, altered mental status, cranial or peripheral motor nerve paralysis, sudden transient deafness. ▪ Other: Acute renal failure, disseminated intravascular coagulation, and pericarditis.	▪ General: Septic or toxic–shock-like syndrome (see Chapter 177), coagulopathy, disseminated intravascular coagulation (see Chapter 144), rhabdomyolysis, pancreatitis. ▪ Respiratory: Adult respiratory distress syndrome. ▪ Neurologic: Brachial plexopathy, demyelinating polyneuropathy, cranial nerve paralysis. ▪ Other: Acute abdominal syndrome, myocarditis, acute renal failure, hemorrhage, opportunistic infections.

Figure 199-2 **A.** Early macular blanchable macules and papules on the ankle and sole. No truncal lesions were present at this time. **B.** Truncal and facial hemorrhagic macules and papules 7 days after the onset of the rash. **C.** Erythematous macular lesions on the palm may develop into a petechial rash that spreads centrally. (Reprinted from Collins SP: Cutaneous conditions. In: *Atlas of Emergency Medicine*, 2nd edition, edited by KJ Knoop, LB Stack, AB Storrow. New York, NY, McGraw-Hill, 2002, p. 382.) **D.** Petechial lesions on the arm of a child with fulminant Rocky Mountain spotted fever. (Used with permission from MMWR, Diagnosis and Management of Tick-borne Rickettsial Diseases: Rocky Mountain Spotted Fever, Ehrlichiosis, and Anaplasmosis—United States. March 13, 2006/55(RR04); 1-27, http://www.cdc.gov/mmwr.)

Thrombocytopenia, anemia, mild hyponatremia, and mild transaminitis may be present. The white blood cell count is typically normal, however an increase in bands may be observed.[6] Severe and life-threatening cardiac, gastrointestinal, hepatic, neurologic, ophthalmologic, renal, and pulmonary manifestations can occur with delayed or inadequate treatment. In patients with severe RMSF who survive the acute illness, long-term sequelae are usually the result of neurologic deficits or acral necrosis. In a case series by Buckingham et al, of 92 children diagnosed with RMSF, the median delay between seeking medical attention and antibiotic therapy was 6 days, with only 49% reporting a tick bite.[8] Table 199-2 outlines the cutaneous and systemic manifestations of RMSF, as well as common laboratory abnormalities.

Pathology. Histopathologic examination shows a septic vasculitis (Fig. 199-4). Early lesions demonstrate dermal edema with a predominantly perivascular lymphohistiocytic infiltrate and extravasated erythrocytes. Lymphohistiocytic vasculitis can progress to

Figure 199-3 Gangrene of the toes in Rocky Mountain spotted fever. (Used with permission from Gary Marshall, MD and MMWR, Diagnosis and Management of Tick-borne Rickettsial Diseases: Rocky Mountain Spotted Fever, Ehrlichiosis, and Anaplasmosis—United States. March 13, 2006/55(RR04);1–27. http://www.cdc.gov/mmwr.)

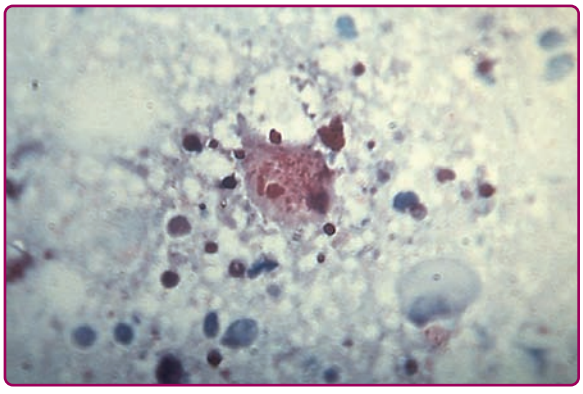

Figure 199-5 Gimenez stain of Rocky Mountain spotted fever in tick lymph cells. [From the Centers for Disease Control and Prevention (http://www.cdc.gov/ncidod/dvrd/rmsf/organism.htm.)]

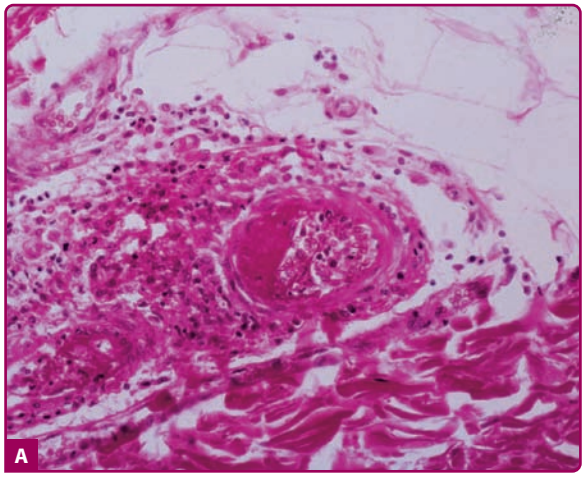
leukocytoclastic vasculitis. Basal cell vacuolization, lymphocytic exocytosis, fibrin thrombi, and capillary wall necrosis can also be appreciated. Immunohistology reveals positive staining for *R. rickettsii* in infected endothelial cells and tick hemolymph. (Fig. 199-5.) Most rickettsial diseases share a similar histology.

Diagnosis and Differential Diagnosis. Serologic examination using the indirect immunofluorescence assay (IFA) is the gold standard for diagnosis of RMSF. It detects convalescent antibodies (at a diagnostic titer of ≥64 IgG and ≥32 IgM) but is seldom diagnostic before the seventh day of disease, and often not until far into the second week. An effective treatment for RMSF should begin by the fifth day of illness. It is vital to begin empiric therapy while awaiting serologies. Because of inferior sensitivity and specificity, the Weil–Felix test (agglutination of certain *Proteus* sp.) and complement fixation tests have been largely supplanted by newer diagnostic methods. Immunohistochemical staining of skin or organ tissue biopsy and polymerase chain reaction (PCR) may also confirm the diagnosis.[9]

When a patient presents without a rash, the differential diagnosis for RMSF is broad (Boxes 199-1 and 199-2). Macules and papules, petechiae, or purpuric lesions may sometimes develop in these diseases as well, further precluding the ability to distinguish them from RMSF on clinical grounds alone.

Treatment. Tetracyclines, specifically doxycycline, are the drugs of choice for all rickettsial diseases in patients of all ages, even during pregnancy. The use of tetracyclines in children with RMSF is no longer a subject of controversy. Although repeated exposure to tetracycline increases the risk of tooth staining, studies suggest that limited use of this antibiotic in children during the first 6–7 years of life has a negligible effect on the color of permanent incisors.[10] Sulfa-based medications are not recommended, as they may result in a more complicated disease course.[11]



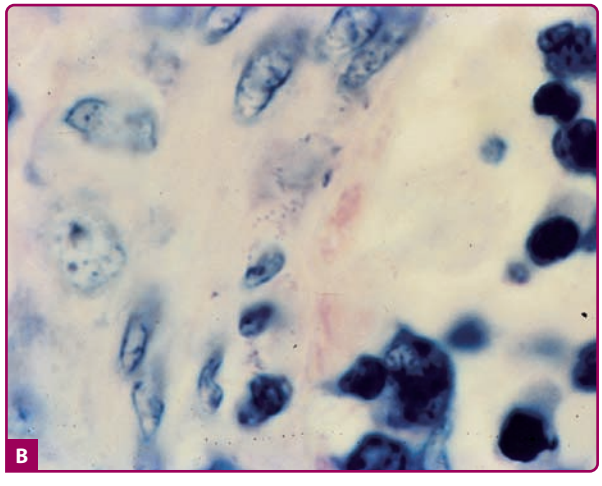


Figure 199-4 **A.** Vascular lesion of Rocky Mountain spotted fever as seen in an arteriole in the skin. An early thrombus is present. **B.** Rickettsiae are seen in endothelial cells from a biopsy of a cutaneous lesion.

BOX 199-1 DIFFERENTIAL DIAGNOSIS OF RICKETTSIAL AND EHRLICHIAL DISEASES

Most Likely

- Enteroviral infection (e.g., coxsackievirus, echovirus)
- Roseola infantum (human herpesvirus 6)
- Drug eruption
- Group A streptococcal pharyngitis
- Vasculitis
- Kawasaki disease
- Measles (coryza, Koplik's spots, cough)
- Epstein–Barr virus/infectious mononucleosis

Consider

- Viral meningoencephalitis
- *Mycoplasma pneumoniae* infection
- Parvovirus B19
- Tularemia
- Leptospirosis
- Immune complex mediated illness
- Atypical erythema multiforme
- Typhoid fever
- Dengue
- Viral hemorrhagic fevers (Ebola, Marburg, Lassa)

Always Rule Out

- Meningococcemia (more rapid-onset rash and leukocytosis, but both may show gangrenous lesions)
- Disseminated gonococcal infection
- Lyme disease
- Tick-borne viral fevers (e.g., Colorado tick fever)
- Thrombotic thrombocytopenic purpura and immune thrombocytopenic purpura
- Toxic shock syndrome
- Stevens–Johnson syndrome
- Secondary syphilis

Chloramphenicol may be used if tetracyclines are contraindicated because of allergies. Side effects include aplastic anemia, reversible bone marrow suppression, and gray baby syndrome in near-term gravidae,[12] Aggressive supportive care is crucial, with particular attention to electrolyte and fluid balance. Treatment and management strategies for RMSF are listed in Table 199-1 and Box 199-3.

Fulminant RMSF leading to more rapid decompensation has characteristically been reported in chronic alcoholics and black males with glucose-6-phosphate dehydrogenase deficiency. These patients have a higher risk of cutaneous necrosis.[3] Prompt empiric administration of appropriate antibiotic therapy is recommended, as it is the most important factor affecting survival.

Prevention. Avoiding tick exposure, wearing protective clothing, performing tick checks regularly while in tick-infested areas, and proper tick extractions are important for lowering the risk of infection. Chemical repellants, such as diethyltoluamide (DEET) in concentrations up to 35%, are safe for use in adults and children. Prophylactic antibiotics after tick exposure are not recommended. Despite its life-threatening nature, vaccine development remains to be a low priority because of the availability of safe and effective antibiotics,[13]

OTHER SPOTTED FEVERS

Tick-Bite Associated

Mediterranean Spotted Fever and African Tick Bite Fever. Several other tick-borne rickettsial species are pathogenic to humans. Mediterranean spotted fever (MSF), also known as *Boutonneuse fever* or *Marseille fever*, caused by *Rickettsia conorii*, was first documented as a cause of human rickettsial disease is 1932. MSF is the prototypical illness of the non-RMSF spotted fever group. African tick bite fever (ATBF), caused by *Rickettsia africae*, is a distinct clinical entity.

Epidemiology. *R. conorii* is transmitted by an infected *Rhipicephalus sanguineus* tick (see Fig. 199-1) and is endemic throughout Africa, the Middle East, and Southern Europe. Contact with dogs is reported in up to 90% of cases of MSF. Epidemiologic characteristics of MSF are summarized in Table 199-1. *R. africae* is transmitted by an infected *Amblyomma* tick endemic to sub-Saharan Africa.

Clinical and Laboratory Findings. The constitutional symptoms, systemic complications, and laboratory abnormalities of the tick-bite–associated spotted fevers are similar to those of RMSF. The classic cutaneous hallmark of this group is the tache noir, occurring in about 13%–68% of patients with *R. conorii* infection (Fig. 199-6A).[14] The tache noir occurs at the site of inoculation as an erythematous, indurated papule with a central necrotic eschar that represents locally aggressive endothelial invasion by rickettsiae. Temporal and morphologic pattern of the rash in this group of spotted fevers is similar to RMSF; however, the eruption may be more diffuse and is less frequently petechial or purpuric (see Fig. 199-6B). The presence of multiple tick bites, multiple eschars (seen in 50% of patients with ATBF), and lymphadenitis, distinguish ATBF from MSF,[1] although children with MSF may have cervical lymphadenopathy.[14]

Diagnosis and Differential Diagnosis. Like RMSF, diagnosis of MSF or ATBF is by IFA. Biopsy from an eschar for immunohistochemistry is particularly sensitive in MSF. PCR or western blot analysis can be used to differentiate between *R. conorii* and *R. africae.* Newer serologic assays and PCR have been useful in identifying the numerous emerging agents of spotted fever around the globe, including *Rickettsia japonica* (Japanese spotted fever) and *Rickettsia slovaca*.[1] *R. slovaca*, along with *Rickettsia raoultii* have been associated with TIBOLA/DEBONEL (tick-borne lymphadenopathy/*Dermacentor*-borne necrosis erythema and lymphadenopathy), a recently recognized

BOX 199-2 SELECTED DIFFERENTIAL DIAGNOSIS OF FEVER AND ERYTHEMATOUS OR PETECHIAL RASH

DISEASE	AGENT	SEASON	ONSET	CLINICAL FEATURES
Rocky Mountain spotted fever	*Rickettsia rickettsii*	Spring to summer	Fever, headache, malaise, gastrointestinal symptoms, rash after 2–4 days; rapid progression to severe systemic illness	Rash starting on ankles/wrists, spreads centripetally, may involve palms/soles, progresses from erythematous macules to petechiae
Endemic (murine) typhus	*Rickettsia typhi*	Sporadic	Fever, malaise, headache, rash after 4–5 days	Erythematous macules and/or papules involving trunk >extremities
Human monocytic ehrlichiosis	*Ehrlichia chaffeensis*	Spring to summer	Fever malaise, headache, rash in ~30% of patients	Erythematous macules and/or papules, or petechial rash; more common in children >adults
Meningococcal disease	*Neisseria meningitidis*	Year-round, but more common late winter to early spring	Fever and rash within 24 h, rapid progression to severe systemic illness.	Erythematous macules and/or papules, petechiae usually beginning on lower extremities and spreads centripetally. Toxic appearing.
Group A streptococcal pharyngitis	*Streptococcus pyogenes*	Fall to winter	Abrupt onset of fever and sore throat, malaise; rash follows acute illness	May cause petechial rash in children who appear well
Fifth disease (erythema infectiosum)	Human parvovirus B19	Late winter to early summer	Low fever and mild constitutional signs before rash onset	"Slapped cheek" appearing erythematous rash on face, lacy erythematous rash on trunk. Papular-purpuric gloves and socks syndrome—young adults
Roseola infantum	Human herpesvirus 6	Year-round	Fever 3–5 days, then rash, commonly in children <2 years of age	Morbilliform rash begins on trunk, spreads and fades rapidly
Enteroviral infection	Echovirus, coxsackie viruses, other non-polio enteroviruses	Summer to early fall most commonly, but occurs year-round	Nonspecific febrile illness, with or without rash	Fine morbilliform rash at fever onset; begins on face and spreads caudally; occasionally petechial

Adapted from MMWR, Centers for Disease Control and Prevention: Diagnosis and Management of Tickborne Rickettsial Diseases: Rocky Mountain Spotted Fever, Ehrlichioses, and Anaplasmosis—United States. March 31, 2006/55(RR04), p 1–27, http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5504a1.htm.

BOX 199-3 MANAGEMENT OF RICKETTSIAL, EHRLICHIAL, AND *ANAPLASMA* INFECTIONS

- Delays in treatment can lead to severe sequelae and fatal outcome.
- Clinical history, symptoms, physical exam, and laboratory findings should guide approach to management and treatment.
- Clinicians may consider a "watch-and-wait" approach for 24–48 h for patients early in the course of illness who have nonsupporting history, nonspecific clinical signs, and normal lab findings.
- Doxycycline is the drug of choice for the treatment of presumptive or confirmed rickettsial disease in both adults and children.
- Limited courses of tetracycline-class antibiotics (e.g., doxycycline) do not pose a substantial threat of tooth staining in children.
- Tetracyclines are typically contraindicated in pregnancy but may be warranted in life-threatening cases of Rocky Mountain spotted fever when clinical suspicion arises.
- When early invasive meningococcal infection cannot be ruled out, antibiotics for *Neisseria meningitides must be started.*
- Prophylactic use of antibiotics after a tick bite is not recommended, as atypical presentations may result, delaying adequate diagnosis and treatment. If prophylaxis is given, a full 10-day course should be administered.
- In patients for whom tetracyclines are absolutely contraindicated, chloramphenicol can be used for rickettsial disease; rifampin or rifabutin may be considered for the ehrlichioses/anaplasmosis.
- When treating ehrlichial infections, consider continuation for 14–21 days to allow for adequate treatment of concomitant Lyme disease in areas endemic for *Borrelia burgdorferi.*

Adapted from MMWR, Centers for Disease Control and Prevention: Diagnosis and Management of Tickborne Rickettsial Diseases: Rocky Mountain Spotted Fever, Ehrlichioses, and Anaplasmosis—United States. March 31, 2006/55(RR04), p 1–27, http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5504a1.htm.

rickettsial disease associated with eschar formation at the tick-bite site and painful lymphadenopathy. TIBOLA/DEBONEL is usually seen in the pediatric population with tick-bites involving the scalp.[15]

The rash of MSF generates a similar differential diagnosis as that of RMSF. If a tache noir is seen, one must also consider brown recluse spider bite, cutaneous anthrax, scrub typhus, rickettsialpox, aspergillosis, or mucormycosis.

Treatment. Guidelines for the treatment of MSF are outlined in Table 199-1. Overall, non-RMSF spotted fevers run a less aggressive course than RMSF. However, MSF has been reported to cause severe cardiac, renal and neurologic complications, as well as death in about 1% of cases.[14] In general, all non-RMSF spotted fevers are treated similarly to MSF. Macrolide antibiotics may offer a better risk/benefit ratio than tetracyclines in the pediatric age group, however, doxycycline is still first-line therapy.[16]

Mite-Bite Associated

Rickettsialpox. Rickettsialpox is an acute, self-limited, febrile disease so named because of its clinical resemblance to varicella (chickenpox). Its etiologic agent is *Rickettsia akari*. *Mus musculus*, the house mouse, is the reservoir, and the vector is the rodent mite, *Liponyssoides sanguineus* (formerly *Allodermanyssus sanguineus*).[17] The colorless rodent mite inflicts a painless bite and is too small to be readily recognized by the victim.

Epidemiology. Most cases of rickettsialpox in the United States have occurred in large metropolitan areas of the Northeastern United States, with approximately one-half of the cases reported from New York City alone. Table 199-1 describes the salient epidemiologic features of rickettsialpox.

Clinical and Laboratory Findings. A primary lesion occurs at the site of the mite bite as early as 1–2 days after transmission. It consists of a painless, erythematous, indurated papule ranging in size from 0.5–3.0 cm. Vesicle formation is followed by desiccation which produces an eschar to form the characteristic tache noir (Fig. 199-7). Regional lymphadenopathy is common. Resolution of the primary lesion occurs within 1 month.

Approximately 7 days after the primary lesion appears, fever, chills, diaphoresis, myalgia (often manifesting as backache), malaise, and headache begin. The fever persists with remissions for about 1 week before abating. Two to three days after the onset of systemic symptoms, a generalized papulovesicular eruption occurs (Fig. 199-7B). Small vesicles or pustules appear with subsequent central crust formation. Roughly 5–40 lesions may be found, typically resolving in 1 week. Less frequently, an enanthem, photophobia, generalized lymphadenopathy, and gastrointestinal symptoms may be noted. Thrombocytopenia is common during the acute febrile illness, and a mild leukopenia with a relative lymphocytosis may be seen.

Pathology. In contrast to RMSF, MSF, ATBF, and typhus group Rickettsioses, the perivascular macrophage, not the endothelial cell, appears to be the target of *R. akari*. Primary lesions are characterized by extensive necrosis and an acute inflammatory infiltrate. Secondary papulovesicular lesions display a subepidermal split with superficial edema, and a perivascular lymphohistiocytic infiltrate that can become vasculitic.

Diagnosis and Differential Diagnosis. Antibody titers peak after 3–4 weeks and could be delayed for up to 8 weeks with antibiotic use. Biopsy for direct immunofluorescence (DIF) with anti-*R. rickettsii* immunoglobulin is highly sensitive; however, due to cross-reactivity among the spotted fever group rickettsiae, confirmatory cross-adsorption testing may be

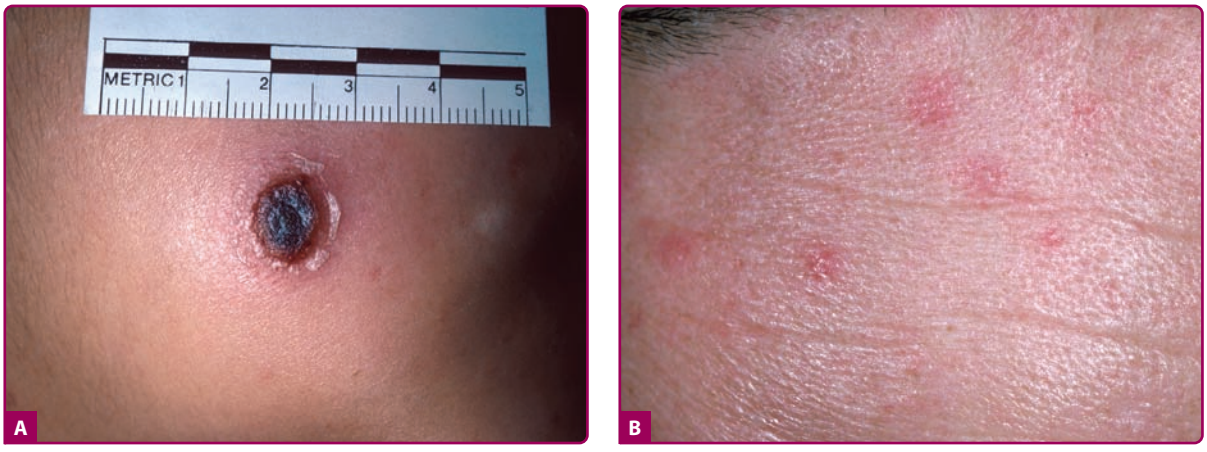

Figure 199-7 **A.** Rickettsialpox: Tache noir. A crusted, ulcerated lesion with eschar and a faint red halo at the site of the mite bite. **B.** Mediterranean spotted fever, 32-year-old Caucasian male with eschar on thigh, followed by fever, and erythematous papules and small pustules. (Used with permission from VisualDx. Copyright Logical Images, Inc.)

considered with *R. akari* and *R. rickettsii* antigens. Tissue for DIF should be taken from a primary eschar, as lesions from the generalized eruption do not contain enough inoculum to become positive by DIF. If immunohistochemistry is inconclusive, PCR can be used to confirm infection.[18]

The differential diagnosis includes varicella, smallpox, gonococcemia, infectious mononucleosis, echovirus (types 9 and 16), and coxsackievirus infection (A9, A16, and B5), in addition to those diseases discussed under the differential diagnosis of MSF. In varicella, one observes a "dewdrop on a rose petal," referring to a primarily vesicular lesion surrounded by macular erythema. This is distinct from the erythematous papule surmounted by a vesicle seen with rickettsialpox.[17] Fever occurs with the rash of varicella but precedes the eruption of rickettsialpox.

Treatment. Rickettsialpox is self-limited. Even without antibiotics, it will resolve within 2 weeks. In the rare severe case, tetracycline antibiotics continued for up to 5 days are the most effective therapy; defervescence is typical within 48 hours.[17]

TYPHUS GROUP

ENDEMIC TYPHUS (MURINE OR FLEA-BORNE TYPHUS).

Endemic typhus is caused mainly by *Rickettsia typhi*, and is classically transmitted to humans by the rat flea (*Xenopsylla cheopis*), with rats serving as the reservoir. *Rickettsia felis* has recently emerged as an important agent of endemic typhus with characteristics of both the typhus and spotted fever group rickettsiae. *R. felis* has been identified in peridomestic cats, dogs, opossums, and their fleas (e.g., cat flea, *Ctenocephalides felis*) in parts of southern Texas, southern California, and Mexico.[19,20]

Epidemiology. Murine typhus has been reported from all continents except Antarctica, although most cases today occur in Africa. It is most likely underdiagnosed and mistaken for a viral illness since flea bites are not usually recalled and most cases are self-limited.[21] Epidemiologic characteristics are outlined in Table 199-1.

Clinical and Laboratory Findings. Most infected persons experience fever, headache, backache, and joint pain 6–14 days after contact with an infected flea. Nonspecific gastrointestinal symptoms may be present, especially in children.[22] Extremely high fever, 41.1°C (106°F), may last up to 2 weeks. Commonly, a rash begins on the chest and spreads to the sides and back. The palms and soles are rarely involved. The rash may last only a few hours and consists of erythematous macules and/or papules. Petechiae are found infrequently. Rash is seen in less than 20% of patients at presentation. Fifty to sixty percent of patients will develop a rash over the course of the illness, with a median onset of 6 days after the onset of fever.[19] More severe complications are uncommon but may include seizures, meningoencephalitis, retinitis, acute hepatitis, endocarditis, renal insufficiency, pneumonia, and respiratory failure. Thrombocytopenia, transaminitis, and hyponatremia are common, though usually mild.

Diagnosis and Differential Diagnosis. Diagnostic IFA titers are present in 50% of patients by day 7, virtually in 100% of patients by day 15; however, these may not distinguish between endemic and epidemic typhus. Western blot and cross-adsorption studies can differentiate the two diseases, however, they require expensive, specialized laboratories.[21] The differential diagnosis of endemic typhus is broad as a result of the nonspecific nature of the cutaneous eruption (see Box 199-2).

Treatment. Treatment for endemic typhus is similar to that of RMSF (see Table 199-1). With institution of appropriate antibiotics, fever typically resolves in 2–3 days. Spontaneous recovery often occurs within 2 weeks in untreated patients. Prior infection with *R. typhi* provides lifelong immunity to subsequent infection.

EPIDEMIC (LOUSE-BORNE) TYPHUS.

Epidemic typhus (also called *prison fever, famine fever*, or

ship fever) is caused by *R. prowazekii*, and is transmitted to humans primarily via the body louse (*Pediculus humanus* var. *corporis*). Epidemic typhus may result in long-term latent asymptomatic infection. A re-emergence of the illness known as Brill–Zinsser disease (BZD) can occur in survivors who may suffer recrudescent infection, even decades after the initial infection.

Epidemiology. Louse infestation occurs when cold weather, poor hygiene, crowding, and poverty are prevalent. These conditions are most commonly found today in refugee camps, and among the homeless and imprisoned. The most recent outbreak of epidemic typhus occurred in refugee camps in Burundi during the mid-1990s.[23] Table 199-1 details the epidemiologic characteristics of epidemic typhus.

The major reservoir for disease is humans, with lice acquiring the infection by feeding on persons with primary illness or BZD. The lice are spread through close personal contact or infested clothing. The infected louse will defecate while taking a blood meal, and the organisms in the feces are then scratched into the skin, enabling transmission. Lice die of infection within 3 weeks, however, their feces can be infectious for up to 100 days, therefore allowing human-to-human transmission through clothes or close contact. Contact with southern flying squirrels (*Glaucomys volans*) is associated with outbreaks of epidemic typhus in the Eastern United States, where the fleas or lice from these rodents can be important vectors.[24]

Clinical and Laboratory Findings. After an incubation period of 1–2 weeks, abrupt onset of intractable headache, fever [to 40°C (104°F)], chills, and myalgia occurs. If left untreated, prostration due to overwhelming hypotension and vascular collapse may ensue. Typically, a rash begins in the axillary folds and upper trunk on the fifth day of illness. Initial lesions consist of erythematous macules that become papular and petechial over several days. In contrast with most rickettsial diseases, the eruption spreads centrifugally but spares the face, palms, and soles. Complications include acral gangrene, cerebral thrombosis, and other neurologic sequelae, multiorgan system failure, and death. Laboratory abnormalities include thrombocytopenia, elevated transaminases, and elevated lactate dehydrogenase. Leukocytosis is seen in a minority of patients.

BZD occurs as a recrudescence of previous infection with *R. prowazekii*. Provocation by immunologic stress induced by poor living conditions may play a role. The illness is usually milder than the primary disease. In the United States it was most commonly seen in those who were exposed to epidemic typhus in World War II.

Diagnosis and Differential Diagnosis. Techniques for diagnosis are identical to those used for other rickettsial diseases, with the IFA test the most widely used method. The differential diagnosis is similar to that of endemic typhus. The diagnosis of epidemic typhus should be considered when the appropriate clinical characteristics are seen in the setting of known or suspected louse infestation, or, in the United States, when a history of an exposure to flying squirrels is elicited. The centrifugal spread, lack of eschar, and predilection for colder months helps differentiate epidemic typhus from other rickettsial infections. Endemic typhus is typically less severe than epidemic typhus. When lice and rats are both prevalent (poor hygienic conditions, prison, etc.), a risk exists for both diseases. In such situations, it is critical to discriminate between *R. typhi* and *R. prowazekii* infections, as the latter has markedly greater epidemic potential.

Treatment. Fatal illness is rare if proper therapy is initiated early (see Table 199-1). Although a single dose of doxycycline may be curative, optimal therapy should be continued for 2–3 days after defervescence. BZD is treated identically to primary epidemic typhus. Therapy failures have been documented with azithromycin for BZD.[25]

Prevention. Prevention begins with regular bathing and clothes washing. Delousing with appropriate agents, such as permethrin, malathion, lindane or DDT, is effective. A vaccine is available, but recommended only for high-risk groups.

SCRUB TYPHUS.

Scrub typhus (*Tsutsugamushi fever* or *chigger fever)*, is a mite-transmitted zoonosis caused by *Orientia tsutsugamushi*. The vector is the larval stage (chigger) of the trombiculid mite (*Leptotrombidium deliense* and other *Leptotrombidium* sp.). The mites and the rodents that carry them serve as the major reservoirs.

Epidemiology. Named for the type of vegetation that harbors the mite vector, scrub typhus is endemic to a region spanning the Indian subcontinent to Eastern Asia and the Western Pacific Rim (Japan, Korea, India, Pakistan, Taiwan, Southeast Asia, and Australia). Scrub vegetation is a transitional terrain between tall forests and cleared land, composed of plantations, fields, groves, and tall grass. Accordingly, the illness is more common in rural settings and is a common occupational disease. Because of the long incubation period, scrub typhus can present in travelers returning to nonepidemic areas.

Clinical and Laboratory Findings. An erythematous papule appears within 2 days of the chigger bite and undergoes ulceration and eschar formation in one-half to two-thirds of patients. The eschar may be absent in intertriginous areas. Regional lymphadenopathy is followed by generalized lymphadenopathy. One to 2 weeks after the bite, there is a sudden onset of high fever [40°–40.6°C, (104°–105°F)]. Chills, headache, cough, myalgia, anorexia, nausea, diarrhea, dyspnea, ocular pain, and conjunctival injection are variably present. A centrifugal macular and then papular eruption occurs in approximately 35% of cases about 4–5 days after the fever begins. The eruption starts on the trunk, spreads to the extremities, and fades within a few days. Hepatosplenomegaly and a relative bradycardia may be appreciated. Severe complications include adult respiratory distress syndrome, myocarditis, pericarditis, disseminated intravascular

coagulation, hemophagocytic syndrome, retinal vein occlusion, renal failure, and hepatitis. Nuchal rigidity, meningoencephalitis, tremors, slurred speech, deafness, and tinnitus are seen rarely. Examination of the cerebrospinal fluid in these cases reveals only a slight monocytosis.

Diagnosis and Differential Diagnosis. The differential diagnosis is similar to that for endemic typhus. Enzyme-linked immunosorbent assay, dot blot urine immunoassay, rapid immunochromatographic flow assay, and PCR have the greatest sensitivity and specificity but are limited by their availability in endemic areas. Diagnostically, IFA remains the gold standard. Conclusive diagnosis is based on a fourfold increase in titer of paired samples drawn at least 2 weeks apart. A single acute titer of more than 1:50 can be used as a preliminary diagnostic cutoff in travelers returning from endemic areas.[26] In 2009, an association was reported between high *O. tsutsugamushi* DNA loads determined by PCR and disease severity.[27]

Treatment. Although single dose or short courses (3 days) of doxycycline may prove to be efficacious, treatment is recommended for 14 days. Naturally occurring doxycycline- and chloramphenicol-resistant strains of *O. tsutsugamushi* have been found in Northern Thailand, Azithromycin, rifampin, and ciprofloxacin are alternatives in this setting.[28] With the institution of proper antibiotics, defervescence occurs abruptly, usually within 24 hours. In untreated patients, fever lasts for about 2 weeks. Vaccine development has yielded disappointing results; however, is crucial in this era of antibiotic resistance.[29]

Prevention. DEET applied to the skin or impregnated into clothing is effective at preventing transmission. Chemoprophylaxis with weekly doxycycline may be efficacious when traveling to endemic areas. Rodent control may paradoxically increase the risk of human disease as chiggers lose their natural host and target humans.

THE EHRLICHIOSES.

The ehrlichial pathogens were reclassified following the identification in 1994 of the so-called *HGE* agent responsible for causing human granulocytic ehrlichiosis. Based on distinct phylogenetic and pathogenic characteristics, this organism was assigned its own genus, *Anaplasma*, and the disease associated with it was renamed human granulocytic anaplasmosis (HGA).[6]

Epidemiology. Human disease attributed to ehrlichial organisms has been reported in the United States since 1986. The causative agent of human monocytic ehrlichiosis (HME) is *Ehrlichia chaffeensis*, and the main reservoirs are deer, dogs, and coyote. The white-footed mouse (*Peromyscus leucopus*) and white-tailed deer (*Odocoileus virginianus*) are the principal reservoirs for *Anaplasma phagocytophilum*, the causative agent of HGA. Table 199-1 describes the principal epidemiologic characteristics of HME and HGA.

HGA infection occurs in a geographic pattern identical to that of Lyme disease (*Borrelia burgdorferi*) (see Chapter 187), namely in the Northeastern United States, parts of the Pacific Northwest, and the upper Midwest United States. The vector for both HGA and Lyme is the *Ixodes* tick (see Fig. 199-1D and E). In addition to *A. phagocytophilium* and *Borrelia burgdorferi*, *Ixodes* ticks can transmit *Babesia microti*, *Borrelia afzelii*, and *Borrelia garinii*. Not surprisingly, most cases of HGA are found in areas with high incidences of Lyme disease and babesiosis.

The lone star tick (*Amblyomma americanum*) and the American dog tick (*D. variabilis*), the vectors of *E. chaffeensis*, also transmit *R. rickettsii* and *Francisella tularensis*, the causative agents of RMSF and tularemia (see Chapter 180), respectively (see Fig. 199-1). It is essential to consider possible coinfection with these potentially life-threatening organisms in patients with known or suspected ehrlichial disease. Though mainly a tick-borne disease, HGA has been reported after blood transfusions, whereas HGE has been believed to occur after contact with contaminated animal tissue.[30,31]

Etiology and Pathogenesis. Ehrlichiae and Anaplasmodiae are small, obligate intracellular bacteria. *E. chaffeensis* is trophic for monocytic cells, whereas *A. phagocytophilum* prefer myeloid or granulocytic cells. The organisms grow within membrane-bound vacuoles, and form intracytoplasmic microcolonies called morulae, which may be seen in peripheral blood smears.[6,32]

Clinical and Laboratory Findings. There is substantial overlap in the clinical presentation and laboratory evaluation of patients with HME, HGA, and RMSF (see Table 199-2). Patients give a history of a tick bite in only about 68% of cases of ehrlichiosis. The clinical course ranges from asymptomatic seroconversion to multisystem organ failure and death (see Table 199-2) The rash of HME is often indistinguishable from that of RMSF, and can present as erythematous macules and papules, petechiae, or as a diffuse erythema. It is observed in approximately 33% of adults and 66% of children with HME. Rash is rare in HGA, the absence of a rash in a patient with systemic findings suggestive of RMSF should prompt consideration of anaplasmosis. Conversely, if a rash is present in a patient with anaplasmosis, coinfection with meningococcus, *R. rickettsii*, or *B. burgdorferi* should be considered. Laboratory abnormalities include leukopenia (often with a left shift), thrombocytopenia, and elevated transaminases. Despite similar presentations, HME usually has a more severe progression and higher case fatality ratio, whereas HMA has a higher prevalence of opportunistic infections.[33]

Pathology. In contrast to the rickettsioses, endothelial cell injury or frank vasculitis are not a typical feature. A single retrospective case study suggests HME may rarely be associated with cutaneous vasculitis such as polyarteritis nodosa.[34]

Diagnosis and Differential Diagnosis. Clinical illness nearly always precedes laboratory diagnosis by any method. Morulae stained with Wright or Giemsa stains are occasionally observed inside the leukocytes

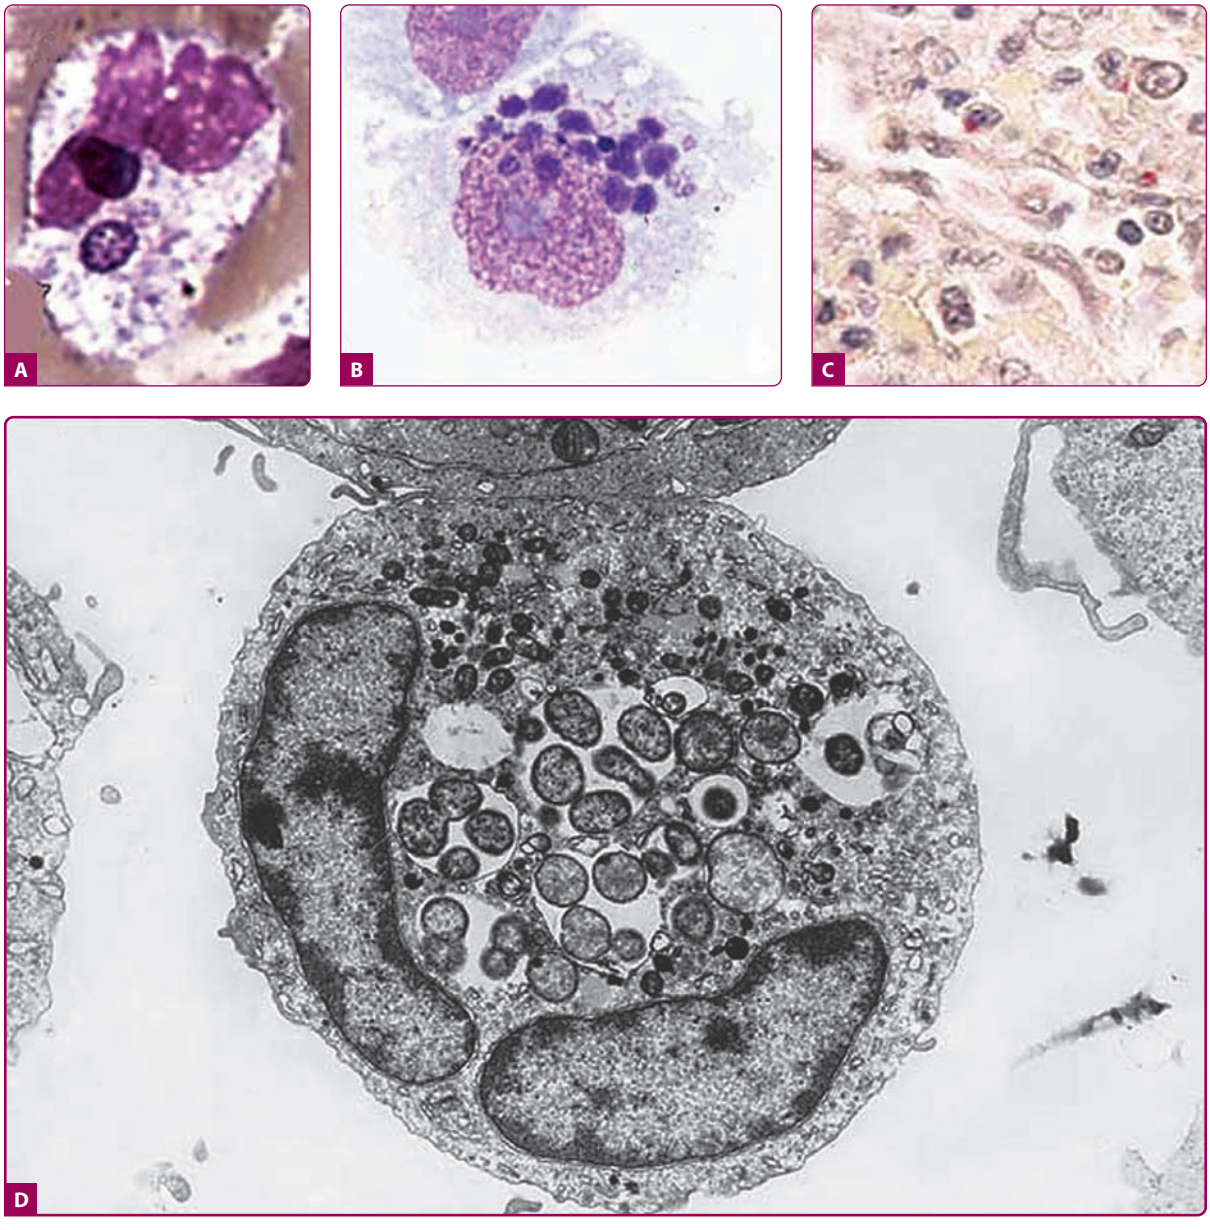

Figure 199-8 **A.** *Anaplasma phagocytophilum* in human peripheral blood band neutrophil (Wright stain, original magnification × 1000). **B.** *A. phagocytophilum* in THP-1 myelomonocytic cell culture (Leukostat stain, original magnification × 400). **C.** *A. phagocytophilum* in neutrophils infiltrating human spleen (immunohistochemistry with hematoxylin counterstain; original magnification × 100). **D.** *A. phagocytophilum* ultrastructure by transmission electron microscopy in HL-60 cell culture (original magnification × 21,960). (Used with permission from Dumler JS et al: Human granulocytic anaplasmosis and Anaplasma phagocytophilum. *Emerg Infect Dis* **11**:1828, 2005. Available from http://www.cdc.gov/ncidod/EID/vol11no12/05–0898.htm.)

in peripheral blood smears, buffy coat preparations, or cerebrospinal fluid, usually during the first week of infection (Fig. 199-8). Smear sensitivities are low and variably dependent upon the experience of the microscopist.[32] Therefore, a negative smear should not delay treatment. False positives can occur with toxic granulation, superimposed platelets, and Döhle's bodies.

Confirmatory testing should be performed with serologic assays available through commercial and state public health laboratories. The sensitivity of the IFA is dependent on the timing of collection and is estimated to be 94%–100% sensitive after 14 days. Paired serum samples taken 2–3 weeks apart should demonstrate a fourfold rise in titers. PCR of whole blood may be more useful than tissue biopsy in HME and HGA, as these pathogens are trophic for circulating leukocytes. Immunohistochemical staining of formalin-fixed, paraffin-embedded tissue may be useful for documenting infection in the first 48 hours of disease.[6]

The differential diagnosis is extensive and similar to RMSF (see Boxes 199-1 and 199-2). The presence of a rash, normal white blood cell count, lack of morulae, and pathologic evidence of vasculitis is more consistent with RMSF.

Treatment. The median duration of disease is 1–2 weeks with treatment. Defervescence usually occurs within 1–2 days. Table 199-1 and Box 199-3 detail appropriate therapy. Treatment with doxycycline for 5–14 days is generally effective, but continued therapy for 14–21 days is indicated if coinfection with *B. burgdorferi* is suspected.[6,32]

Prevention. Preventive measures include avoidance of tick exposure, use of chemical repellants such as DEET, light-colored clothing (to visualize ticks), and careful removal of attached ticks.

SECTION 32

Sexually Transmitted Diseases

Chapter 200 :: Syphilis

:: Kenneth A. Katz

SYPHILIS AT A GLANCE

- A disease caused by the spirochete *Treponema pallidum* subspecies *pallidum* that is usually sexually transmitted.
- In the United States, syphilis disproportionately affects men who have sex with men and blacks.
- The most common and recognizable manifestations are usually cutaneous.
- Syphilis passes through four distinct clinical phases:
  1. Primary stage, characterized by a chancre.
  2. Secondary stage, characterized typically by skin eruption(s) with or without lymphadenopathy and organ disease.
  3. A latent period of varied duration, characterized by the absence of signs or symptoms of disease, with only reactive serologic tests as evidence of infection.
  4. Tertiary stage, with cutaneous, neurologic, or cardiovascular manifestations.
- The recommended treatment for most types of syphilis is benzathine penicillin G, with dose and administration schedule determined by disease stage.
- Persons with human immunodeficiency virus infection are at higher risk of treatment failure and to neurosyphilis.

Syphilis is an infection caused by *Treponema pallidum* subspecies *pallidum*. It can cause serious disease in persons who acquire it after birth and especially devastating disease in persons who acquire it in utero. Many of its manifestations are cutaneous, making it of interest and importance to dermatologists, especially as morbidity from syphilis rises in the developed world and continues in the developing world.

HISTORY

Whether syphilis arose in the New World, the Old World, or both remains a controversial subject.[1–3] Pandemics of syphilis began in the Old World in Naples, Italy, 1 year after Columbus returned from the New World.[2,4,5] Syphilis was much more virulent then, earning it the monicker "great pox,"[4] to distinguish it from another virulent disease with cutaneous manifestations, smallpox. The disease takes its name from a poem, called *Syphilis, Sive Morbus Gallicus* (*Syphilis, or the French Disease*), written in 1530 by Giralomo Fracastoro, a physician and poet of Verona. Part of the poem recounts the story of a shepherd, named Syphilus, who, as punishment for angering Apollo, was afflicted with the disease known as syphilis.[5] Other names besides Morbus Gallicus and the Great Pox by which the disease has been known include lues, the Great Mimic, the Great Masquerader, the Great Imitator, and the Neapolitan disease.[5] The cause of syphilis, the bacterium *T. pallidum*, was discovered by Schaudinn and Hoffman in 1905.[6] Darkfield microscopy and serologic testing for syphilis were pioneered, respectively, in 1906 by Landsteiner and in 1910 by Wasserman.[4]

Syphilis historically has been of major interest to dermatologists, who were leaders in syphilis research and treatment in Europe and the United States.[7–12] One of the leading American dermatology journals, currently called *Archives of Dermatology*, was before 1955 called *Archives of Dermatology and Syphilology*. An editorial explaining the jettisoning of "Syphilology" from the journal's title stated as follows:

> *The diagnosis and treatment of patients with syphilis is no longer an important part of dermatologic practice. The papers on syphilis that are now submitted to the Archives are few and far between. Few dermatologists now have patients with syphilis; in fact, there are decidedly fewer patients with syphilis, and so continuance of the old label, "Syphilology," on this publication seems no longer warranted.*

Elsewhere in the world, however, the link between dermatology and syphilology (and other sexually transmitted diseases) remains stronger.[13,14]

Treatments for syphilis in the prepenicillin era included burning sores with hot irons, rubbing mercury-containing ointments on lesions and other parts of the body, administering mercury orally, and treating with arsenicals, including salvarsan (also called "606" or arsphenamine), which was discovered by Ehrlich and Hata in 1909.[4] Heat treatments were also used. Recognition that *T. pallidum* was heat sensitive led the Viennese psychiatrist Julius Wagner von Jauregg to develop syphilis malariotherapy in 1917,[15] an accomplishment for which he received the Nobel Prize in Medicine in 1927.[16] That therapy involved inoculating syphilis patients with malaria, allowing them to experience, optimally, between 10 and 12 febrile episodes, and then treating them with quinine.[10,16–18] The treatment reportedly led to complete or partial remission of general paresis in a substantial proportion of patients, though it killed an estimated 10% of those receiving the therapy.[17] Heat therapy through malaria inoculation and through other means was practiced in the United States until the early 1950s, when use of penicillin became widespread.[10]

Two studies have provided the most insight into the natural history of syphilis. The first was a retrospective study of approximately 2,000 persons with syphilis in Oslo, where mercury treatments standard in other places were not used.[18] The second was the infamous Tuskegee syphilis study, in which 399 black men with late syphilis from Alabama were prospectively followed from 1932 to 1972.[19] The men were denied treatment for syphilis, even after the discovery of the effectiveness of penicillin for the disease. There were multiple other serious ethical lapses in the study. The aftermath of the study lead to major changes in ethical requirements for conducting clinical research in the United States.[20]

In addition to being more virulent than it is currently, syphilis was also much more common. Of historical interest, persons said to have suffered from syphilis include Ivan the Terrible, Henry VIII, Henri de Toulouse-Lautrec, and Al Capone,[4] and among many others.[21] Osler, aware of the high prevalence and protean manifestations of syphilis, has been quoted as saying "He who knows syphilis knows medicine."[4] By the early 1930s, it was estimated that approximately 10% of Americans had syphilis, with 500,000 new infections and 60,000 cases of congenital syphilis per year.[22] In 1937, Sugeon General Thomas Parran, keenly interested in syphilis, published a book, titled *Shadow on the Land*,[23] that focused on the substantial public health harms of the then-prevalent disease.[22] Parran prioritized syphilis prevention and control, emphasizing screening, treatment, community involvement, and education.[22,24] Nevertheless, syphilis remained prevalent until penicillin, discovered by Fleming in 1928 and first used to treat syphilis in 1943, became widely available in the postwar era.[4] Syphilis incidence then declined sharply in the 1950s, followed by a modest rebound through the mid-1980s. In the late 1980s and early 1990s syphilis reemerged in the United States in the South and in large cities, disproportionately affecting black Americans.[2,25] Incidence then fell to a postwar nadir in 2000, when 5,979 cases (2.1 cases per 100,000 residents) of primary and secondary syphilis were reported nationally. As syphilis incidence waned, CDC released the National Plan to Eliminate Syphilis from the United States in 1999.[26]

EPIDEMIOLOGY

Unfortunately, syphilis incidence in the United States began increasing in late 2000, and that increase has continued nationally through 2009.[2,27] The current syphilis epidemic in the United States and other parts started, and has continued, primarily among men who have sex with men (MSM).[2,28] Incidence of syphilis and other sexually transmitted diseases (STDs) among MSM had declined during the AIDS epidemic, and the subsequent increased incidence among MSM has been attributed to a number of factors, including a decrease in safe sex practices resulting from successful HIV treatments, use of the Internet to meet sex partners, serosorting (i.e., attempting to choose sex partners who share the same HIV status), and an increase in use of recreational drugs, including methamphetamine and erectile-dysfunction medicines.[2,28,29] Of all primary and secondary syphilis cases reported to CDC during 2009, 2% occurred in MSM,[27] of whom an estimated 30%–74% were coinfected with HIV.[27,29] The male-to-female rate ratio for primary and secondary syphilis cases, which measures the extent to which transmission is occurring among MSM, was 5.6 in 2009, an increase compared with 1.2 in 1996 and 5.1 in 2008.[27] The male-to-female rate ratio varies greatly geographically, however, being generally lower in the South and higher in larger cities nationwide. Outbreaks among heterosexual men and women continue to occur sporadically,[30,31] and syphilis among heterosexuals has reemerged as a public health problem.[31] Compared to persons who have never had syphilis, Persons with a history of syphilis are at increased risk of repeat syphilis.[32,33]

In 2009 44,828 cases of syphilis overall were reported to CDC, a 3% decrease from 2008.[27] Those included 13,997 primary and secondary cases (4.6 per 100,000 residents) as well as 13,066 early latent cases and 17,338 late and late latent cases. Ten of the 13 states with rates of primary and secondary syphilis greater than the national average (4.6/100,000 population) were in the South, which accounted for 53% of primary and secondary cases nationwide in 2009. The other three states were New York, California, and Illinois. The rate in the District of Columbia, which reported 163 cases in 2009, was 27.5, higher than that of any state. Of those counties and independent cities that accounted for 50% of reported primary and secondary syphilis cases in 2009, Los Angeles had the highest number of cases (768) and Jefferson County, Texas, had the highest rate (65.0/100,000 population). Rates of primary and secondary syphilis nationwide were highest in persons 20–29 years old. Blacks are disproportionately affected by primary and secondary syphilis, with rates over nine times higher than rates among non-Hispanic whites in 2009 overall, including 8 and 20 times higher among black males and females, respectively,

compared with white males and females.[27] In 2009, there were 427 reported cases of congenital syphilis in the United States.[27] The incidence of congenital syphilis increased 22% from 2005 to 2009, concurrent with an increase in the rate of primary and secondary syphilis among females. Rates have increased primarily in the South and among infants born to black mothers.[34]

Based on those epidemiologic data and other factors, the CDC recommends screening (i.e., testing of asymptomatic persons) for syphilis in the United States for the following groups[38]:

- MSM who have been sexually active within the past year at least annually, and more frequent screening (every 3-6 months) for MSM with multiple or anonymous partners or who have sex in conjunction with illicit drug use (particularly methamphetamine use) or whose partners have sex in conjunction with those activities;
- Pregnant women, at the first prenatal visit, and early in the third trimester for women who are at high risk for syphilis, live in areas of high syphilis morbidity, or are previously untested;
- Persons in correctional facilities, if syphilis screening is justified on the basis of epidemiology in the locality and in the correctional institution.

Internationally, morbidity from syphilis remains substantial. Each year an estimated 12 million new cases of syphilis occur, and 1 million pregnancies are complicated by syphilis.[2]

BIOLOGY AND PATHOPHYSIOLOGY

Treponema pallidum subspecies *pallidum* is a motile, spiral-shaped bacterium for which humans are the only natural host.[16] *T. pallidum* ranges in size from 5 to 16 μm in length and is 0.2 to 0.3 μm in diameter.[35] (Fig. 200-1) The bacterium is surrounded by a cytoplasmic membrane, which is itself enclosed by a loosely associated outer membrane. Between those membranes lies a thin layer of peptidoglycan, which provides structural stability and houses endoflagella, organelles that are responsible for *T. pallidum's* characteristic corkscrew motility. Microscopically the bacterium is indistinguishable from other pathogenic treponemes that cause nonvenereal diseases, including *T. pallidum* subspecies *endemicum* (bejel), *T. pallidum* subspecies. *pertenue* (yaws), and *T. pallidum* subspecies *carateum* (pinta). The *T. pallidum* genome, sequenced in 1998,[36] is 1.14 Mb in length, relatively small for a bacterium.[16]

Figure 200-1 Early chancre presenting as an ulcer with a smooth, clean base on the shaft of the penis.

The bacterium has very limited metabolic capabilities, making it reliant on host pathways for many of its metabolic needs.[16,37] *T. pallidum* does not survive more than a few hours to days outside its host and cannot be cultured in vitro for sustained periods, complicating efforts to understand the organism.[16,37] Instead, it must be propagated in mammals, with rabbits the preferred species because, following testis inoculation, rabbits experience disease manifestations,[37] unlike mice.[16] *T. pallidum* divides slowly, taking from 30 to 50 hours in vitro. That slow reproduction rate has important implications for treatment, which must be present in the body for a long period in order to assure effectiveness against the bacterium.[38]

Following inoculation, *T. pallidum* attaches to host cells, including epithelial, fibroblast-like, and endothelial cells, likely by binding to fibronectin, laminin, or other components of host serum, cell membranes, and the extracellular matrix. It can invade rapidly into the bloodstream—within minutes of inoculation, based on rabbit models—and can cross many barriers in the body, such as the blood–brain barrier and the placental barrier, to infect many tissues and organs. That dissemination leads ultimately to manifestations of syphilis distant from the site of the initial chancre(s) in an infected person and in a developing fetus.

T. pallidum lacks virulence factors common to many other bacteria, including lipopolysaccharide endotoxin.[16] It does, however, produce a brisk immune response, mediated by membrane lipoproteins,[39] that begins shortly after infection. Infection at all stages leads to infiltration by lymphocytes, macrophages, and plasma cells.[37] $CD4^+$ T cells predominate in chancres, and $CD8^+$ T cells predominate in lesions of secondary syphilis.[37] Infection leads also to elaboration of Th1 cytokines, including IL-2 and IFN-γ, although downregulation of the Th1 response during secondary syphilis, coincident with the peaking of antibody titers,[37] might contribute to the organism's ability to evade the host immune response.[40,41] Subtyping studies of *T. pallidum* have linked certain strains of the organism to neurosyphilis.[42]

The humoral immune response begins with production of IgM antibodies approximately 2 weeks after exposure, followed 2 weeks thereafter by IgG antibodies.[39] IgM in addition to IgG continues to be produced during infection and can lead to immune-complex formation.[39] Antibody titers peak during bacterial dissemination, in secondary syphilis.[37] Some antibodies crossreact with other treponemal species, and some are specific for *T. pallidum* subspecies *pallidum*. The immune response is somewhat active against the organism, helping block attachment of the organism to host cells, conferring passive immunity in rabbit models, and enhancing phagocytosis in vitro.[37]

The immune response is sufficient to prevent syphilis reinfection in persons who have untreated syphilis.

In other words, in what is called Colles' law or "chancre immunity," persons with untreated syphilis will not experience another episode of primary syphilis as long they remain untreated.[37] However, the immune response is insufficient to eradicate *T. pallidum* from the host. In addition to suppressing the Th1 response, the organism is thought to evade those host defenses by taking harbor in immune-privileged tissues (e.g., central nervous system, eye, and placenta), failing to be present in sufficient quantities (e.g., during latent infection) to trigger a host response, varying its surface proteins during infection through gene conversion, and overcoming host attempts to prevent bacterial access to iron, which is necessary for bacterial growth.[16,37] The immune response is also not adequate to prevent reinfection after a person is cured of syphilis, although it might modify the course of reinfection. Compared with persons with syphilis for the first time, for example, reinfected persons are less likely to have manifestations of primary or secondary syphilis and more likely to be diagnosed with latent syphilis.[43]

The immune response is also likely responsible for the tissue damage caused in syphilis.[16] Damage to axons located near the site of a chancre might explain why that lesion, although ulcerative, is typically painless.[44]

Interest in a vaccine for syphilis continues, with focus on using outer membrane protein antigens to elicit an immunoprotective response.[45] However, a number of barriers to vaccine development exist. Those include variability in outer membrane protein antigens, the limited number of antigens on *T. pallidum* to which immunoprotective antibodies could bind, the possibility that the formation of a host protein coat around *T. pallidum* might prevent antibody binding, and a potential lack of commercial incentive to produce a vaccine.[45]

CLINICAL COURSE

The natural history of syphilis is presented in Table 200-1. Of note, when considering syphilis in the differential diagnosis in a patient, clinicians must consider the epidemiology and routes of transmission of the disease.

TABLE 200-1
Stages of Syphilis

Contact (⅓ become infected) ↓ (10–90 days) Primary (chancre) ↓ (3–12 weeks) Secondary (mucocutaneous lesions, organ involvement) ↓ (4–12 weeks) Early latent → Relapsing (1/4) (1 year from contact) ↓	
Late latent (more than 1 year)	↘
Remission (⅔)	Tertiary (⅓) Late benign (16%) Cardiovascular (10%) Neurosyphilis (5–10%)

That requires taking a complete sexual history, including ascertaining genders of sex partners and the types of sexual behaviors engaged in with those partners.[46] From a clinical perspective specific behaviors with specific partners are more important than sexual orientation (e.g., gay or straight), because some persons who engage in same-sex sexual behavior do not self-identify as gay.[47]

EXPOSURE AND INCUBATING SYPHILIS

Syphilis is most commonly acquired sexually, when a person comes in contact with infectious lesions of syphilis on another person. Infectious lesions of syphilis in adults, which include chancres, condyloma lata, and mucous patches, can be present anywhere on the body but are typically located in or around the genital, anal, or oral area. Direct contact with infectious lesions during oral, vaginal, or anal sex, or during other sexual activities, can result in inoculation and infection. Lesions on keratinized skin (e.g., palmoplantar lesions and maculopapular rash on the trunk) typically do not contain sufficient treponemes to be infectious, and prophylaxis for persons exposed to noninfectious lesions such as those is neither necessary nor indicated. Infectious lesions of congenital syphilis includes discharge from rhinitis ("snuffles") and bullous lesions on the skin.

Syphilis can also be acquired through nonsexual contact,[48] blood transfusion,[49] accidental inoculation in an occupational setting (e.g., laboratory or healthcare worker[50]) or nonoccupational setting (e.g., tattooing[51]), or through exposure in utero.[52]

Estimates of the risk of acquisition of syphilis following exposure to a person with infectious syphilis are varied and have been derived in two types of sources.[53] The first source are data from three prospective placebo-controlled trials of prophylactic treatment, in which 9%,[54] 28%,[55] or 63%[56] of contacts to syphilis acquired syphilis. The second source is from studies of persons identified as sex contacts in contact-tracing interviews of persons diagnosed with syphilis, in which 18%–88% of contacts acquired syphilis.[53] Nevertheless, the relatively high estimates of syphilis acquisition following exposure underscores the importance of prompt treatment and testing of sex contacts, as discussed later in this chapter. Persons recently exposed to and infected with syphilis who have yet to manifest signs or symptoms of the disease are said to have incubating syphilis.

PRIMARY SYPHILIS

As defined by CDC surveillance case definitions, primary syphilis is a stage of syphilis characterized by one or more chancres, in the presence of laboratory evidence from tissues or sera consistent with syphilis.[57] As with all CDC syphilis surveillance case definitions presented in this chapter, classification by a clinician with expertise in syphilis may take precedence over surveillance case definitions.[57]

Figure 200-2 Chancre on the penile shaft, demonstrating a clean base and elevated borders on the shaft of the penis.

Figure 200-4 Multiple chancres coalescing on the foreskin.

At the inoculation site, a chancre develops after an incubation period that ranges from 10 to 90 days (average, 3 weeks). The chancre starts as a dusky red macule that evolves into a papule and then a round-to-oval ulcer (Figs. 200-1 and 200-2). The typical chancre, also called a Hunterian chancre or "ulcus durum" (hard ulcer), ranges in diameter from a few millimeters to 2 cm and is sharply demarcated with regular, raised borders that are indurated, giving the lesion a cartilaginous feel. The base is usually clean, and the chancre is classically not painful. Up to 35% of chancres, however, are reportedly painful,[58] and multiple chancres (Figs. 200-3 and 200-4) have been reported in 32%–47% of cases.[59] The absence of any of the typical features of a chancre does not rule out syphilis, however. Variations in clinical presentation can result from the number of spirochetes inoculated, the patient's immune status, concurrent antibiotic therapy, and impetiginization.[40,60,61] Patients might not be aware of chancres, especially if painless and located in areas that are not visible, such as the anus, vagina, cervix, or oral cavity.[62]

Common genital locations for a chancre in men include the glans, the coronal sulcus, and the foreskin.[62,63] Retraction of the foreskin when a chancre is present on the underside causes the foreskin to flip suddenly, a sign known as the *dory flop*, after the movement of a dory, a small wooden fishing boat, which flips suddenly when overturned.[63,64] The dory flop sign can help distinguish chancres from other nonindurated causes of genital ulcer disease, such as herpes simplex virus infection and chancroid, that present without the induration that leads to the sudden flip of the foreskin. Uncommon presentations include giant necrotic chancre, phagedenic chancre (a deep, bright-red, necrotic ulcer with a soft base and exudate, resulting from secondary bacterial infection associated with immunosuppression), phimosis resulting from adherence of a chancre on the foreskin to the glans, and balanitis.[65]

Common genital locations in women, in decreasing order, include the cervix, labia majora, labia minora, fourchette, and urethra (Fig. 200-5).[66] Chancres in women can be more edematous than indurated.[63]

Figure 200-3 Multiple chancres on the glans and foreskin.

Figure 200-5 Chancre in a female. An ulcer covered with fibrin and necrotic slough at the orifice of the urethra.

Figure 200-6 Chancre in the perianal area. Fecal material is also present in the area.

Figure 200-7 Chancre on the penis in a man who also had plantar papules (see Fig. 200-8).

Edema indurativum is a unilateral labial swelling with rubbery consistency and intact surface, indicative of a deep-seated chancre.

Extragenital chancres in many areas of the body have been reported.[67,68] Oral sex was identified as the likely mode of syphilis acquisition in 14% of cases overall, and in 20% of cases in MSM, in Chicago during 1998–2002.[69] Other studies have attributed even higher proportions of infections among MSM to exposures during oral sex.[70] Anal sex can lead to development of chancres in the perianal (Fig. 200-6) or anal areas that can be difficult to detect on routine physical examination.[58,71] Digital or other[72,73] contact with the oral, genital, or anal areas or receiving a bite (e.g., on the nipple during sex[74]) can also lead to infection.

The chancre heals in 3–6 weeks without treatment and 1–2 weeks with treatment. Scarring typically does not occur, although thin atrophic scars may occur.[62] Coinfection with herpes simplex virus or *Haemophilus ducreyi*, the causative organism of chancroid, can be present in rare cases.[75–77] Relapses of primary syphilis, called *monorecidive syphilis* or *chancre redux*, arise in the setting of untreated or inadequately treated syphilis and are rare.[78]

In 60%–70% of cases of primary syphilis, painless regional lymphadenopathy arises 7–10 days after the chancre appears, especially when the chancre's location is genital. Unilateral lymphadenopathy is more common earlier in the course of disease, with bilateral involvement later in the course.[78]

A differential diagnosis for chancres is presented in Box 200-1.

BOX 200-1 DIFFERENTIAL DIAGNOSIS OF PRIMARY SYPHILIS

INFECTIOUS

- Herpes simplex
- Chancroid
- Granuloma inguinale
- Vaccinia
- Lymphogranuloma venereum
- Aphthous ulcer
- Erosive candidal vulvitis or balanitis

NON-INFECTIOUS

- Traumatic erosion or ulcer
- Behçet disease
- Squamous cell carcinoma
- Basal cell carcinoma
- Fixed-drug eruption

SECONDARY SYPHILIS

As defined by CDC surveillance case definitions, secondary syphilis is a stage of syphilis characterized by localized or diffuse mucocutaneous lesions, often with generalized lymphadenopathy, in the presence of laboratory evidence from tissues or sera consistent with syphilis. The chancre may still be present.[57]

Lesions of secondary syphilis, classically called "syphilids" or, when affecting the skin, "syphiloderms,"[63] typically erupt 3–12 weeks after the chancre appears (up to 6 months after exposure). In up to 25% of cases lesions of the secondary syphilis develop while the chancre is still present[59,61] (Figs. 200-7 and 200-8), with overlap more common among HIV-infected

Figure 200-8 Plantar lesions of secondary syphilis in a man who also had a penile chancre (see Fig. 200-7).

Figure 200-9 Macular syphilis (roseola syphilitica) with a subtle presentation of nonscaling, oval pink, ill-defined macules and patches on the trunk.

Figure 200-11 Lichenoid syphilitic eruption with pink to violaceous, planar, polygonal papules resembling lichen planus.

persons.[61] Rash is present in nearly all cases of secondary syphilis, although the specific type of rash varies.[59,60,79] Erythematous macules (roseola syphilitica) or maculopapules are commonly present symmetrically on the trunk and extremities in 40%–70% of cases (Fig. 200-10), with papular, papulosquamous, or lichenoid (Fig. 200-11) presentations less common.[59,79] A white scaly ring on the surface of papulosquamous lesions, called Biette's collarette (Fig. 200-12), is characteristic but not pathognomonic for syphilis. The face is typically spared in these generalized syphilids, although seborrheic dermatitis-like lesions around the hairline, termed the Crown of Venus or corona veneris, can form a crown-like pattern.[62] Lesions are not usually pruritic,[63] although pruritus was reported in up to 40% of patients in one study.[63] The presentation of the rash overall can be subtle or florid, or can develop from subtle macules to more florid papules over time.[80] Erythematous to copper-colored round papules, well demarcated and sometimes with an annular scale, are

Figure 200-10 Macular syphilis with a more florid presentation of nonscaling, oval pink, ill-defined macules and patches on the trunk.

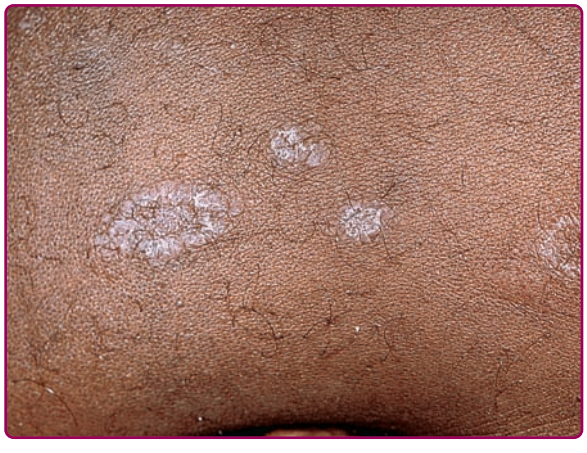

Figure 200-12 Papulosquamous syphilitic eruption with erythematous, well-demarcated, flattened plaques covered with scales (Biette's collarette).

Figure 200-13 Characteristic secondary syphilis lesions on the palms (**A**) and soles (**B**). Palmoplantar lesions may be macular or papular, discrete or diffuse, and nonscaling, slightly scaly, or hyperkeratotic ("syphilitic corn").

present on the palms and soles in nearly 75% of cases (Figs. 200-13A and 200-13B).[59] Plantar lesions can be variously mistaken for calluses (clavi syphilitici). Plantar lesions can also extend to the lateral and posterior aspects of the foot (Fig. 200-14).

Other dermatologic manifestations include a patchy nonscarring alopecia, described as "moth-eaten" (Fig. 200-15) or, less commonly, a diffuse alopecia of the scalp. Loss of lateral third of the eyebrows can occur. Annular papules and plaques can be present around the mouth and nose, in a presentation colloquially referred to as "nickels and dimes"[63] (Fig. 200-16). Papules and plaques, sometimes annular and occasionally papulosquamous, can also be present on the penis and scrotum (Figs. 200-17 and 200-18). Mucous patches are white-to-yellow erosions on the tongue that efface lingual papillae[63] (Fig. 200-19). Confluence of mucous patches on the tongue has been termed *plaques fauches en prairie*. Mucous patches can be present elsewhere in the oral cavity, on other mucous membranes, or at the corners of the mouth, where they appear as "split papules," with an erosion traversing the center (Fig. 200-20). Mucous patches are teeming with spirochetes and, hence, highly infectious. Also highly infectious are condyloma lata, which present as moist, flat, well-demarcated papules or plaques with macerated or eroded surfaces in intertriginous areas, commonly in the labial folds in females or in the perianal region in all patients[63] (Figs. 200-21 and 200-22). However, any moist intertriginous area of the body can harbor condyloma lata, including the axillae, web spaces between toes, and the folds under breasts or an abdominal panniculus. Mucous patches and condyloma lata have been reported in 8% and 17% of patients with secondary syphilis, respectively.[59] Malignant lues is a rare manifestation that presents as crusted or scaly papules and plaques that can ulcerate or become necrotic, with an oyster shell-like surface (Fig. 200-23). These lesions, described as rupioid, are often seen in association with high nontreponemal titers and systemic symptoms.[81] Nail changes including fissuring, onycholysis, Beau's lines, and onychomadesis have been reported.[62] Less common presentations of secondary syphilis include lichenoid, nodular, follicular, pustular, framboesiform, and corymbose eruptions and

Figure 200-14 Plantar lesions of secondary syphilis extending to the lateral aspect of the foot.

Figure 200-15 Moth-eaten alopecia of secondary syphilis, which is more common than diffuse alopecia. Irregular, patchy, nonscarring alopecia is present more frequently on the occipital scalp and occasionally affects the eyebrows and beard.

Figure 200-16 Annular plaques of secondary syphilis on the face, colloquially referred to as "nickels and dimes," in a transgender woman.

Figure 200-18 Papules of secondary syphilis on the penis.

palmoplantar keratodermas.[65,82–85] With the exception of mucous patches and condyloma lata, cutaneous manifestations of secondary syphilis do not contain a substantial number of treponemes and, therefore, are not typically infectious.

The maculopapular rash of secondary syphilis can resemble almost any generalized or localized maculopapular eruption (Box 200-2); mucous membrane lesions resemble mucosal manifestations of other dermatoses, and syphilitic hair loss has to be separated from other etiologies of alopecias.

Without treatment, the secondary stage typically recedes in 4–12 weeks. Scarring typically does not occur although pigmentary changes (leukoderma colli syphiliticum or, if on the neck, "necklace of Venus") can result[62] from inhibition of melanogenesis. Dermal atrophy, possibly related to elastin degradation, may occur. Absence of syphilids in cinnabar-containing red tattoos has been reported as well, possibly resulting from the antitreponemal effect of mercury in cinnabar.[86] In addition to neurosyphilis, discussed later, patients with secondary syphilis can experience systemic symptoms that include (in roughly descending order of prevalence) sore throat, malaise, headache, weight loss, fever, musculoskeletal aches, visual disturbances, and hoarseness.[79] Pharyngitis and tonsillitis,[87] laryngitis,[88] uveitis,[89] gastritis,[90] hepatitis,[90] renal disease (membranous glomerulopathy),[91] and periostitis[92] have all been

reported in secondary syphilis, as have hematologic abnormalities including lymphopenia, anemia, and elevated erythrocyte sedimentation rate.[93]

LATENT SYPHILIS

The secondary stage is followed by an asymptomatic stage with no clinical findings, with seroreactivity by definition the only evidence of infection. Latent syphilis therefore is a diagnosis of exclusion, after signs of syphilis, including those that can be present on accessible mucosal surfaces (e.g., oral cavity, perineum,

BOX 200-2 DIFFERENTIAL DIAGNOSIS OF THE MACULOPAPULAR RASH OF SECONDARY SYPHILIS

perianal area, underneath the foreskin, labia, vaginal walls, cervix), have been excluded.[38] Latency may remain indefinitely, be interrupted by a relapse of secondary syphilis, or progress to the tertiary stage.

For disease surveillance purposes, CDC divides latent syphilis into three subcategories, early latent, late latent, and latent syphilis of unknown duration. Clinical management of patients with late latent syphilis and latent syphilis of unknown duration is identical and differs from clinical management of patients with early latent syphilis.

Early latent syphilis can be diagnosed if, within the year preceding discovery of the reactive serologic test, a person had one of the following[57]:

1. Documented seroconversion or fourfold or greater increase in titer of a nontreponemal test;
2. Unequivocal symptoms of primary or secondary syphilis;
3. A sex partner documented to have primary, secondary, or early latent syphilis; or
4. Reactive nontreponemal and treponemal tests from a person whose only possible exposure occurred within the previous 12 months.

To make a diagnosis of early latent syphilis based on the first or third criterion above, clinicians often need, and should seek, the assistance of the local health department. Because syphilis diagnoses and results of reactive serologic tests for syphilis are reportable in every state and territory of the United States, local or state health departments compile (or attempt to compile) records of all syphilis diagnoses and reactive serologic titers for persons residing in the jurisdiction. Clinicians can contact the "reactor desk" of their local or state health jurisdiction, where syphilis diagnostic and titer histories are maintained, to inquire about a patient's titer history and prior diagnoses and treatments, so that a patient can be staged as having early latent syphilis according to the first criterion above. Public health workers can also search diagnostic and titer histories in their databases for the names of sex partners identified by seroreactive patients, to enable staging patients with early latent syphilis under the third criteria above.

Latent syphilis of unknown duration is a subcategory of latent syphilis that is diagnosed in patients aged 13–35 years who have a nontreponemal titer ≥32 and in whom early latent syphilis cannot be diagnosed according to the criteria previously mentioned.[57] This category is meant to capture persons with syphilis who do not meet criteria for early latent syphilis but who, on the basis of their relatively young age and high titer, are thought to have acquired syphilis—and, possibly, have transmitted it to sex partners—more recently than persons with late latent syphilis.[38] Differentiating persons with latent syphilis of unknown duration from those with late latent syphilis is important for two reasons. First, sex partners of those with latent syphilis of unknown duration are managed like partners of those with primary, secondary, or early latent syphilis, while partners of those with late latent syphilis are managed less aggressively, as discussed later. Second, public health agencies prioritize contact-tracing investigations of persons with latent syphilis of unknown duration over persons with late latent syphilis, since the persons with latent syphilis of unknown duration are likely to have been more recently infectious to sex partners. Elicitation of and follow up with partners of persons with latent syphilis of unknown duration compared with late latent syphilis, is more likely to contribute to syphilis prevention and control efforts.

Late latent syphilis, the final subcategory of latent syphilis, is diagnosed in a patient with latent syphilis who cannot be diagnosed with one of the other two subcategories.[57]

TERTIARY SYPHILIS

Although not a formal stage of syphilis, as defined by CDC surveillance case definitions, "tertiary syphilis" is a commonly used term clinically.[57] A CDC case definition does exist for disease manifestations clinically considered "tertiary syphilis." That case definition is for "syphilis, late, with clinical manifestations other than neurosyphilis (late benign syphilis and cardiovascular syphilis)," which is characterized by inflammatory lesions of the cardiovascular system, skin, bone, and rarely, other structures, in the presence of laboratory evidence from tissues or sera consistent with syphilis.[57] Although neurosyphilis can occur at any stage of disease, as discussed later, late manifestations of neurosyphilis have historically been considered to be a manifestation of tertiary syphilis.

Historically, on the basis of information from the Oslo and Tuskegee studies, approximately one-third of patients with untreated latent syphilis progressed to tertiary syphilis, typically after 15–40 years, while the other two-thirds remain in latency. Because of effective antibiotic therapy, progression to tertiary syphilis is now very rare in the developed world.

Late benign syphilis refers to signs and symptoms of syphilis that occur after secondary syphilis that do not involve the cardiovascular or nervous systems. Lesions of late benign syphilis are caused by delayed type hypersensitivity responses to the small number of treponemes present in the involved tissue or organ.[40]

The hallmark of late benign syphilis is the gumma, a granulomatous nodular lesion with variable central necrosis, which most commonly affect the skin or mucous membranes (80% of gummas).[40] Gummas are nontender pink to dusky-red nodules or plaques that vary in size from millimeters to many centimeters in diameter.[21] They favor sites of previous trauma and may arise anywhere in the body but are more common on the scalp, forehead (Fig. 200-24), buttocks, and presternal, supraclavicular, or pretibial areas. The nodule is initially firm but develops a gummy consistency due to accumulation of necrotic tissue. Gummas may grow horizontally as well as vertically, and many assume geometric configurations. Small ulcers and abscesses may be present within the lesions. As the central gumma heals, new lesions may develop on the periphery, forming scalloped borders. In contrast to noduloulcerative lesions, gummas are deeper and more destructive (Fig. 200-25). Tissue necrosis eventuates in cylindrical, punched-out ulcers with clean granulomatous bases covered with adherent yellow–white slough

Figure 200-24 Disfiguring gummatous infiltration of the glabella and forehead with scattered ulcerations in a 60-year-old woman with late benign syphilis.

Figure 200-26 Two deep, punched-out ulcers in the popliteal fossa covered with an adherent yellow slough at the base. This is the classical appearance of nodular gummas.

(Fig. 200-26). The ulcer may enlarge, remain unchanged, or heal spontaneously even as the gumma enlarges. Superficial gummas heal with atrophic scars, whereas deeper lesions leave thickened, pitted, ridged scars. The lesions are rarely contagious, but infection following contact with gummas has been reported. Pseudochancre redux refers to a solitary gumma of the penis.

Gummas involving the mucous membranes typically affect the palate, nasal mucosa, tongue, tonsils, and pharynx. The lesions ulcerate and can be disfiguring, as when they cause a saddle-nose deformity from destruction of nasal cartilage and bone, or perforation of the nose or palate[40] (Figs. 200-27A and 200-27B). Chronic interstitial glossitis can develop even after penicillin treatment and may undergo malignant degeneration (Fig. 200-28). Besides the skin and mucous membranes, gummas can affect practically any organ, but especially the bones, liver, heart, brain, stomach, and upper respiratory tract.[16] Gummas do not heal without appropriate antibiotic therapy, but in the setting of appropriate therapy respond briskly, leaving scars.[16]

Other manifestations of late benign syphilis affecting the skin include granulomatous nodular and noduloulcerative lesions and psoriasiform plaques.[62] Nodular and noduloulcerative lesions are superficial,

Figure 200-25 Aggressive gumma of the forehead causing destruction of the calvarium, mimicking advanced, destructive basal cell carcinoma.

BOX 200-3 DIFFERENTIAL DIAGNOSIS OF TERTIARY SYPHILIS

Consider

- Sarcoid
- Metastatic carcinoma
- Sarcomas
- Lymphomas
- Granulomatosis with polyangiitis (Wegener's)
- Leishmaniasis
- Vasculitis
- Deep fungal infections
- Lupus vulgaris
- Psoriasis

Figure 200-27 Destruction of the nasal cartilage and bone by a gumma leads to a saddle nose (**A**) and to the perforation of the nasal cartilage and skin and thus to considerable mutilation (**B**).

firm, painless, dull-red, shiny, flat nodules that range in size from several millimeters to 2 cm (Fig. 200-29). They appear in a grouped configuration, can coalesce into large plaques (Fig. 200-30) or ulcerate and can resemble granuloma annulare.[94,95] Psoriasiform plaques are most commonly seen on the arms, back, and face (Fig. 200-31).

The differential diagnosis of tertiary syphilis is shown in Box 200-3.

Historically, cardiovascular manifestations of tertiary syphilis affected 10%–40% of those infected and were thought to be responsible for most deaths caused by syphilis.[16] Syphilis typically causes syphilitic aortitis, leading to aortic regurgitation in 10% of individuals with untreated disease,[96] and can also cause coronary ostial stenosis and saccular aneurysm.[97] *T. pallidum* DNA has been detected in an aortic aneurysm, demonstrating that infection of the aorta leads to direct damage to the tissue.[98]

Figure 200-28 Premalignant, chronic, interstitial glossitis secondary to gummatous infiltration of the tongue.

NEUROSYPHILIS

Neurosyphilis—literally, infection of the central nervous system (CNS) by *T. pallidum*—is commonly considered to be a manifestation of "tertiary syphilis," although neurosypyhilis can in fact occur during any stage of infection. CDC case definitions for neurosypyhilis are divided into confirmed (any stage of infection and a reactive CSF-VDRL), and probable (any stage of

Figure 200-29 A noduloulcerative tertiary syphilitic lesion is a sharply defined and irregularly shaped flat nodule of a dull red color, firm consistency, and superficial ulcerations.

Figure 200-30 Crusted and scaly noduloulcerative tertiary syphilis plaques with characteristic serpiginous borders and scarring.

infection, a nonreactive CSF-VDRL, elevated protein or white blood count without other known causes of those abnormalities, and clinical symptoms or signs of neurosyphilis without other known causes for those symptoms or signs).[27]

"Neuroinvasion," in which *T. pallidum* disseminates to cerebrospinal fluid and meninges, occurs very early in syphilis.[99] Neuroinvasion can be transient, with the body clearing the infection, or more sustained, in which case it is called asymptomatic neurosyphilis, defined by CSF abnormalities. Asymptomatic neurosyphilis, if discovered, is usually treated to prevent progression to symptomatic neurosyphilis, although benefits of treatment for asymptomatic neurosyphilis are not well documented.

Figure 200-31 Plaque of tertiary syphilis may be brick-red in color, covered with scales, and may be indistinguishable from psoriasis.

Early symptomatic neurosyphilis typically manifests as meningitis, resulting in meningismus, fever, or cranial nerve abnormalities (especially cranial nerves II, III, IV, VI, VII, and VIII), or meningovasculitis, resulting in meningitis with stroke, usually affecting the portion of the brain supplied by the middle cerebral artery.[99] Uveitis is the most common ophthalmic manifestation of early neurosyphilis, presenting as eye pain, redness, and photophobia, and sensorineural hearing loss is the most common manifestation of otologic syphilis. Ophthalmic and otologic manifestations of early neurosyphilis are managed in the same way as neurologic manifestations.[38,99]

Early symptomatic neurosyphilis is not uncommon. A review of syphilis cases among HIV-infected men in four large US cities during 2002–2004 showed that almost 2%, including persons at each stage of infection, had symptomatic early neurosyphilis. Ocular abnormalities were most common among those affected, followed by other cranial nerve involvement, acute meningitis, other syndromes (headache, altered mental status, or both), and cerebrovascular accidents. Of those with symptomatic early neurosyphilis, nearly one-third had persistent neurologic deficits 6 months after receiving appropriate treatment.[100]

The two syndromes commonly associated with late neurosyphilis are general paresis of the insane, also known as dementia paralytica, and tabes dorsalis.[99] General paresis presents as a rapidly progressive dementia, accompanied by personality changes. Tabes dorsalis presents with sensory ataxia and bowel and bladder dysfunction, resulting from damage to the posterior columns of the spinal cord. Tabes dorsalis can be accompanied by an Argyll–Robertson pupil (which accommodates but does not react to light) and optic atrophy. These syndromes are now very rare in the developed world.

Clinicians diagnosing a person with syphilis should perform a neurologic review of systems and perform a neurologic examination. According to CDC recommendations, indications for CSF examination in persons with syphilis include neurologic, ophthalmic, or otologic signs or symptoms; evidence of active tertiary syphilis; or treatment failure; HIV infection in and of itself is not an indication for CSF examination.[38] Some experts have recommended a CSF examination on all patients with a nontreponemal serologic test titer ≥1:32 or who are HIV-infected with a $CD4^+$ count ≤350 cells/μL.[101] Because benzathine penicillin G does not cross the blood–brain barrier, treatment with that form of penicillin does not interfere with subsequent CSF examination and should not be delayed on that basis. CSF examinations to assess treatment response are recommended,[38] although serologic response can be used as a proxy for CSF normalization in many cases.[102]

CONGENITAL SYPHILIS

Congenital syphilis refers to syphilis caused by infection in utero with *T. pallidum*. CDC defines a confirmed case of congenital syphilis as signs of disease in an infant or child with specific laboratory evidence of infection with *T. pallidum*.[27] A probable case is defined as a condition affecting an infant whose mother had untreated or inadequately treated syphilis at delivery, regardless of signs in the infant, or an infant or child who has a reactive treponemal test for syphilis and evidence of congenital syphilis on physical examination or radiographs of long bones, a reactive CSF-VDRL, an elevated CSF cell count or protein (without other known cause), or a reactive FTA-ABS IgM antibody test or IgM enzyme-linked immunosorbent assay.[57]

Transplacental fetal infection can occur at any time during pregnancy and at any stage of maternal infection.[103] Probability of transmission of infection depends on the stage of infection in an untreated mother, ranging from 70%–100% in primary syphilis, 40% for early latent syphilis and 10% for late latent syphilis.[104] Because infection is spread hematogenously, a chancre is not present on the fetus or infant.[103] In 30%–40% of cases, congenital syphilis results in stillbirth.[52] Of infants who survive, two-thirds are asymptomatic at delivery and only later develop symptoms.[103] Clinical findings in symptomatic infants are similar to congenital infections caused by cytomegalovirus, toxoplasmosis, herpes simplex virus, rubella, and other infections.[52] The most prominent manifestations of early congenital syphilis, defined as syphilis in a child aged <2 years, include fever, rash, hepatosplenomegaly, and persistent rhinitis ("snuffles").[103] Hydrops fetalis (edema), lymphadenopathy, neurosyphilis, leukocytosis, thrombocytopenia, and periostitis and osteochondritis may also be present, with the pain associated with osteochondritic lesions causing the infant to refuse to move the affected anatomic area ("pseudoparalysis of Parrot").[52,103] If present at delivery, the rash is usually bullous ("syphilitic pemphigus") (Fig. 200-32) and very infectious.[103] Rash that presents at two weeks or more after birth, however, is typically maculopapular, with small copper-red lesions similar to lesions of secondary syphilis most commonly affecting the hands and feet.[52] Desquamation and crusting can then occur.[105] Other cutaneous lesions present can include condyloma lata, mucous patches, fissures around the lips, nares, or anus, and petechiae from thrombocytopenia.[52] The skin of the syphilitic neonate is often dry and wrinkled and, in newborns with fair skin, may have a café-au-lait hue (Fig. 200-33).

Figure 200-32 Bullous eruptions on the soles of a newborn with early prenatal syphilis. Bullae have ruptured and now present as erosions ("syphilitic pemphigus").

Figure 200-33 Early prenatal syphilis in a newborn. The skin is dry and wrinkled, with a yellowish-brownish hue. There is hemorrhagic rhinitis. This is what Diday described as "a little wrinkled potbellied (not seen here) old man with a cold in his head." Note also the aged appearance of the fingers in this newborn.

Late congenital syphilis is defined as disease occurring in a child at least 2 years old that typically manifests over the first two decades of life.[52] Many manifestations of late congenital syphilis result from damage caused during early infection and are not reversible with treatment. Those manifestations include scars ("rhagades") (Fig. 200-34) resulting from

Figure 200-34 Perioral rhagades are linear scars that result from ulcerations that appear during early congenital syphilis and persist to adulthood.

Figure 200-35 The presence of small, notched, peg-shaped upper incisors (Hutchinson teeth) is also part of the late congenital syphilis triad.

cutaneous fissures; a saddle-nose deformity, resulting from destruction of nasal cartilage from snuffles; frontal bossing (Olympian brow), thickening of the sternoclavicular portion of the clavicle (Higoumenakis sign), anterior bowing of the midtibia (saber shins), and scaphoid scapula, all resulting from chronic periostitis; and peg-shaped notched central incisors (Hutchinson teeth) (Fig. 200-35) and mulberry molars, resulting from syphilis vasculitis in developing tooth buds. Other manifestations include eighth nerve deafness and eye abnormalities, including interstitial keratitis, glaucoma, or corneal scarring. Hutchinson's triad refers to Hutchinson teeth, interstitial keratitis, and eighth nerve deafness.[52]

Of note, as with any sexually transmitted disease, the diagnosis of syphilis in a child beyond the neonatal period should raise the question of child abuse.[38]

SYPHILIS AND HUMAN IMMUNODEFICIENCY VIRUS INFECTION

(See Chapter 198)

The interaction of syphilis and HIV infection is complex.[29] The clinical presentation of syphilis varies in minor ways between HIV-infected and HIV-uninfected persons.[29] HIV-infected persons are more likely to present with >1 chancre and with larger and deeper chancres in primary syphilis,[61,106] and are more likely to manifest signs of secondary syphilis while a chancre (or chancres) are present.[61,107] Atypical and aggressive presentations of syphilis in HIV-infected persons might also be more common, although those presentations are not thought to be unique to HIV coinfection.[29,106]

Syphilis has been shown in most studies to transiently increase HIV viral load and decrease $CD4^+$ T cell count during infection, with resolution following treatment.[108–114] Those changes might facilitate HIV transmission by HIV-infected patients coinfected with syphilis.[29,114] An effect of syphilis on progression to AIDS or mortality has not been found.[115] Syphilis has also been associated with HIV acquisition,[116] and all persons presenting with syphilis who are not known to be infected with HIV should be tested for HIV.[38] The disruption of epidermal or mucosal barriers caused by syphilis ulcers, and the migration to these lesions of inflammatory cells that are targets for HIV are two biological mechanisms that might account for the synergy between the two infections. Common behavioral factors (e.g., lack of condom use) also likely contribute to risk of coinfection. All HIV-infected persons entering HIV care should have a serologic test for syphilis, which should be repeated yearly thereafter, or more frequently if indicated (e.g., MSM, pregnant women).[117] HIV infection has also been associated with repeat syphilis infection.[32]

Because of its effect on the immune system, HIV infection is thought to increase risk of neurosyphilis,[29,99] based on studies correlating abnormal cerebrospinal fluid (CSF) findings with advanced HIV disease[101] and failure to normalize CSF-VDRL test results in the presence of HIV infection,[118] especially with lower CD4 cell counts. Additionally, HIV-infected persons with syphilis can experience "neurorelapse," meaning the development of neurosyphilis following appropriate treatment for primary, secondary, or early latent syphilis and declines in nontreponemal titers consistent with cure.[99]

HIV infection can sometimes complicate serologic diagnosis of syphilis and subsequent follow-up, since unusual serologic responses have been observed in HIV-infected persons with syphilis.[38] False-negative serologic test results in the setting of the prozone phenomenon[119] and seronegative syphilis[120] have been reported. Also, serofast reactions (i.e., persistently reactive nontreponemal test results, even following appropriate treatment) can occur in up to 40%.[121] When syphilis is suspected clinically and serology is nonreactive, skin biopsy can be useful diagnostically, as can darkfield microscopy[35] or polymerase chain reaction (PCR)-based assays for *T. pallidum*,[75] if available.

CDC treatment recommendations for syphilis do not depend on HIV infection status, supported by limited data indicating that outcomes are not improved with more intense or prolonged treatment.[29,38,117,122] Titers might decline more slowly in appropriately treated HIV-infected persons,[29,38,123] particularly those who have lower titers on initial diagnosis.[124] Compared with HIV-uninfected persons, HIV-infected persons with primary or secondary syphilis should have more frequent follow-up (Table 200-2).[117]

DIAGNOSTIC TESTS

Diagnosis of syphilis depends on clinical suspicion combined with laboratory testing to directly or indirectly detect infection with *T. pallidum*. Of note, in cases where clinical suspicion for syphilis is high, clinicians should not wait for the results of laboratory testing before administering appropriate treatment.

DIRECT DETECTION OF *T. PALLIDUM*

DARKFIELD MICROSCOPY. Darkfield microscopic examination is the diagnostic test of choice in chancres, moist lesions of secondary syphilis (condylomata lata and mucous patches), and the discharge

TABLE 200-2
CDC Recommendations for Treatment and Follow-up of Adults with Primary, Secondary, or Early Latent Syphilis[38]

Stage of Disease	HIV Status of Person	Recommended Treatment	Alternative Treatment for Penicillin-allergic Persons (Non-Pregnant Women Only[a])	Schedule for Follow-up After Treatment[b]	Timeframe to Expect Fourfold Decline in Titer[c]
Primary or secondary	HIV-uninfected	Benazthine penicllin G, 2.4 million units, administered intramuscularly in a single dose	Doxycycline 100 mg orally twice daily for 14 days	6 and 12 months	6–12 months
	HIV-infected	Benazthine penicllin G, 2.4 million units, administered intramuscularly in a single dose	Doxycycline 100 mg orally twice daily for 14 days	3, 6, 9, 12, and 24 months	6–12 months
Early latent	HIV-uninfected	Benazthine penicllin G, 2.4 million units, administered intramuscularly in a single dose	Doxycycline 100 mg orally twice daily for 14 days	6, 12, and 24 months after treatment	12–24 months
	HIV-infected	Benazthine penicllin G, 2.4 million units, administered intramuscularly in a single dose	Doxycycline 100 mg orally twice daily for 14 days	6, 12, 18, and 24 months	12–24 months

[a]Pregnant women must not be treated with doxycycline. If allergic to penicillin, pregnant women must be desensitized and then treated with benzathine penicllin G.
[b]In practice, many experts advocate follow-up every 3 months for all persons. Additionally, some persons (e.g., MSM or women who become pregnant) should be screened appropriately in addition to being followed at the recommended intervals to assess clinical and serologic response to treatment.
[c]If titers have not declined fourfold after the stated time frame, consider reinfection, treatment failure, or neurosyphilis. If at any time after treatment signs or symptoms of syphilis appear, also consider those same three possibilities.
Note that initial treatment is the same for HIV-uninfected and HIV-infected persons.

from rhinitis in congenital syphilis. Darkfield examination will often be positive before serologic tests become reactive.[125] Because nonpathogenic treponemes are normally present in the oral cavity and can be mistaken for *T. pallidum*, darkfield microscopy cannot be used to test oral lesions. The number of *T. pallidum* organisms in secondary syphilis lesions except for mucous patches and condyloma lata is generally not sufficient to allow darkfield diagnosis.

Universal precautions must be used when collecting and handling darkfield specimens, since lesions of syphilis suitable for darkfield examination are very infectious. Darkfield specimens are prepared by removing crusts from the surface of the lesion, cleaning the surface of the lesion with a sterile saline-soaked gauze, squeezing the base of the lesion with two gloved fingers to induce the presence of a serous exudate on the surface, and collecting the exudate with a glass slide, cover slip, or bacteriological loop. Only if the amount of exudate is insufficient to prevent the slide from drying out prior to microscopic examination should a drop of nonbacteriostatic normal saline be added before covering the slide with a cover slip. The slide is examined within 5–20 minutes by a trained microscopist, using a darkfield microscope, for the presence of organisms with the characteristic morphology and motility of *T. pallidum*.[35] Sensitivity is approximately 74%–79%, but declines as minutes elapse, as dead treponemes cannot exhibit the motility required for diagnosis.[35] Of note, prior application of a topical antibiotic to a lesion can yield a false-negative darkfield specimen.

DIRECT FLUORESCENCE ANTIBODY TEST.

The lesional exudate is smeared on a glass slide and

stained with fluorescein-labeled anti-*T. pallidum* immunoglobulin. In contrast to darkfield microscopic examination, the smear can be held for later evaluation and oral or anal lesions can be examined because only *T. pallidum* is stained. The sensitivity of the test is 73%–100%.[35]

MOLECULAR TESTS. In research settings, PCR-based methods have been used to detect *T. pallidum* DNA from lesions.[75]

HISTOPATHOLOGIC EXAMINATION

Histopathologic examination is not essential for a diagnosis of syphilis, which can in many cases be made on the basis of clinical findings, serologic testing, and, for appropriate lesions and if available, darkfield microscopy. In unusual or questionable cases, however, histopathologic examination can be useful.

PRIMARY SYPHILIS. At the edge of a chancre, the epidermis shows changes similar to those of secondary syphilis, discussed later.[126] The papillary dermis shows edema and a perivascular and interstitial infiltrates characterized by lymphocytes (predominantly $CD4^+$ T cells), histiocytes, and plasma cells, with neutrophils admixed. *T. pallidum* organisms can be visualized along the dermal–epidermal junction and in and around blood vessels, using Levaditis or Warthin–Starry stains or by immunofluorescent techniques.[126]

SECONDARY SYPHILIS. Although clinically different in appearance, lesions of primary and secondary syphilis share many histologic features, with changes more marked in papular lesions and less so in macular lesions.[126] In the epidermis those changes include psoriasiform hyperplasia, exocytosis of lymphocytes, spongiform pustulation, and parakeratosis, in the dermis marked papillary dermal edema and perivascular and/or periadnexal infiltrate composed of lymphocytes and/or histiocytes, sometimes granulomatous, and most intense in the papillary dermis. Plasma cells are present in three-fourths of cases, and *T. pallidum* organisms can be seen on appropriately stained sections in one-third of cases, usually in the epidermis and less commonly around superficial dermal blood vessels.[126]

TERTIARY SYPHILIS. Histopathologically, gummatous lesions are characterized by granulomas with central zones of acellular necrosis. Endarteritis obliterans and angiocentric plasma cell infiltrates of dermal blood vessels can also be present. Nodular lesions show small granulomas in the dermis, accompanied by islands of epithelioid cells, multinucleated giant cells, lymphocytes, and plasma cells.[126]

SEROLOGY

Serologic tests for syphilis include nontreponemal tests, which detect IgG and IgM antibodies to lipoidal material released from damaged host cells and possibly from *T. pallidum,* and treponemal tests, which detect antibodies to *T. pallidum* itself. Accurate serologic diagnosis of syphilis requires both types of test. Sensitivity and specificity of selected serologic tests for syphilis are shown in Table 200-3.

NONTREPONEMAL SEROLOGIC TESTS. The two most widely used nontreponemal tests are the Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin (RPR) tests. The VDRL and RPR begin to become reactive 4–5 weeks after infection, with 100% sensitivity by approximately 12 weeks, and revert to nonreactive in 25%–30% of cases during late latent syphilis. Cases of seronegative secondary

TABLE 200-3
Sensitivity and Specificity of Serologic Tests for Syphilis

Test	Sensitivity (%)				Specificity (%)
	Primary	Secondary	Latent	Tertiary	
Nontreponemal tests					
RPR[35]	86 (77–99)	100	98 (95–100)	73	98 (93–99)
VDRL[35]	78 (74–87)	100	95	71 (37–94)	99 (98–99)
Treponemal tests

EIA[a][140]	85–97	97–100	100 (early latent) 75–100 (late latent)	NA	99–100

[a]Various EIAs from different manufacturers were tested. See citation for details.
RPR = rapid plasma reagin; VDRL = venereal disease research laboratory; TPPA = *Treponema pallidum* particle agglutination; MHA-TP = microhemagglutination assay for *T. pallidum*; FTA-ABS = fluorescent treponemal antibody absorption assay; TPHA = *T. pallidum* hemagglutination; EIA = enzyme immunoassay.

syphilis in HIV-infected persons have been reported.[120] Results can be qualitative (reactive/nonreactive) or quantitative. Quantitative results are reported as titer, which refers to serial dilutions of serum by a factor of 2 (1:2, 1:4, 1:8, and so on). The reported titer represents the most dilute sample that gives a reactive result. RPR and VDRL titers cannot be directly compared, and even for the same test, reported titers may differ slightly between laboratorians and laboratories. Because of the importance of using nontreponemal titers to assess response to treatment, a titer for each person diagnosed with syphilis must be obtained on the day-of-treatment. Without a day-of-treatment titer, it is very difficult to interpret subsequent titers to determine whether the person has responded to treatment appropriately.

In most persons, following appropriate treatment, nontreponemal titers will revert to nonreactive. In persons treated for primary syphilis, nontreponemal tests become nonreactive in 60% by 4 months and in nearly all patients by 12 months.[127] In persons treated for secondary syphilis, the tests usually become nonreactive 12–24 months after treatment. If therapy is administered in the early latent stage, nontreponemal tests may remain reactive in low titers for up to 5 years or longer. Persons with late latent syphilis may have nonreactive nontreponemal test results, even without a history of treatment. In some persons nontreponemal antibodies can persist at a low titer for long periods, and sometimes for life, in what is called a serofast reaction which, as mentioned previously, might be more common in HIV-infected persons.[121]

False-negative results occur during very early infection or in latent and late syphilis. In a small percent of secondary syphilis cases, very high antibody titers inhibit test reactivity, producing a false-negative result, called the prozone phenomenon. To exclude the prozone phenomenon the test must be repeated with diluted serum. Many laboratories do not routinely check for the prozone phenomeon, so clinicians must request rule out of the prozone phenomenon in the appropriate setting (e.g., a patient with a suspicious rash and a negative nontreponemal test result).

Biologic false-positive results constitute approximately 1% of reactive nontreponemal tests and usually have low titers (<1:8). Causes of biologic false-positive results are shown in Table 200-4.

TREPONEMAL SEROLOGIC TESTS. Examples of treponemal serologic tests include the *T. pallidum* particle agglutination (TPPA) test, the microhemagglutination assay for *T. pallidum* (MHA-TP), the fluorescent treponemal antibody absorption assay (FTA-ABS), the T. pallidum haemagglutination test (TPHA), and various treponemal enzyme immunoassays (EIAs) and immunochemiluminescence assays. These tests, which use whole or fragments of *T. pallidum* as antigen, directly detect infection with *T. pallidum*. Compared with nontreponemal tests, they are more cumbersome to perform—except for treponemal EIAs—but have greater sensitivity in the primary and late stages and slightly higher specificity. They have historically been used, and in many setting are still used, to confirm syphilis, since a reactive treponemal test result essentially rules out the possibility of a biologic false positive reaction on a nontreponemal test. A reactive nontreponemal test result followed by a reactive treponemal test result, hence, confirms a diagnosis of syphilis. The test results must be interpreted in light of clinical findings and prior serologic test results in order to determine whether the case of syphilis is new or old, and, if the latter, previously treated successfully or not.

Persons who have had syphilis usually will have reactive treponemal test results for life, even after successful treatment, making a reactive treponemal test in a person with a history of syphilis generally not useful clinically. However, 15%–25% of treponemal tests become nonreactive between 2 and 3 years after treatment of primary syphilis.[128] The tests are highly specific and sensitive during the secondary and the late phases of the disease. Treponemal test titers do not correlate with, and are not used to monitor, disease activity. Sensitivity is low in the weeks after infection but is nearly 100% by 12 weeks. Importantly, treponemal tests can become reactive within 12 weeks of infection, before nontreponemal tests are reliably positive, and clinicians should consider ordering treponemal tests for persons suspected of early infection even if a nontreponemal test result is nonreactive. False-positive results in treponemal tests are also rare but have been associated with infections, autoimmune or connective tissue disease, or narcotic addiction.[39,128,129]

Historically, nontreponemal tests have been less expensive to perform than treponemal tests and, as a result, have been used as the first step of the laboratory algorithm for syphilis diagnosis. However, the automation of EIA tests, a form of treponemal test, has made EIAs less expensive for large-volume laboratories to perform.[39,130] As a result, some large-volume laboratories have begun to use EIAs rather than nontreponemal tests as the first step of the algorithm for laboratory diagnosis of syphilis.[39] In this newer algorithm, a treponemal EIA is performed first. If and only if that EIA result reactive, a nontreponemal test is performed. Reactive results on both tests confirm a diagnosis of syphilis. Again, knowledge of clinical findings and results of prior serologic tests for syphilis is necessary to appropriately interpret the results. In approximately 3% of cases, a reactive treponemal EIA result is followed by a nonreactive nontreponemal test result. In those cases, a tie-breaker test, usually consisting of an alternate treponemal test, can be performed, with data combined with clinical suspicion to determine diagnosis and treatment.[130] Of note, numerous rapid, point-of-care serologic tests for syphilis are available worldwide and have high sensitivity and specificity, although none have been cleared for use in the United States.[39]

CONGENITAL SYPHILIS

Transplacental transfer of maternal nontreponemal and treponemal IgG antibodies to the fetus

TABLE 200-4
Causes of Biologic False-Positive Nontreponemal Tests

[a]Note: Evidence for pregnancy as a cause of biologic false-positive reactions is limited and concern persists for clinicians failing to diagnosis syphilis in pregnancy.

complicates serologic diagnosis of congenital syphilis.[38] Infants born to mothers with reactive nontreponemal and treponemal tests should be evaluated with a quantitative nontreponemal serologic test performed on infant serum, as umbilical cord blood might be contaminated with maternal blood, yielding a false-positive result. According to CDC, no treponemal test is necessary and none can be recommended, although some experts advocate use of a treponemal EIA for IgM (Captia Syphilis-M EIA), which has been cleared by FDA for diagnosis of congenital syphilis.[39] If possible, suspicious lesions or body fluids (e.g., nasal discharge) should be tested using darkfield microscopy or direct fluorescent antibody (DFA).[38]

CEREBROSPINAL FLUID EXAMINATION

CSF should be tested for VDRL reactivity, white blood cell count, and protein level,[38] as well as with other tests that would suggest other diseases in the differential diagnosis.

TREATMENT AND FOLLOW-UP

Based on extensive data from case series and clinical trials as well as clinical experience,[131] parenteral penicillin G is the recommended treatment for all stages of syphilis, with the preparation, dose, and length of

treatment dependent on the clinical manifestations, stage of disease, and age of the patient.[38] Benzathine penicillin G, the recommended preparation of penicillin for most stages of syphilis, has a long half-life, which is critical therapeutically because of the slow dividing time of *T. pallidum*. The choice of penicillin formulation is important in assuring adequate treatment. In the United States, the only penicillin product that is appropriate for treatment of primary, secondary, or latent syphilis is Bicillin L-A®, which contains only benzathine penicillin G. Another similarly packaged product, Bicillin C-R®, contains procaine penicillin G in addition to benzathine penicillin G and is not an appropriate treatment. Substantial confusion and errors relating to those two products have been reported.[132,133]

Penicillin-allergic persons with syphilis who are not pregnant and do not have neurosyphilis may be treated with doxycycline. Pregnant women who are penicillin-allergic must be desensitized to and treated with penicillin, which is the only drug that is known to cross into the placenta and treat infection in the fetus.[38] Reports of treatment failures and emergence in *T. pallidum* of resistance to macrolides including azithromycin, at one point a convenient alternative to penicillin because of its oral formulation, now precludes use of that class of drug in the U.S. and much of the world,[134–136] although it may still be used with caution in some areas.[137] As discussed previously, CDC-recommended treatment regimens do not differ on the basis of a person's HIV infection status.[38]

CDC recommendations for treatment and follow-up of adults with primary, secondary, or early latent syphilis are shown in Table 200-2. For information on children and for congenital syphilis and neurosyphilis, CDC treatment guidelines should be consulted.[38]

Clinical and serologic follow-up is important to monitor response to treatment (Table 200-2). Treatment success is generally defined as a fourfold decline in serologic nontreponemal titer (or reversion to nonreactive result) following appropriate treatment, in the absence of persistent signs or symptoms of syphilis, and within a specified timeframe depending on stage of infection and HIV infection status of the infected person.[38] An example of a fourfold decline in titer is a 1:64 titer declining to 1:16 or lower, or a 1:16 titer declining to 1:4 or lower. CDC recommends follow-up at 6 month intervals until a fourfold decline is documented, except for HIV-infected persons with primary or secondary syphilis, for whom follow-up every 3 months during the first year is recommended, and congenital syphilis, for whom follow-up every 2–3 months is recommended.[38] In practice, however, many experts recommend follow-up at 3-month intervals.

A fourfold titer increase following appropriate treatment indicates reinfection or treatment failure—the latter in some cases associated with neurosyphilis—with treatment depending on which of those is believed to have caused the increase. Reinfection must be assessed by clinical history and physical examination. If treatment failure cannot be ruled out, the patient should be treated with 7.2 millions units of benzathine penicillin G (divided in three weekly doses); CSF examination should be performed to determine whether neurosyphilis is present, and, if it is, the patient should be treated for neurosyphilis as well.

COMPLICATIONS OF TREATMENT

The Jarisch–Herxheimer reaction is a self-limited clinical syndrome consisting of fever, headache, flare of mucocutaneous lesions, tender lymphadenopathy, pharyngitis, malaise, myalgias, and leukocytosis. It occurs within 12 hours of initiating therapy and resolves within 24–36 hours. The fever peaks 6–8 hours after the onset, usually around 39°C (102.2°F), but it can be as high as 42°C (107.6°F). Patients should be warned about the possibility of developing this reaction before receiving treatment. Acetaminophen can be used to attempt to diminish the reaction, although very little evidence of its effectiveness exists.[138] The patient should be encouraged to rest, maintain fluid intake, and seek medical attention if symptoms are severe. The pathogenesis of the Jarisch–Herxheimer reaction is unknown, but is thought to result from cytokine release mediated by the release of lipoproteins from dying *T. pallidum* organisms.[138] In pregnant patients, the Jarisch–Herxheimer reaction may lead to premature contractions or loss of fetal movement, events that should prompt the patient to seek evaluation. However, given the potentially devastating effects of congenital syphilis, prompt treatment of maternal syphilis is critical.[38]

Anaphylaxis from administration of penicillin injection is a life-threatening emergency that is managed by intramuscular injection of epinephrine and diphenhydramine with hydrocortisone intravenously along with emergent transfer to a monitored setting.[47]

At the time of initial treatment, patients should be educated to distinguish an allergic reaction, which precludes further treatment with penicillin or related drugs, from a Jarisch–Herxheimer reaction, which does not.

DISEASE REPORTING AND MANAGEMENT OF PERSONS EXPOSED TO SYPHILIS

As reflected by the efforts to eliminate syphilis in the United States, prevention and control of syphilis are of substantial public health interest in the United States and worldwide.[2,26] Syphilis is a nationally notifiable disease in the United States, meaning that both clinicians and laboratories are mandated by law to report cases or laboratory results diagnostic of or suspicious for syphilis to their local or state public health authorities.[57] Clinicians should contact their local or state health department to familiarize themselves with local reporting requirements, including required forms and need for paper-based or electronic reports, for syphilis and other reportable diseases.

Local or state public health authorities maintain databases of syphilis diagnoses, laboratory results, and

treatments for persons diagnosed with syphilis. That information is available to clinicians taking care of persons with suspected syphilis and can be helpful in staging infections (e.g., determining if criteria for early latent syphilis are met) and assuring appropriate treatment. Clinicians should routinely encourage persons diagnosed with syphilis to inform their sex partners of exposure to syphilis and follow-up with patients to assure that disclosure has occurred. Identifying which sex partners are at risk of infection depends both on the elapsed time since last exposure and stage of infection in the source patient. This risk period is 3 months plus duration of symptoms for primary syphilis, 6 months plus duration of symptoms for secondary syphilis, and 1 year for early latent syphilis and latent syphilis of unknown duration. Clinicians should also inform persons they diagnose with syphilis that the case will be reported to the public health authority and that, in many cases, health department workers (sometimes called Communicable Disease Investigators [CDIs] or Disease Intervention Specialists [DIS]) will contact the person to ensure that treatment was adequate, provide education about syphilis, solicit contact information for sex partners, and inquire about sexual behaviors so that prevention and control resources can be targeted to affected populations. It is a principle of public health practice, including in syphilis contact-tracing investigations, to protect the confidentiality of the source partner.

Management of at-risk sex partners of persons diagnosed with syphilis also depends on elapsed time since exposure.[57] Sex partners exposed during the 90 days preceding the diagnosis of primary, secondary, or early latent syphilis should be examined and tested for syphilis. However, regardless of results of the physical examination and laboratory tests, those partners should be treated presumptively because of the high efficacy of prophylactic treatment and the likelihood (up to 63%) that they been infected but have yet to show clinical or laboratory evidence of disease. Persons exposed >90 days before the diagnosis of primary, secondary, or early latent syphilis should also be examined and tested and treated presumptively if serologic test results are not available immediately and the opportunity for follow-up is uncertain. Sex partners of persons with late latent syphilis should be evaluated and tested, and then managed on the basis of those findings.

Chapter 201 :: Endemic (Nonvenereal) Treponematoses

:: Nadine Marrouche & Samer H. Ghosn

ENDEMIC TREPONEMATOSES AT A GLANCE

- Pinta, yaws, and endemic syphilis (bejel) are nonvenereal infections usually acquired by skin-to-skin-contact.
- They are caused by *Treponema pallidum* subspecies or closely related treponemes.
- They are mostly endemic in rural areas within tropical and subtropical regions of selected countries.
- Like venereal syphilis, these infections are clinically characterized by three successive stages separated by periods of latency.
- Although not fatal, they are disfiguring and disabling.
- Penicillin therapy is highly effective for both the cutaneous and systemic lesions.

INTRODUCTION

The endemic, or nonvenereal, treponematoses are infections caused by bacteria that are closely related to *Treponema pallidum pallidum*, the etiologic agent of venereal syphilis. These include *Treponema carateum* (pinta), *Treponema pallidum pertenue* (yaws), and *Treponema pallidum endemicum* (bejel or endemic syphilis). The diseases are distinguished from venereal syphilis by mode of transmission, age of acquisition, geographic distribution, and clinical features. Unlike syphilis, they are transmitted mostly among children living in tropical and subtropical climates, chiefly by casual contact rather than sexual contact, and congenital infection is unusual. As many as 2.5 million persons are believed to be infected with nonvenereal treponematoses. However, a significant proportion of infected persons remain asymptomatic. Like venereal syphilis, the diseases progress through successive clinical early (primary and secondary) and late stages usually separated by periods of latency.[1]

Without treatment, patients remain potentially infectious indefinitely, although the skin lesions may become inconspicuous or subclinical. Patients do not develop lifelong immune resistance. Cross-immunity is absent in the early stages of endemic syphilis, yaws, and pinta but is variable in late stages. Notably, patients with late pinta are resistant to syphilis, but those with yaws or syphilis at any stage are susceptible to pinta. The level of cross-protection may be proportional to the severity of the initial infection.[1] Untreated treponematoses are nonfatal but may cause cutaneous lesions and deformities of the bone and cartilage. This potentially leads to significant disfigurement, pain, disability, and social isolation, thus incurring a significant economic burden on already disadvantaged populations.

MICROBIOLOGY

The different treponemal species causing venereal and nonvenereal treponematoses are morphologically and serologically identical and induce comparable histopathological changes. This reflects the high antigenic relatedness among these organisms and justifies the long-standing controversy about the origin of these diseases. Some authors had even claimed that the morphologically identical treponemes represent the same organism causing different clinical manifestations under different climatic conditions.[2] Over the past two decades, evidence from molecular studies has accumulated supporting the argument for species specificity. Molecular data have allowed the elucidation of genetic features differentiating *T. pallidum pallidum* from the nonvenereal treponemes.[3–7] It was not until recently that Centurion et al identified subspecies-specific genetic signatures in the *trp* gene family that allow differentiation among the *T. pallidum* subspecies.[8]

PINTA (CARATE, MAL DE PINTA, AZUL)

EPIDEMIOLOGY AND ETIOLOGY

Pinta is an ancient disease that was first described in the sixteenth century in Amerindians.[9] The causative organism is *T. carateum*, which is the least antigenically related to the other human treponemes as it is a separate species from *T. pallidum*. The name of the organism derives from the Colombian word for the disease ("carate"), in reference to the color changes seen in persons having the disease. The organism can be propagated only in primates, and no isolates are known to exist.[10] Consequently, much less is known about this treponeme than any of the others.

The incidence of the disease has remarkably decreased over the last few decades. Today, pinta remains prevalent in scattered foci in rural areas of Central and South America (Southern Mexico, Brazil, Colombia, Venezuela, Peru, and Ecuador), where people still live in crowded, unhygienic conditions. People of all ages may be infected. However, half of

all patients are younger than 15 years of age.[11] The exact mechanism of disease transmission is not fully elucidated, but repeated direct lesion-to-skin contact is the most likely mode. Transmission through insects is unlikely.[1] Because cell-mediated immunity is not completely effective against this organism, untreated infection persists indefinitely.

CLINICAL FINDINGS

Pinta is the most benign of the endemic treponematoses with the skin being the only organ of involvement. As in syphilis, there are three distinct clinical stages. Lesions at different stages may be present in a single patient. Lymphadenopathy may develop during any stage.

PRIMARY STAGE. A small number (1–3) of erythematous macules or papules appear at the site(s) of inoculation after an incubation period of 1–8 weeks. Primary lesions are usually nonpruritic and do not ulcerate. Sites of predilection include exposed areas of the extremities in addition to the face and neck. The initial lesions expand or coalesce with other lesions over several weeks to months, forming irregular scaly lichenified plaques that can reach a diameter of up to 20 cm (Fig. 201-1).[12] Over time, the center of the lesions becomes hypochromic, grayish, light blue, or pale mauve.[1] Eventually, lesions may heal spontaneously with residual depigmentation[13] or may persist for years.

SECONDARY STAGE. After several months and occasionally up to 10 years after the initial infection, secondary lesions (pintids) start to appear. These are highly infectious lesions teeming with spirochetes.[12] Like the primary lesions, pintids start as erythematous scaly papules that enlarge and coalesce into psoriasiform plaques. However, they tend to be smaller and more extensive than the primary lesions. They may encircle the sites of the primary lesions or erupt generally on the body. Pintids may occur on the palms, soles, and groin.[1] Some lesions may be circinate or annular with raised borders where the number of treponemes is highest. Over time, lesions display remarkable variation in color ranging from copper colored to gray to slate blue.[11]

Figure 201-1 Lichenified patch in primary pinta with dyschromic changes.

Figure 201-2 Depigmented and hyperpigmented, mottled patches in late pinta.

TERTIARY STAGE. Late lesions usually develop 3 months to 10 years after the appearance of the secondary lesions. Typically, patients have dyschromic patches that are hyperchromic, hypochromic, and achromic, which impart a mottled pattern with a variegated palette of white, brown, blue, red, and violet. The lesions have irregular borders and vary in size. The most commonly involved areas are the wrists, palms, ankles, and elbows as well as the skin around and within old lesions (Fig. 201-2). It is common for periarticular lesions of pinta to exhibit scarring and atrophy ("cicatricial lesions of pinta").[9] This is in contrast to extensor surface plaques that tend to be hyperkeratotic.[14] Patients with only late-stage lesions may appear to have vitiligo ("vitiligo of pinta").

DIFFERENTIAL DIAGNOSIS

(Box 201-1)

YAWS (FRAMBOESIA TROPICA, PIAN, BUBA, PARU, PARANGI)

EPIDEMIOLOGY AND ETIOLOGY

Yaws is caused by *T. pallidum pertenue*. The spirochete can be propagated in laboratory animals, and various strains have been isolated for investigation.[1] The infection affects rural populations along the tropical belt in areas with high humidity, heavy rain, and annual temperatures at and above 27°C.[15] The spread of the spirochete is facilitated in the setting of poor hygiene, scanty clothing, and overcrowding.[11]

Yaws is the most prevalent nonvenereal treponematosis. An estimated average of 50 million persons was infected in the early 1950s. Massive WHO supported treatment campaigns were carried from the

mid-1950s to the early 1960s, which resulted in a dramatic decrease in the prevalence of the disease.[16] However, due to relaxed surveillance and control measures, under-diagnosis, and the persistence of poor sanitary conditions, a resurgence of yaws has been documented in regions of Africa and Southeast Asia. Sizable foci have been reported in several tropical regions of western and central Africa (Ghana, Togo, Benin, and the Central African Republic), and residual foci remain in South America (Colombia, Guyana, Peru, Ecuador, and Brazil), Haiti, Dominica, Southeast Asia, Indonesia, Papua New Guinea, and the Solomon Islands.[11] Approximately 75% of new cases arise in children younger than 15 years of age.[17,18] Currently, at least 100 million children are estimated to be at risk of becoming infected.[1]

The main route of transmission of yaws is direct skin-to-skin contact and via contact with open wounds, excoriations, or bites.[19] Some experts claim that the disease can be transmitted through domestic utensils or by the eye flies (eye gnats) that are 1.5–2.5 mm long and do not bite but rather feed on body fluids of various animals including humans.[1]

CLINICAL FINDINGS

Yaws shares numerous clinical characteristics with venereal syphilis. In contrast to pinta, the disease is not skin-limited. Among the nonvenereal treponematoses, the disease is characterized by the most destructive and disfiguring skeletal involvement.

PRIMARY STAGE. In the primary stage, skin lesions appear after an incubation period of 10–90 days (on average 3 weeks). Classically, the initial presentation is a single nontender but often pruritic erythematous infiltrated papule (mother yaw or buba madre) that often acquires a papillomatous surface.[1] Its location often indicates the site where the spirochete penetrated the skin, usually the legs, feet, or buttocks.[20] Satellite papules may be present. Over time, the mother yaw enlarges radially reaching up to 5 cm in diameter and occasionally merges with the smaller satellite lesions forming a larger plaque. It often ulcerates, forming the "chancre of yaws", and develops a yellow–brown crust which ultimately sloughs off, uncovering a moist soft base that is often likened to a raspberry, hence the synonym "framboesia" (Fig. 201-3). The ulcer is very rich in treponemes. Fever, regional lymphadenopathy, and arthralgias may accompany this stage.[14] The mother yaw heals over 3–6 months but sometimes remains through the secondary stage of the disease. It typically leaves a depigmented pitted scar with dark margins.[21]

SECONDARY STAGE. The lesions of secondary yaws, known as "daughter yaws" or pianomas, may appear while the mother yaw is still present, but may take up to 2 years to develop.[1] These lesions resemble the mother yaw but are smaller (up to 2 cm) and more disseminated (Fig. 201-4A). They are often accompanied by constitutional symptoms such as fever, malaise, and generalized lymphadenopathy. Over time, daughter yaws may ulcerate and secrete a fibrinous exudate teaming with infectious treponemes (Figs. 201-4B and 201-4C).

The exudate attracts flies, which can cause great suffering to the affected person. Lesions usually favor perioroficial locations, such as around the mouth and nose.[14] In addition to the characteristic exudative papillomas,

Figure 201-3 Ulcerated primary-stage nodule (mother yaw). The genital location is unusual.

Figure 201-4 **A**. Early secondary lesions of yaws (daughter yaws) appearing as eroded and crusted papules and plaques. **B**. Warty secondary-stage papillomas (daughter yaws). **C**. dry papulosquamous patches (pianides), comparable to those seen in venereal syphilis, may appear on any body part.[20] Occasionally, central clearing results in an annular morphology simulating a fungal infection and these have been called "tinea yaws."[14] In the body folds, secondary lesions simulate condyloma lata. More rarely, the mucous membranes, especially the oral cavity, are involved in the form of hypertrophic mucous patches.[1] Hyperkeratotic lesions, affecting mainly palms and soles, are characteristic. They are referred to as "crab yaws" because they get fissured and infected resulting in a painful "crablike" debilitating gait (Fig. 201-5).[17] Periungual hyperkeratosis results in a paronychia which is known as "pianic onychia."[22] Of special interest is the influence of the climate on the clinical expression of yaws. During wet seasons, lesions tend to be more florid and diffuse whereas they are less exudative and confined to the moist intertriginous areas in the setting of a dry climate.[11] They also tend to assume atypical morphologies in dry seasons. Some reports describe an attenuated, less contagious form of yaws in areas of low disease prevalence. This form is less florid with few (even single), small, dry, lesions that are often limited to skin folds.[1]

Figure 201-5 Fissured hyperkeratotic plantar keratoderma in secondary yaws (crab yaws).

Bone and joint manifestations may already occur during this early stage of the disease.[23] These consist of painful osteoperiostitis of the forearm or leg, in addition to the proximal phalanges of the hands or feet. The characteristic "ghoul (monster) hands" appearance reflects swelling of the proximal two phalanges.[1] Some of the early bone changes can be seen on radiographs. Periosteal thickening can often be palpable.[24] Lesions of secondary yaws tend to resolve spontaneously without scarring over weeks to months. The disease then enters a latent stage during which relapses, usually one or two, are common. In relapsing yaws, lesions tend to be confined to the perioral, perianal, and periaxillary areas. Recurrences are possible for as long as 5 years after the initial infection. This is followed by either elimination of the organisms or in most cases a lifelong latency period.[1]

TERTIARY STAGE. Tertiary yaws is estimated to develop in approximately 10% of cases around 5–10 years after inoculation.[11] This stage is characterized by irreversible soft tissue and skeletal deformities. Gummatous suppurative nodules may involve the skin and subcutaneous tissues (gumma framboesiodes). These often break down and coalesce into serpiginous ulcers characterized by significant necrosis. Eventually, keloidal scarring and debilitating contractures ensue.[11,14] Hyperkeratotic lesions on the palms and soles, similar to those occurring in early yaws, are another common cutaneous manifestation of this stage and may lead to palmoplantar keratoderma. Mottled depigmentation of the hands, over the wrists, and along the shins has been described in older adults.[1]

Different forms of skeletal involvement lead to variable manifestations. Hypertrophic periostosis can result in unilateral or bilateral exostosis of the nasal process of the maxillae called "goundou."[25] Destructive ostitis can lead to curvature of the tibia (saber tibia) or, rarely (in 1% of untreated persons), to the dreaded mutilating rhinopharyngitis obliterans, also known as "gangosa." The latter results from massive ulcerative

destruction of the nasal cartilage and other midfacial structures.[9] Joint manifestations include the development of juxta-articular subcutaneous nodules which can ulcerate. These are not to be confused with the nodules of early yaws.[11] Although very rare, ocular (optic disc atrophy), CNS (myeloneuropathy), and cardiovascular (aneurysms) abnormalities have been reported in late yaws.[1,26] Some have even suggested that all known complications of venereal syphilis can occur in yaws.[27]

DIFFERENTIAL DIAGNOSIS

(Box 201-2)

ENDEMIC SYPHILIS (BEJEL, FIRJAL, LOATH, BISHEL, BELESH, NJOVERA)

EPIDEMIOLOGY AND ETIOLOGY

Bejel is the name given by the Arab Bedouins of Syria and Iraq to endemic syphilis.[14] The causative organism is *T. pallidum endemicum*. It is prevalent among rural communities in dry and arid climates, under conditions of crowding and poor hygiene.[11] For centuries, it was encountered in Northern Europe, Southeast Asia, and Southern Africa. Nowadays however, it is mostly prevalent among nomads and semi-nomads in the Arab Peninsula (Iraq, Syria, and Saudi Arabia), and along the Sahel (Southern border of the Sahara desert).[11,14] The recent literature points toward a marked resurgence of the disease in North Burkina Faso,[28] Turkey,[29] and Niger.[30] In endemic areas, children under 15 years of age represent around 80% of all cases and serve as an important disease reservoir.[31] Transmission occurs via direct contact with infectious lesions on the skin and mucous membranes. One study demonstrated the presence of treponemes on a drinking flask, supporting indirect transmission through sharing food and fomites.[32,33]

CLINICAL FINDINGS

Like yaws, the clinical features of bejel resemble those of venereal syphilis, except that mucosal involvement tends to predominate. Although joint pain and bone changes are common, they tend to be less severe than the skeletal manifestations seen in yaws.

PRIMARY STAGE. Early lesions of endemic syphilis start to appear after an incubation period of 2–4 weeks. In contrast to other nonvenereal treponematoses, primary lesions often go unnoticed because they usually involve the oral and nasopharyngeal mucosa. These present as painless, small papules that may become eroded and ulcerated. Lesions on the nipples of breastfeeding women can also be seen. Primary lesions usually resolve in 1–6 weeks.[12]

SECONDARY STAGE. This stage develops around 6 months postinoculation. It is characterized by both mucocutaneous and skeletal manifestations. Painless, often macerated and eroded mucous patches develop on mucosal membranes of the oral cavity, nasopharynx, and might even reach the larynx. Angular stomatitis (also known as split papules) appear at the labial commissures.[1] Skin lesions include vegetating condyloma lata in the moist intertriginous areas of the axillae and groin. These are comparable to those seen in yaws and venereal syphilis.[11] In up to 15% of cases, a diffuse skin rash with generalized lymphadenopathy may develop. As in secondary syphilis, the rash can assume different morphologies such as macular, papular, or annular lesions. Painful periostitis of the long bones and hands, as in yaws, may occur at this stage leading to nocturnal lower extremity pain.[14] Untreated, secondary lesions continue to appear for up to 9 months postinoculation. This is followed by a latent stage of variable length (up to 15 years). Occasionally, it may last for only few months leading to the development of the tertiary stage at a very young age.[21]

TERTIARY STAGE. Tertiary bejel is characterized by mucocutaneous and skeletal manifestations in the

Figure 201-6 Cutaneous gummas in late endemic syphilis. Note the involvement of the elbow.

BOX 201-3 DIFFERENTIAL DIAGNOSIS OF ENDEMIC SYPHILIS

Most Likely

- Condylomata acuminata

- Mycobacterial infection (gummas)
- Lymphomas and sarcomas (gummas)
- Granulomatous diseases (gummas)

Always Rule Out

- Venereal syphilis

form of deforming gummas that tend to be generally less mutilating than those of yaws (Fig. 201-6). In the skin, destructive ulcers result eventually in the formation of depigmented scars with hyperpigmented borders. Mucosal involvement may eventuate in disfiguring complications such as saddle-nose deformity, palate perforation, and gangosa.[12] The larynx has been reported to be solitarily involved.[34] Although joint pain and bone changes are common, they tend to be less severe than the skeletal manifestations seen in yaws. They are often only noticeable by plain radiography. Uveitis, optic atrophy, and even chorioretinitis have been reported.[35] Cardiac involvement seems to be extremely rare and has been reported in the form of aortitis and saccular aneurysms of the aortic arch.[12] An attenuated form of endemic syphilis with fewer, more rapidly healing cutaneous lesions but more frequent periostitis has been reported. As in attenuated yaws, this milder form has been attributed to better nutrition and hygiene, and earlier access to antibiotic therapy.[14]

DIFFERENTIAL DIAGNOSIS

(Box 201-3)

DIAGNOSIS OF THE NONVENEREAL TREPONEMATOSES

A presumptive diagnosis of pinta, yaws, or endemic syphilis in a given patient should be suspected on the basis of the clinical findings in the setting of an endemic area (Table 201-1). However, this task is difficult at times, especially in view of the occurrence of sporadic cases outside areas of endemicity. Health care providers with limited experience in recognizing these diseases frequently misdiagnose them as impetigo, psoriasis, mycobacterial infection, or tropical ulcer, among other diseases. The diagnosis is confirmed by detection of the treponemes under darkfield microscopic examination or with a direct fluorescent antibody (DFA) test, by serology, or by histologic examination. Darkfield microscopy allows microscopic examination of the serous exudates of lesions and permits a rapid demonstration of treponemes; however, it necessitates expertise and is not readily available. DFA test allows a more sensitive and specific microscopic diagnosis. However, this technique is only available in central laboratories.[1] The same serological tests used in the diagnosis of venereal syphilis are used to diagnose the endemic treponematoses; however, no single test is yet available that can differentiate endemic treponematoses from each others or from venereal syphilis. These tests are affordable, readily available, and can be particularly helpful when microscopic tools are nonrevealing or unavailable.[11] Nontreponemal serological tests are usually used for screening, whereas treponemal tests are used for diagnosis confirmation. Nontreponemal tests, including the Venereal Disease Research Laboratory test and the Rapid Plasma Reagin test, use a nonspecific cardiolipin antigen that is cross-reactive among the various treponemes. Positivity indicates either a recent or a current infection. In yaws and endemic syphilis, nontreponemal tests yield reactive results in 2–3 weeks after the onset of the primary lesion. In pinta, these tests give reactive results in 80% of cases within 3 months after the appearance of primary lesions and in essentially all patients with the late stage of the disease.[36] After treatment, serological titers of the nontreponemal tests decrease, which makes them valuable in monitoring

TABLE 201-1
Nonvenereal Treponematoses—Clinical Manifestations

	Pinta	Yaws	Endemic Syphilis
Causative organism	*Treponema carateum*	*Treponema pallidum pertenue*	*Treponema pallidum endemicum*
Transmission	Skin-to-skin contact	Skin-to-skin contact, via eye flies (?)	Skin or mucosal contact, via drinking flasks (?)
Peak ages	1–15 years	1–15 years	Months–15 years
Incubation	7–60 days	10–90 days	15–30 days
Primary lesions	Erythematous papules become psoriasiform plaques	Vegetating, soft, ulcerating papule (mother yaws) with satellites	Small eroded mucosal papule (often overlooked)
Secondary lesions	Erythematous scaly and psoriasiform plaques (pintids); dyschromia	Warty or frambesiform nodules (pianomas), papulosquamous plaques (pianides), palmoplantar plaques, pianic onychia	Mucous patches (split papules), condylomata lata, syphilis-like eruptions
Tertiary lesions	Dyschromic, hypochromic, achromic, and polychromic patches	Serpiginous gummas, pintoid dyschromia, juxta-articular nodes, gangosa, goundou, keratoderma	Gummas, gangosa, juxta-articular nodes on elbows only
Reactive serologic test result	2–3 months after primary lesion	2–3 weeks after primary lesion	2–3 weeks after primary lesion
Treatment	Penicillin	Penicillin	Penicillin

patients post-therapy. The specific treponemal tests, which use *T. pallidum* as an antigen, include the fluorescent treponemal antibody absorption (FTA-ABS) and the microagglutination assays for antibodies to *T. pallidum* (MHA-TP) tests. They are important in excluding false-positive nonspecific tests. In contrast to the nontreponemal tests, they may not only indicate a current or recent infection, but would remain reactive even after adequate treatment, indicating as such a past infection ("serological scar").[1] Other treponemal tests, including enzyme immunoassays, have not shown greater specificity than the FTA-ABS test but may be less expensive.[36] A finger-prick indirect hemagglutination test is advantageous for screening children.[37]

Although serological tests are still the most practical diagnostic tool, they are not subspecies specific. Recent identification, by molecular testing, of reliable genetic signatures for the different treponemal subspecies, may prove in the near future to be a valuable tool not only for research but also for diagnostic purposes.

HISTOPATHOLOGIC FEATURES OF THE NONVENEREAL TREPONEMATOSES

In early pinta, the epidermis shows only mild acanthosis, spongiosis, and lymphocytic exocytosis. The basal cell layer exhibits decreased keratinocyte pigmentation and liquefactive necrosis. In the dermis, melanophages are numerous and there is a mixed perivascular inflammatory cell infiltrate consisting mainly of plasma cells and lymphocytes, with scattered histiocytes and neutrophils. Unlike in venereal syphilis, endothelial cells only occasionally exhibit mild swelling. Identification of treponemes using silver staining or immunofluorescence techniques is possible in the early stages. In the tertiary stage, the epidermis might become atrophic. Langerhans cells are noted to be increased.[38] The inflammatory infiltrate becomes sparse or even absent, especially in the depigmented lesions. Visualization of treponemes becomes more difficult, particularly in hypo/depigmented patches.[11,14]

Findings of yaws are similar to those of pinta, but yaws usually causes ulcer formation. In early yaws, acanthosis, papillomatosis, focal spongiosis, and neutrophilic exocytosis/microabscesses are the main epidermal changes.[39] Throughout the stages of the disease, a diffuse inflammatory cell infiltrate composed mostly of plasma cells is usually seen in the dermis. This is in contrast to venereal syphilis, where a T-cell dermal infiltrate has been identified in the early disease stage.[40] Yaws spirochetes exhibit striking epidermotropism in contrast to venereal syphilis where the spirochetes favor the dermal compartment. Blood vessels show little or no endothelial cell proliferation. Endarteritis is a feature of late lesions.[11,14]

The changes seen in bejel closely resemble those of venereal syphilis particularly with regard to the presence of giant cell granulomas. The epidermal changes seen in secondary bejel lesions resemble those of

BOX 201-4 TREATMENT OF THE NONVENEREAL TREPONEMATOSES

First Line	Benzathine penicillin G	>10 years	1.2 million units IM	Single dose
		<10 years	0.6 million units IM	Single dose
Second Line	Oral erythromycin	Adults	500 mg qid	15 days
		Children <8 years	8–10 mg/kg qid	15 days
	Oral doxycycline	Adults	100 mg bid	15 days
	Oral tetracycline	Adults	500 mg qid	15 days
		Children >8 years	250 mg qid or 25 mg/kg/day	15 days

condyloma lata; however, the dermal infiltrate in bejel is more diffuse rather than perivascular as in syphilis. Organisms are present in primary and secondary stages but not in late disease stages.[11,14]

The dyschromic patches seen in treponematoses may reveal variable alterations in basal keratinocyte pigmentation or melanocytes' number and are, as such, hard to be distinguished histologically from primary dyschromic disorders (such as vitiligo). Therefore, clinical parameters (history, physical exam, and epidemiology) are, when combined, important factors that help differentiate syphilis and the nonvenereal treponematoses from primary pigmentary disorders.

TREATMENT AND PREVENTION OF THE NONVENEREAL TREPONEMATOSES

The WHO recommends a single intramuscular injection of benzathine penicillin for the treatment of early and late stages of the endemic treponematoses (Box 201-4). With proper penicillin therapy, cure rates up to 97% are possible and lesions become noninfectious within 24 hours. In addition, the titers of the nontreponemal serological tests show a gradual decline and eventually become negative. In pinta, the achromic patches persist for life.[1] Treatment failures with penicillin have been reported in a few cases in Papua New Guinea, Colombia, and Ecuador. However, in such cases, reinfection should always be ruled out.[1,41] Erythromycin is indicated for the treatment of infections in those who are allergic to penicillin. Other macrolide antibiotics are also probably effective, despite a scarcity of reported experience. In persons allergic to penicillin, other alternatives may include tetracycline and doxycycline.[14] Close contacts should also receive therapy.

Mass treatment programs constitute an important strategy devised by the WHO to control the endemic treponematoses. Recommendations for prophylactic treatment depend on the number of seropositive children younger than 6 years of age[1] and are as follows:

1. If the prevalence is more than 50%, treatment is given to the entire population.
2. If the prevalence ranges between 10% and 50%, treatment is given to patients, their contacts, and all children under the age of 15 years.
3. If the prevalence is less than 10%, then treatment is administered only to patients and their close contacts.

Eradication campaigns have been effective using a 7- to 10-day course of oral penicillin, at a dose of 50 mg/kg per day in four divided doses up to 1,200 mg daily. However, experience has shown that mass treatment campaigns alone are insufficient.[42] Treatment of those infected and those at risk must be followed by periodic clinical follow-up, serosurveillance, and screening campaigns.[43]

Concurrent infection with human immunodeficiency virus appears to exacerbate nonvenereal treponematosis, and based on the experience with venereal syphilis, it appears prudent to screen persons at risk for human immunodeficiency virus infection.[44]

ACKNOWLEDGMENT

The authors would like to acknowledge Dr. Miguel Sanchez, the author of the seventh edition of the chapter, for his complete and comprehensive review of the topic.

Chapter 202 :: Chancroid

:: Stephan Lautenschlager

CHANCROID AT A GLANCE

- A sexually transmitted acute ulcerative disease usually localized at the anogenital area and often associated with inguinal adenitis or bubo.
- *Haemophilus ducreyi*—a Gram-negative, facultative anaerobic coccobacillus—is the causative agent.
- Although the number of cases is decreasing overall, chancroid is still common in many developing countries (Africa, the Caribbean Islands, and Southwest Asia).
- Painful, soft ulcers with ragged undermined margins develop 1–2 weeks after inoculation (usually prepuce and frenulum in men and vulva, cervix, and perianal area in women).
- Nonsexual transmission has been reported recently.
- Chancroid facilitates the transmission of HIV.
- Laboratory culture of *H. ducreyi* is problematic, but greater sensitivity can be expected by DNA amplification methods, which are currently not routinely available.
- Azithromycin and Ceftriaxone are recommended as single-dose treatment, enhancing compliance.

EPIDEMIOLOGY

Chancroid is most common in developing countries, especially in Africa and Asia, where it was isolated from over 50% of patients with genital ulcers until the 1990s.[1–3] These endemic regions also have some of the highest rates of HIV infection in the world, and chancroid is common in all 18 countries where adult HIV prevalence surpasses 8%.[4] More recent reports from Southeast Asia and Africa suggest that the incidence of chancroid may be declining in the face of a rapidly rising incidence of genital herpes.[5–9] Chancroid outbreaks have been reported in a number of cities in industrialized countries during the last two decades, predominantly in the United States.[10] After an epidemic in California in 1981, the number of cases peaked in 1987 at 5,035 cases. In a ten city study, chancroid was confirmed in 12% of genital ulcers in Chicago and 20% in Memphis.[11] In contrast, only 23 cases of chancroid were reported to the Centers for Disease Control and Prevention (CDC) in 2007.[12] The true incidence in most areas remains unclear and is probably vastly underreported because confirmatory culture media or DNA amplification methods are not commercially available.[13] The global epidemiology of chancroid is so poorly documented that it is not included in WHO estimates of the global incidence of curable sexually transmitted diseases.[4] Overall, chancroid accounted for 8 cases (3%) of genital ulcers in a sexually transmitted infection (STI) clinic in Paris from 1995 to 2005.[14]

The prevalence of chancroid is higher in lower socioeconomic groups. Recent epidemics in the industrialized countries have usually been associated with commercial sex work, the use of crack cocaine, with syphilis and an increased risk of HIV infection.[15,16] Lower-class prostitutes appear to be a reservoir in all reported outbreaks of this disease and men have a markedly higher incidence of chancroid than women.[10] Several studies in Africa showed that chancroid-ulcer is an important risk factor for the heterosexual spread of HIV-1.[17,18] In West Africa, it has been shown that 2% of female sex workers were carrying the organism asymptomatically.[19] The duration of infectivity in the absence of treatment was estimated to be 45 days for women. The transmission rate from females to males is not known, in contrast to a reported transmission rate from males to females of 70% per sex act.[20] Nonsexual transmission has been recently reported.[21,22]

CLINICAL FINDINGS

The incubation period is between 3 and 7 days, rarely more than 10 days. No prodromal symptoms are known. The chancre begins as a soft papule surrounded by erythema. After 24–48 hours it becomes pustular, then eroded and ulcerated (Fig. 202-1); vesicles are not seen. The edges of the ulcers are often ragged and undermined (Fig. 202-2). The ulcer is usually covered by a necrotic, yellowish-gray exudate (eFig. 202-2.1 in online edition), and its base is composed of granulation tissue that bleeds readily on manipulation. In contrast to syphilis, chancroid ulcers are usually tender and or painful not indurated (soft chancre). The diameter varies from 1 mm to 2 cm. Half of the males present with a single ulcer and most lesions are found on the external or internal surface of the prepuce, on the frenulum, or on the glans (eFig. 202-2.2 in online edition). Meatus and shaft of the penis and the anus (eFig. 202-2.3 in online edition) are involved less frequently. Edema of the prepuce is often seen. Rarely, if the chancre is localized in the urethra, *Haemophilus ducreyi* causes purulent urethritis.[33]

In females the lesions are mostly localized on the vulva (Fig. 202-3), especially on the fourchette, the

Figure 202-1 Early sharply circumscribed ulcer in the *coronal sulcus*.

labia minora, and the vestibule. Vaginal, cervical, and perianal ulcers have also been described. Extragenital lesions of chancroid have been reported on the breasts, fingers, thighs, and inside the mouth. Trauma and abrasion may be important for such extragenital manifestations.

Painful inguinal adenitis (bubo) occurs in up to 50% of patients within a few days to 2 weeks (average 1 week) after onset of the primary lesion (Fig. 202-4). The adenitis is unilateral in most patients, and erythema of the overlying skin is typical. Buboes can become fluctuant and may rupture spontaneously. The pus of bubo is usually thick and creamy. Buboes are less common in female patients. Besides the common types of chancroid described above, a number of clinical variants have been reported (Table 202-1). Mild systemic symptoms can rarely accompany chancroid, but systemic infection by *H. ducreyi* has never been observed. The significance of the recent detection of genetic material of *H. ducreyi* in oesophageal lesions of HIV patients[34] requires further study.

Figure 202-2 Ragged edges of a soft ulcer.

Figure 202-3 Vulvar chancroid with undermined edges.

DIFFERENTIAL DIAGNOSIS

The three classic etiologic agents for genital ulceration are (1) *H. ducreyi*, (2) *Treponema pallidum*, and (3) herpes simplex. The clinical appearance of the diseases caused by these three organisms can be extremely variable in both men and women, and therefore, clinical diagnosis of genital ulcer disease can be made with reasonable certainty only for a minority of patients.[45] The etiology of genital ulcers (Table 202-2)[46] also differs considerably by geographic region. In industrialized countries, isolated painful chancres are most likely due to herpes simplex virus.[47] In a high percentage of genital ulcers, no pathogen can be isolated but coinfections with syphilis (*ulcus mixtum*) or herpes simplex are not uncommon as well.[5,8]

Figure 202-4 Small soft ulcer on the internal surface of the prepuce with painful, fluctuant inguinal adenitis (bubo).

TABLE 202-1
Clinical Variants of Chancroid

Giant Chancroid	Single lesion extends peripherically and shows extensive ulceration.
Large Serpiginous Ulcer	Lesion that becomes confluent, spreading by extension and autoinoculation. The groin or thigh may be involved (*Ulcus molle serpiginosum*).
Phagedaenic Chancroid	Variant caused by superinfection with fusospirochetes. Rapid and profound destruction of tissue can occur (*Ulcus molle gangraenosum*).
Transient Chancroid	Small ulcer that resolves spontaneously in a few days may be followed 2–3 weeks later by acute regional lymphadenitis (French: *chancre mou volant*).
Follicular Chancroid	Multiple small ulcers in a follicular distribution.
Papular Chancroid	Granulomatous ulcerated papule may resemble donovanosis or condylomata lata (*Ulcus molle elevatum*).

COMPLICATIONS

In about half of the untreated patients, the course is that of spontaneous resolution without complications. Due to delay in treatment, various complications may occur (Box 202-1).

PROGNOSIS AND CLINICAL COURSE

The disease is self-limited and systemic spread does not occur. Occasionally, without treatment, genital ulcer and inguinal abscess have been reported to persist for years. Local pain is the most frequent complaint. If no clinical improvement is evident 1 week after the start of therapy, incorrect diagnosis, coinfection with another STI, concomitant HIV infection, poor compliance, or a resistant strain of *H. ducreyi* must be considered.

Infections do not confer immunity and reinfections are possible. To avoid reinfections, patients must be instructed to use condoms properly.

TABLE 202-2
Differential Diagnosis of Chancroid

TREATMENT

Since the 1970s, β-lactamase-producing strains of *H. ducreyi* emerged and treatment failures were common. Subsequently, further plasmid-mediated resistance to tetracycline, sulfonamides, chloramphenicol, and aminoglycosides also has been reported.[51] Little is known about chromosomally mediated resistance in *H. ducreyi*, but decreased susceptibilities to various antibiotics in the absence of identifiable resistance plasmids suggests such mechanisms.[51] Based on in vitro susceptibility, the most active drugs against *H. ducreyi* are Azithromycin, Ceftriaxone, Ciprofloxacin, and Erythromycin. Worldwide, several isolates with intermediate resistance to either Ciprofloxacin or erythromycin have been reported. Regimens actually recommended by the CDC, by WHO, and by the European STD guidelines (revised in 2011) are listed in Table 202-3.[52–54] Antibiotic combinations (e.g., Ceftriaxone and Streptomycin) showed synergy in an animal model and may be promising to improve single-dose treatment, but clinical evaluation is needed.[55] Local treatment consists of antiseptic dressings (i.e., povidone-iodine). Suppurative nodes should not be incised; if necessary, they can be punctured to prevent spontaneous rupture and sinus tract formation. A large syringe should be used and the fluctuant buboes entered laterally through normal skin. In patients with phimosis, a circumcision may be necessary when all active lesions have healed. In pregnancy, Ceftriaxone is the preferred drug, but Azithromycin can be used as well.[56]

Even after correct treatment, relapses occur in about 5% of patients and retreatment with the original regimen is recommended. Usually reinfection by an untreated sexual partner is the suspected cause of relapse.

HIV infection and lack of circumcision appear to be associated with increased likelihood of infection with *H. ducreyi* and treatment failure.[57] In resource-poor areas of the world, syndromic management can be recommended, but local epidemiology must be considered.[37,53] Flow charts for the management of genital ulcers have been developed that do not require laboratory identification of the causative pathogen.[37] If a patient complains of one or more small blisters or an ulcer with a history of recent blisters, then herpes management should be followed. If an isolated small

ulcer and painful matted gland is present, lymphogranuloma venereum, chancroid, and syphilis should be treated, and if only an ulcer is present, syphilis and chancroid should be treated.[37]

RELATION BETWEEN HIV INFECTION AND CHANCROID

Over the past decade, renewed interest in chancroid has led to evidence that genital ulcers promote the heterosexual transmission and acquisition of HIV-1.[58–62] Effective treatment of genital ulcers can reduce the incidence of HIV-1, and this strategy has become a cornerstone of HIV prevention programs in many parts of the world.[63]

Furthermore, it was shown that concomitant HIV infection has clinically significant effects on the course of the chancroid disease, and failure of single-dose[17] or short-course[59] therapy for chancroid in men is associated with HIV-1 seropositivity. A wide variation of the clinical picture of chancroid has been observed in HIV-infected patients.[59]

Epidemiologic control of chancroid may be a very important strategy to interrupt the heterosexual spread of HIV in some parts of the world. Accordingly, patients with chancroid should also be tested for HIV antibodies. HIV-seropositive patients with culture-proven chancroid should be monitored closely and treated with a multiple-day regimen.

PREVENTION

The augmentation of the HIV epidemic by *H. ducreyi* has made chancroid control an urgent priority. Patients should be advised to abstain from sexual activity until all clinical lesions have cleared. Sexual contacts of the patient (within ten days of symptom presentation) should be examined and treated regardless of whether symptoms of the disease are present, since asymptomatic carriage of *H. ducreyi* is possible.[19] Antibiotics may provide some protection from reinfection, since a single dose of azithromycin lasted as long as 2 months after treatment.[64] Chancroid survives in populations in which many men are having sex with a few women. As a result of increased condom use and social programs such as presumptive treatment plans, the cases of chancroid in Nairobi, Kenya, have decreased dramatically to less than 10% of genital ulcers.[4] In Thailand, a decrease of 95% (from 30,000 to less than 2,000 cases) was achieved in the 1990s.[4,65] On the basis of these results, eradication of chancroid seems to be a feasible public health objective.[4]

Chapter 203 :: Lymphogranuloma Venereum

:: Rim S. Ishak & Samer H. Ghosn

LYMPHOGRANULOMA VENEREUM `AT A GLANCE

- Systemic sexually transmitted disease caused by L serovars of *Chlamydia trachomatis*.
- Endemic in Africa, Southeast Asia, and South and Central America, and rare in developed countries.
- Recent outbreaks among men who have sex with men in Europe and North America.
- Clinically manifest as inguinal and anorectal syndromes, in three stages.
- Hematogenous spread with manifestations of systemic infection.
- Diagnosis by identification of organism and by serology or genotyping.
- Doxycycline or erythromycin treatment curative if given early.

EPIDEMIOLOGY

Lymphogranuloma venereum (LGV) is a sexually transmitted disease due to specific *Chlamydia* variants that is rare in developed countries. It is endemic in East and West Africa, India, Southeast Asia, South and Central America, and some Caribbean Islands; and accounts for 7%–19% of genital ulcer diseases in areas of Africa and India.[1,2] The peak incidence occurs in persons 15–40 years of age, in urban areas, and in individuals of lower socioeconomic status. Men are six times more likely than women to manifest clinical infection.[3] The incidence of LGV is low in the developed world where cases are usually limited to travelers or military personnel returning from endemic areas. Since 2003, however, outbreaks of LGV have appeared in Europe, Australia, and North America, particularly in the form of proctitis, among human immunodeficiency virus (HIV) positive men who have sex with men (MSM).[4–11]

LGV is contracted by direct contact with infectious secretions, usually through any type of unprotected intercourse, whether oral, vaginal, or anal. Transmission efficiency is unknown.[12,13] Sexual practices such as fisting and sex-toy sharing may be other routes of transmission.[4] In a recent study that compared sexual behaviors in men with LGV and men with non-LGV chlamydial proctitis, fisting was a major predisposing factor.[14] An epidemic of LGV has been reported among "crack" cocaine users in the Bahamas.[15]

Due to underdiagnosis and underreporting, the epidemiology of LGV remains poorly understood. Common diagnostic laboratory methods are nonspecific and not readily available in endemic areas. Even in industrialized countries, only a few laboratories offer specific assays to LGV serovars. Without such assays, many LGV cases are misdiagnosed as common chlamydial urogenital infection. Underdiagnosis of LGV is also largely due to the presence of an asymptomatic carrier state. Women, in particular, may harbor asymptomatic persistent infection in the cervical epithelium, thus serving as reservoirs of the infection as they do for other urogenital chlamydial infections and gonorrhea. Recently, a large study conducted in the United Kingdom found that only 6% of MSM were asymptomatic carriers of LGV *Chlamydia* serovars; the majority of cases of LGV in the rectum and urethra were symptomatic.[16] Infectivity in men usually ceases after healing of the primary mucosal lesion. Interestingly, most of the detected cases in the recent outbreaks are in men who practice receptive anal sex, suggesting that a high proportion of men who practice insertive anal sex are mis- or undiagnosed. The reasons behind this are unclear but may be organism-related, host-related (sexual practices such as fisting and the use of sex toys, intravenous drug use, HIV status, etc.) or physician-related (failure to diagnose genital LGV). The resurgence of LGV as a health problem may simply reflect increased awareness rather than increased incidence.

ETIOLOGY AND PATHOGENESIS

LGV (tropical or climatic bubo, lymphopathia venerea, Nicolas–Favre disease) is caused by *Chlamydia trachomatis* serovars (serologic variants) L1, L2, and L3.[17] Most of the recent outbreaks are caused by a number of strains of *C. trachomatis* L2 serovar (L2b), suggesting that these outbreaks most likely represent increased awareness of a slowly evolving endemic.[7–9,16,18,19]

Chlamydiae are obligate intracellular bacteria characterized by two distinct morphologic forms: (1) the small metabolically inactive and infectious elementary body, and (2) the larger metabolically active and noninfectious reticulate body. (eFig. 203-0.1 in online edition). *C. trachomatis* has been subdivided into several serovars that differ in their major outer membrane proteins, and which are associated with several diseases. Serovars A, B, and C are the causes of trachoma ocular infections, whereas serovars D-K are responsible for ocular, genital and respiratory infections.[20] In contrast to the A-K serovars that remain confined to the mucosa, LGV serovars are more invasive and have a high affinity for macrophages.[17] After being inoculated onto the mucosal surface, the organisms replicate within macrophages, and find their way to the draining lymph nodes (LNs), and cause lymphadenitis.

CLINICAL FINDINGS

CUTANEOUS LESIONS AND RELATED PHYSICAL FINDINGS

Clinical manifestations are protean, depending on the sex of the patient, acquisition mode, and the disease stage. Three clinical stages characterize LGV. Nonspecific cutaneous lesions such as erythema nodosum, erythema multiforme, urticaria, and scarlatiniform exanthema may occur with any of these stages.[21]

PRIMARY STAGE. Three to 30 days after infection, 5- to 8-mm painless erythematous papule(s) or small herpetiform ulcers appear at the site of inoculation (Fig. 203-1). Painful ulcerations[22] and nonspecific urethritis[23] are less common. In males, the lesion is usually found on the coronal sulcus, prepuce, or glans penis; and in females on the posterior wall of the vagina, vulva, or, occasionally, the cervix. Inoculation may also be rectal or pharyngeal. The primary lesion is transient, often heals within a few days, and may go unnoticed.

SECONDARY STAGE. A few weeks after the primary lesion appears, marked LN involvement and hematogenous dissemination occur, manifested by variable signs and symptoms, including fever, myalgia, decreased appetite, and vomiting. Photosensitivity may develop in up to 35% of the cases, often 1–2 months after bubo formation.[24] Less commonly, patients may develop meningoencephalitis, hepatosplenomegaly, arthralgia, and iritis.[25,26] The lymphadenitis episodes often resolve spontaneously in 8–12 weeks. Depending on the mode of transmission, two major syndromes are distinguished.

Figure 203-1 Lymphogranuloma venereum: soft painless erosion on the prepuce.

The acute genital syndrome (GS) or inguinal syndrome is characterized by inguinal and/or femoral LN involvement and is the major presentation in men. Initially, the skin overlying the affected LN is erythematous and indurated. Over the subsequent 1–2 weeks, the LN enlarge and coalesce to form a firm and tender immovable mass (bubo) (Fig. 203-2),

Figure 203-2 Early bubo consisting of unilateral enlargement and coalescence of inguinal lymph nodes. The overlying skin is erythematous and indurated. Note the absence of the primary lesion in this case. (Used with permission from Shukrallah Zaynoun, MD.)

Figure 203-3 Lymphogranuloma venereum: bilateral, firm, immovable masses above Poupart's ligament.

which may rupture and drain through the skin, forming sinus tracts. Bilateral involvement occurs in one-third of the cases (Fig. 203-3). Nodal enlargement on either side of the inguinal ligament, the "groove sign," is pathognomonic of LGV, but only presents in 10%–20% of cases[27] and is rarely bilateral.[28] In women, inguinal lymphadenitis is unusual because the lymphatic drainage of the vagina and cervix is to the deep pelvic/retroperitoneal LN. When these nodes are involved, low abdominal/back pain that exacerbates upon lying supine and pelvic adhesions may ensue.

The acute anorectal syndrome (ArS) is characterized by perirectal nodal involvement, acute hemorrhagic proctitis, and pronounced systemic symptoms. It is the most common presentation in women and in homosexual men who practice anal sex. The major source of rectal spread in women is the internal lymphatic drainage of the lower two-thirds of the vagina. Patients may complain of anal pruritus, bloody rectal discharge, tenesmus, diarrhea, constipation, and lower abdominal pain.[5,29] In a recent study, 96% of MSM patients presented with signs and symptoms of proctitis.[30] Despite affecting mostly HIV-positive MSM, LGV has not behaved as an opportunistic infection in the recent outbreak, and clinical features have not differed between HIV-positive and HIV-negative cases.[31]

TERTIARY STAGE. This stage is more seen in women with untreated ArS, and includes rectal strictures (most common) and abscesses, perineal sinuses, rectovaginal fistulae (leading to "watering can perineum"), and "lymphorrhoids" (perianal outgrowths of lymphatic tissue). Esthiomene (Greek, "eating away") is a rare primary infection of the external genitalia (mostly in women), leading to progressive lymphangitis and genital destruction. Infertility and "frozen pelvis" are potential sequelae of ruptured deep pelvic nodes in women. Late sequelae of the GS are less common and include urethral strictures and genital elephantiasis with ulcers and fistulas (in 4% of cases).[32] Penile deformities such as the saxophone penis may also occur.[33]

OTHER UNUSUAL MANIFESTATIONS

Extragenito-anal inoculation of LGV is rare. Oropharyngeal infection may manifest initially as pinhead-sized vesicles on the lip, and later on as cervical lymphadenopathy with constitutional symptoms, closely mimicking lymphoma. Tonsillitis, supraclavicular and mediastinal lymphadenopathy, and pericarditis rarely occur.[34–38] Ocular autoinoculation of infected discharges may lead to conjunctivitis with marginal corneal perforation, often with preauricular lymphadenopathy.[39] Inhalation of LGV serovars L1 and L2 may accidentally occur in laboratory workers and lead to pneumonitis with mediastinal and supraclavicular lymphadenopathy.[40]

LABORATORY TESTS

Diagnosis of LGV may be difficult, but LGV should be suspected in any patient with infected sexual contacts, genital ulcer, perianal fistula, or bubo. The accuracy of clinical diagnosis has been reported to be as low as 20%.[41] Therefore, laboratory tests are important to establish the diagnosis and are usually divided into two broad categories: (1) nonspecific tests that do not distinguish between LGV and (2) non-LGV serovars, and specific LGV tests. In practice, a positive test on LN aspirate is considered diagnostic of LGV, in contrast to a positive test on primary genital lesion where further specific testing is required to rule out common chlamydial urogenital infections.

SPECIFIC TESTS FOR LYMPHOGRANULOMA VENEREUM

Nucleic acid amplification using polymerase chain reaction (PCR) may be performed on all specimens, and has been the diagnostic method of choice in the recent outbreak. Several generations of PCR analysis have been developed over the past decade; however, most of them lacked the ability to differentiate between LGV and non-LGV strains. In 2008, a new diagnostic technique with a quadriplex reverse transcriptase PCR assay was developed. This unique technology can detect individual LGV and non-LGV infection, as well as mixed infections in rectal specimens. However its main disadvantage is that it is available only in the Centers for Disease Control and Prevention and in a few US laboratories.[42] Other newly introduced biomolecular techniques exploring immune-mediated lysis,[23] heparin sulfate lysis,[43,44] use of pooled antibody,[18] and structural genetic differences[45] seem to be promising.

NONSPECIFIC CHLAMYDIAL TESTS

The complement fixation test is the most commonly used test. Titers greater than 1:256 are highly suggestive of LGV and titers below 1:32 exclude the diagnosis unless the disease is in its early stages.[46] The microimmunofluorescence test for the L-type serovar is more sensitive & specific but less readily available.[47] In addition, culture studies may be preformed; however, they do not distinguish between LGV and non-LGV serovars, are tedious, and require special growth media. Nevertheless, a positive culture without centrifugation is highly suggestive of LGV.

In addition, direct fluorescence microscopy using conjugated monoclonal antibody against *C. trachomatis* on smears from bubo material or genital swab can be done.[48] Serology assays are sensitive but nonspecific due to cross reactivity with other chlamydial infections. In addition, they do not differentiate current from prior infection. Frei test, the earliest diagnostic modality to identify LGV, consists of an intradermal skin test assessing delayed hypersensitivity to chlamydial antigens. It is no longer used because of its low sensitivity and limited specificity due to cross reaction with *C. trachomatis* D-K.[17] Finally, other non specific laboratory findings include mild leukocytosis, false-positive VDRL, cryoprecipitates, rheumatoid factor, and high serum levels of immunoglobulin A and immunoglobulin G.[49]

DIAGNOSTIC PROCEDURES

Bubo aspiration to obtain material for culture and direct microscopy should be performed through a lateral approach, and may require injection of 2–5 mL of sterile saline before the aspiration due to the paucity of milky fluid.[48] Proctoscopic examination reveals, in the setting of the ArS, multiple discrete and irregular superficial ulcerations and friable granulation tissue, usually confined to the distal 10 cm of the anorectal canal.[50,51]

HISTOPATHOLOGIC EXAMINATION

Primary lesions reveal nonspecific ulceration with granulation tissue, and endothelial swelling. Organisms are rarely demonstrated using Giemsa stain. Biopsy of affected LN reveals suppurative granulomatous inflammation. Necrotic foci may enlarge into stellate abscesses, which, in turn, may coalesce into discharging sinuses. These findings are not specific to LGV and can be found in chancroid, cat-scratch disease, tularemia, and some deep fungal infections. The pathology of LGV-proctocolitis is similar to that of Crohn disease and includes crypt distortion, submucosal fibrosis, and follicular inflammation with occasional granuloma formation.[50]

DIFFERENTIAL DIAGNOSIS

(See Box 203-1)

In contrast to LGV primary stage, chancroid ulcers are usually larger and more painful, and granuloma inguinale ulcers have abundant friable granulation tissue without associated lymphadenitis. Acute GS may be hard to differentiate from chancroid. Buboes

BOX 203-1 DIFFERENTIAL DIAGNOSIS OF LYMPHOGRANULOMA VENEREUM (STAGE SPECIFIC)

- Primary stage
  - Ulcerogenital diseases (herpes simplex virus, chancre, chancroid, granuloma inguinale)
  - *Neisseria gonorrhoeae* and/or common chlamydial urogenital infection
  - Noninfectious causes: trauma, Zoon balanitis, fixed drug eruption
- Secondary stage
  - Acute genital syndrome
    - Ulcerogenital diseases with lymphadenopathy (syphilis, chancroid, herpes simplex virus)
    - Incarcerated inguinal hernia
    - Reactive inguinal lymphadenitis to a lower extremity focus of infection
    - Bubonic plague (in endemic areas)
    - Acquired immunodeficiency syndrome
    - Kaposi sarcoma
    - Tularemia
    - Mycobacterial infections
  - Acute anorectal syndrome
    - Inflammatory bowel disease
  - Oropharyngeal lymphogranuloma venereum
    - Lymphoma
    - Infectious mononucleosis
    - Cat-scratch disease
- Tertiary stage
  - Malignancy
  - Filariasis and other parasitic infections
  - Pseudoelephantiasis (no lymphadenitis) of tuberculosis and granuloma inguinale
  - Deep fungal infection
  - Hidradenitis suppurativa
  - Trauma

containing little or no pus are, however, more likely to be caused by LGV.[44] Suspecting LGV proctitis in HIV-positive MSM who present with signs and symptoms of Crohn's disease is important, even in the absence of LGV pathognomonic findings. Both conditions have similar proctoscopic findings; however, Crohn's disease is more proximally localized.

COMPLICATIONS

In addition to the complications seen in the tertiary stage, the ulcerative nature of LGV may facilitate the acquisition and transmission of blood-borne pathogens such as HIV[52] and hepatitis C.[17] LGV may also lead to immune disturbances ranging from mild gammaglobulinemia to rare but fatal immunoblastic lymphoma.[53] Recently several case reports have described an association between LGV and sexually acquired reactive arthritis (SARA) in HLA-B27 positive individuals.[54,55]

PROGNOSIS AND CLINICAL COURSE

Antibiotic treatment, if given early, is curative, with the acute ArS responding more dramatically than the acute GS.

TREATMENT

Oral doxycycline, 100 mg twice daily for 3 weeks, is the treatment of choice. When contraindicated, oral erythromycin base, at a dose of 500 mg four times a day for 3 weeks, may be given. Treatment with azithromycin (1 g once weekly for 3 weeks or in a single dose)[56] is likely curative but still lacks data regarding its efficacy and safety in pregnancy. It should be noted that the duration of treatment needed to eradicate *C. trachomatis* is longer for the LGV serovars compared with the other less invasive serovars of *C. trachomatis*. Therefore, when in doubt about the *Chlamydia* serovar, a 3-week course of antibiotics is advised. Therapy may be prolonged in HIV-positive patients and, in general, should not be stopped until the complete resolution of all signs and symptoms (Box 203-2).

Surgery is often required in late stages and includes lateral aspiration of buboes through intact skin (direct incision has a high risk of fistula formation), rectal stricture dilatation, abscess drainage, rectovaginal fistula repair, genital reconstruction, and colostomy. Avoidance of sexual activity until complete resolution of signs and symptoms is important.[57]

PREVENTION

LGV seems to be a rapidly spreading universal problem. Effective control should include periodic evaluation of high-risk individuals, reinforcement of health

BOX 203-2 TREATMENT OF LYMPHOGRANULOMA VENEREUM

First line	Oral doxycycline	100 mg bid	3 weeks
Second line	Oral erythromycin	500 mg qid	3 weeks
Third line	Oral azithromycin	1 g once weekly	3 weeks

education aiming at early recognition and counseling, improving community and clinician awareness of LGV, and increasing the availability of specific diagnostic tests. All sexual contacts should be traced and treated. LGV case reporting should be mandatory by law for more reliable monitoring of prevalence trends.[8]

Chapter 204 :: Granuloma Inguinale

:: Abdul-Ghani Kibbi, Ruba F. Bahhady, & Myrna El-Shareef

GRANULOMA INGUINALE AT A GLANCE

- Granuloma inguinale or donovanosis is a chronic ulcerative debilitating disease that mainly affects the genital organs.
- Caused by the Gram-negative bacteria *Klebsiella granulomatis*.
- Affects mostly people of lower socioeconomic status living in the tropical and subtropical areas.
- Diagnosis is made by demonstrating intracellular Donovan bodies on histology.

EPIDEMIOLOGY AND MODE OF TRANSMISSION

The mode of transmission of granuloma inguinale (GI) is controversial. It is generally considered sexually transmitted, but fecal contamination and autoinoculation remain a possibility, especially in the setting of infected children and adults without sexual activity and primary involvement of remote extragenital sites.[1,2] Transmission rate between sexual partners is low compared with other sexually transmitted diseases and was found to be not more than 50%. The incidence of GI is also relatively low among both prostitutes and their conjugal partners. Nevertheless, this disease predominantly affects sexually active individuals.[3] Moreover, donovanosis, being an ulcerative disease, increases the risk of human immunodeficiency virus (HIV) transmission.[4–6] Transvaginal transmission of donovanosis during delivery has been reported, with an apparent predilection to ear structures of the newborn.[7,8] Patients tend to belong to the low socioeconomic classes. No racial predilection has been proved,[9–11] and both male and female predominance have been reported.[5,6,11] Afflicted people are likely to delay seeking medical attention due to the painless nature of the ulcers and the possible embarrassment or fear from medical or surgical intervention. Late cases can be very debilitating and are much more difficult to manage.[12]

GI is endemic in warm, moderately humid areas like South Africa, India, Southern China, and Brazil.[5,13] There are new endemic areas of donovanosis, mainly South and Central America, India, and Papua New Guinea,[12] but the overall incidence of GI seems to be decreasing, especially in Papua New Guinea.[1] The disease has nearly been eradicated from Australia, with only five cases reported in 2004,[14] and is rare in North America and Europe.[15–17]

ETIOLOGY

Donovanosis is caused by the organism *Klebsiella granulomatis*, previously called *Calymmatobacterium granulomatis*. The name has been changed after sequencing the *phoE* and 16S ribosomal RNA genes and demonstrating close homology with *Klebsiella pneumoniae* and *Klebsiella rhinoscleromatis*.[5,12]

K. granulomatis is a Gram-negative, nonmotile, pleomorphic bacterium that stains well with Giemsa,

Wright's, or silver stains but is periodic acid-Schiff-negative. The mature form is encapsulated, while the immature form is not. The immature nonencapsulated form may assume a closed-safety-pin appearance due to bipolar chromatin densities.

It is difficult to culture and store this organism; however, it may be cultured using embryonic chick heart or chick embryo amniotic fluid. It has also been cultured in human peripheral blood mononuclear cells after decontaminating the specimen with amikacin, vancomycin, and metronidazole,[12] and in HEp-2 cells after adding gentamicin and cycloheximide.[5]

K. granulomatis is a facultative organism that resides in the cytoplasm of large mononuclear cells. It is pathogenic only to humans and the developing chick embryo. It was isolated from the feces of two out of four patients with donovanosis, although it has not been successfully cultured from feces. It is still unknown if this organism has a natural habitat.[18]

CLINICAL FINDINGS: HISTORY AND CUTANEOUS LESIONS

The incubation period extends from 3 days to 3 months but is usually 2–3 weeks. Single or multiple papules or nodules later develop and grow into a painless ulcer that may extend to the adjacent tissues and moist folds, forming "kissing lesions." The penis, scrotum, and glans are the most commonly affected sites in males; and the labia and perineum are most commonly affected in females.[11] Vaginal and cervical involvement has also been reported and sometimes mistaken for squamous cell carcinoma.[5] In one case report, GI has mimicked ovarian cancer presenting as a pelvic mass.[19] The anus and colon may be infected, especially in homosexual males.[5,20]

Figure 204-1 Granuloma inguinale on the inner prepuce. Two beefy red, erosive plaques that bleed easily. (Used with permission from Shukrallah Zaynoun, MD.)

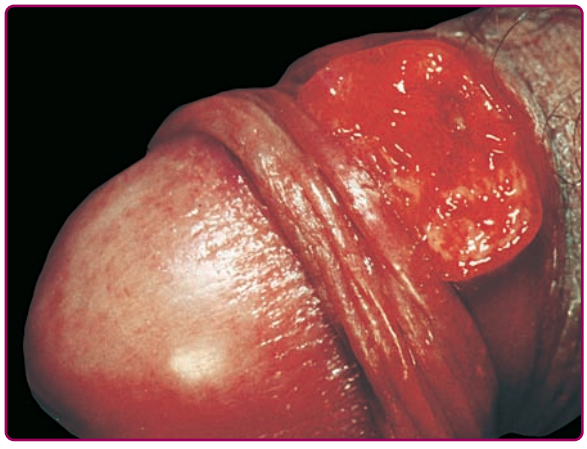

Figure 204-2 Granuloma inguinale. Nodular variety evolving into a large, exuberant ulcer. (Used with permission from A. Eichmann, MD.)

GI most commonly presents as beefy red, easily bleeding, foul-smelling ulcers with granulation tissue[5] (Fig. 204-1). The ulcers may have hypertrophic or verrucous borders resembling condylomata acuminata.[16] It may also present as soft, red nodules that eventually ulcerate (Fig. 204-2). In long-standing donovanosis, the lesions may be necrotic, quite destructive of tissue, and have a copious gray, foul-smelling exudate (Fig. 204-3).[5,16] The tissue overlying the regional lymph nodes may evolve into an abscess or pseudobubo that later ulcerates.[5] The lymph nodes per se are rarely involved unless there is a bacterial superinfection.[16] In the rare dry cicatricial form, the nonbleeding ulcers form band-like scars and lead to digital lymphedema due to constriction.[16]

HIV coinfection may alter the clinical presentation of GI. The natural history is usually more rapid, and ulcers may persist for longer periods, lead to more

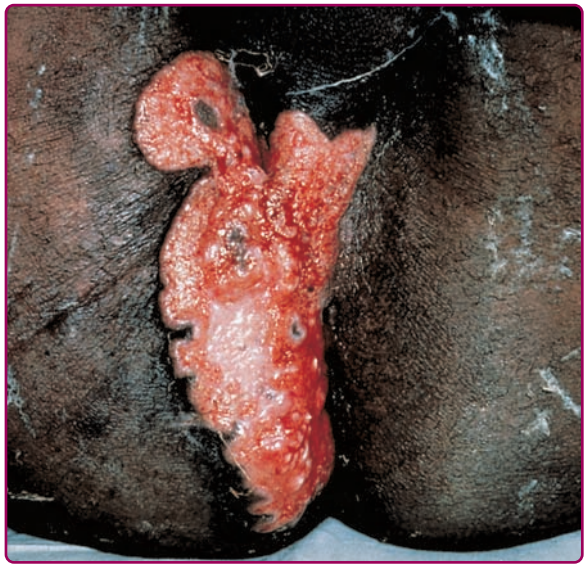

Figure 204-3 Granuloma inguinale. Large ulcerovegetative type.

tissue destruction, and need more prolonged antibiotic treatment. In addition, HIV patients with GI may have concomitant infection with other organisms such as those causing malacoplakia (most commonly *Escherichia coli*), which has been reported in GI of the cervix in two AIDS patients.[21] Furthermore, extragenital dissemination of GI has been reported in HIV-positive patients.[15]

DIAGNOSIS AND LABORATORY TESTS

Demonstrating the Donovan bodies on smear or biopsy specimen makes the diagnosis of GI, although they are more easily visualized with properly done smears rather than biopsy (Fig. 204-4).[16] Secondary bacterial infection and debris may affect the smear result; thus, it is recommended to wipe the ulcers gently with cotton swabs first before taking the smear but not to clean the ulcers with saline first.[1] Tissue for smear or crush preparations are better taken from the advancing edge of the ulcer, and tissue preparation should be made immediately, before the desiccation of histiocytes.

Serology is not helpful in making the diagnosis. Polymerase chain reaction has so far only been used for research purposes.[22] Histologically, the epidermis may exhibit pseudoepitheliomatous hyperplasia and/or ulcerations, depending on the site biopsied. In the dermis, a dense mixed inflammatory cell infiltrate is usually seen composed of polymorphonuclear cells, plasma cells, histiocytes, and rare lymphocytes. Edema and endothelial cell swelling are often noted. The hypertrophic and the cicatricial forms of GI may exhibit fibrosis.[3,20] Clusters of Donovan bodies are seen in the vacuolated cytoplasm of the large mononuclear cells. Using Giemsa, Wright's, or silver stains, these Donovan bodies appear as safety-pin-like structures measuring 1–2 µm × 0.5–0.7 µm. Rapi-Diff may also be used as a modified version of Giemsa preparation for a quick diagnosis.[23] These Donovan bodies may also be occasionally found extracellularly or within neutrophils.[20]

BOX 204-1 DIFFERENTIAL DIAGNOSIS OF GRANULOMA INGUINALE

Most Likely

- Primary syphilis (hard indolent ulcer) with indolent lymphadenopathy
- Secondary syphilis (pale, white, moist plaques)
- Lymphogranuloma venereum (prominent inguinal lymphadenopathy)
- Chancroid (painful ulcers with painful lymphadenopathy)
- Malacoplakia
- Note that the above diseases may coexist.

Always Rule Out

- Long-standing necrotic lesions of the penis, vulva, or cervix
  - Squamous cell carcinoma
  - Genital amebiasis
  - Chronic herpes simplex of the immunosuppressed
- Extragenital involvement
  - Leishmaniasis
  - Scrofuloderma
  - Deep mycosis
  - Pyoderma gangrenosum
  - Paracoccidioidomycosis
  - Mediofacial granuloma
  - Langerhans cell histiocytosis
- Disseminated form with bone involvement
  - Tuberculosis

The differential diagnosis of Donovan bodies (Box 204-1) includes the Frisch bacilli in Mikulicz cells of rhinoscleroma, the amastigotes of leishmania, the chlamydial inclusion bodies of lymphogranuloma

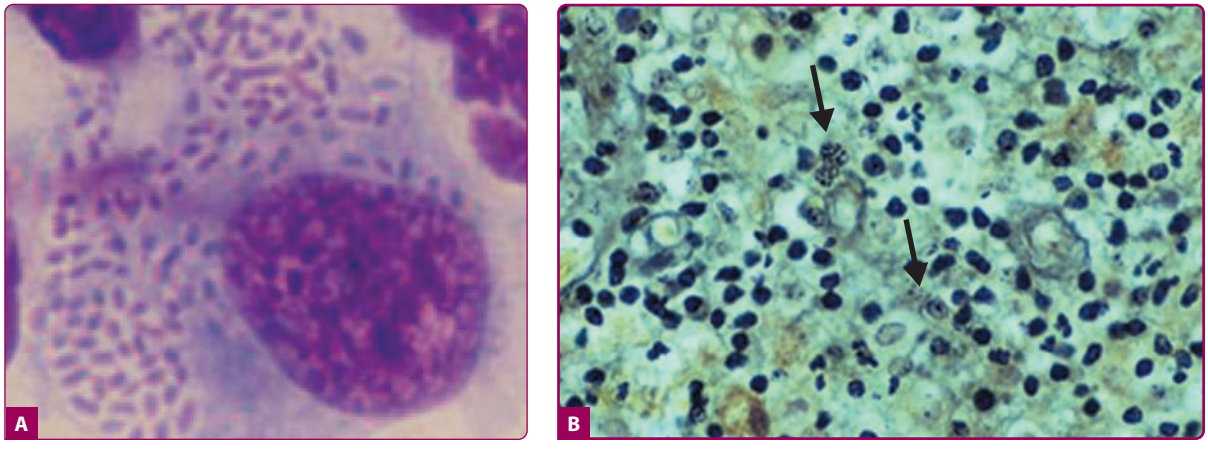

Figure 204-4 Granuloma inguinale. **A:** Pund cell stained by rapid Giemsa (RapiDiff) technique showing numerous Donovan bodies. **B:** Donovan bodies are readily stained with Giemsa stain. (Part A from O'Farrell N: Donovanosis. In: *Harrison's Principles of Internal Medicine*, 18th ed, edited by Longo DL, Fauci AS, Kasper DL, et al. New York, McGraw-Hill, 1321, 2012.)

venereum, histoplasmosis, and the Michaelis–Gutmann bodies of Malacoplakia.[20,21,23]

COMPLICATIONS

Genital complications of donovanosis include genital swelling that may progress to pseudoelephantiasis, phimosis, paraphimosis, and progressive tissue destruction that may lead to the destruction of the whole penis or other involved organs.[6,24] There is also an increased risk of squamous cell carcinoma in long-standing cases.[5,11] More recently, squamous cell carcinoma (SCC) has developed in GI ulcerations of shorter duration in an HIV-infected patient.[25]

Extragenital involvement has been reported in around 6% of the cases, occurring either as a primary infection or by spreading from a genital site by autoinoculation or systemic hematogenous dissemination.[6,13] Primary extragenital sites reported include particularly the oral mucosa, and also the neck, scalp, chest, arms, and legs. Oral involvement usually presents as swelling, ulcerations, and bleeding of the gum and palate. Bone involvement may lead to loss of teeth. Long-standing infection results in fibrosis, gum and cheek adhesions, and microstomia.[5,6] Hematogenous dissemination may present with fever, anorexia, and weight loss. It may lead to the involvement of bones, notably, and visceral organs like including the bowel, liver, spleen, and lungs. The most commonly affected bone is the tibia, comprising more than 50% of reported cases. There are few reported cases of GI manifesting as otitis media with mastoiditis, psoas abscess, and cervical lymphadenopathy.[2,7,26]

In addition, the fact that GI ulcers are painless and bleed easily upon contact increases the risk of HIV transmission remarkably.[9,27]

PROGNOSIS AND CLINICAL COURSE

GI shows no tendency for spontaneous healing. If left untreated, GI may extend to internal organs, including the ovaries, adnexa, uterus, epididymis, and bladder. Fistulas may form and lead to genital fibrosis and deformity.[5,11] Systemic dissemination may be fatal, especially in cases of misdiagnosis.[6]

TREATMENT

Untreated ulcers do not resolve spontaneously. Appropriate antibiotic therapy should be initiated once a diagnosis is established to avoid complications that could result in serious sequelae (Box 204-2).[28,29]

It is presumed that the inclusion of azithromycin in the WHO recommendation as a first-line treatment despite its high cost is advantageous because it can be administered intermittently and on a weekly basis, while patients are under supervision. The patient should continue treatment for at least 3 weeks and until all clinically visible ulcers have completely healed. Serial biopsy specimens may be needed.[11] If the patient does not improve within the first few days of treatment, the addition of gentamicin 1 mg/kg intravenously every 8 hours needs to be considered.

The Centers for Disease Control and Prevention recommend the same treatment regimens for HIV-positive patients with GI, although there have been a few reports of failure of such treatment.[28] The Centers for Disease Control and Prevention also strongly recommend gentamicin 1 mg/kg intravenously every 8 hours for HIV-infected patients with GI if there is no improvement within the first few days.

Beyond the recommended protocol of treatment, a trial with thiamphenicol has resulted in complete

BOX 204-2 TREATMENT OF GRANULOMA INGUINALE

	CDC (2006)	WHO (2003)
Recommendations[a]	Doxycyline 100 mg twice daily	Azithromycin, 1 g on first day, then 500 mg once a day OR Doxycycline, 100 mg twice daily
Alternatives[a]	Azithromycin 1 g orally once per week Ciprofloxacin 750 mg orally twice a day Erythromycin base 500 mg orally four times a day Trimethoprim-sulfamethoxazole one double-strength (160 mg/800 mg) tablet orally twice a day	Erythromycin, 500 mg orally, four times daily Tetracycline, 500 mg orally, four times daily Trimethoprim 80 mg/sulfamethoxazole 400 mg, two tablets orally, twice daily for a minimum of 14 days

[a]Duration of treatment with any regimen is for at least 3 weeks and until the lesions heal.

resolution of GI penile ulcers in eight out of ten patients; two of whom were HIV-infected patients. All patients were reevaluated regularly 3 months after treatment ended and were still disease-free.[30] Pregnant or lactating patients with GI are to avoid doxycycline and ciprofloxacin in their treatment regimens.

Relapse may occur **6–18 months** after apparently effective treatment, requiring follow-up by the physician. Long-standing cases may be complicated by secondary bacterial infections or by fistulas and abscess formation, which require surgical intervention and render antibiotic treatment alone ineffective.[13]

PREVENTION

All partners who had sexual contact with a patient with GI within 60 days before the onset of symptoms need to be examined. Sexual partners need not be treated unless they develop signs and symptoms of GI.

Children born to mothers with untreated donovanosis need to receive prophylactic azithromycin at a dose of 20 mg/kg for 3 days.[8]

Chapter 205 :: Gonorrhea, Mycoplasma, and Vaginosis

:: Ted Rosen

GONORRHEA, MYCOPLASMA AND VAGINOSIS DISEASES AT A GLANCE

- More than 20 million new sexually transmitted diseases (STDs) occur annually in the United States.
- In the United States, chlamydia is currently the most common reported STD. It is also the most common cause of pelvic inflammatory disease in women.
- Urethritis is a common presenting symptom of STDs in both men and women.
- Diagnosis can usually be made through direct microscopy, culture, and/or newer diagnostic methods such as nucleic acid amplification tests.
- Early and appropriate antimicrobial therapy of STDs results in good prognosis.
- Prevention of STDs includes sexual abstinence or safe sex practices.

GONORRHEA

EPIDEMIOLOGY

More than 600,000 people are estimated to acquire new gonococcal infections in the United States yearly according to the Centers for Disease Control and Prevention (CDC), although only about half are actually reported through the public health system. This makes gonorrhea the second most commonly reported infectious disease in the United States, second only to chlamydia. The rate of new infections declined after the implementation of a national gonorrhea control program in the United States during the mid-1970s and continued to decrease through the late 1990s. It has since stabilized at near 100 cases per 100,000 population.[1] The prevalence of infection may have decreased due to sexually transmitted disease (STD) screening programs that have incorporated immediate, on-site, single-dose treatment, when indicated. Safer sex practices in response to the human immunodeficiency virus (HIV) epidemic may also be a factor contributing to the decline of new gonorrheal infections. The highest rate of reported gonococcal infections is among sexually active teenagers and young adults, aged 15–24. There is notable ethnic disparity, with the reported gonorrhea rate in African-Americans being twenty times

higher and in Hispanics twice as high when compared to Caucasians.[1] Such racial disparity is multifactorial and may be due to differences in accessibility to health care, lack of use of available resources, and sexual partner preferences. Risk factors for acquisition of gonorrheal infection include new or multiple sex partners, younger age, unmarried status, commercial sex work, minority ethnicity, substance and alcohol abuse, lower socioeconomic and educational levels, inconsistent condom use, and any previous STD infection. Prior gonorrhea is an especially important risk factor for acquisition of a new gonococcal infection, as recidivism is particularly common.[2] As is true of most STDs, alcohol ingestion to the point of inebriation is associated with risky sexual behavior, including unprotected intercourse and sex with multiple partners, and is thus a major factor in acquisition of gonorrhea.[3]

Since the 1980s, prevalence rates among men and women have been similar in all age categories, although for any given age range, the prevalence will be slightly higher in women. The highest rates in women are for those between the ages of 15 and 19 years and in men between the ages of 20 and 24 years.[1] However, one should never exclude the diagnosis of any STD based upon age alone. A relatively high divorce rate and the wide availability of drugs to treat erectile dysfunction have both contributed to a resurgence of STDs (including gonorrhea) amongst those middle-aged and older individuals living in industrialized countries.[4] A higher rate of new infections among men having sex with men (MSM) has also been reported in some major cities.[5]

ETIOLOGY AND PATHOGENESIS

Albert Ludwig Sigismund Neisser first discovered the causative agent of gonorrhea in 1879. This infection is due to *Neisseria gonorrhoeae*, a Gram-negative, aerobic coccus-shaped bacterium typically found in pairs. The organisms are usually visualized intracellularly, located within polymorphonuclear leukocytes (Fig. 205-1). Gonorrhea is acquired through sexual contact, or, much less commonly, as a result of poor hygiene or the complementary/alternative "medical" use of urine. It can also be transmitted vertically from mother to child during normal vaginal birth, characteristically causing an inflammatory eye infection (ophthalmia neonatorum).

Pathogenesis involves bacterial attachment to columnar epithelial cells via pili or fimbriae. The most common sites of attachment include the mucosal cells of the male and female urogenital tracts. Outer membrane proteins, PilC and Opa, on the bacteria aid in attachment and local invasion. Invasion is mediated by bacterial adhesins and sphingomyelinase, which contribute to the process of endocytosis. Gonococci also induce upregulated target cell integrins, which prevent mucosal cell shedding, a natural defense mechanism. Certain gonococcal strains produce immunoglobulin A proteases that cleave the heavy chain of the human immunoglobulin and block the host's normal bactericidal immune response. Once inside the cell, the organism undergoes replication and can grow in both aerobic and anaerobic environments. After cellular invasion, the organism replicates and proliferates locally, inducing an inflammatory response. Outside the cell, the bacteria are susceptible to temperature changes, ultraviolet light, drying, and other environmental factors. The outer membrane contains lipooligosaccharide endotoxin, which is released by the bacteria during periods of rapid growth and contributes to its pathogenesis in disseminated infection. Delays in proper antibiotic treatment, physiologic changes in host defenses, resistance to immune responses, and highly virulent strains of bacteria contribute to hematogenous spread and disseminated infection. Humans are the only natural hosts of *N. gonorrhoeae*.[6]

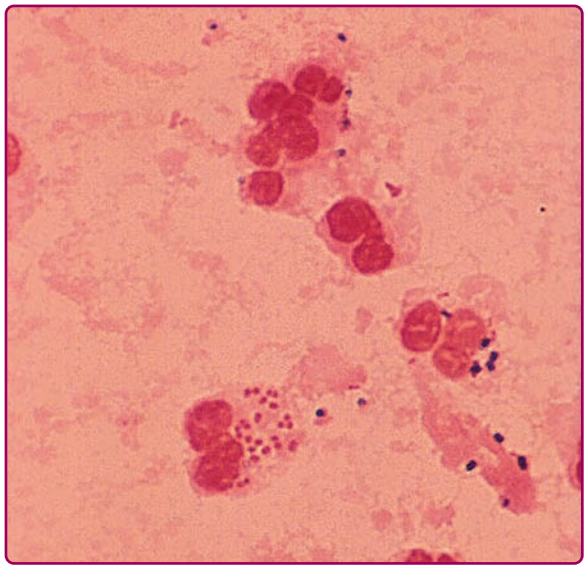

Figure 205-1 Diagnostic Gram-stained smear of urethral discharge of a man with acute gonorrhea. Gonococci (*red*) within a polymorphonuclear leukocyte. There are also some Gram-positive cocci in this smear (*dark blue*). (Used with permission from Angelika Stary, MD.)

CLINICAL FINDINGS: HISTORY AND PHYSICAL FINDINGS

N. gonorrhoeae infection tends to involve mucous membranes predominantly lined by columnar epithelial cells. The urethra, cervix, rectum, pharynx, and conjunctiva are the areas most commonly involved.

LOCALIZED DISEASE (MEN). The incubation period in men is typically from 2 to 8 days, although it may rarely be longer since most infections are symptomatic by 2 weeks following exposure. Only about 10% of infections are asymptomatic in men. The most common manifestation of gonococcal infection in men is urethritis, characterized by a spontaneous, often profuse, cloudy or purulent discharge from the penile meatus. (Fig. 205-2). Mucosal membrane inflammation in the anterior urethra leads to pain or burning upon urination and meatal erythema and swelling

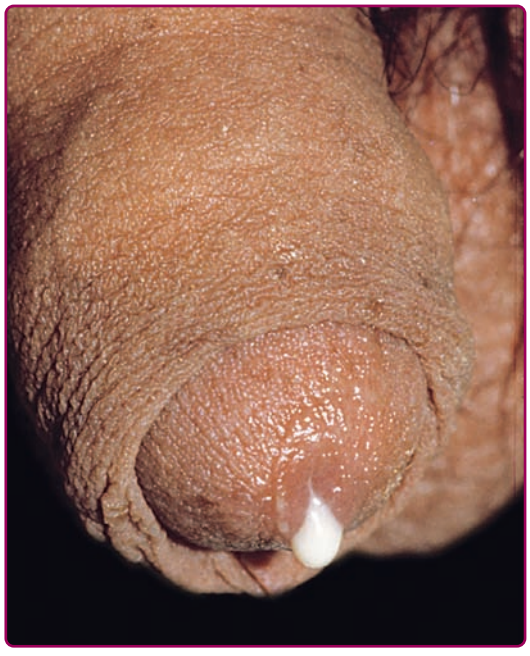

Figure 205-2 Acute gonorrhea in a male manifesting as creamy purulent discharge from the urethra.

(Fig. 205-3). In some cases, there is so much soft tissue inflammation that the entire distal penis becomes swollen, so-called "bull head clap." (Fig. 205-4) Testicular pain and swelling may indicate epididymitis or orchitis and may be the only presenting symptom. However, epididymitis is more commonly caused by *Chlamydia trachomatis* or by combined infection with *N. gonorrhoeae*. There have been rare instances of genital skin furuncles due to gonorrhea.[7]

Proctitis is a manifestation of gonococcal infection manifesting in those who practice unprotected anoreceptive intercourse. Thus, it is most common in MSM. Symptoms may include a rectal mucopurulent discharge, pain on defecation, constipation, and

Figure 205-3 Acute gonorrhea in a noncircumcised male. There is a purulent discharge from the urethra and concomitant inflammation of the prepuce and glans.

Figure 205-4 Swelling of the distal shaft characterizes "bull head clap," which is actually a manifestation of urethral gonococcal infection.

tenesmus. As a result of gonococcal proctitis, MSM are at a higher risk of acquiring HIV infection due to both damaged anorectal epithelial integrity and local recruitment of HIV-target cell types (CCR5/CD4$^+$ T cells and DC-SIGN+ dendritic cells).[8]

Pharyngitis caused by *N. gonorrhoeae* was once thought to be rare. However, the commonplace practice of fellatio amongst heterosexual adolescents and young adults, as well as among MSM, often in lieu of penetrative intercourse, has made pharyngeal gonorrhea much more common.[9] While it may be asymptomatic, pharyngeal disease may serve as a source for disseminated gonococcal disease. When present, symptoms range from cervical lymphadenopathy and mild-to-moderate pharyngeal erythema to severe ulceration with pseudomembrane formation.[10]

LOCALIZED DISEASE (WOMEN). Fifty percent of women infected with *N. gonorrhoeae* are asymptomatic. Appropriate screening, prompt diagnosis, and treatment are crucial in women due to serious complications that can result in sterility. The endocervix is a common site of local infection. Symptoms of urethritis include mucopurulent discharge, vaginal pruritus, and dysuria. However, vaginitis does not occur except in prepuberal girls or postmenopausal women because the vaginal epithelium of sexually mature women does not support growth of *N. gonorrhoeae*. Other sites of infection include Bartholin's and Skene's glands, which results is swelling and tenderness.[7] Organisms may invade the upper genital tract, including the uterus, fallopian tubes, and ovaries, resulting in pelvic inflammatory disease (PID).

PID occurs in about 10%–40% of uncomplicated gonorrheal infections in women and is characterized by fever, lower abdominal pain, back pain, vomiting, vaginal bleeding, dyspareunia, and adnexal or cervical tenderness during movement associated with a pelvic examination. Sequelae of untreated infection include tubo-ovarian abscesses, subsequent ectopic pregnancies, chronic pelvic pain, and infertility due to chronic inflammation with resultant scarring. Symptoms tend to occur or worsen at the time of menses and cannot be

distinguished from nongonococcal etiologies.[11,12] Fitz-Hugh–Curtis syndrome, involving inflammation of the liver capsule, is associated with genitourinary tract infection and may be present in up to one-fourth of women with PID caused by either *N. gonorrhoeae* or *C. trachomatis*. Presenting symptoms include right upper quadrant pain and tenderness with abnormal liver function tests.[13] This syndrome must be distinguished from acute viral hepatitis.

Women may also develop proctitis through autoinoculation from cervical discharge or as a result of direct contact from an infected partner's penile secretions. As is true in men, symptoms may include rectal mucopurulent discharge, pain on defecation, constipation, and tenesmus. The incidence of gonococcal pharyngitis is higher than that in men due to the common practice of fellatio, especially among adolescents. It is estimated that, in adolescent women, 11%–26% of cases of gonorrhea are comprised solely of asymptomatic pharyngeal infection.[9]

NEWBORNS AND CHILDREN. Neonates may acquire *N. gonorrhoeae* during passage through the birth canal from contact with infected secretions. Such ocular infections are known as ophthalmia neonatorum, and are characterized by profuse, purulent ocular discharge.[14] and can lead to severe corneal perforation or scarring. Most states, by law, require the prophylactic use of silver nitrate drops, erythromycin, or tetracycline ophthalmic ointment for prevention of ophthalmia neonatorum. However, the efficacy of prophylactic ocular antibiotics has been recently questioned, and its use in low-risk patient populations may someday be discontinued.[15] Pharyngeal or genital gonococcal infection in children is often a sign of sexual abuse and warrants further investigation.[14]

DISSEMINATED DISEASE. Spread of infection from the primary site of inoculation to other parts of the body through the bloodstream leads to disseminated gonococcal infection (DGI), also known as gonococcemia. Disseminated disease occurs in 0.5%–3% of cases and is associated with a classic triad of dermatitis, migratory polyarthritis, and tenosynovitis. Pain and swelling may occur in a single joint or in multiple joints asymmetrically. True septic arthritis due to gonorrhea is more typically monoarticular or pauciarticular, whereas polyarticular disease is most often associated with active bacteremia.[16]

Skin findings consist of small- to medium-sized macules or, most typically, hemorrhagic vesicopustules on an erythematous base located on palms and soles (Fig. 205-5) or on the trunk and elsewhere on the extremities. Skin lesions may develop necrotic centers. The concurrence of some degree of hemorrhage and necrosis led to the term "gun metal gray" to describe the cutaneous lesions of DGI. On the palms and soles, lesions may be tender, but in other sites they tend to be both nonpruritic and painless. Skin lesions disappear after appropriate treatment has been administered. Cutaneous lesions may be present in 40%–70% of cases of disseminated disease. Histologically, perivascular neutrophilia, dermal vasculitis, and epidermal neutrophil infiltration may be seen.

Figure 205-5 Disseminated gonococcal infection. Tender, hemorrhagic, and necrotic pustules on the fingers and palms.

LABORATORY TESTS

Organisms are Gram-negative, intracellular diplococci visualized microscopically inside polymorphonuclear cells. Because of high specificity (>99%) and sensitivity (>95%), a Gram stain of a urethral specimen that demonstrates polymorphonuclear leukocytes with intracellular Gram-negative diplococci can be considered diagnostic for infection with *N. gonorrhoeae* in symptomatic men.[17] However, because of lower sensitivity, a negative Gram stain can not be considered sufficient for ruling out gonococcal infection in asymptomatic men at high risk for infection. In addition, Gram stains of endocervical specimens, pharyngeal, or rectal specimens also are not sufficient to detect infection, and, therefore, are not recommended.[17] Vaginal specimens are never recommended for diagnostic purposes, since the vaginal mucosa resists gonococcal invasion.

Bacterial culture has been the "gold standard" diagnostic test for years, although newer and more specific tests are now being widely used. Culturing *N. gonorrhoeae* requires media containing heme, nicotinamide adenine dinucleotide, yeast extract, carbon dioxide, and other supplements required for isolation. Culture can be performed on modified Thayer-Martin medium. In men, culture and Gram stain are performed on secretions or urethral swabs. Endocervical and endourethral specimens for culture and Gram's stain yield accurate results in women. Cultures on pharyngeal and rectal swabs may also be performed if infection is suspected in these areas.

The US Food and Drug Administration has approved certain chemiluminescent DNA probes that can be used on endocervical or urethral specimens for diagnosis of gonorrhea. However, distinguishing gonococcal from nongonococcal infection may be difficult with DNA probes. Newer techniques include the use of nucleic acid amplification tests, such as polymerase chain reaction (PCR), transcription-mediated amplification, and strand displacement amplification on urine or urethral specimens. Overall, nucleic acid

BOX 205-1 DIFFERENTIAL DIAGNOSIS FOR ALL MUCOSAL-BASED VENEREAL DISEASES

LOCALIZED

- Urinary tract infection
- Chlamydia
- Gonorrhea
- Pelvic inflammatory disease
- Trichomoniasis
- Herpes simplex virus
- Bacterial vaginosis
- Vaginitis
- Endometriosis
- Mycoplasmal infection
- Orchitis and epididymitis
- Lymphatic occlusion due to pelvic neoplasm

SYSTEMIC

- Septic arthritis
- Rheumatoid arthritis
- Psoriatic arthritis
- Bowel-bypass syndrome
- Hepatitis B and C
- Behçet disease
- Reiter syndrome
- Lyme disease
- Rheumatic fever

ALWAYS RULE OUT

- Ectopic pregnancy
- Pregnancy
- Appendicitis
- Meningococcemia
- Coinfection with syphilis and HIV
- Sexual abuse (in children)

amplification tests are highly sensitive and specific and may be able to detect even the presence of one organism.[18] However, the precise test considered "optimal" in terms of specificity, sensitivity, practicality, and cost effectiveness remains to be determined and is subject to ongoing controversy.[19] Even nucleic acid detection tests may yield false positive and false negative results. In addition, diagnosis via any nonculture method does not allow for antibiotic sensitivity testing.

In DGI, cultures, and if available, nucleic acid amplification testing, should be done on blood, joint fluid, and skin lesions. Synovial fluid from affected joints must be analyzed for cell count, Gram stain, and culture. Of necessity, diagnosis may rely on clinical suspicion and pertinent findings, because tests for DGI yield positive results only in a small number of cases.

DIFFERENTIAL DIAGNOSIS

Box 205-1 shows the differential diagnosis for all mucosal-oriented venereal diseases.

COMPLICATIONS

Permanent sequelae of gonococcal infection in women may be infertility as a result of untreated PID. Untreated DGI can lead to septic arthritis, yielding permanent joint damage. Meningitis and endocarditis are rare manifestations of DGI, which can lead to death or permanent disability due to central nervous system or cardiac damage.

PROGNOSIS AND CLINICAL COURSE

Prognosis is excellent if infection is treated early with appropriate antibiotics. Previously treated gonococcal infection does not reduce the risk of reinfection. DGI has a good prognosis if treated appropriately and before permanent damage to joints or organs occurs.

TREATMENT

Ten percent to 30% of people with gonococcal infection are coinfected with *Chlamydia*. Thus, routine dual therapy with doxycycline or azithromycin has been recommended and shown to be cost effective. Dual therapy also decreases the development of antimicrobial resistance. Box 205-2 shows current CDC recommendations, as revised in 2010, for uncomplicated cervical, urethral, pharyngeal, and

BOX 205-2 TREATMENT OF LOCALIZED, UNCOMPLICATED GONOCOCCAL INFECTION OF CERVIX, RECTUM, PHARYNX OR URETHREA

- Single dosage of any of the following:
  - Ceftriaxone, 125 mg IM
  - Cefixime, 400 mg PO

Alternate single-dose cephalosporin re`gimens may be considered on an individual basis, and include: Ceftizoxime 500 mg IM, Cefotaxime 500 mg IM, Cefoxitin 2.0 g IM administered with probenecid 1.0 g PO

Some evidence exists that the following single-dose regimens might also be effective: Cefpodoxime 400 mg PO and Cefuroxime axetil 1.0 g

- For patients allergic to cephalosporins, spectinomycin, 2 g in a single IM dose.
- In dual therapy for chlamydia, add either:
  - Azithromycin, 1 g orally in a single dose
  - Doxycycline, 100 mg orally twice a day for 7 days

TABLE 205-1
Management of Disseminated Gonococcal Infection

Recommended Regimen	
Ceftriaxone	1 g IM or IV every 24 hours (intravenous route preferred)
Alternative Regimens	
Cefotaxime	1 g IV every 8 hours
Or	
Ceftizoxime	1 g IV every 8 hours
Or	
Spectinomycin	2 g IM every 12 hours
Following clinical improvement, parenteral therapy may be switched to oral therapy for seven additional days:	
Cefixime	400 mg BID PO
Or	
Cefpodoxime	400 mg BID PO

rectal gonococcal infections.[20] Due to the increased prevalence of antimicrobial resistance, quinolones are no longer recommended for the routine treatment of any gonococcal infections.[21] Spectinomycin, the recommended alternative to cephalosporins, has had an inconsistent history of availability and as of 2010, is not available in the United States. However, dosage regimens for spectinomycin are maintained in Box 205-2 should this situation change in the near future.

Patients with DGI may require hospitalization due to septic arthritis, meningitis, or endocarditis. The recommended regimen for DGI is ceftriaxone, 1 g intramuscularly (IM) or intravenously (IV) every 24 hours, continuing for 24–48 hours after improvement is noted. Treatment may then be switched to oral doses of the antibiotics listed in Table 205-1. Treatment of gonococcal meningitis should consist of ceftriaxone, 1–2 g IV every 12 hours for 10–14 days. Therapy for gonococcal infections in neonates is shown in Box 205-3. Gonococcal ophthalmia neonatorum should be treated with ceftriaxone, 25–50 mg/kg IV or IM, not to exceed 125 mg in a single dose. For treatment regimens of PID and epididymitis, the reader is referred to a CDC Web site.[20]

Sexual partners of those found to have gonococcal infections should be evaluated. However, since this is not always feasible, empiric treatment may be advisable. In general, treatment of partners of female or heterosexual male patients diagnosed with gonorrhea empirically is as or more effective than the traditional reliance on referral, testing and as needed treatment.[22] One way of doing this is via expedited partner therapy (having the index patient deliver therapy to the partner); such expedited therapy decreases the risk of persistent or recurrent infection in the index patient.[23] No studies have evaluated empiric treatment of gonorrhea (or chlamydia) in MSM. State laws vary with regard to expedited partner therapy and must be considered. Moreover, this type of empiric therapy misses the opportunity to counsel partners and treat comorbid disease, when detected.

BOX 205-3 TREATMENT OF GONOCOCCAL INFECTION IN NEONATES

- Ceftriaxone, 25–50 mg/kg/day IV or IM in a single daily dose for 7 days, or for 10–14 days if meningitis is documented

Or

- Cefotaxime, 25 mg/kg IV or IM every 12 hours for 7 days, or for 10–14 days if meningitis is documented

CONTRAINDICATIONS

Patients with documented allergy to later generation cephalosporins can be managed with spectinomycin. Fluoroquinolones can be considered, but only if documented sensitivity to this class of drugs has been established by culture.

CHLAMYDIA

EPIDEMIOLOGY

Infection with *C. trachomatis* is the most common reported STD in the United States, with more than 1.2 million reported cases in 2009.[1] Due to a high rate of asymptomatic infection, the prevalence of infection may actually be much higher. The national rate of chlamydial infection is 409.2 per 100,000 population, representing a 3% increase from the prior reporting year.[1] This may be as a result of wider screening and more sensitive and specific tests. The highest rates of infection reported are in women between the ages of 15 and 24 years. Following the expanded availability of less invasive urine testing for chlamydia, men are getting evaluated with greater frequency, resulting in an increase of over 45% in the chlamydia rate among men between 2004 and 2009.[1] While the overall rate of reported chlamydia among men is lower than among women, the CDC estimates that the actual overall prevalence of chlamydia is similar among men and women. Infection rates among African-Americans have been eight times higher and in Hispanics three times higher than those reported in same-gender Caucasians.[1] Chlamydial infection is also disproportionately high among Native American and Eskimo populations. Risk factors are similar to those related to gonococcal infections, and include young age, new or multiple sex partners regardless of age, unprotected sexual intercourse, inconsistent condom use, commercial sex work, and low socioeconomic and educational status.

ETIOLOGY AND PATHOGENESIS

The Greek-derived word *chlamys* means "cloak draped around the shoulder." This refers to the draping of intracytoplasmic inclusions containing *C. trachomatis* around the nucleus of an infected cell. *C. trachomatis* is a nonmotile, Gram-negative, obligate intracellular organism with 15 serotypes: A through C cause chronic conjunctivitis and are endemic in Africa and Asia, D through K cause urogenital tract infections, and L1 though L3 cause lymphogranuloma venereum (see Chapter 203). The bacteria have a two-phase life cycle. The infectious form is known as the *elementary body*, which enters host cells through endocytosis. Replication through binary fission occurs inside the host cell, using host-derived adenosine triphosphate, with formation of reticulate bodies. Large intracytoplasmic inclusions inside cells are made up of hundreds of reticulate bodies, which then convert back to infectious elementary bodies to be released from the cell.

Urogenital tract infection is the area most commonly affected in men and women. Transmission is through oral, anal, or vaginal intercourse with symptoms occurring 1–3 weeks after exposure. However, asymptomatic infection occurs in up to 80% of women and 50% of men. Coinfection with other STDs occurs frequently, most commonly with gonorrhea. Various serotypes have been associated with an increased risk of cervical squamous cell carcinoma, suggesting that *Chlamydia* species may act as a cofactor with oncogenic, high-risk HPV in neoplastic transformation.[24,25] Newborns can be infected from passage through the birth canal of an infected mother.[26]

CLINICAL FINDINGS: HISTORY AND PHYSICAL FINDINGS

The most common manifestation of disease is urethritis, characterized by a watery or mucoid discharge from the urethra that may be accompanied by variably severe dysuria in both men and women. Note that the discharge due to *Chlamydia* is classically less purulent, less profuse, and less spontaneous when compared to urethral gonorrhea. However, there is considerable clinical overlap, and neither the nature of the discharge nor the severity of accompanying dysuria can be reliably used to make a specific diagnosis. Rectal infection may result in proctitis in both men and women; symptoms resemble those seen with gonococcal proctitis (detailed previously). Infection due to specific serovars (L1–L3) may also present as lymphogranuloma venereum.[27] (For further details on LGV, see Chapter 203).

In men younger than age 35 years, *C. trachomatis* is the most common cause of epididymitis. Thus, aside from urethral discharge, men may also present with unilateral scrotal pain and swelling. It remains questionable whether chlamydial species commonly cause prostatitis. In a recent large-scale study that utilized very sensitive detection technology, only 3% of chronic prostatitis patients were found to harbor *C. trachomatis* infection.[28]

In women, the columnar epithelium of the endocervix is commonly affected. Other symptoms, beside those of urethritis, include intermenstrual or postcoital bleeding and vague but persistent lower abdominal pain. As with gonococcal infection, a severe complication in women that can result in sterility is PID, with ascending infection to the uterus and fallopian tubes. In the United States, chlamydial species are currently the most common causes of PID. Symptoms may include fever, lower abdominal pain, back pain, vomiting, vaginal bleeding, dyspareunia, and adnexal or cervical motion tenderness on physical examination. Sequelae of untreated infection include tubo-ovarian abscesses, ectopic pregnancies, chronic pelvic pain, and infertility due to chronic inflammation with resultant scarring. Five to ten percent of women with chlamydial PID may develop perihepatitis.

Newborns may develop conjunctivitis and pneumonia after being infected from passage through the birth canal of an infected mother. Signs of ophthalmia neonatorum may include injected conjunctivae, purulent discharge, or swollen eyelids. Subacute, afebrile pneumonia as a consequence of neonatal chlamydial infection usually presents after 1–3 months. Symptoms include cough and wheezing.[29] Animal experiments suggest that neonatal respiratory chlamydial infection predisposes to asthma later in life.

LABORATORY TESTS

Traditionally, chlamydial infection was diagnosed by tissue culture with specimens obtained from the endocervix in women, urethra in men, and rectum, or conjunctivae, as indicated. More rapid and sensitive tests have replaced culture in recent years. A direct fluorescent antibody test, which is highly specific, can be performed on endocervical and penile urethral specimens with rapid results (Fig. 205-6). Enzyme immunoassays, which are less specific than the direct fluorescent antibody test, can be used to detect chlamydial antigens through the formation of a color change. Less invasive tests involving nucleic acid hybridization and nucleic acid amplification, such as PCR and ligase chain reaction, are more commonly being used to detect even

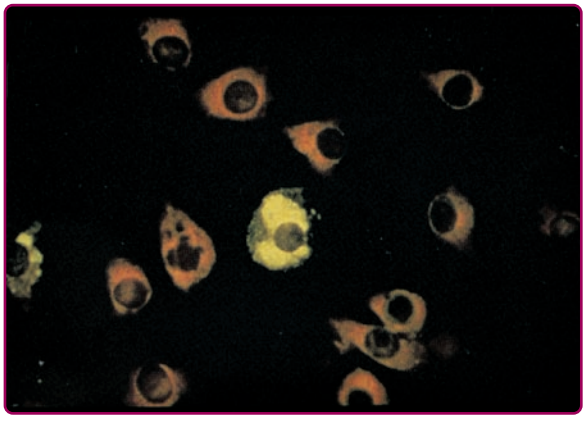

Figure 205-6 Detection of *Chlamydia trachomatis* by direct immunofluorescence with monoclonal antibodies.

small amounts of chlamydial DNA in urethral, vaginal, endocervical swabs and in first voided urine samples. At least one recent meta-analysis suggested that nucleic acid amplification tests are considerably more sensitive that point-of-care rapid diagnostic tests.[30] It should be noted that the nucleic acid amplification and hybridization tests are less accurate for chlamydial detection from rectal and oropharyngeal sites than from genital sites.

There is also some debate about exactly who should receive chalmydial testing, aside from those whose symptoms suggest that diagnosis. The CDC recommends annual screening of all sexually active women under the age of 25 and for older women with risk factors (e.g., those who have a new sex partner or multiple sex partners). Studies done in the 1990s point to a reduced prevalence of infection and reduced rate of subsequent PID following institution of routine *C. trachomatis* screening. However, a recent meta-analysis suggests that the benefits attendant to widespread screening for *Chlamydia* are greatly exaggerated.[31] Evidence is also insufficient to recommend routine screening for *C. trachomatis* in sexually active young men, based on feasibility, efficacy, and cost-effectiveness. Screening in MSM is controversial, although in high-prevalence locales, this is probably advisable.

COMPLICATIONS

Reactive arthritis (see Chapter 20) can occur up to 1 month after symptoms of nongonococcal urethritis (NGU), including NGU due to chlamydia. The classic triad associated with this syndrome is NGU, arthritis, and conjunctivitis. Additional symptoms may include fever, malaise, myalgias, asymmetric joint stiffness, lower back pain, cutaneous lesions involving the genitals, and aortic regurgitation as a result of inflammation around the aortic valve. Individuals with the haplotype HLA-B27 are at increased risk of developing the reactive arthritis syndrome. Upper genital tract complications in women have already been detailed above.

PROGNOSIS AND CLINICAL COURSE

Early treatment with appropriate antibiotic therapy results in excellent prognosis and reduces the risk of long-term complications, such as infertility from PID. It is important to complete an appropriate course of antibiotics. First-time therapy with antibiotics has been shown to be up to 95% effective in eradicating infection. It is important to counsel patients on the risks of coinfections with other STDs and to arrange for partner referral.

TREATMENT

The treatment of chlamydial infection is summarized in Box 205-4. Although azithromycin and doxycycline are considered equipotent, in patients who have erratic health-care-seeking behavior, poor treatment compliance, or unpredictable follow-up, azithromycin is more cost-effective in treating chlamydia because it enables the provision of a single-dose of directly observed therapy. Sexual contact should be avoided until treatment is completed. The CDC recommends that sex partners of those infected with *Chlamydia* also receive treatment in order to prevent prompt reinfection of the original patient. Recent studies have shown that many young heterosexual women who have been diagnosed with chlamydia became reinfected by male partners who were neither diagnosed nor treated.[32,33] CDC guidelines call for infected men and women to be retested for chlamydia approximately 3 months after initial treatment. For heterosexuals, the CDC recommends that, where feasible and allowed by state law, antibiotic treatment be delivered by patients to their partners (expedited therapy) if other strategies for reaching and treating partners are not likely to succeed.[1]

BOX 205-4 TREATMENT OF *CHLAMYDIA* INFECTION

- Azithromycin, 1 g PO in a single dose

Or

- Doxycycline, 100 mg PO twice a day for 7 days

Alternative regimens:

- Erythromycin base 500 mg PO, four times daily for 7 days

Or

- Erythromycin ethylsuccinate 800 mg PO, four times daily for 7 days

Or

- Ofloxacin 300 mg PO, twice daily for 7 days

Or

- Levofloxacin 500 mg daily for 7 days

Recommended treatment for pregnant women:

- Azithromycin 1 g PO as a single dose
- Amoxicillin, 500 mg PO three times a day for 7 days

Recommended treatment for ophthalmia neonatorum:

- Erythromycin base or ethylsuccinate 50 mg/kg/day orally, divided into four doses daily, for 14 days

GENITAL MYCOPLASMAS

EPIDEMIOLOGY

Species of *Mycoplasma* are the smallest, free-living, self-replicating bacteria. These organisms developed by degenerative evolution from lactobacilli, and lack a cell wall. These organisms have retained the ability to colonize the respiratory and urogenital tracts of humans. *Mycoplasma* sp. and other *Ureaplasma* sp. are referred to as the genital mycoplasmal organisms and may be found in the lower urogenital tracts of sexually

active adults. Seven mycoplasmal strains have been isolated from the genital tract: (1) *Mycoplasma hominis* and (2) *Mycoplasma genitalium* are commonly identified, while (3) *Mycoplasma fermentans,* (4) *Mycoplasma penetrans,* (5) *Mycoplasma pneumoniae,* (6) *Mycoplasma primatum,* and (7) *Mycoplasma spermatophilum* are rare at this site.[34] Molecular biological findings have made it possible to distinguish between two species of *Ureaplasma*: (1) *Ureaplasma urealyticum* and (2) *Ureaplasma parvum*. Risk factors for genital mycoplasmas include: multiple partners, younger age, ethnic minority, and past or present bacterial vaginosis (BV).

Forty percent to 80% of sexually active women in the United States have urogenital colonization with *Ureaplasma* organisms. *M. hominis* has also been isolated in 20%–50% of sexually active women. Rates of colonization tend to be lower in men, except in the setting of HIV coinfection. The rates of colonization in children and nonsexually active adults are even lower yet. Newborns may be infected by passage through the birth canal of an infected mother. While the most common cause of symptomatic NGU remains *Chlamydia* sp., the genital mycoplasmas may also cause this disorder. *Ureaplasma* organisms have been found to be the cause of over 20% of nonchlamydial NGU, while *M. genitalium* accounts for 10%–20% of cases of nonchlamydial NGU.[35] The detection of *M. hominis* in a urethral smear is irrelevant to NGU, as numerous studies have isolated *M. hominis* independently of symptoms.[34]

ETIOLOGY AND PATHOGENESIS

The bacteria can attach to and penetrate epithelial cells by adhesion proteins on the back of the cell body. The structure and function of adhesion proteins for *M. genitalium* (P110 and P140) and *M. hominis* (P100) are well characterized. The abundance of urea to metabolize predisposes ureaplasmas to the urinary tract. The specific adhesion proteins for *Ureaplasma* sp. are still unknown. All genital mycoplasmas multiply as parasites, as they are unable to complete various metabolic reactions. Cholesterol is required for growth and is taken from the epithelial cell; ureaplasmas need urea as well. Because of their parasitic nature and specific nutritional requirements, *Mycoplasma* species tend to remain localized to mucosal surfaces. Disseminated infection is rare and tends to occur only in immunocompromised hosts or in cases of epithelium severely traumatized by instrumentation.

M. genitalium and *Ureaplasma* sp. have been isolated from the lower urogenital tracts of men with urethritis and in 10% of women with cervicitis and 10%–20% of women with PID.[34] *M. hominis* has been isolated from a few cases of salpingitis. There is no clear relationship between genital mycoplasma and epididymitis and/or prostatitis. In cases of bacterial vaginitis (see below), coinfection with *Mycoplasma* species (particularly *M. hominis*) may worsen the condition. *Ureaplasma* sp. and *M. hominis* have been isolated from the blood of febrile women postpartum and postabortion.

CLINICAL FINDINGS: HISTORY AND PHYSICAL FINDINGS

Patients with genital mycoplasmal infections may go undiagnosed as such because these organisms may produce symptoms that are usually attributed to other, more common causative agents such as *Chlamydia*. This may also be due to the high rate of coinfection with such organisms. As with chlamydia, various genital mycoplasmas infections can result in urethritis, cervicitis, PID, endometritis, salpingitis, and chorioamnionitis. Other species can cause respiratory infection, septic arthritis, surgical wound infections, neonatal pneumonia, and meningitis. Infection with these organisms needs to be considered if workup for the more commonly isolated organisms is negative. Physical findings and symptomatology are indistinguishable from those seen with chlamydial NGU.

LABORATORY TESTS

Laboratory tests for genital mycoplasmas may be limited because most specimens must be sent to reference laboratories. Culture specimens should be obtained from the urethra or first voided urine in men, and from the cervix, urethra, and vagina in women. *M. hominis* and *U. urealyticum* can be cultured on special media, which is enriched with horse serum as a nutrient source. PCR assay is required to detect *M. genitalium,* and may also optionally be used by laboratories to identify other *Mycoplasma*. First voided urine is actually the preferred specimen to submit when the reference laboratory plans to utilize nucleic acid amplification testing.[34] While various commercial tests are available for antibodies (CBR, hemagglutination, immunofluorescence), the mere detection of *Mycoplasma* antibodies is not sufficient, to verify infection due the possibility of prior colonization and cross reactions. Increased titer levels may be a sign of acute infection. Because *Mycoplasma* does not possess a cell wall, Gram stain will not detect these organisms.

COMPLICATIONS

Invasion by different species of *Mycoplasma* and *Ureaplasma* can cause disseminated disease, especially in immunocompromised hosts who have deficiencies in antibody production. Disseminated disease may result in respiratory tract invasion, osteomyelitis, or infectious arthritis. Bacteremia as a result of *M. hominis* has been shown after renal transplantation. *M. hominis* has also be found in surgical wound infections, pericardial effusions, prosthetic heart valves, subcutaneous abscesses, and in synovial fluid of people with rheumatoid arthritis.

There is an increased frequency of *M. hominis* and ureaplasmas in cervical cultures from women who are unable to conceive, suggesting a causative role in infertility. The role of *M. genitalium* in infertility is not well studied in this regard. While this may represent

an overinterpretation, for some cases of premature rupture of the fetal membranes, preterm labor, intraamniotic infection, and chorioamnionitis, the presence of genital mycoplasmas suggests that these organisms may play a role in the pathogenesis of these complications of pregnancy.[36]

PROGNOSIS AND CLINICAL COURSE

Prognosis in immunocompetent hosts is excellent with prompt diagnosis and appropriate treatment.

TREATMENT

Because these organisms lack a cell wall, they are inherently resistant to β-lactam and cephalosporin antibiotics. Treatment for genital mycoplasmas is similar to treatment for chlamydia. *M. genitalium* is the most difficult of these organisms to treat, with failure rates ranging from 67% (levofloxacin) to 16% (single-dose azithromycin).[34]

Trichomonas vaginalis

EPIDEMIOLOGY

Trichomonas vaginalis causes a condition called trichomoniasis, which affects about 2–3 million women annually in the United States. Worldwide, it has been estimated to affect more than 180 million women. It is difficult to estimate the number of men infected because most infections in men are asymptomatic. However, 30%–40% of men who are exposed have detectable organisms in the lower genitourinary tract. It is currently not a reportable disease, making epidemiologic estimates crude.

ETIOLOGY AND PATHOGENESIS

Trichomoniasis is an STD caused by parasitic protozoan that infects mucosal epithelium, causing microulceration. In women, organisms may be isolated from the vagina, urethra, cervix, Bartholin and Skene glands, and bladder. In men, organisms may be found in the external genital area, anterior urethra, epididymis, prostate, and semen. The incubation period before symptomatic infection is usually between 4 and 28 days. In women, manifestation of infection ranges from an asymptomatic carrier state to inflammatory vaginitis. Due to the increase in vaginal acidity, a situation favorable for parasitic growth and reproduction, symptoms tend to occur during or after menstruation. Most men are asymptomatic carriers.

CLINICAL FINDINGS: HISTORY AND PHYSICAL FINDINGS

Women who are infected may complain of a malodorous, yellow–green vaginal discharge, vulvar pruritus, swelling and erythema, dyspareunia, lower abdominal discomfort, or dysuria. Infection tends to occur in sexually active women and men. Men are usually asymptomatic, although some may complain of urethral discharge and dysuria or urinary frequency. Both men and women may be asymptomatic carriers. Newborns may become infected from passage through the birth canal of an infected mother. Infection in a child may be a sign of sexual abuse.

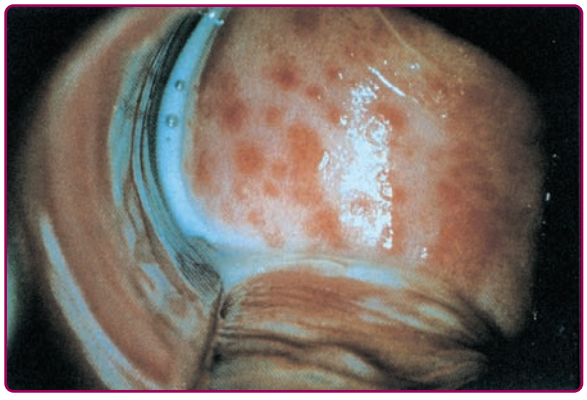

Figure 205-7 *Trichomonas vaginalis* infection: "strawberry" appearance of cervix with punctuate bleeding erosions. (Used with permission from U. Lauper, MD.)

On physical examination, punctate hemorrhages may be seen on the vaginal wall and cervix. A term commonly associated with such hemorrhages is "colpitis macularis" or "strawberry cervix" (Fig. 205-7). This is a specific sign of trichomoniasis, but is also seen in 1%–2% of women during a regular pelvic exam. It may be visualized in up to 45% of cases through the use of colposcopy. Findings consistent with the generic diagnoses of balanitis, epididymitis, and prostatitis rarely may be present in men. Coinfection with other STDs may produce a more complex presentation.

LABORATORY TESTS

Vaginal pH tends to be elevated above 4.5 in trichomoniasis, as well as in BV, thereby making this a nonspecific finding. There are three basic methods to search for the causative parasite. A saline wet mount of a vaginal discharge specimen is the simplest, least costly, and therefore the most common diagnostic test. The ovoid-shaped protozoa can be visualized microscopically, best by phase contrast or dark-field examination (Fig. 205-8). Direct microscope examination, while highly specific, is only 60%–70% sensitive.[37] The most sensitive test is anaerobic culture, which usually is positive within 48 hours, and is the preferred (albeit most costly) detection method. There are now several commercially available, rapid result, point-of-care tests that can be performed on vaginal discharge specimens: an immunochromatographic test (OSOM Trichomoas Rapid Test), with results available in 10 minutes and a nucleic acid probe test (Affirm VP III), which requires 45 minutes to complete.[37] The latter test has the advantage of simultaneously searching for and identifying the presence of *T. vaginalis*, *Gardnerella vaginalis*, and

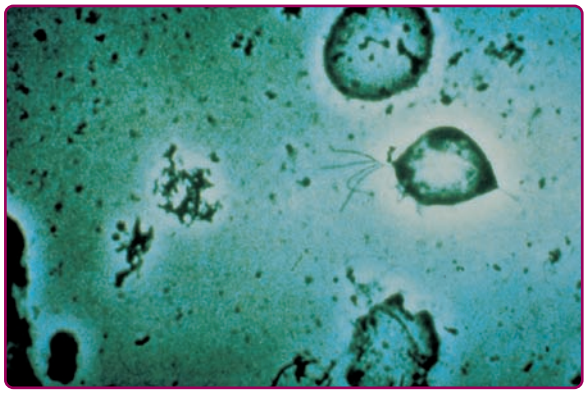

Figure 205-8 *Trichomonas vaginalis*, phase contrast microscopy. (Used with permission from U. Lauper, MD.)

Candida albicans. Both of these rapid result tests share a sensitivity of about 83% and specificity of over 97%.[37] Several additional PCR-based laboratory tests (Amplicor and APTIMA) have recently been approved that represent modifications of existing *Chlamydia*/GC detection techniques, although their sensitivities are lower than the point-of-care tests. For diagnosing infection in men, urethral, first void urine or semen cultures may be performed.

COMPLICATIONS

Recently, studies have shown a link between *T. vaginalis* infection and complications in pregnancy, such as premature delivery, early rupture of membranes, and low birth weight in newborns. Trichomoniasis has also been associated with an increased risk of HIV transmission.[38] Less commonly, it has been linked to atypical PID.[39]

PROGNOSIS AND CLINICAL COURSE

Prognosis is excellent with resolution of infection occurring after appropriate treatment. Treatment of sexual partners may help avoid reinfection. Persistent infection despite appropriate treatment with metronidazole may require susceptibility testing. This can be obtained from the CDC. Specimens for such testing by the laboratory service of the CDC Division of STD Prevention should be submitted through the clinician's own state health department.

TREATMENT

Treatment is summarized in Box 205-5. The nitroimidazoles metronidazole and tinidozoleare the only agents approved for treatment of trichomoniasis, the clinical efficacy of both drugs being identical.[40] It should be noted that alcohol ingestion during and for 24 hours after the last dose of metronidazole (72 hours after tinidazole) may be associated with a sensitivity reaction consisting of nausea, vomiting, flushing, and tachycardia. There is also a propensity for drug–drug interactions with cimetidine, warfarin, phenytoin, and lithium; appropriate adjustments must be made to ensure safe use of the nitroimidazoles when these other agents are being used. While safety of nitroimidazole use in pregnancy is uncertain, most experts condone this practice.[41]

BOX 205-5 TREATMENT OF TRICHOMONIASIS

- Metronidazole, 2 g PO in a single dose

Or

- Tinidazole, 2 g PO in a single dose

Alternative recommendations

- Metronidazole, 500 mg PO twice a day for 7 days

BACTERIAL VAGINOSIS

EPIDEMIOLOGY

BV is the most common vaginal infection in women of childbearing age. It is estimated that approximately 16% of pregnant women in the United States may have BV at a given time. Incidence rates are difficult to determine due to the high prevalence of asymptomatic infection and lack of screening methods. Risk factors appear to include sex at an early age, new or multiple sex partners, smoking, and douching or use of bidet toilets.[42,43] Some studies have shown an increased prevalence among women who have sex with women, perhaps based on transfer of pathogenic vaginal flora related to frequent use of lubricant and shared vaginal sex toys.[44] Women who have never had sex are extremely rarely affected.

ETIOLOGY AND PATHOGENESIS

BV is a polymicrobial syndrome that occurs when there is an imbalance of the bacterial flora normally present in the vagina. The shift occurs from hydrogen peroxide-producing lactobacilli to a greater concentration of bacterial organisms including *G. vaginalis*, *Mobiluncus* sp., *M. hominis*, anaerobic Gram-negative rods belonging to the genera *Prevotella*, *Porphyromonas*, and *Bacteroides*, and *Peptostreptococcus* sp.[45] It is not known to be transmitted through sexual contact, and the exact etiology has not been defined.

CLINICAL FINDINGS: HISTORY AND PHYSICAL FINDINGS

As many as 50%–75% of women with BV may be asymptomatic.[46,47] Women with BV may complain of a fishy odor and thin, white or gray vaginal discharge. Vulvo-vaginal pruritus and inflammation are rare. On physical examination, a milky, homogenous vaginal coating may be seen adherent to the vaginal wall.

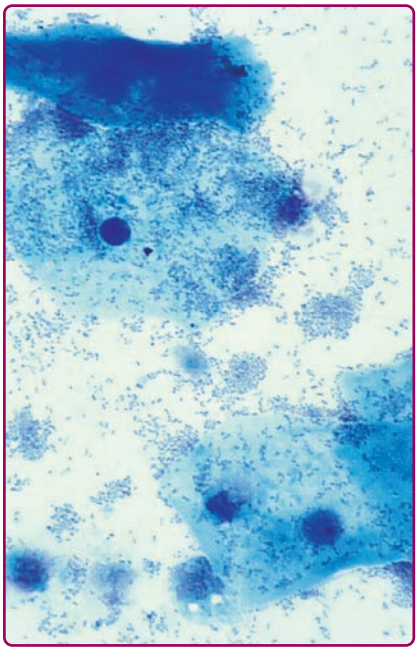

Figure 205-9 Bacterial vaginosis. Clue cells are large epithelial cells covered with bacteria. (Used with permission from Angelika Stary, MD.)

LABORATORY TESTS

According to the Amstel criteria for diagnosing BV, three of the following four must be present:[1] (1) thin, homogenous vaginal discharge;[2] (2) a positive whiff test, which involves the production of a fishy odor when mixing vaginal fluid with 10% potassium hydroxide;[3] (3) vaginal fluid pH greater than 4.5; and[4] (4) the presence of clue cells (epithelial cells covered with bacteria) on microscopic examination (Fig. 205-9).[47] Clue cells, being the most reliable indicator of BV, must make up at least 20% of the epithelial cells on saline wet mount. Another diagnostic test involves the use of Gram staining to distinguish between the normal bacterial flora of Gram-positive rods and lactobacilli from the Gram-negative morphotypes seen in BV. Due to the variety of bacterial species, culture is not a reliable diagnostic test. However, a DNA probe-based test (affirm VP III) and a newly developed immunochromatographic test (OSOM BVBlue) disclose high concentrations of *G. vaginalis*, which is suggestive of this diagnosis.

COMPLICATIONS

BV has been shown to be a risk factor for premature labor and preterm birth in pregnancy.[48] BV has also be associated as a risk factor for transmission and acquisition of HIV.[49] Studies have produced conflicting data as to whether BV is associated with a higher risk of acquiring cervical intraepithelial neoplasia.[50,51] Some studies have linked BV to postpartum fever, postpartum endometritis, postoperative gynecologic complications, and postabortal infections; however, more studies are needed to investigate the relationship between BV and possible sequelae.[52]

PROGNOSIS AND CLINICAL COURSE

BV has a good prognosis with appropriate treatment. Some infections may resolve on their own without therapy. A large number of infections are asymptomatic, and complications are rare. Many of the reported complications remain debatable as to whether they are true sequelae of BV. Recurrent infections have been reported, and a longer treatment regimen may be warranted in such cases.

TREATMENT

Treatment of BV is summarized in Box 205-6. The established benefits of therapy for BV in nonpregnant women are to (1) relieve vaginal symptoms and signs of infection and (2) reduce the risk for infectious complications after a variety of gynecological procedures (endometrial biopsy, hysterectomy, hysterosalpingography, placement of an IUD, cesarean section, uterine curettage, and abortion) In pregnant women, treatment of BV also reduces the risk of portpartum infectious complications as well as the risk of preterm labor.[53,54]

PREVENTION

Obviously, the best prevention against STD acquisition is abstinence until the establishment of a monogamous

BOX 205-6 TREATMENT OF BACTERIAL VAGINOSIS

- Metronidazole, 500 mg PO twice daily for 7 days

Or

- Metronidazole gel, 0.75%, 5 g intravaginally once daily for 5 days

Or

- Clindamycin cream, 5%, 5 g intravaginally qhs for 7 days

In pregnant women:

- Metronidazole, 250 mg PO three times daily for 7 days

Or

- Metronidazole 500 mg PO twice daily for 7 days

Or

- Clindamycin, 300 mg twice daily for 7 days

Alternative regimens

- Tinidazole 2.0 g orally once daily for 3 days

Or

- Tinidazole 1.0 g orally once daily for 5 days

Or

- Clindamycin 300 mg twice daily for 7 days

Or

- Clindamycin ovules, 100 g intravaginally qhs for 3 days

sexual relationship. However, clearly this is not a pragmatic suggestion for a majority of individuals in present day society. Some 60% of high school students will have had sex before graduation[55]; "one night stand" and "sex on the first date" mentalities are common among young adults; a longer life span in general insures that some older individuals will take new sex partners later in life. As an alternative, it is important for clinicians to educate their patients about how STDs are acquired, the possible adverse short- and long-term sequelae of STDs and the details of safe(r) sex practices. This is especially true for those individuals who fall into high-risk demographic groups. Routine screening for the various mucosal-based venereal diseases should be performed by appropriate health care providers when indicated to facilitate timely diagnosis and therapy, thereby reducing the likelihood of continued transmission.

ACKNOWLEDGMENT

The author thanks Annabelle L. Garcia, Vandana K. Madkan, and Stephen K. Tyring, who were authors of this chapter in the seventh edition.

Chapter 206 :: Leishmaniasis and Other Protozoan Infections

:: Joelle M. Malek & Samer H. Ghosn

LEISHMANIASIS AND OTHER PROTOZOAN INFECTIONS AT A GLANCE

- A complex of diseases caused by the protozoa *Leishmania* and transmitted by the bite of infected phlebotomine sandflies.
- Four major human diseases: (1) localized cutaneous leishmaniasis, (2) diffuse cutaneous leishmaniasis, (3) mucocutaneous leishmaniasis, and (4) visceral leishmaniasis.
- Resulting disease dependent mainly on interaction between *Leishmania* species and the immunologic status of the host.
- Diagnosis by organism isolation or by serology but species identification only possible with isoenzyme analysis and new molecular techniques.
- Management ranging from observation to systemic therapy, primarily with antimonials, and vaccines in development.

LEISHMANIASIS

EPIDEMIOLOGY[1]

Leishmaniasis, a truly ancient disease,[2] was recognized on Amerindian pottery drawings dating back to the first century AD.[3] It was named after W.B. Leishman who identified organisms in smears taken from the spleen of a patient who died from "dum-dum fever" in India in 1901. The disease burden remains important in the twenty-first century with up to 2 million individuals developing systemic disease annually and accounting for around 70,000 deaths per year.[4]

The various types of leishmaniasis are confined primarily to the Mediterranean basin, Southern Europe, Central Africa, and parts of Southern and Central Asia [Old World (OW)], and Central and South America [New World (NW)]. The infection is endemic in 88 countries, 72 of which are developing countries.

In Western countries, the incidence is increasing due to human immunodeficiency virus (HIV)-*Leishmania* coinfection, military appointment, and tourism in endemic countries.[5,6] New Zealand, Antarctica, and the Pacific islands are *Leishmania*-free. Australia was thought to be devoid of *Leishmania* species until 2004, when it was discovered in red kangaroos that had developed ulcers over their limbs or ears, raising the possibility of imported species becoming endemic, or of a current still unrecognized human form of the disease.[7]

More than 90% of localized cutaneous leishmaniasis (LCL) cases occur in Afghanistan, Algeria, Iran, Iraq, Saudi Arabia, Syria, Brazil, and Peru.[8] In the United States, most LCL cases are imported; however, the Southern and Central parts of Texas are considered endemic for *Leishmania mexicana*.[9,10]

The World Health Organization (WHO) has classified leishmaniasis as a category 1 disease (emerging and uncontrolled). The recent geographic spread is attributed to massive rural-urban migration and agro-industrial development projects that bring nonimmune urban residents into endemic rural areas. Other incriminated factors include natural disasters, cessation of malaria spraying leading to increased sandfly population, reconstructions, control programs, global warming, wars, and deforestation.

Risk factors for contracting the disease include residing in an endemic area and in a ground floor, the design and construction material of the house, and the presence of domesticated animals. The prevalence of the disease increases until the age of 15 then seems to stabilize, probably reflecting development of immunity.[11] In general, males have greater likelihood of developing the disease. This can be explained by behavioral differences in exposure as well as by hormonal modulation of disease susceptibility or resistance.[12]

See Box 206-1 for various forms of leishmaniasis and their abbreviations.

BOX 206-1 ABBREVIATIONS USED FOR VARIOUS FORMS OF LEISHMANIASIS

- LCL: localized cutaneous leishmaniasis
- DCL: diffuse cutaneous leishmaniasis
- VL: visceral leishmaniasis
- VTL: viscerotropic leishmaniasis
- MCL: mucocutaneous leishmaniasis
- PKDL: post-kala-azar dermal leishmaniasis
- LR: leishmaniasis recidivans

ETIOLOGY AND PATHOGENESIS[13]

ETIOLOGY AND LIFE CYCLE. The genus *Leishmania* consists of parasitic protozoa of the phylum Sarcomastigophora, order Kinetoplastida, and family Trypanosomatidae. At least 21 species are pathogenic for humans and all are essentially transmitted by the bite of an infected female phlebotomine sandfly.[4] Cases of venereal[14] and vertical[15,16] transmission, as well as transmission from infected blood transfusion[17] or needles[18–22] have, however, been reported.

Leishmania are dimorphic parasites; in the gut of the sandfly or in culture, they exist in the spindle-shaped motile (single anterior flagellum) promastigote form (10–20 µm). In the cells of the host reticuloendothelial system, *Leishmania* exist in the oval nonmotile amastigote form (2–6 µm) that has a relatively large basophilic nucleus and a smaller rod-shaped kinetoplast of extranuclear DNA at the base of the lost flagellum.[23] Infected macrophages are ingested by the fly during a blood meal and the amastigotes are released into the stomach of the insect where they immediately transform into the promastigote form. The latter migrate to the alimentary tract of the fly, multiply extracellularly by binary fission, and in few days, reach the esophagus and the salivary glands of the fly where they change into infective metacyclic promastigotes, which will be released into the skin at next bite. They are then phagocytosed by host macrophages where they transform into amastigotes that multiply by binary fission and get released following cellular burst to infect other macrophages (eFig. 206-0.1 in online edition)

RESERVOIR HOSTS.[24,25] Leishmaniasis is mostly zoonotic, being incidentally transmitted to humans from wild and domestic animals (primary reservoir hosts) (Table 206-1).[24,26–29] However, visceral leishmaniasis (VL) caused by *Leishmania donovani* and OW-cutaneous leishmaniasis (OW-CL) caused by some *Leishmania tropica* strains are anthroponotic diseases (i.e., humans are the primary reservoir hosts).

INSECT VECTORS.[30] The insect vector of leishmaniasis, the female phlebotomine sandfly, is grouped under the Suborder Nematocera of the order Diptera. Three genera [(1) *Phlebotomus* in the OW, and (2) *Lutzomyia* and (3) *Psychodopygus* in the NW], and around 70 species are implicated as vectors.[31] They are widely distributed and have predilection to intertropical and warm temperate zones. Only the female sandfly is hematophagus. Phlebotomine sandflies are less than 3 mm long, and do not fly far from their breeding site. Their activity is mostly crepuscular or nocturnal while the host is asleep. They rest during the day and lay their eggs in dark, cool, humid, and organic matter-rich places such as rodent burrows, bird's nests, and house wall fissures. Being exophilic and exophagic, they prefer to rest and to have their meal outdoors, which limits their control through house spraying.

PATHOGENESIS.[31] The resulting disease depends on the fate of the phagocytosed amastigotes. This in turn is function of numerous parasite- and host-related factors, as well as other factors that may account for geographical differences.[8,32]

In general, parasites interfere with the signaling pathways, intracellular kinases, transcription factors, and gene expression of macrophages, compromising their ability to generate leishmanicidal substances. In addition, they impair dendritic cell activation, migration, and ability to secrete T helper 1 (Th1) cytokines.

PARASITE-RELATED FACTORS.[33] Sandfly saliva is increasingly recognized as an essential element in the pathogenesis of the disease. Besides containing vasodilators, anticoagulants, and immunomodulators, it may also increase the inoculum size and the diameter of the lesion.[34] Intraspecific variations of sandfly saliva may even affect the overall clinical outcome of *Leishmania infantum*-induced disease by shifting the adaptive immunity from a Th1 to a Th2 immune response. The development of anti-saliva antibodies after exposure may account for the decline with age of susceptibility to the infection in endemic areas.[11]

Other parasite-related factors include infectivity, pathogenicity, virulence, and tissue tropism.[35–39] These differ from one species to the other. For example, lipophosphoglycan and gp63 are two important promastigote virulence factors that impair infected cells' overall functions with the former being clearly involved in *Leishmania major* disease but absent in *L. mexicana*.[11]

Although viscerotropic species tend to spread to the reticuloendothelial system, they may become dermotropic as a consequence of treatment such as seen in post-kala-azar dermal leishmaniasis (PKDL).[40] Similarly, *L. tropica*, classically dermotropic, may cause visceral disease.[41,42]

HOST-RELATED FACTORS.[11,31,43] Malnutrition, immunosuppression, and host genetic background influence host susceptibility as well as resistance to the disease. The output of acquired T cell immunity, which depends on the net effect of the opposing Th1 and Th2 responses, largely determines the course and the therapeutic response of the infection. A dominant Th1 response resulting in the production of interferon-γ (IFN-γ) and nitric oxide leads to a leishmanicidal state of macrophages, and accounts for subclinical infection or self-healing LCL

TABLE 206-1
***Leishmania* Species, Major Vector and Host Reservoirs**

	Leishmania Species	Vector	Main Reservoir Hosts	Disease Caused	Geographic Location
Old World (OW) Leishmaniasis					
OW Leishmaniasis	*Leishmania major*	*Phlebotomus*	▪ The great gerbil *Rhombomys opimus* ▪ The fat sand rat *Psammomys obesus* ▪ *Meriones* spp. ▪ Rodents	LCL DCL (1 isolate in Ethiopia)	▪ Central Asia ▪ West Asia (Jordan, Israel, Palestine, Syria, Saudi Arabia) and North Africa (Libya) ▪ Pakistan, India ▪ Sub-Saharan Africa
	Leishmania tropica		▪ Humans ▪ Hyraxes? ▪ Unknown	LCL, LR, VTL	▪ West and Central Asia ▪ East Africa ▪ West Mediterranean Basin
	Leishmania aethiopica		Hyraxes	LCL, DCL, MCL (rarely)	East Africa (Kenya, Sudan, Ethiopia)
	Leishmania donovani		Humans, dogs	LCL, VL, PKDL	India, Sudan, Kenya, China, Pakistan, Nepal, Tanzania,
New World Leishmaniasis					
Leishmania mexicana complex	*L. mexicana*	*Lutzomyia*	Rodents Wood rat in Texas	LCL, DCL LCL, LR, MCL, DCL, VL	Central America, Mexico, Texas South America
	Leishmania amazonensis		Spiny rats Less commonly: rodents, marsupials, and carnivores		
	Leishmania pifanoi		Unknown	LCL	Venezuela, South America
	Leishmania venezuelensis		Domestic cat?	LCL	
	L garnhami		Opossum	LCL	
Leishmania (Viannia) or *Leishmania braziliensis* complex	*L. (V) braziliensis*	*Lutzomyia Psychodopygus*	Rodents Less commonly: canids, felids, equines	LCL, MCL, LR, uta	South America, Central America, Mexico
	Leishmania (Viannia) panamensis	*Lutzomyia*	Sloths Less commonly: marsupials, rodents	LCL, LR, MCL, DCL	Central America, Colombia, Ecuador
	L. (Viannia) peruviana		Domestic dogs Less commonly: humans, rodents, Marsupials	LCL	Peruvian Andes
	L. (Viannia) Guyanensis		Sloths Less commonly: anteaters and opossums	LCL, LR, MCL (rarely)	Guyana, Brazil
	L. (Viannia) lainsoni		Lowland Paca, brown capuchin monkeys	LCL	Brazil, Bolivia, Peru
	L. (Viannia) colombiensis		Sloths Less commonly: anteaters and armadillos	LCL, VL (rarely, reported in Venezuela)	Colombia, Venezuela
OW and NW Leishmaniasis					
	Leishmania chagasi/ Leishmania infantum	*Lutzomyia, Phlebotomus*	Dog, fox, opossum, porcupine	LCL, infantile VL	Mediterranean basin; Middle East and Central Asia to Pakistan ; China; Central and South America

LCL = localized cutaneous leishmaniasis; DCL = diffuse cutaneous leishmaniasis; LR = Leishmaniasis recidivans; VTL = viscerotropic leishmaniasis; MCL = mucocutaneous leishmaniasis; VL = visceral leishmaniasis; PKDL = post-kala-azar dermal leishmaniasis.

and the positive Montenegro skin test (that assesses delayed-type hypersensitivity to leishmanial antigen). A dominant Th2 response accounts for progressive disease such as diffuse cutaneous leishmaniasis (DCL), and is characterized by anergy to leishmanial antigen (negative Montenegro skin test). Mucosal leishmaniasis patients will have both Th1 and Th2 responses, with slight predominance of Th2 immunity, explaining persistence of the disease. To summarize, T-cell immunity would be intact in LCL, defective in DCL, and pathologically exuberant in mucocutaneous leishmaniasis (MCL). Humoral immunity seems to play little or no role in determining the course of the infection. High titers of anti-leishmanial IgG correlate more with chronic, nonhealing, and visceral disease.

Figure 206-1 **A**. Acute Old World-localized cutaneous leishmaniasis: multiple nodules on the arm caused by *Leishmania major*. **B.** Multiple, nodular, ulcerated lesions on the trunk at the site of sand fly bites. Note that the ulcerated nodules look similar to volcanoes seen from above ("volcano sign").

CLINICAL FINDINGS

The clinical spectrum includes cryptic infection, LCL, and other forms including disseminated infection [DCL, MCL, VL, VTL (viscerotropic leishmaniasis), PKDL, leishmanid].[31]

CRYPTIC LEISHMANIASIS. Both cutaneous and visceral infection can remain subclinical or manifest with mild, nonspecific, and transient symptoms.[8,31,44,45]

LOCALIZED CUTANEOUS LEISHMANIASIS.[46] LCL constitutes 50%–75% of all incident cases. It is the mildest form of *Leishmania* diseases and the one that prevails in the OW.[3] It can be caused by all *Leishmania* species. Most cases heal spontaneously within 1 year and are characterized as acute LCL. Disease lasting more than 1 year is termed chronic LCL.

ACUTE LCL

Old World Localized Cutaneous Leishmaniasis. OW-CL (*Aleppo boil, Baghdad boil, Oriental sore, leishmaniasis tropica, Biskra button, Delhi boil, Bouton d'orient, Lahore sore, Rose of Jericho, Kandahar sore, the little sister*) is caused mainly by *L. major, L. tropica, Leishmania aethiopica*, and to a lesser extent *L. infantum* (Table 206-1).[24,26–29] Two major types, (1) the moist type (caused by *L. major*) (Fig. 206-1) and (2) the dry type (caused by *L. tropica*), are identified (Table 206-2).[47–50] Both types may coexist in the same patient.[40]

TABLE 206-2
Major Types of Old World-Localized Cutaneous Leishmaniasis

		Moist Type	Dry Type
Synonyms		Zoonotic cutaneous leishmaniasis	Anthroponotic cutaneous leishmaniasis
Species		*Leishmania major*	*Leishmania tropica*
Areas		Rural	Urban
Incubation Period		2–8 weeks	Up to 8 months
Clinical Picture	**Number of Lesions**	Multiple (Up to 100 insect bite-like lesions on exposed body parts, most of them resolve and only few evolve into LCL)	Single lesion over face
	Ulceration	More prominent and early, hemorrhagic crust	Less prominent and late, serous crust
Period of Healing		6 months (3–12 months)	Twice as long as moist type
Course/Outcome		Mild, self-limited, atrophic scars	Risk of progression to chronic LCL, Leishmaniasis recidivans or VL
Treatment		Observation or local treatment	Systemic treatment often required

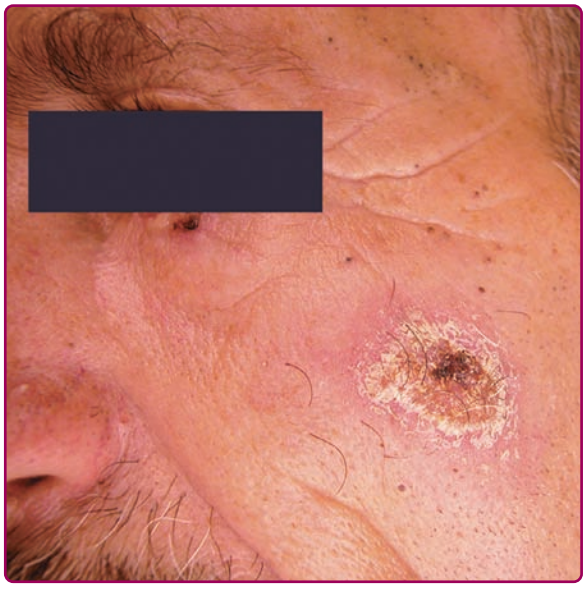

Figure 206-2 Acute Old World-localized cutaneous leishmaniasis. Single crusted erythematous plaque over the cheek.

L. aethiopica may cause a similar cutaneous disease to *L. tropica* but carries a higher risk of evolving into DCL in up to 20% of affected individuals.[47] *L. infantum*, the causative agent of Mediterranean VL in children, may cause a self-limited skin disease in adults.[51–53] Species identification cannot be made clinically and requires biochemical/molecular techniques.

The morphologic spectrum of OW-LCL is wide. Lesions start as erythematous papules that enlarge over few weeks to form nodules/plaques and often ulcerate and become crusted (Figs. 206-2–206-4; eFigs. 206-4.1 and 206-4.2 in online edition). The "volcanic" noduloulcerative morphology is characteristic and consists of painless crateriform ulcer with a rolled margin and a necrotic base that is often covered with an adherent crust (Fig. 206-5). Other presentations include "iceberg nodules,"[54] and eczematoid, psoriasiform,[50] erysipeloid,[55,56] zosteriform, paronychial,

Figure 206-3 Acute Old World-localized cutaneous leishmaniasis. Crusted erythematous nodule over the right perioral area in a young Middle Eastern girl.

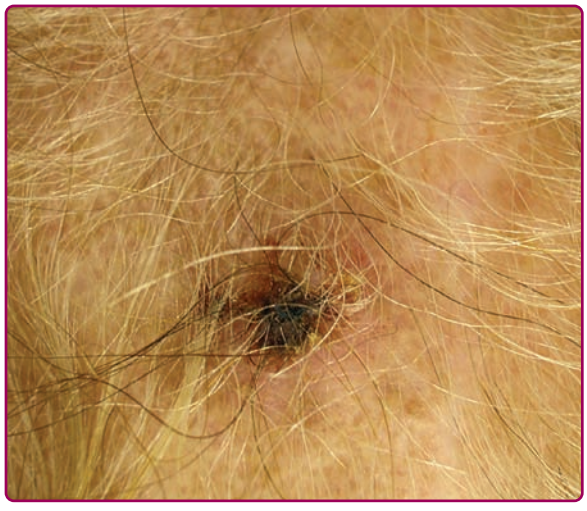

Figure 206-4 Acute Old World-localized cutaneous leishmaniasis. Crusted and ulcerated erythematous papule over the scalp.

chancriform, annular, palmoplantar,[57] verrucous, and keloidal[58] lesions. Satellitosis (Fig. 206-6), regional lymphadenopathy, localized lymphadenitis,[59] sporotrichoid lymphatic spread (eFig. 206-6.1 in online edition), subcutaneous lymphatic nodules,[54,60] and localized hypoesthesia[61] may occur. Mature lesions may be elongated and oriented parallel to skin creases.[54] Secondary bacterial infection is common.[62]

New World Localized Cutaneous Leishmaniasis (NW-LCL). NW-LCL (*valley sickness, Andean sickness, white leprosy, chiclero ulcer, uta, pian bois, and bay sore*) is caused by *L. mexicana and Leishmania (Viannia) braziliensis* complexes mainly (Table 206-1). Infection with *L. mexicana* or *Leishmania (Viannia) guyanensis* causes only cutaneous disease in contrast to infection with *L. (V) braziliensis* and *Leishmania (Viannia) panamensis*, which may, in 40%–80% of the cases, progress to MCL. Pure cutaneous disease is very similar to OW-LCL and isolated ulcers in exposed areas are the most common presentations. The progression of the lesions gives rise to a characteristic scar consisting of thin pale skin at the ulcer site with a hyperpigmented border.[3] About 50% of the lesions caused by *L. mexicana* heal within 3 months, whereas those caused by *L. braziliensis* persist much longer and are often associated with lymphadenopathy.[63,64] *L. mexicana*, however, is the causative organism of chiclero ulcer, a chronic mutilating infection of the pinna of the ear of forest workers in Mexico and Central America. (Fig. 206-7) *Lutzomyia flaviscutellata* is the major vector. In Brazil, the lower limbs are commonly affected, causing the typical Bauru ulcers.[3] Uta, the Andean cutaneous form of leishmaniasis, is caused by *L. braziliensis* and predominantly affects exposed areas in children. Its principal vector is *Lutzomyia peruensis*. An atypical nodular form of NW-CL caused by *Leishmania d. chagasi* has been reported from Honduras[65,66] and Nicaragua.[67] Unusual clinical pictures have been reported, especially in immunosuppressed patients.[3,68]

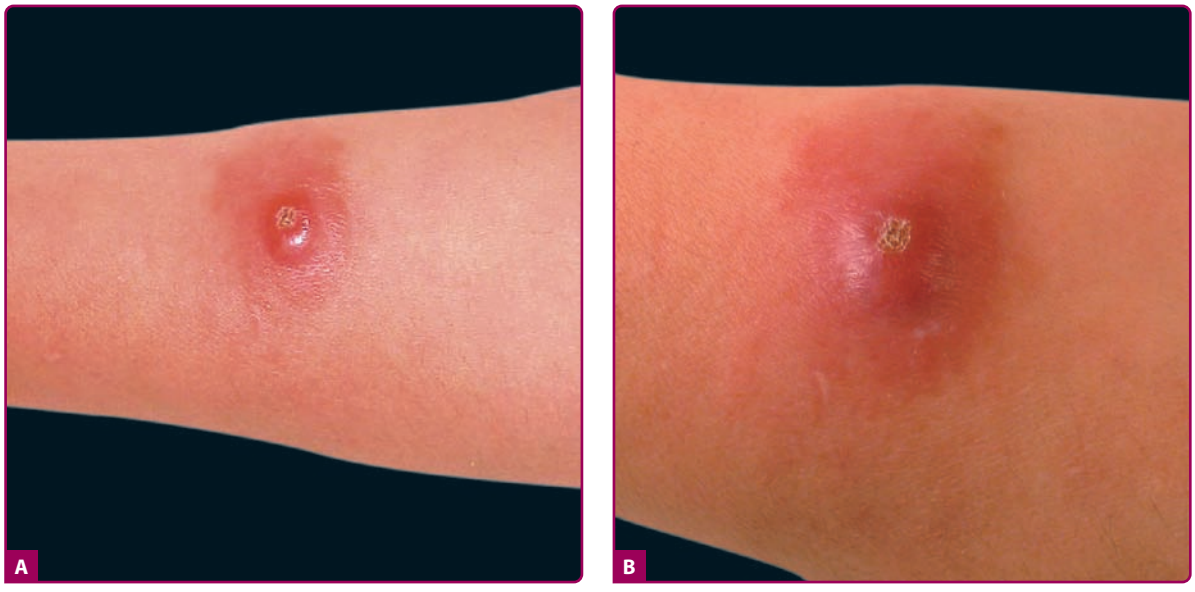

Figure 206-5 **A** and **B.** Acute Old World-localized cutaneous leishmaniasis. Classical "volcaniform" noduloulcerative lesion over the forearm.

Complications of LCL. Common complications include permanent scarring, disfigurement, and social stigma. Autoinoculation or koebnerization following trauma, tattooing, or surgery have been reported.[69] Major complications of LCL include chronic LCL, DCL, and MCL (in NW-LCL). Acute immunodeficiency syndrome (AIDS) and other immunosuppressive conditions increase the risk of mucocutaneous and visceral dissemination,[70–73] and of recurrence following therapy.[74] Disseminated cutaneous leishmaniasis, defined as more than ten pleomorphic lesions in noncontiguous areas of the body, has been reported in increasing frequency to complicate NW-LCL and HIV-associated OW-LCL.[69]

CHRONIC LCL. Typically, the lesions evolve from papules to chronic disfiguring indurated nodules/plaques that are larger than average acute LCL lesions and may exhibit variable degrees of scaling, ulceration, verrucosity, and scarring. (Fig. 206-8) The diagnosis may be challenging because of the paucity of organisms seen on histologic examination.

Leishmaniasis Recidivans. Leishmaniasis recidivans (LR) is a rare form of chronic LCL and accounts

Figure 206-9 Disfiguring lupoid leishmaniasis of several years duration in a Middle Eastern man.

for 3%–10% of all LCL cases. It is caused mostly by *L. tropica* in the OW, and less commonly by *L. (V) braziliensis* in the NW as well as *Leishmaniasis amazonensis*, *L. (V) panamensis, and L. (V) guyanensis*. Erythematous scaly papules, often with apple jelly appearance, at the borders of a completely or partially healed CL lesion, are characteristic. It may complicate vaccination with a live strain of *Leishmania*[75] and usually occurs in the setting of hyperactive T-cell immunity and low antibody titers. Reactivation of dormant infection (up to 15 years after apparent resolution) after an unknown stimulus such as trauma or topical corticosteroids, rather than reinfection with different strains, is believed to account for most of the cases. In fact, several studies have demonstrated persistence of the intracellular living organisms in "healed" *Leishmania* lesions, this being more likely to occur if therapy was incomplete or deficient.[76,77]

Lupoid Leishmaniasis. Lupoid leishmaniasis shares similar etiology and clinical picture with LR; however, the former is not a recurrent lesion.[62] The lesion characteristically occurs over the face and may resemble clinically lupus vulgaris or discoid lupus erythematosus.[78] In the absence of molecular identification of parasites, the diagnosis may be delayed for several years leading to mutilation (Fig. 206-9).[79]

OTHER FORMS OF LEISHMANIASIS

DIFFUSE CUTANEOUS LEISHMANIASIS. DCL, also called pseudolepromatous leishmaniasis, is an anergic rare form of cutaneous leishmaniasis that occurs in the setting of deficient cell-mediated immunity and mimics clinically and histologically lepromatous leprosy. It is usually caused by *L. aethiopica* in the OW and by *L. amazonensis* and *L. mexicana* in the NW. Immunosuppressed patients, especially HIV-infected individuals, may develop a severe form of DCL (>200 lesions) with no species-specific relation.[4,80,81] Following a classical LCL lesion, dissemination occurs (immediately in 30% of cases but up to 11 years in others)[47] in the form of nonulcerated and parasite-laden nodules (eFig. 206-9.1 in online edition) with predilection for exposed areas of the body such as the face, where lesions may coalesce leading to leonine facies. Viscera are not involved. A progressive/chronic course with relapse after therapy is classical.

MUCOCUTANEOUS LEISHMANIASIS. MCL may complicate up to 10% of LCL patients and is characterized by the chronic and progressive spread of lesions to the nasal, pharyngeal, and buccal mucosa; lesions appear 1–5 years after resolution of the primary lesion(s), or less commonly while they are still present. It is often a complication of NW-LCL caused by *L. (V) braziliensis*, *L. (V) panamensis*, *L. amazonensis, and L. (V) guyanensis.* Ninety percent of cases occur in Bolivia, Brazil, and Peru.[82] In the OW, similar mucosal lesions caused by *L. aethiopica* may be seen but have a better prognosis.[4,83,84]

MCL results from direct extension or hematogenous/lymphatic spread to the upper respiratory tract, and rarely ocular and genital mucosa, and liver.[40] Bony structures are usually spared. Stuffy nose, epistaxis, coryza, hyperemia, and nasal septum crusting and ulceration are frequent presenting symptoms and signs. If untreated, the disease evolves into either septal perforation with resulting collapse of the nasal bridge and free hanging nose (tapir nose or parrot beak) or partial/total naso-oropharyngeal mutilating ulceration (espundia) (Fig. 206-10). In rare cases, the lips, cheeks, soft palate, or larynx are involved.[11] Lymphadenopathy is common in *L. braziliensis*-induced disease and may be associated with hepatomegaly and systemic symptoms.[4]

Figure 206-10 Mucocutaneous leishmaniasis, South American. Painful, mutilating ulceration with destruction of portion of the nose.

The major causes of mortality are secondary infection, pharyngeal obstruction, and respiratory failure. Cure rates decrease with advanced disease.[4]

VISCERAL LEISHMANIASIS.[3] VL (*Sikari disease*, *Burdwan fever*, *Shahib's disease*, *tropical splenomegaly*, *kala-azar*, *death fever*, *dum-dum fever*) is endemic in the tropical and subtropical parts of the world. Ninety percent of cases occur in Bangladesh, Ethiopia, India, Nepal, Brazil, and Sudan.[82] The causative agents are *L. donovani* and *L. chagasi/infantum* and to a lesser extent *L. amazonensis*, *and Leishmania (Viannia) colombiensis*. Infection with *L. donovani* occurs in the OW (India and Sudan), is anthroponotic and highly endemic, and involves *Phlebotomus argentipes* as a vector. Other infections are zoonotic and dogs are the major reservoir hosts. *L. infantum* afflicts mainly malnourished children in China, Africa, the Middle East, and the Mediterranean basin.

Hematogenous dissemination of the parasite to the reticuloendothelial system follows skin inoculation. However, congenital (transplacental) transmission may occur.[16] Most infections remain subclinical. The incubation period and the duration of the disease are variable. The cardinal features of VL are persistent high undulating fever, leucopenia, anemia, splenomegaly, and hypergammaglobulinemia. Other findings include emaciation, burning feet (peripheral neuropathy), hepato-gastrointestinal disturbances, epistaxis, thrombocytopenia, and lymphadenopathy. Skin lesions develop later in the course of the disease and consist of ashy hyperpigmented patches on the temple, around the mouth, and on the abdomen, hands, and feet in light skin-persons; hence, the name kala-azar (in Hindi, black sickness). Other findings include hair and skin depigmentation (in Kenyan patients),[40] cutaneous nodules and mucosal ulcers (in Sudanese patients),[40] trichomegaly (Pitalugo's sign), petechiae, and jaundice.[40]

Without treatment, the fatality rate in developing countries approaches 100% in 2 years with the major complications being cachexia, secondary infections, enteritis, and pneumonia. Hemolytic anemia, acute renal damage, and severe mucosal hemorrhage are less common.

VL/HIV Coinfection.[85] Most coinfection cases have intravenous (IV) drug use as a common denominator[86] and represent diagnostic and therapeutic challenges, since VL precipitates the onset of AIDS and HIV increases the risk of VL. The problem is mostly described in Spain, Italy, France, and Portugal.[82,86–89] *L. infantum* is the major causative agent; however, other *Leishmania* species that do not normally visceralize have been isolated.[80,81,90] MCL-, PKDL-, and DCL-like pictures may result[91] and cutaneous lesions are highly variable.[71] Multiple dermatofibroma- and Kaposi's sarcoma-like papulonodular lesions may occur,[86] and should be differentiated from parasitic colonization of Kaposi's sarcoma.[92] The presence of amastigotes in atypical locations tend to correlate with the degree of immunosuppression.[93] People with both conditions have worse prognosis, shortened survival time, higher relapse rate and inferior response to treatment compared with HIV-negative patients. VL is now being proposed to be integrated in the Centers for Disease Control and Prevention (CDC) clinical category C as an AIDS-defining illness.[3]

POST-KALA-AZAR DERMAL LEISHMANIASIS.[94] PKDL is extremely rare in the NW and is mostly seen, in two major forms, in Sudan and India (eTable 206-2.1 in online edition). As the name implies, it is a cutaneous manifestation of VL that usually develops months to years after resolution of VL, and rarely during its treatment.[96,98] In India, PKDL is the most common skin manifestation of leishmaniasis (eFigs. 206-10.1 and eFigs. 206-10.2 in online edition). Affected patients are the major reservoirs of the infection.[98] High blood concentration of the immunosuppressive cytokine interleukin-10 in VL patients is predictive of PKDL development. The parasite count is low and detection of organisms is not always possible. With polymerase chain reaction (PCR) technique, however, *Leishmania* parasites are recovered in skin lesions in up to 83% and 94% of Sudanese and Indian PKDL, respectively. The development of skin lesions in PKDL is closely linked to *Leishmania*-specific lymphocyte reactivity, or in HIV patients, to immune reconstitution during HAART treatment. The reason behind the two major clinical forms of PKDL remains essentially unclear.[94]

VISCEROTROPIC LEISHMANIASIS.[41] Caused by *L. tropica*, this variant has been described among American veterans of Operation Desert Storm. Visceral infection manifests as fever, malaise, and variable hematologic and hepato-gastrointestinal findings. Classic signs of VL are absent and the skin is usually not involved; however, a recent report in a young Afghani refugee living in the United States demonstrated cutaneous lesions.[99] Positive culture from bone-marrow aspirates and good response to antimonials are typical.

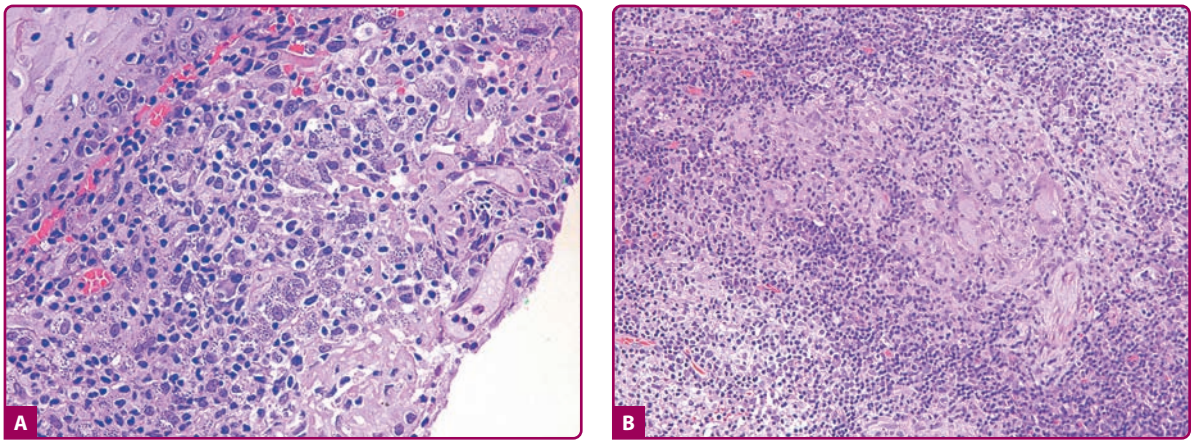

Figure 206-11 Histologic examination (hematoxylin and eosin). **A.** Acute cutaneous leishmaniasis. Moderately dense lymphohistiocytic infiltrate with numerous parasitized macrophages containing amastigotes (Leishman bodies). **B.** Chronic cutaneous leishmaniasis. Tuberculoid granulomatous dermatitis. Note the presence of multinucleated giant cells, the surrounding lymphoplasmacytic infiltrate, and the absence of parasites.

LEISHMANID. This term refers to an id reaction consisting of a diffuse, asymptomatic, and symmetric papular eruption in the setting of acute LCL or LR.[100] It typically resolves within 8 weeks of its appearance. Leishmanid may develop during treatment and is not an indication to withhold therapy.[47]

DIAGNOSIS[101,102]

Given the potential treatment toxicity, confirmation of the diagnosis is always mandatory. Even when smear, histology, and culture results are combined, the parasite may not be detected in 10%–20% of cases.[40,54] The diagnostic challenge is often greater in NW disease and in chronic lesions.[63,103] The sensitivity of both tissue smear and culture approaches 90% when specimens are taken during the first weeks of infection.[3] The best approach is to use several diagnostic methods.

Taken from the infiltrated margin, a skin biopsy may be divided into three parts: one for an impression smear, one for histological examination, and another one for culture.

Several smear techniques may be used with a success rate ranging between 50% and 80%.[40] They are obtainable from fine needle aspirates or tissue scrapings, air-dried, fixed with methyl alcohol, stained with Giemsa stain, and viewed under oil-immersion microscopy. Impression smears, made by gently pressing the skin biopsy against a glass slide 2–5 times, provide better sensitivity than H&E examination.[104]

The histopathologic examination of early lesions of LCL reveals a dense and diffuse mixed inflammatory cell infiltrate composed predominantly of histiocytes, and scattered multinucleated giant cells, lymphocytes, and plasma cells[105] (sometimes with intracytoplasmic homogenous eosinophilic immunoglobulin material called Russell bodies). The hallmark of the disease (in around 70% of the cases) is the presence of numerous extracellular and intracellular (within histiocytes) amastigotes (also known as Leishman–Donovan bodies) (Fig. 206-11A).[40] Giemsa stain stains the parasite nonmetachromatically and the kinetoplast bright red. The organisms may also be highlighted by the Wright and Feulgen stains. Monoclonal antibodies such as G2D10 can identify amastigotes and promastigotes in smear, biopsy or culture specimens, constituting a rapid screening test for leishmaniasis.[106] The histologic differential diagnosis includes diseases characterized by parasitized macrophages. The presence of halo surrounding the yeasts in Histoplasmosis, safety pin-like encapsulated Donavan bodies in Granuloma inguinale, and Mikulicz cells in Rhinoscleroma distinguishes these conditions from Leishmaniasis. Other considerations are blastomycosis, paracoccidiomycosis, toxoplasmosis, and trypanosomiasis. As the lesion evolves, the number of amastigotes per section decreases and the histology approaches that of chronic LCL where the predominant histologic pattern is nodular/diffuse noncaseating tuberculoid granulomatous dermatitis (Fig. 206-11B). Epidermal hyperplasia and ulceration are variable. Scarring with marked loss of elastic fibers may be seen.

In DCL, a diffuse infiltrate composed of vacuolated macrophages with numerous intra- and extracellular amastigotes is characteristic. The major differential diagnosis is lepromatous leprosy. In MCL, the histopathologic findings are similar to those of LCL but organisms are usually sparse. In PKDL, Pautrier-like epidermal microabscesses and a dense lymphoplasmacytic infiltrate with papillary dermal edema (in early lesions) are characteristic.[47]

Culture (at room temperature), by means of a biphasic medium such as Novy-Mac-Neal-Nicolle (NNN) or chick embryo medium, is the gold standard of diagnosis, but with a sensitivity of only 50%.[40] It can be performed using aspirates, scrapings or fresh skin biopsies.[69] Promastigotes often appear after several days but occasionally may take few weeks. Species identification is not possible based on their morphology.

Molecular techniques using species-specific oligonucleotide probes for kinetoplast DNA may be used on all specimens. PCR methods are particularly useful and offer superior specificity and sensitivity in the diagnosis of cutaneous leishmaniasis, MCL, and VL, especially in cases where organisms are scarce.[107–111] Their widespread use, however, is hindered by cost as well as by the technical expertise they require. False-positive reactions and species identification in NW-CL may be at times problematic.[11]

Isoenzyme analysis is currently considered to be the gold standard for *Leishmania* speciation. It consists of enzyme electrophoresis of cultured promastigotes and is based on the fact that morphologically similar promastigotes of different species have different enzyme profiles; however, it is lengthy and costly.

Serology in cutaneous leishmaniasis is not useful due to its low sensitivity (antibodies present in low titre[112]) and specificity (due to cross-reaction with leprosy, malaria, and other trypanosomal infections).

The Montenegro skin test (Leishmanin) is analogous to the tuberculin test and consists of phenol-killed promastigotes injected in the dermis.[3] This allows the detection of exposure to *Leishmania* without distinguishing between past and active infection.[113] Up to 50% of people living in endemic areas may test positive without a history of previous or active disease. The test is positive once crusting has developed, and negative in anergic states such as DCL and PKDL or often in lesions (less than 3-months-old).

Laboratory animal inoculation (xenodiagnosis) is useful when the parasite load is low.[40] Electron microscopy offers no advantage over light microscopy and its use is limited.[40]

In VL, microscopic detection and/or culture of parasites in tissue aspirates from spleen (sensitivity >97%), lymph nodes (sensitivity 60%), or bone marrow (sensitivity 55%–97%) is diagnostic. However, as these techniques are invasive, several serologic and molecular methods have been developed. Anti-K39 antibody based on a recombinant antigen from *L. chagasi* has high sensitivity and specificity. It is an immunochromatographic strip test using finger prick blood and is helpful in resource-poor regions. As a last resort, PCR of peripheral blood or tissue aspirate can be done and is extremely sensitive.[114]

DIFFERENTIAL DIAGNOSIS

(Box 206-2)

PROGNOSIS AND CLINICAL COURSE[31]

The clinical course is disease dependent. In general, lifelong species-specific immunity follows drug-induced cure or natural resolution.[115] Cross-species immunity may also develop.[116] Sterile immunity does not occur and persistent tissue infection seems to be the rule even following adequate therapy.[39,117–119]

BOX 206-2 DIFFERENTIAL DIAGNOSIS OF VARIOUS TYPES OF LEISHMANIASIS

- ACUTE LCL
  - Arthropod bite
  - Infections (pyoderma, Majocchi granuloma, tuberculosis, and atypical mycobacterial and deep fungal infections)
  - Sarcoidosis
  - Pyoderma gangrenosum
  - Malignancy: basal cell/squamous cell carcinoma, keratoacanthoma, lymphoma
  - Foreign body granulomas
  - Pseudolymphoma
- CHRONIC LCL
  - Infections: lupus vulgaris, leprosy
  - Sarcoidosis
  - Discoid lupus
  - Lymphoma and reactive lymphoid hyperplasia
- DCL
  - Infections: lepromatous leprosy, deep fungal infections
  - Xanthomas
  - Lymphoma
- MCL
  - Infection: leprosy, syphilitic gumma, yaws, tuberculosis, deep fungal infections such as paracoccidioidomycosis
  - Granulomatosis with polyangiitis (Wegener's)
  - Malignancy: nasopharyngeal carcinoma, squamous cell carcinoma and lymphoma
- VL
  - Infections: malaria, syphilis, tuberculosis, typhoid fever, brucellosis, histoplasmosis, schistosomiasis
  - Systemic lupus erythematosus
  - Leukemia/lymphoma
  - Tropical splenomegaly syndrome
- PKDL
  - Infections: syphilis, yaws, leprosy

LCL = localized cutaneous leishmaniasis; DCL = diffuse cutaneous leishmaniasis; MCL = mucocutaneous leishmaniasis; VL = visceral leishmaniasis; PKDL = post-kala-azar dermal leishmaniasis.

TREATMENT[120–123]

Given the clinical diversity of leishmaniasis and the lack of adequately controlled therapeutic trials, each case needs to be individualized based on the parasite species (Table 206-3), extent of the disease, host immune and nutritional status, presence of intercurrent diseases, geographic region, and cost, availability and toxicity of the various therapeutic options. In general, NW-CL tends to be more severe and progressive than OW-CL. In addition, NW-CL caused by

TABLE 206-3
Treatment Options Based on *Leishmania* Species

OW-CL	*Leishmania major*	Expectant observation Local therapy
	Multiple, progressive or sporotrichoid	Systemic therapy
	Leishmania tropica *Leishmania aethiopica* *Leishmania infantum*	Systemic therapy
NW-CL	*Leishmania mexicana* complex	Expectant observation Systemic therapy
NW-MCL	*Leishmania braziliensis* Complex	Systemic therapy

OW = Old World; CL = cutaneous leishmaniasis; NW = New World; MCL = mucocutaneous leishmaniasis.

L. braziliensis may eventuate into "espundia," thus necessitating systemic therapy. As a rule, patients should be monitored until the lesions have completely healed. Follow up at 6 months is appropriate.

Since most lesions caused by *L. major* and *L. mexicana* heal spontaneously within 4 months, an expectant approach is favored as it may confer protective immunity. Multiple, persistent, progressive, deep, sporotrichoid, and secondarily infected lesions should, however, be treated as well as lesions on cosmetically or functionally important sites such as joints.

Local therapy (Box 206-3) is appropriate for small, noninflamed and localized lesions that are not at risk to progress to MCL. Topical imiquimod alone is ineffective.[141] Systemic therapy is reserved for complicated CL such as DCL and CCL, MCL, VL, relapsing disease, or disease complicated by HIV coinfection. In general, OW-CL requires shorter courses compared to NW-CL. Systemic therapies used for leishmaniasis are summarized in Table 206-4. Sodium stibogluconate and meglumine antimoniate are pentavalent antimony derivatives with slightly differing antimony concentrations and comparable efficacy and safety profiles. They are the mainstay of systemic treatment.[178] Indian VL is treated with 20 mg/kg/day intramuscularly or IV once daily for 40 days versus 28 days if the disease is contracted elsewhere. Antimony resistance is a serious issue in India and in Iran.[179–182] Resistant cases may benefit from combining antimonials with pentoxifylline,[156] allopurinol,[183–186] paromomycin,[187,188] azithromycin,[189–191] IFN-γ,[192–194] granulocyte-macrophage colony-stimulating factor,[195] and topical imiquimod.[196,197]

BOX 206-3 LOCAL THERAPY FOR LEISHMANIASIS

- Excision/curettage or laser ablation.[97]
- Cryotherapy,[124] thermotherapy,[36] electrotherapy,[125] photodynamic therapy.[126]
- Intralesional antimonial,[127–130] combined with cryotherapy.[131]
- Paromomycin ointment[127,132,133] alone or combined with 12% methylbenzethonium chloride.[126]
- Topical azoles.[134]
- Others: ethanolic formulation of amphotericin B,[135,136] topical glyceryl trinitrate,[137] hypertonic sodium chloride,[138,139] intralesional metronidazole,[140] intralesional interferon-γ,[11] topical or intralesional zinc sulfate.[11]

PREVENTION AND VACCINES

Essential to prevention is the promotion of personal protective measures through the use of protective clothing, insect repellents containing 30%–35% DEET, permethrin-treated bed nets and clothing; the avoidance of endemic areas; and staying on higher floors of buildings in the evening.[198] One way of reservoir control of *L. major* was achieved by destroying burrows made by the rodent host. In endemic areas where dogs could be hosts of parasites, a dog collar coated with deltamethrin could be a useful way to control transmission.[11] Targeting anthroponotic foci that are at the origin of deathly epidemics, suspecting leishmaniasis in persons with skin lesions or febrile illnesses returning from endemic areas, and deferring prospective blood donors from donating blood for at least 1 year after their return are other measures. Control of HIV in Southern Europe where leishmaniasis is closely associated with HIV has generated positive outcome.[114]

New diagnostic tests, drugs, and vaccines are in development.[116,199,200] Vaccine development for tropical diseases is often limited by the lack of financial return.[201] "Leishmanization," the self-inoculation of the live parasite in inconspicuous areas of the body, has been practiced in endemic areas to prevent disfiguring facial lesions, but was later abandoned due to its complications. Killed promastigotes vaccines with and without adjuvant BCG seem to be useful in some endemic areas.[116,202] Adjuvants such as BCG are important to prime a Th1 response. Attenuated live parasites- and plasmid DNA-based vaccines using leishmanial antigens have shown efficacy in mouse models.[116] Experimental vaccines containing a component of sandfly saliva proteins appear to be promising.[203] Despite being experimentally successful, a safe nonliving prophylactic vaccine has not yet been able to confer significant protection in humans.[204] The recent sequencing of the *Leishmania* genome might lead the way to new ways for prevention, control, and treatment of the condition.[205–207]

AFRICAN TRYPANOSOMIASIS[208,209]

EPIDEMIOLOGY

African trypanosomiasis (Af-T) afflicts humans (sleeping sickness) and cattle (nagana), and affects up to half

TABLE 206-4
Systemic Therapies for Leishmaniasis[3,11,69,126,142–144]

Systemic Treatment/ Dose	Mechanism of Action	Indications	Effectiveness	Adverse Effects
Pentavalent antimonials: sodium stibogluconate (Pentostam) IV and meglumine antimoniate (Glucantime) IM/IV 20 mg/kg/day for 20–30 days	Inhibition of glycolysis and oxidation of fatty acids of the parasite	Complicated OW-LCL, NW-LCL with potential of mucosal dissemination, DCL, MCL, VL.	Superior to all other drugs except pentamidine in NW-LCL. Cure rate variable depending on species and disease: ranges from 35%–95%. High treatment failure in India and Iran.	Dose dependant and resolve after discontinuation of drug. Pain at injection site, myalgias (68%), pancreatitis (18%), hepatitis, marrow suppression, QT prolongation, fatigue, headache, rash, and nausea.
Pentamidine[143] 2–4 mg/kg/day IV or IM or every other day for 4–7 days.	Not established yet	NW-LCL in French Guyana (first-line treatment), MCL.	Superior to all other drugs in NW-LCL.	Risk of diabetes mellitus in high-dose course, nephrotoxicity, hypotension, arrhythmias, nausea, vomiting, diarrhea, pancytopenia, cough, bronchospasm, confusion, and hallucinations.
Amphotericin B 1 mg/kg every other day for up to 30 days IV 15 mg/kg total dose.	Binding to sterols present in parasite's membrane causing a change in permeability	Second-line therapy when other treatments fail LCL, MCL.	>97% efficacy for VL in all regions.	Hyperpyrexia, hypotension, thrombophlebitis, renal complications, anemia, and hepatitis
Liposomal amphotericin B[145] 3 mg/kg/day IV for 5 days, then on day 10.	Same as above	VL not yet studied for LCL.	100% cure rate against *Leishmania braziliensis* Single dose (10 mg/kg) as efficacious as conventional Amphotericin B (1 mg/kg every other day for 15 doses) for VL in India.	Less renal toxicity than amphotericin B
Imidazoles:[6,146–151] Itraconazole 200 mg/day orally for 6 weeks. Fluconazole 200 mg/day orally for 42 days. Ketoconazole 600 mg/day for 28–30 days.	Inhibition of demethylation of lanosterol, blocking ergosterol synthesis.	LCL	Oral itraconazole: good efficacy against *Leishmania tropica* Oral fluconazole: efficacy against *Leishmania major* Oral ketoconazole: 89% efficacy against both *L. major and L. tropica*, and 76% against *Leishmania panamensis*.	No significant side effects, hepatotoxicity.
Miltefosine[152] 2.5 mg/kg/day for 28 days orally	Inhibits phosphatidylcholine biosynthesis in parasites.	VL (Indian) LCL	94% efficacy in Indian VL, less efficacy in African VL.	Diarrhea, vomiting, reproductive toxicity in animals.
Paromomycin sulfate[153] 15 mg/kg daily for 21 days IM	Inhibition of protein synthesis	Indian VL	94% efficacy in Indian VL, 59% efficacy against *L. braziliensis* and *L. mexicana*, under investigation for VL in Africa.	Rarely: nephrogenic, ototoxic, hepatotoxic.
Zinc sulfate[154,155] 2.5–10 mg/kg/day orally for 30–40 days	Boosting of Th1 reaction as well as phagocytosis of parasites	LCL	84%–97% efficacy against *L. major* or *L. tropica*	Necrosis at injection site
Pentoxifylline 400 mg orally 2–3 times/day (with pentavalent antimony)[156,157]	Inhibits TNF-α	MCL, LCL	Reduces healing time as well as need for second course of pentavalent antimony, is effective for MCL patients resistant to pentavalent antimony, Can prevent renal functional alterations induced by meglumine antimonate in rats	No significant side effects related to pentoxifylline

Other reported systemic therapies: Terbinafine,[158] Metronidazole,[140,159,160] Dapsone,[161,162] interferon-γ, [163] Allopurinol, [164–167] Trimethoprim-sulfamethoxazole,[168,169] Rifampin,[170] Nifurtimox,[171,172] Quinolones,[173] Pyrimethamine,[174] Anti-interleukin-10 (experimentally lead to sterile cure),[118] Azithromycin.[175–177]
IV = intravenous; IM = intramuscular; OW = Old World; LCL = localized cutaneous leishmaniasis; NW = New World; DCL = diffuse cutaneous leishmaniasis; MCL = mucocutaneous leishmaniasis; VL = visceral leishmaniasis; Th1 = T helper 1; TNF = tumor necrosis factor.

a million people every year in the middle latitudes of Africa, where the vector is found. Fatality rate is close to 100% in untreated patients. The disease is very rare in the United States.[209]

ETIOLOGY AND PATHOGENESIS

Trypanosoma brucei, a unicellular organism, enters the bloodstream of a mammalian host via the bite of a blood-feeding infected male or female tsetse fly of the genus *Glossina*. Other ways to contract the disease, although uncommon, include placental transmission, blood transfusion, and sexual contact.[210,211]

The tsetse flies are attracted by dust clouds of moving objects and animals, as well as black and blue colors. They bite most during early daylight and at dusk, and ingest trypomastigotes from infected blood meals (eFig. 206-11.1 in online edition).

Trypomastigotes have a glycoprotein-coated surface that has a protective role against lytic factors found in human plasma. Furthermore, the extensive antigenic variation of the glycoprotein present on the parasite's surface allows evasion from humoral immunity. This also explains why a vaccine targeting trypanosomes would be extremely difficult to develop.[212]

CLINICAL FINDINGS

Af-T presents in two distinct forms. West African or Gambian trypanosomiasis (GT) (caused by *Trypanosoma b. gambiense*) is a chronic predominantly anthroponotic disease present in rural areas west of the Rift Valley. East African or Rhodesian trypanosomiasis (RT) (caused by *Trypanosoma b. rhodesiense*) is an acute fatal disease (within weeks, if untreated) that infects mainly livestock/game animals east of the Rift Valley, and sporadically herdsmen, hunters, photographers, and tourists.[213–215] Water requirements of the *palpalis* group of tsetse flies and the savannah habitat of *Glossina morsitans* determine the geographic distribution of GT and RT, respectively. This ecological separation, however, is not as strict as it was in the past with an overlap of the two forms of the disease in Uganda.[212]

In RT, a painful chancre develops at the site of the tsetse bite and resolves within 1–3 weeks leaving no scar. It consists of a circumscribed, rubbery, indurated, 2–5 cm dusky red nodule, often with a central eschar (Fig. 206-12). In GT, however, the initial lesion consists of a single nonspecific nodule that is often mistaken for an insect bite or a folliculitis.[3]

Afterward, Af-T will evolve in two stages: (1) the hemolymphatic or early stage and (2) the meningoencephalitic or late stage. In contrast to the late stage, when the skin is not involved, cutaneous changes may be seen in the early stage and are more commonly observed in RT and in light-skin patients. Perhaps for this reason, skin lesions are rarely reported in native Africans.

The hemolymphatic stage occurs 3–10 days after the initial bite development with the parasites entering the circulation and causing irregularly spiking

Figure 206-12 East African trypanosomiasis. The trypanosome chancre consists of erythematous nodule with central bulla and ulceration. This patient was treated with Suramin and survived. (From Case Records of the Massachusetts General Hospital, Case 20–2002. *N Engl J Med* **346**:2069, 2002, with permission of the Massachusetts Medical Society.).

fever. Hepatosplenomegaly, constitutional symptoms, normocytic anemia, thrombocytopenia, and pruritus (especially presternal) develop, and may be related to circulating immune complexes.[3] Local lymphadenopathy progresses to generalized lymphadenopathy in virtually all African natives and in about half of Europeans patients. Involvement of the posterior cervical (Winterbottom's sign) and supraclavicular lymph node (LN) is characteristic only of GT. The disease is more severe in RT where severe parasitemia, myocarditis and rarely, fatal disseminated intravascular coagulopathy develop.[209] Trypanids are distinctive eruptions that develop 6–8 weeks after the onset of fever in approximately half the light-skin patients, and consist of poorly defined, centrally pale, evanescent, annular, targetoid, or blotchy erythematous macular, hemorrhagic, urticarial, or erythema nodosum-like lesions, commonly on the trunk.[216] These lesions might be due to a type III hypersensitivity reaction.[3] A sensation of formication may be associated. The eruption waxes and wanes over weeks with accentuation upon exposure to cold, heat, or sweat. Painless swelling of the face (imparting a sad look), and of the hands and feet may occur. Other findings include ichthyosis, acroparesthesias, icterus, petechiae, and generalized flushing.

The late stage is characterized by central nervous system (CNS) involvement weeks to months after exposure in RT, and months to years after exposure in GT and occurs when parasites cross the blood–brain barrier. Severe headache develops then chronic meningoencephalitis, somnolence, coma, and death

ensues. Delayed bilateral pain out of proportion to a sharp squeeze applied to soft tissues, known as Kerandel's deep delayed hyperesthesia, is characteristically found in European patients but is uncommon in African patients.[217] Patients may also develop behavioral changes, psychosis and focal neurologic symptoms. Marked weight loss can ensue.[212]

DIAGNOSIS

Diagnosis of Af-T is via detection of trypanosomes in blood film or Giemsa-stained thick smears, chancre/LN aspirate, buffy coat, bone marrow, or CSF. Histologically, long, thin trypanosomes are best seen using Giemsa stain, in the midst of a perivascular lymphoplasmacytic infiltrate. Because of antigenic variability, serologic tests lack sensitivity and specificity.[213] Differentiation of RT from GT is usually based on epidemiology. PCR is the method of choice but cost limits its use in African countries.[218] New diagnostic tools are being developed.[219–221]

Control of Af-T in endemic areas is highly cost-effective and entails case detection and treatment, keeping tsetse populations at low levels,[221] and mass screening of at-risk populations.

TREATMENT

A lumbar puncture is essential for the differentiation between the early and late stages because treatment will vary accordingly.[216] Four registered drugs are currently provided free of charge by the WHO.[141,164,165,206] Suramin and pentamidine are the drugs of choice for early-stage RT and early stage GT, respectively. Melarsoprol, an arsenical, is a powerful trypanocide able to cure both RT and GT in all stages; however, due to its toxicity mostly on the central nervous system, its use is restricted to late-stage disease of both forms. Eflornithine is cytostatic and can only be used in GT. Of concern, HIV-positive patients receiving treatment for RT may succumb to full-blown AIDS.[218] Other drugs that can be used for late stage disease include nitrofurazone and difluoromethylornithine.[3] Combination therapy of the available drugs was investigated and all trials showed better results than monotherapy. Of note, combination therapy containing melarsoprol leads to severe drug reactions. A multicountry study comparing nifurtimox (registered for the treatment of Chagas disease) and eflornithine to eflornithine alone was undertaken for late-stage GT. The combination therapy resulted in fewer infusions, shorter treatment duration, and fewer adverse effects.[222,223]

CHAGAS' DISEASE (AMERICAN TRYPANOSOMIASIS)[224]

EPIDEMIOLOGY

American trypanosomiasis (Am-T) is a zoonotic disease caused by *Trypanosoma cruzi* and transmitted to humans by blood-sucking triatomine bugs (kissing bugs, assassin bugs, reduviid bugs). It is endemic in many rural areas of Central and South America and Mexico. In the United States, up to 300,000 individuals are affected and up to 45,000 have the clinical disease.[225,226]

ETIOLOGY AND PATHOGENESIS

Triatomine bugs are large (3–4 cm), "cone-nosed" bedbugs that thrive in poor housing conditions and become infected with *T. cruzi* by feeding on contaminated blood. An infected triatomine bug takes a blood meal usually at night, and releases trypomastigotes in its feces near the site of the bite wound, usually a mucocutaneous junction. Human infection occurs when mucous membranes especially the conjunctiva or skin breaks are contaminated with the feces upon rubbing/scratching (eFig. 206-12.1 in online edition). Other reported ways of transmission of the disease seem to be via the intake of reduviid feces-contaminated fruits and fruit products.[3] Congenital (transplacental) transmission[227] and transmission by blood transfusion and organ transplantation[224,228–230] may also occur.

CLINICAL FINDINGS

Am-T progresses in three stages (Box 206-4).

DIAGNOSIS

Diagnosis and treatment are problematic. In the first stage, diagnosis involves microscopic demonstration of trypomastigotes in blood specimens especially thin smears, hemoculture, or xenodiagnosis. Thereafter, detection of organisms becomes difficult, and diagnosis relies more on serologic testing or PCR. The WHO recommends using at least two antigen detection tests for confirmation of the disease.[237]

TREATMENT

Treatment is indicated for acute infections, congenital infections, patients who are immunosuppressed or children with chronic disease.[237] Both drugs that are available, benznidazole and nifurtimox, are toxic[238] and most effective when given during the first stage of the infection or in congenital infections. Because of their toxicity, potential carcinogenic risk, decreased efficacy in chronic disease, and the presumably autoimmune nature of the latter, treatment of chronic disease has long been considered controversial. Later studies, however, revealed the persistence of the parasite in heart muscle as well as digestive tissue in patients with the chronic condition.[235,239] In addition, patients with chronic cardiomyopathy who were given benznidazole had less clinical deterioration a decade later as well as lower serologic titers. Therefore, chemotherapeutic intervention at any stage of the disease is currently recommended.[240] Allopurinol and itraconazole have also been tried for chronic disease.[3]

BOX 206-4 CLINICAL STAGES OF CHAGAS DISEASE

The acute phase (first stage)	Transient parasitemia: usually asymptomatic or associated with fever, lymphadenopathy, mild hepatosplenomegaly, and morbilliform/urticarial rash; lasting for about 8 weeks.
	Chagoma: painful inflammatory reaction at the site of inoculation: 1–3 cm erythematous, often ulcerated nodule with a surrounding pale halo. Local lymphadenopathy often present.
	Schizotripanides or transient skin rash resembling measles.
	Romaña's sign (or ophthalmoganglionar complex): Unilateral conjunctivitis with palpebral edema (from conjunctival inoculation).
	May be fatal in young children or immunosuppressed individuals.
The indeterminate phase (second stage)	Low levels of the parasite in blood and other tissues → chronic asymptomatic and infectious state.
	Reactivation of the infection following organ transplantation (disseminated painful subcutaneous and/or ulcerated nodules [224,231,232]).
The symptomatic chronic phase (third stage)	In 10%–30% of patients often many years after initial infection Lethal dilated cardiomyopathy, arrhythmias, megaesophagus, and megacolon
	Pathogenesis: was thought to be mediated by molecular mimicry;[233,234] however, parasites persistence in tissues were recently demonstrated by PCR and in situ hybridization.[235]
	Genetic variability of *Trypanosoma cruzi* might determine the clinical presentation of chronic disease.[236]

Preventive measures are aimed to eradicate the vectors, improve diagnostic tests, develop less toxic and more efficient drugs, and implement serologic screening of organ donors and recipients. Control programs have reduced the incidence of Am-T by 70% in some countries of South America.[241]

CUTANEOUS AMEBIASIS[242]

EPIDEMIOLOGY

Entamoeba histolytica, of the class Sarcodina and genus *Entamoeba*, is a pathogenic ameba that can cause intestinal and extraintestinal diseases. Amebiasis is the second leading cause of death from parasitic diseases. Higher incidence is reported in Mexico and in developing tropical countries.[243] In developed countries, risk groups include male homosexuals, travelers, immigrants, and institutionalized patients.

ETIOLOGY AND PATHOGENESIS

Entamoeba exists in two forms: (1) the capsuled cyst (10–15 µm) or infective stage, and (2) the mobile trophozoite or tissue-invasive stage. Both forms are passed in the feces. Human beings are the only natural hosts and infection generally occurs by ingestion of mature cysts in fecally contaminated food, water, or hands. Anal sex and contaminated enema equipment are other modes of transmission.[242]

Trophozoites have marked phagocytic, proteolytic, and cytolytic capabilities, releasing proteases, collagenase, hyaluronidase, N-acetylglucosaminidase, phospholipase-A, and secretagogues.[244] They can therefore invade human colonic mucosa, and occasionally penetrate through to the portal circulation, reaching the liver and other organs, and causing fatal lesions. Some mammalian cells are resistant to trophozoite adherence.[242] Most cases of asymptomatic noninvasive "luminal amebiasis" are caused by *Entamoeba dispar*, rather than *E. histolytica*.[245]

CLINICAL FINDINGS

Depending on the extent of invasion and the transmission mode, the clinical spectrum includes three major presentations:

1. Invasive intestinal disease (dysentery, colitis, and amebomas).
2. Invasive extraintestinal disease (liver abscess, peritonitis, and pleuropulmonary abscess).
3. Cutaneous disease can be either primary or secondary:
   - In primary cutaneous amebiasis, an extremely rare condition, the skin is affected without underlying intestinal or extraintestinal disease. It is thought to be secondary to direct inoculation from scratching with contaminated fingers in areas with poor hygiene. Penile lesions are often acquired through anal intercourse with infected individuals.[243,246]
   - In secondary cutaneous amebiasis, the skin can be infected following extension from an underlying/contiguous intestinal or extraintestinal abscess, draining catheter, fistula, colostomy or laparotomy incision.[243,246,247] Trophozoites can also spread through contaminated stool to the anogenital

Figure 206-13 Cutaneous amebiasis. (From Weinberg S, Kristal L, Prose NS: *Color Atlas of Pediatric Dermatology*, 4th edition. New York, McGraw-Hill, 2007.)

skin. This is often seen in children with diarrhea following direct and prolonged contact with infected feces in their diapers.[244,248] Autoinoculation via contaminated hands may account for more distal lesions.[249–251]

Both types of cutaneous transmissions are rare and result in rapidly progressive, foul smelling, and painful punched-out ulcers with glairy, hemopurulent, raw beef-like base; necrotic, cordlike and undermined borders; and surrounding erythema (Fig. 206-13). Lesions may reach up to 20 cm in diameter and are often destructive if untreated. Chronic urticaria may be associated[252] and local lymphadenopathy is common. Without prompt diagnosis and treatment, the prognosis is poor. In rare cases, even primary cutaneous amebiasis has a fatal outcome.[246]

DIAGNOSIS

The diagnosis relies on identification of cysts and/or trophozoites in infected stool, mucosa, or skin. This method, however, cannot distinguish between *E. histolytica* and *E. dispar.* Enzyme-linked immunosorbent assays are useful in this regard. Stool culture and PCR are only available as research tools. Serology may be helpful but false-negativity may occur in early infection. Skin biopsy reveals ulceration, mixed inflammatory cell infiltrate, and areas of necrosis where trophozoites may be identified as round or oval cells (20–50 µm) with basophilic cytoplasm, an eccentric nucleus with central karyosome, and often displaying erythrophagocytosis (sign of pathogenicity).[253]

TREATMENT

For symptomatic intestinal or extraintestinal disease, the drug of choice is oral or intravenous metronidazole (250–800 mg every 8–12 hours for 10 days), followed by treatment with one of the luminal agents iodoquinol, paromomycin, diloxanide furoate, dehydroemetine, or chloroquine.[123]

OPPORTUNISTIC AMEBAS

EPIDEMIOLOGY AND ETIOLOGY

The free-living amebas belonging to the genera *Naegleria, Acanthamoeba, Balamuthia* and lately described *Sappinia* are ubiquitous in air, soil, and water; they rarely cause disease in immunocompetent patients; reported presentations include acanthamebic keratitis (in contact lens wearers) and primary amebic meningoencephalitis (caused by *Naegleria fowleri*). Immunocompromised AIDS and organ transplant patients are at risk of disseminated disease[254] as well as at risk of developing granulomatous amebic encephalitis, a rare gradually progressive fatal neurologic disease caused by *Acanthamoeba* species.[255–259] Free-living amebas can also harbor bacteria, such as *Legionella, Mycobacterium avium, Burkholderia* spp., *Escherichia coli, and Vibrio cholerae*, possibly serving as vectors of bacterial infections in humans.[260]

The portal of entry of the amebas is usually the nasal mucosa, from which they can reach the CNS. They can also enter through a skin break or through the respiratory tract with subsequent hematogenous dissemination to the CNS.[257]

CLINICAL FINDINGS

Cutaneous lesions have been mainly reported in *Acanthamoeba*-induced disease, mostly in HIV-positive patients. *Balamuthia mandrillaris*-related skin involvement, however, is being increasingly reported. In HIV-positive patients, skin lesions are the most common (75%–90% of the cases) and sometimes the sole manifestation of disseminated disease.[255,261] The extremities (lower more than upper) and the face are commonly involved. Numerous widely distributed papules, plaques, nodules, pustules, as well as cellulitis, nonhealing ulcers with rolled borders, eschars, and palatal ulceration have been described. Lymphadenopathy may be present.[262] An asymptomatic plaque over the central face with possible satellite lesions along with neurologic symptoms is a characteristic presentation of *B. mandrillaris* disease.[3]

One study suggested that the immunologic state of the patient determines the clinical outcome of cutaneous acanthamebiasis. Unexpectedly, immunocompromised patients were found to develop multiple subacute skin lesions without CNS involvement and to respond better to therapy. On the other hand, immunocompetent patients had a worse prognosis with slowly progressive cutaneous lesions and more CNS involvement.[262]

DIAGNOSIS

Histopathologically, a dermal and/or subcutaneous predominantly neutrophilic infiltrate is present, sometimes with vasculitic, and granulomatous changes.[255,263]

The identification of 20–30 µm trophozoites with abundant vacuolated cytoplasm, and central nuclear karyosome is diagnostic but may be difficult because of their macrophage-like appearance.[255] Gomori methenamine silver and periodic-acid-Schiff stains may highlight the organisms. *B. mandrillaris* may occasionally exhibit more than one nucleolus distinguishing it from *Acanthamoeba*. Definite diagnosis and speciation is possible using indirect immunofluorescence, culture or PCR.[3]

TREATMENT

The disease is often fatal but early treatment using a combination of IV pentamidine and oral fluconazole, sulfadiazine, isethionate, or 5-fluorocytosine may improve the outcome. HIV patients may benefit from antiretroviral therapy.[254]

TOXOPLASMOSIS[264–267]

ETIOLOGY

Toxoplasmosis, caused by the parasitic protozoan *Toxoplasma gondii* (class Sporozoa), is one of the most common human infections worldwide. The main reservoirs of *T. gondii* infection are members of the cat family (Felidae), which become infected by carnivorism; dogs and rabbits can also host the parasite. Viable organisms invade the feline intestinal epithelium where they undergo an asexual cycle followed by a sexual cycle and then form oocysts, which are excreted in large numbers and are resistant to harsh environmental conditions and disinfectants. Human infection results mainly from ingestion of cyst-containing undercooked meat or milk, but can also result from ingestion of the oocytes from fecally contaminated hands or food, organ transplantation,[268] blood transfusion,[269] or transplacental transmission.[270] The parasites become tachyzoites and form tissue cysts, mostly in skeletal muscle, myocardium, brain, eye and placenta, and may remain asymptomatic. Invasion of the reticuloendothelial/endothelial systems results in suppuration and granuloma formation.

CLINICAL DIAGNOSIS

Three major clinical forms are identified:

1. Congenital toxoplasmosis occurs in 1 per 1,000 live births in the United States. The risk of transmission is highest in the third trimester; however, the disease is more severe if transmitted in early pregnancy.[3] Approximately 10% of affected newborns will have chorioretinitis and blindness, and 20% will have generalized or CNS disease. Infection may manifest as abortion,[270] stillbirth, microcephaly, tram-track intracerebral calcifications,[271,272] deafness, hydrocephalus, mental retardation, or seizures. Skin lesions include purpura, jaundice, blueberry muffin lesions (dermal erythropoiesis), and erythroderma. Untreated subclinical infection may reactivate during the second to third decade of life, mostly in the form of retinochoroiditis.[273]
2. Acquired toxoplasmosis in immunocompetent persons is often asymptomatic in 80%–90% of cases.[274,275] However, 10%–20% of patients, preferentially including pregnant women, develop cervical or occipital lymphadenopathy and a flu-like illness. Rarely, myocarditis, pneumonitis, encephalitis, and polymyositis may occur. Cutaneous manifestations are protean reflecting the heterogeneous immune responses to the organism,[264] and include among others dermatomyositis-like syndrome[276–281] and pityriasis lichenoides (Box 206-5).[275,282–285] Toxoplasmosis should be sought in patients with an acute dermatomyositis-like picture. Both conditions share a common underlying pathogenic mechanism related to the expression on muscle fibers of human leukocyte antigen class I as well as production of certain cytokines.[3]
3. Toxoplasmosis in immunodeficient patients is often secondary to reactivation of latent infection and presents as disseminated disease. Toxoplasmic encephalitis is the most common cause of intracerebral lesions in AIDS patients. Disseminated papular/nodular eruption may occur.[85,264,294–296] Rare cases of graft-versus-host disease-like rash have been reported in patients who underwent hematopoietic stem cell transplant. Histology may not be helpful in differentiating between the two conditions.[297] A high degree of suspicion of toxoplasmosis and molecular confirmation are important to distinguish between the two conditions.[298]

BOX 206-5 SPECTRUM OF CUTANEOUS LESIONS SEEN IN ACQUIRED TOXOPLASMOSIS IN IMMUNOCOMPETENT PERSONS

- Dermatomyositis-like syndrome.[276–281]
- Pityriasis lichenoides.[275,282–285]
- Cellulitis.[279–281]
- Others: Sweet's syndrome,[286] cold urticaria,[287] erythroderma,[288] palmoplantar maculopapular rash,[267] morphea,[289] mastocytosis,[290] lichen planus pilaris, pityriasis rubra pilaris, capillaritis, papular acantholytic dermatosis, keratosis lichenoides chronica,[291] chronic prurigo,[279] scarlatiniform eruption, panniculitis,[292] erythema-multiforme,[293] roseola, papular urticaria.[3]

DIAGNOSIS

Diagnosis is routinely made by serology. Protozoa may be identified in bronchoalveolar lavage or LN specimens,

or skin biopsies. Tachyzoites, visualized with Wright or Giemsa stains, are crescent-shaped and have a prominent, centrally placed nucleus. The most common histologic finding is subacute histiolymphocytic vasculitis with demonstration of trophozoites within macrophages.[293] Epidermotropic infection and neural infiltration may occur.[299] Immunoperoxidase stains are specific and are particularly helpful when small tissue specimens are submitted. PCR-based testing has a high diagnostic value in acute disease and has become the preferred method of diagnosis, particularly in prenatal diagnosis of toxoplasmosis and in immunocompromised patients with disseminated toxoplasmosis. PCR detection of the parasite in fluid specimens (blood, amniotic fluid, CSF, urine, vitreous, and aqueous fluid.) as well as fetal and brain tissues is indicative of active infection.[300–303]

TREATMENT

Treatment should be initiated in all patients with acute or active disease or congenital infection, and in immunosuppressed individuals.[3] Sulfadiazine and pyrimethamine act synergistically and together provide effective therapy.[123] Clindamycin can be used in sulfonamide-allergic patients. Co-trimoxazole was recently reported to be effective in the treatment of toxoplasmic lymphadenitis.[304]

Chapter 207 :: Helminthic Infections

:: Kathryn N. Suh & Jay S. Keystone

HELMINTHIC INFECTIONS AT A GLANCE

- Helminthic infections are a major cause of morbidity and mortality, particularly in tropical and developing countries.
- The majority of infected individuals have a low worm burden and are asymptomatic.
- Dermatologic symptoms and cutaneous findings may be associated or presenting features of helminthic infections.
- Dermatologic manifestations may differ in returning travelers and in immigrants from endemic areas.
- Migratory lesions, subcutaneous masses, papular eruptions, urticaria, and pruritus are the most common presenting dermatologic symptoms of helminthic infections.
- Cutaneous larva migrans is the most common helminthic dermatosis identified.
- Recognition of skin findings or helminthic infections and an appropriate epidemiologic history can guide appropriate investigations and effective therapy.

Helminths (worms) are variably sized multicellular parasites that can infect a wide range of mammals, including humans. Those causing human disease belong to three groups: (1) nematodes (roundworms), (2) trematodes (flukes), and (3) cestodes (tapeworms) (Table 207-1); trematodes and cestodes are collectively referred to as platyhelminths (flatworms). This chapter focuses only on those helminths that more commonly cause dermatologic disease.

TABLE 207-1
Helminths Causing Infection in Humans

Helminth	Disease	Portal of Entry	Source of Infection
Nematodes (Roundworms)—Intestinal			
Ancylostoma duodenale, Necator americanus	Hookworm	Skin	Larvae in soil, occasionally in food
Ascaris lumbricoides	Ascariasis	Gastrointestinal	Eggs from contaminated food, soil
Enterobius vermicularis	Enterobiasis (pinworm)	Gastrointestinal	Eggs in environment
Strongyloides stercoralis	Strongyloidiasis	Skin	Larvae in soil
Nematodes (Roundworms)—Tissue			
Ancylostoma braziliense, Ancylostoma caninum	Cutaneous larva migrans	Skin	Larvae in soil
Dirofilaria spp.	Dirofilariasis	Skin	Infective mosquitoes
Dracunculus medinensis	Dracunculiasis	Gastrointestinal	Infective copepods in water
Filariae			
Brugia malayi, Brugia timori	Filariasis	Skin	Infective mosquitoes
Mansonella ozzardi, Mansonella perstans, Mansonella streptocerca	Filariasis	Skin	Infective midges and/or flies
Loa loa	Loiasis	Skin	Infective deer flies
Onchocerca volvulus	Onchocerciasis	Skin	Infective black flies
Wuchereria bancrofti	Filariasis	Skin	Infective mosquitoes
Gnathostoma spinigerum, others	Gnathostomiasis	Gastrointestinal	Larvae in animal flesh (raw fish, amphibians)
Toxocara canis, Toxocara cati	Visceral larva migrans	Gastrointestinal	Eggs in contaminated food, soil
Trichinella spiralis	Trichinosis	Gastrointestinal	Larvae in animal flesh (usually pork, bear)
Trematodes (Flukes)			
Clonorchis sinensis	Clonorchiasis	Gastrointestinal	Metacercariae in seafood (raw fish)
Fasciola hepatica, others	Fascioliasis	Gastrointestinal	Metacercariae on watercress, in water
Fasciolopsis buski	Fasciolopsiasis	Gastrointestinal	Metacercariae on plants, in water
Heterophyes heterophyes	Heterophyiasis	Gastrointestinal	Metacercariae in seafood (raw fish)
Metagonimus yokogawai	Metagonimiasis	Gastrointestinal	Metacercariae in seafood (raw fish)
Paragonimus westermani, others	Paragonimiasis	Gastrointestinal	Metacercariae in seafood (crabs, crayfish)
Schistosoma mansoni, Schistosoma japonicum, others	Schistosomiasis	Skin	Cercariae in water
Schistosomes, non-human (avian)	Cercarial dermatitis	Skin	Cercariae in water
Cestodes (Tapeworms)			
Diphyllobothrium latum (fish tapeworm)	Diphyllobothriasis	Gastrointestinal	Larvae in seafood (raw fish)
Echinococcus spp.	Echinococcosis (hydatid disease)	Gastrointestinal	Eggs in contaminated food
Hymenolepis nana (dwarf tapeworm)	Hymenolepiasis	Gastrointestinal	Eggs in contaminated food, water
Spirometra mansonoides, others	Sparganosis	Gastrointestinal	Larvae in contaminated water or animal flesh (snakes, amphibians, fish)
Taenia multiceps, others	Coenurosis	Gastrointestinal	Eggs in contaminated food, water
Taenia saginata (Beef tapeworm)	Taeniasis	Gastrointestinal	Larvae in contaminated food (beef)
Taenia solium (Pork tapeworm)	Taeniasis; cysticercosis	Gastrointestinal	Larvae in contaminated food (pork)

EPIDEMIOLOGY

Globally, helminthic infections are among the most common diseases of humans. However, the true prevalence of helminthiases is difficult to determine, particularly since the majority of infected individuals harbor relatively few worms and are asymptomatic. Large worm burdens and symptomatic disease affect a relatively small proportion of those who are infected.

While some helminths such as *Enterobius vermicularis* and *Toxocara canis* are found worldwide, others are more geographically restricted (eTable 207-1.1 in online edition). Most infections occur in developing tropical or subtropical countries, where environmental conditions are conducive to the completion of the life cycle of many helminths, and the requisite animal hosts and vectors for ongoing transmission exist. In addition, the high population density, poverty, and poor sanitation

commonly found in these areas further facilitate the transmission of these diseases. Knowledge of the geographic distribution of specific helminths is important for the clinician, and will help to direct appropriate investigations and management.

Helminthic infections are less prevalent in temperate and northern climates, although some diseases are endemic even in these regions (eTable 207-1.1 in online edition). In developed countries and colder climates, helminthic diseases are more often imported by travelers to or immigrants from endemic areas. Less frequently, helminthic infections in developed nations can be locally acquired (e.g., trichinellosis resulting from improperly prepared food) or transmitted via person-to-person spread (e.g., enterobiasis).

SKIN DISEASES IN TRAVELERS

Dermatologic disorders are the third most common illness in travelers.[1] In several observational studies, 5%–17% of travelers to varied destinations developed a dermatologic condition during or after travel.[2–6] These figures cannot necessarily be generalized to all travelers; however, as the studies included travelers assessed only in specialty (travel and tropical medicine) clinics, and may also have been subject to geographic biases (due to the specific population of travelers studied and/or the more common travel destinations among these travelers).

Infections, including tropical skin diseases, are common causes of dermatoses among travelers. Insect bites, allergic reactions, and other rashes are among the most prevalent noninfectious dermatologic diagnoses in travelers. Of the helminthic skin infections, cutaneous larva migrans (CLM) is by far the most commonly reported in travelers and accounts for 5%–25% of all skin diseases in this group.[6–8] Most other helminthic infections that may be associated with dermatologic findings are relatively rare in travelers.

SKIN DISEASES IN IMMIGRANTS AND REFUGEES

The prevalence of dermatologic conditions in immigrants and refugees has not been exhaustively studied. Two studies suggest that skin conditions among these populations occur no more frequently[3] or, in one study, much less commonly[5] than in travelers; however, these studies are subject to the same biases noted above.

The helminths that cause skin findings in this population, and the clinical presentation, may also differ from those in travelers. For example, filarial infections are more commonly encountered in individuals who have resided in endemic areas for prolonged periods rather than in travelers,[8] since they usually require repeated exposures to insect vectors in order for effective transmission to occur. Strongyloidiasis is also more prevalent in immigrants from endemic areas, particularly Southeast Asia, and often presents with eosinophilia or nonspecific abdominal symptoms.[9] Acute onchocerciasis may occur in short-term (at least

Figure 207-1 Onchocercal dermatitis. (Used with permission from Herman Zaiman, MD.)

1 month) visitors to endemic areas and characteristically presents with a hyperimmune response manifest by pruritus and rash (Fig. 207-1),[10,11] in spite of low-parasite loads. In contrast, infected immigrants more commonly have chronic onchodermatitis, chronic skin changes including atrophy, hypopigmentation and lichenification, and onchocercal nodules (Fig. 207-2).

LIFE CYCLE AND TRANSMISSION OF HELMINTHS

All helminths have complex life cycles that include maturation from eggs (or other infective forms) to larvae (or other immature forms) to adults. Human disease results from ingestion of eggs or other infective forms or, alternatively, exposure of the skin to infective forms (larvae or cercariae) by direct contact or via the bite of

Figure 207-2 Onchocercal nodule over iliac crest. (Used with permission from Jay S. Keystone, MD, FRCPC.)

an insect vector. Humans may be the primary hosts for some helminths (e.g., *Strongyloides stercoralis*), or may be incidental or accidental hosts (e.g., avian schistosomes, animal hookworm, and *T. canis*). Helminths that are well adapted to humans can mature from the infective stage into adult forms in the human host; infection generally persists for the lifespan of the adult worm, which in some cases can be for many years. In contrast, animal helminths cannot mature into adult forms in humans (who in this setting are therefore "dead-end" hosts), although infection can still cause tissue damage and clinical findings.

In general, helminths do not multiply in the human host. Most helminths (with the notable exception of *S. stercoralis*) are incapable of completing an entire life cycle in the human host, and depend on the environment (e.g., soil, water), plants, or other animal hosts or insects, for their survival. Consequently, transmission of infection requires the presence of appropriate environmental conditions, specific intermediate hosts (in whom only the asexual reproductive cycle occurs) and/or specific insect vectors, explaining in large part the localized geographic distributions of many helminthic diseases.

Examples of helminthic diseases acquired by ingestion of infective forms (eggs or metacercariae) in contaminated food or water include *Ascaris lumbricoides* and *Fasciola hepatica*. In ascariasis (eFig. 207-2.1 in online edition), swallowed eggs are consumed, larvae are released within the gastrointestinal tract, and migrate through the portal-systemic circulation to the lungs, from where they are swallowed. Skin disease such as urticaria may occur during the larval migration phase. Once in the gastrointestinal tract, larvae mature into adult worms where sexual reproduction may take place; either eggs or adult worms can be shed in stool. Eggs must mature in soil before releasing infective larvae. In fascioliasis, infective metacercariae excyst in the small intestine and migrate through the intestinal wall and peritoneum to their target tissue, the biliary tract, where they become adults. Again, skin findings typically occur as immature forms migrate. Eggs produced by adult flukes are passed in feces and become infective for humans only after maturation in a suitable (intermediate) snail host.

Schistosomiasis results from penetration of intact skin by infective cercariae (eFig. 207-2.2 in online edition). Dermatologic findings in early disease manifest either at the time of cercarial penetration (swimmer's itch or cercarial dermatitis), or during migration of immature forms (schistosomulae) from the skin and through tissue to the venous systems of their target organs (which may vary depending on the infecting species), where they mature into adults. Migration of schistosomulae in previously unsensitized individuals (usually travelers) can result in acute illness (Katayama fever) consisting of fever, myalgias, cough, and wheezing, and may be accompanied by urticaria. Sexual reproduction leads to the release of eggs into the local circulation. En route to the bladder or bowel, eggs may sometimes become trapped in ectopic tissues, including skin, where they cause a granulomatous reaction. In skin, this may lead to a chronic papular eruption. Eggs excreted in urine or feces hatch in fresh water, releasing cercariae, which must undergo further maturation in one of several intermediate snail hosts in order to infect humans.

Infection can also result from penetration of intact skin by larvae, exemplified by human hookworm infection (eFig. 207-2.3 in online edition). Larval skin penetration may cause localized papular or vesicular lesions, or creeping eruption. Larvae then migrate to the circulatory system where they are carried to the lungs, penetrate the alveoli, and ascend the bronchial tree, are swallowed, and enter the gastrointestinal tract. Skin findings may also occur during larval migration to the lungs. Maturation into adult worms occurs in the small intestine, where they reproduce and release eggs into stool. Under the appropriate environmental conditions, eggs mature into infective larvae in soil. In contrast, larvae of animal hookworms (e.g., *Ancylostoma braziliense*) cannot mature beyond the larval stage in humans and tunnel aimlessly in the skin before the infection eventually extinguishes itself.

Larvae can also be introduced through intact skin by insect bites (e.g., in filarial infections). The insect vector and the target tissue both vary according to the infecting species; cutaneous disease may be seen during either migration of larval forms through tissue, or as a result of adult worms in tissue. Microfilariae released from mature adult worms are taken up by an insect during a subsequent blood meal, and then undergo maturation to infective forms within the insect before being introduced into another human host.

ETIOLOGY AND PATHOGENESIS

A variety of helminths can infect humans and cause cutaneous findings (Table 207-2). Cutaneous manifestations can be seen at every phase of the helminth life cycle in humans: by larvae or cercariae during skin penetration; during larval migration and tissue invasion; and due to the presence of eggs and adult worms in skin and soft tissues. Skin lesions also may occur during either early (acute) or chronic infection.

The pathogenesis of skin lesions in helminthic infections is varied. Direct penetration of skin may lead to a localized immune response, as seen in CLM or cercarial dermatitis. Migration of helminths can cause a generalized immune response (urticaria; maculopapular eruptions), particularly due to migration of larvae or immature forms (e.g., with *Ascaris* or *Toxocara* infection); a local inflammatory reaction to adult worms or eggs may also develop, as occurs with cutaneous nodules due to *Onchocerca volvulus* and in schistosomiasis. Skin changes can also result from disruption of the normal skin structures due to lymphedema, as with filarial infections. Finally, ill-defined systemic immune reactions such as erythema nodosum (EN) or erythema marginatum, rarely reported manifestations of several helminthic infections, may also be present. Skin findings of helminthic infections do not generally result from hematogenous spread of parasites, in contrast to many bacterial and viral infections.

Helminths induce a dramatic expansion of the T helper 2 (Th2) lymphocyte subset, with elevated levels of immunoglobulin E (IgE), peripheral eosinophilia,

and an increase in tissue mast cells. It is unclear whether these Th2-derived responses are important in the protective immune response against the parasite, are responsible for immune-mediated pathology, or both.[12] Despite high levels of IgE and other features of Th2 cell activation, allergic responses are rarely observed in infected individuals except during the invasive phase of infection, when pruritus and/or urticaria may occur. Infected hosts have evolved elaborate immune evasion strategies that permit long-lived helminthic infections, including the induction of tolerance to parasite antigens.

APPROACH TO THE PATIENT

With the exception of CLM, most travelers and immigrants who present with dermatologic complaints will not have a diagnosis attributable to a helminthic infection. However, clearly these must be considered if the epidemiologic and exposure history and clinical findings are consistent with a helminthic infection, since these are treatable infections that have important clinical implications, such as disseminated strongyloidiasis in an immunocompromised host.

As with all diseases of travelers and immigrants, a thorough history is essential in order to direct the clinician toward the correct diagnosis. The history should focus on aspects related to travel (or residence in endemic areas), general medical conditions, and medications. In addition, specific details of the dermatologic complaints must also be obtained. Finally, the clinician should be knowledgeable about (or know how to find out about) outbreaks of disease that may have been ongoing during an individual's travel or residence in a given area.

EXPOSURE HISTORY: TRAVEL AND AREAS OF RESIDENCE

The travel history (or history of residence in endemic areas) must be thorough in order to elucidate likely exposures to helminths. Specific details may be more readily obtained in recently returned travelers than immigrants, although immigrants are much more likely to be aware of local and endemic diseases (albeit often by local names). Details to be obtained include the exact dates, durations, and locations of travel or residence; purpose of travel; activities or occupations, inquiring specifically about those that would increase exposure to specific helminths (Table 207-3); dietary intake; a history of similar signs and symptoms in other family members or fellow travelers; and the use of preventive measures.

The exact destinations of travel (urban vs. rural), not only the country or countries visited, are important to obtain. Although some diseases may be endemic throughout a world region or area (eTable 207-1.1 in online edition), the prevalence of others may vary greatly, sometimes within a given country. For example, onchocerciasis and loiasis are endemic in West Africa, but generally not in other parts of Africa, and both infections are found only in rural areas, unlike Bancroftian filariasis (*Wuchereria bancrofti*) that is often transmitted in urban centers. The risk of disease may not be present in all areas of a country in which a disease is considered to be endemic; for example, schistosomiasis is found in Brazil, but only in the northeastern region. Duration of travel or residence in an endemic area (and hence duration of exposure) is relevant for some diseases; schistosomiasis can be acquired after a single exposure to infective cercariae in freshwater, whereas filariasis is often acquired only after numerous bites, and therefore is rare among short-term travelers to endemic areas.

The purpose of travel is also correlated with the likelihood of exposure to specific pathogens. Rural and adventure travelers are more likely to be exposed to helminthic infections than are business travelers, travelers whose itineraries are limited to urban areas, and those whose travels are of shorter durations.

Certain activities and occupations will place individuals at greater risks of helminthic infections while abroad (Table 207-3). Examples of common exposures and associated diseases include barefoot walking or walking in open shoes (sandals) (e.g., CLM, strongyloidiasis); freshwater swimming in Africa (e.g., schistosomiasis); and dietary indiscretions such as consumption of salads or undercooked or contaminated meat or fish (e.g., ascariasis, echinococcosis, fascioliasis, gnathostomiasis). Although direct exposure to animals is not a risk factor for helminthic infections, the risk of CLM is greater in areas with a higher prevalence of stray dogs and cats. For those infections that are vector borne, such as filarial infections transmitted by mosquitoes, black flies, and deer flies, the use of preventive measures such as appropriate clothing, insect repellent, and bed nets can reduce the risk of infection.

GENERAL MEDICAL HISTORY

In addition to the travel history, a general medical history should be obtained. Skin findings may be related to underlying medical conditions, or to any associated treatment for these. The differential diagnosis of skin lesions in a returned traveler or immigrant also includes noninfectious disorders such as contact dermatitis (including to jewelry), drug eruptions, and photosensitivity reactions (that may be precipitated by travel-related medications such as doxycycline). A list of prescription and nonprescription medications or supplements should be obtained, in particular those that may have been started recently and/or prescribed abroad, as well as any recent use of topical medications or products.

DERMATOLOGIC HISTORY AND PHYSICAL FINDINGS

The dermatologic history should include details regarding the initial presentation, morphology, and anatomic distribution of skin lesions; the progression and duration of lesions; time of onset relative

TABLE 207-3
Exposures to Helminthic Infections

Exposure or Activity	Disease/Syndrome	Comments
Barefoot walking or walking in open shoes (sandals)	Cutaneous larva migrans Human hookworm (*Ancylostoma duodenalis*, *Necator americanus*) Strongyloidiasis	
Swimming or water exposure	Schistosomiasis (human) Cercarial dermatitis (schistosomiasis, avian)	Freshwater exposure in Africa, Arabian peninsula (*Schistosoma mansoni* and *Schistosoma hematobium*); or South America (*S. mansoni*) Freshwater or saltwater exposure
Dietary indiscretion Contaminated food or water (also via contaminated fingers) Contaminated water Raw or undercooked meat Raw or undercooked seafood, crustaceans, amphibians, reptiles Contaminated plants	 Ascariasis Enterobiasis (pinworm) Toxocariasis Dracunculiasis Sparganosis Cysticercosis (*Taenia solium*) Sparganosis Trichinellosis Gnathostomiasis Paragonimiasis Sparganosis Fascioliasis	 Infected pork Infected rodent meat Infected meat (mainly pork, but other wild and domestic meats) Watercress
Insect bites[a] Mosquito Fly	 Dirofilariasis Lymphatic filariasis (*Brugia* spp., *Wuchereria bancrofti*) Filariasis (*Mansonella* spp.) Loiasis Onchocerciasis	 Use of personal protective measures (insect repellent, bed nets) can be protective
Other Topical poultices	 Sparganosis	 Poultices containing infected amphibian, reptile, or rodent meats

[a]History of bites is not reliable.

to potential exposures; and any associated local and systemic signs and symptoms. Although some manifestations of helminthic infections, such as urticaria or maculopapular eruptions, are nonspecific, the differential diagnosis of helminthic dermatoses can often be narrowed based on the description and morphology of the lesion(s) present. For some diseases such as CLM, skin findings are virtually pathognomonic and the diagnosis can be established by history and careful examination of skin lesions, often without the need for additional investigations.

MORPHOLOGIC CHARACTERISTICS AND DISTRIBUTION OF SKIN LESIONS DUE TO HELMINTHIC DISEASES.

Skin lesions due to helminthic infections can assume a variety of morphologies. The most commonly encountered problem is that of migratory skin lesions. CLM (creeping eruption) is the most common cause of migratory lesions in general. Subcutaneous nodules, papular eruptions, and urticaria and pruritus are also common manifestations of helminthic infections.

Migratory Skin Lesions. Migratory lesions can be caused by multiple helminths. Migratory lesions can be linear (serpiginous) or may be more ill-defined areas of erythema and swelling, and may be painless, painful, or pruritic. Table 207-4 lists the most common

Figure 207-3 Cutaneous larva migrans. (Used with permission from Jay S. Keystone, MD, FRCPC.)

TABLE 207-4
Differential Diagnosis of Migratory Skin Lesions

Helminth	Morphology of Lesion	Description	Most Common Location
Ancylostoma braziliense, Ancylostoma caninum	Serpiginous (CLM)	Typically one to three serpiginous lesions, 3 mm wide and up to 20 cm in length; intensely pruritic, may be vesicobullous; movement up to several cm per day	Feet, buttocks
Ancylostoma duodenale, Necator americanus (human hookworm)	Serpiginous	Pruritic tracks due to larval migration	Feet
Dracunculus medinensis	Localized area of edema or swelling with movement beneath	Moving mass may be seen just before emergence of adult worm through skin	Feet
Fasciola hepatica	Migratory subcutaneous swellings	Erythematous, painful, pruritic subcutaneous nodules may have a migratory component; larval track marks may also be seen	Abdomen, back, extremities
Loa loa	Migratory subcutaneous swelling or serpiginous	Migration of adult worm across conjunctivae or under skin	Skin, eye
Gnathostoma spinigerum	Serpiginous (CLM) Migratory subcutaneous swellings (eosinophilic panniculitis)	Migration of larvae can cause creeping eruption; movement 1 cm/hour Intermittent single or multiple erythematous swellings; may be migratory, pruritic or painful; last 1–4 weeks, with recurrences in different anatomic areas after variable asymptomatic periods	Trunk, upper body Thighs
Paragonimus westermani	Migratory subcutaneous swellings or nodules	Firm migratory swellings or nodules, may be migratory; slightly tender and slightly mobile, up to 6 cm diameter; swellings contain immature flukes	Lower abdomen, inguinal region
Spirometra mansonoides, others (sparganosis)	Migratory subcutaneous swellings	Slow-growing, typically painful swellings that may be migratory; may be pruritic	Abdomen, lower extremities
Strongyloides stercoralis (larva currens)	Serpiginous (larva currens)	Movement at 5–10 cm/hour; intensely pruritic, transient, but recurrent	Buttocks, groin, trunk, thighs

CLM = cutaneous larva migrans.

helminthic causes of migratory lesions, as well as characteristic features of these lesions.

Serpiginous and linear lesions are most commonly due to CLM (most frequently caused by *A. braziliense* and *Ancylostoma caninum*; see also Section "Hookworm-Related Cutaneous Larva Migrans"). Usually one to three (or more) erythematous, serpiginous, and intensely pruritic lesions due to intradermal larval migration are present (Fig. 207-3); bullae and vesicles may also be present (Fig. 207-4). Lesions usually measure 3 mm in width and 15–20 cm in length. Lesions of CLM may rarely be accompanied by severe folliculitis, or may present as papules alone without a linear element (papular larva migrans). Serpiginous skin lesions in *S. stercoralis* infection, a pathognomonic manifestation of strongyloidiasis known as larva currens, typically present as recurrent, transient, and rapidly moving skin lesions (Fig. 207-5). Larval migration may occur at rates of 5–10 cm/hour, and the lesions usually disappear within hours only to recur over subsequent weeks to years. Lesions typically occur on the buttocks and in the perianal region, as larvae exit the

Figure 207-4 Cutaneous larva migrans with vesicular and bullous lesions. (Used with permission from Jay S. Keystone, MD, FRCPC.)

gastrointestinal tract and reinfect the host by penetrating the perianal skin. Linear migratory lesions can also be seen occasionally in human hookworm infection (*Ancylostoma duodenale* and *Necator americanus*) at the site of larval penetration, and in gnathostomiasis (usually relatively slow migration at 1 cm/hour). Linear migratory lesions can also be seen in *Loa loa* infection, and result from movement of the adult worm (not larvae) in tissue, typically under the skin or also across the bulbar conjunctivae (Fig. 207-6).

Figure 207-5 Larva currens in chronic strongyloidiasis. Multiple serpiginous, inflammatory lesions are visible on the buttocks.

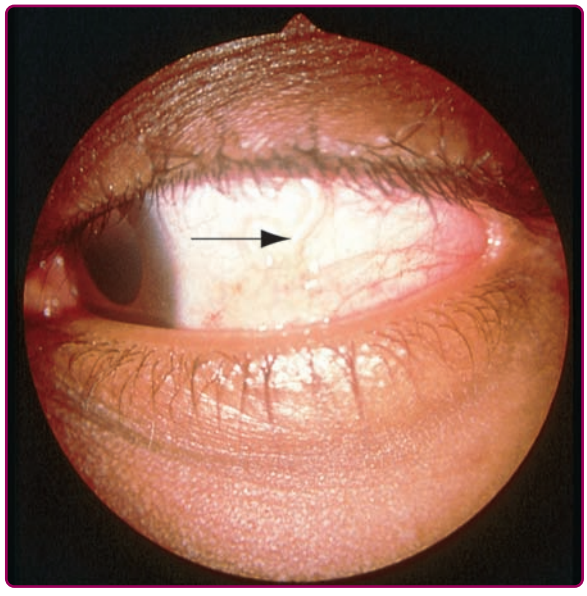

Figure 207-6 Loiasis. Adult worm crossing bulbar conjunctiva of the eye (*arrow*). (Used with permission from Murray Wittner, MD, PhD.)

Migratory subcutaneous swellings and nodules are characteristic of infections due to *Fasciola*, *Gnathostoma*, and *Paragonimus*, and in sparganosis (*Spirometra* species). Lesions may be painful or pruritic. Migratory swelling due to the movement of adult worms is also seen in dracunculiasis, in which movement within a bullous, vesicular, or edematous lesion on the foot is often noted prior to eruption of the skin lesion and egress of the adult worm (Fig. 207-7). Since the implementation of global eradication and drinking water monitoring

TABLE 207-5
Differential Diagnosis of Nodular Skin and Subcutaneous Lesions

Helminth	Description of Nodular Lesion	Most Common Location
Brugia malayi	Hydrocele/scrotal mass due to lymphatic obstruction.	Scrotum
Dirofilaria spp.	Single erythematous, well-defined firm nodule or mass, usually 1–5 cm diameter; usually asymptomatic but may be tender; rarely may be migratory (usually not).	Head and neck, breasts, extremities, scrotum
Dracunculus medinensis	Edematous lesion/mass may be seen just before emergence of adult worm through skin; movement underneath lesion due to movement of adult worm	Feet
Echinococcus spp.	Firm subcutaneous (or muscular) nodules or masses; usually single but may be multiple; may feel fluctuant; nontender. Rarely with fistulization and inflammation of skin (*Echinococcus multilocularis*). True cutaneous lesions are rare.	Abdomen
Gnathostoma spinigerum	Intermittent single or multiple erythematous swellings; may be migratory, pruritic or painful; last 1–4 weeks, with recurrences in different anatomic areas after variable asymptomatic periods.	Trunk, upper body, thighs
Loa loa	Calabar swelling—localized angioedema, 5–20 cm diameter, usually lasting 2–4 days but recurrent; due to migration of adult worms.	Eyelid, upper extremities, periarticular regions (especially knee, wrist)
Mansonella perstans	Calabar swellings—localized swellings lasting 1–4 days, recurrent.	Face, upper extremities (especially forearms), hands
Onchocerca volvulus	Well-defined, fixed painless nodules containing adult worms in deep dermis and subcutaneous tissue.	Over bony prominences including skull (South America), ribs, iliac crest (Africa), others
Paragonimus westermani	Firm swellings or nodules, may be migratory; slightly tender and slightly mobile, up to 6 cm diameter; swellings contain immature flukes.	Lower abdomen, inguinal region
Spirometra mansonoides, others (sparganosis)	Slow-growing, typically painful swellings that may be migratory; may be pruritic.	Abdomen, lower extremities
Taenia multiceps, others (coenurosis)	Solitary subcutaneous (or muscular) nodule, usually 2–6 cm diameter; painless	Trunk (especially intercostal regions), anterior abdominal wall; head, neck, extremities less commonly
Taenia solium (cysticercosis)	Painless, fixed, well-circumscribed rubbery subcutaneous nodules in 50% of patients with cysticercosis; may be single or multiple; average size 2 cm in diameter.	Trunk, extremities
Wuchereria bancrofti	Hydrocele/scrotal mass due to lymphatic obstruction.	Scrotum

programs in endemic countries, cases of dracunculiasis have decreased dramatically and the disease has almost been eliminated.[13]

Subcutaneous Nodules and Masses. Subcutaneous and soft tissue masses may have variable characteristics, including overlying erythema, pain or tenderness, and pruritus. They may be single or multiple, and fixed or mobile. The more common etiologies of nodular lesions are listed in Table 207-5.

Solitary nodules or masses are found in echinococcosis, filariasis due to *Brugia malayi* and *W. bancrofti* (both of which may cause scrotal masses in men, due to lymphatic obstruction), dirofilariasis, and coenurosis. *Multiple nodules* are typical of cysticercosis (*Taenia solium* infection), in which small, painless subcutaneous or intramuscular nodules are present, although single nodules can also occur. Subcutaneous cysticercosis, although reported in over 50% of infected individuals in older case series,[14] currently occurs in less than 10% of cases. Most other helminths that manifest as subcutaneous nodules or masses may present with single or multiple lesions. *Painless nodules* are most characteristic of coenurosis, cysticercosis, dirofilariasis, echinococcosis, and onchocerciasis. *Painful nodules* are seen in paragonimiasis and sparganosis. Transient painful lesions that resolve and subsequently recur in different anatomic areas are characteristic of *Gnathostoma* infection and loiasis. *Fixed lesions* are typical of cysticercosis, echinococcosis, and onchocerciasis.

Papular and Macular Lesions. Papules and macules occur in relatively few helminthic infections

TABLE 207-6
Differential Diagnosis of Papular and Macular Lesions

Helminth	Description	Most Common Location
Ancylostoma braziliense, caninum (CLM)	Pruritic erythematous papule(s) within days of larval penetration; may be vesicular; also papular larva migrans.	Feet, buttocks
Ancylostoma duodenale, Necator americanus (human hookworm)	Ground itch: in sensitized individuals, pruritic papular lesions at sites of larval entry; may be vesicular.	Feet, hands
Mansonella perstans, streptocerca	Multiple pruritic papules; hypopigmented and hyperpigmented macules and lichenification may be present.	Upper chest (M. streptocerca)
Onchocerca volvulus	Acute: multiple pruritic papules, may become vesicular or pustular; may be erythematous and edema may be present. Chronic: intensely pruritic, flat papules (3–9 mm) or macules, may be hyperpigmented or lichenified.	Face, trunk, extremities Shoulders, buttocks, waist, extremities
Schistosoma species (avian)	Erythematous papular or maculopapular lesions, may be vesicular or urticarial; intensely premitotic; onset within 24 hours of saltwater or freshwater exposure, lasts 1–3 weeks.	Any surface exposed to water
Schistosoma species (human)	Acute: erythematous papular and urticarial lesions in previously sensitized individuals; onset within hours of freshwater exposure, lasting 1 week. Chronic: bilharziasis cutanea tarda; slightly pigmented 2–4 mm firm, pruritic, oval papules or papulonodular lesions, may be verrucous or polypoid; may appear in crops; due to granulomatous reaction to eggs in skin.	Any surface exposed to water Trunk, especially periumbilical region; buttocks, genitalia

CLM = cutaneous larva migrans.

(Table 207-6). Papular lesions may occur at sites of skin penetration by infective larvae or cercariae in CLM and schistosomiasis. In CLM, papules are typically in the feet or buttocks, similar to the distribution of migratory lesions. In schistosomiasis, exposure to infected freshwater (for avian or human schistosomes) or salt water (avian schistosomes) may cause pruritus, which is followed rapidly by a papular eruption in previously sensitized individuals. Chronic papular lesions (bilharziasis cutanea tarda) may be present in chronic schistosomiasis. Papular lesions may also be manifestations of acute or chronic infection with *O. volvulus*, and have been reported in disseminated and chronic strongyloidiasis.

Urticaria and Pruritus. *Pruritus* (Table 207-7) may be present in the absence of skin findings, either as a primary symptom of infection (e.g., filariasis due to *Mansonella perstans*), or before the onset of skin lesions (e.g., schistosomiasis). Pruritus is a common feature of most helminthic infections, with the noteworthy exceptions of lymphatic filariasis (e.g., due to *Brugia* species and *W. bancrofti*) and tapeworm infections. *Pruritus ani* is characteristic of strongyloidiasis and enterobiasis (pinworm infection).

Urticaria are often present in the acute phase of infection, during which larvae or other immature forms actively invade human tissues. Helminths that infect humans by penetration of skin may cause a local urticarial rash at the sites of penetration. Migration of immature forms in the circulation may cause a generalized hypersensitivity reaction; urticaria is common during this phase of infection by many helminths (Table 207-7).

Localized Edema. Although edema or swelling may be an associated feature of many helminthic skin lesions, localized edema is highly suggestive of the presence of certain infections.

Eyelid edema in particular may be seen in gnathostomiasis and onchocerciasis (Calabar swelling), and violaceous periorbital edema is characteristic of trichinosis. *Limb edema* is highly suggestive of lymphatic filariasis (due to *Brugia* species and *W. bancrofti*). Rarely, limb edema ("gros bras camerounais") may occur with acute onchocerciasis, usually in conjunction with

TABLE 207-7
Helminthic Infections Causing Urticaria and Pruritus

Helminth	Comments
Nematodes (Roundworms)	
Ancylostoma braziliense, *Ancylostoma caninum*	Pruritus and urticaria after skin penetration and during larval migration
Ancylostoma duodenale, *Necator americanus* (human hookworm)	Pruritus and urticaria after skin penetration and during larval migration
Ascaris lumbricoides	Pruritus and urticaria during larval migration (with Loeffler's syndrome)
Enterobius vermicularis	Pruritus ani
Filariae	
Loa loa	Pruritus and urticaria
Mansonella spp. (*ozzardi*, *perstans*, *streptocerca*)	Pruritus occurs early, may be only symptom
Onchocerca volvulus	Pruritus and urticaria in acute or chronic disease
Gnathostoma spinigerum, others	Pruritus and urticaria during larval migration
Strongyloides stercoralis	Pruritus and urticaria after skin penetration and during larval migration, including with chronic infection; pruritus ani
Toxocara spp. (*canis*, *cati*)	Pruritus and urticaria during larval migration
Trichinella spiralis	Pruritus and urticaria during larval migration
Trematodes (Flukes)	
Fasciola hepatica	Urticaria during migration of adult flukes
Paragonimus westermani	Urticaria during larval migration
Schistosoma spp. (human and avian)	Transient urticaria with pruritus within 24 hours of exposure to cercariae; urticaria with Katayama fever (acute schistosomiasis)

pruritus, and typically only after exposures in travelers and expatriates visiting West and Central Africa.[15,16]

Changes In Skin Texture or Pigmentation. *Hypopigmentation* of skin can be a feature of chronic infection caused by *O. volvulus* ("leopard skin"), *M. perstans*, and *Mansonella streptocerca*. Hypopigmented macules are the most common cutaneous findings in streptocerciasis.[17] In onchocerciasis, depigmentation is characterized by perifollicular pigmentation within macular or minimally depressed areas, with yellow-brown hypopigmentation, and is particularly noticeable in dark-skinned individuals (see Section "Onchocerciasis" in Chapter 75). *Hyperpigmentation* can also occur with mansonellosis due to *M. streptocerca*, as well as in chronic schistosomiasis. *Lichenification* in the context of chronic pruritus is a feature of onchocerciasis ("sowda" in Arabic), and to a lesser extent mansonellosis; hyperpigmented plaques eventually coalesce and become lichenified over time, particularly over the lower extremities and in young adults in Yemen and Sudan. *Verrucous lesions* may be seen in chronic schistosomiasis (bilharziasis cutanea tarda). *Ichthyosis* may also be present in chronic onchocerciasis.

Other Cutaneous Manifestations. *Petechiae* may be present with trichinellosis and are frequently seen in disseminated strongyloidiasis, in which they are particularly prominent on the trunk. *Vesicles or bullae* may be seen at the site of larval skin penetration in up to 15% of patients with CLM, in human hookworm infection, and occasionally in dracunculiasis, onchocerciasis, and strongyloidiasis. *Ulcers* are uncommon findings in most helminthiases with the exception of dracunculiasis, in which multiple ulcers are common. Ulcerative genital lesions, particularly in women, may occasionally be present in schistosomiasis and tend to occur more often with acute disease (e.g., in travelers).[18]

EN is rare in helminthic infections, but has been described as a clinical finding with hookworm infection,[19] and in visceral larva migrans,[20] sparganosis,[21] and lymphatic filariasis. It has also been reported in one patient in conjunction with *A. lumbricoides* infection,[22] although EN in this patient may also have been due to concomitant *Chlamydia pneumoniae* pneumonia. *Erythema multiforme* has been reported in CLM.[23] *Eosinophilic panniculitis* has been documented in gnathostomiasis[24] and toxocariasis.[25,26] *Eosinophilic cellulitis* (Well's syndrome) may occur in ascariasis,[27] onchocerciasis, and toxocariasis.[28] *Eosinophilic folliculitis* due to helminths has rarely been described in CLM and in toxocariasis.[29] *Exfoliative dermatitis* of the affected limb may occur during the resolution phase of *W. bancrofti* infection.

INTERVAL BETWEEN EXPOSURE AND ONSET OF SYMPTOMS. The time of onset of skin disease (and other key symptoms) relative to travel and likely exposures can be helpful in establishing a diagnosis (Table 207-8). Some infections such as acute schistosomiasis or CLM become evident within hours to days of exposure, whereas others may not present until months to years after infection.

PROGRESSION AND DURATION OF SKIN LESIONS. Skin lesions due to helminthic infections can persist for variable durations (Table 207-8). For those helminths that cause infection by penetration of skin, local dermatologic findings last only for a short time during infection by human helminths, but may persist longer with animal helminths (e.g., CLM). During the chronic phase of infection, however, the duration of cutaneous manifestations varies depending on the infecting helminth. For infections in which skin findings are the result of inflammatory reactions to larvae or eggs in tissues (e.g., onchocerciasis and schistosomiasis, respectively), clinical manifestations can persist for the lifespan of the adult worms, which in some cases may be years. Even with appropriate therapy for chronic infections, chronic skin changes may not resolve completely.

TABLE 207-8
Interval from Exposure to Onset, and Duration, of Cutaneous Symptoms

Species	Typical Interval Between Exposure and Onset of Cutaneous Symptoms	Typical Duration of Symptoms
Nematodes (Roundworms)		
Ancylostoma braziliense, Ancylostoma caninum	Usually 1–5 days, typically within one month	2–14 weeks, rarely longer (up to 2 years)
Ancylostoma duodenale, Necator americanus (human hookworm)	Ground itch—1–2 days Urticaria—1–3 weeks	1–2 weeks
Ascaris lumbricoides	Urticaria—10–14 days	Several weeks
Dirofilaria spp.	Subcutaneous nodules— several months	
Dracunculus medinensis	Edema, vesicle or bulla formation, ulceration with worm protrusion—1 year	Several weeks
Enterobius vermicularis	Pruritus ani—weeks to months	30–45 days (self-limited), or until treated
Filariae		
Brugia spp. (*malayi, timori*)	Hydrocele—years	Years
Loa loa	Calabar swelling, urticaria: >6 months to years Adult worm migration—years	Several days to weeks Years
Mansonella spp. (*ozzardi, perstans, streptocerca*)	Pruritus, dermatitis, hypopigmentation—unknown	Years
Onchocerca volvulus	Onchodermatitis—months to years Onchocercoma—years	Years Years
Wuchereria bancrofti	Hydrocele—years	Years
Gnathostoma spinigerum, others	Creeping eruption—1–2 days Migratory masses—3–4 weeks	Up to 3 months 1–2 weeks, but recur for years
Strongyloides stercoralis	Larva currens—months to years Chronic urticaria, larva currens—years Petechiae, purpura (in disseminated disease)—variable	Hours, but recur for years Years —
Toxocara spp. (*canis, cati*)	Urticaria—weeks to months	Years
Trichinella spiralis	Eyelid edema, petechiae—1–3 weeks	2–3 weeks
Trematodes (Flukes)		
Fasciola hepatica	Urticaria—6–12 weeks (with abdominal pain, fever, weight loss)	Several weeks to months
Paragonimus westermani	Urticaria—2 days to 2 weeks Subcutaneous nodules—2–3 weeks	Several weeks Years
Schistosoma spp. (human and avian)	Swimmer's itch: <24 hours Urticaria—2 weeks to months Bilharziasis cutanea tarda— years	Days to 3 weeks 2–10 weeks Years
Cestodes (Tapeworms)		
Echinococcus spp. (*granulosis, multilocularis*)	Years	Years
Spirometra mansonoides, others (sparganosis)	20 days to 3 years	Years
Taenia multiceps, others (coenurosis)	Months to years	Years
Taenia solium (cysticercosis)	Variable—months to years	Years

COMPLICATIONS OF CUTANEOUS HELMINTHIC INFECTIONS

Secondary complications including excoriation and secondary superinfection are not uncommon, especially when pruritic lesions are present. Skin changes such as lichenification and pigment changes, as noted above, may be persistent. Other significant complications of cutaneous helminthic diseases are addressed in the discussion of specific helminths.

ASSOCIATED SYMPTOMS AND RELATED PHYSICAL FINDINGS

Apart from the skin, symptoms of helminthic infections tend to most frequently involve the respiratory, gastrointestinal, and neurological systems, and the eye. Disease may also occur in many other tissues due to aberrant migration of larvae and adult worms.

Because the skin lesions of many helminthic infections tend to occur in acute (larval) infection, and

nondermatologic symptoms often result from the presence of adult helminths or their products of reproduction, it is important to appreciate that skin findings often precede other manifestations of disease. However, dermatologic and nondermatologic symptoms may coexist in some acute infections, as well as in chronic infections.

PULMONARY DISEASE. Helminthic diseases in which pulmonary symptoms and skin disease may be present are listed in eTable 207-8.1 in online edition. *Loeffler's syndrome*, a hypersensitivity syndrome consisting of dyspnea, wheezing, cough, and fever, typically results from larval migration through lung tissue and may be seen in infection caused by human hookworms, *Ascaris*, and *Strongyloides*. Because these symptoms are due to larval migration, they begin shortly after infection and may occur coincidentally with an urticarial rash. Loeffler's syndrome typically lasts for 1–2 weeks.

Other pulmonary symptoms are generally not simultaneous with dermatologic symptoms, occurring after larvae have matured into adult forms. *Hemoptysis* is uncommon; among helminthic infections it is most frequently a feature of paragonimiasis, but can also be a symptom of echinococcal disease and disseminated strongyloidiasis. *Pleural effusions* also occur rarely, and in helminthic infections are more likely to be eosinophilic. The most common parasitic etiology is *Paragonimus*, but effusions can also be caused by a variety of other helminths (eTable 207-8.1 in online edition).[30–32]

GASTROINTESTINAL DISEASE. Helminthic infections causing gastrointestinal symptoms are listed in eTable 207-8.2 in online edition. *Abdominal pain* is most commonly seen in ascariasis and human hookworm infection, after dermatologic manifestations have resolved, and in strongyloidiasis. Abdominal pain in strongyloidiasis is typically epigastric in location. Because *S. stercoralis* can complete its entire life cycle within the human host, larvae and adult worms may coexist simultaneously, and thus abdominal symptoms may be coincident with larva currens and pruritus ani. Right upper quadrant abdominal pain may also be a manifestation of acute fascioliasis, caused by larval penetration of the hepatic capsule; urticaria may also be present during this phase. *Diarrhea* can be a symptom of strongyloidiasis, and rarely of schistosomiasis.[33] *Hepatitis* may be seen in acute fascioliasis. *Liver masses* or abdominal masses may be the presenting symptom of echinococcosis. *Hepatomegaly* is one of the classic findings of visceral larva migrans (toxocariasis), typically occurring in children and usually in conjunction with fever, respiratory symptoms (wheezing), and occasionally urticaria. Hepatomegaly has also been reported as a finding of several other helminthiases. *Granulomatous hepatitis* may also cause hepatomegaly, and is most commonly encountered in schistosomiasis (due to granuloma formation around eggs in the periportal circulation), but can also be a feature of ascariasis (eggs), strongyloidiasis (larvae), and toxocariasis (larvae). *Biliary disease* may be due to either occlusion of the biliary tract by adult worms or flukes (e.g., ascariasis, fascioliasis, strongyloidiasis) or due to compression of the biliary tract by a mass lesion (e.g., echinococcosis). *Hepatic fibrosis* can be a complication of chronic schistosomiasis.

NEUROLOGIC DISEASE. Helminthic infections most commonly affecting the central nervous system include neurocysticercosis and strongyloidiasis. *Seizures*, typically focal but sometimes generalized, are the most common presentation of neurocysticercosis. Neurocysticercosis should be considered in the presence of subcutaneous cysticercosis. The clinical presentation of neurocysticercosis is determined by the number, size, and location of intracranial lesions, as well as the viability of cysts (dying cysts produce more inflammation and are more likely to be associated with seizures). Globally, neurocysticercosis is among the most common causes of seizure disorders. Seizures may also occur with infection due to *Schistosoma* species, *Paragonimus*, and in sparganosis. *Meningitis* can be seen in strongyloidiasis. *S. stercoralis* larvae may be visualized in cerebrospinal fluid, but more commonly meningitis is a result of Gram-negative bacteremia, due to Gram-negative enteric organisms that are carried across the bowel mucosa during larval penetration in disseminated disease; abdominal petechiae or purpura are often present. *Eosinophilic meningitis or meningoencephalitis* may be a feature of cysticercosis, gnathostomiasis, paragonimiasis, schistosomiasis, toxocariasis, and less commonly strongyloidiasis, among others.[34] *Mass lesions or cysts* can be caused by *Echinococcus* spp., *Paragonimus, Taenia* spp. causing coenurosis, and *Toxocara*. In schistosomiasis, intracranial infection is most commonly associated with *Schistosoma japonicum* infection and may result from the development of granulomas around ectopic eggs. Other central nervous system manifestations of helminthic infections, including brain abscesses, transverse myelitis and myelopathy, and intracranial hemorrhage, may occasionally be seen.

OCULAR DISEASE. While ocular involvement is most frequently associated with infections due to *Loa loa* and *O. volvulus* (river blindness), disease involving the conjunctiva, sclera, and all chambers of the eye can be occasional features of most helminthic infections. Onchocerciasis is one of the major causes of blindness worldwide. Ocular symptoms and findings are often related to the presence of larvae or microfilariae migrating through and causing inflammatory reactions in various chambers of the eye and the retina. Onchodermatitis is common in chronic infection, and skin findings and eye disease may be present simultaneously. Ocular disease is also one of the most frequent presentations of sparganosis; in one case series in Thailand,[35] ocular disease accounted for half of all cases.

Conjunctivitis is the typical ocular manifestation of gnathostomiasis and sparganosis, but has also been reported in a variety of other infections. *Keratitis* is most commonly present in onchocerciasis and coenurosis. *Uveitis* is characteristic of onchocerciasis and schistosomiasis. *Retinitis or chorioretinitis* may be present in onchocerciasis. *Migration of adult worms* through the eye may be seen in loiasis and dirofilariasis, and

less commonly fascioliasis and gnathostomiasis, and gives rise to a foreign body sensation in the eye. *Granulomatous nodules* in the eye or conjunctivae may be present in schistosomiasis and *M. perstans* infection.[36] *Eyelid swelling* (Calabar swelling) may be due to onchocerciasis, and to filariasis caused by *M. perstans.*

LYMPHADENOPATHY. Lymphadenopathy is an uncommon finding in helminthic infections, with the exception of filarial infections. *Regional lymphadenopathy* can be present with lymphatic filariasis (due to infection with *Brugia* spp. and *W. bancrofti*), as well in loiasis, mansonellosis due to *M. streptocerca*, and onchocerciasis. *Generalized lymphadenopathy* may be present in lymphatic filariasis, and in acute schistosomiasis (Katayama fever).

OTHER SYMPTOMS. *Fever* and urticaria can be features of Loeffler's syndrome (eTable 207-8.1 in online edition), which may be the initial manifestation of infection due to *A. lumbricoides*, human hookworm, *S. stercoralis*, and in toxocariasis. Fever in acute trichinellosis usually occurs in conjunction with other symptoms including myalgias. Fever is also a finding in acute schistosomiasis (Katayama fever) and may also be present in other helminthiases, typically during larval migration. *Gram-negative sepsis* may occur in disseminated strongyloidiasis (see Sections "Neurologic Disease and Strongyloidiasis").

LABORATORY EVALUATION

Results of routine blood tests, including eosinophilia, are neither sensitive nor specific for diagnosing helminthic infections. While most hematological and biochemical tests are nonspecific, the presence of eosinophilia can be suggestive of specific diseases when combined with clinical findings and/or the exposure history, and should prompt additional investigations.[37,38] Diagnosis of helminthic infections may also be aided by results of ancillary investigations (e.g., chest radiography, abdominal imaging).

EOSINOPHILIA. Eosinophilia, defined as an absolute eosinophil count of greater than 500 eosinophils/mm^3, should prompt appropriate investigations for helminthic infections as noted above. Eosinophilia is not typical of infections due to most pathogens other than helminths; helminth antigens are effective stimuli for inducing eosinophilia. Levels of eosinophils in the blood can be affected by host factors including the response to other bacterial, viral or fungal coinfections (which lower eosinophil counts), the use of systemic steroids (which lower eosinophil counts), and an immunosuppressed state. In helminthic infection, eosinophil counts vary according to the stage of infection and the infecting helminth. Eosinophilia is not a feature of infection due to intestinal lumen dwelling helminths, except during the larval migration phase for those helminths in which this occurs; in contrast, helminthic infections in which adults, larvae, or eggs persist in tissues are typically associated with eosinophilia. Eosinophil counts are typically normal during the penetration phase and reach their highest levels (often markedly elevated) during the invasive phase of the cycle. Eosinophilia often accompanies the urticarial rash during the invasive stage of infection; thereafter, the eosinophil count often decreases slowly and may fluctuate more or less above the normal value during the chronic phase of infection. A transient hypereosinophilia may be also observed approximately 10 days after the start of effective antihelminthic treatment, and eosinophilia may persist for 1–2 months after successful helminth eradication.

Helminths typically causing eosinophilia are listed in Table 207-9. Severe or high-grade eosinophilia (an eosinophil count of >3,000/mm^3) is suggestive of infection caused by relatively few of these parasites (Table 207-9).

ADDITIONAL LABORATORY TESTS. Other laboratory tests may be abnormal but may not aid with establishing a specific diagnosis. Other than leukocytosis, which may reflect only the presence of eosinophilia, hematologic studies obtained when skin lesions are present are unlikely to be helpful. Evidence of disseminated intravascular coagulation may be present in disseminated strongyloidiasis. Iron deficiency anemia due to chronic low-grade intestinal bleeding is a feature of established hookworm infection but occurs well after the resolution of cutaneous disease.

Biochemical testing may reveal abnormal liver function tests and enzymes in acute fascioliasis and toxocariasis, when urticaria may be present. Granulomatous hepatitis may be suggested by an obstructive picture, with a disproportionately elevated alkaline phosphatase. Most biochemical tests are otherwise

TABLE 207-9
Helminthic Infections that May Be Associated with Eosinophilia

Disease	Comments
Ascariasis[a]	Marked eosinophilia in early infection
Cysticercosis	
Dirofilariasis	
Dracunculiasis	
Fascioliasis[a]	Marked eosinophilia in early infection
Filariasis[a]	Eosinophilia may be marked especially in loiasis and with pulmonary symptoms
Gnathostomiasis[a]	
Hookworm infection (CLM)[a]	Can be marked during larval migration
Paragonimiasis[a]	Marked eosinophilia in early infection
Schistosomiasis[a]	Especially during early infection (Katayama fever)
Sparganosis	
Strongyloidiasis[a]	Eosinophilia may be moderate in chronic infection
Toxocariasis (VLM)[a]	

[a]Marked eosinophilia (eosinophil count >3,000/mm^3) may be present.
CLM = cutaneous larva migrans; VLM = visceral larva migrans.

nonspecific and are of limited use in determining the correct diagnosis.

RADIOLOGIC INVESTIGATIONS. Symptomatic patients with Loeffler's syndrome and acute schistosomiasis will typically have diffuse patchy infiltrates on chest radiographs; urticaria may be present at this time. Radiologic findings consistent with acute respiratory distress syndrome may be present in disseminated strongyloidiasis. Chest X-rays may also be abnormal in paragonimiasis (cystic lesions, pleural effusion). Pleural effusions may be present in infection due to other helminths as well (eTable 207-8.1 in online edition). A solitary pulmonary nodule may be noted in dirofilariasis.

Abdominal imaging [ultrasound, computed tomography (CT), or magnetic resonance imaging (MRI)] should be directed by abdominal symptoms and is suggestive of a diagnosis in relatively few helminthic infections. Septated hepatic cysts are characteristic of echinococcosis, and hepatic masses or nodules (hypodense lesions up to 10 mm in size) may be visualized on ultrasound or CT scan in fascioliasis. Tracts or tunnels representing migration of immature flukes through the liver may also be noted in fascioliasis.[39,40]

Imaging studies of the central nervous system are diagnostic in neurocysticercosis, in which CT or MRI usually reveals parenchymal cysts and occasionally intraventricular cysts.

DIAGNOSIS OF HELMINTH INFECTIONS

The definitive diagnosis of most helminthic infections rests on identification of one or more of the various stages of the helminth (e.g., larvae, eggs, adult worms) in tissue specimens, blood, or excretions (stool or urine). Occasionally adult worms may be observed during medical procedures (e.g., endoscopy, or during surgery). In many helminthic infections causing skin disease, however, cutaneous findings occur during the larval migration phase, and hence precede the presence of adult worms and the production of eggs or larvae. The diagnosis of a helminthic infection is therefore often difficult during the penetration and acute phase of the disease; diagnosis may be suspected because of associated epidemiologic and clinical findings. In chronic infection, the diagnosis can be established based on the identification of parasite eggs or larvae, or occasionally adult worms, but the sensitivity of stool examination can also vary depending on the parasite.

Serologic assays are available for many helminthic infections, but vary greatly in their sensitivity and specificity; their utility is also limited by cross-reactivity of tests among the various helminths. Another significant limitation to serologic testing relates to the delayed appearance of antibodies after acute infection. Although antibody production typically begins during the invasive (acute) phase of disease, when skin lesions are clinically apparent, titers may be negative at this time. Serologic tests may need to be repeated several weeks later, after resolution of cutaneous findings; an increase in titers (seroconversion) retrospectively supports or establishes the clinical diagnosis. Similarly, positive antibody titers may reflect prior infection but do not necessarily imply active or acute disease, although a decrease in antibody titer may be seen following appropriate therapy in some infections, notably strongyloidiasis.

Additional diagnostic tests may include pathologic examination of tissue specimens or blood (for microfilariae), microscopic examination of other specimens (e.g., bronchoscopy specimens in disseminated strongyloidiasis), or molecular testing. Diagnostic tests for helminthic infections are summarized in eTable 207-9.1 in online edition.

TREATMENT

Recommended and alternate therapies for treatment for helminthic infections causing cutaneous findings can be found in recent reviews and guidelines,[41,42] and in eTable 207-9.2 in online edition.

SPECIFIC HELMINTHIC DISEASES OF MAJOR IMPORTANCE

Sections that follow below describe key features of the most common and important helminthic infections. CLM syndrome and enterobiasis (pinworm infection) are encountered relatively frequently by clinicians in developed countries. Strongyloidiasis, although not as commonly seen, must be considered in the appropriate clinical context; failure to diagnose and treat the infection may have significant clinical consequences for immunocompromised patients in particular, in whom disseminated strongyloidiasis carries a significant mortality risk. For these reasons, these three infections will be described below. An outline of the other helminthic infections that may present with dermatologic findings is available online.

CUTANEOUS LARVA MIGRANS SYNDROME

The terms CLM and creeping eruption are often used interchangeably when referring to disease caused by animal hookworms. Technically, however, CLM refers to a syndrome in which the larvae of any animal nematode infect humans AND in which the infected human is a dead-end host. These nematodes include animal hookworms, *Gnathostoma* species, and agents of zoonotic filariases including *Spirulina* X,[43] *Pelodera strongyloides*, and zoonotic *Strongyloides* species. By definition, CLM syndrome does NOT include diseases in which creeping eruption is due to: (1) nonlarval forms of parasites (e.g., dracunculiasis, loiasis); (2) larval forms of human nematodes such as *S. stercoralis* (larva currens); or (3) larval forms of trematodes such as *Fasciola gigantica*. Creeping eruption refers to the clinical finding (sign) of a migratory serpiginous lesion but does not denote the etiology of the lesion.

Clinically, the hallmark of CLM is a creeping eruption. The different helminthic diseases causing creeping eruption can often be distinguished based on the epidemiologic and exposure history, the characteristics of the cutaneous trail(s) (location, number, width and length, rate of movement) (Table 207-4), and the duration of symptoms (Table 207-8), in addition to other clinical and laboratory findings. The correct diagnosis is required for appropriate treatment.

HOOKWORM-RELATED CUTANEOUS LARVA MIGRANS. Hookworm-related (Hr) CLM (creeping verminous dermatitis, sandworm eruption, plumber's itch, duck hunter's itch) is most commonly caused by animal hookworms, and in particular *A. braziliense*. Other skin-penetrating hookworm larvae that produce similar disease include *A. caninum, Uncinaria stenocephala* (hookworm of European dogs), and *Bunostomum phlebotomum* (hookworm of cattle). *A. caninum* causes eosinophilic enteritis as well as cutaneous disease. Cats and dogs are hosts for *Ancylostoma ceylanicum* and *A. caninum*.

HrCLM is widely distributed but is most commonly found in tropical and subtropical areas, especially the Southeastern United States, Caribbean, Africa, Central and South America, India, and Southeast Asia. Contact with sand or soil contaminated with animal feces is required for infection to occur; infection can be prevented by avoiding skin contact with fecally contaminated soil. Larvae penetrate human skin and migrate up to several centimeters a day, usually between the stratum germinativum and stratum corneum. This induces a localized eosinophilic inflammatory reaction. Most larvae are unable to undergo further development or invade deeper tissues, and die after days to months.

Typical skin lesions appear 1–5 days after exposure. The characteristic lesion of HrCLM is an erythematous, raised, and vesicular, linear, or serpentine cutaneous trail (Fig. 207-3).[44] Vesicular or bullous lesions may be seen at the site of larval skin penetration in up to 15% of patients with CLM (Fig. 207-4).[7,45] Lesions are approximately 3 mm wide and may reach 15–20 cm in length. They can be single or multiple, are intensely pruritic, and may be painful. The hookworm larvae advance a few millimeters to a few centimeters daily. The most common anatomic sites (usually 3–4 cm from the penetration site) include the feet (Fig. 207-3) and buttocks (Fig. 207-8), although other sites may be affected. Excoriation and impetiginization are uncommon (10% of cases). Skin lesions usually last between 2 and 8 weeks, but have been reported to last for up to 2 years. Systemic signs and symptoms (wheezing, dry cough, urticaria) have been reported in some patients.[46]

A less frequent but well reported clinical presentation is that of hookworm folliculitis, consisting of 20–100 eosinophilic follicular papules and pustules confined to a particular area of the body, usually the buttocks.[47–49] Patients with folliculitis usually also have creeping eruption. Papular lesions without CLM (papular larva migrans) are a less common presentation.[50] Other cutaneous signs related to the subcutaneous migration of helminth larvae have been occasionally described, such as urticaria and panniculitis.[26]

Figure 207-8 Cutaneous larva migrans of the buttocks. (Used with permission from Jay S. Keystone, MD, FRCPC.)

The diagnosis of HrCLM is based on clinical findings. Hookworm folliculitis can also be diagnosed clinically when creeping eruption is also present; if not, skin biopsy may be required. Histopathologic findings include larvae trapped within the follicular canal, the stratum corneum, or the dermis, together with an inflammatory eosinophilic infiltrate.[47] Skin scrapings in patients with folliculitis may reveal live and dead larvae when examined by light microscopy with mineral oil.

Both albendazole (400 mg po daily for 3 days) and ivermectin (200 µg/kg daily for 1 or 2 days) are effective therapies for HrCLM.[51] Treatment of hookworm folliculitis may require repeated treatments. Topical therapy with thiabendazole or 10% albendazole may also be used. Because larvae have usually migrated beyond the end of the visible skin lesion and their location cannot be reliably determined, surgical excision or cryotherapy are not recommended.

ENTEROBIASIS (PINWORM INFECTION)

Enterobiasis (threadworm, pinworm or seatworm infection; oxyuriasis) is caused by *E. vermicularis*. It is among the most widely distributed helminthic infections and is found worldwide. Transmission is by the fecal-oral route; infection results from ingestion of *E. vermicularis* eggs (e.g., by contact with contaminated fomites or via contaminated fingers) and rarely by inhalation and ingestion of aerosolized eggs in dust. The highest rates of infection are among children. Infection can be prevented by treatment of infected cases and good personal hygiene.

Nocturnal anal and perianal pruritus is the primary clinical feature. The worm may be seen around the anus. The skin may become impetiginized, and cellulitis may occur as a complication. Women may rarely develop vulvovaginitis; a nodular lesion of the vulva has also been described.[52] Nondermatologic extraintestinal manifestations are rare but have been reported. Epidemiologically, enterobiasis is often associated with an intestinal protozoan, *Dientamoeba fragilis*, which may produce gastrointestinal upset. The differential diagnosis includes strongyloidiasis, atopic dermatitis, contact dermatitis, and neurodermatitis.

The diagnosis is established by identification of *E. vermicularis* eggs in the perianal area, most effectively by the sticky tape method. A piece of tape, sticky side out, can be attached to a wooden tongue depressor and firmly pressed against the perianal skin immediately on waking in the morning, before defecation or bathing. The tape is removed and placed sticky side down on a slide, and examined under a microscope. Sensitivity of this method is 70% with three specimens and increases to almost 100% with seven specimens. Eggs are found in stool in only 10%–15% of infections. Occasionally, the adult worm (white, up to 4 mm in length) is found in the perianal area, vulva, vagina, or underclothes. When ectopic sites are involved, the parasite may be identified in tissue sections.

Enterobiasis is self-limited if reinfection does not occur. Treatment with one dose of albendazole 400 mg, mebendazole 100 mg, or pyrantel pamoate 11 mg/kg, is effective. Treatment of household members is also recommended as household transmission is common. Treatment should be repeated once, 2 weeks after the first course of therapy, since medications are relatively ineffective against developing larvae and newly ingested eggs. Specific personal hygiene measures are also important for eradication of infection.

STRONGYLOIDIASIS

Strongyloidiasis is caused by *S. stercoralis*, which is endemic to Africa, Asia, Southeast Asia, and Central and South America. Disease is also found in the Caribbean, and to a much lesser extent in Europe, Japan, Australia, and parts of the Southern United States. Humans are the only hosts. Infection caused by *Strongyloides fuelleborni*, found sporadically in Africa and Papua New Guinea, is relatively rare. The prevalence of infection can be high in endemic areas, as well as among institutionalized mentally impaired persons, in former prisoners of war, and in refugees and immigrants from endemic areas. Infection results from penetration of skin or mucous membranes by infective larvae, usually from soil; the risk of infection is high for persons with frequent soil contact (e.g., walking barefoot) in warm, moist areas contaminated by human feces. Appropriate sanitation and avoidance of soil contact by skin in endemic areas reduce the risk of infection. Persons infected with human T-cell lymphotrophic virus type 1 (HTLV-1) and those receiving immunosuppressive therapy may develop hyperinfection (disseminated disease). Persons with a history of prior residence or activities that place them at an increased risk for strongyloidiasis should be evaluated for presence of the infection, and should be treated even if asymptomatic. This is especially important in persons who receive or will receive immunosuppressive therapy.

Most infected persons have low worm burdens and are persistently infected for life, often with minimal or no symptoms. If symptoms are present they are generally intermittent, with long asymptomatic periods between episodes. Cutaneous manifestations may be seen at any phase of infection. Following skin penetration, an urticarial eruption or larva currens may develop. Larva currens, a migratory serpiginous and intensely pruritic lesion caused by intradermal migration of larvae, can be differentiated from CLM by the high rate of movement (up to 5–10 cm/hour). Larva currens typically disappears within a few hours, only to recur over the course of weeks to years. During the invasive phase of the infection, transient pulmonary manifestations (cough, wheezing, infiltrates) are of pulmonary migration and may be associated with urticaria. Chronic strongyloidiasis gives rise to nonspecific gastrointestinal complaints (epigastric pain, nausea, vomiting, diarrhea, constipation, malabsorption, weight loss). Perianal larva currens may be present (Fig. 207-5) and is pathognomonic of chronic infection. Persons chronically infected with *Strongyloides* may also experience pruritus ani and chronic urticaria, which may be complicated by prurigo nodularis or lichen simplex chronicus.[53]

Hyperinfection syndrome most often occurs in the presence of impaired cellular immunity, typically because of the use of systemic steroids but also with other immune compromised states including HTLV-1 infection. Interestingly, human immunodeficiency virus infection is not associated with an increased risk of disseminated disease. Insidious gastrointestinal symptoms may be present. Pulmonary disease is the most common extraintestinal manifestation of hyperinfection syndrome and is characterized by diffuse pulmonary infiltrates with dyspnea, cough, wheezing, or hemoptysis. Diarrhea and abdominal pain occur frequently, with inflammation leading to small bowel wall edema; ileus may develop in late stages. In uncontrolled hyperinfection, filariform larvae also penetrate organs not normally involved in the life cycle, including the urinary tract, liver, brain, and skin. The finding of larvae in stool may be an early sign of hyperinfection even in those with minimal symptoms. The dermatologic manifestation of hyperinfection and disseminated strongyloidiasis is a rapidly and progressively diffuse petechial and purpuric eruption, often with a reticular pattern, typically involving the trunk and proximal extremities (Fig. 207-9).[54–56] The

Figure 207-9 Disseminated strongyloidiasis, with nonpalpable purpura on the abdominal wall. (Reprinted with permission from Grossman ME, Roth J: *Cutaneous Manifestations of Infection in the Immunocompromised Host*. Baltimore, Williams & Wilkins, 1995.)

"thumbprint sign," a unique pattern of periumbilical purpura resembling multiple thumbprints,[57] may also be seen. Gram-negative bacillary infections including bacteremia, peritonitis, meningitis, and sepsis may result from the concurrent migration of bacteria and larvae across the bowel wall. The mortality rate for disseminated disease is approximately 50%.

Peripheral eosinophilia is present in up to 80% of patients with intestinal disease, and may be high-grade during larval migration, but it is rarely a feature of disseminated infection (although pulmonary eosinophilia may be noted in the latter), and may be absent in patient on systemic steroids and who are otherwise severely immunocompromised. In chronic disease, the eosinophil level fluctuates and is often mildly elevated (mild to moderate increase) but may be normal. Hence, the absence of eosinophilia does not rule out strongyloidiasis.

The diagnosis of larva currens is based on its characteristic clinical features. The identification of larvae in the stool, small bowel contents, and, rarely, in other body fluids confirms the diagnosis. Larvae first appear in the stool 2–4 weeks after exposure. Multiple stool examinations are often necessary to make the diagnosis; a single stool specimen may fail to detect larvae in up to 70% of cases, although sensitivity approaches 100% with seven consecutive stool samples. The agar plate method, in which a stool sample is placed on solid bacterial medium, incubated, and subsequently examined for bacterial tracks created by larvae dragging enteric bacteria as they migrate across the plate, is more than 90% sensitive.[58] Serologic testing has a sensitivity of approximately 90% but lacks specificity, may cross-react with other helminthic infections (in particular filariasis, ascariasis, and acute schistosomiasis), and cannot reliably distinguish between recent and treated infection since antibodies may persist for years following effective treatment. However, since several recent studies have shown that antibody levels drop significantly over the first year following successful therapy, serology is often used to determine test of cure. Skin biopsy of the larva currens eruption often fails to reveal larvae, whereas they may be visualized in biopsy specimens of purpuric and petechial lesions with hyperinfection.

Treatment of strongyloidiasis in asymptomatic individuals is often successful. Ivermectin 200 µg/kg daily for 2 days is the recommended therapy. Albendazole 400 mg twice daily for 7 days is an alternative, although data are more limited and the drug is not approved by the US Food and Drug Administration for this indication. In contrast, patients with disseminated disease may require prolonged or repeated courses of therapy; some experts also suggest that combination therapy with ivermectin and albendazole be used in this setting. If possible, immunosuppressant therapy should be discontinued in those with hyperinfection.

OTHER HELMINTHIC DISEASES

The sections below briefly describe helminths that can cause dermatologic disease that are not covered in the hard copy textbook. Diagnosis of all infections outlined below is summarized in eTable 207-9.1 in online edition, and treatment in eTable 207-9.2 in online edition, and will not otherwise be discussed in detail.

INTESTINAL NEMATODES (ROUNDWORMS)

ASCARIASIS (*Ascaris lumbricoides*). Ascariasis (roundworm infection) is usually caused by *A. lumbricoides* and rarely *Ascaris suum*. It is distributed worldwide, with a higher prevalence in tropical and subtropical climates. Infection occurs via the fecal–oral route; humans become infected by ingesting infective eggs in contaminated food and water, and on contaminated hands. Disease can be prevented by proper sanitation and avoidance of ingestion of fecally contaminated soil.

Urticaria occurs only during the invasive phase of the disease and may be associated with the pulmonary manifestations of Loeffler's syndrome (cough, wheezing, and dyspnea), which occurs 10–14 days after ingestion of eggs. Urticaria resolve spontaneously at the end of this phase. Gastrointestinal symptoms occur much later and in the absence skin findings. Eosinophilia may accompany the invasive stage. The mainstay of diagnosis is the identification of eggs in feces, which does not occur until after dermatologic manifestations have resolved, approximately 6–8 weeks after onset of infection.

Differential Diagnosis. The differential diagnosis includes other causes of urticaria.

HOOKWORM INFECTION (*Ancylostoma duodenale, Necator americanus*). Humans are the main reservoir for *A. duodenale* and *N. americanus*, and become infected when infective larvae penetrate intact skin (e.g., when walking barefoot on contaminated soil). The disease is most common in rural tropical and subtropical areas but can also occur in temperate areas when sanitation is poor. Infection can be prevented by proper sanitation, and avoidance of barefoot walking.

Cutaneous manifestations may be seen at two stages of infection. Within 1–2 days after contact, the area of skin penetrated by the larvae may have localized erythema, edema, and papular or papulovesicular lesions (ground itch).[59] This eruption is most commonly located on the feet and lasts 1–2 weeks. The pulmonary migration phase, seen in a minority of patients, begins 1–3 weeks after infection and presents with cough, wheezing, and shortness of breath; urticaria may be present and disappear spontaneously at the end of this phase. Peripheral eosinophilia begins as early as 2–3 weeks after initial infection, and may be high-grade during the invasive phase. The diagnosis is made by identification of eggs in stool, but eggs are not passed until after skin findings have resolved, approximately 6–8 weeks after onset of infection. In chronic infection, abnormal laboratory values include iron deficiency anemia, hypoalbuminemia, and gross or occult blood in feces.

Differential Diagnosis. Ground itch may be confused with cellulitis, a cellulitis-like reaction after an arthropod bite or sting, and folliculitis. For the differential diagnosis of acute urticaria, see Chapter 38.

TISSUE NEMATODES (ROUNDWORMS)

DIROFILARIASIS (*Dirofilaria immitis*).

Dirofilariasis (dog heartworm infection) is most prevalent in North and South America, Australia, Europe, Japan, India, and China. Sporadic infections with other *Dirofilaria* spp.—*Dirofilaria tenuis* (raccoon), *Dirofilaria repens* (dog), and *Dirofilaria ursi* (bear)—have been reported from all continents.[60]

The characteristic cutaneous finding in dirofilariasis is a solitary, erythematous to flesh-colored, well-defined, firm subcutaneous nodule or mass.[61] The lesion is usually 1–5 cm in diameter and may be tender; rarely, the lesion is migratory.[62] Nodules most commonly occur in the head, neck, breast, extremities, and scrotum. *Dirofilaria immitis* also causes pulmonary disease (most often asymptomatic but may cause cough, chest pain, low-grade fever, and occasionally hemoptysis). In pulmonary dirofilariasis, chest X-rays demonstrate a solitary coin lesion that may be calcified.

Differential Diagnosis. Other helminthic causes of nodular lesions (Table 207-5), as well as epidermal inclusion cysts, lipomas, other benign tumors, and malignant tumors make up the differential diagnosis of subcutaneous dirofilariasis.

DRACUNCULIASIS (*Dracunculus medinensis*).

Dracunculiasis (Guinea worm disease, Medina worm infection) is transmitted by ingestion of infective copepods in water. The disease was endemic in Sub-Saharan Africa but as a result of a widespread water filtration and monitoring program,[13,63] the disease has been almost completely eliminated. In 2009, only 3,190 cases were reported worldwide, compared with 25,000 in 2006.[13]

Symptoms associated with the migration of the worm may precede the emergence of the worm. The characteristic clinical findings include a bullous lesion, typically on the foot, that ruptures and ulcerates after contact with water (Fig. 207-7). Cellulitis and abscess formation can occur. Most infected individuals harbor multiple worms, but usually fewer than six. The adult worm may be palpated or can be seen emerging from the ulcer, and typically dies after reaching the skin and releasing larvae.

Differential Diagnosis. The differential diagnosis includes causes of localized cutaneous bullae, ulcers, and carbuncles.

FILARIAL INFECTIONS.

Filarial infections have been broadly grouped into three categories of disease based on their location of disease: (1) lymphatic, (2) cutaneous, and (3) body cavity.[64] Morbidity is almost entirely attributable to those species that cause lymphatic disease, and to a lesser extent cutaneous disease. Body cavity infection, due to *Mansonella ozzardi*, is usually asymptomatic and will not be discussed below. Filarial infections are summarized in eTable 207-9.3 in online edition.

Lymphatic Filariasis (*Brugia malayi and Brugia timori; Wuchereria bancrofti*). Lymphatic filariasis is caused mainly by *W. bancrofti* (Bancroftian filariasis), which causes 90% of disease, and *B. malayi* (Malayan filariasis), which accounts for only 10% of all cases.[65] Infection caused by *B. timori* is rare. Lymphatic filariasis is widely distributed in both urban and rural areas of tropical and subtropical areas, with the largest number of infections occurring in India, South Asia, East Asia, the Pacific Islands (eFig. 207-9.1 in online edition), and Sub-Saharan Africa. *W. bancrofti* is also endemic in northern parts of South America (Guyana, Surinam, and some coastal regions of Brazil). In developed countries, infections are seen primarily in immigrants and persons with prolonged visits to endemic areas.

Infection is transmitted to humans by mosquitoes, and can be prevented by avoidance of mosquito bites. The incubation period is usually 5–18 months, during which time microfilariae migrate to the lymphatic system, mature into adults, mate, and release microfilariae (larvae); occasionally symptoms develop within 3 months of exposure. Lymphatic filariasis is first acquired in childhood, often with as many as one-third of children in endemic areas infected before the age of 5.[66] However, the characteristic symptoms typically occur years after infection and the prevalence of clinical disease increases after age 20 in endemic areas. Adult worms live an average of 10–15 years, and microfilariae probably 6–12 months. Symptoms and sequelae can persist after the death of all parasites.

Clinical manifestations may be acute, chronic, or recurrent.[67] Initial infection may be subclinical but may also cause recurrent lymphangitis with characteristic retrograde progression, lymphadenitis, orchitis, epididymitis, or occasionally fever. Lymphangitis typically recurs 6–10 times per year, with each episode lasting 3–7 days. The affected body part clinically appears normal between early episodes, although during the resolution of the acute phase of *W. bancrofti* filariasis, there may be extensive exfoliation of the skin of the affected limb. Intermittent fevers and adenolymphangitis can recur during the lifetime of the adult worm. Travelers (>1 month) to endemic areas less frequently acquire infection but may present with more intense inflammatory reactions to filarial parasites. The findings may include lymphangitis, lymphadenitis, groin pain from the associated lymphatic inflammation, urticaria, and peripheral eosinophilia.

Chronic disease with sequelae of lymphatic obstruction (lymphedema, elephantiasis, hydrocele, and chyluria), becomes evident 10–15 years after infection. The skin over the involved area can become hypertrophic, verrucous, and fibrotic with redundant skin folds (Fig. 207-10). Fissures, ulceration, secondary bacterial infection, and gangrene may occur. The lower extremity, scrotum, and penis are most commonly affected, and less frequently the upper extremity, breast, and vulva are involved. Treatment does not reverse the late findings of scarring and lymphatic obstruction.

Figure 207-10 Lymphatic filariasis. (Used with permission from Jay S. Keystone, MD, FRCPC.)

Eosinophilia, sometimes high-grade, and elevated IgE levels are common. Infiltrates may be present on chest radiography in individuals with tropical pulmonary eosinophilia. The diagnosis is made by demonstrating microfilariae at night in blood, urine, and other body fluids, and tissue. However, persons with active filarial infection may not be microfilaremic. Inguinal lymph node ultrasound may show active microfilariae ("filarial dance sign"), more commonly seen in men than in women. Lymph node biopsy is contraindicated.

Differential Diagnosis. Acute infection may resemble bacterial lymphangitis and other causes of nodular lymphangitis (e.g., sporotrichosis, leishmaniasis). Other causes of lymphedema and elephantiasis must be considered during evaluation of chronic disease.

Cutaneous Filariasis: Loiasis (*Loa loa*). Loiasis is endemic in rural areas of Central and West Africa, affecting an estimated 3–13 million residents. *Loa loa* is transmitted by the day-biting *Chrysops* fly; infection can be prevented by avoiding bites from *Chrysops* in endemic areas, diethylcarbamazine chemoprophylaxis, and treatment of infected humans to reduce source of parasites. Symptoms usually begin an average of 24 months after exposure, but can begin as early as 4 months or as late as a decade or more after infection. Microfilariae first appear in the bloodstream 5–6 months after the person becomes infected. The adult worm can live longer than 20 years in the human host.

The characteristic finding of loiasis is the Calabar swelling (Fig. 207-11),[68] a localized area of angioedema due to migration of adult worms through subcutaneous tissues. Calabar swellings usually begin years after infection, typically around joints of the upper extremities, generally last 2–4 days, and may be associated with pruritus or pain. They range in size from 5–20 cm in diameter and may be recurrent. Fatigue, myalgias, arthralgias, and fever are rare. A rapidly moving creeping eruption that usually lasts only a few hours may occur when the adult worm migrates under the skin; adult worms may also be seen moving across the bulbar conjunctiva of the eye (Fig. 207-6). Pruritus may also occur. Peripheral eosinophilia (high-grade), leukocytosis, and elevated IgE are often present.

Figure 207-11 Calabar swelling in loiasis. (Used with permission from Jay S. Keystone, MD, FRCPC.)

Differential Diagnosis. The differential diagnosis includes all of the causes of migratory and nodular skin lesions (Tables 207-4 and 207-5).

Cutaneous Filariasis: Mansonelliasis (*Mansonella perstans, Mansonella streptocerca*). Infection due to both *M. perstans* and *M. streptocerca* is often asymptomatic, but symptoms when present are primarily cutaneous. *M. perstans* is endemic in Sub-Saharan Africa, as well as parts of Central and South America. It is transmitted by biting *Culicoides* midges. Like lymphatic filariasis, infection during childhood is common, and reinfection may occur.[69] In highly endemic areas, the prevalence of infection may be as high as 80%.[70] Cutaneous manifestations include Calabar-like swellings, typically in the forearms, hands and face, and pruritus with or without a papular rash.[71] The exact interval between infection and onset of symptoms is unclear.

M. streptocerca is endemic in forested areas of West and Central Africa. Transmission is also by infected midges. Cutaneous manifestations of *M. streptocerca* infection include pruritus, papular lesions, and hypopigmented, hyperpigmented, or lichenified macules, typically found on the upper chest.

Eosinophilia is often present in *Mansonella* infections, but may also be due to the high prevalence of coinfection with other filarial or helminthic infections.

Cutaneous Filariasis: Onchocerciasis (*Onchocerca volvulus*). Onchocerciasis (river blindness; *erysipelas de la costa* in Mexico and Guatemala; *sowda* in Arabic speaking areas; *craw-craw* in West Africa) is concentrated in rural areas of Equatorial Africa and the Arabian peninsula (eFig. 207-11.1 in online edition), and in Latin America (eFig. 207-11.2 in online edition). Onchocercia-

sis is transmitted by black flies of the genus *Simulium*. In the human, infective larvae mature to adult worms that are encapsulated in fibrous tissue and reside in nodules in the subcutaneous tissue and deep fascia. The incubation period is usually 1–2 years with a range of months to several years, although microfilariae may first appear 3–15 months after exposure; symptoms may precede microfilaremia but often develop only after months or years of infection. Microfilariae can survive in humans for up to 2–3 years, and adult worms for 10–15 years. The primary means of preventing onchocerciasis is through vector control and mass treatment with ivermectin of the population in endemic areas.

Infected individuals may be asymptomatic. Clinical manifestations most commonly involve the skin and eye. Six different patterns of skin changes have been described in onchocerciasis: (1) acute papular onchodermatitis and (2) chronic papular onchodermatitis (Fig. 207-1), (3) lichenified onchodermatitis, (4) atrophy, (5) depigmentation (see Section "Onchocerciasis" in Chapter 75), and (6) onchocercal nodules (Fig. 207-2). More than one pattern of skin involvement may be present simultaneously, or one pattern of skin involvement may evolve into another pattern.

Pruritus is often the first symptom of infection. Acute papular onchodermatitis most often involves the face, extremities, and trunk, and includes widespread small pruritic papules, vesicles and pustules, sometimes with associated erythema and edema. Short-term visitors to endemic regions typically present with acute pruritus and rash (Fig. 207-1),[11] and demonstrate immune hyperresponsiveness despite low levels of parasites[10]; skin nodules and eye involvement are usually absent. After exposures in forested areas of West and Central Africa, travelers and expatriates may have an acute form of onchocerciasis characterized by acute pruritic and erythematous swelling of a limb known as *gros bras camerounais*[15] or onchocerciasis-associated limb swelling.[16]

The skin lesions of chronic papular onchodermatitis are macules and lichenoid papules varying in size from 3–9 mm in diameter. Pruritus is common, and postinflammatory hyperpigmentation may be present. The most commonly affected anatomic areas are the buttocks, shoulders, and waist (Fig. 207-1). Palpable asymptomatic onchocercal nodules containing the adult worm involve the deep dermis and subcutaneous tissue (Fig. 207-2), and occur over bony prominences such as the skull, iliac crest, knee, rib, sacrum, scapula, and trochanter.

Peripheral eosinophilia and elevated IgE levels are common findings.

Differential Diagnosis. Acute onchodermatitis may resemble miliaria, insect bites, scabies, or eczema. Chronic onchodermatitis may resemble a chronic or lichenoid eczema or atopic dermatitis. Skin changes resembling lichenified onchodermatitis can be due to conditions causing significant pruritus or rubbing. Atrophic changes resemble those associated with aging. Onchocercal depigmentation may be confused with postinflammatory hypopigmentation or depigmentation. The differential diagnosis for onchocercal nodules includes other parasitic causes of nodules (Table 207-5) and epidermal inclusion cysts.

GNATHOSTOMIASIS (*Gnathostoma spinigerum*)

Gnathostomiasis is caused by *Gnathostoma spinigerum* and less commonly other *Gnathostoma* species.[72] It is endemic in Southeast Asia, especially Thailand and Japan. Since the 1970s, the prevalence of gnathostomiasis has increased in Peru, Ecuador, and Mexico. Sporadic cases have been reported in the Americas, Africa, Europe, and Australia. In the last two decades, an increase has been noted in the cases in travelers returning from endemic countries.[73–75] Infection is acquired by ingestion of larvae in undercooked or raw flesh of infected animals (typically fish, amphibians, and reptiles) or contaminated water. Imported fish and other animal flesh can be a source of infection outside of endemic areas.

The penetration phase occurs within 1–2 days of larval ingestion and includes acute urticaria and fever, malaise, anorexia, nausea, vomiting, diarrhea, and epigastric pain, which resolve spontaneously within 2 days.[76] Migration of the larvae in the skin and subcutaneous tissue causes migratory swellings (eosinophilic panniculitis), creeping dermatitis (1 cm/hour), papules, and nodules.[77] Solitary or multiple migratory swellings usually occur 3–4 weeks after infection, are intermittent, and associated with erythema, pruritus, and pain (Fig. 207-12). The swellings develop rapidly, persist for 1–4 weeks, then resolve, only to reappear in a different anatomic location after an asymptomatic interval of weeks to months. Over time, episodes become less frequent, less intense, and shorter in duration, but may continue for months to years. Rarely, infection may present as a papular lesion or limb swelling. The most common anatomic locations include the trunk, upper body, and thighs. Peripheral eosinophilia may be high-grade during larval migration.

Differential Diagnosis. The differential diagnosis includes causes of migratory lesions (Table 207-4), panniculitis, limb swelling (e.g., loiasis, onchocerciasis, eosinophilic cellulitis, other), and skin nodules (Table 207-5).

Figure 207-12 Subcutaneous swelling of gnathostomiasis. (Used with permission from Jay S. Keystone, MD, FRCPC.)

TOXOCARIASIS (*Toxocara canis, Toxocara cati*).

Toxocariasis (visceral larva migrans) is most commonly caused by the dog roundworm *T. canis*. It is most prevalent in tropical and temperate climates where humans and dogs coexist, but is found worldwide. Transmission is via the fecal–oral route, with the highest rates of infection in children and individuals with pica.

Most infections are asymptomatic or mild. Severe illness can occur, with disease involving the liver, heart, brain, spinal cord, eyes, and muscle. The most common cutaneous symptoms include urticaria during larval migration, and chronic pruritus or prurigo.[78,79] In acute infection, urticaria is often accompanied by other symptoms including fever, abdominal pain, wheezing, and myalgias. Since larvae can survive and wander through tissues for 10 years or more, urticaria may also persist after resolution of acute symptoms. Other less common cutaneous manifestations include eosinophilic panniculitis,[25,26] eosinophilic cellulitis (Well's syndrome),[28] and eosinophilic folliculitis.[29] Henoch–Schonlein purpura[80] and subcutaneous granulomas[81] have also been reported. Peripheral eosinophilia, often high-grade, may be persistent, and liver enzymes may be elevated during acute infection.

Differential Diagnosis. The differential diagnosis mainly includes other causes of urticaria.

TRICHINOSIS (*Trichinella spiralis*).

Trichinosis (trichinellosis) is present in most countries, but there is marked variation in the incidence. Humans are accidental dead-end hosts and become infected by eating raw or undercooked flesh of animals infected with *Trichinella*, most commonly bears or boars. Human infection can be sporadic or epidemic. Sporadic infections can occur worldwide by shipment of contaminated meat.

Infection may be asymptomatic. Symptomatic disease occurs during larval migration and varies in severity. Death is uncommon (1%–2% of recognized infections) and is usually related to neurologic or cardiac involvement.

Abdominal pain, diarrhea, and vomiting occur during the first week of infection. Ten days after the ingestion of larvae, fever (in 90% of the cases), cutaneous manifestations (75% of cases),[82] fatigue, and severe myalgia develop. The most frequent skin findings are periorbital and facial edema (75%–95% of cases), conjunctivitis, and less commonly a macular or papular (sometimes urticarial) rash. Hand swelling and volar surface erythema followed by desquamation have been reported.[83] Subconjunctival and subungual hemorrhages can occasionally be seen (eFig. 207-12.1 in online edition). Peripheral eosinophilia may be marked and may persist for months. Muscle enzymes (creatine phosphokinase, CPK) are increased.

The diagnosis is usually based on the epidemiological history (e.g., an ongoing epidemic, or suspected dietary exposure), the clinical triad (fever, facial edema, myalgias), and laboratory findings (eosinophilia, increased CPK). A definitive diagnosis is possible after the 17th day and relies on the identification of the parasite in muscle.

Differential Diagnosis. The differential diagnosis includes allergic reactions, dermatomyositis, vasculitis, causes of urticaria, and eosinophilia–myalgia syndrome.

TREMATODES (FLUKES)

FASCIOLIASIS (*Fasciola hepatica, Fasciola gigantica*).

Fascioliasis caused by *F. hepatica* is found worldwide in sheep- and cattle-raising areas[84,85] and has been reported from all continents. Disease due to *F. gigantica* is rare. Infection, which may be asymptomatic, results from ingestion of encysted cercariae on water plants (e.g., watercress).

Symptomatic acute infection presents with fever, abdominal pain, nausea, and diarrhea, which occur during the migration of immature flukes. Urticaria and wheezing may be present during the invasive phase. Less commonly, ectopic subcutaneous nodules may develop; lesions are typically erythematous, pruritic and painful, occurring on the abdomen, back, and extremities. Rarely, eosinophilic panniculitis may be present. Chronic infection does not typically involve the skin. Eosinophilia is typically present during the invasive phase. The identification of eggs in stool only occurs well after symptoms of invasive disease have subsided. Serology may be helpful.

PARAGONIMIASIS (*PARAGONIMUS WESTERMANI*).

Paragonimus westermani is widely distributed in East and Southeast Asia and Africa. Other species of *Paragonimus* can infect humans and are found in Asia, Africa, and the Americas.[86–88] Worldwide, an estimated 10 million persons are infected with paragonimiasis. Infection is prevalent in Asia, where raw, undercooked, salted, pickled, or marinated crustaceans are frequently eaten.

Infection is often asymptomatic. Urticaria may occur early. Migratory subcutaneous nodules containing immature flukes may appear as early as 2 weeks, and are present in 10% of those with *P. westermani* infection and 20%–60% of patients with *Paragonimus skrjabini* and *Paragonimus szechuanensis* infection. Lesions may be up to 6 cm in diameter, are migratory, firm, slightly mobile, and tender to palpation. The lesions are most commonly located on the lower abdomen and inguinal region. Pulmonary involvement is common in chronic infection, but often asymptomatic. Peripheral eosinophilia may be present.

SCHISTOSOMAL INFECTIONS

Cercarial Dermatitis. Cercarial dermatitis (swimmer's itch) occurs worldwide and may be acquired by contact with infective cercariae of many species of non-human schistosomal parasites, in both freshwater and salt water. Attack rates during outbreaks usually range from 55%–100% of those exposed, with highest attack rates in those with a history of previous cercarial dermatitis.[89]

Clinical findings are confined to the skin and are usually distributed on skin surfaces exposed directly to water. Pruritus may begin while swimming, followed rapidly by the appearance of an erythematous macular rash that persists for several hours. Ten to fifteen hours after exposure, papules, vesicles, and urticaria develop. Marked pruritus is characteristic. Symptoms peak 48–72 hours after exposure, and gradually resolve spontaneously over the next several weeks.

Schistosomiasis (*Schistosoma hematobium, Schistosoma intercalatum, Schistosoma japonicum, Schistosoma mansoni, Schistosoma mekongi*). An estimated 200 million people worldwide are infected with schistosomiasis (bilharziasis) and over half-a-billion live in endemic areas (eFigs. 207-12.2 and 207-12.3 in online edition). Humans are the only important reservoir for *S. haematobium*. Infection can be acquired after a brief exposure in an endemic area; many outbreaks have been reported in travelers,[90,91] typically after swimming, wading, rafting, or bathing in slow-moving freshwater in endemic areas. Attack rates in nonimmune exposed persons (e.g., travelers) can be as high as 100%. Cutaneous manifestations can be seen at every phase of the infection.

Cercariae penetrate intact skin within 30 seconds to 10 minutes and may elicit a local inflammatory response (penetration phase). The first exposure to cercariae typically results in erythema and pruritus that resolve within hours. In those previously sensitized, a pruritic, erythematous, papular, and urticarial rash develops, usually lasting 1 week. Migration of the larvae (schistosomulae) in the body usually occurs 2–6 weeks after exposure and leads to an acute parasitic toxemia with a hypersensitivity reaction and circulating immune complexes. This invasive phase (Katayama fever) has historically been described with *S. japonicum* (Katayama fever, sensu stricto), *S. mansoni,* and, to a lesser extent, with *S. haematobium*. Symptoms of Katayama fever are most prominent in primary infection in nonimmune persons and include fever, fatigue, myalgia, and headache that may persist for several weeks. Abdominal symptoms and diarrhea may also be present. Urticaria, purpura, subungual hemorrhages, and edema of the face, the extremities, genitals, and trunk may be seen during the invasive phase.

Chronic schistosomiasis (bilharziasis cutanea tarda) may begin after years of infection and result from a granulomatous inflammatory reaction to the deposition of eggs in the dermis (Fig. 207-13), which may continue for the lifespan of the adult worm (up to 10 years). It is seen primarily in persons who have lived in endemic regions. Lesions are skin-colored or slightly pigmented, 2- to 4-mm firm, pruritic, oval papules that appear in crops and clusters, typically on the trunk and especially the periumbilical region, and remain unchanged without treatment. Lesions also appear in the genital area buttocks, especially on the vulva in women and the scrotum and penis in men. Chronic lesions may also include painless, skin-colored, pink or brown eroded papules and warty, vegetative, polypoid lesions that may be ulcerated and necrotic, with fistulous tracts. Chronic disease can be complicated by lymphedema and elephantiasis, secondary bacterial infection, and squamous cell carcinoma.

Figure 207-13 Ectopic deposition of *Schistosoma mansoni* eggs.

Prominent eosinophilia may be present in early infection, especially during the invasive phase, and subsequently fluctuates more or less above the normal value during the chronic phase. Onset of eosinophilia may lag behind appearance of clinical symptoms. Acute disease can be suspected based on the history of exposure and cercarial dermatitis. Identification of eggs in the stool occurs only after the acute phase of infection.

Differential Diagnosis. The differential diagnosis during acute disease includes other causes of urticaria. Bilharziasis cutanea tarda of the genitals and buttocks must be differentiated from syphilis, condyloma latum, condyloma acuminatum, other granulomatous diseases, malignancy, and hemorrhoids.

CESTODES (TAPEWORMS)

COENUROSIS (*Multiceps multiceps, Multiceps serialis*).

Reported human cases of coenurosis, caused most commonly by *Multiceps multiceps* and less often by *Multiceps serialis*, are rare and sporadic, with the majority from Africa.[92] Infections have occurred in Asia, Europe, and North America,[93] particularly in areas where sheep are common. Intramuscular and subcutaneous cysts are the most common presentation, especially in cases from Africa,[92] but disease may also involve the eye and the central nervous system.[93]

CYSTICERCOSIS (*Taenia solium*).

T. solium (pork tapeworm) is a common parasite in Central and South America, Africa, parts of Asia, and Eastern Europe, although domestic acquisition of infection

has also been well documented in the United States. Cysticercosis is the most common helminthic infection of the central nervous system. Humans acquire cysticercosis by ingesting eggs in food, water, or on fingers contaminated with human feces, but may also acquire intestinal disease from eating undercooked or raw pork containing cysts with infective larvae.

Humans can have either form of disease, or both; intestinal taeniasis is found in up to 50% of patients with cysticercosis.

Less than 10% of patients with cysticercosis present with subcutaneous nodules, although earlier studies reported a detection rate of 50%.[14] Nodules are mobile, well-defined and characteristically nontender, measuring 2 cm in size on average, and commonly found on the extremities and the trunk. The time from infection to the appearance of subcutaneous nodules is highly variable and may be from months to years. Neurocysticercosis is frequently asymptomatic; symptomatic disease presents with seizures in more than two-third of cases.[94] Ectopic disease in other sites is less common.

Differential Diagnosis. The differential diagnosis of subcutaneous nodules includes benign cysts, soft-tissue tumors, and other parasitic causes of nodules (Table 207-5).

ECHINOCOCCOSIS (*Echinococcus granulosus, Echinococcus multilocularis*).

Echinococcus granulosus (cystic hydatid disease) is prevalent in southern South America, the Mediterranean region, parts of the former Soviet Republic, the Middle East, Asia, and Northern and Eastern Africa. Infections are sporadic in other world regions, except Antarctica. *Echinococcus multilocularis* (alveolar hydatid disease) is more limited in distribution, and has been documented in North America, Europe, Asia, India, and Iran. Infection caused by other species (*Echinococcus vogeli, Echinococcus oligarthrus*, and others) is rare. Humans are incidental intermediate hosts who become infected by ingesting infective eggs (shed in feces of dogs or, for *E. multilocularis*, foxes) in contaminated food or water.

Most echinococcal infections are asymptomatic; symptoms develop years after infection and are related to the location and size of cysts. Cysts are usually single, but in 25% of cases multiple cysts are present. Most cysts are hepatic (50%–75%) and pulmonary (20%–30%), with other sites infrequently involved. Typically, the signs and symptoms include an enlarging firm but fluctuant, nontender abdominal mass (Fig. 207-14), epigastric and right upper quadrant pain, jaundice, hepatomegaly, nausea, and vomiting. True skin and soft-tissue manifestations are rare except when cyst leakage occurs. Significant leaks may produce an "anaphylactoid reaction" with eosinophilia, urticaria, and wheezing. Urticaria alone may occur alone in mild cases. Echinococcal cysts implant in soft tissues in less than 2% of infected patients.[95] Infection with *E. multilocularis* has been reported to cause supraumbilical cutaneous and subcutaneous nodules with ulceration, surrounding inflammation, and painless cutaneous fistulae resulting from extension of an underlying visceral lesion.[96] Eosinophilia is usually absent, except in the case of cyst leakage.

Figure 207-14 Abdominal bulge due to intraperitoneal echinococcosis. (Used with permission from Jay S. Keystone, MD, FRCPC.)

Differential Diagnosis. The differential diagnosis includes other cutaneous nodules (Table 207-5) and other cystic lesions of soft tissues.

SPARGANOSIS (*Spirometra mansoni, Spirometra erinacei, Spirometra mansonoides*).

Spirometra species are found in animals on all continents, but most reported human cases are from China, Japan, and Southeast Asia. Cases have also been reported from Africa, Australia, the Caribbean, Southern Europe, and the Americas. Infection is acquired by ingestion of infective tapeworm larvae in contaminated water or animal (fish, amphibian, reptile) flesh, or by use of infected flesh in topical poultices.

The severity of infection depends on the route of infection, the number of parasites, and the anatomic locations involved.[97] Ingestion of larvae leads to a slow-growing subcutaneous or intramuscular nodule (Fig. 207-15), which is occasionally migratory, 3 weeks

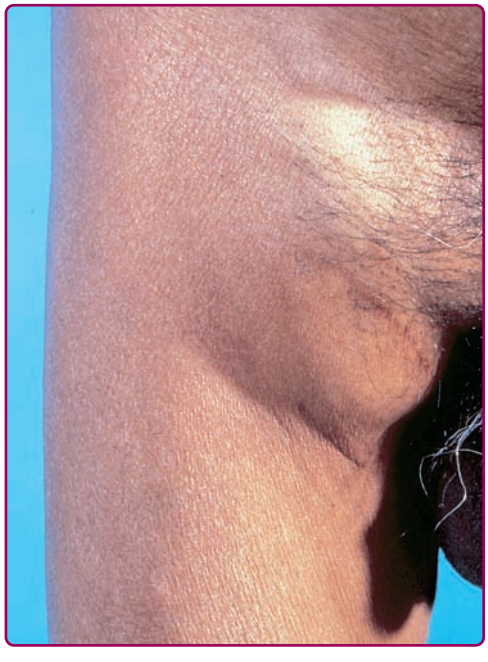

Figure 207-15 Soft tissue swelling of sparganosis. (Used with permission from Jay S. Keystone, MD, FRCPC).

to 14 months after ingestion. The lesion may be pruritic and tender or nontender and may persist for years. Sparganosis due to the application of poultices made with infected flesh is characterized by localized pruritus, erythema, edema, and subcutaneous nodules that are painful to palpation

SUMMARY

Helminthic infections can cause a spectrum of cutaneous disease. Migratory lesions of CLM are most likely to be encountered by clinicians in the developed world. Recognition of specific dermatologic findings, in conjunction with a thorough epidemiologic and exposure history, can establish the diagnosis and/or direct further investigations, and lead to appropriate therapy.

Chapter 208 :: Scabies, Other Mites, and Pediculosis

:: Craig N. Burkhart & Craig G. Burkhart

SCABIES

SCABIES AT A GLANCE

- Human infestation caused by host-specific itch mite that lives its entire life cycle within the epidermis.
- Causes a diffuse, pruritic eruption after an incubation period of 4–6 weeks.
- Is transmitted by close physical contact or by fomites.
- Topical therapy is most popular, but oral ivermectin is effective.
- Because of the common occurrence of asymptomatic mite carriers in the household, all family members and close contacts should be treated simultaneously.

EPIDEMIOLOGY

Scabies is worldwide and affects all ages, races, and socioeconomic levels. Prevalence varies considerably with some underdeveloped countries having rates from 4% to 100% of the general population.[1] An infested host usually harbors between 3 and 50 oviparous female mites,[2] but the number may vary considerably among individuals. For example, patients with crusted formerly "Norwegian" scabies (Fig. 208-1) who have a defective immunologic or sensory response (i.e., leprosy, paraplegic, or HIV-infected patients) harbor millions of mites on their skin surface, with minimal pruritus.

It has been well established that close personal contact is a prime route of transmission. Although sometimes considered a sexually transmitted disease, the equally high prevalence in children attests that casual contact or sharing of objects among children and other

Figure 208-1 Crusted scabies. Hyperkeratotic plaques populated with thousands of mites.

family members is also sufficient to transmit the disease. Transmission via inanimate objects has been best demonstrated with crusted scabies. This condition is notoriously contagious, and anyone roaming within the general vicinity of these patients risks acquiring the infestation. Indeed, 6,000 mites/g of debris from sheets, floor, screening curtains, and nearby chairs have been detected.[3] Mites are also prevalent in the personal environment of normal scabies patients.[4,5] In one study, live mites were recovered from dust samples taken from bedroom floors, overstuffed chairs, and couches in every patient's dwelling.[5]

ETIOLOGY AND PATHOGENESIS

Scabies is an infestation by the highly host-specific mite, *Sarcoptes scabiei* var. *homini*, family Sarcoptidae, class Arachnida. The mite is pearl-like, translucent, white, eyeless, and oval in shape with four pairs of short stubby legs. The adult female mite is 0.4 × 0.3 mm with the male being slightly smaller—just slightly too small to be seen by the naked eye. The scabies mite is able to live for 3 days away from the host in a sterile test tube, and for 7 days if placed in mineral oil mounts.[4,6] Mites cannot fly or jump.

The life cycle of mites is completed entirely on human skin. The female mite by a combination of chewing and body motions is able to excavate a sloping burrow in the stratum corneum to the boundary of the stratum granulosum.[7,8] Along this path, which can be 1 cm long, she lays two to three eggs a day during her life span of 30 days. Eggs hatch in 10 days and larvae leave the burrow to mature on the skin surface. The male mite lives on the surface of the skin and enters burrows to procreate.

CLINICAL FINDINGS

The diagnosis of scabies is suspected by pruritus associated with a characteristic distribution of lesions and epidemiologic history. Pruritus typically appears 4–6 weeks after initial infestation; with subsequent reinfestations, symptoms develop within 2 days.[9] Similar to the human response to other insects such as fleas, yellow jackets, and mosquitoes, there is a wide range of clinical responses to an infestation with scabies and some individuals remain asymptomatic despite being infested. These individuals are considered "carriers."

On physical examination, patients display excoriations and eczematous dermatitis that favors the interdigital webs (Fig. 208-1), sides of fingers, volar aspects of the wrists and lateral palms (Fig. 208-2), elbows, axillae, scrotum, penis (Fig. 208-3), labia, and areolae in women. The head and neck are usually spared in healthy adults, but in infants, elderly, and immunocompromised, all skin surfaces are susceptible. Indurated, crusted nodules can be seen in children on intertriginous areas. In crusted scabies, (Fig. 208-1) hyperkeratotic plaques develop diffusely on the palmar and plantar regions, with thickening and dystrophy of the toenails and fingernails.

Figure 208-2 Scabies. Several thread-like burrows are present in the web spaces of the fingers and on the knuckles, a common location for these lesions in scabies. Longitudinal scraping of a burrow will often reveal the mite or mite products under microscopic examination.

The pathognomonic lesion is a burrow, which is a thin, thread-like, linear structure (Fig. 208-2) 1–10 mm in length. It is a tunnel caused by the movement of the mite in the stratum corneum. When present, the burrow is best seen in the interdigital webs and wrists; however, it can be difficult to find in early stages of the condition, or after the patient has extensively excoriated the lesions. Identification of a burrow can be facilitated by rubbing a black felt-tip marker across an affected area. After the excess ink is wiped away with an alcohol pad, the burrow appears darker than the surrounding skin because of ink accumulation in the burrow.

A definitive diagnosis is made by microscopic identification of the scabies mites, eggs, or fecal pellets (scybala). This is accomplished by placing a drop of mineral oil over a burrow and then scraping longitudinally with a number 15 scalpel blade along the length of the burrow or a suspicious skin area, being careful not to cause bleeding. The scrapings are then applied to a glass slide and examined under low power (Fig. 208-3). Confocal microscopy and dermoscopy can also be used to examine the mite in vivo[10,11] and a skin biopsy can be diagnostic, if the mite happens to be transected

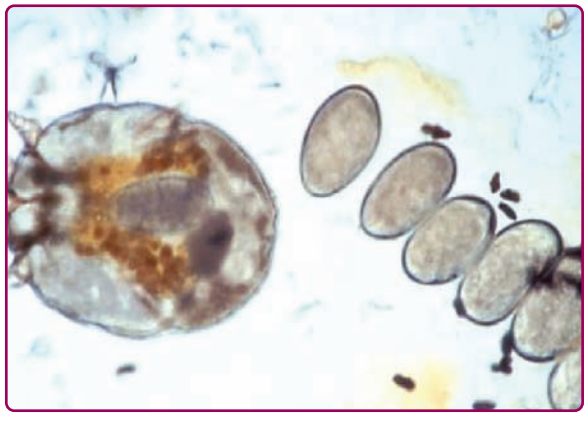

Figure 208-3 Scabies. Microscopic examination of a mineral oil preparation after scraping a burrow reveals a gravid female mite with oval, gray eggs and fecal pellets.

in the stratum corneum (see eFig. 208-3.1 in online edition). An enzyme-linked immunosorbent assay has been developed for serologic testing of other mite infestations in animals; however, no serologic tests for scabies exist for humans.[12] Despite the possibility of confirming the presence of mites via multiple methods of testing, the diagnosis usually is based on clinical impression, and solidified by response to treatment.

DIFFERENTIAL DIAGNOSIS

(See Box 208-1)

COMPLICATIONS

Secondary impetiginization may occur and poststreptococcal glomerulonephritis has resulted from scabies-induced pyodermas caused by *Streptococcus pyogenes*. Lymphangitis and septicemia have also been reported in crusted scabies (see eFig. 208-3.2 in online edition). Finally, scabies infestation can also trigger bullous pemphigoid.[13,14]

TREATMENT

Scabies is treated by a combination of a scabicide and fomite control. With all insecticidal therapies, a second application, usually a week after the initial treatment, is required to reduce the potential for reinfestation from fomites as well as to kill any nymphs that may have hatched after treatment as a result of a semiprotective environment within the egg. All household and close contacts must be simultaneously treated to prevent reinfestation from asymptomatic carriers.

Topical scabicides are applied overnight to the entire skin surface with special attention to finger and toe creases, cleft of the buttocks, belly button, and beneath the fingernails and toenails. In adults, one can exclude treating the scalp and face. Most treated individuals experience relief from symptoms within 3 days, but patients must be informed that even after adequate scabicidal therapy, the rash and pruritus may persist for up to 4 weeks. The itching experienced during this time period is commonly referred to as "postscabetic itch." Patients should be educated that excessive washing of the skin with harsh soaps will aggravate their skin irritation. Instead, oral antihistamines and emollients can be beneficial. The treatments for scabies are summarized in Box 208-2 but a few comments are warranted:

- Lindane has received a "black box" warning as well as restrictive labeling changes by the US Food and Drug Administration (FDA) to greatly restrict its

BOX 208-2 TREATMENT FOR SCABIES

DRUG	DOSE	COMMENTS
Permethrin 5% cream	Apply for 8 hours, repeat in 7 days	Most common treatment presently; pregnancy category B, tolerance seems to be developing
Lindane 1% lotion	Apply for 8 hours, repeat in 7 days	US Food and Drug Administration "black box" warning now in effect[a]; banned in California
Crotamiton 10% cream	Apply for 8 hours on days 1, 2, 3, and 8	Has antipruritic qualities; effectiveness is marginal
Precipitated sulfur 5%–10%	Apply for 8 hours on days 1, 2, 3	Considered safe in neonates and during pregnancy; limited efficacy data; inexpensive
Benzyl benzoate 10% lotion	Apply for 24 hours	Not available in United States
Ivermectin 200 µg/kg	Taken orally on day 1 and 8	Highly effective with good safety profile; not recommended for children less than 15 kg or for pregnant or lactating women

[a]Black box warns against usage in premature infants and individuals with known uncontrolled seizure disorders, as well as cautious usage in infants, children, the elderly, and individuals with other skin conditions, such as dermatitis and psoriasis, and people who weigh less than 110 lbs (50 kg) as they may be at risk of serious neurotoxicity.

usage.[15,16] Moreover, it is banned in California.[17] A physician should write a prescription for lindane only when cognizant of all the caveats are noted by the FDA.[18] (See Box 208-2 footnote.)

- There are no documented cases of scabies resistance to permethrin, but tolerance is beginning to develop.[19] Pregnant females, breast-feeding mothers, and children under 2 years should limit their two applications (1 week apart) to 2 hours only when using permethrin.
- Crotamiton is considerably less effective than all other options offered.
- Five to ten percent sulfur is messy, malodorous, tends to stain, and can produce irritant dermatitis, but is inexpensive and may be the only choice in areas of the world in which a lack of funds dictates therapy.[20] The efficacy and toxicity of sulfur has not been critically evaluated in recent years, but many feel that it is the safest choice for neonates and pregnant females.[21]

Ivermectin is an anthelmintic agent derived from a class of compounds known as avermectins. It has been used in veterinary medicine since 1981, and has excellent antiparasitic properties.[22,23] Ivermectin has been approved since 1996 by the FDA for treatment of two diseases, namely onchocerciasis and strongyloides. Clinical efficacy for scabies has been impressive at a dosage of 200 µg/kg given twice 1 week apart.[24,25] Given that millions of people have been treated for onchocerciasis worldwide without significant side effects, it appears to be extremely safe. Nevertheless, because the drug acts on nerve synapses utilizing glutamate or γ- aminobutyric acid, and because the blood–brain barrier is not fully developed in young children, it is not recommended for use in children less than 15 kg (33 lbs) or in pregnant or lactating women. Success rates approach 100% in studies where entire households and close contacts of infested individuals are treated while maintaining strict fomite controls.[23,26]

In crusted scabies, the combination of oral ivermectin and a topical scabicide are recommended as the oral medication will not penetrate into the thickness of the keratinous debris under the nails.

PREVENTION

Several measures should be considered to reduce the potential of reinfestation by fomite transmission. Because of the common occurrence of asymptomatic mite carriers in the household, all family members and close contacts should be treated simultaneously. After treatment, treated individuals should wear clean clothing, and all clothing, pillow cases, towels and bedding used during the previous week should be washed in hot water and dried at high heat. Nonwashables should be dry-cleaned, ironed, put in the clothes dryer without washing, or stored in a sealed plastic bag in a warm area for 2 weeks. Floors, carpets, upholstery (in both home and car) play areas, and furniture should be carefully vacuumed. Fumigation of living spaces is not recommended. Pets also do not need to be treated because they do not harbor the human scabies mite.

OTHER MITES BESIDES SCABIES

OTHER MITES AT A GLANCE

- Scabies and *Demodex* live in the skin, most other mites drop off human host after feeding.
- Some species are vectors of human disease.
- Chiggers can cause pruritic vesicular, papular, or granulomatous lesions.

There are 45,000 described species of mites that belong to the subclass Acarina and the class Arachnida. Some of the mites that can affect humans are listed in Table 208-1. Human infestation by these mites occurs only accidently (save for *Demodex* species).

Demodex folliculorum hominis and *Demodex brevis* are the only mites that routinely live on humans. These organisms reside in the hair follicle and the infundibulum of the sebaceous gland, respectively. Their presence has been linked with rosacea, perioral dermatitis, and suppurative folliculitis, although a causal role for mites in these diseases has not been established.

Although animal and fowl mites are not primary parasites of humans, *Pyemotes* sp. can cause straw itch, oak leaf eruption, or itch mite eruptions. These mites can cause epidemics of dermatitis with outbreaks in the last decade occurring in several Midwestern States. *Pyemotes ventricosus* and *Pyemotes tritici* occur in animal handlers, farmers participating in harvesting of grain, and those exposed to decorative grain.[27,28] *Pyemotes herfsi*'s normal host is the leaf galls on oak trees, and therefore this eruption characteristically occurs in people who spend time outdoors in or near wooded areas. Typical bites appear on exposed skin as red macules with a small blister center 10–16 hours after contact.

Harvest mites (also called berry bugs, red bugs, scrub-itch mites, and chiggers) are in the family Trombiculidae and are distributed worldwide.[29] In the United States they inhabit mostly the southeast, south, and midwest, in areas of grasslands, forest, and damp areas along lakes and streams. Humans are susceptible to the larvae from April until the first frost. The minute, reddish larvae of Trombicula are less than 0.5 mm long and feed on skin cells of animals, including humans. Rather than sucking blood, these mites inject digestive enzymes into the skin breaking down cells, which can subsequently cause severe reactions and swelling. Each bite has a characteristic red papule with a white, hard central area. After feeding, they drop off their hosts and mature into adults, which are harmless to humans. Rarely does a victim realize when the bite is occurring, as itching from a chigger bite does not develop until 1–2 days after the bite. Chiggers prefer warm covered areas of the body, and thus the bites are often clustered behind the knees, or beneath tight undergarments such as socks, underwear, or brassieres.

TABLE 208-1
Mites (Besides Scabies)

Type of Mite	Scientific Name	Clinical Features/Disease Association
Follicle	*Demodex folliculorum hominis* and *Demodex Brevis*	Associated with rosacea, idiopathic facial burning
Fowl	*Dermanyssus gallinae* and *Demodex Avium*	Pruritic papules, sometimes with a hemorrhagic center
Straw itch	*Pyemotes tritici* and *Pyemotes ventricosus* and *Pyemotes herfsi*	Patchy dermatitis on trunk and arms during and after harvesting
Harvest or red (Chiggers)	Genus *Trombicula Eurotrombicula Alfreddugesi* and *Eurotrombicula Splendidus*	Scrub typhus vector; papular to vesicular lesions found on ankles, waist, or warm skinfolds most common in United States
Animal	*Ornithonyssus bacoti*, *Liponyssoides sanguineus*, *Cheyletiella* sp. "walking dandruff"	Endemic/murine typhus vector; rickettsialpox vector; nonspecific pruritic eruption on body parts in close contact with infested pets
House dust	*Dermatophagoides* sp.	Atopic dermatitis, allergies

The house dust mite is a cosmopolitan guest in human habitation and feeds off flakes of shed human skin. The mites are harmless, but their bodies and excreta are believed to play a role in human disease. They are a common precipitant of asthma, hay fever, and allergic respiratory symptoms worldwide. In addition, atopic dermatitis may be exacerbated in some patients by dust mite allergens.[30,31]

PEDICULOSIS

Pediculosis, the infestation of man by lice, has been a human affliction since antiquity. Three species of lice infest humans: (1) *Pediculus humanus capitis*, the head louse, (2) *Pediculus humanus humanus*, the body or clothing louse, and (3) *Phthirus pubis*, the pubic, or crab, louse.

PEDICULOSIS CAPITIS (HEAD LICE)

PEDICULOSIS CAPITIS AT A GLANCE

- Infestation occurs worldwide affecting hairs of the scalp most commonly in children between the ages of 3 and 12.
- Presence of 0.8 mm eggs (nits) firmly attached to scalp hairs is most common sign of infestation.
- Spread by close physical contact and sharing of headgear, combs, brushes, and pillows.
- Resistance to traditional over-the-counter preparations is growing; topical malathion and ivermectin should be considered in resistant cases.

EPIDEMIOLOGY. Head lice infestations occur worldwide and are most common in children between the ages of 3 and 12.[32] Based on pediculicide sales in the United States, an estimated 10–12 million children are infected each year. Head lice affect all levels of society, and all ethnic groups; however, the incidence is low among African-Americans in the United States, possibly due to an anatomic inability of female lice in America to deposit eggs on coarse curly hair.[33]

Transmission is by means of direct head-to-head contact or by indirect (fomite) transmission through combs, brushes, blow-dryers, hair accessories, upholstery, pillows, bedding, helmets, or other headgear.[34–36–39] Lice can be dislodged by air movement, blow-dryers, combs, and towels, and passively transferred to fabric, facilitating new infestations.[29–33]

ETIOLOGY AND PATHOGENESIS. Head lice are blood-sucking, wingless, highly host-specific insects belonging to the order Anoplura. They are almost 2 mm long with three pairs of claw-like legs that are well adapted for grasping hair. Their entire life cycle is on the scalp. More than 95% of infested individuals have fewer than 100 adult lice in their scalps. The female louse lays 5–10 eggs per day during her 30-day life span. After 10 days, the eggs hatch producing larvae, which are referred to as nymphs or "instars." Instars look like miniature adult louse and go through three stages of development that take 14 days for full maturation. The eggs are laid about 1 cm from the scalp surface, firmly attached to individual hairs with a proteinaceous glue that closely resembles the amino acid composition of the human hair shaft itself.[40,41]

Lice typically survive less than 2 days away from the scalp, although under favorable conditions of heat and humidity, survival has been reported at 4 days. Nits can survive for 10 days away from the scalp.

CLINICAL FINDINGS. Pediculosis capitis is confined to the scalp with nits (Fig. 208-4) found most readily in the occipital and retroauricular regions.

Figure 208-4 Nit sheath. Microscopic view of an egg, containing an unhatched louse, attached to a hair shaft.

Most patients experience pruritus. The average incubation before symptoms is 4–6 weeks. Some individuals remain asymptomatic despite infestation, and can be considered "carriers."

Bites of the mites may produce 2 mm erythematous macules or papules, but usually an examiner only finds excoriations, erythema, and scaling. Other findings may include a low-grade fever, regional lymphadenopathy, and irritability.

Infestations are diagnosed by demonstrating egg capsules (nits) and live lice. Nits are readily seen by the naked eye and are an efficient marker of past or present infestation. They can be differentiated from dandruff, hair casts and the like, as nits are not easily removed from the hair shaft.[42] The color of newly laid or viable eggs is tan to brown; the remains of eggs that have hatched are clear, white, or light in color. The presence of adult lice confirms active infestation. However, lice are fast, avoid light, and blend in with the hair, making them difficult to find. Finding live adult lice or immature nymphs is best achieved with fine combing the hair with a nit comb. Wet combing, in which water and conditioner are applied to the hair prior to using the nit comb, increases the yield by prying the adult lice from the hair follicles.[41,42]

DIFFERENTIAL DIAGNOSIS. See Box 208-3.

COMPLICATIONS.

Secondary bacterial infections can occur with *pediculosis capitis*. In fact, head lice are thought to be the most common cause of pyodermas of the scalp in the developed world.[43]

Head lice and body lice are closely related, so it is not surprising that head lice can serve as host for rickettsiae and have the potential of transmitting diseases.[44,45] Head lice in laboratory experiments have been readily infected with *Rickettsia prowazekii*.[46] *Bartonella quintana*, which causes trench fever, has also been isolated in head lice.[47,48,71,72] Transmission of these infections to humans by pediculosus capitis, however, has never been described and it is highly unlikely to occur outside of experimental conditions.

BOX 208-3 DIFFERENTIAL DIAGNOSIS OF HEAD LICE

- Seborrheic dermatitis (dandruff)
- Insect bites
- Eczema
- Psoriasis
- Hair gel hair spray
- Piedra (a fungal infection)
- Pseudonits (desquamated epithelial cells with sebaceous plugs encircling the hair)
- Delusions of parasitosis

TREATMENT.

Standard treatment recommendations for pediculosis capitis utilize a two-step process of confirming active infestation with live lice and then treating with an over-the-counter or prescription pediculocidal therapy. Pediculocide choice is typically based on local resistance patterns and access of patients to a physician for prescription medications.[49] However, with increasing resistance to pediculocides, a multimodal approach, similar to *Staphylococcus aureus* therapy, is warranted to prevent widespread resistance to currently available products (see Fig. 208-5).[50] This is especially important when treating with prescription pediculocides.

Physical methods to treat infestations, including shaving one's head to avoid infestation, dates back to the sixth century BC, when priests and wealthy Egyptians removed scalp hair and wore wigs. The routine of head shaving for military services today was founded on the same principle. While a buzz haircut may be a solution for boys, such an approach would be traumatic psychologically for girls. Combing out nits is difficult, tedious, time-consuming, and somewhat painful. While wet combing can be an adjuvant to topical insecticidal therapy, is not by itself sufficient in most situations.[44]

Pediculicides remain the most effective treatment for head lice.[51–58] Given (1) variable ovicidal activity, (2) possible lack of patient compliance, (3) growing resistance to pediculocides, and (4) the potential of fomite reinfestation, it is recommended to repeat treatment with all insecticidal treatments in 1 week.

The array of treatments for head lice is summarized in Box 208-4. One of the leading factors for the increasing number of infestations is resistance of lice to topical therapies.[59–65] Since the introduction of insecticides years ago, the louse has adapted by several genetic alterations. The agents with the highest success rates, namely malathion and ivermectin, are prescription products. One trial has shown oral ivermectin given

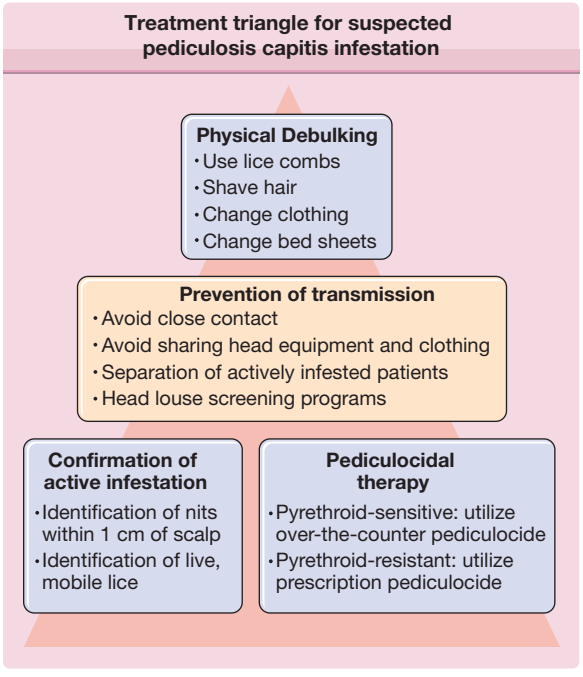

Figure 208-5 Treatment triangle for suspected pediculosis capitis infestation. Although including all items within this figure is impractical for many patients, utilizing one to two elements from each aspect of the entire regimen will increase the efficacy of therapy and reduce the spread of resistance. (Modified from Grayson ML: The treatment triangle for staphylococcal infections. *N Engl J Med* **355**(7):724-727, 2006.)

twice at a 7-day interval to be more effective than topical malathion lotion.[66] However, both pediculocides are highly effective and treatment decisions should be based on local resistance patterns and individual patient characteristics.

There are a number of anecdotal and market-driven reports with occlusive and suffocation methods (such as with application of petrolatum, mayonnaise, dimethicone, vegetable oil, mineral oil, hair pomade, and olive oil).[67,68] To accurately evaluate pediculicidal activity of any compound, one must appreciate that head lice have the ability to "resurrect" from a state of seeming death, in which respiratory and motor function appear to have ceased.[69,70] These insects are less dependent than mammals for continuous nervous control of respiration and circulation, and the exact point of death is not readily defined. Indeed, the World Health Organization recommends pediculicidal testing to be read 24 hours after application of insecticide since otherwise mortality rates are overestimated.[71] Not following these guidelines has lead to overestimates of the efficacy of several alternative treatments with occlusive agents and essential oils from health food stores. Such products slow the movements of adult lice and may allow them to be more easily combed out of their scalps, but these substances are usually not lethal to lice.

Patients should be counseled in at least some effective measures to prevent reinfestation by fomite transmission. After treatment, treated individuals should wear clean clothing, and all clothing, hats, pillow cases, towels and bedding used during the previous week should be washed in hot water and dried at high heat. Nonwashables should be dry-cleaned, ironed, put in the clothes dryer without washing, or stored in a sealed plastic bag in a warm area for 2 weeks. Combs and brushes may be washed in very hot water (65°C) or may be coated with the pediculicide for 15 minutes. Floors, carpets, upholstery (in both home and car) play areas, and furniture should be carefully vacuumed to remove any hairs with viable eggs attached. Fumigation of living spaces is not recommended and pets do not need to be treated because they do not harbor the human head louse. There is no reliable evidence that strict "no nit"

BOX 208-4 TREATMENT OF HEAD LICE AND CRAB LICE

	ADMINISTRATION	RISK FACTORS
Pyrethrins synergized (RID, Pronto, etc.)[a]	Topically for 10 minutes[b]	Allergy to chrysanthemums, ragweed, or related plants
Permethrin 1%[a] (Nix)	Topically for 10 minutes[b]	None
Permethrin 5%	Topically overnight[b]	None
Malathion 0.5%	Topically overnight	High flammability; burning/stinging at sites of eroded skin
Carbaryl 0.5%	Topically overnight	Not available in United States
Lindane 1%	Topically for 4 minutes[b]	US Food and Drug Administration "black box" warning now in effect;[c] banned in California
Topical ivermectin	Topically for 10 minutes	Not currently commercially available
Ivermectin, oral 200 µg/kg	Orally on days 1, 8, and 15	Very good efficacy on adult lice; not ovicidal, hence nits are safe until they hatch; not recommended for pregnant females or children weighing less than 15 kg

[a]Available over-the-counter.
[b]Application to dry scalp and hair followed by adequate wash out with non-medicated shampoo (head lice).
[c]See Box 208-2.

policies at schools are necessary to prevent spread of the infestation, and they should be abandoned in favor of family education regarding effective treatment.

PEDICULOSIS CORPORIS (BODY LICE)

PEDICULOSIS CORPORIS AT A GLANCE

- Infestations most commonly found in homeless, refugees, and victims of war and natural disasters.
- Diagnosis made by presence of nits in lining of clothing, particularly the seams.
- Infections transmitted by body lice include epidemic typhus, trench fever, and relapsing fever.

ETIOLOGY AND PATHOGENESIS. *Pediculus humanus humanus*, body lice, have a very similar morphology to head lice, except they are 30% larger. The body louse's lifespan is 20 days during which the female may lay up to 300 eggs. The lice lay their eggs in the seams of clothing, while obtaining their blood meals from the host. The body louse can survive without a blood meal for up to 3 days.

EPIDEMIOLOGY. Pediculosis corporis requires exposure to the louse and favors an inability to wash and change clothing. Thus, it is most commonly found on homeless individuals, refugees, victims of war and natural disasters, or those forced into crowded living condition with poor hygiene. The infestation is usually transmitted by contaminated clothing or bedding. After exposure, the inability to wash or change clothes allows the infestation to persist.

CLINICAL FINDINGS. Symptomatically, patients complain of pruritus. Most commonly, the only sign of body lice is excoriations, often linear and primarily on the back, neck, shoulders, and waist. Postinflammatory pigmentation is seen in chronic cases. Adult lice are not easily seen except in heavy infestations. Diagnosis is made by closely examining the lining of the clothing, particularly at the seams, for the presence of nits. The clothing may also be shaken over a sheet of white paper, at which time the lice may be seen moving about on the paper.

DIFFERENTIAL DIAGNOSIS. Box 208-5.

COMPLICATIONS. Several important human diseases are transmitted by the body louse. The major diseases include epidemic typhus (caused by a rickettsiae, *R. prowazekii*), murine typhus (caused by *Rickettsia typhi*), trench fever (caused by *B. quintana*), and relapsing fever (caused by a spirochete, *Borrelia recurrentis*).[73–77] Lice obtain organisms, such as rickettsiae and spirochetes, from ingestion of blood meals from infested hosts. Transmission of microorganisms from body lice is not from the louse bite, but rather by (1) contaminated fecal material being scratched into excoriated skin of bite sites, (2) inhalation of dry, powdery louse feces from handling typhus-contamined bedding or clothing or (3) infected lice having its gut ruptured, allowing an infective blood meal to enter excoriations on the skin. In addition, excoriation can lead to secondary infection with *S. aureus*, *S. pyogenes*, and other bacteria.

BOX 208-5 DIFFERENTIAL DIAGNOSIS OF BODY LICE

- Scabies
- Atopic dermatitis
- Contact dermatitis
- Drug reaction
- Viral exanthem
- Other animal parasites
- Systemic causes of pruritus
- Delusions of parasitosis

TREATMENT. The most important treatment of body lice is disinfestation of all clothing and bedding. Beds should be burned or sprayed with lice sprays, because the body louse may lay eggs on the seams of the mattress or couch. Clothing is best treated like biohazardous waste, bagged, and tightly sealed in specially marked, plastic, biohazard bags. The waste is handled separately from other trash until it can be incinerated, maintaining a temperature of 65°C for 30 minutes. If this is not possible, clothing and bedding should be fumigated, machine washed in hot water, and dried on high heat or dry-cleaned. Hot ironing of the seams of upholstered furniture should also be performed and exposure to infested items should be strictly avoided for 2 weeks. The patient should be treated from head to toe with a topical insecticide or given oral ivermectin.

PEDICULOSIS PUBIS (CRAB LICE)

PEDICULOSIS PUBIS AT A GLANCE

- Best to call "crab lice" (rather than "pubic lice") as infestations may involve other hair-bearing sites such as mustache, beard, axillae, eyelashes, eyebrows, and scalp hair.
- Transmitted by sexual or close contact as well as via fomites (contaminated clothing, towels, and bedding).
- Topical therapy options similar to pediculosis capitis, but ivermectin orally, is preferred for this infestation.

ETIOLOGY AND PATHOGENESIS. Pediculosis pubis is caused by infestation of the body with *Phthirus pubis*. Crab lice range from 0.8 to 1.2 mm in length and have wide, short bodies resembling tiny crabs. They have a serrated edge on their first claw, which gives them traction on flat, hairless, surfaces; thus, they can navigate across the entire body surface. They most commonly are found in the pubic and perianal region, but occasionally they also reside in mustache, beard, axillae, eyelashes, eyebrows, and scalp hair. In hirsute individuals, they are also found on the short hairs of the thighs and trunk. The louse has a lifespan of less than 3 weeks during which time the female will lay about 25 eggs on human hairs. The adult crab louse can survive for 36 hours off the human host, while the eggs are viable for up to 10 days.

EPIDEMIOLOGY. Crab lice can be found in all levels of society and all ethnic groups. Patients with crab lice often have another concurrent sexually transmitted disease. Although pediculosis pubis is considered a sexually transmitted disease, transmission has been documented to occur from contaminated clothing, towels, and bedding.

CLINICAL FINDINGS. In the case of crab lice, all hairy parts of the body should be examined, especially the eyelashes, eyebrows, and perianal area. Many individuals have two different hair-bearing sites infested.[78] These lice can be mistaken for scabs or moles, or can blend in with skin color making them difficult to detect. Infested patients have an average of 10–25 adult organisms on their body. Nits can also be identified near the base of hairs (Fig. 208-6). The diagnosis can be confirmed by microscopic examination of the plucked hair to identify the nits and/or adult lice. Although rare, skin lesions named maculae caerulea (eFig. 208-6.1 in online edition), representing hemorrhage, can be seen with pubic lice with slate gray to bluish, irregular-shaped macules about 1 cm in diameter. Pediculosis palpebrarum, or phthiriasis palpebrarum, is the infestation of the eyelashes with crab lice.

Figure 208-6 Pediculosis pubis. Several lice and their dot-like nits attached to the hair shafts can be seen in the pubic area of this patient. (Used with permission from D.A. Burns, MD.)

DIFFERENTIAL DIAGNOSIS. Box 208-6.

TREATMENT. Shaving is not curative as the louse will seek another hairy area of the body to reside. Crab lice are treated with the same topical therapy as that for pediculosis capitis (Box 208-4).[79] In vitro and in vivo resistance to pyrethrins have been shown.[80] There is a lack of appreciation for their tendency to inhabit rectal hair.[78] Unless the physician is certain that only one body area is involved, all hairy areas of the body should be treated because (1) it is not uncommon to have other areas infested, and (2) lice can migrate away from a treated areas to other hair-bearing locations. For this reason, oral ivermectin is recommended for this entity.[71] However, as ivermectin treatment relies on the insect obtaining a blood meal, so the nits are not affected and the patient requires repeat oral ivermectin on day 8 and day 15.

Phthiriasis palpebrarum (Fig. 208-7) has traditionally been treated with petrolatum (Vaseline), but this treatment is slow and needs to be applied at least five times a day for weeks. Ivermectin is the first-line therapy for this condition.[81]

Fomite precautions mirror those discussed previously for pediculosis capitis. Treatment failure is

Figure 208-7 Pediculosis pubis. Eyelash infestation with Pthirus pubis. Nits can be seen attached to the eyelashes. (Used with permission from D.A. Burns, MD.)

usually a result of failure to treat all hairy areas (especially perirectally) or reinfestation from neglecting to treat sexual contacts. Other household members are also infested occasionally and should be carefully questioned for symptoms and/or examined.

Chapter 209 :: Bites and Stings of Terrestrial and Aquatic Life

:: Jennifer S. Daly & Mark Jordan Scharf

BITES AND STINGS AT A GLANCE

- Dog bites account for 80%–90% of all mammalian bites involving humans, but cat bites are more likely to become infected.
- Whether or not postexposure prophylaxis with rabies immunoglobulin and human diploid cell rabies vaccine is needed depends on the circumstances surrounding the bite.
- In the United States, there are approximately five to six deaths from snakebites and probably 6,000 to 7,000 snakebite envenomations each year.
- Most stingray injuries occur when bathers, waders, or fishermen accidentally step on rays as they lie partially covered with sand in shallow waters. The extreme pain caused by the venom may be relieved by soaking the affected body part in very warm water.

Humans are a part of the environment and ideally live peacefully with other animals and plants. However, sometimes the interactions between man and the environment prove harmful to one or the other. The first two sections of this chapter consider the harmful effects of land-borne animal bites, as well as the bacterial and viral infections they may transmit. The last section reviews bites and stings and other forms of injury that may be inflicted by marine life.

BITES OF LAND ANIMALS

EPIDEMIOLOGY

Dog bites account for 80%–90% of all mammalian bites involving humans. Four to five million dog bites are estimated to occur each year in the United States, and, in 2001, it was estimated that 368,245 persons were treated for dog bite-related injuries.[1] The human victim is often a 5– 9-year-old boy who may have been teasing or playing with the dog. Sometimes the bite occurs when a person is trying to break up a pair of fighting dogs or trying to aid an animal. In the United States 4%–5% of dog bites are work related and include bites sustained by postal carriers. Overseas, a higher percentage are produced by untamed animals.[2–4] Most dog bite injuries involve the upper extremities, especially the hands. Cat bites are the second most common type of mammalian bite after dog bites, but the wounds following a cat's bite are nearly twice as likely to become infected as wounds from dog bites.[5]

CLINICAL APPROACH (PATHOGENESIS AND TREATMENT)

The evaluation and treatment of all bite wounds should include taking a careful history of the incident, the type of animal, the site of the bite, and the geographic setting. Hand wounds, puncture wounds, and crush injuries are likely to become infected. Specimens from infected bites should be cultured and a Gram-stained smear prepared; the wound should then be washed, well-irrigated, and left open. Most patients with bites on the hands, deep cat bites, deep cat scratches, and sutured wounds should be treated with amoxicillin/clavulanic acid or ceftriaxone because of the risk of

Pasteurella multocida infection; if the patient is allergic to these agents a quinolone or a tetracycline should be used. Evidence that the use of prophylactic antibiotics is of benefit exists only for bites of the hand. However, once the patient has an infection, intravenous antibiotics and surgical drainage are often required.[4,6–8] Tetanus immune status should be evaluated, and rabies prophylaxis should be considered, depending on the type of animal, local epidemiologic factors, and ability to quarantine the animal for 10 days.[9]

Human bites and monkey bites deserve special mention, because 30% become infected with aerobic or anaerobic mouth organisms. Infection caused by anaerobes may spread through the metacarpal–phalangeal space and causes severe damage. The same procedure should be followed as for other animal bites; that is, culture and Gram stain, thorough washing, and debridement. Wounds, especially hand wounds, should be left open if possible. Evidence suggests that patients with human bites that penetrate the epidermis should be treated prophylactically with amoxicillin/clavulanic acid for 7–10 days or, if the patient is allergic to penicillins, with a fluoroquinolone plus an antianaerobic agent such as clindamycin.[7,10] Clenched-fist injuries should be evaluated by a hand surgeon because of the high likelihood of infectious complications, including septic arthritis and osteomyelitis.[2]

SPECIFIC BACTERIAL INFECTIONS CAUSED BY ANIMAL BITES

Pasteurella multocida INFECTION.

(See Chapter 183). An organism commonly infecting bite wounds is *P. multocida,* a bacterium present in the nasopharynx in 50%–66% of dogs and 70%–90% of cats. The most common pattern is that of local infection with adenitis after a dog or cat bite or scratch. *P. multocida* is the most common pathogen in cat bite infections and may also complicate 26% of dog bite wounds.[5] The infection usually presents within 24–48 hours, often within several hours. In patients with a cat bite, the infection may be followed by tenosynovitis or osteomyelitis as a result of inoculation of the organism into the periosteum by the long, sharp tooth of the animal. *Pasteurella* infections have also been reported after bites of large cats such as lions and tigers.

Systemic infection may also occur as bacteria may enter the respiratory tract through the inspiration of contaminated barn dust, or by inhalation of infectious droplets sprayed by the sneeze of an animal. In such cases, the bacteria probably colonize the respiratory tract and in some patients cause active infection. Bronchiectasis, emphysema, peritonsillar abscess, and sinusitis have all been described with this organism. Finally, systemic infection with bacteremia or meningitis may occur.

P. multocida is a small, Gram-negative, ovoid bacillus that grows well on blood agar but does not grow on selective Gram-negative media such as MacConkey agar. Because of the superficial resemblance of *P. multocida* to *Haemophilus influenzae* and *Neisseria* organisms, infections of the respiratory tract and central nervous system with this bacillus may be misdiagnosed initially.

Treatment of the patient with presumptive *P. multocida* infection should consist of careful washing of the wound and an attempt to leave it open. The empiric antibiotic of choice is amoxicillin/clavulanic acid orally for 7–10 days, with careful follow-up examination of the wound. *P. multocida* is susceptible to penicillin alone, and patients may be switched to penicillin if they have a pure infection with this organism. A fluoroquinolone, a tetracycline, and a trimethoprim-sulfamethoxazole are alternatives. In most patients, the antibiotic is aimed at both the patient's skin flora (such as *Staphylococcus aureus*) and organisms from the animal's mouth. Given the increasing prevalence of community acquired methicillin resistant *S. aureus* (MRSA), patients should be treated with vancomycin, clindamycin, tetracycline, or trimethoprim-sulfamethoxazole if MRSA is suspected (see Chapters 176 and 177).[11]

Staphylococcus intermedius INFECTION.

S. intermedius is an organism associated with dogs weighing more than 40 lb. It is more commonly found in canine gingival flora than is *S. aureus* (39% vs. 10%).[12] It is a Gram-positive, coagulase-positive coccus that can be differentiated from *S. aureus* in the laboratory by biochemical testing. In comparison with *S. aureus*, *S. intermedius* does not produce acetoin from glucose and has β-galactosidase activity. If these tests are not performed (i.e., if only a latex assay is use to identify *Staphylococci*), the laboratory may incorrectly report an isolate as *S. aureus* or unspecified *Staphylococcus*. Antibiotic treatment is the same as that for infections with *S. aureus*, although resistance to oxacillin is uncommon in *S. intermedius* and is growing in importance for *S. aureus*.[11]

Capnocytophaga canimorsus INFECTION.

C. canimorsus is a capnophilic ("carbon dioxide-loving"), facultatively anaerobic, slow-growing, Gram-negative rod associated with dog bites.[13–16] The organism has been found in the oral cavity of 17% of cats and 24% of dogs. Most infections occur in splenectomized or immunocompromised hosts, although fatal infections including meningitis have been reported in immunocompetent hosts and present as overwhelming sepsis.

INFECTION BY *Porphyromonas* SPECIES.

Porphyromonas sp. are slow-growing anaerobic bacteria found in the deep gingival pockets of animal and humans. The organism is difficult to culture, requiring 4–6 days for colony formation as well as vitamin K and hemin in the media.[17,18] Citron and co-workers[19] found *Porphyromonas* sp. in 28% of culture specimens from patients with infected dog and cat bite wounds.

CAT SCRATCH DISEASE.

Bartonella henselae is the most common etiologic agent of cat scratch disease. *Afipia felis* and other *Bartonella* species may cause some cases (see Chapter 182).

TULAREMIA. (See Chapter 183).

RAT-BITE FEVER. (See Chapter 183).

SPECIFIC VIRAL INFECTIONS CAUSED BY ANIMAL BITES

RABIES

Epidemiology. The most notorious viral disease to occur after an animal bite is rabies, which is caused by a Rhabdovirus. Its epidemiology has changed in the past few years as a result of improved control of rabies in the domestic animal population. Now, nonimmune dogs and domestic animals account for only 8% of cases, whereas sylvatic animals, such as skunks, raccoons, red and gray foxes, and bats, represent the greatest potential danger. Rodents, such as squirrels and hamsters, are probably inconsequential as sources of rabies. However, cases of rabies in cattle are increasing.[20] Postexposure prophylaxis, which is nearly 100% effective, has reduced the number of cases of human rabies from more than 100/year a century ago to an average of 1–4 cases a year in the United States today. In 2004, of the eight cases in the 49 states and Puerto Rico, four were acquired as a result of patients' receiving transplanted organs from an infected donor.[20,21] While in the United States death in humans from rabies is rare, WHO estimates that 55,000 deaths occur each year in developing countries, half in children under 15 years.[22]

Live virus is introduced into nerve tissue at the time of the bite, multiplies at the site, and then spreads to the central nervous system. It replicates in gray matter and then spreads along autonomic nerves to the salivary glands, adrenal glands, and heart. The incubation period varies with the site of the bite from 5 days to as long as several years. Clinical features include a prodromal period of 1–4 days, followed by high fever, headache, and malaise. Paresthesia at the site of inoculation occurs in 80% of patients. The next sequence of events is familiar: agitation, hyperesthesia, dysphagia, excessive thirst, paralysis, and death.

Diagnosis. The diagnosis of clinical rabies is difficult and is often not made until after the death of the patient. Viral isolation methods may yield positive results for specimens of saliva or cerebral spinal fluid during the first 2 weeks of the illness, and saliva is infectious, so isolation precautions are needed. Serum antibodies may be detected as early as day 6 and usually by day 13. The fluorescent antibody method for detection of the viral antigen is the most rapid and sensitive means of making the diagnosis, and no matter where the actual bite site is, once patients have central nervous system disease, the diagnosis can be made from a biopsy of skin from the highly innervated hair-covered area of the neck or from brain tissue.

Prevention and Treatment. The most effective prevention for rabies is to avoid contact with any wild animal or any unfamiliar domestic animal. Persons at risk of unavoidable contact with rabies, such as spelunkers, veterinarians, virologists, and travelers spending time in countries where rabies is enzootic, should receive preexposure prophylaxis with the human diploid cell rabies vaccine (HDRV) series (three intramuscular injections on days 0, 7, and 21 or 28) given in the deltoid muscle and repeated every 2 years. In persons vaccinated intradermally (using a lower intradermal dose), the neutralizing antibody titer should be followed, because the immune response may not be fully protective.[23]

The need for postexposure prophylaxis can be determined by the answers to the following questions: (1) What is the status of animal rabies in the locale where the exposure took place? (2) Was the attack provoked or unprovoked? (3) Of what species and size was the animal? (4) What was the state of health and vaccination record of the animal? (5) Will the brain of the animal be examined within 48 hours? (6) Can the animal be effectively quarantined? Most animals transmit rabies virus in saliva only a few days before becoming ill themselves; bats, however, may harbor the virus for many months.

BITES BY HOUSEHOLD PETS. If the dog or cat responsible for the bite is healthy and available for observation for 10 days, the patient should not be treated unless the animal develops rabies. At the first sign of rabies in the animal, the patient should be treated with rabies immunoglobulin (RIG) and the vaccine HDRV. The symptomatic animal should be killed and tested as soon as possible. If the animal is rabid or suspected of being rabid, or if it does not have up-to-date vaccination records, the patient should be treated with RIG and HDRV (see Section "Specifics of Treatment").[24]

BITES BY WILD ANIMALS. All skunks, bats, groundhogs, foxes, coyotes, raccoons, bobcats, and other carnivores should be regarded as rabid unless laboratory test results prove negative. The patient should be treated with RIG and HDRV.

BITES BY OTHER ANIMALS. Bites by other animals (livestock, rodents, lagomorphs such as rabbits and hares, and ferrets) should be considered individually.[23] Local and state public health officials should be consulted about the need for prophylaxis. Bites by squirrels, hamsters, guinea pigs, gerbils, chipmunks, rats, mice, and other small rodents almost never call for anti-rabies prophylaxis.

SPECIFICS OF TREATMENT. The most important step is to cleanse the wound immediately with a brush and soap to remove as much virus as possible. The wound should be rinsed well and then scrubbed a second time with green soap or 70% alcohol, which is rabicidal. If vaccine treatment is indicated, both RIG and HDRV should be given as soon as possible, regardless of the interval after exposure, unless the patient has been previously vaccinated and a serologic assay shows current immunity. In this case, only HDRV is needed and should be given on day 0 and day 3. For nonimmune hosts, administration of RIG

is the most urgent. If HDRV is not immediately available, RIG should be started and HDRV given as soon as it is obtained. RIG (20 IU/kg) should be given immediately—50% around the site of the bite and 50% in the thigh or the arm. This passive immunization will result in the early appearance of antibody but will also inhibit development of the active antibody from HDRV, hence the need for a 28-day series. Active immunization is accomplished using HDRV, given intramuscularly for a total of five doses on days 0, 3, 7, 14, and 28. Serum for rabies antibody testing should be collected 2 weeks after the fifth dose. If there is no antibody response, an additional booster should be given.

MANAGEMENT OF THE PATIENT WITH CLINICAL RABIES. In the rare cases in which a patient is admitted with the clinical diagnosis of rabies, several steps should be taken immediately. First, the diagnosis must be suspected and the patient placed on isolation precautions while the diagnosis is made rapidly by fluorescent antibody staining of specimens from various tissues, as well as immunofluorescence staining of the source animal's brain tissue. Elevated antibody titers in the absence of immunization are clear evidence of infection. The first signs of clinical rabies are usually nonspecific, such as malaise, anorexia, fatigue, headache, and fever. The acute neurologic illness that follows is most commonly characterized by intermittent episodes of hyperactivity. In some cases, however, a progressive paralysis occurs. The usual period from onset of symptoms to onset of coma is 10 days. Risk of exposure for hospital staff includes contact with open wounds or mucous membranes with saliva or other potentially infectious material such as neurologic tissue, spinal fluid, or urine. Blood, serum, and stool are not considered infectious.

Basic clinical management consists of anticipating and preventing all treatable complications of the rabies infection and induction of coma to manage the patient until the patient generates an immune response.[25] Pulmonary hypoxia should be prevented by tracheostomy at the first sign of respiratory difficulty, monitoring of actual partial pressure of oxygen, and use of supplemental oxygen. There are no specific antiviral treatments for rabies, although ribavirin has been tried.[25] Anticonvulsant therapy should also be instituted. Extreme increases in intracranial pressure may be prevented by insertion of a cerebrospinal fluid reservoir that allows withdrawal of the intraventricular fluid and measurement of intracranial pressure. Cardiac arrhythmias may be anticipated with careful monitoring. Rabies had been regarded as uniformly fatal, but there have been patients who have survived with prolonged cardiorespiratory support, and there is serologic evidence that some animals have survived. An aggressive approach to treatment of the patient with known rabies infection is worthwhile. In 2004, a 15-year-old girl without a history of prior rabies vaccination survived after her physicians used a treatment based on induced coma as well as other supportive measures and antiviral agents.[20,25] The World Health Organization has complied information regarding treatment and prevention accessible on their Web site.[22]

HERPESVIRUS SIMIAE (B VIRUS) INFECTION. Herpesvirus simiae (B virus) is enzootic in Old World monkeys, especially rhesus, cynomolgus, and other macaques. The illness in monkeys is similar to that caused by herpes simplex in humans, and asymptomatic monkeys may shed the virus in saliva. Most cases in humans have occurred after direct exposure to macaque monkeys or monkey tissue through bites, scratches, or cuts.[26] A vesicular lesion develops at the wound site with progressive lymphadenitis and fever. Over the next few days to weeks patients develop a severe illness, which is characterized by rapidly progressive ascending neuropathy and encephalitis. The illness is rare and before the availability of antiviral therapy, 72% of cases were fatal. A cluster of four cases occurring in 1987 in Pensacola, Florida, were treated with acyclovir. The two patients who received acyclovir when their infections were localized responded well to therapy and were maintained on oral acyclovir. All macaques should be presumed to be shedding B virus and should be handled accordingly. All monkey-inflicted injuries should be cleansed, specimens should be collected for viral culture, and a physician should evaluate the patient. Clinical and serologic monitoring is critical, and high-risk or infected patients should be treated according to established guidelines. The use of acyclovir or ganciclovir initially and acyclovir for years has led to improved survival in infected patients.

SNAKEBITES

In the United States, there are approximately five to six deaths from snakebites and probably 6,000 to 7,000 snakebite envenomations each year.[26] The largest number of venomous snakebites occur in the Southwestern States. Worldwide as many as 125,000 fatal snakebites may occur each year.[27] Because of regional differences in varieties of snakes, management recommendations including specific antivenom recommendations differ by geographic area. The World Health Organization has published guidelines to help insure the quality and availability of antivenom immunoglobulins worldwide, and has an online database that can be used to explore the global distributions of venomous snake species, and access information on antivenom products and their manufacturers.[28]

The two major poisonous snakes in the Americas are the pit viper (family Viperidae, subfamily Crotalinae, which includes the rattlesnake, water moccasin, and copperhead) and the coral snake (family Elapidae). Poisonous snakes are found in all states of the United States except Maine, Hawaii, and Alaska.[29] The northern copperhead, also called the highland moccasin, is pink or reddish brown and is marked with large chestnut brown barrels resembling dumbbells or hourglasses (Fig. 209-1). The bite is painful but rarely fatal. The timber rattler is dark brown with chevrons of black and brown (Fig. 209-2).

The degree of toxicity of a snakebite depends on the potency of the venom, the amount injected, the size and condition of the snake, and the size of the

Figure 209-1 Northern copperhead.

Figure 209-3 Copperhead snakebite.

person bitten. Pain occurs at the site of the bite (usually within 5 minutes). Signs and symptoms at the bite site include wheal with local edema, numbness, and, within moments, ecchymosis and painful lymphadenopathy (Fig. 209-3).

Nausea, vomiting, sweating, fever, drowsiness, and slurred speech may develop. Bleeding of the gums and hematemesis are common hemorrhagic manifestations. If edema and erythema have not developed within 8 hours after the bite, it can be assumed that significant envenomation did not occur. Estimated mortality rates for victims who receive antivenom in a health care facility are less than 1% and probably less than 0.1%.

For proper treatment, it is extremely important to establish that the bite is from a poisonous snake. Many patients experience symptoms related to fear that may mimic symptoms from venom. The patient should have distinct fang punctures and immediate local pain, followed by edema and discoloration within 30 minutes. It is helpful to inspect the snake, because those that are poisonous may be differentiated from those that are not by the presence of fangs and the shape of the pupils (Fig. 209-4). Availability of a photograph of snakes common to a specific geographic area is important for all hospital emergency wards to aid practitioners in deciding if the patient has been bitten by a poisonous snake.

Although there are still insufficient evidence-based criteria for first aid and out-of-hospital treatment for snakebite envenomations, a rational approach is outlined in Table 209-1.[30] In summary, the patient should be stabilized and transported as rapidly as possible to a health care facility capable of administering antivenom, and the affected site should be immobilized below the level of the heart. Constricting bands such as watches or jewelry should be removed; the routine use of venous compression bands is not recommended.[29] The patient should be kept as immobilized as possible.[29] Venous compression techniques are designed to impede the return of venous and lymphatic flow from the bite site without sacrificing blood flow to the extremity. In cases in which there is likely to be a significant delay in transport and the victim is developing systemic signs of envenomation such as hypotension, these techniques may be of value.[30] Arguments against the use of venous compression techniques include the time that it takes to apply the treatments, which

Figure 209-2 Timber rattlesnake.

TABLE 209-1
First Aid and Out-of-Hospital Treatment for Snakebite Envenomation

1. The patient should be stabilized and transported as rapidly as possible to a health care facility capable of administering antivenom. Consult the CDC and WHO Web sites for updated information on antivenom availability and use.[28]
2. The affected site should be immobilized below the level of the heart, constricting bands such as watches or jewelry should be removed, and the patient should be kept as immobile as possible.[29]
3. The use of venous compression bands or pressure immobilization is not recommended,[29] although there is controversy surrounding their use if there is likely to be a significant delay in transport and the victim is developing systemic signs of envenomation such as hypotension, and in such a case these techniques may be of value.[30]
4. The value of using a suction device to extract venom is debated in the literature.[29] If such a device is applied in the field and fluid is accumulating in the suction cup, it can be left in place until the patient reaches a medical facility.[30]
5. The use of cryotherapy, incision, or excision of the bite site, arterial tourniquets, and electroshock therapy as part of emergency field therapy should be discouraged.

CDC = Centers of Disease Control and Prevention; WHO = World Health Organization.

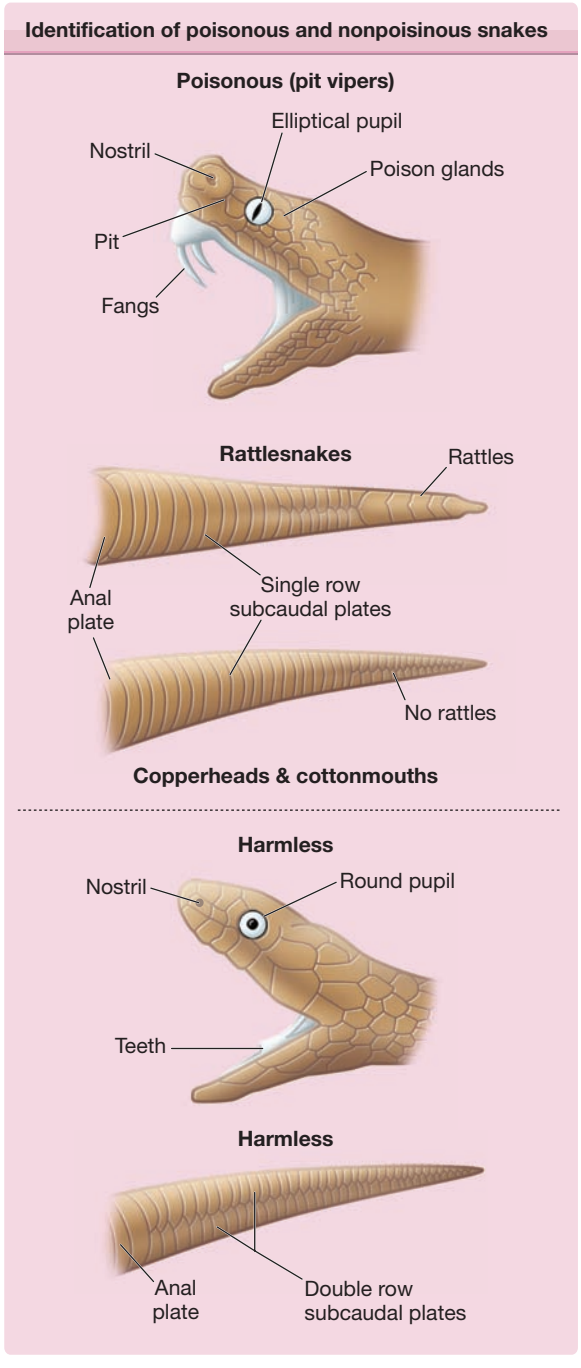

Figure 209-4 Identification of poisonous and nonpoisonous snakes. (From Wingert WA, Wainschel W: A quick handbook on snake bites. *Resid Staff Physician*, 1977, p 56, with permission.)

may further delay transport time. Additional arguments against the use of these techniques include the potential for concentrating the venom in the affected limb, which may worsen local necrosis, along with the possibility of a bolus effect when the compression is released.[30] Another possible disadvantage of the use of these compression techniques is the potential for them to cause arterial compression if the affected limb swells in reaction to the toxin. If a decision is made to use a venous compression band in the field, arterial pulses should be palpable distal to the ligature, and the dressing should be checked frequently to make sure that it is has not become too tight. If a venous compression dressing has been applied in the field and is not causing vascular compromise, it should be left in place until the patient reaches a health care facility and antivenom is at the bedside.[30]

The role of surgical intervention in the treatment of snakebite envenomations is limited in most cases. Surgery is appropriate only if medical treatment fails. This includes elevation of the bitten body part in conjunction with the administration of four to six vials of Crotalidae polyvalent immune Fab (ovine) (FabAV) over the course of 1 hour, fails.[29] Debridement of truly necrotic skin and subcutaneous tissues is recommended 4–5 days after envenomation. In cases of bites to a digit, if there is severe swelling and the finger is tense, blue, or pale, a digit dermotomy may be of use. True compartment syndrome involving an extremity is a rare complication of snakebite envenomation. Fasciotomy should be used only in cases of increased compartment pressure that has not responded to prompt and sufficient treatment with antivenom.[31]

The primary treatment for crotaline snake venom poisoning is prompt and adequate dosing with antivenom. Antivenom is most effective if given within 4 hours of the snakebite (Box 209-1).

FabAV should be used for all severe American crotaline snakebites, but not those of the coral snake. The dosage should be guided by the severity and progression of local changes and systemic clinical signs. Because some patients develop recurrent manifestations of envenomation after initial treatment, both a loading dose of four to six vials of FabAV and then, once initial control has been achieved, three maintenance doses 6, 12, and 18 hours later are recommended.[29]

Supportive treatment is indicated, including hospitalization with careful evaluation of baseline hematocrit, platelet count, and prothrombin time. Coagulopathy should be corrected by using antivenin, because fresh frozen plasma is ineffective.[29] The wound should be cleansed and covered. Antitetanus therapy and antibiotic prophylaxis with penicillin, ampicillin/sulbactam, or tetracycline should be initiated for severe bites.

BOX 209-1 ANTIVENOM FOR CROTALINE SNAKE BITES

- Emergency information and antivenom are available in the United States through the nationwide poison control center network, which can be reached 24 hours a day by calling 800-222-1222.[29]
- The World Health Organization Web site has a database with information and pictures to aid providers in finding the correct antivenom[28]: http://apps.who.int/bloodproducts/snakeantivenoms/database/.

BITES AND STINGS OF AQUATIC ORGANISMS

SEAL BITE

Normally, a seal bite occurs on the finger of a trainer or a seal hunter—thus the term *seal finger* or *spaek finger*.[32,33] The etiologic agent is unclear and is controversial. One study suggests that a virus similar to that causing Orf may be the culprit,[33] although *Mycoplasma* sp. have been isolated, and some patients respond to tetracycline (see Chapter 183). The incubation period of 4–8 days is followed by throbbing pain, erythema at the site, and swelling of the joint proximal to the bite. Untreated, seal finger progresses to cellulitis, tenosynovitis, and arthritis. Tetracycline, 500 mg orally four times a day for 10 days, remains the antibiotic of choice.[30,32] It is also helpful to immobilize and elevate the finger as well as soak it several times a day (see Chapter 183).

INJURIES CAUSED BY JELLYFISH, PORTUGUESE MAN-OF-WAR, SEA ANEMONES, AND CORALS

Stings caused by jellyfish, Portuguese man-of-war, sea anemones, and corals are the most common envenomations experienced by humans in marine environments. All of these creatures are members of the phylum Cnidaria, formerly known as *Coelenterata*. They are divided into three major classes. The first class, Hydrozoa, includes the Portuguese man-of-war, fire corals, and hydroids. Jellyfish belong to the second class, Scyphozoa. The third class, Anthozoa, encompasses sea anemones and true corals. Approximately 100 of the 9,000 species of Cnidaria that have been identified may cause injury to humans.[34]

Cnidarians are radially symmetric animals with body walls formed by an inner and outer layer of cells enclosing a jelly-like substance. They may be either free floating in the water like jellyfish or sessile like corals.[34] Almost all cnidarians possess nematocysts, or stinging capsules, which are usually concentrated on some form of tentacle. Each nematocyst contains a toxin or group of toxins and a coiled thread-like apparatus with a barbed end that functions like a flexible hypodermic syringe (Fig. 209-5). When the nematocyst comes into contact with a victim, the barbed end is discharged, and the toxin is injected into the skin.

Cnidarian stings range from mild, self-limited irritations to extremely painful and serious injuries, depending on the toxin of the species involved and the magnitude of the envenomation. Stings from certain species such as the cubomedusae, or box jellyfish, can be fatal.

In most cases, jellyfish stings elicit toxic reactions that may be localized and/or systemic. Although immediate-type hypersensitivity reactions, including urticaria, angioedema, and anaphylaxis, occur less frequently, they require prompt medical intervention, because shock and death may ensue in highly sensitized individuals. Allergic contact dermatitis, delayed and persistent hypersensitivity reactions, granuloma annulare, and erythema nodosum are other possible cutaneous reactions to jellyfish stings.[35]

Figure 209-6 *Cyanea capillata*, also known as *sea nettle* or *lion's mane*, is a common cause of jellyfish stings. (BW Halstead, used with permission from World Life Research Institute.)

Figure 209-7 *Chrysaora fuscescens* is commonly known as the Pacific Sea Nettle or West Coast Sea Nettle. Its sting causes much discomfort but only rarely does the patient require medical attendtion.

INJURIES CAUSED BY JELLYFISH

Sea Nettles. Among the organisms most commonly causing jellyfish stings are the sea nettles, which comprise two different species, both of which inhabit Atlantic as well as Indo-Pacific waters. *Cyanea capillata* and its relatives are the larger of the two species, with a bell measuring up to 1 m and numerous tentacles reaching 30 m in length (Fig. 209-6).[36] *Chrysaora fuscescens* (Fig. 209-7) is found in the Pacific waters off the coast of California. *Chrysaora quinquecirrha* is smaller, with a white or rusty bell that may reach 30 cm with four digestive tentacles hanging from it. Although sea nettle stings are seldom lethal, they can be quite painful.[37] Initially the victim experiences a sharp burning pain in the area contacted by the tentacles. Within minutes, the sting area develops a zigzag, whip-like pattern of raised red welts 2–3 mm wide (Fig. 209-8). The duration of acute pain may vary, but the pain often begins to abate in 30 minutes. The wheals usually subside by 1 hour, but purplish brown petechial and postinflammatory pigmentation may persist for several days.

Portuguese Man-of-War. *Physalia physalis* is the species name for the Portuguese man-of-war, which is a member of the class Hydrozoa and is therefore not a true jellyfish. *P. physalis* is encountered in both Atlantic and Mediterranean waters, and is easily recognized by its translucent blue to pink or purple bladder-like float with multiple tentacles (Fig. 209-9). *P. physalis* is distinguished from its Pacific ocean relative *Physalia utriculus*, commonly known as the *blue bottle*, by its larger bell, which ranges in size from 10 to 30 cm, and multiple fishing tentacles extending up to 30 m; in contrast, *P. utriculus* has only a single tentacle that rarely exceeds 5 m.[38] These tentacles are armed along their entire length with hundreds of thousands of nematocysts arranged in stinging batteries, with each battery containing hundreds of nematocysts. The nematocysts remain active even after portions of the tentacles are broken off in storms or when these animals are stranded on the shoreline by high winds or waves.

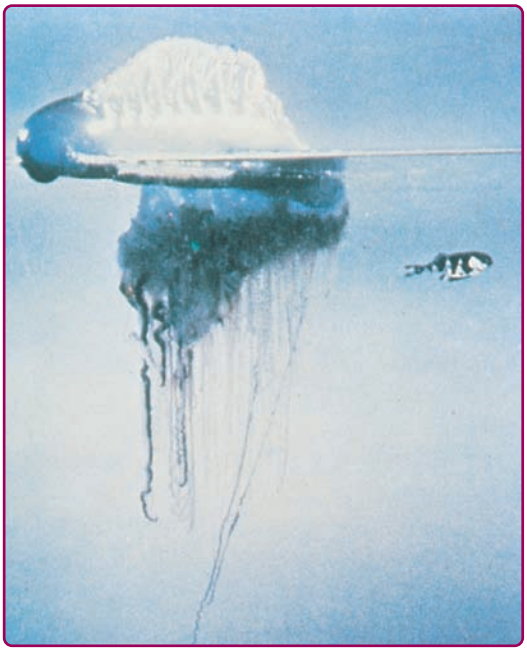

Figure 209-9 *Physalia physalis*, the Portuguese man-of-war, is distinguished by its bladder-like float and numerous trailing tentacles. (BW Halstead, used with permission from World Life Research Institute.)

Figure 209-10 This diver surfaced directly under a large Portuguese man-of-war and suffered a severe sting with bulla formation and tissue necrosis. (S Anderson, used with permission from World Life Research Institute.)

A beached Portuguese man-of-war can cause a severe sting when stepped on or touched. Children who are stung after handling these animals and then cry and rub their eyes may develop an acute conjunctivitis.

Stings of *P. physalis* are more painful and severe than those caused by sea nettles and are more extensive and serious than those caused by *P. utriculus*. At the moment of contact with the tentacles of *P. physalis*, the victim experiences a sharp, shock-like, burning pain. There may be painful paresthesias or numbness in the sting area. Initially, the sting area appears as an irregular single line or multiple lines composed of red papules, beaded streaks, or erythematous welts that correspond to the areas of tentacle contact. The wheals resolve in hours but may progress to vesicular, hemorrhagic, necrotic, or ulcerative stages before healing (Fig. 209-10).[39]

Postinflammatory striae may persist for weeks to months. Severe localized complications of *P. physalis* stings may also include arterial spasm in the sting site that can result in distal digital gangrene.[40,41]

Within 10–15 minutes of a *Physalia* sting, the victim may develop symptoms of an envenomation reaction characterized by nausea, abdominal cramps, muscular pains, backache, irritability, dyspnea, and chest tightness. Intravascular hemolysis and acute renal failure were reported in a 4-year-old girl after a severe sting by *P. physalis*.[42] Most reports of death due to stings of *P. physalis* are not well-documented, but well-substantiated case reports of human fatalities do exist.[43–45]

Cubomedusae (Class Cubozoa): Box Jellyfish. Of all the species of jellyfish that cause painful stings and distress to swimmers, the species with the most established record of lethality are the cubozoans. *Chironex fleckeri* or box jellyfish causes at least one death each year in Australia.[46] The fatality is usually a child, presumably because the size of the victim and the total area of the sting determine the likelihood of death. Until recently, most of the published cases of *C. fleckeri* stings involved fatal or nearly fatal envenomations, but less serious stings do occur in endemic areas.[47–49]

C. fleckeri (commonly known as the *sea wasp*) is an advanced species of jellyfish, with a semitransparent cubic bell that may grow to a volume of 9 L and weigh more than 6 kg (Fig. 209-11).[46] Trailing from the bell are up to 60 stinging tentacles, which may reach 2–3 m in length. When a human comes into contact with a box jellyfish, some of the tentacles are torn off and adhere to the skin. Rescuers of *C. fleckeri* sting victims must exercise caution, because they also are at risk of envenomation until the tentacles have been neutralized and removed.

The stings appear initially as linear welts that give the patient the appearance of having been whipped.[46] Fresh stings of *C. fleckeri* are easily recognized because they have a diagnostic, frosted, cross-hatched, or ladder-like appearance (Fig. 209-12). Microscopic diagnosis is also possible from blade scrapings or tape-strippings from the sting site. The intense pain may persist for many hours. Severely stung areas of skin take on a dusky cyanotic appearance and blister formation and necrosis may occur. The healing process is slow and may be complicated by bacterial superinfection and scarring.

Death may ensue within minutes due to cardiotoxic and neurotoxic agents in the venom that can produce ventricular arrhythmias and cardiac arrest, and respiratory failure, respectively.[48] Intravascular hemolysis caused by the toxin can precipitate acute renal failure. First aid for these victims frequently

Figure 209-11 The deadly box jellyfish, *Chironex fleckeri*, is found in Indo-Pacific waters off the coast of Northern Australia. (Used with permission from R Hartwick.)

involves cardiopulmonary resuscitation. Intravenous verapamil has been proposed for both treatment and prophylaxis of ventricular arrhythmias.[50,51] Antivenom is available for *C. fleckeri* stings, and its early use in severe envenomations may be lifesaving and significantly reduces the pain and inflammation at the sting site.[47]

TABLE 209-2
Prevention of Jellyfish Stings

1. Swim only at patrolled beaches with properly trained lifeguards and adequate treatment facilities.
2. Avoid swimming in infested waters, especially after a storm, because stings may result from remnants of floating damaged tentacles.
3. Beware of apparently dead or beached jellyfish.
4. When snorkeling or scuba diving, wear protective clothing such as a wet suit, long-sleeved shirt, pants, or long woolen underwear, and gloves. In areas where Irukandji syndrome occurs, wear a Lycra stinger suit.
5. Use sunblock containing jellyfish and "sea lice" repellent.
6. Bathing beaches should be closed during periods of high jellyfish infestation.

Irukandji syndrome is a severe and delayed response (usually 30 minutes but between 5 and 40 minutes) to the sting of a small box jellyfish, termed the *Irukandji jellyfish*, that has resulted in the death of two tourists in the Cairns–-Port Douglas region of Australia.[52] The classic syndrome consists of local signs of inflammation together with severe back pain, excruciating muscle cramps, piloerection, sweating, nausea, vomiting, headache, and palpitations. The most severe cases may progress to include extreme hypertension and cardiac failure. Only one species, *Carukia barnesi*, has been clearly linked to this syndrome, but it is thought that at least six different species of small jellyfish, each with only one tentacle arising from each corner of the bell (carybdeids), may be etiologic agents. The stings most often occur in deep water. Treatment includes application of vinegar to discharge nematocysts and victim transport for medical attention including pain control and α-blockade, because the venom is thought to act as a presynaptic neuronal sodium agonist and to stimulate norepinephrine release.

Prevention and Treatment of Jellyfish Stings. Tables 209-2–209-4 give details on the prevention of jellyfish stings and first aid for and treatment of the stings. Systemic reactions may occur, and the treatment for these includes support of vital

TABLE 209-3
First Aid Treatment of Jellyfish Stings

1. Remove or rescue the victim from the water.
2. Stabilize vital functions: Airway, breathing, circulation.
3. Immobilize the affected part to prevent further envenomation by adherent tentacles.
4. Identify the type of jellyfish sting by considering locale, time of year, and indigenous species and by observing the sting pattern. Preserve a portion of the tentacle for future identification. Tape-strip or scrape the sting site for microscopic analysis of the nematocysts if no tentacles are available.
5. To prevent further envenomation of the victim and to reduce the chance of a sting to the rescuer, disarm the nematocysts before removing the adherent tentacles.

TABLE 209-4
Organism-Specific and Follow-up Treatment of Jellyfish Stings

1. If *Chironex fleckeri* or other box jellyfish species that cause the Irukandji syndrome are suspected, douse or spray dilute acetic acid (3%–10%) or household vinegar over all areas of tentacle contact for at least 30 s.
2. For sea nettles, mix sodium bicarbonate (baking soda) with water to form a slurry and pour over the affected area or apply the powder directly to the tentacles.
3. For *Physalia physalis* stings, a slurry of baking soda is indicated. Vinegar had been reported to neutralize nematocysts of *P. physalis*, but work with species from Australia indicate that it may cause a discharge of nematocysts in some cases.
4. If vinegar or baking soda is unavailable, papain, available as a powdered meat tenderizer, may be applied directly as a powder or mixed in water as a slurry to sting areas and tentacles of both sea nettles and Portuguese man-of-war.
5. If nothing else is available, the tentacles can be rinsed off with seawater.
6. Do not use fresh water, methylated spirits, or alcohol in any form to deactivate tentacles, because these all may cause a rapid massive discharge of nematocysts.
7. After the tentacles have been disarmed, they may be carefully removed with a forceps or gently scraped away from the skin with shaving cream and a razor or a plastic card, shell, or knife.

functions with cardiopulmonary resuscitation, oxygen, and intravenous fluids.[53,54] Application of a venous-lymphatic constriction bandage proximal to the wound site should be considered in the case of severe stings when systemic reactions are present or likely to occur, when topical deactivation of tentacles is not possible, and when transport to receive specific antivenin for *C. fleckeri* stings is available. The antivenin is prepared from sheep serum and may therefore pose a risk of allergic reaction in sensitive individuals.[35,37] The preferred route of administration is intravenous, but the antivenin may be given intramuscularly. In severe stinging, it has proved lifesaving. It is also the only treatment that can alleviate the intense pain and may reduce inflammation at the sting site and decrease the chance of scarring. Intravenous administration of verapamil has been advocated for both treatment and prophylaxis of arrhythmias.[50,51] For pain in severe stinging, parenteral narcotic analgesics and ice packs, as well as antivenin, should be considered. Local reactions may be treated with topical anesthetic ointments, creams, lotions, or sprays to relieve itching or burning pain.[34] For delayed-type hypersensitivity reactions, which may occur days to weeks after the stinging (see Fig. 209-13), topical glucocorticoids, topical tacrolimus, antihistamines, and systemic glucocorticoids should be used as necessary.[36]

Secondary infections should be treated with the appropriate parenteral antibiotics, and antitetanus therapy should be considered. Application of ice or cold packs can relieve the pain of mild to moderate stings of many types of jellyfish, and aspirin or acetaminophen, alone or in combination with codeine, can be used to relieve persistent pain.

Figure 209-13 Delayed-type hypersensitivity reaction occurring about 2 weeks after jellyfish stings on the leg.

SEA ANEMONE DERMATITIS. Sea anemones are members of the phylum Cnidaria, class Anthozoa. They are sessile creatures with flowery tentacles armed with nematocysts (Fig. 209-14). The stings of sea anemones may cause dermatitis in sponge fishermen, sponge divers, and beachcombers who gather snails and crabs from rocky hollows along the shore. Their toxicity to humans depends on the species. After the immediate reaction has subsided, delayed-type hypersensitivity reactions can develop at the site of a sting from a sea anemone (Fig. 209-15).

The genus *Sagartia* is the cause of sponge fisherman's disease.[34] This anemone lives at the base of sponges sought by commercial fishermen. When they harvest or sort the sponges with their bare hands or forearms, they are likely to come into contact with the tentacles of *Sagartia*. Itching and burning occur at the sting site within minutes, accompanied by erythema, edema, and vesicles.[34]

Treatment of sea anemone stings is similar to that of jellyfish envenomations (see Section "Prevention

Figure 209-14 The flowery tentacles of the sea anemone can cause envenomations similar to jellyfish stings. (Used with permission from Marty Gilman, Worcester, MA.)

Figure 209-15 Delayed-type hypersensitivity reaction to a presumed sea anemone sting. This 11-year-old girl stepped into a hole while wading in shallow waters on the South Carolina coast. She experienced an immediate burning pain with erythema and swelling of both lower legs that subsided within a day. Several days later she developed a pruritic linear eruption. A diagnosis was made of a delayed-type hypersensitivity reaction that developed in the sting site and corresponded with the tentacle marks from what was presumed to be a sea anemone envenomation.

and Treatment of Jellyfish Stings").[56] The tentacles should be removed carefully.[34] Both vinegar and Stingose (an aqueous solution of 20% aluminum sulfate and 11% surfactant) have been suggested for application to neutralize the sites of anemone stings.[57] Sea anemone sting sites often heal slowly and may require treatment with antibiotics.

INJURIES CAUSED BY FIRE CORAL AND CORAL CUTS. Corals are colonial organisms belonging to the phylum Cnidaria. Coral injuries may be caused by nematocyst stings or lacerations. Both injuries may occur at the same time and may be complicated by foreign-body reactions, bacterial infections, and localized eczematous reactions. For most true corals nematocyst envenomation is a relatively innocuous experience, resulting in mild pruritic erythema that requires little if any treatment. Calamine lotion or antipruritic lotions may bring relief.[58]

In contrast to the stings of true corals, the sting of the fire coral, *Millepora alcicornis*, is quite painful, as many scuba divers and snorkelers from the Florida Keys to the Caribbean will attest (Fig. 209-16). The wet mucous membrane or slime surrounding the organism contains numerous nematocysts that readily discharge on contact with the skin, causing immediate burning and stinging pain. Within 1 to several hours a pruritic erythematous papular eruption appears, which in severe

Figure 209-16 The mustard-colored finger-like outcropping in the upper left quadrant of this formation of coral and hydroids is a typical example of fire coral.

cases may become pustular and, in rare cases, may progress to necrosis and eschar formation.[58] Lesions heal in 1–2 weeks, often with postinflammatory hyperpigmentation. A delayed and persistent allergic contact dermatitis has also been reported to occur from a fire coral sting in the Red Sea.[59]

Fire coral stings should be rinsed with seawater to remove undischarged nematocysts. The sting area can then be compressed with either 5% acetic acid (vinegar) or 40%–70% isopropyl alcohol for 15–30 minutes or until the pain is relieved.[37,60] Seawater compresses, hot to the point of tolerance, are also reported to inactivate the toxin. A topical steroid cream or ointment may relieve pruritus and promote healing.

Coral cuts, lacerations caused by the razor-sharp exoskeletons of coral, are notorious for their slow-healing and propensity for secondary infection. Factors that complicate healing include the following: (1) wounds often involve the lower extremities and these generally heal more slowly because of decreased tissue blood supply; (2) wound edges are often irregular, contused, crushed, and abraded; (3) contamination of wounds is likely because of pathogenic bacteria in shore waters; and (4) foreign bodies, including marine algae growing on the coral or portions of the coral itself, may be implanted in the wound.

Treatment of coral cuts should begin with vigorous cleansing of the wound with soap and water with a soft brush or rough towel, followed by copious irrigation with saline to remove foreign bodies. If the wound is extensive, local anesthesia may be required to allow adequate cleansing, exploration, and debridement and to achieve good hemostasis. Hydrogen peroxide washing of the wound before dressing it is recommended.

The decision whether to perform primary closure of a coral cut wound or to allow it to heal by secondary intention depends on the location of the wound, the degree of tissue trauma at the wound margins, and the likelihood of subsequent infection. Tape-stripping is preferable to suturing of leg wounds, because sutured leg wounds have a high chance of abscess formation. Once the wound is closed, antibiotic ointment and rest are advisable. Tetanus prophylaxis should be given according to immunization history.

Figure 209-17 The poison bun sponge, *Fibula nolitangere*, can cause a severe irritant or toxin-induced contact dermatitis.

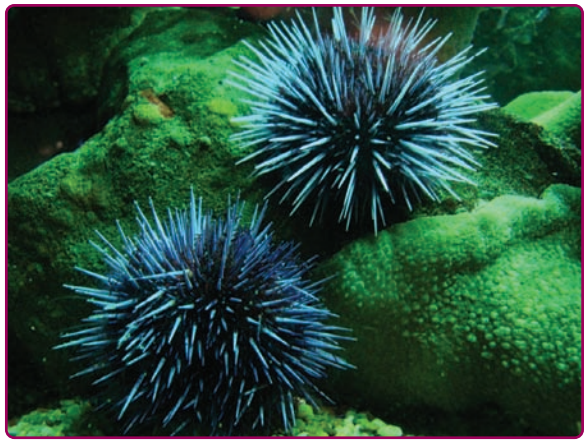

Figure 209-19 Purple sea urchin, *Strongylocentrotus purpuratus,* commonly found along the Pacific coast of the United States.

DERMATITIS FROM SPONGES

Sponges are members of the phylum Porifera, class Desmospongiae. They are simple multicellular animals that live attached to the sea bottom. Sponges grow by forming a series of hollow-centered branching tubes composed of a fibrous material called *spongin*, which contains spicules of calcium carbonate or silica.[34,61,62] Spicules of certain species of sponges are capable of penetrating the skin, causing a localized irritant or foreign-body reaction. Treatment of sponge spicule dermatitis involves tape-stripping of the affected area.

At least 13 species of sponges can cause a toxic dermatitis. Of these, the most commonly encountered are the West Indian and Hawaiian fire sponge, *Tedania ignis*; the poison bun sponge, *Fibula nolitangere* (Fig. 209-17); and the red sponge, *Microciona prolifera*, found in the Northeastern United States.[63] These creatures are covered by a surface secretion, or slime, that produces an irritant or toxin-induced dermatitis when contacted by bare skin.[62]

Symptoms of itching, prickling, stinging, or burning appear within minutes of exposure and are followed within a few hours by pain, swelling, and stiffness. If the fingers are involved, they often become immobile within 24 hours. The first cutaneous sign of sponge poisoning is local erythema, which progresses to a papular, vesicular, or bullous eruption with weeping of a serous or purulent fluid.[62,63] Desquamation of the site occurs within several days. Erythema multiforme and anaphylactoid reactions have been reported in highly sensitized individuals. Treatment of sponge dermatitis is similar to that of severe poison ivy.[63]

INJURIES CAUSED BY ECHINODERMS: SEA URCHINS, STARFISH, AND SEA CUCUMBERS

SEA URCHINS. Sea urchins are spiny creatures that belong to the phylum Echinodermata, class Echinoidea. They are encased in a fragile, roughly spherical, calcareous shell, which is protected by a formidable array of mobile spines and pincer-like organs known as *pedicellariae* (Fig. 209-18).[64,65]

Bathers, surfers, divers, and fishermen are all at risk for sea urchin injuries. These creatures, such as the purple sea urchin, hide in rocks in low tide zones along the Pacific coast between Alaska and Mexico (Fig. 209-19).

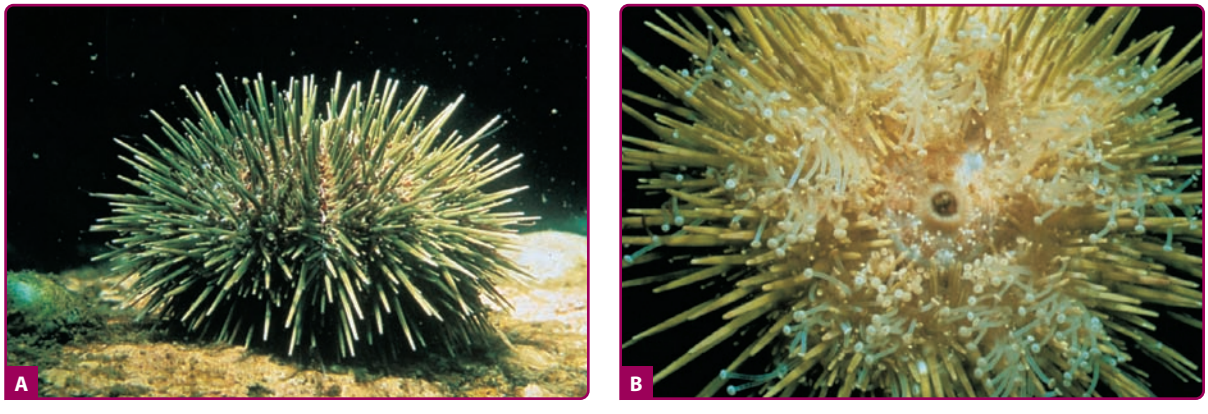

Figure 209-18 Lateral (**A**) and ventral (**B**) views of a sea urchin demonstrate this animal's protective spines and venomous pedicellaria underneath. (Used with permission from Marty Gilman, Worcester, MA.)

Injuries may occur when the victim steps on an urchin, driving the spines into an unprotected foot, or as a result of loss of balance or wave action, in which case the hands or other body parts may be impaled. Sea urchin spines are composed of calcium carbonate and are covered with a proteinaceous membrane.[62] Injuries from sea urchins may be inflicted either by penetrating wounds from the animals' spines, which often break off and become imbedded in the wound, or by bites from the pedicellaria. In certain species, the spines or pedicellaria are venomous. This fact may explain why the pain of some sea urchin wounds is so excruciating and out of proportion to the apparent injury.

Encounters with sea urchins can result in both immediate and delayed reactions. Immediate reactions are usually localized and are initially manifested by a severe burning pain at the wound site, which quickly becomes red and swollen and may bleed profusely. There may be a black or purple discoloration at the site of the spine penetration due to either retained spines in the wound or to a tattoo-like effect from dye released by spines that have exited intact, but this discoloration will likely disappear within 48–72 hours.[60] Paresthesias may develop at the wound area. Systemic symptoms are not common but can occur in injuries due to particularly venomous species. Symptoms may include nausea, syncope, paresthesias, ataxia, muscle cramps, paralysis, and respiratory distress.[63]

Delayed-type hypersensitivity reactions may occur with erythema and intense pruritus days after the initial injury.[66] In one of these cases, the diagnosis was confirmed by patch testing with extracts of the ground sea urchin spines.[67] Nodular reactions are localized to the area of spine penetration and are not usually painful. Nodules may take on colors from the dye in the spines[64] and may have a central umbilication or a keratotic surface[64] (Fig. 209-20).

The diffuse form more commonly involves the fingers or toes and is manifested by a fusiform swelling of the affected digit with accompanying pain and loss of function.[63,64] In addition to joint synovitis and arthritis, osteoarticular complications of sea urchin spine penetration may include tenosynovitis with or without destruction of the underlying bone, fasciitis, and bursitis.[68] Sea urchin spine wounds may also cause direct mechanical injuries to nerves and may be complicated by secondary infection.[69]

Initial first aid for the pain from immediate reactions is to soak the affected area in hot water [43°C to 46°C (110°F to 115°F)] for 30–90 minutes until maximal relief is obtained. Infiltration of the wound site with 1%–2% lidocaine without epinephrine may be required in some cases to produce significant pain relief.[70] Spines protruding from the wound may be carefully removed. They are very fragile; therefore, it is difficult to extract the entire spine intact. Tumescence of the skin with a local anesthetic may allow superficially imbedded spines to be extracted when radiographs demonstrate no evidence of joint or bony impingement.[65] More invasive attempts at spine removal should not be made without the benefit of aseptic surgical facilities and radiographs to confirm the spine locations. Removal of the spines may be aided by the use of an operating microscope. Antibiotics are indicated for secondary infections, and tetanus prophylaxis should be given if indicated.

STARFISH. Certain species of starfish may produce puncture wound injuries similar to those caused by sea urchins. The crown-of-thorns starfish, *Acanthaster planci*, accounts for most severe starfish envenomations.[63] The ice pick-like spines of *A. planci*, which may reach 4–6 cm in length, are covered with a thin skin and glandular tissue that produce a poisonous slime.[70] The resulting wound is quite painful and may be accompanied by numbness and paresthesias. Systemic symptoms including nausea, vomiting, and muscle weakness are infrequent and short lived.[63] Fragments of spines and their surrounding integument may become imbedded in the wounded area, resulting in granulomatous reactions.

Treatment is similar to that of sea urchin wounds.

Figure 209-20 **A** and **B.** Nodular reactions to imbedded sea urchin spines. (Used with permission from Karen Rothman, MD.)

SEA CUCUMBERS. Sea cucumbers are sausage-shaped, bottom-feeding echinoderms that can produce a papular contact dermatitis by means of a toxic liquid substance, known as *holothurin*, that is secreted from their body walls.[34] Conjunctivitis, even blindness, can result from corneal involvement if the toxin comes in contact with the eyes.[63] Prevention of sea cucumber dermatitis involves protecting the skin and eyes from contact with these creatures and educating children and curious divers about the risk of handling them. Treatment consists of washing the affected area with soap and water to remove the toxin and then treating as for a mild contact dermatitis.

DERMATITIS AND BITES FROM MARINE WORMS

BRISTLEWORM DERMATITIS. Bristleworms are multisegmented marine worms of the phylum Annelida, class Polychaeta (which means "many bristles"; Fig. 209-21). Each segment of the worm is armed with rows of silky or bristle-like, hollow, venom-filled setae that can easily penetrate and break off in the unprotected skin of a victim as do cactus spines.[70] Contact with the bristleworm results in an erythematous papular or urticarial eruption at the site, accompanied by symptoms of paresthesias, intense itching, or burning pain.[34,70] The bristles are too small and fragile in most cases to be removed with a forceps; however, tape-stripping with cellophane adhesive tape can be effective. After the setae have been removed, the application of ammonia soaks or alcohol or water compresses may bring symptomatic relief.

LEECH BITES. Leeches are another class of segmental worms whose bites may be encountered in freshwater or saltwater as well as on land. Although freshwater leeches are capable of attaching painlessly to their human hosts, saltwater leeches produce bites with pain similar to that of a bee sting. Leeches inject a powerful anticoagulant, hirudin, into the wound, as well as other antigenic substances that are capable of eliciting allergic reactions (including anaphylaxis) in sensitized individuals. Local symptoms of leech bites include bleeding from the puncture marks, pain, swelling, redness, and severe pruritus; urticarial, bullous, or necrotic reactions may occur in sensitized persons.[34]

Severe ulcerations may result if the leech is removed forcibly and its mouth parts are left behind in the bite site. Leeches must be induced to fall off by applying a noxious agent (such as alcohol, vinegar, brine, or a match flame) to their site of attachment.

Figure 209-21 *Hermodice carunculata*, the West Indian bristleworm, can inflict a painful wound with its hollow, venom-filled bristle-like setae. (Used with permission from Marty Gilman, Worcester, MA.)

CERCARIAL DERMATITIS (CLAM DIGGER'S ITCH). Cercarial dermatitis, also known as *schistosome dermatitis* or *swimmer's* or *clam digger's itch*, is an acute pruritic eruption resulting from penetration of the skin by the cercarial forms of certain parasitic flatworms of the family Schistosomatidae.

Symptoms of cercarial dermatitis begin with urticaria-like lesions and a prickling sensation of the skin, which lasts about half an hour after exposure to cercaria-infested waters. Severe pruritus of the affected area occurs 10–12 hours later. Within 24 hours, erythematous papules appear that may progress to vesicles and later to pustules. Pain and swelling of the area accompanies the intense itching, which usually peaks in 48–72 hours. Headache, fever, and superinfection with lymphangitis are occasionally present.

In the Great Lakes region, several species of *Schistosoma cercariae* that cause swimmer's itch have been reported, and many other such species have been discovered throughout the world in both freshwater and saltwater.[71,72] A severely disabling form of cercarial dermatitis affects the paddy workers and rice farmers of the Far East. Cercarial dermatitis has also been described in individuals exposed to shallow coastal waters, notably on Long Island Sound where the condition affects clam diggers, giving rise to the name, *clam digger's itch* (Fig. 209-22). There is one reported case of cercarial dermatitis occurring on the hands and arms of a patient after he cleaned the aquarium in which he kept native water snails.[73]

Humans are accidental hosts in the life cycle of dermatitis-producing schistosomes. The cycle begins when the primary host, a waterfowl, marsh bird, finch, muskrat, mouse, or deer, passes schistosomal eggs in its feces into a body of water. Each egg hatches in 10–15 minutes, releasing a secondary stage miracidium. The miracidia are free-swimming and must locate and infect their definitive snail host within 12 hours or they will die. The miracidia migrate to the snail's digestive gland, where they develop into multiple sporocysts. In about 5 weeks, the sporocysts give rise to hundreds of fork-tailed cercariae that measure 0.75 mm in length. The cercariae are released from the snail under favorable conditions of light and heat, and are carried toward the shore by prevailing winds and currents.[72] When an appropriate host is encountered, the cercaria attach to the skin with their oral suckers and penetrate the epidermis and dermis by means of histolytic enzymes. They lose their tails in this process and are now called schistosomula. The schistosomula

Figure 209-22 Intensely pruritic papulovesicles suggestive of a severe reaction to flea bites in a patient with clam digger's itch. The left hand, which was not in the water and was holding the pail for collecting the clams, was spared.

migrate via the blood vessels through the heart and lungs to the intrahepatic veins, where they mature into adult male and female trematode flukes. When the worms mate, they pass in pairs through the mesenteric venules of the intestinal wall where the female lays hundreds of eggs.[72] The eggs then penetrate the gut wall and are discharged in the feces, and the cycle is repeated.

When cercariae that do not cause schistosomiasis in humans accidentally attach to the skin, they may penetrate the epidermis but are unable to reach the bloodstream. The organisms die in the superficial papillary dermis and undergo total histolysis within 3–4 days. The cercarial protein residua stimulate a delayed-type hypersensitivity response, which may increase in severity with repeated exposures. Skin biopsies taken at 3–4 days reveal an amorphous eosinophilic mass at the site of the dissolved cercaria, with an intense lymphocytic infiltrate. Later, histiocytes appear in the middle and deep papillary dermis.

The differential diagnosis of cercarial dermatitis includes insect bites from chiggers, mosquitoes, and fleas; contact dermatitis from poison ivy; and the stings of other marine coelenterates. In Africa, Asia, South America, and Puerto Rico, swimmer's itch must be distinguished from the dermatitis associated with human schistosomiasis, which produces an eruption with very similar but milder and more transient symptoms.[74] Swimmer's itch must also be distinguished from sea bather's eruption (SE), which is discussed in the next section.

Prevention of cercarial dermatitis in waters where swimmer's itch is known to be a problem is difficult. Coating the skin with petrolatum and various chemical repellents has been tried, but the effectiveness of these methods remains unproven. Clothing barriers may be of some help.

Treatment of cercarial dermatitis is largely symptomatic. In mild cases, antipruritic or drying lotions, oatmeal or starch baths, and antihistamines may alleviate pruritus. Aspirin may be helpful for the pain and swelling, and a bedtime sedative may be required to allow the patient much-needed sleep. Proper washing and hygiene should be maintained to prevent bacterial superinfection. In severe cases, potent topical glucocorticoids and occasionally systemic glucocorticoids may be required.

SEA BATHER'S ERUPTION

SE, also known as *marine dermatitis* and often misnamed *sea lice infestation*, is an acute dermatitis that begins shortly after bathing in seawater. SE is often confused with swimmer's itch (cercarial dermatitis, see previous section), not only because they both occur after exposure to water but also because the common names of these two conditions are easily confused. For many years, the cause of SE remained a mystery, but it is now known that the responsible agents in at least two types of SE are the larval forms of marine coelenterates. In waters off the coast of Florida and in the Caribbean, the tiny larvae of the thimble jellyfish, *Linuche unguiculata*, are to blame.[75] Off the coast of Long Island, New York, researchers found that the larval forms of the sea anemone *Edwardsiella lineata* were responsible for the eruption.

In addition to having a different etiology, SE can be distinguished from cercarial dermatitis by several other characteristics: SE primarily involves areas of the body covered by bathing suits from which water evaporates slowly, as opposed to uncovered areas as is typical of swimmer's itch. Most symptoms are not noted until the bather has left the water (although some of those affected have complained of a prickling sensation while still in the water).

The eruption is caused by minute stings from the nematocysts of the coelenterate larvae, which become trapped underneath swimwear or may adhere to hairy areas of the body. In addition to SE after contact with the larvae, which are most abundant in May and June, swimmers and bathers may also develop SE after contact with the other two free-swimming stages of *L. unguiculata*, the ephyrae and medusae stages.[76]

The lesions begin within 4–24 hours after exposure as erythematous macules, papules, or wheals that may itch or burn (Fig. 209-23).[34] These lesions may progress to vesiculopapules, which crust over and heal in 7–10 days. Associated systemic symptoms may include chills and a low-grade fever as well as nausea, vomiting, diarrhea, headache, weakness, muscle spasms, and malaise. Febrile and systemic symptoms are more common in children and adolescents.[77] In the presence of such constitutional symptoms, caregivers who fail to recognize the pattern of the eruption or who fail to take a history of exposure to saltwater may mistakenly make the diagnosis of a viral syndrome.

Figure 209-23 Sea bather's eruption in a young girl after a swim at a Florida beach. (Used with permission from Karen Rothman, MD.)

In waters along the coast of South Florida, the season for SE is between March and August with a peak in May. The incidence among bathers during May and June 1993 in Palm Beach County was reported to be 16%.[77] The strongest risk factor for developing SE is a previous history of the condition, which is consistent with the theory that SE represents a hypersensitivity response to the nematocyst stings. Other risk factors include age younger than 16 years and surfing. Showering with swimwear removed was found to be a protective measure.[77]

Prevention of SE includes the measures listed in Table 209-5. Treatment of SE is symptomatic and includes the use of antipruritic lotions, colloidal baths with starch or oatmeal, antihistamines, and topical glucocorticoids. Severe unremitting cases may warrant systemic glucocorticoid therapy.[75] Secondary bacterial infections may complicate the condition and should be diagnosed and treated appropriately.

TABLE 209-5
Prevention of Seabather's Eruption

1. Bathers should remove their swimwear and shower as soon as possible after leaving the water. Because fresh water may cause discharge of the nematocysts, it is important that the suits be removed before showering begins.
2. Bathing suits should be rinsed with soap and water and heat dried, because the eruption can recur when the suit is air-dried.
3. T-shirts should not be worn in the water. Women may consider wearing a two-piece suit to reduce the surface area under which larvae may be trapped.
4. Whole-body Lycra swimsuits or wet suits with snug-fitting collars and cuffs may be protective, but the eruption may still occur along the collar or cuff edges.
5. Highly sensitized individuals should avoid swimming in infested waters during outbreaks of seabather's eruption.

INJURIES CAUSED BY MOLLUSKS

CONE SHELL ENVENOMATIONS. Cone shells are univalvular gastropods whose ornate cone-shaped shells are highly prized by shell collectors and divers. A number of species have a highly developed venom apparatus that can inflict a lethal sting. Most of the dangerous cone shell species are found in the shallow waters of the Indo-Pacific. Cone shells are carnivorous. They live on the ocean bottom and, depending on the species, may hunt worms, other mollusks, or fish. Cone shells kill their prey by means of a spear-like venomous radular tooth that is thrust out from the animal's proboscis. Cone shell venom contains several different kinds of neurotoxins, and death may result from respiratory paralysis. There is so far no antivenin for cone shell toxin, and mortality rates after envenomations from the more dangerous species (*Conus geographicus* and *C. magus*) may be as high as 15%–20%.[34]

Injuries from cone shells are of the puncture wound variety. The degree of pain is variable, ranging from a mild stinging sensation, similar to that of an insect bite, to excruciating pain. Early symptoms may include edema, ischemia, numbness, and paresthesias of the wound site. Paresthesias may become widespread, with the lips and mouth commonly affected.[34,63] Localized muscular paralysis may progress to generalized weakness or paralysis with eventual respiratory distress and cardiopulmonary failure.[78] Neurotoxic symptoms that indicate severe envenomation include diplopia, blurred vision, aphonia, dysphagia, and coma. Rare cases of disseminated intravascular coagulation have been reported after cone shell envenomation.

Great care must be exercised in handling live cone shells. Thick protective gloves should be worn, and the soft under portion of the animal should be avoided. Cone shells should never be placed in pockets of clothing or swimwear, because they have been known to sting through clothing.[55]

Treatment of cone shell envenomations is supportive. The victim should be kept at rest and the sting area kept dependent and immobilized. A compression dressing should be applied to occlude lymphatic-venous, but not arterial, flow.[55] Local suction may be helpful if it can be applied immediately to the wound site with a plunger device, such as the Extractor Vacuum Pump (Sawyer Products, Safety Harbor, Florida).

OCTOPUS BITES. Octopuses are an advanced group of mollusks belonging to the class Cephalopoda. The octopus bites with a parrot-like chitinous beak located on the ventral side of the head in the middle of its eight tentacles (Fig. 209-24). Species of octopi range in size from a few centimeters to 1–2 m in diameter.[79] They are shy and reclusive creatures that tend to avoid encounters with humans; however, bites can occur when curious divers, fishermen, or beachgoers encounter these animals and handle them carelessly. Most octopus bites are not life threatening to humans.

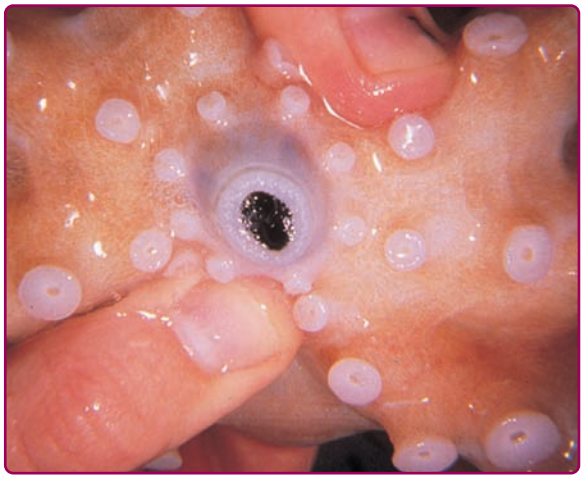

Figure 209-24 Ventral view of the underside of an octopus exposing the animal's centrally located mouth and parrot-like beak. (From Fulghum DD: Octopus bite resulting in granuloma annulare. *South Med J* **79**:1434, 1986, with permission.)

The bite site may be immediately painful, as after a bee sting, and is recognized by the presence of two small puncture wounds, which may bleed profusely.[55] Symptoms from octopus bites are usually mild and transient and consist of redness, swelling, and itching.[79]

The most dangerous species of octopus, the Australian blue-ringed octopus, *Hapalochlaena maculosa*, is found in Australian coastal waters. Mortality rates after bites from *H. maculosa* may be as high as 25%. *H. maculosa* produces a toxin in its salivary glands that is introduced into the bite site by the animal's powerful beak and contains a fraction identical to tetrodotoxin; this toxin blocks peripheral nerve conduction and results in paralysis of the victim with subsequent respiratory failure. The bite of the blue-ringed octopus may or may not be painful, so that victims may not realize they have been bitten until neurologic symptoms develop.[63]

There is no antivenin for bites of *H. maculosa.* Treatment is supportive and similar to that recommended in the previous section for severe cone shell envenomations.

INJURIES CAUSED BY VENOMOUS FISH SPINES

Ichthyoacanthotoxicosis is the proper term for envenomations as a result of puncture wounds or lacerations inflicted by the spines of venomous fish. There are more than 200 species of venomous fish in the world that can cause injury to humans.[63] The most notorious of these species are the stingrays, catfish, lionfish, scorpionfish, stonefish, weevers, toadfish, and spiny dogfish. All of these fish have in common a venom apparatus consisting of a single spine or multiple spines, in various locations, which are covered by an integumentary sheath enclosing various forms of venom glands. When the spine of the animal penetrates the victim, the sheath is torn and the venom glands release their toxins into the wound. The toxins from some of these fish may remain potent for 24–48 hours after the death of the fish.[80]

Figure 209-25 A close-up view of a stingray stinger without its outer membrane and venom glands, demonstrating the retroserrated spine. (Used with permission from David Fulghum, MD.)

STINGRAYS. Stingrays are one of the most common causes of venomous fish stings confronting humans, with as many as 1,500 to 2,000 stingray attacks reported each year in the United States alone.[70,81] Rays are grouped into one of four categories: (1) gymnurid (butterfly rays), (2) urolophid (round stingrays), (3) myliobatid (bat or eagle rays), and (4) dasyatid (proper stingrays). The groupings are based on their relative stinging ability, which depends on the size, number, and location of the caudal stinging appendages. The most dangerous group, the dasyatid or true stingrays, have the largest spines located further out on their tails, which makes them the most potent striking weapons. The spines have retroserrated teeth, so that removal is difficult (Fig. 209-25).

Most stingray injuries occur when bathers, waders, or fishermen accidentally step on rays as they lie partially covered with sand in shallow waters.[82,83] Severe lacerations and puncture wounds are inflicted by the ray as it defensively whips its tail upward and forward when stepped on or threatened (Fig. 209-26).[82,83] The majority of wounds, therefore, are located on the dorsum of the foot or lower leg. Penetrating wounds to other locations have occurred to fishermen stung while attempting to remove rays from their lines or nets. Rarely these injuries are fatal. Soaking in warm water relieves the pain.

CATFISH. Both freshwater and saltwater catfish are armed with stout, sharp spines located immediately in front of the soft rays of their dorsal and pectoral fins. Catfish defensively lock these spines into an extended position when they are handled or threatened. Bathers may sustain stings on their feet or legs if they step on a catfish, but most catfish stings involve the hand or upper extremity of fishermen or seafood processors.[84] To prevent these injuries, it has been suggested that the offending spines be removed with a pair of pliers before cleaning of the fish is attempted.

Swimmers and bathers in the Amazon River are at risk for urologic injuries if they encounter a very

Figure 209-26 Stingrays reflexively swing their barbed tails up when stepped on, causing painful lacerations and puncture wounds. (The leg used for this photograph was a prosthesis; the stingray was alive.) (Used with permission from David Fulghum, MD.)

small species of catfish called the *candiru*, which has the ability to enter the human urethra. Barbs on the head of this fish prevent it from swimming backward out of the orifice, and surgical intervention is often required to extract the fish.

SCORPIONFISH. Scorpionfish, family Scorpaenidae, are divided into three main groups on the basis of their stinging apparatus. All have venomous spines of varying sizes and toxicity, which may be found in dorsal, pelvic, and anal locations, depending on the species.

Scorpionfish, genus *Scorpaena*, have stings that are of intermediate severity. They are bottom dwellers with superior camouflage abilities that allow them to blend in almost invisibly with their surroundings (Fig. 209-27).

Figure 209-27 *Scorpaena plumieri*, a species of scorpion fish, is found in the waters of the West Indies. Its camouflage abilities are exceeded only by its painful sting.

Their spines are long and heavy and have moderate-sized venom glands.

Stonefish, genus *Synanceja*, are the most dangerous members of the scorpionfish family. They live in shallow waters, sometimes partially buried in sand or mud, or in holes of rocky shoals, reef areas, or tidal pools.[70] Injuries occur when a wader steps on the erect venomous dorsal spine that the stonefish raises in defense. Stonefish spines are short and thick and have very large and well-developed venom glands. The wounds caused by stonefish are quite severe and may be fatal. A stonefish antivenin is available.

WEEVERFISH. In European coastal waters, the weeverfish is one of the most common and serious causes of venomous fish spine injuries.[85] These fish are equipped with between five and eight venomous dorsal spines and two venomous opercular spines (one on each side of the head near the gill plate).[86] Waders and bathers are at risk when they step on weeverfish that lie partly buried in mud or sand in shallow waters.

LOCAL AND SYSTEMIC SYMPTOMS OF FISH SPINE ENVENOMATIONS. The toxicity of a given venomous fish sting depends on a number of factors, including the species of fish involved, the location and severity of the wound, the amount of venom released, and the first aid and subsequent medical care provided to the victim. In general, these wounds produce pain out of proportion to the apparent severity of the injury. The pain is immediate and intense. In the case of scorpionfish stings, the pain may be so severe as to cause the victim to thrash about wildly, scream, and finally lose consciousness.

Initially, the sting site may appear pale or cyanotic. The area around the wound may be anesthetic or hyperesthetic. Erythema and edema soon develop, giving the appearance of a cellulitis. Vesicles may form. In severe stinging, especially those caused by stonefish, the wounded area may become indurated and develop areas of ischemic necrosis with subsequent sloughing and ulcer formation.

Systemic effects from toxic fish spine envenomations may range from mild to severe, depending on the species involved and the amount of venom entering the wound. They can include headache, nausea, vomiting, diarrhea, abdominal cramps and pain, fever, local lymphangitis and lymphadenitis, joint aches, muscle weakness, diaphoresis, peripheral neuropathy, limb paralysis, restlessness, delirium, seizures, cardiac arrhythmias, myocardial ischemia, pericarditis, hypotension, and respiratory distress, and can lead to death.[78,84,87,88]

PREVENTION. Prevention of toxic fish spine wounds begins with knowledge of and appreciation for the various venomous species that may be encountered in a given area. Waders and bathers should shuffle their feet to scare away and avoid stepping on rays or scorpionfish. Fishermen must exercise care when removing rays or catfish from their fishing lines or when cleaning fish with venomous spines. Fish hobbyists and divers should wear protective clothing and avoid handling venomous species.

TREATMENT. Puncture wounds and lacerations from venomous fish spines should be irrigated immediately with sterile saline or water, if available, and with seawater as a last resort.[55] The wounded area should then be soaked as quickly as possible in hot (not scalding) water of approximately 43°C to 46°C (110°F to 115°F) for 30–90 minutes or until maximal pain relief is achieved. Hot soaks may be repeated if the pain returns. Because the wound or extremity may be partially anesthetic, the person administering first aid must test the water's temperature for the victim.[54,89] One source of hot water that is often overlooked and may be useful in an emergency is hot seawater from a boat motor's cooling system.

Local infiltration of the wound with 1%–2% lidocaine without epinephrine may bring about significant pain relief and allow exploration of the wound after radiographs have been obtained to locate retained portions of spines.[60,70] Longer-acting anesthetics such as procaine and bupivacaine may be chosen to provide a longer period of pain relief. The wound should be thoroughly cleaned to remove any remnants of integumentary sheath. Abdominal and thoracic wounds and deep wounds to the hands, feet, or fascial compartments of the legs should be explored in the operating room.[70] Debridement of necrotic tissues may be required at the time of exploration, and sequential debridement may be necessary. In general, these wounds should be left open or closed loosely with tape or suture to allow for adequate drainage and to prevent abscess formation.

Tetanus prophylaxis should be administered if indicated, and antibiotics are recommended if the wound is more than 6-hours-old, is extensive, or involves deep puncture injuries to the hand or foot. The choice of antibiotic should be based on the bacteriology of the marine environment in which the wound occurred and, subsequently, on results of deep wound or tissue cultures. Empiric antibiotic therapy for infections of wounds occurring in saltwater should include coverage for *Vibrio* species. Before final wound culture results are known, initial choices of parenteral antibiotics include intravenous ciprofloxacin, imipenem-cilastatin, a third-generation cephalosporin, gentamicin, tobramycin, or trimethoprim-sulfamethoxazole.

Stonefish stings complicated by severe reactions may be treated with antivenin by slow intravenous infusion. Antivenom is not usually required for the stings of lionfish and other species of scorpionfish except for stonefish.[70] Stonefish antivenom is available from the Australian Commonwealth Serum Laboratory, Melbourne, Australia.

FISH BITES

There are many species of fish whose bites are dangerous to humans. Among the best known are the sharks and barracudas, whose bites may cause severe injuries.

Although they are well-publicized by the news media, shark attacks are relatively rare events. The average number of shark attacks worldwide is between 50 and 100 annually.[90] Only 32 of the 400 known species of sharks have been reported to attack humans. Most shark attacks involve surfers, scuba divers, and swimmers. Because sharks are attracted to bright or shiny objects, as well as to those with contrasting colors, these items should not be worn in the water. Sharks are also attracted by any sort of blood in the water; therefore, women who are menstruating should refrain from water sports in areas in which sharks may be prevalent, and no one should swim with an open bleeding wound. Spear fishermen should never tie their catch to themselves, and they should place their catch in the dive boat as soon as possible. Although most shark bites are not life-threatening, more severe attacks may cause extensive soft-tissue loss with massive hemorrhage, which, in the worst cases, can result in amputation of a limb or death.[91,92]

Barracuda attacks are even rarer than shark bites. They tend to occur in turbid waters where these predators may mistake jewelry or other brightly colored objects worn by bathers for the baitfish on which they feed. Barracuda bites typically produce straight or V-shaped lacerations.

Divers and aquarium hobbyists must be careful when feeding or handling moray eels, which have powerful jaws and knife-like teeth. Although they are not considered venomous by most sources, they can produce deep puncture wounds and lacerations (Fig. 209-28).[55] When biting, moray eels tend to lock onto their prey; decapitation of the eel or disarticulation of its jaw may be required to release the victim.[93] As with all deep puncture wounds or lacerations, victims of moray eel bites should receive tetanus prophylaxis. Empiric antibiotic therapy for prophylaxis or treatment can include ciprofloxacin or cefuroxime for coverage of *Vibrio* or *Pseudomonas* species.[93]

WATERBORNE INFECTIONS

A variety of infections may result from exposures to aquatic environments. Pathogenic organisms may be actively introduced into the bite, sting, or laceration wounds caused by marine life; preexisting wounds may be passively infected when exposed to contaminated waters. *V. carchariae*, a halophilic (saltwater-loving)

Figure 209-28 Moray eel bites are uncommon, but their incidence has increased because divers feed these animals at popular dive sites. (Used with permission from Marty Gilman, Worcester, MA.)

TABLE 209-6
Wound Infections Associated with Waterborne Organisms

Organism	Clinical Features
Aeromonas hydrophilia	Cellulitis (may be bullous), fasciitis, myonecrosis, bacteremia.
Edwardsiella tarda	Cellulitis, abscess, osteomyelitis, bacteremia.
Erysipelothrix rhusiopathiae	Slowly progressive cellulitis without adenopathy or lymphangitis, almost always involving the hand; septic arthritis; subacute bacterial endocarditis.
Mycobacterium balnei or *Mycobacterium marinum*	Swimming pool granuloma; fish fancier's finger; chronic cellulitis and culture-negative ulcers; often the primary lesion is on the hand and then a series of lesions develop in draining lymphatics.
Pfisteria piscicida	Raw, red pock-marked lesions in fish in polluted waterways; in humans, rashes, respiratory problems, and memory deficits.
Protothecosis	Papular or eczematoid dermatitis in immunosuppressed patients; localized infection of the olecranon bursa.
Pseudomonas species	Trench foot; Gram-negative toe web space infections; swimmer's ear; hot tub folliculitis.
Streptococcus iniae	Cellulitis and bacteremia after skin injuries during the handling of fresh fish raised by aquaculture.
Vibrio vulnificus, other *Vibrio* sp.	Cellulitis, sometimes with bulla formation; may progress to septicemia, especially in alcoholics, diabetics, and immunosuppressed patients; metastatic cellulitis, meningitis, and death may result from fulminant infections.

Gram-negative bacillus, was reported as the cause of a wound infection after a shark bite.[94] Table 209-6 lists those organisms commonly associated with waterborne infections (see also Chapter 183). A host of other agents, such as *Streptococcus* and *Staphylococcus* sp., *Bacteroides fragilis*, *Clostridium perfringens*, *Escherichia coli*, *Salmonella enteritidis*, marine *Vibrio* sp., *Chromobacterium violaceum*, and *Chlorella*, also require consideration when dealing with infections associated with aquatic settings.[70]

CUTANEOUS MANIFESTATIONS OF SEAFOOD INGESTION AND SEAFOOD POISONING

Dermatologic reactions may appear after the ingestion of seafood. Urticaria, angioedema, and, rarely, leukocytoclastic vasculitis may occur in individuals sensitized to fish or shellfish. Many seafoods, such as kelp, contain large amounts of iodine, which may cause acneiform eruptions.

Scombroid food poisoning involves the ingestion of spoiled fish from the Scombridae family of fish, such as tuna, mackerel, and Bonita. If these fish are not kept cold enough after being caught, their flesh develops scombrotoxins as a consequence of the bacterial breakdown of histidine into histamine, saurine, and possibly other toxic by-products. These can cause striking erythema and flushing of the face, neck, and upper trunk, as well as pruritus and urticarial and angioedematous eruptions. Antihistamines can provide symptomatic relief in severe cases.

Ciguatera toxin, which is produced during blooms of toxic dinoflagellates, is incorporated into the marine food chain and concentrated in the flesh of a variety of fish. It is heat stable, and symptoms may occur after eating cooked or raw fish containing the toxin. Dermatologic symptoms of ingesting these fish may include generalized pruritus and diffuse erythematous macular and papular exanthems, which may progress to blister formation and desquamation.

ACKNOWLEDGMENT

The authors wish to thank Dr. Bruce Halstead of the World Life Research Institute, Colton, California, for allowing us to reprint the photographs from the first and second editions of *Poisonous and Venomous Marine Animals of the World*.

Chapter 210 :: Arthropod Bites and Stings

:: Robert A. Schwartz & Christopher J. Steen

ARTHROPOD BITES AND STINGS AT A GLANCE

- Many arthropod species are capable of inflicting bites and stings on humans.
- Reactions to arthropod assaults can range from mild to life threatening.
- Arthropods also serve as vectors for systemic diseases.
- The terrestrial arthropods of medical importance include the orders Arachnida (arachnids), Chilopoda (centipedes), Diplopoda (millipedes), and Insecta (insects).

Arthropod bites and stings are a significant cause of morbidity worldwide. Although many arthropod attacks produce only mild, transient cutaneous changes, more severe local and systemic sequelae can occur, including potentially fatal toxic and anaphylactic reactions. Arthropods also serve as vectors for numerous systemic diseases. The medically significant classes of nonaquatic arthropods are Arachnida, Chilopoda, Diplopoda, and Insecta (Fig. 210-1).[1]

HISTOPATHOLOGY

Many arthropod bites produce a similar histologic reaction pattern. In the acute phase, there is a superficial and deep, perivascular and interstitial inflammatory infiltrate, which is characteristically wedge shaped. The infiltrate is usually mixed in composition with an abundance of lymphocytes and eosinophils, although neutrophils and histiocytes can also be seen. Neutrophils may predominate in reactions to fleas, mosquitoes, fire ants, and brown recluse spiders. Over the most prominent superficial infiltrates, spongiosis can be seen, sometimes with progression to vesicle formation or epidermal necrosis. Older, excoriated areas are usually altered by the effects of scratching, with the development of parakeratosis, serum exudates, and a dermal infiltrate with neutrophils and more abundant lymphocytes. Although not commonly seen on histology, insects or insect parts, including burrowed scabies mites, eggs, feces, or the retained mouthparts of ticks, may be visible. Chronic lesions, which most often result when arthropod parts are retained in the skin, may have a pseudolymphomatous appearance (see Chapter 146).

TREATMENT PRINCIPLES

The morbidity from arthropod bites and stings varies with the species inflicting the injury. Although species-specific clinical findings and treatment will be discussed in further detail, there are several applicable general treatment principles. Local wound care is essential following arthropod assault. Wounds should be cleansed; any remaining arthropod parts, including stingers, should be removed expeditiously. Patient discomfort should be addressed and can involve a variety of treatment modalities, including the use of ice packs, application of topical corticosteroids and antipruritics, injection of local anesthetics, and, less frequently, the use of systemic analgesics. Supportive measures for systemic toxic and allergic reactions, including anaphylaxis, should be instituted when necessary. Secondary infection should be treated with appropriate antibiotics. Bites from several terrestrial arthropods species may require tetanus prophylaxis. Severe envenomation from particular species, such as the black widow spider, may require antivenom administration. Documented hypersensitivity to some species can be treated with desensitization immunotherapy.

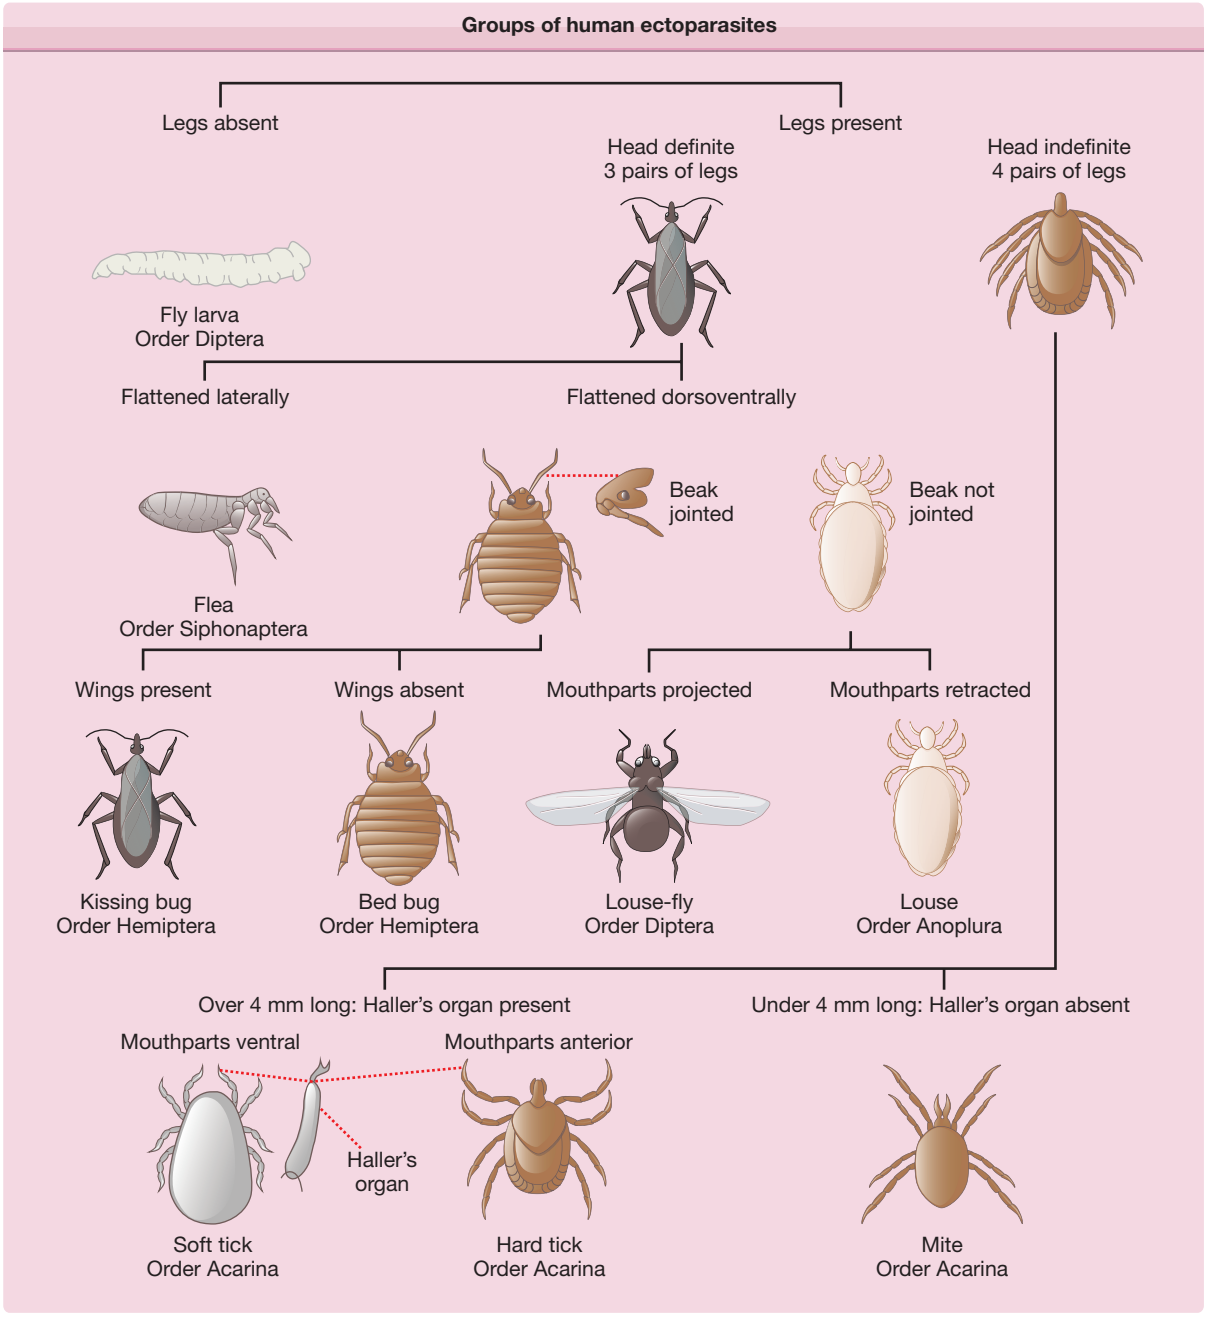

Figure 210-1 Pictorial key to groups of human ectoparasites. (Used with permission from C.J. Stojanovich and H.G. Scott, US Department of Health, Education, and Welfare, Public Health Service.)

Awareness of the potential arthropod-borne illnesses spread by each species is also important.

DIFFERENTIAL DIAGNOSIS

(Box 210-1)

ARACHNIDA

The class Arachnida contains three orders of medical significance: (1) Araneae (spiders), (2) Acarina (ticks and mites), and (3) Scorpiones (scorpions). Arachnids are distinguished anatomically from other arthropods by a lack of wings or antennae and the presence of four pairs of legs and two body segments. Larval ticks, which only have three pairs of legs, are an exception to this rule (see Fig. 210-1).

ARANEAE

Spiders are carnivorous members of the animal kingdom that use webs and venom to capture and kill prey. Within the United States, three genera contain species

BOX 210-1 DIFFERENTIAL DIAGNOSIS OF ARTHROPOD BITES AND STINGS

- Black widow bite: acute abdomen (appendicitis, etc.), meningitis, tetanus, drug withdrawal, acute renal failure, acute myocarditis, acute coronary syndrome, other arthropod bite
- Brown recluse bite: hobo spider bite, chemical burn, Lyme disease, cutaneous anthrax infection, pyoderma gangrenosum, ecthyma, trauma, vasculitis, neoplasm, other arthropod bite
- Scorpion sting: other arthropod bite, tetanus, botulism, Guillain–Barré, organophosphate toxicity, medication overdose
- Centipede bite: other arthropod bite, cellulitis
- Millipede "burn": contact dermatitis, conjunctivitis
- Insect bites (flies, fleas, bedbugs, kissing bugs): other arthropod bites (scabies, lice), atopic dermatitis, contact dermatitis, papular urticaria, delusions of parasitosis
- Hymenoptera bite/sting: other arthropod bite, anaphylaxis
- Lepidopterism: other arthropod bite, contact dermatitis, atopic dermatitis, phytodermatitis

whose bites are toxic to man: (1) *Latrodectus*, (2) *Loxosceles*, and (3) *Tegenaria*. The American Association of Poison Control Centers reported over 15,000 spider bites in the United States in 2004.[2] In the same year, only one death was attributed to spider envenomation in the United States.

LATRODECTUS. Members of the *Latrodectus* genus, or widow spiders, are often black in color and have a red, hourglass-shaped marking on their abdomens (Fig. 210-2). Although there are more than 20 species of widow spiders, *Latrodectus mactans*, the Southern black widow spider, is the most common and notorious in the United States and can be found in all but the most northern parts of the country. Other widow spiders encountered in the United States include *Latrodectus various* (Northern black widow), *Latrodectus hesperus* (Western black widow), *Latrodectus bishopi* (red-legged widow), and *Latrodectus geometricus* (brown widow). Members of the *Latrodectus* genus are nonaggressive, trapping spiders that spin webs in protected areas and await their prey. Human bites are often the result of accidental or deliberate provocation. Webs are typically found on the corners of doors and windows, underneath woodpiles, in garages and sheds, and on the undersides of eaves. Webs can also be found around outdoor toilet seats, a location that has led to bites on or near the genitalia.[3]

Figure 210-2 Black widow spider with characteristic red hourglass marking on the underside of its abdomen.

Clinical Findings. Bites of the black widow spider (*L. mactans*), which are often painful, usually only result in mild dermatologic manifestations. Within the first 30 minutes, localized erythema, piloerection, and sweating may appear at the wound site. A sensation of numbness or aching pain may develop shortly after the bite. Urticaria and cyanosis may occur at the bite site. Black widow venom contains the neurotoxin α-latrotoxin, which acts by opening ion channels at presynaptic nerve terminals, thereby causing an irreversible release of acetylcholine at motor nerve endings and catecholamines at adrenergic nerve endings.[4] Consequently, black widow bites may produce agonizing crampy abdominal pain and muscle spasm that may mimic an acute abdomen.[4] Other signs and symptoms include headache, paresthesias, nausea, vomiting, hypertension, lacrimation, salivation, seizures, tremors, acute renal failure, and sometimes, paralysis; fortunately, death is uncommon. Based on the spectrum of symptoms, black widow bite may be misdiagnosed as drug withdrawal, appendicitis, meningitis, or tetanus, to name a few.[4]

Management. Although many widow spider bites require only local wound care, more serious reactions may necessitate hospitalization. Those patients at increased risk for serious complications include the very young, very old, and those with underlying cardiovascular disease. Current treatments for black widow envenomation include intravenous calcium gluconate (10%), narcotic analgesics, muscle relaxants, and benzodiazepines.[5] *L. mactans* antivenom prepared from equine serum is also available. Additionally, there appears to be an effective cross-reactivity among antivenom for a number of other *Latrodectus* species.[6–8] The benefits of the antivenom in treating complications of widow bites should be weighed against the potential for allergic reaction to the antivenom. Patients should also be up to date on tetanus immunization.

LOXOSCELES. Members of the *Loxosceles* genus, also called *recluse spiders* or *fiddle-back spiders*, are nonaggressive spiders characterized by a dark brown marking on their cephalothorax in the shape of a fiddle or violin (Fig. 210-3). The brown recluse spider, *Loxosceles reclusa*, is the most well-known member of this genus

Figure 210-3 Brown recluse spider with characteristic fiddle-shaped marking on cephalothorax.

and is most abundant in the American Midwest and Southeast. Other medically significant members of this genus include *Loxosceles deserta* (desert recluse), *Loxosceles rufescens* (Mediterranean recluse), *Loxosceles kaiba* (Grand Canyon recluse) and *Loxosceles arizonica* (Arizona recluse). Recluse spiders are so named because they will often seek out shelter in undisturbed places such as closets, attics, and storage areas for bedding and clothing. Bites usually occur when the spider feels threatened or provoked, such as when someone tries to put on clothing that contains the spider.[1]

Clinical Findings. Bites of the brown recluse spider (*L. reclusa*) vary from mild, local reactions to severe ulcerative necrosis, a reaction known as *necrotic arachnidism*. After a bite, transient erythema may develop with the formation of a central vesicle or papule. The hallmark "red, white, and blue" sign of a brown recluse bite is characterized by a central violaceous area surrounded by a rim of blanched skin that is further surrounded by a large asymmetric erythematous area (Fig. 210-4A). In a small percentage of cases, the initial wound may progress to necrosis (see Fig. 210-4B), which usually begins 2–3 days after the bite, with eschar formation occurring between the fifth and seventh days.[9] Eventually deep ulcers develop (see eFig. 210-4.1 in online edition). The bite reaction may mimic pyoderma gangrenosum or erythema migrans of Lyme disease.[10] Cutaneous anthrax and chemical burns have been mistaken for a brown recluse spider bite.[11,12] The potential for misdiagnosis has led to the development of a sensitive enzyme-linked immunosorbent assay for *Loxosceles* species venom that may eventually be available for clinical application.[13]

Brown recluse venom contains a number of proteins, including sphingomyelinase D, esterase, hyaluronidase, and alkaline phosphatase, which all contribute to tissue destruction. Sphingomyelinase D, the major component of the venom, cleaves sphingomyelin to form cermade-1-phosphate and choline and also hydrolyzes lysophosphatidylcholine to produce lysophosphatidic acid.[14] Lysophosphatidic acid then triggers a proinflammatory response and causes platelet aggregation and increased vascular permeability.[14] Sphingomyelinase D is also capable of inducing complement-mediated hemolysis.[15] Systemic symptoms may develop within 1–2 days after envenomation and include nausea, vomiting, headache, fever, and chills. Rare but serious sequelae of brown recluse bites include renal failure, hemolytic anemia, hypotension, and disseminated intravascular coagulation.[16,17]

Management. General treatment measures for recluse bites include cleansing the bite site and the application of cold compresses. Patients may also require analgesics to control pain. Antibiotics may be useful in reducing secondary bacterial infection of the wound site. Warm compresses and strenuous exercise should be avoided. Although *Loxosceles* antivenom

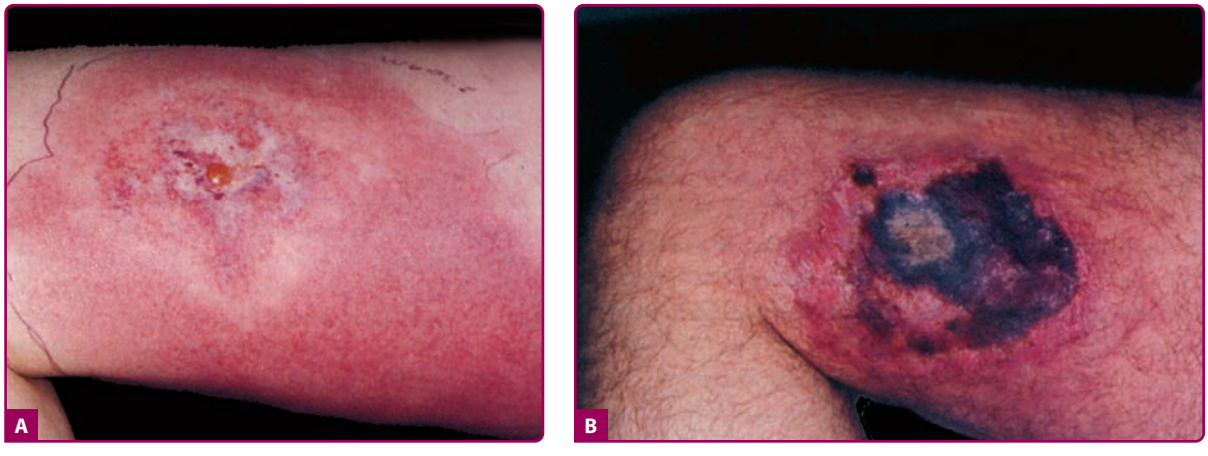

Figure 210-4 **A.** Clinically typical brown recluse spider bite showing the "red, white, and blue" sign. **B.** Late brown recluse spider bite with overlying eschar.

have been developed and are frequently used in South America, there is little evidence to support their effectiveness, particularly against local cutaneous effects.[8] A number of treatment modalities have been suggested, including hyperbaric oxygen, dapsone, intralesional and systemic corticosteroids, colchicine, and diphenhydramine.[18,19] However, one study that used a rabbit model to compare dapsone, colchicine, intralesional triamcinolone, and diphenhydramine showed no effect on eschar size from any of these medications.[18] Necrotic wounds heal slowly, sometimes over many months, and may require surgical excision and reconstruction to close the resulting defect. Surgical interventions should be delayed until the wound has stabilized.

TEGENARIA. *Tegenaria agrestis*, the hobo spider or "aggressive house spider," is the predominant cause of necrotic arachnidism in the Pacific Northwest of the United States and can be found in an area ranging from Alaska to Utah.[20] Although *Loxosceles* species are not typically found in the same geographic distribution, bites from hobo spiders are often mistaken for brown recluse bites. These spiders are brown in color with a gray herringbone pattern on the abdomen.[21] The hobo spider typically builds funnel-shaped webs in crawl spaces, basements, wood piles, and bushes. Most hobo spider bites occur from July to September when the more venomous male spiders are seeking mates.

Clinical Findings. The local cutaneous effects after envenomation by the hobo spider, which can range from mild to serious, are similar to those caused by the brown recluse.[22] The initial bite is often painless. Induration and paresthesia of the bite site may develop within 30 minutes. A large erythematous area may form around the site. Vesicle formation often occurs during the first 36 hours. Eschar formation may follow in severe cases, with necrosis and sloughing of the underlying tissue.

Management. Wounds usually heal within several weeks. The most common systemic symptom after a hobo spider bite is a severe headache, which can persist for up to 1 week.[23] Other symptoms may include fatigue, nausea, vomiting, diarrhea, paresthesias, and memory impairment. Although rare, death may ensue due to severe systemic effects, including aplastic anemia.[23]

TARANTULA. Tarantulas are indigenous to certain regions of the United States and are also kept as exotic pets. Tarantulas are members of the family Theraphosidae and are hair covered and larger than many other types of spider, with leg spans of up to 12 inches reported in certain species. Unlike the other venomous spiders discussed, tarantula bites generally only produce mild local symptoms. However, more serious reactions can be caused by urticating hairs on the spider's abdomen. When threatened, tarantulas may rub their back legs together in a motion that flicks these hairs off. These hairs may become embedded in the skin or eyes. Cutaneous responses to the hairs range from mild, local pruritus to granulomatous reactions. Ocular sequelae from hairs embedded in the cornea range from conjunctivitis and keratouveitis to corneal granulomas and chorioretinitis.[24–27] Although cutaneous reactions can be treated with topical corticosteroids, ocular involvement requires ophthalmologic evaluation.

SCORPIONES

The order Scorpiones (scorpions) comprises terrestrial arachnids most commonly encountered in tropical or arid regions, including the southwestern United States, northern Africa, Mexico, and the Middle East. These nocturnal creatures seek shelter under stones and bark during the day. As with other arachnids, scorpions are generally shy and sting humans only when provoked. Although capable of producing significant local wounds, the potential for serious, even lethal, cardiovascular complications following a scorpion sting remains of primary concern.[1] The scorpion of principal interest in the United States is *Centruroides exilicauda* (formerly *Centruroides sculpturatus*), whose sting is potentially fatal (Fig. 210-5). *Centruroides* species possess a small spine at the base of the stinger, a feature which may help distinguish them from other species of scorpion.[28,29]

CLINICAL FINDINGS. Scorpion stings usually produce an immediate, sharp, burning pain. This may be followed by numbness extending beyond the sting site. Regional lymph node swelling, and, less commonly, ecchymosis and lymphangitis, may develop. *C. exilicauda* venom contains a powerful neurotoxin, capable of producing muscle spasticity, nystagmus, blurred vision, slurred speech, excessive salivation, respiratory distress, pulmonary edema, and myocarditis.[30–35]

Figure 210-5 *Centruroides* scorpion.

Infants and young children are at the greatest risk for serious complications.[29]

MANAGEMENT. Mild scorpion envenomations may only require symptomatic treatment, including analgesics and local ice compresses. Any child stung by a scorpion, especially if identified as *C. exilicauda*, should be hospitalized for close monitoring of respiratory, cardiac, and neurologic status.[36] Specific antivenom is the treatment of choice for severe envenomation. Critically ill children with neurotoxic effects of scorpion envenomation can benefit greatly and promptly with intravenous administration of scorpion-specific F(ab')(2) antivenom.[29] Lack of it may have serious consequences. Studies indicate that *C. exilicauda* antivenom is safe, with a low incidence of anaphylactic reaction following infusion and a rapid onset of symptom relief.[34,37] Although serum sickness is common after antivenom infusion, it is usually self-limited and can be managed with antihistamines and corticosteroids.[34,37]

ACARINA

The order Acarina contains ticks and mites (see Fig. 210-1). Ticks are the most numerous members of this order, with approximately 800 known species. They are important worldwide as vectors of systemic disease, capable of transmitting viruses, rickettsia, spirochetes, bacteria, and parasites to humans.

MITES. (See Chapter 208).

TICKS. Ticks are divided into two families: (1) Ixodidae (hard ticks) and (2) Argasidae (soft ticks). Hard ticks are responsible for the majority of tick-related disease. Ticks pass through multiple stages during their life cycle, including egg, larva, nymph, and adult, and require blood meals for transition between the latter three stages. Ticks are distinguished from other mites by the presence of a barbed hypostome, which is inserted into the skin for feeding (Fig. 210-6). Ticks ingest blood from a diversity of vertebrate hosts including birds, reptiles, and mammals.[38] Adult hard ticks are capable of ingesting several hundred times their unfed body weight when taking a blood meal and may survive for months without feeding. When searching for a suitable host, hard ticks exhibit a unique behavior called "questing" during which the tick crawls to the edge of a leaf or blade of grass and holds its front pair of legs stretched out in order to grab onto a passing host.[39–41] Humans often become infested by contact with tall grass or brush that harbors the unfed ticks or by their association with domestic animals like cats or dogs. Ticks are attracted to the smell of sweat, the color white, and body heat. Once on a host, a tick may spend up to 24 hours in search of a protected site to feed, such as a skin fold or the hairline. Tick feeding time ranges from 2 hours to 7 days, with the tick dropping off of the host once fully engorged.

Many different tick species are responsible for local tick bite reactions and transmission of disease in human

Figure 210-6 *Dermatocentor variabilis* feeding. The tick has been attached for 24 hours.

hosts. In the United States, *Ixodes scapularis* (deer tick or black-legged tick), *Dermacentor andersoni* (American wood tick), *Dermacentor variabilis* (American dog tick), *Ixodes pacificus* (Western black-legged tick), and *Amblyomma americanum* (Lone Star tick) are among the most common. In the Eastern Hemisphere, important tick species include *Ixodes ricinus* (castor bean tick or sheep tick) and *Ixodes persulcatus* (Taiga tick). Among the diseases transmitted by ticks are Lyme disease (see Chapter 187), ehrlichiosis, babesiosis, Rocky Mountain spotted fever (see Chapter 199), Colorado tick fever, Q fever, and tularemia (see Chapter 180).

Clinical Findings. The majority of tick bites occur in the spring and summer, coinciding with the life cycle of the tick. Tick bites are usually painless, as the tick introduces an anesthetic and anticoagulant substance when biting. Often, a person will not even know he or she has been bitten, but will see or feel an attached tick while scratching or bathing. Tick bites may incite foreign body granuloma formation, reactions to injected toxins and salivary secretions, and other hypersensitivity responses. Rarely, delayed hypersensitivity reactions occur with fever, pruritus, and urticaria.[42] A red papule is usually seen at the bite site, and may progress to localized swelling and erythema.[42,43] A cellular response to the bite can lead to induration and nodularity after a few days. Foreign-body reactions may occur when mouthparts are retained in skin after incomplete removal of the tick. Chronic tick bite granulomas may present diagnostic problems and persist for months to years.

Tick paralysis is a potentially lethal complication of tick infestation and is thought to be caused by a neurotoxin contained within tick salivary secretions. The illness may start with headache and malaise and rapidly progress to an acute ascending lower motor neuron

paralysis, similar to that of Guillain–Barré syndrome, which may result in respiratory failure and death.[44,45] Several species of tick are capable of causing tick paralysis, including *D. andersoni*, *D. variabilis*, and *A. americanum*. Typically, the onset of symptoms occurs 4–6 days after attachment of the tick. Symptoms resolve once the tick is removed from the patient. Supportive measures, including mechanical ventilation, may be required until symptoms resolve.

Management. After potential exposure, the skin should be inspected for ticks to remove them before they begin feeding and risk transmitting disease. Once a tick has inserted its hypostome into the skin, it must be forcibly removed. Although many methods have been suggested for removing ticks, physical methods, such as slow, steady pulling on the tick, are probably the safest and most useful. Retained tick parts should be removed surgically if necessary to prevent development of foreign body granulomas. Antibiotic prophylaxis after tick bites is controversial. Although there is some evidence that prophylaxis may help prevent acquisition of Lyme disease and other vector-borne illnesses, the risks of antibiotic therapy must be weighed against the risks and prevalence of vector-borne illnesses in a particular region. In areas highly endemic for Lyme disease, the benefits of prophylactic treatment may outweigh the risks, especially in cases in which the tick has been attached to the host for an extended period of time and can accurately be identified as a vector for Lyme borreliosis. In these cases, the authors suggest a course of oral doxycycline (see Chapter 187).

CHILOPODA AND DIPLOPODA

The arthropod classes Chilopoda and Diplopoda are composed of centipedes and millipedes, respectively. Centipedes and millipedes are terrestrial arthropods with multiple body segments.

CENTIPEDES

Centipedes, which have one pair of legs per body segment, are nocturnal carnivores that may produce extremely painful bites with a pair of poisonous claws. The *Scolopendra* species is found throughout the southwestern United States and may attack when its habitat is disturbed. In addition to severe pain and erythema following a bite, localized sweating, edema, secondary infection, and ulceration may be seen. There are also case reports of proteinuria, acute coronary ischemia, and myocardial infarction following centipede bite.[46–50] Treatment consists of analgesia, including injection of local anesthetics, antihistamines, and tetanus prophylaxis. Antibiotics may be required to treat secondary infection.

MILLIPEDES

Millipedes, which have two pairs of legs per body segment, usually feed on living and dead plant matter. They lack poison claws and neither bite nor sting. However, millipedes possess repugnatorial glands on either side of each segment and may emit a toxic substance if threatened. The oily, viscous liquid can cause a brownish discoloration of the skin that can persist for months and may produce burning and blistering.[51–53] Severe reactions are mainly seen in tropical species. Some species are capable of squirting the toxin several inches. This can result in various eye lesions including periorbital edema, periorbital discoloration, conjunctivitis, and keratitis.[54] Although ophthalmologic evaluation should be considered for eye exposures, thorough immediate cleansing with soap and water is usually adequate for skin contact.

INSECTA

The class Insecta contains several orders of medical importance: Anoplura (lice; see Chapter 208), Diptera (flies, mosquitoes), Coleoptera (beetles), Hemiptera (bedbugs, kissing bugs), Siphonaptera (fleas), Hymenoptera (ants, bees, wasps), and Lepidoptera (butterflies and moths). Insects can be distinguished from other arthropods by the presence of three body segments, a pair of compound eyes, paired antennae, and six legs.

DIPTERA

The order Diptera, or true flies, contains several important families: Culicidae (mosquitoes), Simuliidae (black flies), Ceratopogonidae (biting midges), Tabanidae (horse flies and deer flies), Psychodidae subfamily Phlebotominae (sandflies), and Glossinidae (tsetse flies). Not only do members of this order inflict cutaneous injury with their bites, they are also, collectively, responsible for the transmission of more disease worldwide than any other arthropod order.

The family Culicidae contains more than 2,000 species of mosquito, many of which transmit disease. Several genera of mosquito, including *Anopheles*, *Culex*, and *Aedes*, serve as vectors for malaria, yellow fever, dengue fever, filariasis, and encephalitis viruses, including West Nile virus, which caused the largest arboviral meningoencephalitis outbreak ever recorded in North America.[55] Because male mosquitoes lack piercing mouthparts, female mosquitoes inflict all human bites. Mosquito bites incite the formation of pruritic wheals and papular lesions, which form in response to irritating salivary secretions that are injected by the mosquito to prevent coagulation. Mosquito bites may have an urticarial, vesicular, eczematous, or granulomatous appearance. Bite reactions usually subside over several days.

Other biting flies include midges, black flies, horseflies, tsetse flies, and sandflies. Black flies of the family Simulidae are vectors for onchocerciasis (African river blindness, see Chapter 207) and tularemia (see Chapter 180). Within the Tabanidae family, *Tabanus* species (horse flies) also serve as vectors for tularemia, and *Chrysops* species (deer flies or mango flies) are responsible for transmission of *Loa loa* filariasis (see Chapter 207) and tularemia. Cutaneous myiasis (Fig. 210-7) may

Figure 210-7 Cutaneous myiasis: a domed nodule resembling a furuncle at the site of deposition of a botfly larva. The lesion has a central pore through which the posterior end of the larva intermittently protrudes. The inset shows the larva that has been extracted.

be caused by the deposition of fly larvae into intact skin or open wounds by several species, including *Dermatobia hominis* (human botfly).[56,57] Numerous species of sandflies also spread disease with *Phlebotomus* species transmitting Old World leishmaniasis (see Chapter 206) and *Lutzomyia* species transmitting New World leishmaniasis and Carrión disease (bartonellosis; see Chapter 206). *Glossina* species (tsetse flies) serve as vectors for African trypanosomiasis (see Chapter 206).

Diptera bites should be cleansed thoroughly with soap and water to avoid secondary infection. A short course of topical steroids and systemic antihistamines may be used to control pruritus. Rare allergic reactions should be treated aggressively. Cutaneous myiasis is often best treated with local surgical excision of the larva and involved surrounding tissue. The antihistamines cetirizine or ebastine taken prophylactically as a single 10-mg dose have been demonstrated in studies to decrease wheal formation and subsequent pruritus following mosquito bites.[58,59]

COLEOPTERA

The Coleoptera order is the largest order in the animal kingdom, containing over 300,000 species of beetles. Although beetles generally do not bite or sting humans, many species of beetle contain chemicals that can cause blistering of human skin.[60] Although some beetles are capable of emitting these chemicals, most cases of blister beetle dermatosis are the result of a beetle being crushed against the skin. The most well-known beetle to cause blister beetle dermatosis is *Lytta vesicatoria*, the Spanish fly, which is found in Southern Europe and contains the chemical cantharidin. Cantharidin, which causes vesiculation of the skin, is used in the treatment of warts and molluscum contagiosum. Several other species of beetle found in different regions of the world, including the central and southeastern United States, contain similar chemicals and can cause blistering.[61,62] *Paederus* species (rove beetles) contain the vesicant pederin and are another cause of beetle dermatitis.[62] Washing of affected areas immediately after exposure may help prevent vesiculation. Blisters should be treated with local wound care until resolved.

Another beetle with dermatologic significance is the carpet beetle. The most common species found in the United States are *Attagenus megatoma* (black carpet beetle) and *Anthrenus scrophulariae* (common carpet beetle). Although adult carpet beetles are of little clinical importance, cutaneous exposure to carpet beetle larvae, which feed on wool, carpets, clothing, and other organic material, can cause an allergic papulovesicular dermatitis.[63]

HEMIPTERA

The Hemiptera order encompasses two families of clinical significance: (1) the Cimicidae, which includes *Cimex lectularius* (bedbugs), and (2) the Reduviidae, which includes *Triatoma* species (kissing bugs). Although most members of this order are herbivores, these two families are frequent human parasites.

CIMICIDAE. The common bedbug (*C. lectularius*; see Fig. 210-1) has been a scourge of mankind for centuries. The bedbug is a nocturnal feeder that stays hidden during the day in cracks and crevices of headboards, in picture frames, behind loose wallpaper, or any other dark place that accommodates its flattened body.[1] After a potential victim has gone to bed, the insects come out of hiding for a blood meal. They are attracted to the warmth and carbon dioxide production of their victim. Bedbugs usually complete their meal in a matter of minutes and then return to hiding. Although bedbugs can survive for 1 year or more without feeding, they usually seek a blood meal every 5–10 days.[1] Bedbugs are common and are distributed worldwide. They can be spread in clothing and baggage of travelers and visitors, on secondhand mattresses, and via laundry.

Along with other blood-sucking arthropods, the role of bedbugs in infectious disease transmission has gained increasing interest in recent years. Although laboratory studies have shown that these insects are capable of incubating and shedding pathogens such as hepatitis B virus for several weeks after feeding on an infected bloodmeal, there is currently no convincing evidence that *Cimex* species act as vectors in their natural state.[64]

Bedbug bites are usually painless and may be overlooked unless large numbers of bites are present. Bites are usually multiple and may be grouped in a linear fashion. A row of three bedbug bites is sometimes referred to as *breakfast, lunch, and dinner*[65] (Fig. 210-8). Reactions to the bites consist of wheals and papules, often with a small hemorrhagic punctum at the center. Bullous reactions to bites are also possible in sensitized individuals, and hypersensitivity reactions have been reported.[65–67] Flecks of blood may also be found on bed linens. Minimal symptomatic treatment of bites and good local wound care to prevent pruritus and secondary infection are sufficient in most cases.[67] In the presence of a secondary infection, topical antiseptic

Figure 210-8 Papular urticaria: bedbug bites. These are pruritic urticarial papules, arranged in a row (breakfast, lunch, and dinner).

lotion or antibiotic cream should be applied.[66] Topical corticosteroids and oral antihistamines may be used for pruritus. Once a bedbug infestation has been diagnosed, a professional exterminator is often necessary to eradicate the insects. Evidence for disease transmission is lacking.

REDUVIIDAE. The kissing bug, or assassin bug, belongs to the family Reduviidae and is distinguished by a triangular shape on its back formed by the meeting of the membranous wings. All reduviid bugs possess piercing mouthparts used to feed on blood. Most species of Reduviidae are found in the Americas, with a few species located in Africa, Asia, and Europe. Within the United States, these insects are found in the Southwest from Texas to California.[68] Reduviidae are of great clinical significance because they act as vectors for *Trypanosoma cruzi*, the causative agent of Chagas disease, which affects an estimated 15 million to 20 million people living in South America and Central America (see Chapter 206). Kissing bugs earned their name for their predilection to bite on or near the lips. After taking a blood meal, reduviids characteristically turn around and defecate immediately. The trypanosomes are inoculated when the victim subsequently scratches the infected feces into the wound.[1]

Although they are nocturnal feeders and usually prey on rodents, during periodic flights they move toward the lights of desert homes. Defensive bites of reduviids are extremely painful. The painless bite of a feeding reduviid occurs only while the host is sleeping, because the blood meal takes several minutes to complete. Bites have been associated with papular, urticarial, and bullous reactions. A small proportion of victims may develop generalized, acute allergic reactions that cause the victim to awaken with sudden onset anaphylactic signs and symptoms.[69] Defensive bites may incite more severe local cutaneous reactions, including necrosis and ulceration.

SIPHONAPTERA

Fleas belong to the insect order Siphonaptera (see Fig. 210-1). These small bloodsucking insects are wingless and are capable of jumping to a height of 18 centimeters. Members of the family Pulicidae, most notably the rat fleas (*Xenopsylla cheopis* and *Xenopsylla brasiliensis*), transmit bubonic plague (*Yersinia pestis*) (see Chapter 180). Other members of this family are also capable of transmitting disease, including the cat flea (*Ctenocephalides felis*), which is a vector for bubonic plaque and endemic typhus (*Rickettsia prowazekii*).

Fleabites produce minimal irritation in nonsensitized individuals, typically resulting in linear or clustered urticarial papules, frequently found on the lower legs (Fig. 210-9). In sensitized individuals, most often young children, the antigenic saliva is capable of producing papular urticaria, an eruption characterized by recurrent or chronic pruritic papules occurring on exposed skin areas.[1,70] Bullous reactions to fleabites may also develop in patients with hypersensitivity (see eFig. 210-9.1 in online edition.) Conservative topical therapy with corticosteroids and antipruritics, along with oral antihistamines, is usually sufficient for most fleabites. Antibiotics may be necessary should secondary bacterial infection develop. Once a flea infestation occurs, complete eradication of the insects is necessary to prevent additional bites.

The Tungidae family contains a tropical flea species called *Tunga penetrans* (the sand flea, chigoe flea, or jigger) that is the etiologic agent of tungiasis, an infestation caused by penetration of the adult female flea into human skin to lay eggs.[71] The usual sites of attachment are feet, particularly plantar surface, subungul or periungal skin or web spaces, and legs, but any body surface in contact with ground can be affected. Solitary or multiple erythematous papules slowly enlarge over a few weeks to 4–10 mm in diameter (Fig. 210-10). A fully developed as white or yellowish firm somewhat translucent nodule may be painful,

Figure 210-9 Papular urticaria: fleabites. Multiple, pruritic urticarial papules, usually <1 cm in diameter; they may be topped by a vesicle. Here, they occur on the legs of a child.

Figure 210-10 Tungiasis: a necrotic periungual papule on the fifth toe. The larva can be visualized by removing the overlying crust.

especially if subungual, or the pain may reflect secondary impetigo and rarely lymphangitis and septicemia. Dermoscopy facilitates visualization of ovoid eggs, and thus the diagnosis of tungiasis.[72] Tungiasis may be also be associated with pain, pruritus, and, sometimes, autoamputation of toes.[73] Death from tetanus has also been reported. One need elicit a history of travel or residence in an endemic area. Treatment options include surgical excision of the affected area or killing the adult female flea with cryotherapy or topical agents. Tetanus prophylaxis is recommended, and systemic antibiotics should be used when necessary. Prevention can be enhanced in endemic areas by avoiding walking along beaches barefoot or in sandals and not sitting or lying in the sand in parts of Nigeria, the Caribbean, India, and Brazil.

HYMENOPTERA

The order Hymenoptera contains the families Apidae and Bombidae (bees), Vespidae (wasps), and Formicidae (ants). Many members of this order have evolved poison glands used for defense and/or hunting. Aside from local cutaneous reactions, Hymenoptera stings are an important problem because of their high incidence and ability to produce fatal anaphylactic reactions.[74]

All Hymenoptera stings are inflicted by female insects via a modified ovipositor or egg-laying apparatus. Most Hymenoptera stings occur when the nest or individual insects are threatened. The honeybee stings with a barbed ovipositor, which it leaves impaled into the skin. The honeybee dies after stinging because it eviscerates itself to expel its paired venom sacs. The stinger should be removed as swiftly as possible after a sting because the musculature attached to the stinger can continue to pump venom into the skin. If possible, the stinger should not be squeezed during removal with fingers or tweezers as additional venom can be injected into the victim. One method for removal is to scrape the edge of a credit card or the dull blade of a butter knife along the skin at an angle almost parallel to the surface. This will dislodge the stinger while minimizing the injection of additional venom. Other Hymenoptera species lack a barbed stinger and may sting repeatedly.

Imported fire ants (*Solenopsis invicta*), originally from Brazil, are an aggressive species that has become well established in the southeastern United States. *Solenopsis* venom contains a nonproteinaceous, hemolytic factor identified as a dialkylpiperidine, solenopsin D, which induces mast cell degranulation.[75] Imported fire ants often attack in groups. Their sting results in an intense inflammatory, wheal-and-flare reaction that becomes a sterile pustule and may progress to localized necrosis and scarring. Sensitized individuals may experience significant bullous reactions following a sting. When attacking, the ants tend to bite the flesh with their powerful jaws and then pivot and sting in a circular pattern, resulting in ring-shaped lesions.

CLINICAL MANIFESTATIONS. Hymenoptera stings typically produce immediate burning and pain, followed by the development of an intense, local, erythematous reaction with swelling and urticaria. This "typical" reaction to hymenoptera stings usually subsides within several hours. However, more severe local reactions can occur, including extensive swelling at the sting site and prolonged induration lasting for up to 1 week. A cell-mediated immune response has also been implicated in these reactions.[76] Generalized systemic reactions to hymenoptera stings occur in approximately 0.4% to 3.0% of patients. Anaphylactic reactions may be evident as generalized urticaria, angioedema, and bronchospasm.

MANAGEMENT. Treatment of a Hymenoptera sting is governed by the severity of the reaction. Mild local cutaneous reactions may only require local cleansing, application of ice, and possible injection of local anesthetic to control pain. Oral or parenteral diphenhydramine may help control urticaria and pruritus. Anaphylaxis must be treated vigorously with subcutaneous epinephrine (0.5 mL of 1:1000 dilution) and the institution of intramuscular epinephrine, exit to an emergency room, and the supportive measures. Individuals with known Hymenoptera hypersensitivity should always carry a preloaded epinephrine-filled syringe for emergency self-administration. Desensitization therapy should be considered for any patient with a positive intradermal skin test to Hymenoptera venom and a history of sting-induced anaphylaxis. Fire ant hypersensitivity is a potentially deadly condition for which rush immunotherapy may be a good option to achieve protection quickly.

LEPIDOPTERA

The Lepidoptera order is the second largest order of insects and contains over 100,000 species of caterpillars, moths, and butterflies. An estimated

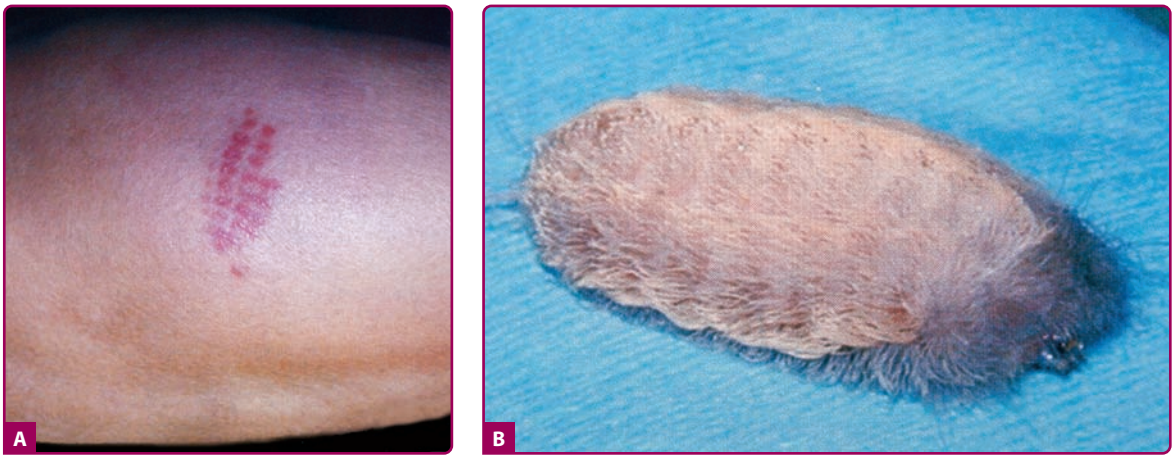

Figure 210-11 **A.** Cutaneous reaction from contact with a puss caterpillar showing the typical grid-like pattern. **B.** Pus caterpillar (*Megalopyge opercularis*) demonstrating the corresponding grid-like pattern of its hairs.

100–150 species within this order are thought to produce *lepidopterism*, the term used to describe the aggregate of medical effects caused by caterpillars, moths, and butterflies.[77,78] Multiple theories regarding the mechanisms of lepidopterism have been proposed, including mechanical irritation by pointed hairs (setae), toxin injection through hollow setae, and cell-mediated hypersensitivity to the hairs. One well-known cause of erucism or caterpillar dermatitis is *Lymantria dispar* (gypsy moth caterpillar).[79,80] Cutaneous contact with hairs from this caterpillar may produce a pruritic dermatitis characterized by multiple erythematous papules often arranged in linear streaks. Urticaria, angioedema nad anapylaxis may occur with processionary caterpillars (genus *Thaumetopoea*). Wind-borne hairs may produce keratoconjunctivitis and respiratory symptoms. *Megalopyge opercularis* (asp or puss caterpillar), which can inject venom through its hollow syringe-like hairs, is capable of inflicting an intensely painful sting, and may produce a characteristic train-track pattern of purpura at the sting site (Fig. 210-11).[81,82] Other species that cause lepidopterism in the Americas include *Automeris io* (io moth), *Euproctis chrysorrhoea* (brown-tailed moth), *Sibine stimulate* (saddleback moth), and *Hemerocampa pseudotsugata* (Douglas-fir tussock moth).

Treatment for lepidopterism is largely symptomatic. Systemic antihistamines, topical preparations containing menthol and camphor, and moderate to high potency topical corticosteroids can be used to control pruritus. Systemic steroids may be beneficial for severe reactions. The intractable pain caused by the sting of the puss caterpillar may require oral or parenteral narcotic analgesics. Embedded setae can be removed from the skin by "stripping" with adhesive tape. There is an antivenom available that should be employed for potentially fatal Lonomia genus caterpillar envenomation, still responsible for deaths in southern Brazil.[83]

PREVENTION

Several relatively simple steps can be taken to minimize the occurrence of arthropod bites. Spider bites can be reduced by wearing gloves while working in crawl spaces, garages, or basements or when manipulating woodpiles or rubbish piles. In scorpion endemic areas, shaking out clothing and footwear before putting them on is advisable. Wearing appropriate clothing with good coverage and avoiding rubbing against high brush and grass may help avoid tick bites. Bright colors and artificial scents like perfume, which are attractants for mosquitoes and other flying insects, are best avoided on warm summer nights. In tropical regions, proper footwear is essential to preventing tungiasis. Infestations of living areas by arthropods, including fleas and bedbugs, are difficult to eliminate and may require the assistance of a professional exterminator.

Chemical repellents are also useful in preventing arthropod bites. Several different chemical compounds have been studied, including *N*,*N*-diethyl-3-methylbenzamide (DEET, previously diethyltolu-amide), picaridin (KBR 3203), and *p*-menthane-3,8-diol (Eucalyptus oil). The most effective repellent for all biting flies, including mosquitoes, is DEET, which is available in many products in concentrations up to 100%. Generally, a product containing 10% to 30% DEET provides adequate protection for most outdoor activities, with higher concentrations of DEET providing longer protection times. Although DEET has an excellent safety record, there are reports of encephalopathy developing, particularly in children, after exposure to this chemical.[84,85] For this reason, only products with DEET concentrations of less than 10% should be used on children. Permethrin, an insecticide often used to treat pediculosis and scabies, is available as a tick repellent that can be sprayed on clothing and fabrics, including tents and sleeping bags, and remains effective through

several wash cycles. Combined use of permethrin-treated clothing and DEET applied to the skin provides the maximum protection.

Occupational Skin Diseases and Skin Diseases Due to Biologic Warfare

PART 10

Occupational Skin Diseases

Chapter 211 :: Occupational Skin Diseases Due to Irritants and Allergens

:: Golara Honari, James S. Taylor, & Apra Sood

OCCUPATIONAL SKIN DISEASES DUE TO IRRITANTS AND ALLERGENS AT A GLANCE

- Skin disorders are the second most commonly reported occupational disease, accounting for approximately 20% of occupational disorders.
- Irritant and allergic contact dermatitis comprise a significant number of cases of occupational skin disease. The majority involve workers in the manufacturing and service industries.
- Chronic cumulative irritant contact dermatitis is the most common form of occupational irritant contact dermatitis.
- Approximately 80% of individuals with occupational contact dermatitis have hand involvement.
- Patch testing should be performed to rule out an allergic contact dermatitis in all cases in which an initial chronic irritant dermatitis is suspected.

Occupational dermatoses are any abnormal conditions of the skin caused or aggravated by substances or processes associated with the work environment. Occupational skin diseases (OSDs) are a major public health problem because they are common, are often chronic, and have significant economic impact on society and on workers.[1] A thorough knowledge of potential irritants, allergens, and other causative factors in the workplace, as well as the workers' compensation system, is essential for the dermatologist dealing with occupational dermatoses.

EPIDEMIOLOGY

The US Department of Labor publishes annual incidence statistics on the safety and health of employees in private industry (http://www.bls.gov/). In 2008, of the 3.8 million nonfatal job related injuries and illnesses reported among the private industry establishments, 5.1% (193,800 cases) were work-related illnesses, of these, skin disorders were the second most common reported illness, accounting for almost 38,000 cases.[2] Occupational contact dermatitis is the most commonly reported OSD, and in most countries, the reported incidence of occupational contact dermatitis varies from

5 to 19 cases per 10,000 full-time workers per year.[3] Incidence rates also vary based on the specialty of the reporting physicians; rates are six to eight times higher in some studies when cases are reported by occupational physicians rather than by dermatologists.[4]

The number of OSD cases has declined,[5] especially in the past 8 years, possibly due to better prevention, the ease with which workers' compensation cases are accepted, and a change in reporting patterns of employees or employers.[6] However, a large number of minor or transient cases still go unreported or untreated, so the exact incidence is not known. Occupational skin disease still accounts for a significant percentage of days away from work. In 2008, dermatitis led to 3,170 (8.4%) of the skin disease cases resulting in days away from work and 2,630 (83%) of these cases were caused by contact dermatitis.[2]

Distribution of nonfatal occupational injury and illness cases by category is demonstrated in Figure 211-1. Surface wounds and bruises and trauma-induced injuries are not considered among the skin disease and illnesses. Surface wounds and bruises accounted for 11,2870 (12.24%) of all traumatic injuries and disorders cases involving days away from work in 2008.[7]

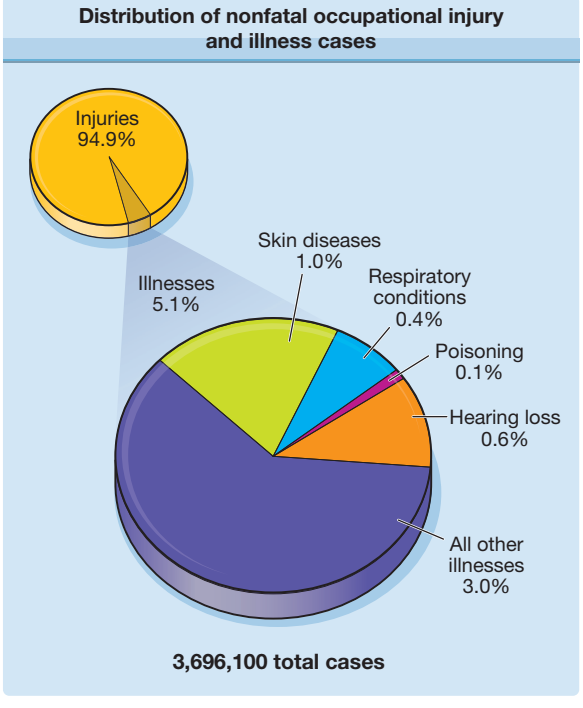

Figure 211-1 Distribution of nonfatal occupational injury and illness cases by category of illness; private industry; 2008. Only 5% of injury and illness cases reported among private industry establishments in 2008 were illnesses. Nearly 6 in 10 illnesses were categorized as "all other illnesses," which includes such things as repetitive motion cases and other systemic diseases and disorders. (Adapted from US Bureau of Labor Statistics: *2008 Survey of Occupational Injuries & Illnesses*, http://www.bls.gov/iif/oshwc/osh/os/osch0039.pdf, accessed Feb 7, 2009.)[41]

IRRITANT CONTACT DERMATITIS

(See Chapter 48.)

Irritant contact dermatitis (ICD) is a nonimmunologic inflammatory reaction of the skin to contact with a chemical, physical, or biologic agent. ICD is the most common OSD, accounting for up to 80% of cases, although some authors have found a relatively equal distribution of ICD and allergic contact dermatitis (ACD).[3] Chapter 48 discusses ICD in detail. Exogenous and endogenous factors influencing ICD are listed in Tables 48-1 and 48-2. In addition to the more common acute and chronic eczematous reactions, the clinical spectrum of ICD includes ulceration, folliculitis, acneiform eruptions, miliaria, pigmentary alterations, alopecia, contact urticaria, and granulomatous reactions (Table 211-1).[8]

MAJOR CATEGORIES OF IRRITANT CONTACT DERMATITIS

The two major types of occupational ICD are acute ICD and cumulative ICD. These and the many other subtypes are discussed in Table 48-3, which summarizes their time onset and prognosis.

ACUTE IRRITANT CONTACT DERMATITIS, INCLUDING CHEMICAL BURNS. Acute eczematous dermatitis after exposure to a potent irritant, often an acid or alkali, may overlap with chemical burns. Highly irritating chemicals may induce a reaction in anyone if the concentration and duration of action are sufficient. The intrinsic nature of the chemical is also important. Common irritants in the workplace are discussed in Common Occupational Irritants later in the chapter. In national statistics for work-related injuries, acute ICD reactions are often classified as chemical burns (Fig. 211-2).

CUMULATIVE IRRITANT CONTACT DERMATITIS. Cumulative ICD, the most common type of ICD, develops slowly after multiple subthreshold exposures to mild irritants (soap, water, detergents, industrial cleansers, solvents, etc.) under a variety of conditions.[9] Some of the high-risk occupations for ICD are listed in Table 211-2. For a comprehensive list, see the sources presented in eTable 211-0.1 in online edition. The other categories of ICD, as well as predisposing factors, including exogenous as well as endogenous factors, are discussed in Chapter 48. Atopic individuals have an increased susceptibility to skin irritation and account for a large percentage of workers' compensation dermatitis claims.

LOW-HUMIDITY DERMATITIS. Workers, especially atopic individuals who are subjected to low relative humidity at work (Table 211-3),[10] are also at risk for developing dermatitis, especially with the presence of other irritants. When relative humidity is below 35%–40%, the stratum corneum becomes drier and more brittle, and shows increasing permeability to marginal

TABLE 211-1
Clinical Features of Irritant Contact Dermatitis and Suggested Etiology

- **Eczema** (acute and cumulative irritant exposure)
  - Industrial cleaners
  - Water, soaps, and detergents
  - Weak acids and alkalies
  - Oils and organic solvents
  - Oxidizing agents (H_2O_2, benzoyl peroxide)
- **Ulcerations and burns**
  - Strong acids, especially chromic, hydrofluoric, nitric, hydrochloric, sulfuric
  - Strong alkalis, especially calcium oxide, sodium hydroxide, potassium hydroxide, ammonium hydroxide, calcium hydroxide, sodium metasilicate, sodium silicate, potassium cyanide, trisodium phosphate
  - Salts, especially arsenic trioxide, dichromates
  - Solvents, especially acrylonitrile, carbon bisulfide
  - Gases, especially ethylene oxide, acrylonitrile
- **Folliculitis and acneiform eruptions**
  - Arsenic trioxide
  - Glass fibers
  - Oils and greases
  - Tar
  - Asphalt
  - Chlorinated naphthalenes
  - Polyhalogenated biphenyls
  - 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin (TCDD)
  - Polyhalogenated dibenzofurans
- **Miliaria**
  - Occlusive clothing
  - Adhesive tape
  - Ultraviolet and infra-red radiation
  - Aluminum chloride
- **Pigmentary changes**
  - **Hyperpigmentation**
    - Any irritant or allergen, especially phototoxic agents such as psoralens, tar, asphalt, phototoxic plants, others
    - Metals,[a] such as inorganic arsenic (systemically), silver, gold, bismuth, mercury
    - Radiation: ultraviolet, infra-red, microwave, ionizing
  - **Hypopigmentation**[a]
    - *p*-tert-Amylphenol and butylphenol
    - Hydroquinone
    - Monobenzyl and monomethyl ether of hydroquinone
    - *p*-tert-Catechol
    - *p*-Cresol
    - 3-Hydroxyanisole
    - Butylated hydroxyanisole
    - 1-tert-Butyl-3,4-catechol
    - 1-Isopropyl-3,4-catechol
    - 4-Hydroxypropriophenone
  - **Alopecia**
    - Borax
    - Chloroprene dimers
  - **Urticaria**
    - Numerous chemicals, cosmetics, animal products, foods, plants, textiles, woods
  - **Granulomas**[b]
    - Keratin
    - Silica
    - Beryllium
    - Talc
    - Cotton fibers
    - Bacteria
    - Fungi
    - Parasites and parasite parts

[a]Also potential allergens.
[b]some listed agents are also allergens.
Adapted from Lammintausta K, Maibach H: Contact dermatitis due to irritation. In: *Occupational Skin Disease*, 2nd edition, edited by RM Adams. Philadelphia: WB Saunders, 1990, p. 11.

Figure 211-2 Acute irritant contact dermatitis on the hand caused by an industrial solvent. There is massive blistering on the palm.

irritants. Symptoms such as pruritus and burning may be the only complaints and are more distressing than physical signs, which may involve exposed or covered areas. Differential diagnosis includes irritation from airborne substances, other dermatoses, and psychogenic causes.

AIRBORNE IRRITANT DERMATITIS. Airborne irritants are an important cause of contact dermatitis. The pattern is fairly characteristic, with subjective symptoms of stinging, burning, or smarting sensations. Objective findings range from barely visible diffuse lesions to more severe dermatitis of the eyelids, cheeks, nasal folds, and neck. Some airborne irritant particles cause symptoms only if occluded under clothing in the flexures and other intertriginous body areas.

The most frequent causes are irritating dusts and volatile chemicals, such as solvents, ammonia, formaldehyde, epoxy resins and their hardeners, cement dust, fibrous glass, and sawdust, especially from irritating woods.[11] See Table 48-4 for a list of other airborne irritants.

TABLE 211-2
Occupations at Increased Risk for Irritant or Allergic Contact Dermatitis[8,9,14,21,31,42,43]

Occupation	Irritants	Allergens
Agricultural workers	Fertilizers, germicides, dust, diesel, gasoline, oils, pesticides, plants, solvents, wet-work	Pesticides, animal feeds, barley and oats, fungicides, germicidal products, cement, plants, veterinary medications, wood dust, preservatives, wool
Bakers	Acids, flour, spices, soaps and detergents, oven cleaners, essential oils, yeast, enzymes	Ammonium persulfate; benzoyl peroxide; dyes; essential oils; enzymes; flavors; flour; some fruits
Construction workers	Acids, fibrous glass, concrete, solvents, hand cleaners	Cement, chromium, chromium compounds, cobalt, epoxy resins, nickel, resins, rubber allergens, wood dust
Cooks	Wet work, soaps and detergents, vegetable and fruit juices, raw meat and fish, spices, sugar and flour, heat	Flavors and spices, formaldehyde, garlic, sodium metabisulfite (antioxidant for vegetables)
Cosmetologists	Soaps and detergents, bleaches, solvents, permanent wave solutions, shampoos, wet-work	Dyes, amine-based products including parphenylene diamine, glyceryl monothioglycolate (perming solution), rosin, preservatives, rubber allergens, ethylmethacrylate, methylmethacrylate
Dentists and Dental technicians	Wet work, adhesives (epoxy and cyanoacrylates), essential oils, orthodontic plasters, amalgam mixtures, solvents	Dental impression material, eugenol, anesthetics, mercury, disinfectants, methacrylates, latex, rubber accelerators
Florists	Wet work, soaps and detergents, fertilizers, herbicides, pesticides, mechanical and chemical plant irritants	Plants, pesticides, insecticides
Health care workers	Wet work, soaps and detergents, alcohol, ethylene oxide, medications	Latex gloves, anaesthetics, antibiotics and antiseptics, phenothiazines, formaldehyde, glutaraldehyde, chloroxylenol
Housekeepers	Wet work, soaps and detergents, cleaners, polishes, oven cleaners, disinfectants	Potassium dichromate, preservatives, rubber accelerators, latex
Machinists	Solvents, coolants, cutting oils, degreasers, acids, corrosion inhibitors, heat, soaps and detergents, metal filings and swarf	Additives/preservatives in cutting fluids, chromium, nickel
Automobile Mechanics	Abrasive skin cleaners, diesel, gasoline, greases, oils, solvent, transmission fluid, motor oils	Chromium, cobalt, epoxy resin; nickel
Painters	Paints, solvents, adhesives, paint removers, paintbrush cleaners, soaps and detergents	Turpentine, thinners, chromium, formaldehyde, epoxy products, polyester resins

DIAGNOSIS OF IRRITANT CONTACT DERMATITIS

The diagnosis of ICD is based on a history of exposure to a known potential irritant, the clinical appearance, and the distribution of lesions.[12] Subacute and chronic irritant dermatitis are almost always diagnoses of exclusion. Patch testing (see Chapter 13) helps to distinguish ACD from ICD or to diagnose a superimposed ACD or ICD. More detailed criteria for the clinical diagnosis of ICD are discussed in Chapter 48 and especially Boxes 48-1 and 48-2 and Table 48-7.

TABLE 211-3
Low-Relative-Humidity Environments That Increase Risk of Dermatitis[44,45]

- Soft contact lens manufacturing workers
- Silicon chip manufacturing workers
- Aircraft crews on long-distance flights
- Office workers
- Resident staff in hospitals and hotels
- Traveling salespersons (from automobile heaters)

COMMON OCCUPATIONAL IRRITANTS

SOAPS AND DETERGENTS. Soaps and detergents are weak skin irritants; however, excessive use can cause cumulative insult dermatitis in susceptible individuals. The choice of cleanser varies with the job for which it is intended; for example, machinists and auto mechanics need a cleanser with a high detergent and abrasive action. The inappropriate use of products intended as industrial cleansers can also result in dermatitis.

TABLE 211-4
Selected Chemical Burns That Require Unique Therapies[14,74,75,76]

Chemical	Treatment Basics (Then Transport to Hospital Emergency Department for Further Evaluation and Treatment)
Burning metal fragments of sodium, potassium, and lithium	Extinguish with Class D fire extinguisher (containing sodium chloride, sodium carbonate or graphite base) or with sand; cover with mineral oil; extract metal particles mechanically.[a]
Hydrofluoric acid	Flush with running water; then administer calcium gluconate gel (2.5%) followed by intralesional injection, if needed.
White Phosphorus	Remove particles mechanically; wash with soap and water; then apply copper ($CuSO_4$) sulfate in water for several minutes, remove black copper phosphide, and wash with water. Vigorous water irrigation and removal of phosphorus particles mechanically; The use of a Wood lamp (ultraviolet light) results in the fluorescing of the white phosphorus and may facilitate its removal. A brief rinse with 1% copper sulfate solution may be helpful. Copper sulfate combines with phosphorus to form a dark-copper phosphide coating on the particles that makes them easier to see and debride, and also impedes further oxidation. However, copper sulfate can cause hemolysis and hemoglobinuria, and should be used with caution.[74] More recently Kaushik and Bird recommend vigorous water washing rather than using copper sulfate.[75]
Phenolic compounds	Decontaminate with undiluted 200–400 molecular weight polyethylene glycol (PEG), which can be located in the chemical section of hospital pharmacies, followed by copious water irrigation. Isopropanol or glycerol may be substituted if PEG is not available.[76] initial soap and water washing followed by treatment with polyethylene glycol 300 or 400 or ethanol (10%) in water.
Bromine or iodine	Wash frequently with soap and water followed by treatment with 5% sodium thiosulfate.

[a]Use of water to extinguish burning metal fragments is contraindicated because of the formation of highly alkaline hydroxides.

WATERLESS HAND CLEANERS. Waterless hand cleaners are formulated to remove tough oil and grease stains and are widely used at work sites where there is no convenient source of water. They should be applied sparingly because they may contain petroleum-derived solvents and may result in dermatitis if overused. Instant hand sanitizers, which often contain high concentrations of alcohol, can be drying to the skin.

ACIDS AND ALKALIS, INCLUDING CHEMICALS THAT CAUSE BURNS. Chemical burns are an important cause of occupational injury.[13] Copious irrigation is the primary method of treating all chemical burns; however, certain types of burns require specific antidotes and therapies (Table 211-4).[14]

Inorganic Acids. Inorganic acids are used in large quantities in industry; some of the occupations at risk for exposure are listed in Table 211-5. Acids are common causes of chemical burns and can cause erythema, blistering and necrosis, and discoloration of the skin. Mechanisms of action of common industrial irritants, including acids, are listed in Table 211-6.

Organic Acids. Organic acids, such as acetic, acrylic, formic, glycolic, benzoic, and salicylic acids, are less irritating than some other acids but can cause chronic irritant dermatitis after prolonged exposure. Formic acid has greater corrosive potential than other organic acids. Fatty acids, such as palmitic, oleic, and stearic acids tend to have low irritant potential.

Hydrofluoric Acid. Hydrofluoric acid (HF) is extremely irritating, even in low concentrations (15%–20%). Fluoride ions penetrate deep into the tissues and bind to calcium and magnesium ions, causing severe tissue damage including bone destruction, especially of the terminal digits of the hand.[14] After exposure to lower concentrations of HF, the onset of symptoms may be delayed until release of fluoride ions occurs in deep tissues. Exposure to HF is a medical emergency requiring topical or subcutaneous administration of calcium gluconate after lavage to bind the fluoride ions (see Table 211-4).

Chromic Acid. Chromic acid is highly irritating, causing ulcerations of the skin ("chrome holes") and perforation of the nasal septum. It can be absorbed and lead to renal failure.[15]

Alkalis. Alkalis saponify surface lipids and penetrate easily, leading to severe and extensive tissue destruction, including deep ulcerations that heal very slowly (see Table 211-5).

Cement. Exposure to wet cement may cause severe alkaline and thermal burns due to the exothermic reaction of calcium oxide with water to form calcium hydroxide.[16] Kneeling in wet cement for prolonged periods leads to deep burns of the knees ("cement knees") and shins.[17] Burns may also result from the trapping of wet cement in gloves and boots.

TABLE 211-5
Industrial Chemicals Presenting Risk for Burns and Acute Irritant Reactions[9,13–21,31,42,46]

Chemical	Industries Presenting Risk
Acids	
Sulfuric	Manufacture of fertilizers, inorganic pigments, textile fibers, explosives, pulp and paper
Hydrochloric	Production of fertilizers, dyes, paints, and soaps
Formic	Textile industry (dyeing and finishing), leather manufacture (delimer and neutralizer), production of natural latex (coagulant)
Acrylic	Manufacture of acrylic plastics (monomer)
Chromic	Chrome plating, copper stripping, and aluminum anodizing operations
Hydrofluoric	Etching and frosting of glass, rust removal, dry cleaning (spot cleaning)
Alkalis	
Calcium, sodium, and potassium hydroxides	Manufacture of bleaches, dyes, vitamins, plastics, pulp and paper, and soaps and detergents
Others	
Arsenic	Smelting of copper, gold, lead, and other metals; semiconductor industry
Beryllium	Aerospace and other industries involved in the production of hard, corrosion-resistant alloys
Cobalt	Manufacture of alloys, ceramics, electronics, magnets, paints and varnishes, or cosmetics; electroplating
Mercury	Industries involved in the manufacture or use of bactericides, dental amalgams, and catalysts
Phosphorus	Manufacture of insecticides and fertilizers

TABLE 211-6
Mechanisms of Action of Common Industrial Irritants[47]

Action	Irritant
Keratin and protein dissolution	Alkalis, soaps
Lipid dissolution	Organic solvents
Dehydration	Inorganic acids Anhydrides Alkalis (calcium oxide)
Oxidation	Bleaches
Reduction	Salicylic acid Formic acid Oxalic acid
Keratogenesis	Arsenic Tars Petroleum

From Birmingham DJ: Dermatoses in occupational diseases. In: *Occupational Diseases: A Guide to their Recognition*, edited by MM Key et al. NIOSH Publication No. 77-181. Washington, DC, US Government Printing Office, 1977.

OTHER CHEMICALS AND AGENTS

Phosphorus. Phosphorus can cause deep, destructive burns. It ignites spontaneously on exposure to air. The affected area should be kept moist until the chemical is completely removed. Severe metabolic derangements have been reported after phosphorus burns, and patients should be closely monitored for multiorgan failure.[18]

Ethylene Oxide. Ethylene oxide burns may result from contact with porous materials and devices that have been sterilized with ethylene oxide but not properly aerated.[19] Ethylene oxide may cause delayed irritant reactions (see Table 48-5). Rarely, allergic contact dermatitis is reported to ethylene oxide.[66]

Phenol. Phenol is rapidly absorbed through intact skin and can cause local necrosis and nerve damage.

Solvents. The chief uses of solvents are in the manufacture of other chemicals and as carriers for chemical reactions, as pressure transmitters for hydraulic systems, and as coatings, industrial cleaners, printing inks, and pharmaceuticals. After water, the most common solvents are aliphatic and aromatic hydrocarbons, esters, ethers, ketones, amines, and nitrated and chlorinated hydrocarbons (eTable 211-6.1 in online edition).[20,21] Volatile solvents, in particular, act by dissolving the intercellular lipid of the epidermis, causing transient "whitening" of the skin and a feeling of dryness.

Fibrous Glass. Glass fibers, or man-made vitreous fibers, cause a highly pruritic contact dermatitis that may resemble scabies. Fibers larger than 3.5 m are generally responsible. Contact can be direct, indirect (through clothing), or through the air. Fibers may cause simple mechanical irritation by penetration into the skin, or secondary ACD from the associated finishing resins (e.g., epoxy).

Fabrics. Wool and rough synthetic clothing can cause irritant dermatitis, especially in atopic individuals. Fire-retardant fabrics, "NCR" paper (carbonless copy paper), and paper facemasks, such as are used in the semiconductor and other industries, can also induce irritation.

Plants. Florists, horticulturists, gardeners, nursery personnel, farm workers, grocery store workers, and outdoor workers are at risk for developing dermatoses caused by plants (see also Chapters 13 and 48). eTable 211-6.2 in online edition lists the various clinical types of plant dermatoses.

ALLERGIC CONTACT DERMATITIS

(See Chapter 13.)

ACD is reported less frequently than ICD in the work environment, possibly because most workers are not patch-tested, and thus the disorder is not diagnosed and reported. In a multicenter study conducted by the North American Contact Dermatitis Group that examined 839 cases identified as occupational dermatitis (29% of 2,889 patients referred for evaluation of contact dermatitis), 54% were primarily allergic dermatitis, 32% were irritant dermatitis, and 14% were conditions other than contact dermatitis that were aggravated by work.[22] In this series, ACD was seen most commonly in nurses; the other occupational groups represented were assemblers, nurse's aides and orderlies, machinists, students, machine operators, auto mechanics, those performing compressing and compacting jobs, and cooks. Allergens strongly associated with occupational exposure were rubber (thiuram and carbamate accelerators), epoxy resin, and ethylenediamine. The recent increase in the use of computers has led to an increase in computer-related skin diseases; including ACD caused by plasticizers and possibly neoprene and rubber accelerators in the equipment.[23]

The principal occupational contact allergens are listed in Table 211-7. Additional more recently reported occupational allergens are discussed in eTable 211-7.1 and eTable 211-7.2 in online edition describes difficulties in the diagnosis of ACD.

The mechanism of ACD and its clinical manifestations are described in Chapter 13. It is important to remember that if a worker develops ACD 2 or 3 days after initial contact with an allergen, the induction of sensitivity must have occurred previously, perhaps during an earlier job.

CONTACT URTICARIA AND IMMEDIATE CONTACT REACTIONS

(See Chapter 38)

Contact urticaria syndrome (CUS) comprises a heterogeneous group of inflammatory reactions that usually appear within minutes after cutaneous or mucosal contact with the eliciting agent and disappear within 24 hours, usually within a few hours. CUS has four stages: stage 1—localized urticaria, dermatitis, or itching, tingling, or burning; stage 2—generalized urticaria; stage 3—rhinoconjunctivitis, asthma, or gastrointestinal symptoms; and stage 4—anaphylaxis.

There are three varieties of contact urticaria (CU): (1) nonimmunologic CU, (2) immunologic CU, and (3) CU of uncertain mechanism (see also Chapter 38).

TABLE 211-7
Major Occupational Contact Allergens[42,48]

- Acrylics
- Biocides—isothiazolinones, formaldehyde releasers
- Chromate
- Cobalt
- Colophony
- Dyes
- Epoxy resin systems (may need to test with specific resin worker uses)
- Formaldehyde
- Formaldehyde resins
- Fragrances and essences
- Nickel (initial sensitization is usually nonoccupational)
- *para*-Phenylenediamine (PPD)
- Plants and woods
- Rubber-processing chemicals

NONIMMUNOLOGIC CONTACT URTICARIA

In nonimmunologic CU, exposed individuals develop reactions without previous sensitization. Depending on the nature of the substance, its concentration, the area of skin exposed, and the mode of exposure, the reaction usually remains localized; and systemic symptoms of wheezing, rhinorrhea, and syncope do not occur. Causative urticants include benzoic acid, sorbic acid, cinnamic acid, cinnamic aldehyde, and nicotinic acid esters.[24,25]

Affected occupational groups and the causative agents to which they may be exposed include the following: gardeners—nettles, various plants, caterpillar hairs, moths, and other insects; cooks—fish, mustard, cayenne pepper, and thyme; and medical and related personnel—alcohol, balsam of Peru, benzocaine, methyl salicylate, tar extracts, tincture of benzoin, witch hazel, and dimethyl sulfoxide.

IMMUNOLOGIC CONTACT URTICARIA

(See Chapter 38.)

Immunologic CU, an immunoglobulin E-mediated immediate allergic reaction, occurs in persons previously sensitized to a specific agent. Atopic individuals, especially those with atopic dermatitis, are more susceptible. The prototype is natural rubber latex (NRL) allergy, which results from a reaction to one or more proteins present in NRL.[26] The highest prevalence of NRL allergy is in individuals with spina bifida. Also affected are health care workers; kitchen workers; cleaners; others who wear NRL gloves; and workers involved in the manufacture of rubber bands, surgical gloves, and latex dolls.

The next most common cause of immunologic CU is food items such as raw potato and meat. Other causes are antibiotics and other medications, preservatives, disinfectants, fragrances, epoxy resin hardeners, several woods, birch pollen, and formaldehyde in clothing.

CONTACT URTICARIA OF UNCERTAIN MECHANISM

CU of uncertain mechanism includes reactions to ammonium persulfate, which is used as a booster in bleaching hair. The dermatitis, which occurs mostly in clients, has a sudden onset and is characterized by

erythema, edema, severe itching, urticaria, and occasionally syncope, with wheezing and dyspnea. Hairdressers should be made aware of the seriousness of this problem. Both nonimmunologic and immunologic mechanisms have been demonstrated to be present in the immediate reactions to ammonium persulfate.

DIAGNOSIS OF CONTACT URTICARIA

Other than for NRL allergy, there are few statistical data on CU. Data from Finland indicate that farmers (from exposure to cow dander) account for the most cases but that the highest incidence is found among bakers.[25] Recent data from Australia included 143 cases of occupational CU diagnosed over 12 years, which represented 8.3% of 1,720 cases of occupational skin diseases. Natural rubber latex allergy in health care workers accounted for the majority of cases, followed by foodstuffs in food handlers and ammonium persulfate utilized in hair dressers. The most frequently affected sites of CU were the hands, all of which were occupational, followed by the arms and face.[69] Diagnosis of immunologic CU typically involves skin testing with the suspected substance and serologic assays for specific immunoglobulin E. When a chemical hapten is the suspected cause, it must be conjugated with a protein, usually human serum albumin, a nonstandard procedure.[71]

CU occurs from direct contact with skin (most cases) or mucosa (e.g., latex and chlorhexidine; the latter may be associated with systemic toxicity), or from contact with airborne allergen (e.g., cinchona, mulberry, xylene). Exposure may be accidental or caused by equipment failure (e.g., xylene). Standard ingredients (e.g., Tinofix) or trace contaminants or impurities (e.g., an anhydride present in sorbitan sesquioleate) may be responsible. CU may be associated with other urticaria such as delayed pressure urticaria. Occasionally, only erythema, burning, and itching occur, but at least some people should develop urticaria at the application site for the agent to be regarded as causing CU. Combined CU and delayed allergic eczematous reactions may occur.[27]

DIAGNOSIS OF OCCUPATIONAL SKIN DISEASE

ASPECTS OF EVALUATION

Making medical determinations in cases of putative occupational skin disorders and in workers' compensation cases confronts the physician with several challenging tasks: (1) weighing patient assertions and demands concerning the work relatedness of the disease, job changes, and job modifications; (2) serving as gate keeper with regard to time off from and date of return to work; (3) dealing with lack of adequate workplace information—job description, list of chemicals used at the workplace, and exposures, including material safety data sheets; (4) balancing clinical judgment against technology (e.g., determining whether hand eczema in a machinist is work related when patch test results are negative); (5) establishing causation in the legal sense, which usually requires only probability of work association (within reasonable certainty or more than 50% medical certainty), rather than absolute certainty, such as fulfilling Koch's postulates.[28,29]

The medicolegal essentials in evaluating OSD in the workplace consist of the following:

1. Making an accurate diagnosis, including taking a detailed medical and occupational history, performing a complete skin examination, and ordering diagnostic tests as indicated (Table 211-8).
2. Determining causation. Mathias[30] has proposed that a Yes answer to four of the following seven questions is adequate to establish occupational causation and aggravation in contact dermatitis cases:
   a. Is the clinical appearance compatible with contact dermatitis?
   b. Are there workplace exposures to potential irritants or allergens?
   c. Is the anatomic distribution of the eruption compatible with job exposure?

TABLE 211-8
Diagnostic Workup for Occupational Irritant and Allergic Contact Dermatitis[49–51]

History
- Duration, site of onset, progression, symptoms (itching, burning, pain), improvement away from work, treatment to date including response, history of any overt contact allergies
- Occupational history, including current job and process description, changes in current job, previous employment, protective clothing used if any, other workers affected
- Hobbies and part-time jobs
- Medical history, including medical, dermatologic, and surgical history, especially any history of atopic dermatitis, seasonal allergies, and asthma
- Family history of atopy, psoriasis, or other chronic skin conditions

Examination
- Site(s) of eruption
- Morphology of lesions (erythema, eczema, lichenification, pigmentary changes, urticaria, etc.)
- Pattern of involvement

Diagnostic Tests (if indicated)
- Patch testing
- Photopatch testing
- Tests for immediate hypersensitivity (see Fig. 211-3)
  - Radioallergosorbent assay test (RAST)
  - Open and semiopen patch tests (read at 10 and 45 minutes)[49]
  - Prick test
  - Scratch-chamber test[50]
- Repeat open-application "use" test
- Potassium hydroxide examination for fungi, glass fibers
- Fungal, bacterial, and viral smears and cultures
- Skin biopsies
- Dimethylglyoxime test for detecting nickel, other tests (detection of chromates and formaldehyde)
- Chemical analysis

d. Is the temporal relationship between exposure and onset consistent with contact dermatitis?
e. Have causal nonoccupational exposures been excluded or made highly unlikely?
f. Does the dermatitis improve away from work exposure to the suspected irritant or allergen?
g. Do patch or provocation tests identify a probable cause?

The Mathias criteria were found to be valid and useful in a study of occupational contact dermatitis and the concepts are applicable to other occupational dermatoses.[70]

3. Providing recommendations for treatment, prevention, disability status (if any), job placement, rehabilitation, and use of other resources (industrial hygiene consultation and consultations with other medical specialists, such as allergists, pulmonologists, or occupational medicine physicians).

DIAGNOSTIC TESTING

PATCH TESTING. Because of the importance of ACD in the etiology of OSD, patch testing (see Chapter 13) should be performed in almost all cases of contact dermatitis, even in patients who are thought to have only ICD. Testing should be performed using commercially prepared allergens. Further testing with substances in the worker's environment, including topical medications, protective equipment such as gloves, sensitizing ingredients in cleansers or other products, and occasionally the products themselves (e.g., cutting oils), is sometimes indicated. eTable 211-8.1 in online edition lists additional patch testing series that may be useful in making a diagnosis. Slodownik et al recently showed that in 1,532 patients who were patch tested for occupational dermatoses, 101 patients (6.6%) reacted to their own products, which in 20 (1.3%) of these patients was the only clue for detecting the responsible allergen.[42] Testing with irritants such as most solvents, soaps, cement, and the like should not be done, and patch testing with other environmental chemicals should be performed only by knowledgeable individuals to avoid false-positive irritant reactions. Standard texts can be consulted for patch test concentrations. See eTable 211-0.1 in online edition.

TESTS FOR IMMEDIATE HYPERSENSITIVITY. If type I immediate hypersensitivity is suspected, testing of agents in nonirritating concentrations can be carried, out (Fig. 211-3). Radioallergosorbent tests and skin prick testing, including to the patients own food samples, are recommended as part of the routine assessment of patients in high risk occupations for OCU, particularly if the hands are affected and there is a history of atopy and exposure to urticants.[69]

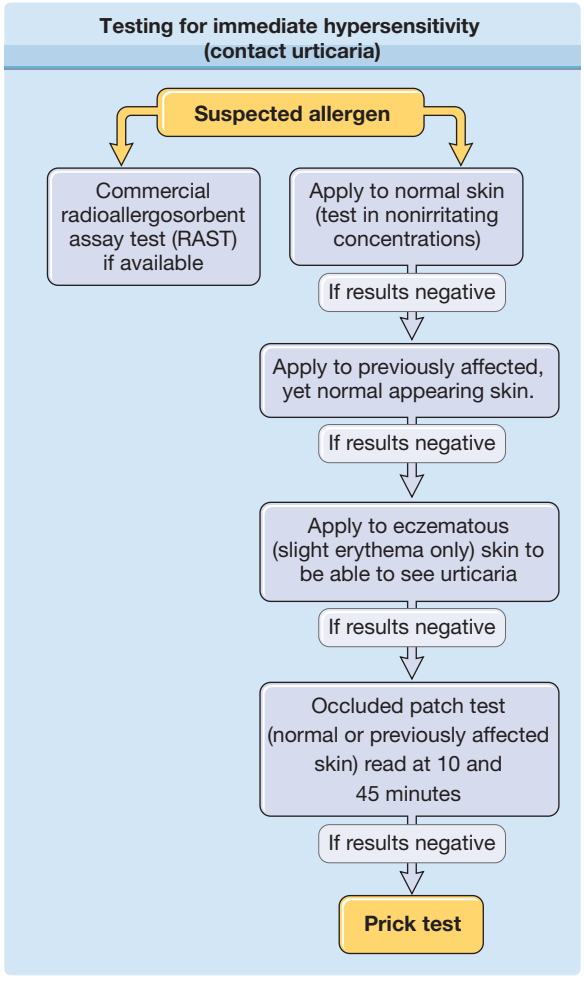

Figure 211-3 Testing for immediate hypersensitivity (contact urticaria). (Adapted from Taylor JS et al: Contact urticaria. In: *Occupational Skin Disease*, 3rd edition, edited by RM Adams. Philadelphia, WB Saunders, 1999, p. 111.)

TREATMENT AND PREVENTION

Initial treatment for OSDs depends on the cause and is essentially the same as that for diseases of nonoccupational origin. However, it is important that patients be told the specific cause(s) of their disease and methods to avoid recurrences, and be given information on the appropriate use of skin cleansers, topical treatments, and protective clothing as well as on other preventive measures. Most occupational skin disorders are preventable, and their avoidance requires environmental, personal, and medical methods.[31]

ENVIRONMENTAL METHODS AND WORKPLACE VISITS

Environmental methods are the preferred control measures, but they are sometimes also the most expensive measures to implement. Environmental methods involve industrial hygiene and environmental engineering interventions such as the following:

1. Hazard identification: workplace visits are an important but often overlooked part of the evaluation of workers with OSD. Hazard identification and assessment of means of

exposure can be evaluated by direct observation and may be required for problem solving, especially when more than one worker is affected.
2. Substitution of less irritating and allergenic chemicals [e.g., rubber gloves without thiurams and carbamates, an alternative resin (phenolic or polyester) for epoxy resins, an alternative metalworking fluid without a sensitizing additive].
3. Isolation and enclosure of the process.
4. Local exhaust ventilation.
5. Chemical dispensers.
6. Good housekeeping.

PERSONAL METHODS

BARRIER CREAMS. Barrier creams have been called *invisible gloves*, but they are an inadequate substitute for protective clothing and are often used when gloves, sleeves, and facemasks cannot be conveniently or safely used. Several types are available: ordinary emollient creams, water-repellant creams, oil- and solvent-resistant creams, and products for use against poison ivy and poison oak. The most effective barrier creams are sunscreens and sunblocks, which ideally should be worn by all outdoor workers. Problems associated with the use of barrier creams are a false sense of security, improper selection and use, allergy to an ingredient (often a preservative or fragrance), potential for increased absorption of occupational chemicals, and inadequate or infrequent application.

SKIN CLEANSERS. Skin cleansers are discussed in Section "Common Occupational Irritants."

PROTECTIVE CLOTHING. Protective clothing ranges from gloves, aprons, hoods, boots, and work shoes to full-body clothing. Fabrics that resist heat, cold, acids, alkalis, solvents, and ultraviolet radiation are available. Certain types are resistant to mildew and fire. Personal protective equipment is addressed by the Occupational Safety and Health Administration in specific standards for general industry, shipyards, marine terminals, and long-shoring, including the US Government Code of Federal Regulations (29 CFR Part 1910).[32] Manufacturers of personal protective equipment provide catalogs with guidelines for the selection of clothing for various exposures. Forsberg provides a handy reference guide.[33] eTable 211-8.2 in online edition lists major glove materials and present general guidance regarding their suitability for use in handling certain chemicals.

MEDICAL METHODS

Physicians often overlook certain medical aspects of prevention. Basic principles consist of the following:

1. Initial and subsequent employment physical examinations should include appraisals of the skin and evaluation of fitness for work.
2. Workers with skin disease may require accommodation in the workplace.
3. Potentially sensitizing topical preparations (neomycin, bacitracin, benzocaine, etc.) should be avoided when treating OSD.
4. Well-motivated workers should undergo medical and vocational rehabilitation; this is covered by many workers' compensation plans.

FITNESS FOR WORK AND WORKPLACE ACCOMMODATION

The Americans with Disabilities Act of 1990 brought to the fore issues of job placement and accommodation. Most individuals with chronic skin conditions can perform normal work activities, but in some instances accommodation in the workplace is required.[34]

PROGNOSIS AND PERSISTENCE

Although the prognosis of chronic OSD is guarded, there has been improvement, with clearance reported in 70%–84% of cases.[35] Minimizing workplace exposure and maximizing patient knowledge regarding potential irritants and allergens is one of the most important factors in improving prognosis.[35,36] Certain conditions, such as chromium sensitivity, have a poor prognosis and are notoriously long lasting. Atopic dermatitis, especially in occupations in which there is frequent or prolonged contact with water, soaps, and detergents, is also associated with a poor prognosis.

Of the several causes of persistence of OSD, the most important is an incomplete or incorrect diagnosis. Other factors include failure to eliminate the cause(s), improper job placement, improper therapy, the presence of secondary diagnoses (e.g., allergy to topical medications or multiple contact allergies), exposure to cross-reacting substances at home or in vocational activities, and improper cleansing of the skin. Some workers develop an ongoing dermatitis termed *persistent postoccupational dermatitis* for which there is no obvious present cause, precipitated by prior occupational dermatitis. This has significant implications for prognosis and workers' compensation.[37,38]

IMPAIRMENT AND DISABILITY EVALUATION

Evaluation of patients with OSD is discussed in more detail in other sources.[28,29,72] However, dermatologists should be aware of the *Guides to the Evaluation of Permanent Impairment*, published by the American Medical Association.[73] The *Guides* chapter on skin disease has been used for more than 30 years to evaluate patients with permanently impairing skin disorders (diseases that have reached maximum medical improvement—often after 6–12 months' duration) of both occupational and nonoccupational origin. The *Guides* are used by a number of state workers' compensation authorities

and provide examples of five classes of impairment ranging from 0% to 95%.

HEALTH RISK ASSESSMENT

The current scientific approach to risk reduction in occupational health is based on risk assessment, which is separated into four basic elements: (1) hazard identification, (2) dermal exposure assessment, (3) dose-response assessment, and (4) risk characterization.[39,40]

HAZARD IDENTIFICATION

Hazard identification involves determining whether exposure to an agent can cause disease or injury using material safety data sheets. Material safety data sheets provide information only about substances considered hazardous; those present in concentrations of less than 1% are not required to be listed, and the physician may need to call for additional information.

DERMAL EXPOSURE ASSESSMENT

Dermal exposure assessment determines the nature and size of populations exposed to a chemical agent via the skin, as well as the magnitude and duration of the exposure. Considerations regarding exposure include the method of exposure: spills, contaminated tools or rags, aerosols or sprays, or permeation of protective clothing. Thus, work activity (e.g., task duration and frequency, amount of chemical used), work substance (molecular weight, particle size, solubility, volatility, etc.), and worker (e.g., surface area exposed, personal hygiene, presence of dermatitis) are three major factors.

DOSE-RESPONSE ASSESSMENT

Dose-response assessment describes the quantitative relationship between the dose at the target and the toxicologic effect. Persons with atopic dermatitis have increased transepidermal water loss and enhanced reactivity to irritants.

RISK CHARACTERIZATION

Risk characterization involves the integration of the data to determine safe exposure by comparing exposure levels with levels at which no adverse effects are observed, while allowing for a safe margin of error. With the exception of nickel and chrome exposure, few skin exposures have been characterized in this way, and it may be difficult to do so. Also, attention must be given to percutaneous absorption as well as to dermal exposure.

MEDICO-LEGAL REPORTS

Physicians may be asked to report on patients with putative occupational skin diseases. These may range from brief diagnosis and treatment medical reports to more complex impairment and disability evolutions for workers compensation authorities, or attorneys. Evaluation guidelines may be provided by the authority or attorney requesting the report; if not physicians should consult their own state's workers compensation guidelines, if any, or the federal government in case of federal employees. Dermatologists are usually asked to evaluate "outlying" claims such as persistent and recurrent hand eczema persisting despite job change or modification, contested claims for work-related causation or percentage of disability, and transient skin complaints with few objective findings. Workers compensation claims become more difficult to resolve the longer the patient remains out of work. References by Clark and Zirwas and by Taylor provide further information and guidance for impairment and disability evaluation for dermatologic conditions.[28,29,72,73]

Formal return to work guidelines is primarily utilized for musculoskeletal complaints rather than skin disorders. Workers with severe enough dermatitis to miss work often are eligible for temporary total disability which is typically short term, less than 6 months. For disorders lasting longer than 6 months, the AMA Guides to the Evaluation of Permanent Impairment may be utilized, but states differ on which edition of the Guides is accepted. Unduly restrictive limitations upon return to work, such as avoiding all contact with chemicals, may jeopardize a worker's job. Before writing such recommendations they should be discussed with the patient/employee and employer. Change of jobs does not always result in clearing of a worker's dermatitis and some union–management contracts may restrict worker placement. Some skin diseases become chronic and do not clear with treatment and allergen and irritant avoidance. Possible reasons are listed in Section "Prognosis and Persistence." eTable 211-8.3 in online edition discusses fitness to work with skin disease and lists selected conditions that may disqualify an individual for work. eTable 211-8.4 in online edition lists some work-aggravated skin disorders that may require accommodation by an employer.

A physician's report should list and summarize all diagnoses. A summary statement regarding causation is then made; for example, within a reasonable degree of medical certainty (51% or greater) the disease is (or is not) related to work. A physician is not required to have such an opinion and in some cases may not be able to make a determination of probable cause. Impairment is then discussed including a description of specific clinical findings related to impairment; if permanent refer to the specific section of the AMA Guides.[73] Specific recommendations for medical and pharmaceutical therapy should be included along with a brief explanation of the treatment. Recommendations for prevention including work restrictions are made next, including suggestions for environmental modification (exhaust ventilation, splash guards, etc.) and personal protective equipment. The effect of future exposures to chemical, physical and biological agents should be addressed, along with any need for rehabilitation. Some states and insurance carriers may provide rehabilitation services.

Chapter 212 :: Occupational Noneczematous Skin Diseases Due to Biologic, Physical, and Chemical Agents: Introduction

:: Paul X. Benedetto, James S. Taylor, & Apra Sood

OCCUPATIONAL SKIN DISEASES DUE TO BIOLOGIC, PHYSICAL, AND CHEMICAL AGENTS AT A GLANCE

- Certain occupations are associated with an increased risk of infection (viral, bacterial, fungal, parasitic), arthropod bites and stings, or infestations.
- Mechanical trauma is common in the workplace and can have skin manifestations.
- Preexisting skin conditions may be aggravated by work-related mechanical trauma.
- Occupational skin granulomas can be immunogenic (e.g., beryllium induced) or nonimmunogenic (e.g., silica induced).
- Occupational skin diseases can result from excessive heat, cold, and other atmospheric factors such as low humidity in the workplace.
- Exposure to silica, vinyl chloride, and other chemical agents can cause systemic sclerosis and limited scleroderma-like disease.
- Occupational chloracne is one of the most sensitive indicators of toxic exposure to halogenated aromatic hydrocarbons such as dioxins and PCBs.
- Occupational skin cancers due to exposure to chemical carcinogens or to ultraviolet light are a major health concern.

Noneczematous skin diseases caused by biologic, physical, and chemical agents in the workplace are discussed in this chapter. Trauma-related eczema is also included. For epidemiology, incidence, and management of occupational skin diseases, refer to Chapter 211.

SKIN DISEASES DUE TO BIOLOGIC AGENTS

Workers in healthcare, food services, cleaning and maintenance, and outdoor occupations are at a risk of developing skin infections. Table 212-1 lists some of the occupations associated with increased risk of certain infections.[1]

Establishing a definite relationship between work and a specific infection is not always simple. Laboratory isolation of the infective organism and a supporting medical history and physical examination are helpful.

Another area of particular concern is the rise in incidence of multidrug-resistant organisms. This has been a growing problem for many years with the dilemma playing a particularly important role in the management of wounded military personnel. With an increased number of troops being deployed overseas to active combat in Iraq and Afghanistan, the issue of antibiotic resistance complicates wound management in situations where resources may be relatively sparse.[2] The most frequently identified strains of resistant organisms contaminating battlefield wounds are *Staphylococcus aureus*, *Acinetobacter baumanii*, *Klebsiella pneumonia*, and *Pseudomonas aerugenosa*.[3,4]

TABLE 212-1
Occupational Skin Infections[1–27]

Occupational Groups at Risk[137]	Infections
Agricultural workers, farmers, shepherds, cattle workers, ranchers, animal scientists, animal breeders, veterinarians	Orf, milker's nodules, tinea barbae dermatophyte infections, mycetoma, chromoblastomycosis, sporotrichosis, cutaneous larva migrans
Athletes (wrestlers, surfers, swimmers, football, hockey and beach volleyball players, triatheletes)	Herpes gladiatorum, tinea corporis gladiatorum, impetigo, furunculosis, seabather's eruption, swimming pool granuloma (*M. marinum*), pseudomonas ("hot tub") folliculitis, acne mechanica, cutanea larva migrans
Butchers, meat handlers, abattoir workers[138]	Staphylococcal and streptococcal infections, cutaneous anthrax, viral warts, erysipeloid, tularemia, brucellosis, leptospirosis
Construction and other outdoor workers	Blastomycosis, coccidioidomycosis, arthropod bites
Cooks, bakers, food handlers, dishwashers, cannery workers, bartenders, others doing wet work	Candidal intertrigo, paronychia, pseudomonas folliculitis
Fish merchants and fishermen	Staphylococcal, streptococcal infections, erysipeloid, vibrio vulnificus, aeromonas hydrophilia
Foresters, hunters	Tularemia, Lyme disease
Gardeners	Sporotrichosis
Hairdressers, manicurists	Staphylococcal and streptococcal infections
Healthcare workers (physicians, nurses, dentists, physician and dental assistants, respiratory therapists, paramedics)	Herpes simplex (herpetic whitlow), HIV infection, hepatitis, staphylococcal and streptococcal infections, candidiasis
Laboratory workers	Brucellosis, tularemia, HIV infection, hepatitis, monkeypox
Military personnel	Staphylococcal and streptococcal infections, dermatophyte infections, arthropod bites, leishmaniasis
Pet shop workers, aquarium handlers, fish tank cleaners	Fish tank granuloma (*Mycobacterium marinum*), monkeypox
Veterinarians	Cutaneous tuberculosis, cutaneous anthrax, brucellosis, tularemia, orf

HIV = human immunodeficiency virus.

BACTERIAL INFECTIONS

STAPHYLOCOCCAL AND STREPTOCOCCAL INFECTIONS. (See Chapter 176.) Secondary bacterial skin infections due to *Staphylococcus* and *Streptococcus* are common complications of abrasions, lacerations, burns, and puncture wounds. Butchers and meat handlers are likely to develop infected cuts and scratches, paronychia, abscesses, and lymphangitis. Folliculitis and boils are common in farm workers and construction workers. Workers in hot, humid, and dirty environments[5] (see eFig. 212-0.1 in online edition) or those working in close contact with infected persons, such as nurses, hairdressers, and manicurists, are at risk. Metalworking and other industrial fluids contaminated with bacteria are another potential source of infection for workers and have even been implicated in an outbreak of *Pseudomonas folliculitis*.[5,6] The increase in multidrug-resistant bacterial strains and the emergence of community-acquired methicillin-resistant *S. aureus*[7] may present a therapeutic challenge.

Infectious eczematoid dermatitis frequently follows contact dermatitis that is untreated and in an area where there is constant rubbing. In this case, the patient was a logger working in an area with poor access to medical attention.

ANTHRAX. (See Chapters 183 and 213.) Anthrax, caused by *Bacillus anthracis*, is primarily seen in cattle, sheep, horses, goats, and wild herbivores. Occupational exposure to infected animals or their products (such as skin, wool, and meat) is the usual pathway of exposure for humans. Agricultural workers, stockbreeders, butchers, and meat processors can become infected by contact with diseased animals. Contaminated hides, goat hair, wool, and bones can infect dockworkers, freight handlers, warehouse workers, and employees of processing plants that handle these products. Tanners, carpet makers, and upholsterers are also at risk, as well as laboratory workers handling specimens.[8]

Anthrax also poses a particular risk to the general population and military personnel as an agent of germ warfare owing to the highly infectious nature of its spores (see Chapter 213).[9–11] Closely following the attacks of September 11, 2001, a series of anthrax exposures were reported, the result of contaminated letters sent via the United States Postal Service. A total of 22 cases, including 10 cases of inhalational anthrax and

12 cases of cutaneous anthrax, occurred over a 1 month period.[12] During the ongoing investigation conducted by the FBI and the CDC, a laboratory worker assigned to the case was exposed to the organism via infected vials and contracted cutaneous anthrax.[13] These attacks highlighted the dangers of infectious agents as potential weapons of biological warfare and renewed interest in appropriate administration of the anthrax vaccine.

MYCOBACTERIAL INFECTIONS

Cutaneous Tuberculosis. (See Chapter 184.) Tuberculosis verrucosa cutis, a slow-growing warty papule or plaque caused by the exogenous inoculation of *Mycobacterium tuberculosis* or *Mycobacterium bovis* in previously sensitized individuals, has been reported in pathologists and morgue attendants (prosector's or anatomist's wart).[14] Surgeons, veterinarians, farmers, and butchers are also at risk, although the condition is rare at the present time.

The Bacille Calmette–Guérin (BCG) vaccine, prepared using live attenuated *M. bovis*, is given to prevent the development of tuberculosis. There have been reports of scrofuloderma, with skin changes overlying cold abscess formation in the underlying subcutaneous tissue at the site of inoculation. Additionally lupus vulgaris (LV), or paucibacillary cutaneous infection caused by hematogenous, lymphatic or contiguous spread from the site of inoculation[15] has occurred after an extended latency period of up to 17 years after administration of the vaccine.[16] Although the United States has never routinely administered the BCG vaccine, in some instances, individuals who are at particularly high risk (e.g., healthcare workers repeatedly exposed to drug-resistant strains of *M. tuberculosis*) may receive the vaccine.[17] Furthermore, it was standard policy to inoculate school-aged children even in the United Kingdom until 2005. Given reports of long latency between vaccine administration and occurrence of lupus vulgaris, continued awareness and surveillance is advisable when caring for UK citizens.

Nontuberculous Mycobacterial Infections. Numerous atypical (i.e., nontuberculous) mycobacteria cause cutaneous and systemic disease. *Mycobacterium marinum* causes swimming pool or fish tank granuloma, a solitary or disseminated granulomatous infection seen in fishermen, fish tank cleaners, aquarium workers (eFig. 212-0.2 in online edition), and workers cleaning contaminated swimming pools.[18] Surgeons are also at risk. Granulomas also may form in a linear fashion along lines of lymphatic drainage (so-called sporotrichoid spread).

Less common atypical mycobacteria may cause infection in the setting of immunosuppression (such as AIDS), as well as in immune competent hosts with high-risk exposure in an occupational setting. There have been case reports of *Mycobacterium simiae* causing a cutaneous granulomatous infection in animal handlers scratched by primates.[19] Infection with this particular mycobacterium is complicated by its multidrug resistance and requires culture and susceptibility testing.[20] There are also reported cases of veterinarians and livestock handlers contracting cutaneous mycobacterial infections, such as cutaneous infection with *M. bovis* caused by exposure to an infected alpaca and lupus vulgaris caused by *M. bovis* sp. *caprae* caused by exposure to dairy cattle.[21,22]

BRUCELLOSIS. (See Chapter 183.) Brucellosis is a zoonosis transmitted to humans via contact with infected animals or ingestion of untreated milk or milk products. Farmers, livestock breeders, meatpackers, veterinarians, and laboratory workers are at risk.[23] An epidemic caused by sniffing bacterial cultures has been reported.[24]

TULAREMIA. (See Chapter 183.) Tularemia is caused by *Francisella tularensis*, a Gram-negative bacillus transmitted by ticks, fleas, and deerflies. Animal reservoirs include wild rabbits, squirrels, birds, sheep, beavers, muskrats, and domestic dogs and cats. Tularemia is seen in hunters, trappers, game wardens, butchers, fur handlers, and laboratory workers. It is highly infectious, and great care should be exercised in handling infected tissues and excreta. All laboratory personnel who may handle samples from a case of suspected tularemia should be forewarned.

ERYSIPELOID. (See Chapter 183.) Erysipeloid is almost always an occupational disease and is caused by *Erysipelothrix rhusiopathiae*, a Gram-negative rod that infects freshwater and saltwater fish, ducks, emus, turkeys, chickens, and other farmed animals such as sheep.[25] Butchers, fishermen, scuba divers, and retailers of fish and poultry are commonly affected.[26]

VIRAL INFECTIONS

HERPES SIMPLEX. (See Chapter 193.) Infection with herpes simplex virus (HSV) is the most common viral infection of occupational origin. Infections due to HSV type 1 or 2 are seen in occupations in which there is exposure to infected secretions from the mouth or the respiratory tract. Dentists, dental assistants, nurses, and respiratory technicians are particularly vulnerable, and herpetic whitlow is a common problem.[27] Infection with HSV-1 after a needle-stick injury has also been reported.[28] Herpes labialis is a common problem in woodwind and brass instrumentalists.[29] HSV infection on the body surfaces of wrestlers and rugby players, known as herpes gladiatorum, is temporarily disqualifying for infected athletes. In healthcare professions, the implementation of universal precautions has led to a significant reduction in the prevalence of infection.[30]

HEPATITIS AND HUMAN IMMUNODEFICIENCY VIRUS INFECTION. Needle-stick injuries are a well-recognized occupational hazard for healthcare workers, putting them at risk of acquiring an infectious disease from blood-borne pathogens. The average risk of human immunodeficiency virus (HIV) transmission after a percutaneous exposure to HIV-infected blood has been estimated to be approximately 0.3%.[31,32] For hepatitis B, the risk of clinical hepatitis if the blood was positive for both hepatitis B surface antigen and hepatitis B envelope antigen is reported to be 22% to

31%; the risk is 1% to 6% if the blood was positive for hepatitis B surface antigen but negative for hepatitis B envelope antigen.[32] A 95% decline in hepatitis B virus infection in healthcare workers was noted from 1983 to 1995, largely due to widespread immunization of healthcare workers with the hepatitis B vaccine.[33] The average incidence of antihepatitis C virus seroconversion after accidental percutaneous exposure to a hepatitis C virus-positive source is 1.8% (range, 0%–7%).[32] The most accurate data on needle-stick and sharps injuries are derived from prospective studies, which yield an estimated annual incidence ranging from 562 to 839 injuries per 1,000 healthcare workers per year.[34] Nurses have the most patient contact, and it is not surprising that this occupational group accounts for most reported cases.[34,35] Immediate evaluation of the injured employee is necessary to assess the risk related to exposure and the need for postexposure prophylaxis (antiretroviral therapy for HIV, immunoglobulins and vaccination for hepatitis B virus). A substantial reduction in needle-stick injuries with the use of needleless systems or newer safety needle devices and blunt suture needles has been noted, though still not widely implemented due to questions of relative efficacy compared to older technology.[33,36] Examples of needleless systems include, but are not limited to, intravenous delivery systems that administer medication or fluids through a catheter port or connector site using a blunt cannula or other nonneedle connection, and jet injection systems that deliver subcutaneous or intramuscular injections of liquid medication through the skin without the use of a needle.

The CDC has published guidelines for the management of postexposure prophylaxis (PEP) in the setting of occupational exposure to HIV.[37] The indication for PEP depends on the type of exposure, such as percutaneous injury versus mucous membrane and nonintact skin exposure, as well as the severity of injury and the volume of fluid exposure. In cases of less high-risk exposure, such as solid needle superficial injuries and mucous membrane or nonintact skin exposures from HIV-positive individuals who are asymptomatic or known to have low viral loads, a basic two-drug PEP regimen is the current CDC recommendation. In higher risk exposures, such as deep puncture wounds and wounds from large-bore hollow needles from symptomatic individuals and those with high viral load or in acute seroconversion, the current recommendation is a three-drug postexposure prophylaxis regimen. Ideally, drugs in the regimen are chosen from different classes of antiretrovirals and exert their effects at different stages in the viral replication cycle, thus increasing efficacy and reducing or prolonging potential drug resistance. The drug classes include nucleoside reverse transcriptase inhibitors (NRTI), nucleotide analogue reverse transcriptase inhibitors (NtRTI), nonnucleoside reverse transcriptase inhibitors (NNRTI), protease inhibitors (PI), and fusion inhibitors (FI).

VIRAL WARTS. (See Chapter 196.) Handlers of meat, poultry, and fish have a high prevalence of viral warts, which is likely attributable to the acquisition of minor cuts and abrasions during work. Human papillomavirus 7 has been isolated more frequently in this group of patients.[38]

MOLLUSCUM CONTAGIOSUM. (See Chapter 195.) Professional wrestlers and boxers are prone to developing molluscum.

ORF (ECTHYMA CONTAGIOSUM). (See Chapter 195.) Orf, caused by a parapoxvirus, is endemic in sheep and goats, and is easily transmitted to humans through direct contact. Veterinarians, farmers, and shepherds are at risk.[39]

MILKER'S NODULES. (See Chapter 195.) The paravaccinia virus, which infects the udders of cows and produces ulcers in the mouths of calves, can be transmitted to dairy farmers and veterinarians, causing milker's nodules (or pseudocowpox)[40] (see eFig. 212-0.3 in online edition).

MONKEYPOX. (See Chapter 195.) An outbreak of human monkeypox in the United States in 2003 was traced to a shipment of infected exotic African rodents, some of which escaped, that produced secondary infection in wild prairie dogs housed at the same pet store. Exposure to these infected prairie dogs resulted in 37 human infections involving exotic pet dealers, pet owners, and veterinary care workers.[41] Although human-to-human transmission rate of monkeypox virus is thought to be low, the Centers for Disease Control and Prevention recommends strict contact, droplet, and airborne precautions for healthcare workers. The case-fatality rate has been less than 10% in Africa, with children being more vulnerable to fatal infection.[42] Smallpox vaccination is recommended for healthcare workers and household contacts of confirmed monkeypox cases per Centers for Disease Control and Prevention guidelines.

FUNGAL INFECTIONS

DERMATOPHYTIC SKIN INFECTIONS. (See Chapter 188.) Dermatophytic skin infections are seen more frequently in farmers and animal husbandry workers.[43] Infections with *Trichophyton rubrum* and *Trichophyton mentagrophytes*, which are seen in the general population, may occur in work situations involving increased perspiration and occlusion. *Microsporum gypseum*, *T. mentagrophytes*, and *verrucosum verrucosum* cause infection in agricultural and other outdoor workers (see eFig. 212-0.4 in online edition). *M. canis* infects veterinarians and laboratory workers. Physiotherapists who perform hydrotherapy are also more likely to develop fungal skin infections.[44] An unusual tinea corporis infection in a scientist due to a laboratory strain of *Arthroderma benhamiae* has been reported.[45] There is a report of a laboratory worker developing erythema multiforme secondary to cutaneous infection with *T. mentagrophytes* contracted from contact with research animals.[46]

CANDIDIASIS. (See Chapter 189.) Infection with *Candida albicans* is common in occupations that expose

the skin to moisture and occlusion, such as those that require wearing gloves for long periods of time. Food handlers, surgeons and nurses, dental assistants, dishwashers, laundry workers, and tollbooth attendants are at risk.

SPOROTRICHOSIS. (See Chapter 190.) Sporotrichosis, caused by *Sporothrix schenckii*, is acquired by inoculation through puncture wounds from thorns, sticks, or splinters. It is seen in farmers, nursery and forestry workers, and those in other outdoor occupations. Gardeners working with sphagnum moss used for packing plant roots may also be at risk. There have been reports of disseminated and bilateral sporotrichosis mimicking sarcoidosis and prurigo nodularis, respectively.[47,48]

MYCETOMA (MADURA FOOT). (See Chapters 185 and 190.) Mycetoma, caused by various species of fungi and actinomycetes, is seen mainly in farmers and outdoor workers in tropical and subtropical countries; walking barefoot is a risk factor.

CHROMOBLASTOMYCOSIS. (See Chapter 190.) Chromoblastomycosis, a deep mycosis, often follows a puncture wound or other trauma during which soil-inhabiting fungi of *Phialophora*, *Hormodendrum*, and *Fonsecaea* species are injected deep into the tissues. Agricultural and other outdoor workers are at risk.

BLASTOMYCOSIS. (See Chapter 190.) Those at risk of blastomycosis include agricultural, forestry, and construction workers, farmers, and persons working with heavy earth-moving equipment in endemic areas, such as the Mississippi and Ohio River basins.[49]

COCCIDIOIDOMYCOSIS. (See Chapter 190.) Coccidioidomycosis is acquired by the inhalation of dust containing the spores of *Coccidioides immitis*. Farmers, construction workers, bulldozer and heavy equipment operators, and laboratory workers are susceptible.

PARASITIC DISEASES

(See Chapters 206 and 207.)

There has been an increase in the incidence of cutaneous leishmaniasis in the US military personnel who were deployed to southwest or central Asia or other areas in which leishmaniasis is endemic, with hundreds of cases having been reported to date.[50–52] The larvae of *Ancylostoma braziliense* and *Necator americanus* cause creeping eruption (cutaneous larva migrans) in agricultural workers, fishermen, sewer workers, and lifeguards. Skin divers, lifeguards, dockworkers, and caretakers who maintain lakes and ponds are prone to development of swimmer's itch caused by the cercariae of a schistosome; there is also a report of swimmer's itch developing after cleaning of an aquarium.[53] Dogger Bank itch is seen in fishermen and dockworkers in the North Sea, who are exposed to the marine bryozoan *Alcyonidium gelatinosum*.

In contrast to swimmer's itch, lifeguards, swimmers and professional divers can develop seabather's eruption, commonly called "sea lice," which is papulopustular dermatosis caused by the thimble jellyfish, *Linuche unguiculata*. The life cycle of *L. unguiculata* has three distinct stages: (1) larva (planula), (2) ephyra, and (3) adult (medusa). The eruption appears to be a hypersensitivity reaction to the venomous nematocysts discharged by the larval form of the jellyfish becoming trapped under clothing, and occurs most frequently from spring through summer. There have been reports of the eruption being caused by nematocysts discharged by adult jellyfish as well.[54,55]

ARTHROPOD STINGS, BITES, AND INFESTATIONS

(See Chapters 209 and 210.)

The bites of bees, wasps, hornets, ants, ticks, mites, centipedes, and millipedes frequently cause work-related skin disease. Outdoor workers, food handlers, chicken farmers (chicken mites), workers in food-processing plants, restaurant workers, and dockworkers may be affected. Epidemics of scabies have occurred in nursing homes, hospitals, and other residential facilities for the aged[56] Lyme disease (see Chapter 187) is transmitted through a tick bite and can affect outdoor construction workers, loggers, ranchers, and park rangers in wilderness areas.[57]

SKIN DISEASES DUE TO PHYSICAL AGENTS

MECHANICAL TRAUMA-INDUCED SKIN DISORDERS

The skin may be subjected to friction, pressure, cuts, lacerations, and abrasions in the workplace. Repeated mechanical trauma such as low-intensity pressure or friction, the most common mechanical trauma, leads to hyperpigmentation and lichenification, whereas heavier and persistent friction leads to hyperkeratosis and callus formation (eFig. 212-0.5 in online edition). Sudden shearing forces may lead to the formation of friction blisters, erosions, or ulcers.[58] Prolonged and excessive pressure may produce hyperpigmentation and thickening, characteristic as the stigmata of various occupations[59] (Fig. 212-1). Besides calluses and corns, occupational marks include discolorations, telangiectasias, tattoos, and deformities. Greater automation and better protective clothing, especially a wider selection of gloves, have decreased the incidence of occupational marks. In musicians, clinical presentation and location of skin lesions are usually specific for the instrument used (e.g., fiddler's neck, cellist's chest, guitar nipple, flautist's chin).[60] In athletes, repetitive trauma from running may lead to black heel or talon noir as well as blisters and jogger's toe.[60] Corns may also develop due to extreme pressure associated with bony deformities, poor foot mechanics, or improper footwear.[61] A new group of skin disorders related to prolonged computer use leading to repetitive trauma (mousing callus)

Figure 212-1 Nail dystrophy in a slaughterhouse worker. While holding a knife in his right hand to cut off the hide, he pulled and tugged on the hide with his left hand. Note the calluses over the distal interphalangeal joints on the left.

and prolonged pressure (computer palms) has been described.[62,63] Underlying skin conditions in patients such as psoriasis and lichen planus may be aggravated by occupational trauma (koebnerization). Preexisting dermatitis caused by friction and pressure may predispose to the development of allergic sensitization.[64]

Hyperkeratotic hand eczema is a chronic hyperkeratotic, scaly, fissured dermatitis involving the palms seen in workers engaged in manual work involving repeated friction and pressure (Fig. 212-2). Pulpitis may be seen on the fingertips in women engaged in domestic work as a dry, scaly, fissuring, painful dermatitis.[65] A similar condition may be seen in dental personnel allergic to acrylates, in which paresthesias of the fingertips are reported. Posttraumatic eczema (dermatitis in loco minoris resistentiae) is dermatitis at the site of cutaneous trauma. The eczema usually develops within a few weeks of the acute injury and may persist or recur for long periods of time.[65] The damage and functional alteration of the skin is thought to play a role in precipitating the eczema. Table 212-2 lists the types of posttraumatic eczema and provides some examples.[66]

Figure 212-2 Chronic hypertrophic dermatosis of the palms in a 59-year-old machinist. He was transferred to work in a storeroom, where he continually handled tools, and was forced to retire because of persistence of the dermatosis with its fissuring and bleeding.

GRANULOMAS

Granulomas may form due to penetration of the skin by foreign material; they may be immunogenic or nonimmunogenic. Table 212-3 lists the causes of occupational skin granulomas.[67] The penetration of human hair into the interdigital spaces of barbers and of cow and sheep hair into the hands of animal tenders can produce foreign-body granulomas.[68]

THERMAL BURNS AND OTHER HEAT-INDUCED SKIN DISORDERS

Workers are at risk for thermal burns as a result of scalding; contact with liquid metal, hot equipment,

TABLE 212-3
Classification of Occupational Granulomas

Causative Substance (Setting)

Immunogenic granulomas
- Beryllium (metal production, X-ray screen production)
- Zirconium (steel working)
- Cadmium (paint and rubber industry)

Nonimmunogenic granulomas
- Silica (sandblasting, mining, land mine explosions)
- Starch (occupations requiring the use of surgical gloves)
- Cactus spines (farming, outdoor work)
- Sea urchin spines (diving)
- Wood splinters (farming, forestry)
- Hair (hairdressing, farming, animal handling)
- Sheep wool (sheep raising)
- Metal (metal fragment/chainsaw blade/shrapnel)[139]

Adapted from Goh CL: Non-eczematous occupational contact reactions. In: *Condensed Handbook of Occupational Dermatology*, edited by L Kanerva et al. Berlin, Springer-Verlag, 2004, p. 135.

and tar; and flame burns after explosions. Kitchen workers and adolescents working in fast food restaurants may develop scalds from hot grease.[69] Roofers frequently incur hot tar burns, whereas explosives and flammable liquids cause most industrial burns. Persons working in foundries and smelting plants are at risk for molten metal burns. Firefighters are also at risk, although the use of protective gear reduces the extent of burn injuries.[70] Workers experiencing prolonged or repeated exposure to heat and those using laptops on their laps for prolonged periods can develop erythema ab igne.[71] Acne vulgaris, rosacea, and herpes simplex may be aggravated by the heat of open furnaces, heat torches, ovens, and stoves. Heat-induced cholinergic urticaria may result from strenuous physical exercise or a very warm work environment.

ELECTRICAL BURNS

In industrial settings, electrical burns are usually high-voltage injuries, which may result in serious tissue destruction. Outdoor workers are at a risk for lightening burns, which show characteristic fern-like patterns (see Chapter 95).

COLD-INDUCED SKIN DISORDERS

(See Chapter 94.)

Frostbite, chilblains, immersion foot, and cold urticaria are common in workers employed in cold environments, such as military personnel stationed in cold climates, ski patrolmen and mountain rescue workers. Icemakers, liquefied gas makers, refrigeration workers, and persons engaged in winter sports are also at risk.

VIBRATION SYNDROME

The vibration of hand-held tools may induce a type of vascular spasm in the fingers and hands known as white fingers or vibration-induced white finger.[72] Operators of vibrating impact and power tools such as jackhammers, pounding machines, riveting hammers, chain saws, and hand grinders may develop this condition, especially in cold climates. The vascular symptoms may be associated with neuromuscular symptoms and even with bony changes, collectively known as hand-arm vibration syndrome.[73] Earlier symptoms are mild and consist of numbness and tingling, followed by blanching and stiffness of one or more fingers, with paresthesias and weakening of intrinsic muscles developing in the later stages. Vibration frequencies between 30 and 300 Hz are most strongly associated. Smoking is also considered a risk factor. Improvements in the design of chain saws and other vibrating tools have resulted in a decrease in the prevalence of vibration-induced symptoms.

SKIN DISEASES DUE TO CHEMICAL AGENTS AND RADIATION

CHEMICAL HYPOPIGMENTATION/ LEUKODERMA

(See also Table 212-1.)

Most cases of occupational leukoderma are caused by either chemical or thermal burns, or as a postinflammatory effect of irritant or allergic contact dermatitis in which tissue injury is enough to destroy melanocytes. A third category, chemical leukoderma, may follow cutaneous exposure to a number of phenolic or catecholic derivatives, which structurally resemble tyrosine, an amino acid precursor of melanin synthesis. These include monobenzylether of hydroquinone, *p*-tert-butylphenol, *p*-tert-butyl catechol and congeners along with a number of other chemicals, which cause pigment loss in humans and in animal models. At low doses these substances simply inhibit melanin synthesis, but at higher doses may be cytotoxic to melanocytes, resulting in irreversible pigment loss. These chemicals may be present in industrial and consumer products. The essential chemical requirement for melanocyte toxicity appears to be a nonpolar side chain in the para position on the phenolic or catecholic ring structure. Depigmentation is not always preceded by inflammation of the affected skin, but is frequently associated with allergic contact dermatitis to the same chemical responsible for the pigment loss.

Chemical leukoderma may appear identical to idiopathic vitiligo with similar anatomic distribution. Scalp hair is rarely involved and eye color is not changed. Time from exposure to onset of pigment loss ranges from 2 weeks to 6 months. Wood's light exam of the entire skin is important to detect nascent areas of involvement.

Diagnosis is more easily made when a number of cases are clustered in a factory with a history of exposure to a known depigmenting agent. Patch testing with putative depigmenting chemicals may be preferable on covered areas such as the buttocks and may result in leukoderma at sites of positive or negative tests for up to six weeks after application. Satellite depigmentation may occur after patch testing strong depigmenting chemicals. Black guinea pigs have been used as an alternative test method.

A detailed history is important to exclude other causes of depigmentation. Differentiation from vitiligo may be impossible, and many authorities believe chemical leukoderma may evolve into vitiligo, presumably in genetically predisposed individuals. Most cases occur by direct contact but inhalation or ingestion may be operative. More recent causes have included paraphenylenediamine containing and semipermanent hair colors, Indian *bindi* (PTBP), *alta*, and *roli* (cause unknown), and rubber shoes and synthetic wallets (MBEH).[74–78]

OCCUPATIONAL CONNECTIVE TISSUE DISORDERS

Raynaud phenomenon and scleroderma-like skin lesions with osteolytic changes in the bones of the

fingers are well described in vinyl chloride workers (see also Chapters 157 and 170).[79] The syndrome has been called occupational acro-osteolysis. Exposure to other organic solvents, such as chlorinated hydrocarbons, polyvinyl acetate glues, has also been reported to cause scleroderma-like disease (eTable 212-3.1 in online edition).[79–81] Systemic sclerosis and scleroderma-like skin changes after silica exposure with or without associated pulmonary silicosis is eponymously referred to as Erasmus syndrome and has been described in underground miners (coal, gold, uranium, lead miners), stone masons, and those in related occupations.[82] The simultaneous operation of vibrating tools during mining may contribute to the development of the disease.

OCCUPATIONAL AND ENVIRONMENTAL ACNE

OIL ACNE. (See Chapter 80.) Oil acne is a folliculitis occurring on skin that comes in contact with oils, especially heavy industrial oils or straight cutting oils used by machinists. Areas with the greatest exposure to oil-soaked clothing, such as the arms and thighs, are most frequently involved. Oil acne is also caused by airborne oil mist.[83] Oil acne is treated with the usual topical and systemic modalities for acne vulgaris. Systemic antibiotics are often needed, as is isotretinoin in severe cases. Key factors in preventing oil acne are avoiding contact with oils and grease, including practicing good personal hygiene. Work clothes should be changed daily and frequent cleansing of the skin at risk with soap and water is advised. With better engineering controls and protective clothing, the occurrence of oil acne has decreased.[84]

COAL TAR AND PITCH ACNE. (See Chapter 80.) Coal tar oils, creosote, and pitch can produce a comedonal type of acne, with a predilection for exposed areas, particularly the malar regions.[85] Coal tar plant workers, roofers, road maintenance workers, and construction workers are at risk. Coal tar derivatives are not only acnegenic but also carcinogenic and photosensitizing. A phototoxic reaction may also occur and cause hyperpigmentation, known as coal tar melanosis. Pitch and tar papillomas, keratoses, and acanthomas may develop as a late complication.[86] Pitch acne is also treated with standard acne vulgaris therapies. Prevention includes good exhaust ventilation systems in the workplace and wearing clean uniforms and protective coverings, as well as showering at the end of shifts.

ACNE MECHANICA. Repeated or prolonged physical insults to the skin from pressure, occlusion, friction, rubbing, or heat may provoke acne lesions by inducing the rupture of microcomedones, an eruption that can be strikingly inflammatory. Occupational cases may appear under face masks in hospital workers or cleanroom workers in the semiconductor industry, and under belts, straps, tight-fitting work clothing, football shoulder pads and helmets, hats and telephones. Fiddler's neck and violinist's neck is also a variant.[87]

Clinically, crops of inflammatory papules and pustules appear in affected areas of skin. Deep, inflammatory nodules may result from prolonged pressure. It has been emphasized that acne mechanica is a complication of acne vulgaris and that external physical forces merely exacerbate the underlying disease focally.[88] Improvement of mechanical acne may occur promptly after removing the source of mechanical and physical factors. Skin washing and use of topical cleansing agents may reduce the risk of acne mechanica.

CHLORACNE. (See Chapter 80.) Chloracne, the most clinically striking form of acne, is one of the most sensitive indicators of occupational or environmental exposure to toxic halogenated aromatic hydrocarbons, which share relative molecular planarity, and which typically occur as trace contaminants during synthesis of industrial chemicals. Exposure can be percutaneous or by inhalation or ingestion and is a cutaneous sign of potential systemic toxicity. One of the most potent inducers of chloracne is 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), which has been identified in multiple industrial outbreaks as well as in putative poisoning cases in Austria and the Ukraine.[89,90] Other chloracnegenic chemicals include other halogenated dioxins, naphthalenes, biphenyls, dibenzofurans, azobenzenes, and azoxybenzenes, with the chloracnegenic potential being closely correlated with the potential to induce the enzyme aryl hydrocarbon hydroxylase (AHH)91 and are listed in eTable 212-3.2 in online edition.[92]

In 2009, a new chloracnegen was reported from the United Kingdom in an outbreak of chloracne among seven male pharmaceutical discovery chemists, who synthesized novel polycyclic halogenated chemical compounds classified as triazoloquinoxalines. As with dioxins, the triazoloquinoxalines were synthetic intermediates in the project, being synthesized in small-scale (mg/g) quantities. Toxicological investigations found that the triazoloquinoxalines showed high activity in the chemically activated *luciferase* gene expression (CALUX) cell bioassay for estimation of dioxin-like activity and were several times more chloracnegenic than dioxins on a weight for weight basis. Triazoloquinoxalines also showed the basic structural features and physiochemical properties that are typical of chloracnegens, such as high metabolic stability, a polycyclic structure, a lipophilic nature, and the potential to be halogenated.[93]

Clinically, the distribution is characteristic, with multiple closed comedones and straw-colored cysts primarily over the malar crescents and retroauricular folds, sparing the nose; the posterior neck, trunk, and extremities as well as the buttocks, scrotum, and penis may also become involved. TCDD impairs differentiation of keratinocytes.[94] Polychlorinated biphenyls (PCBs) and TCDD cause follicular hyperkeratosis and palmoplantar hyperhidrosis. PCBs can also cause skin, mucus membrane, and nail hyperpigmentation, as well as conjunctivitis. Ingestion alone of PCBs and their thermally degraded polychlorinated dibenzofurans (PCDFs) caused chloracne in two mass nonoccupational "oil-poisoning" episodes, one in Japan in 1968 and the other in Taiwan in 1979, the largest

epidemics of chloracne to date. Subsequent clinical studies showed that the causative PCBs and furans were transplacental dermato- and neuroectodermal toxins causing nail dystrophy and dental abnormalities and growth and developmental delays.[95–97]

Findings in the pathogenesis of chloracne include a reduction in sebum excretion as a hallmark of the disorder along with fewer *Propionibacterium acnes* organisms in the follicles as compared with acne vulgaris.[98] Dioxins, for example, TCDD have been shown to impede androgen action possibly through interfering with androgen receptors.[93] The biological mechanisms of chloracne induction are still debated but it was suggested that dioxins exert their chloracnegenic effect by activating skin stem cells and shifting the differentiation commitment of the stem cell progeny.[99]

One of the most important initial steps in chloracne pathogenesis and toxicity of dioxins is the activation of the AHH receptor, a transcription factor that binds to the Ah receptor nuclear translocator (ARNT) to regulate the transcription of numerous genes, including *cytochrome P450 CYP1A1*, *GSTA1*, and *TGF*-α. These changes of gene expression play critical roles in the cornification and epidermal barrier of the skin and may disturb normal proliferation and differentiation of human epidermal cells.[100,101]

It has been demonstrated that all of these responses are opposed by ligand-activation of the epidermal growth factor (EGF) receptor (R), an important regulator of keratinocyte cell fate. EGF represses the dioxin-mediated gene transcription induction of *CYP1A1* in cultured normal human keratinocytes by inhibiting the recruitment of the transcriptional coactivator protein p300 to the *CYP1A1* gene. EGF also inhibits the dioxin-dependent induction of certain parameters in keratinocytes that are reflective of dioxin-induced chloracne. This EGFR signaling may modulate the incidence and severity of chloracne and be of potential therapeutic relevance to human poisonings by dioxin.[102]

Chloracne tends to resolve slowly upon cessation of chemical exposure. Its duration correlates with the severity of the disease that usually reflects the degree and extent of exposure. Dioxins are highly lipophilic, have a long half-life in fat tissue and low turnover rate in the body.

The modalities that are useful in acne vulgaris are often ineffective in chloracne. Topical application of retinoic acid (0.005%–0.3% concentration) gel or cream is of some benefit in controlling comedones, but other topical agents are of little use.[103] A combination of tetracycline and short courses of orally administered prednisone may help with severe inflammatory cases. There are anecdotal reports of both unsuccessful and efficacious use of oral 13-*cis*-retinoic acid (isotretinoin),[103] which, if instituted early, may prevent cyst formation. Local therapy with acne surgery and dermabrasion has been reported. Light cautery following topical anesthesia with EMLA cream has been used successfully in six patients with resistant chloracne lesions.[104]

Olestra, a nonabsorbable, nondigestible, lipophilic dietary fat substitute has been reported to accelerate the patients' intestinal excretion of TCDD by eight- to tenfold. Sufficiently to reduce the normally observed elimination half life of TCDD from about 7 years to 1 to 2 years.[105]

Based on clinical findings alone, it may be difficult to differentiate chloracne from early acne vulgaris (eTable 212-3.3 in online edition) and solar comedones (Favre–Racoucht syndrome). Scarring may be mild to severe, depending on the degree of chemical exposure and skin involvement.[106,107] eTable 212-3.4 in online edition differentiates chloracne from other types of environmental acne such as oil folliculitis, pitch acne, and tropical acne.[53]

OCCUPATIONAL SKIN CANCER

The first cancer to be linked to an environmental exposure was scrotal cancer in chimney sweeps, reported by Sir Percivall Pott in 1775. The percentage of skin cancers induced by the work environment is disputed; some studies suggest that it is as high as 70% to 80%,[108] but other studies indicate a much lower percentage.[109] The common causative agents implicated in occupational skin cancers and occupations with potential exposure are listed in Table 212-4.

ULTRAVIOLET LIGHT. (See Chapters 112 and 113.) Ultraviolet (UV) radiation acts as both a tumor initiator and tumor promoter. Most studies report a significant association between work-related sun exposure and skin cancer[110] as well as actinic keratoses[111] (see eFig. 212-2.1 in online edition), but other studies have found no definite association[112] or a very slight increased risk,[113] perhaps because of greater self-selection for indoor jobs among those with fair skin and a tendency to burn compared to those with less-susceptible skin types.[114]

Exposure to UV radiation, particularly UVB light, is thought to play a critical role in the pathogenesis of malignant melanoma (see Chapter 124),[115] although some studies do not show an increased risk of

TABLE 212-4
Agents Inducing Occupational Skin Cancers and Industries Presenting Exposure Risk[51–75]

Causative Agent	Industries/Activities with Potential Exposure
Polycyclic aromatic hydrocarbons	Coal gasification, aluminum production, iron and steel foundries, coke production, shale oil extraction, tar distilling, asphalt and roofing material work, wood impregnation
Arsenic	Glass working; copper, zinc, and lead smelting; pesticide and herbicide production; semiconductor industry
Ultraviolet light	Outdoor work, welding
Ionizing radiation	Nuclear power plants, radiography, uranium mining

developing melanoma in outdoor workers compared to indoor workers.[116] This is consistent with the epidemiologic link of melanoma to intermittent intense UV exposures, more often experienced in association with vacations or recreational activities than employment. However, a recent study of patients diagnosed with melanoma residing in close proximity to one another in Connecticut attempted to assess the impact of chronic ambient ultraviolet B radiation in the development of their cancers. The study quantified average UV radiation at that latitude utilizing calibrated meteorological equipment and controlled for intermittent sun exposure based on patient history and utilizing regression analysis. The authors concluded that chronic exposure to UV radiation may play an additive role to intermittent intense sun exposure and may indeed be an independent risk factor for the development of melanoma.[117] No large studies of a clear association of malignant melanoma with occupational exposure corroborate these findings. Nonoccupational exposures to nonsolar radiation, such as UV lamps and tanning beds, is reportedly associated with an increased risk of melanoma.[118]

A recent review found a statistically significant increased risk of malignant melanoma in patients who worked at petroleum-refining plants and were exposed to petroleum hydrocarbons and solvents such as polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), benzene, aromatic hydrocarbons, and heavy oils.[119] A potentially causal relationship between the occupational exposure and melanoma was postulated given the higher prevalence of melanoma in these workers on nonsun-exposed sites. In another longitudinal analysis from 1946 to 2002 conducted at one of the world's largest tar refineries, an increased prevalence of nonmelanoma skin cancers, and cancers developing in atypical sites such as the nasal epithelium, was documented. The study also reported several cases of malignant melanoma in these workers, but it is unclear if their rate of developing melanoma was higher than expected in the general population.[120]

The association between squamous cell carcinoma (see Chapter 114) and cumulative UV exposure is stronger, which makes outdoor occupations a significant risk factor. However, other occupational exposures, such as exposure to chemical carcinogens, may also play a critical role,[121] and an additive effect cannot be excluded.

To determine the role of the workplace in the development of actinic skin damage and skin cancer, one must consider a detailed occupational history with job descriptions from earliest employment, as well as nonoccupational activities, hobbies and sports, and other recreational pursuits, including those in which the patient engaged at a younger age.

POLYCYCLIC AROMATIC HYDROCARBONS. Exposure to polycyclic aromatic hydrocarbons (PAHs) accounts for most of the reported occupational skin tumors.[122] PAHs are hydrophobic, nonpolar compounds that form DNA adducts[120] and act as complete carcinogens.[123] Coal tar and petroleum products such as tar, pitch, coke, carbon black (soot), creosote, anthracene, crude paraffin, asphalt, fuel and diesel oils, lubrication and coolant oils, and untreated mineral oils, as well as oils, waxes, and tars from the distillation products of shale oil and lignite, contain PAHs.[124] High occupational exposures to PAHs can occur in several industries and occupations (see Table 212-4), and workers can be exposed to PAHs through inhalation or skin contact. The risk for melanoma, as well as internal cancers, has been reported to be increased in oil refinery workers.[125]

An association between scrotal cancers and the use of cutting oils has been noted, probably related to the addition of shale oil.[126] Used engine oil has also been associated with a case of extramammary Paget disease of the scrotum and groin in a patient with longstanding occupational exposure.[127] Creosote used in wood treatment has been suggested as a cause of skin and lip cancer when associated with sunlight exposure.[128] Roofers and road pavers are also at increased risk for skin cancers and internal cancers due to the potential carcinogenicity of bitumen and of PAHs from coal tar products.[129] Tar refinery workers are at increased risk of developing nonmelanoma skin cancers, mainly on facial areas, forearms, and hands.[130] Use of topical tar products to treat dermatologic disease has been suggested to pose a skin cancer risk but has never been documented to do so.

ARSENIC. Arsenic-containing drinking water is clearly associated with various skin and internal organ malignancies.[131] The methylated, trivalent form of arsenic is more toxic than the pentavalent form.[132] Although arsenic induces chromosomal abnormalities in experimental systems and human tissues, it does not induce cancers in animal models.

Long-term arsenic exposure may lead to arsenical keratosis, squamous cell carcinoma, basal cell carcinomas, and Bowen disease. Merkel cell carcinoma has also been reported in a person with chronic arsenicalism.[133] Table 212-4 lists occupations at risk for exposure to arsenic.

IONIZING RADIATION. (See Chapter 240.) Exposure to ionizing radiation has been known to be a cause of occupational skin cancer since the early 1900s. Atomic bomb survivors have an increased risk of developing basal cell carcinoma.[134] X-ray-induced skin cancers appear to be associated with a higher frequency of multiple skin lesions, recurrences, and major surgical sequelae[135] (Fig. 212-3). There have been reports of a high prevalence of melanoma among airline pilots and flight attendants exposed to cosmic radiation; however, some observers feel that this association is due to lifestyle effects.[136]

DIAGNOSIS, TREATMENT, AND PREVENTION

General concepts in the diagnosis, treatment, and prevention of occupational skin disorders are discussed in Chapter 211.

Figure 212-3 Radiodermatitis and squamous cell carcinoma in a woman who had worked as an X-ray technician for years, holding young patients still during X-ray examinations, including fluoroscopy, but without protection.

SECTION 35

The Skin in Bioterrorism and Biologic Warfare

Chapter 213 :: Cutaneous Manifestations of Biologic, Chemical, and Radiologic Attacks

:: Scott A. Norton & Jeffrey N. Lackey

BIOLOGIC, CHEMICAL, AND RADIOLOGIC TERRORISM ATTACKS AT A GLANCE

- Potential biologic weapons are classified by the Centers for Disease Control and Prevention into Category A, B, and C levels of risk.
- Category A comprises smallpox, anthrax, plague, tularemia, botulism, and viral hemorrhagic fevers.
- Category B comprises a large number of pathogens ranging from *Brucella* and *Listeria* to the toxins produced by *Clostridium perfringens*.
- Category C comprises a number of viruses, rickettsioses, multidrug-resistant tuberculosis, and rabies.
- Chemical weapons are categorized into blistering agents (such as sulfur mustard), nerve agents, blood agents, urticating agents, and incapacitating agents.
- Radiologic weapons include what is called a *dirty bomb*, which produces low levels of radiation contaminating an entire zone.

The bombings of the World Trade Center's twin towers on September 11, 2001, and the spate of anthrax cases that soon followed introduced new responsibilities to the medical and public health communities.[1–3] Physicians now have a societal responsibility to know the principles of responding to outbreaks of disease caused by biologic weapons. The dermatologist's role in recognizing bioterrorism is particularly significant because many pathogens produce illnesses with prominent cutaneous findings.[4,5] The dermatologic aspects of smallpox, for example, are the most obvious and dramatic aspects of the disease. Other conditions, such as anthrax, frequently—although not always—manifest in the skin. It is likely that the diagnosis of an index case of a bioterror outbreak will rest on dermatologic findings, subtle or overt.

Public health authorities recognize that terrorism may involve other sorts of unconventional weapons, including chemical and radiologic weapons. This chapter provides an overview of the manifestations of unconventional weapons that terrorists might use.

BIOLOGIC WEAPONS

The Centers for Disease Control and Prevention (CDC) stratified potential bioweapons into three levels of risk (Tables 213-1, 213-2 and 213-3) based on ease of manufacture, ease of dissemination, subsequent person-to-person transmission, lethality, and psychosocial effects (literally, how terrified a community will be). When an organism is intentionally dispersed as part of warfare, terrorism, or criminal activity, a goal is to infect huge numbers of people. Hence, the dispersal system may be engineered to disseminate the disease widely, often as airborne spread that results in pulmonary or inhalational disease. Some—but not all—of the pathogens are then transmissible from person to person, thereby potentiating the public health effects of—and the terror associated with—biologic weapons.

CATEGORY A AGENTS AND DISEASES

(Table 213-1)

ANTHRAX. (See Chapter 183.) In late 2001, an outbreak of 22 cases in several states along the Eastern Seaboard of the United States was due to an intentional, criminal act of bioterrorism.[10,11] The outbreak occurred when envelopes of spores were distributed through the postal system, contaminating many offices and infecting mail handlers and letter recipients. Initially, it was thought the anthrax spores were finely engineered into an easily aerosolized form, but more recent examinations suggest that even crudely milled spores can cause such an outbreak. The Federal Bureau

TABLE 213-1

Biologic Agents or Diseases Most Likely to be Used in Terrorism or Warfare (Centers for Disease Control and Prevention and National Institutes of Health Category A Agents or Diseases)[a]

Disease	Pathogen or Agent	Weaponized Route of Transmission	Cutaneous Findings	Percent with Cutaneous Findings in Bioterror Attack	Chapter in *Dermatology in General Medicine*
Smallpox	*Variola*	Airborne, then person to person.	Enanthem followed by classic vesicopustular eruption.	All	195
Anthrax	*Bacillus anthracis*	Airborne. No person-to-person transmission.	Edematous papule or plaque evolving into an ulcer surmounted by a black eschar.	Roughly 50%, based on 2001 experience	183
Plague	*Yersinia pestis*	Airborne, then person to person.	None in pure pulmonary form. Distal purpura and gangrene in septicemic form. Buboes in bubonic form.	Not known	183
Tularemia	*Francisella tularensis*	Airborne without subsequent person-to-person transmission.	None in pure pulmonary form. Membranous pharyngitis and oropharyngeal ulcers in oropharyngeal form. Ulceroglandular syndrome.	Not known	183
Botulism	Toxin produced by *Clostridium botulinum*	Airborne, less likely through intentional contamination of food or water. No person-to-person transmission.	Cranial nerve palsies followed by descending paralysis that spares sensation and cognition. Xerostomia, facial palsies, pupils fixed and dilated.	Possibly 100% will have xerostomia, facial palsies, and fixed and dilated pupils	183
Viral hemorrhagic fevers	Examples include filoviruses, such as Ebola and Marburg; arenaviruses, such as Lassa, Junin, and Machupo; flaviviruses, such as dengue; and bunyaviruses, such as hantavirus and Rift Valley fever	Airborne, then possible subsequent transmission depending on agent. Dengue, e.g., is transmitted by the mosquito *Aedes aegypti*.	Petechiae, purpura, and frank hemorrhage.	Not known	—

[a]Category A diseases or agents are the highest priority because they can be easily disseminated or transmitted from person to person, result in high mortality rates and have the potential for major public health impact, might cause public panic and social disruption, and require special action for public health preparedness.

TABLE 213-2
Centers for Disease Control and Prevention and National Institutes of Health Category B Agents or Diseases[a]

Disease	Pathogen or Agent	Cutaneous Findings	Chapter in *Dermatology in General Medicine*, 8th Edition
Brucellosis	*Brucella* sp.		183
Glanders	*Burkholderia mallei*		183
Melioidosis	*Burkholderia pseudomallei*		183
Typhus	*Rickettsia prowazekii*		199
Water safety threats	Examples include bacteria (e.g., *Vibrio cholerae)*, viruses (e.g., Norwalk virus) and protozoa (e.g., *Cryptosporidium parvum*)	Usually none	
Food safety threats	Examples include *Listeria monocytogenes* and *Escherichia coli* O157:H7	Rare	
Psittacosis	*Chlamydia psittaci*	None	
Q fever	*Coxiella burnetii*	None	
Ricin poisoning	Prepared from *Ricinus communis* (castor beans)	None	
Staphylococcal enterotoxin B		None	
Viral encephalitis	Examples include α viruses that cause equine encephalitides	Rare	
Clostridium perfringens toxin	Epsilon toxin of *C. perfringens*	None	

[a]Category B diseases and agents are the next highest priority because they are moderately easy to disseminate; result in moderate morbidity rates and low mortality rates; and are not part of the Centers for Disease Control and Prevention's routine surveillance system.[6–8]

of Investigation now believes that the perpetrator was a scientist working at the US Army's infectious disease laboratory at Fort Detrick, MD. The motive, however, remains unknown.

THE EASY WEAPONIZATION OF THIS HIGHLY LETHAL AGENT MAKES IT ONE OF THE MOST FEARED BIOLOGIC WEAPONS.

During the Cold War, several nations were known to have produced massive quantities of weaponized anthrax, evidence of which became widely known after a 1979 mishap at the Soviet Union's Sverdlosk bioweapon facility. A cloud of anthrax spores was accidentally released and dozens of people downwind died from inhalational anthrax. The Sverdlosk disaster, however, led to the notion that weaponized anthrax caused only inhalational illness. The letter-borne anthrax incidents of late 2001 showed otherwise when only 11 of the 22 victims had inhalational disease, four of whom died. The others had cutaneous anthrax.

Clinical Findings. Inhalational disease can have longer incubation periods than cutaneous disease, perhaps as long as 40–60 days. If a person is on antibiotics (for another reason or for anthrax prophylaxis), *Bacillus anthracis* may remain in its more protected spore form until the antibiotics are discontinued. The initial symptoms of inhalation anthrax are flu-like and nonspecific, characterized by fever, fatigue, and malaise, but soon followed by chills, high fever, nonproductive cough, and dyspnea. Cyanosis, shock, multiorgan failure, and death may ensue. Chest radiographs characteristically show symmetric mediastinal widening due to hemorrhagic lymphadenitis of mediastinal nodes. In inhalational disease, as well as in septicemic anthrax, which may follow cutaneous or gastrointestinal anthrax, bacteremia may lead to fulminant meningitis.[10,11,14,15]

Patients with inhalational anthrax often present initially with a flu-like illness that progresses virulently into severe febrile illness accompanied by tachypnea, stridor, and cyanosis. In inhalation anthrax, the chest X-ray shows significant mediastinal widening and hilar adenopathy because of edema and hemorrhagic necrosis of draining nodes. The pulmonary parenchyma is usually spared; hence, the disease is identified as *inhalational anthrax*, not pulmonary anthrax.[12]

Diagnosis. The acute onset of a painless edematous noduloulcerative lesion with a black eschar should elicit the possible diagnosis of cutaneous anthrax, especially in the epidemiologic setting of exposure to imported animal products, recent travel to endemic areas, or presence of known use of weaponized anthrax (see Fig. 183-1 and eBox 213-0.1 in online edition).[16]

TABLE 213-3

Examples of Centers for Disease Control and Prevention and National Institutes of Health Category C Agents or Diseases[a]

- Nipah virus
- Hanta virus
- Tick-borne hemorrhagic fever virus, specifically Crimean–Congo hemorrhagic fever[b]
- Tick-borne encephalitis complex
- Yellow fever[b]
- Avian influenza virus and severe acute respiratory syndrome virus[c]
- Multidrug-resistant tuberculosis
- Rabies
- Other rickettsioses (e.g., those caused by *Rickettsia typhi, Rickettsia conori, Rickettsia rickettsia, Orientia tsutsugamushi*)

[a]Category C agents or diseases include emerging pathogens that could be engineered for mass dissemination in the future because of availability, ease of production and dissemination, and potential for high morbidity and mortality rates and major public health impact.[6,7,9] Category C agents and diseases generally lack specific dermatologic findings.

[b]Yellow fever virus and most hantaviruses can cause thrombocytopenia, hemorrhage, and hemodynamic instability that can lead to mucosal bleeding.

[c]The H5N1 strain of influenza A virus (avian influenza) and severe acute respiratory syndrome virus have the potential for rapid, widespread, human-to-human transmission, with high morbidity, mortality, and disruption to societal order.

An additional clinical clue is the presence of edema vastly out of proportion to the observed size of the cutaneous lesion. Diagnostic steps include obtaining swabs of exudates for Gram stain and culture, biopsy specimens for histopathology and immunohistochemical staining, and to draw blood samples for culture and serology. *The CDC requests that practitioners notify local or state health departments before attempting a laboratory diagnosis of cutaneous anthrax.*

The diagnosis is usually suspected on the basis of the character of the lesion and the occupational history, hobby exposure, or likelihood of bioterrorism. Demonstration of large Gram-positive rods in aspirated fluid from beneath the eschar, or on skin punch biopsy, also using a direct fluorescent antibody technique supports the diagnosis. Definitive diagnosis requires culture of the organism and demonstration of its susceptibility to specific bacteriophage lysis. Occasionally, the organism can be isolated from the blood during the acute cutaneous illness as well as in disseminated anthrax. Retrospective serodiagnosis is possible with the demonstration of a titer rise in electrophoretic immunotransblots of antibody to protective antigen and enzyme-linked immunosorbent assay for detection of antibodies to a particular toxin called *lethal factor*.

Therapy. Naturally occurring anthrax is susceptible to penicillin and doxycycline but weaponized anthrax may have been engineered to be resistant to these antibiotics. Therefore, a fluoroquinolone such as ciprofloxacin is recommended for initial treatment of confirmed or suspected anthrax, even in pregnant women and children in whom this class of antibiotic is rarely administered. Once drug sensitivities have been established, the patient may be switched to another antibiotic as clinically indicated. Current treatment of cutaneous anthrax in adults in the setting of bioterrorism involves the use of ciprofloxacin (500 mg po bid) or doxycycline (100 mg po bid) for 60 days because possible coexposure to inhaled anthrax spores.[10,11] Antibiotics kill activated *B. anthracis* bacilli but do not reverse the effects of toxins already produced. For that, one must use anthrax Immunoglobulin (AIG).

Two types of vaccine are available for immunization against anthrax.[7] The first vaccine (anthrax vaccine adsorbed, AVA) is licensed for human use in the United States to protect workers in occupations that might expose them to *B. anthracis*. Since 1998, it has often been given to members of the Armed Forces of the United States. It can also be used as part of a postexposure prophylactic regimen. The vaccine is a sterile culture filtrate (composed primarily of protective antigen) of an attenuated strain of *B. anthracis* adsorbed to an aluminum hydroxide adjuvant and administered in five doses over 18 months. The second vaccine is for immunization of livestock against anthrax and consists of viable spores of an attenuated, nonencapsulated, toxigenic strain.

PLAGUE. (See Chapter 183.) Plague is caused by *Yersinia pestis*, an aerobic Gram-negative bacillus with "safety-pin" bipolar staining (see Chapter 183). In nature, plague is usually limited to enzootic cycles between rodent reservoirs and flea vectors. Most human infections occur via fleabites and typically lead to bubonic plague, which is highly lethal but generally not communicable to others. In naturally occurring disease, human-to-human transmission occurs mainly if the patient's condition changes from bubonic form of plague to the pneumonic form. Once in the lungs, the pathogens are dispersed within droplets that others inhale, leading to additional cases of pneumonic plague. This form of plague is more deadly than bubonic, having a fatality rate among untreated cases that approaches 100%. Hence, deliberate spread of aerosolized plague bacteria could kill massive numbers of people.[19,20]

The Japanese military tested plague as a biological weapon during the occupation of Manchuria before and during World War II. Rather than spreading the bacteria via airborne routes, the Japanese allegedly distributed common fleas—*Pulex irritans*—that had been infected with *Yersinia pestis*.[19]

Pneumonic plague does not produce buboes, which are the result of transcutaneous transmission via fleabites. Instead, pneumonic plague produces skin lesions if it evolves into septicemic plague. Then the patient may develop acral ecchymoses and distal gangrene, often accompanied by disseminated intravascular coagulation. These lesions resemble purpura fulminans, septic emboli, or meningococcemic purpura, and possibly gave rise to the term *Black Death*.

Plague in any form is a reportable disease in every jurisdiction worldwide. Confirmatory laboratory tests include culture of *Y. pestis* from a clinical specimen or

detection by polymerase chain reaction. Serologic tests are not useful in the acute setting.[21]

In the event of an outbreak of pneumonic plague, the keystone of protection is isolation of cases and the use of prophylactic antibiotics, specifically doxycycline, a quinolone such as ciprofloxacin, chloramphenicol, or cotrimoxazole. The human vaccine against plague has been withdrawn. For cases, the preferred regimen is parenteral gentamicin combined with oral (see Table 180-1).

TULAREMIA. (See Chapter 183.) Tularemia, like plague, ordinarily exists in enzootic cycles and infects humans most commonly after an arthropod bite. The usual arthropod vector to transmit tularemia is a tick (such as *Dermacentor andersoni, D. variabilis*, or *Amblyomma americanum*) and less commonly a deerfly, *Chrysops discalis*, or in Northern Europe, certain mosquitoes. Furthermore, like plague, tularemia occasionally presents in a pulmonary form, with the pathogens entering the lungs either through septicemic spread from a lymphocutaneous focus, or directly through the inhalation of aerosolized bacteria. The infectious inoculum for *Francisella tularensis* is extremely small, perhaps as few as 50 organisms.[22,23] Because pneumonic tularemia is highly lethal, the intentional dispersal of airborne organisms has the potential to cause devastating outbreaks of disease. Unlike pneumonic plague, however, pulmonary tularemia cannot be spread from person to person.

Clinical Findings. Tularemia can be acquired through several routes and present in several clinical forms. Pulmonary tularemia, which presumably would be the main form seen after intentional airborne spread, lacks cutaneous lesions. Airborne spread could, however, lead to other forms of the disease, such as oculoglandular and gastrointestinal, which in some cases have mucocutaneous findings.

Treatment. Tularemia is a reportable disease and any pulmonary case or cluster of other cases should launch an epidemiologic investigation. In the event of an outbreak of pneumonic tularemia, health authorities should consider community prophylaxis with doxycycline or ciprofloxacin. Streptomycin (or in its absence, gentamicin) treats all forms of tularemia successfully when administered early in the course of the disease. Clinical improvement is evident within 24–48 hours, but treatment should be continued for at least 7–10 afebrile days. Tetracycline and chloramphenicol are acceptable alternatives but should be given for longer periods than 21 and 14 days, respectively, to reduce the risk of relapse.[23] In the United States, the National Institutes of Health and the Department of Defense are funding development of a newer vaccine.

SMALLPOX. For epidemiology, etiology, and pathogenesis, clinical manifestations, prognosis, and vaccination see Chapter 195.[24–27]

After the World Health Organization declared that naturally occurring smallpox was eradicated, laboratories worldwide destroyed their stocks of variola—except for a few facilities that maintained small amounts of virus, putatively for research purposes. With the collapse of the Soviet Union and the dismantling of its military medical research system, there have been concerns that rogue states or terrorist organizations have obtained unmonitored stocks of virus. Any recurrence of smallpox represents a catastrophic medical, public health, and criminal event of extraordinary proportions.

The differential diagnosis of smallpox and varicella is described in eBox 213-0.2 in online edition.

The CDC has an algorithm for the evaluation of suspected smallpox and offers a differential diagnosis. The algorithm, *Evaluating patients for smallpox: acute, generalized vesicular or pustular rash illness protocol* (available at http://www.bt.cdc.gov/agent/smallpox/diagnosis/pdf/spox-poster-full.pdf), identifies three features at the core of a clinical diagnosis of smallpox (Box 213-1).[28]

Dermatologists who serve as bioterrorism resources for their communities or hospitals must become familiar with smallpox vaccination programs. Vaccinia, an orthopoxvirus related to smallpox and to the cowpox originally used in Jenner inoculations, can produce several cutaneous adverse effects, which require some expertise to diagnose and manage. These conditions are reviewed in detail in Chapter 195.

BOX 213-1 CORE FEATURES IN THE CLINICAL DIAGNOSIS OF SUSPECTED SMALLPOX

- Febrile prodrome occurring 1–4 days before rash onset with fever ≥38.3°C (101°F) and at least one of the following: prostration, headache, backache, chills, vomiting, or severe abdominal pain.
- Classic smallpox lesions are deep-seated, firm or hard, round, well-circumscribed vesicles or pustules that are sharply raised and feel like small, round objects embedded under the skin. As they evolve, the lesions may become umbilicated or confluent.
- Lesions in the same stage of development: On any one part of the body (e.g., face or arm), all lesions are in the same stage of development—that is, all are vesicles or all are pustules.

CATEGORY B AGENTS AND DISEASES WITH POSSIBLE CUTANEOUS MANIFESTATIONS

(Table 213-2.)

BRUCELLOSIS. (See Chapter 183.) Brucellosis is a zoonotic infectious disease that is usually transmitted to humans by direct contact with infected animals or animal products or by ingestion of contaminated dairy products. It can also be transmitted via aerosolized

propagules and requires a small inoculum, perhaps 10–100 organisms, to cause human disease. Hence, it is regarded as a possible biologic weapon. Indeed, during the Cold War, the United States and other nations allegedly experimented with the weaponization of *Brucella suis*.[8,29,30]

Deliberate spread of aerosolized bacteria would cause pulmonary disease, which has a mortality rate, even when untreated, of less than 5%. The disease can cause profound fatigue and requires prolonged treatment; hence, victims could be incapacitated for months. Subsequent human-to-human transmission will not occur. Cutaneous manifestations of brucellosis are uncommon and nonspecific and are discussed in detail in Chapter 183.

MELIOIDOSIS AND GLANDERS. (See Chapter 183.) Melioidosis and glanders are clinically similar diseases caused by the related bacteria *Burkholderia pseudomallei* and *Burkholderia mallei*, respectively. The clinical presentations of the two illnesses are similar but the pathogens have markedly different environmental niches. Glanders naturally occurs in horses, donkeys, mules, and other equids—although it is extremely rare worldwide today. Melioidosis is found in fresh water and damp soils in tropical regions, notably Southeast Asia, particularly Singapore and northeast Thailand, and in the coastal areas of northern Australia.[31,32]

As biologic weapons, these organisms would be disseminated in aerosols to cause respiratory outbreaks. Only a small inoculum of either is required to cause illness. The incubation period is roughly 10–14 days, and the subsequent pulmonary disease has a mortality rate of more than 95% untreated or approximately 40% when treated with appropriate antibiotics. Pulmonary disease can lead to bacteremia or septicemia, which can produce cutaneous and subcutaneous abscesses (see Chapter 183).[32–34]

The first case of human glanders in the United States in more than 50 years was reported in 2002 in a microbiologist who was inadvertently exposed at an Army Research Laboratory. He developed axillary lymphadenopathy and bacteremic infection with hepatic and splenic abscesses but responded well to prolonged treatment with imipenem and doxycycline.[35]

CATEGORY C BIOWEAPONS

(See Table 213-3.)

Category C is an expanding list of diseases, mostly caused by emerging pathogens that could possibly be engineered for mass dissemination and major public health impact.[9] The number of diseases in Category C continues to expand as new diseases, such as severe acute respiratory syndrome, avian flu (caused by the H5N1 strain of influenza A virus), and Nipah virus infection are recognized for their potential for high morbidity, mortality, and societal disruption.[9]

Most diseases currently in Category C lack specific dermatologic findings. In nature, many are arthropod-borne viral hemorrhagic fevers that present with the systemic effects of vascular compromise, widespread hemorrhage, and hypovolemic shock. These conditions are often accompanied by cutaneous manifestations of thrombocytopenia and hemorrhage, namely petechiae, purpura, and frank bleeding from orifices and mucosal surfaces. The most severe of these, Crimean–Congo hemorrhagic fever caused by a bunyavirus, is usually transmitted by hard ticks in the genus *Hyalomma*. Several other pathogens, such as yellow fever virus, are transmitted by mosquitoes. If—or when—used for bioterrorism, Category C pathogens will likely be transmitted by aerosolization, contamination of drinking or food supplies, or in ways yet to be engineered.

CHEMICAL WEAPONS

(Table 213-4.)

Chemical weapons were used on a grand scale during World War I by the Imperial German Army and then by the Allied Forces in response. The morbidity, mortality, and terror associated with these weapons exceeded that of any known conventional weapon.[36] Soon after the 1918 Armistice, international treaties limited—then ultimately banned—the use of chemical agents during warfare. Although these prohibitions are regarded as international law, not all nations have signed and ratified the various treaties. Furthermore, the ban on chemical weapons specifies use during declared wars with adversary nations. The treaties do not, however, explicitly forbid the use of chemical weapons against noncombatants or within one's own country.

The Japanese cult, Aum Shinrikyo, used another chemical weapon, the nerve agent sarin, in Tokyo's subways in an act of domestic terrorism. Although no one was killed, this attack underscores the fact that rogue organizations can obtain or develop their own unconventional weapons.

Chemical weapons are divided somewhat loosely into categories based on their effects on human victims: blister agents, nerve agents, blood agents, urticating agents, choking agents, and incapacitating agents. Table 213-4 identifies prototypical members of the major categories and describes mechanistic and clinical features of these agents. The class with the most severe effects on the skin is that of blister agents.[36,38]

Blister agents, notably sulfur mustard (HD), are the most commonly used chemical weapons. HD was first used during World War I in battles around Ypres, Belgium, hence its other name, *yperite*. Because of a mustard- or garlic-like odor, the compound is often called *mustard gas*. Saddam Hussein's Iraqi military forces used HD against the Iranian army (1980–1988) and against Iraqi citizens in Kurdish villages, such as Halabja.

HD is a relatively simple compound; it can be synthesized by combining two moieties, sulfur dichloride and ethylene. It is inexpensive to manufacture, stable in storage, and can be delivered by many means—therefore, it is likely to be the chemical weapon of choice for a terrorist organization.

HD is an amber-colored, viscous liquid that is lipid soluble, thereby passing easily into and through

TABLE 213-4
Major Categories of Chemical Weapons and Their Major Effects

Class of Agent	Example of Agent	Physical Form of Weaponized Substance	Mechanism of Action	Route of Exposure	Time to Onset of Signs and Symptoms	Nondermatologic Signs and Symptoms	Cutaneous Reactions	Immediate Treatment[a] Includes	Definitive Treatment Includes	Differential Diagnosis
Blood agent	Hydrogen cyanide	Liquid or vapor	Inactivates cytochrome oxidase, thereby preventing cells from using oxygen.	Inhalation, cutaneous, mucosal	Seconds to minutes	Low dose: dizziness, nausea, headache, eye irritation. High dose: loss of consciousness; cessation of respiration.	Often with cherry red skin.	Remove from environment. Remove clothing. Flush skin with copious water. Oxygen.	Oxygen. Amyl nitrite or sodium nitrite, followed by sodium thiosulfate. Respiratory support.	Carbon monoxide poisoning. Hydrogen sulfide (sewer gas) poisoning
Blistering agent	Mustard gas, mustard agent, yperite, sulfur mustard	Liquid or vapor	Alkylating agent (related to medical nitrogen mustard) but precise mechanism in the skin is not known.	Inhalation, cutaneous, mucosal	Hours to days	Red, irritated eyes with conjunctivitis and lid edema. Vomiting. Nasal irritation, cough.	Erythema, pruritus, blistering.	Remove from environment. Remove clothing. Flush skin with copious water or hypochlorite. Irrigate eyes with saline.	No antidote exists. Definitive eye care. Pain relief. Respiratory support. If the blister agent is Lewisite rather than sulfur mustard, use Dimercaprol (British antilewisite).	Exposure to other irritants (e.g., caustics, ammonia, sodium hydroxide)
Nerve agent	Tabun, sarin, VX	Liquid or gas	Inhibits acetylcholinesterase, allowing excess acetylcholine to accumulate (which overstimulates muscles, glands, and nerves) and allowing unrestrained parasympathetic (specifically muscarinic) activity.	Inhalation, cutaneous, mucosal	Vapor: seconds to minutes Liquid: minutes to hours	Pinpoint pupils, lacrimation, asthma-like wheezing, fasciculating muscles, perspiration, hypersalivation, diarrhea. Higher doses: seizures, apnea, loss of consciousness.	Perspiration and piloerection.	Remove from environment. Remove clothing. Flush with copious amounts of water or warm soapy water. Atropine and pralidoxime.	Repeated doses of atropine to reduce secretions. Pralidoxime as needed. Consider diazepam to prevent seizures, inc atropine-induced seizures. Respiratory support.	Organophosphate pesticide poisoning

(continued)

TABLE 213-4
Major Categories of Chemical Weapons and Their Major Effects (Continued)

Class of Agent	Example of Agent	Physical Form of Weaponized Substance	Mechanism of Action	Route of Exposure	Time to Onset of Signs and Symptoms	Nonderma-tologic Signs and Symptoms	Cutaneous Reactions	Immediate Treatment[a] Includes	Definitive Treatment Includes	Differential Diagnosis
Urticating agent	Phosgene, nettle gas, oxime	Gas	Not known.	Inhalation, cutaneous, mucosal	Seconds to minutes	Burning eyes, rhinorrhea, hoarseness, dyspnea, cough.	Immediate pain and severe burning on skin contact. Soon, urticaria-like edema, followed by blisters on day 2. May cause deep necrosis of skin.	Remove clothing. Flush with copious amounts of water or sodium bicarbonate solution.	Supportive burn care.	Exposure to other irritants (e.g., caustics, ammonia, sodium hydroxide)
Choking agent	Phosgene, carbonyl chloride, carbonic acid dichloride	Gas or liquid that vaporizes easily	Not known. Increases permeability of alveolar capillaries leading to noncardiogenic pulmonary edema.	Inhalation	Hours	Dyspnea, chest tightness, wheezing, red mucosa; erythema, causes noncardiac pulmonary edema.	None	Remove from environment. Oxygen. Consider intubation. Flush eyes with water.	Oxygen, respiratory support.	Industrial gas exposure (e.g., ammonia, hydrochloric acid)

[a]Personal protective measures [e.g., chemical hazard suit and protective mask (gas mask)] are usually necessary before one can assist a victim of a chemical weapon attack.

the skin. If HD lands on someone's skin, roughly 80% evaporates quickly, 10% passes through the skin and enters systemic circulation, and 10% remains in the skin. Victims first experience an irritated, gritty feeling in their eyes. This progresses over hours to a chemical conjunctivitis and massive lid edema. Ocular effects can last several weeks and may destroy the cornea or even rupture the globe. Victims also suffer severe nausea and vomiting within several hours of exposure.

The skin starts itching within hours and then develops a diffuse nonspecific erythema later on the first day. Blisters begin to appear at 1–2 days, starting as small vesicles that coalesce to form large, extensive bullae.

HD penetrates the skin within minutes and there is no antidote. Therefore, for decontamination to be effective, it must be started immediately. Responders must don full protective gear (chemical hazard suit and a protective breathing mask) and remove the victim from the contaminated environment. The victim's clothes must be removed completely and the body washed—flooded—with copious amounts of water. Warm soapy water is better and a hypochlorite solution (one part household bleach to nine parts water) is best. The eyes must be flushed with saline.

Subsequent care is largely supportive and the patient feels better when given nonsteroidal anti-inflammatory drugs to counter inflammation and placed in a cool environment. It is necessary to manage fluids and electrolytes and to remain vigilant for secondary infection. In-vivo animal studies suggest that débridement of blisters increases the rate of wound healing, but human studies have not been conducted. Healing is largely a matter of time and leaves persistent dry, itchy, discolored (hypo- and hyperpigmented) skin at the affected areas.[36–42]

RADIOLOGIC WEAPONS

Terrorist organizations are unlikely to possess true nuclear weapons but may have what is known as a *dirty bomb*. This type of weapon presents a radiation hazard by using conventional explosives, such as dynamite, to scatter radioactive debris or dust, which then contaminates an area. Dirty bombs do not trigger nuclear chain reactions but instead produce low levels of radiation. Accordingly, exposed individuals are unlikely to experience acute radiation injury. The immediate effects of a dirty bomb will most likely be due to the force of the blast, which can harm people and destroy property. The lasting effects of a dirty bomb include contamination of a zone, rendering it uninhabitable until the difficult task of area decontamination is complete.

Individuals exposed to radiation from a dirty bomb must rid themselves of lingering radioactive dust or debris. Ideally, this will be conducted at a designated decontamination station. Victims must remove all clothes and then wash their entire bodies thoroughly with soap and water. The decontamination station should contain, collect, and dispose of the clothes and water in a manner that is safe and appropriate for radioactive waste.

In the event of a suspected attack with a chemical or radiologic weapon, medical personnel must coordinate with public health and law enforcement agencies at the local, state, and federal level.[36,40–45]

PART 11 Therapeutics

Topical Therapy

Chapter 214 :: Principles of Topical Therapy

:: Aieska De Souza & Bruce E. Strober

PRINCIPLES OF TOPICAL THERAPY AT A GLANCE

- The efficacy of a topically applied drug depends on its inherent potency and on its ability to penetrate skin.
- Some factors that affect penetration include: concentration of medication, thickness and integrity of the stratum corneum, frequency of application, occlusiveness of the vehicle, and compliance.
- Topical formulations (vehicles) are meant to enhance the beneficial effects of the medication.
- Either the vehicle or its active ingredient(s) may cause local toxicity.
- Topical medications may induce systemic toxicity.

Sensible topical drug therapy involves not only the selection of an appropriate agent, but also a thoughtful consideration of the areas of the body affected, the state of the diseased skin, the concentration of the drug, the type of vehicle (e.g., ointment, cream, lotion), the method of application, and a defined duration of use that both maximizes efficacy and minimizes adverse side effects. Behind each of these considerations are basic principles that help guide the practitioner toward a rational plan of therapy.

CUTANEOUS DRUG DELIVERY

The therapeutic efficacy of a topical drug relates to both its inherent potency and the ability of that drug to penetrate the skin.[1] In fact, many potent agents, such as hydrocortisone and fluocinolone acetonide, are quite poorly absorbed after topical application. Conversely, many well-absorbed agents with weak potency have negligible therapeutic use. Percutaneous absorption necessitates passage through the stratum corneum, epidermis, papillary dermis, and into the bloodstream. (See Chapter 215 for information on the pharmacokinetics of topical therapy.)

In contrast to many orally administered drugs that are nearly completely absorbed within a few hours, topical medicines generally have a poor total absorption and a very slow rate of absorption. For example, less than 2% of a topically applied corticosteroid such as hydrocortisone is absorbed after a single application left on the skin for more than 1 day. Furthermore, peak rates of absorption are reached up to 12–24 hours after application. Fortunately, low absorption does not necessarily translate into low efficacy. Drugs such as topical corticosteroids are effective because of their inherent potency and can exert clinically significant effects in spite of low absorption. In this light, absorption represents only one of many facets of efficacy.

OTHER FACTORS THAT AFFECT ABSORPTION

STRATUM CORNEUM

The stratum corneum is the rate-limiting barrier to percutaneous drug delivery. This cornified layer is composed of ceramides, free fatty acids, and cholesterol in a 1:1:1 molar ratio. By weight, the stratum corneum consists of 50% ceramides (acylceramides being the most abundant), 35% cholesterol, and 15% free fatty acids. The stratum corneum thickness and, thus, drug penetration will vary depending on body site.[2] Box 214-1 lists varying body sites and their relative resistance to percutaneous absorption.

There are two main routes for permeation through the stratum corneum: (1) the transepidermal and (2) the transappendageal pathways. The transappendageal, or shunt route, involves the flow of molecules through the eccrine glands and hair follicles via the associated sebaceous glands.[3] In the transepidermal route, molecules pass between the corneocytes via the intercellular micropathway, or through the cytoplasm of dead keratinocytes and intercellular lipids, defined as the *transcellular micropathway*.[3,4] The intercellular pathway is considered the most important route for cutaneous drug delivery.

An important consideration in topical therapy is that diseased skin may have an altered (increased, decreased, or absent) stratum corneum, thus changing the body site's barrier function. Abraded or eczematized skin presents less of a barrier. Solvents, surfactants, and alcohols can denature the cornified layer and increase penetration; as a result, topical medications with these components may enhance absorption. Importantly, simple hydration of the stratum corneum enhances the absorption of topically applied steroids by four to five times.[5]

OCCLUSION

Occlusion via closed, airtight dressings or greasy ointment bases increases the hydration and temperature of the stratum corneum, limits rub-off/wash-off of the drug and, consequently, enhances drug penetration. Occlusion techniques range from application under an airtight dressing such as vinyl gloves, plastic wrap, and hydrocolloid dressings to occlusion with cotton gloves or socks at night for treatment of hands and feet, to application of a medication already impregnated into an airtight dressing, as seen in flurandrenolide tape. To derive the greatest benefit from occlusion, the patient should hydrate the skin by immersion in water for approximately 5 minutes before the application of a cream or ointment. Clinically, this may correspond to application immediately after bathing and before drying completely. With many drugs, occlusion increases drug delivery by 10–100 times the amount of drug delivered when not occluded.[6] This approach can lead to more rapid onset times and increased efficacy when compared with topical application alone. On the other hand, occlusion may also lead to a more rapid appearance of the drug's adverse effects, such as the ability of topical corticosteroids to induce local skin atrophy or suppression of the hypothalamus–pituitary–adrenal axis. Occlusion may promote infection, folliculitis, or miliaria. In the case of topical anesthetics such as lidocaine and prilocaine, occlusion hastens absorption into both the skin and the bloodstream, which has led in rare cases to cardiac complications from lidocaine toxicity or methemoglobinemia from prilocaine toxicity.

BOX 214-1 REGIONAL DIFFERENCES IN PENETRATION[a]

1. Mucous membrane
2. Scrotum
3. Eyelids
4. Face
5. Chest and back
6. Upper arms and legs
7. Lower arms and legs
8. Dorsa of hands and feet
9. Palmar and plantar skin
10. Nails

[a]Most penetration with number 1 and less penetration with increasing numbers.

FREQUENCY OF APPLICATION

The frequency of drug application likely has little effect on increasing a topical drug's overall efficacy.[6,7] One daily application is enough for most topical glucocorticoids, for example, but the nonspecific emollient or protective effect of creams and ointments are likely enhanced by more frequent applications. Regardless, increasing the contact time for a topical drug augments its total absorption.

QUANTITY OF APPLICATION

The quantity of the drug applied likely has a negligible effect on drug absorption. Obviously enough drug must be dispensed and spread to cover the affected areas. Further, the quantity of drug applied might affect patient adherence to the prescribed regimen. For example, too much applied drug might negatively alter the subjective experience of having a medication on the skin, i.e., the drug may feel "wrong" (greasy, caked, chalky, etc.) or is cosmetically unattractive (shiny, white color). Regardless, the amount prescribed must be adequate to treat the affected body surface area for the necessary length of time. In this regard, patient education is critical to prevent wasteful overuse or ineffective underuse of the medication. The amounts of topical medications to dispense, based on the estimated body surface area, frequency of application, and duration of therapy, are presented in Table 214-1. For topical medications like sunscreens that are used over large areas, underapplication is a problem

TABLE 214-1
Suggested Amounts of Topical Medications to Dispense—Cream or Ointment

Area Treated	Estimated% Body Surface Area	Single Application (g)	Twice a Day for 1 Week (g)	Three times a Day for 1 Week (g)
Face	3	1	15	20
Scalp	6	2	30	45
One hand	3	1	15	20
One arm	7	3	45	60
Anterior trunk	14	4	60	90
Posterior trunk	16	4	60	90
One leg including foot	20	5	70	100
Anogenital area	1	1	15	20
Whole body	100	30–40	450–500	600–1,000

From New York University's Dermatologic Formulary—Skin and Cancer Unit.

for most patients. However, for smaller areas, patients may apply a large amount of an ointment, for example, leading to complaints of greasiness or rubbing off on clothing, which can be minimized by using an appropriate amount.

ADHERENCE

Topical medication adherence is a critical although often overlooked aspect of medication efficacy. Generally, adherence to a treatment regimen is associated with female gender, employment, being married, and low prescription costs. Lower adherence is seen for patients with extensive disease, and paradoxically, disease on the face.[8] One 8-week survey using electronic monitoring showed that adherence to treatment for a twice-daily topical prescription decreased from 84% the first week to 51% during the eighth week, with topical nonadherence being especially notable on weekends.[9] Furthermore, adherence is negatively affected by depression, which is common in people with chronic skin conditions and found in up to 20% of patients with psoriasis.[10]

TACHYPHYLAXIS. Defined as the decrease in drug response when used over a prolonged period of time, tachyphylaxis is commonly observed during corticosteroid topical therapy. It is now thought that adherence may be a contributing factor, rather than loss of corticosteroid receptor function.[5,11] Increase in adherence may be achieved by asking patients to use it only on weekends (weekend therapy) or specific days of the week (pulse therapy).[5]

REBOUND EFFECT. Worsening of preexisting dermatoses can occur in patients who have been using topical potent corticosteroids for prolonged regimens.[5] Either tapering down the corticosteroid strength to moderate- or low-potency corticosteroids or increasing the duration of time between applications of the topical drug might prevent the rebound effect.

MISCELLANEOUS FACTORS

Vigorous rubbing or massaging of the drug into the skin not only increases the surface area of skin covered, but also increases blood supply to the area locally, augmenting systemic absorption. It may cause a local exfoliative effect that will also enhance penetration. The presence of hair follicles on a particular body site also enhances drug delivery, with the scalp and beard areas presenting less of a barrier when compared with the relatively hairless body sites. Although having a thinner stratum corneum, the skin of older individuals is poorly hydrated, with fewer hair follicles and, therefore, may impede drug delivery.

Reducing the particle size of the active ingredient increases its surface area–volume ratio, allowing for a greater solubility of the drug in its vehicle. This forms the basis for the increased absorption of certain micronized drugs.[12]

CLASSIFICATION AND CLINICAL APPLICATION OF TOPICAL FORMULATIONS

The vehicle is the inactive part of a topical preparation that brings a drug into contact with the skin. Before the mid-1970s pharmaceutical companies performed limited testing of the impact of the vehicle on the potency of a given formulation. The lack of a scientific analysis of the vehicle led to the marketing of topical drugs that, while having different concentrations of the same active ingredient, nevertheless exhibited similar bioavailability and potency. For example, older preparations of triamcinolone acetonide showed no real

BOX 214-2 VEHICLE INGREDIENTS COMMONLY USED IN TOPICAL PREPARATIONS

- Emulsifying agents
  - Cholesterol
  - Disodium mono-oleamidosulfosuccinate
  - Emulsifying wax
  - Polyoxyl 40 stearate
  - Polysorbates
  - Sodium laureth sulfate
  - Sodium lauryl sulfate
- Auxiliary emulsifying agents/emulsion stabilizers
  - Carbomer
  - Catearyl alcohol
  - Cetyl alcohol
  - Glyceryl monostearate
  - Lanolin and lanolin derivatives
  - Polyethylene glycol
  - Stearyl alcohol
- Stabilizers
  - Benzyl alcohol
  - Butylated hydroxyanisole
  - Butylated hydroxytoluene
  - Chlorocresol
  - Citric acid
  - Edetate disodium
  - Glycerin
  - Parabens
  - Propyl gallate
  - Propylene glycol
  - Sodium bisulfite
  - Sorbic acid/potassium sorbate
- Solvents
  - Alcohol
  - Diisopropyl adipate
  - Glycerin
  - 1,2,6-Hexanetriol
  - Isopropyl myristate
  - Propylene carbonate
  - Propylene glycol
  - Water
- Thickening agents
  - Beeswax
  - Carbomer
  - Petrolatum
  - Polyethylene
  - Xanthan gum
- Emollients
  - Caprylic/capric triglycerides
  - Cetyl alcohol
  - Glycerin
  - Isopropyl myristate
  - Isopropyl palmitate
  - Lanolin and lanolin derivatives
  - Mineral oil
  - Petrolatum
  - Squalene
  - Stearic acid
  - Stearyl alcohol
- Humectants
  - Glycerin
  - Propylene glycol
  - Sorbitol solution

differences in potency among the 0.025%, 0.1%, and 0.5% concentrations. By contrast, modern drug development attempts to maximize drug bioavailability by optimizing vehicle formulation. Additionally, during the current drug development process, dose-response studies determine the maximal effective concentration within a given vehicle, above which any further increase in concentration serves no therapeutic benefit.

The vehicle of a topical formulation often has beneficial nonspecific effects by possessing cooling, protective, emollient, occlusive, or astringent properties. Rational topical therapy matches an appropriate vehicle that contains an effective concentration of the drug. The vehicle functions optimally when it is stable both chemically and physically and does not inactivate the drug. The vehicle also should be nonirritating, nonallergenic, cosmetically acceptable, and easy to use. Additionally, the vehicle must release the drug into the pharmacologically important compartment of the skin. Finally, the patient must accept using the vehicle or else compliance will be poor. For example, although ointments are often pharmacodynamically more effective than creams, patients generally prefer creams to ointments, and thus, it is no surprise that more prescriptions are written for cream-based formulations. Box 214-2 lists many commonly used ingredients in topical preparations. Many of these compounds may serve more than one function in a particular formulation.

POWDERS

Powders absorb moisture and decrease friction. Because they adhere poorly to the skin, their use is mainly limited to cosmetic and hygienic purposes. Generally, powders are used in the intertriginous areas and on the feet. Adverse effects of powders include caking (especially if used on weeping skin), crusting, irritation, and granuloma formation. Further, powders may be inhaled by the user. Most powders contain zinc oxide for its antiseptic and covering properties, talc (primarily composed of magnesium silicate) for its lubricating and drying properties, and a stearate for improved adherence to the skin. Calamine is a popular skin-colored powder composed of 98% zinc oxide

and 1% ferric oxide and acts as an astringent to relieve pruritus. Other drugs formulated as powders include some over-the-counter antifungals.[12]

POULTICES

A poultice, also referred to as a *cataplasm*, is a wet solid mass of particles, sometimes heated, that is applied to diseased skin. Historically, poultices contained meal, herbs, plants, and seeds. The modern poultice often consists of porous beads of dextranomer. Poultices are used as wound cleansers and absorptive agents in exudative lesions such as decubiti and leg ulcers.[12]

OINTMENTS

Ointments are semisolid preparations that spread easily. They are petrolatum-based vehicles, capable of providing occlusion, hydration, and lubrication. Drug potency often is increased by an ointment vehicle due to its ability to enhance permeability.[5] Ointment bases used in dermatology can be classified into five categories: (1) hydrocarbon bases, (2) absorption bases, (3) emulsions of water-in-oil, (4) emulsions of oil-in-water, and (5) water-soluble bases. Dermatologists commonly refer to the hydrocarbon bases and absorption bases as *ointments* and the water-in-oil/oil-in-water emulsion bases as *creams*. In pharmaceutical terms, all of these preparations are ointments and are specifically indicated for conditions affecting the glabrous skin (palms and soles) and lichenified areas.[5]

HYDROCARBON BASES. Also called *oleaginous bases*, hydrocarbon bases are often referred to as *emollients* because they prevent the evaporation of moisture from the skin and are composed of a mixture of hydrocarbons of varying molecular weights, with petrolatum being the most commonly used (white petrolatum, except for being bleached, is identical to yellow petrolatum). They are greasy and can stain clothing. The silicon ointments are composed of alternating oxygen and silicon atoms bonded to organic groups, such as phenyl or methyl, and are excellent skin protectants. They can be used for diaper rash, incontinence, bedsores, and colostomy sites. Hydrocarbon bases are generally stable and do not contain preservatives. They cannot absorb aqueous solutions, and thus are not used for water-soluble drugs.[12]

ABSORPTION BASES. Absorption bases contain hydrophilic substances that allow for the absorption of water-soluble drugs. The hydrophilic (polar) compounds may include lanolin and its derivatives, cholesterol and its derivatives, and the partial esters of polyhydric alcohols such as sorbitan monostearate. These ointments are lubricating and hydrophilic, and they can form emulsions. They function well as emollients and protectants. They are greasy to apply but are easier to remove than the hydrocarbon bases. They do not contain water. Examples include anhydrous lanolin and hydrophilic petrolatum.[12]

WATER-IN-OIL EMULSIONS (CREAMS). Emulsions are two-phase systems involving one or more immiscible liquids dispersed in another, with the assistance of one or more emulsifying agents. A water-in-oil emulsion, by definition, contains less than 25% water, with oil being the dispersion medium. The two phases may separate unless shaken. The emulsifier (or surfactant) is soluble in both phases and surrounds the dispersed drops to prevent their coalescence. Examples of surfactants used include sodium lauryl sulfate, the quaternary ammonium compounds, Spans (sorbitan fatty acid esters), and Tweens (polyoxyethylene sorbitan fatty acid esters). Preservatives are frequently added to increase the emulsion's shelf life. Water-in-oil emulsions are less greasy, spread easily on the skin, and provide a protective film of oil that remains on the skin as an emollient, while the slow evaporation of the water phase provides a cooling effect.[8]

OIL-IN-WATER EMULSIONS. An oil-in-water emulsion contains greater than 31% water. In fact, the aqueous phase may comprise up to 80% of the formulation. This type of formulation is the one most commonly chosen to deliver a dermatologic drug. Clinically, oil-in-water emulsions spread very easily, are water washable and less greasy, and are easily removed from the skin and clothing. Invariably, they contain preservatives, such as the parabens, to inhibit the growth of molds. Additionally, oil-in-water emulsions contain a humectant (an agent that draws moisture into the skin), such as glycerin, propylene glycol, or polyethylene glycol (PEG), to prevent the cream from drying out. The oil phase may contain either cetyl or stearyl alcohol (paraffin alcohols) to impart a stability and velvety smooth feel upon application to the skin. After application, the aqueous phase evaporates, leaving behind both a small hydrating layer of oil and a concentrated deposit of the drug.[12]

WATER-SOLUBLE BASES. Water-soluble bases consist either primarily or completely of various PEGs. Depending on their molecular weight, PEGs are either liquid (PEG 400) or solid (PEG 4,000). These formulations are water soluble, will not decompose, and will not support the growth of mold, and therefore require no preservative additives. They are much less occlusive than water-in-oil emulsions, nonstaining, greaseless, and easily washed off of the skin. Without water, this ointment poorly delivers its coformulated drug. Therefore, it will be useful in scenarios where the practitioner desires a high surface concentration and low percutaneous absorption of the drug. For example, topical antifungal drugs and topical antibiotics (e.g., mupirocin) are formulated in this type of base.

Gels are made from water-soluble bases by formulating water, propylene glycol, and/or PEGs with a cellulose derivative or carbopol. A gel consists of organic macromolecules uniformly distributed in a lattice throughout the liquid. After application, the aqueous or alcoholic component evaporates, and the drug is deposited in a concentrated form. This provides a faster release of the drug independent of its water solubility.

Gels are popular because of their clarity and ease of both application and removal. They are suitable for facial or hairy areas because after application little residue is left behind.[5] Nevertheless, they lack any protective or emollient properties. If they contain high concentrations of alcohol or propylene glycol, they tend to be drying or cause stinging. Gels require preservatives.[12] Newer gel formulations may contain the humectant glycerin, the emollient dimethicone, or the viscoelastic polysaccharide hyaluronic acid, which can mitigate some of the associated irritation. Nonaqueous gels, with bases such as glycerol, may be used for poorly solubilized therapeutics such as 5-aminolevulonic acid.[13]

Microspheres, or microsponges, are formulated in an aqueous gel. Medication, in this case tretinoin, is combined into porous beads 10–25 μm in diameter. The beads are made up of methyl methacrylate and glycol dimethacrylate.

PASTES

Pastes are simply the incorporation of high concentrations of powders (up to 50%) into an ointment such as a hydrocarbon base or a water-in-oil emulsion. The powder must be insoluble in the ointment. Invariably, they are "stiffer" than the original ointment. The powders commonly used are zinc oxide, starch, calcium carbonate, and talc. Pastes function to localize the effect of a drug that may be staining or irritating (i.e., anthralin). They also function as impermeable barriers that serve as protectants or sunblocks. Pastes are less greasy than ointments, more drying, and less occlusive.[12]

LIQUIDS

Liquids can be subdivided into solutions, suspensions, emulsions (discussed in Section "Ointments"), and foams.

SOLUTIONS. A solution involves the dissolution of two or more substances into homogenous clarity. The liquid vehicle may be aqueous, hydroalcoholic, or nonaqueous (alcohol, oils, or propylene glycol). An example of an aqueous solution is aluminum acetate or Burow solution. A hydroalcoholic solution with a concentration of alcohol of approximately 50% is called a *tincture*. A collodion is a nonaqueous solution of pyroxylin in a mixture with ether and ethanol, and is applied to the skin with a soft brush. Flexible collodions have added castor oil and camphor and are used, for example, to deliver 10% salicylic acid as a keratolytic agent. Liniments are nonaqueous solutions of drugs in oil or alcoholic solutions of soap. The base of oil or soap facilitates application to the skin with rubbing or massage. Liniments can be used as counterirritants, astringents, antipruritics, emollients, and analgesics.[12]

SUSPENSIONS (LOTIONS). A suspension, or lotion, is a two-phase system consisting of a finely divided, insoluble drug dispersed into a liquid in a concentration of up to 20%. Nonuniform dosing can result if the suspended particles coalesce and separate out of a homogeneous mixture, therefore shaking of the lotion before application may be required. Examples include calamine lotion, steroid lotions, and emollients containing urea or lactic acid. The applied lotion leaves the skin feeling cooler via evaporation of the aqueous component. Lotions are easier to apply and allow for uniform coating of the affected area, and are often the favorite preparation in treating children. Lotions are more drying than ointments, and preparations with alcohol tend to sting eczematized or abraded skin.[12] Lotions are suitable for application to large surface areas due to their ability to spread easily.[5]

SHAKE LOTIONS. Shake lotions are lotions to which a powder is added to increase the surface area of evaporation. As a result of the increased evaporation, the application of shake lotions effectively dries and cools wet and weeping skin. Generally, shake lotions consist of zinc oxide, talc, calamine, glycerol, alcohol, and water, to which specific drugs and stabilizers may be added. Shake lotions tend to sediment, and derive their name from the need to shake the preparation before each use to obtain a homogeneous suspension. In addition, after water has evaporated from the lotion, the powder component may clump together and become abrasive. Therefore, patients should be instructed to remove the residual particles before the reapplication of shake lotions.[12]

FOAMS. Foams are triphasic liquids composed of oil, organic solvents and water, which are kept under pressure in aluminum cans. Foams are formulated with a hydrocarbon propellant, either butane or propane.[14] The foam lattice is formed when the valve is activated. Once in contact with the skin, the lattice breaks down, the alcohol evaporates within 30 seconds, and leaves minimal residue in the skin. The alcohol component of the foam is thought to act as a penetration enhancer, momentarily altering the barrier properties of the stratum corneum and increasing drug delivery through the intercellular route.[14] Previous studies have demonstrated that foam vehicles are highly effective in delivering greater amount of active drug at an increased rate when compared to other vehicles that traditionally depend upon hydration of the intercellular spaces within the stratum corneum.[14] Foams have not been associated with an increase in the adverse events and compliance seams to be better with this formulation, especially for localized conditions affecting the scalp.[14]

AEROSOLS

Topical aerosols may be used to deliver drugs formulated as solutions, suspensions, emulsions, powders, and semisolids. Aerosols involve formulating the drug in a solution within a pure propellant. Usually, the propellant is a blend of nonpolar hydrocarbons. When applied to abraded or eczematized skin, aerosols lack the irritation of other formulations, especially when the quality of the skin makes direct application painful or difficult. Furthermore, aerosols dispense a drug as a thin layer with minimal waste, and the unused portion

cannot be contaminated. Aerosol foams, a relatively new vehicle for drug delivery, are commonly used to deliver corticosteroids such as betamethasone valerate and clobetasol propionate. The foam contains the drug within an emulsion formulated with a foaming agent (a surfactant), a solvent system (such as water and ethanol), and a propellant. On application, a foam lattice forms transiently until it is broken by both the heat of the skin and the heat of rubbing the foam onto the skin. Foams that are alcohol based leave very little residue within seconds of their application. Furthermore, a given corticosteroid formulated in a foam vehicle demonstrates comparable potency when compared with the same corticosteroid in other vehicles.[1,15] Although aerosols allow for the ease of application (especially to hair-bearing areas) and high patient satisfaction, they suffer from the disadvantages of being expensive and potentially ecologically damaging.[12]

PENETRATION ENHANCERS

CHEMICAL ENHANCERS. A penetration enhancer is a compound that is able to promote drug transport through the skin barrier. Skin hydration and interaction with the polar head group of the lipids are mechanisms for increasing penetration. Water, alcohols (mainly ethanol), sulphoxides (dimethylsulphoxide/DMSO), decylmethylsulphoxide/DCMS, azones (laurocapram), and urea are some of the most commonly used compounds.[4] Urea is thought to act as a penetration enhancer due to its keratolytic properties and by increasing the water content in the stratum corneum. Other substances that may also act as enhancers include propylene glycol, surfactants, fatty acids, and esters.

Vesicular systems are widely used in dermatologic and cosmetic fields to enhance drug transport into the skin through the transcellular and follicular pathways. Examples of vesicular systems include liposomes (phospholipid-based vesicles), niosomes (nonionic surfactant vesicles), proliposomes and proniosomes, which, respectively, are converted to liposomes and niosomes upon hydration.[16]

PHYSICAL ENHANCERS. Physical methods such as the application of a small electric current (iontophoresis), ultrasound energy (phono- or sonophoresis) and the use of microneedles increase cutaneous drug penetration.[4] Microdermoabrasion is the application of crystals (generally aluminum oxide) on the skin and the collection of such crystals and skin debris under vacuum suction. This technique enhances drug permeation and facilitates drug absorption by altering the architecture of the stratum corneum.[17]

STABILIZERS

Stabilizers are nontherapeutic ingredients and include the preservatives, antioxidants, and chelating agents. Preservatives protect the formulation from microbial growth. The ideal preservative is effective at a low concentration against a broad spectrum of organisms, nonsensitizing, odor free, color free, stable, and inexpensive. Unfortunately, the ideal preservative does not exist. The parabens are the most frequently added preservatives, and are active against molds, fungi, and yeasts, but less effective against bacteria. Alternative agents include the halogenated phenols, benzoic acid, sodium benzoate, formaldehyde, the formaldehyde-releasing agents, and previously, thimerosal. Most commonly used preservatives may act as contact sensitizers.

Antioxidants or preservatives prevent the drug or vehicle from degrading via oxidation. Examples include butylated hydroxyanisole and butylated hydroxytoluene, used in oils and fats. Ascorbic acid, sulfites, and sulfur-containing amino acids are used in water-soluble phases. Chelating agents, such as sodium EDTA and citric acid, work synergistically with antioxidants by complexing heavy metals in aqueous phases.

THICKENING AGENTS

Thickening agents increase the viscosity of products or suspend ingredients in a formulation. Examples include bees-wax and carbomers. In addition to functioning as an ointment vehicle, petrolatum may be added to an emulsion to increase its viscosity. As in this example, an ingredient may have a therapeutic effect as well as acting as part of a vehicle.

TOXICITY OF TOPICAL DRUGS

LOCAL EFFECTS

Either the vehicle or its active ingredients may cause local toxicity to the applied site. Local adverse effects are usually minor and reversible. Major cutaneous side effects include irritation, allergenicity, atrophy, comedogenicity, formation of telangiectases, pruritus, stinging, and pain. The mechanism of toxicity may be as simple as the desiccation of the stratum corneum (the removal of sebum and oils by the preparation's emulsifiers, for example), or involve a more complex effect on either the cells of the epidermis or dermis and the structures these cells comprise (i.e., epidermis, adnexae). Local damage may occur either directly at, or within close proximity to, the treated site. Further, irritation and damage may appear even after a drug has been discontinued. Often the therapeutic effects of the active ingredient mask or immediately treat the toxic effects of the formulation so that acutely toxic effects are transient.[18] For example, an allergic contact dermatitis to a preservative in a topical steroid may be masked by the effects of the steroid itself.

IRRITANT CONTACT DERMATITIS. Irritation is driven less by drug penetration and more by drug concentration. Thus, lowering the concentration of an irritating drug may lower the risk of side effects. However, a change in formulation may reduce the

preparation's efficacy. Nevertheless, often using a less concentrated preparation over a greater period of time is as therapeutically efficacious while minimizing adverse effects; for example, the use of benzoyl peroxide 2% to 5% preparations in contrast to 10% preparations.[18] In some instances, though, skin irritancy might be central to drug efficacy. For example, although not conclusively shown, the power of immunomodulating agents such as imiquimod might rely on an increased innate (inflammatory or irritant) immune response.

SUBJECTIVE OR SENSORY IRRITANT CONTACT DERMATITIS. Patients may detect burning or stinging sensations without any signs of cutaneous irritation after applying a topical medication.[19,20] Several compounds may induce sensory irritant contact dermatitis in predisposed individuals, such as tacrolimus,[21] sorbic acid, propylene glycol, benzoyl peroxide hydroxy acids, mequinol, ethanol, lactic acid, azelaic acid, benzoic acid, and tretinoin.[19,20]

ALLERGIC CONTACT DERMATITIS. In contrast to local irritation, contact allergy development depends on local penetration. Allergy, of course, is driven by antigen recognition and presentation, and thus, percutaneous absorption of the drug must be at a level that guarantees interaction with the immune effector cells of the skin. Therefore, the contact allergenicity of a drug relates most significantly to percutaneous absorption. In some instances, cutaneous allergy may be therapeutic, for example, the treatment of patients with cutaneous T-cell lymphoma with topical nitrogen mustard. The shift in malignant T cells from T helper (Th) 2 to Th1-type cytokine expression is believed to lead to apoptosis of the malignant T cells and tumor regression.[22]

MALIGNANCIES. Rarely, topical therapy may result in neoplasia. For example, the risk of secondary malignancies, such as keratoacanthomas, basal and squamous cell carcinomas, lentigo maligna and primary melanoma have been reported with the long-term use of nitrogen mustard.[22]

OTHERS. The application of topical corticosteroids to the periorbital skin has been reported both to induce cataracts and increase in intraocular pressure.[5]

SYSTEMIC EFFECTS

One should be aware of the potential systemic toxicities of topical drugs. Although generally safer than the other routes of administration, topical application can result in systemic toxicities ranging from end-organ toxicity (central nervous system, cardiac, renal, etc.), teratogenicity, and carcinogenicity to drug interactions. These outcomes may relate to the drug itself, its metabolites, or even a component of the vehicle.

The kinetics of topically applied drugs differ significantly from those administered by other routes. One important consideration is the lack of hepatic first-pass metabolism of a topical drug. This is especially relevant to drugs such as salicylic acid that are relatively innocuous when given enterally, but may manifest central nervous system toxicity when applied topically. Additionally, acting as a reservoir, the stratum corneum may store large amounts of a topical drug, and a subsequently long diffusion period of many days may ensue, delivering a steady supply of drug to the systemic circulation.

Percutaneous toxicity directly relates to percutaneous absorption. Therefore, factors that modulate absorption also influence toxicity: the concentration of the drug, its vehicle, the use of occlusion, the body site and area treated, frequency of use, the duration of therapy, and the nature of the diseased skin. For example, 6% salicylic acid in Eucerin used for 11 days in the treatment of psoriasis has been associated with epistaxis and deafness, while the same concentration of salicylic acid in hydrophilic cream under occlusion for 4 days for the treatment of dermatitis (involving the same amount of body surface area) may result in hallucination.[18] Similar to their effect on systemically administered drugs, renal and hepatic diseases, by influencing drug clearance, also contribute to an increased potential for drug toxicity.

Young children have a greater surface area–volume ratio, and thus are at greater risk of percutaneous toxicity than adults. This phenomenon necessitates alternative drugs, formulations, and dosing schedules for children with widespread cutaneous disease. Patients with acute flares of cutaneous illness (for example, psoriasis or atopic dermatitis) may require the treatment of a larger body surface area in a relatively abbreviated period of time. These patients may also increase their dose and frequency of application during such flares. Coupled with the likely increased percutaneous absorption of the diseased skin, these scenarios exponentially increase the possibility of systemic toxicity, and patient education is vital to prevent adverse outcomes.[12] To reduce the risk of toxicity from topical drugs and to increase treatment efficacy, many practitioners will rationally advocate systemic approaches (i.e., methotrexate, cyclosporine, injectable or infusable biologics, or ultraviolet radiotherapy) to patients whose disease involves an extensive body surface area.

TYPE I HYPERSENSITIVITY REACTIONS. In rare instances, anaphylactic shock can be precipitated by topical drug application. For example, when applied to diseased or abraded skin, bacitracin ointment can induce an immediate-type (type I) hypersensitivity reaction in susceptible individuals. Such reactions might be represented by a local and then subsequently generalized pruritus leading to cardiopulmonary arrest.[12] Nonimmunologic acute toxicity results from substances such as pesticides and chemical warfare agents that rapidly diffuse through the skin and reach target organs.

MALIGNANCIES. Systemic calcineurin inhibitors have been associated with increased risk of lymphoma and nonmelanoma skin cancer. But the topical use of such drugs does not appear to be related

to cancer.[23,24] In fact, the risk for lymphoma with the use of topical calcineurin inhibitors was assessed in animal studies that demonstrated an increased risk only when blood levels were 30 times higher than those measured after topical application in human subjects.[24] Numerous studies have demonstrated the efficacy and safety of topical calcineurin inhibitors. More than 50 cases of lymphoma have been reported, although the topical calcineurin inhibitor use may be coincidental. Nevertheless, there is a clear need for additional follow-up information to establish the long-term safety profile of this class of drugs. Two long-term trials currently being conducted might help address these concerns.[24]

ENDOCRINE SYSTEM. Topical corticosteroids can rarely cause hypothalamic–pituitary–adrenal axis suppression, growth retardation, hyperglycemia, iatrogenic Cushing syndrome and femoral head osteonecrosis.[5] Factors that enhance drug absorption are directly related to an increase in these side effects; therefore, carefully monitoring must be ensured when prescribing usage in large surfaces areas, prolonged use of potent corticosteroids, usage under occlusion, high potency corticosteroids, or use for the pediatric age group (due to their increased surface to body mass ratio).

Transdermal drug delivery, in contrast to topical drug delivery, uses topical application of therapeutic drug as a delivery system for systemic therapy. Transdermal patches have been approved by the US Food and Drug Administration since 1981 (scopolamine being the first) for the delivery of 13 different medications, with more seeking approval. The most commonly used patches are for nitroglycerin and fentanyl. Advantages of this approach include controlled release, a steady blood-level profile with zero-order kinetics, lack of a plasma peak, and, in some cases, improved patient compliance. These patches remain on the skin for 12 hours to 1 week. A patch consists of a plastic backing, a reservoir of medication, either a rate-controlling membrane or a polymer matrix system for controlled diffusion, followed by an adhesive facing the skin. The most common adhesives used are acrylates, silicones, and polyisobutylenes. These patches have been tested and are approved for use on the thighs, buttocks, lower abdomen, upper arms, and chest; application to other sites can lead to either sub- or supratherapeutic blood levels. Adverse effects of patches include local irritation and allergic contact dermatitis to either an adhesive or to the drug itself and may necessitate discontinuation. Topical therapies are a mainstay of treatment for the dermatologist. An understanding of the interactions between a drug's concentration, penetration, availability, and treatment of diseased skin allows physicians to maximize both efficacy and tolerability of topical therapy. An understanding of local and systemic toxicities allows selection of appropriate, safe therapy for patients and minimizes unwanted effects. Appropriate selection of topical agents and patient education on proper use can optimize therapeutic outcomes.

Chapter 215 :: Pharmacokinetics and Topical Applications of Drugs

:: Hans Schaefer, Thomas E. Redelmeier, Gerhard J. Nohynek, & Jürgen Lademann

PHARMACOKINETICS AT A GLANCE

- Compounds applied topically to the skin surface migrate along concentration gradients.
- The drug or its formulation may affect the skin barrier, resulting in time-dependent changes of the barrier function.
- There are significant regional variations in the barrier properties of the skin.
- Formulations differ in their physicochemical properties—this influences the kinetics of release and/or absorption and the onset, duration, and extent of a biologic response.
- The primary compartment that limits the percutaneous absorption of compounds is the stratum corneum.
- Diffusion within the viable tissue, as well as metabolism and resorption, also influence the bioavailability of compounds in specific skin compartments.
- Metabolic activity is a primary consideration in the design of prodrugs and may influence the bioavailability of drugs delivered via dermatologic or transdermal formulations.

Pharmacokinetics related to topical applications of drugs describes the time-dependent drug concentration following the application of the drug to the skin surface, its subsequent passage through the skin barrier into the underlying skin layers, and its distribution into the systemic circulation. The subject continues to hold the attention of research scientists and clinicians alike because of its relevance to dermatologic therapy and the possibility of topical application of current systemic medication that cannot be administered orally, such as peptides or proteins. However, this is an inherently complex subject, despite the advent of new insights into the principal factors that govern diffusion of a drug into and across the skin.

The major difficulty in developing an accurate description of the percutaneous absorption of a drug is related to the size of the compartments. A topical application of a cream or ointment is generally spread to a thickness of not greater than 10 µm. The thickness of the stratum corneum is also approximately 10 µm, whereas the viable epidermis, dermis, and, to a greater extent, the systemic compartment, represent a large sink in which absorbed drugs undergo dilution to levels that often remain undetectable to all but the most sensitive techniques. The determination of the time-dependent changes in the concentration of a drug in individual compartments is technically challenging. After topical application of a drug formulation, several parameters can affect this process (Box 215-1).

DIFFUSION

LAWS OF DIFFUSION

Compounds applied topically to the skin surface migrate along concentration gradients according to well-described laws governing diffusion of solutes in solutions and/or their diffusion across membranes. For a detailed discussion of relevant equations, readers are referred to several comprehensive reviews.[1–4]

FICK'S LAWS

Diffusion of uncharged compounds across a membrane or any homogeneous barrier is described by Fick's first and second laws. The first law

$$J = -D\,(\Delta C/\Delta \delta)$$

BOX 215-1 PARAMETERS THAT AFFECT DRUG AMOUNTS IN SKIN COMPARTMENTS

- Formulations may undergo drastic changes in composition and structure.
- Drug or formulation may affect the skin barrier, resulting in time-dependent changes of the barrier function.
- Skin barrier may be affected by the type and progression of a disease.
- Regional variations in the barrier properties of the skin.
- Skin may respond to topical drug, enhancing or retarding percutaneous absorption.
- Metabolic capacity of skin may lead to exposure of skin or systemically to both parent drug and pharmacologically active metabolite(s).

states that the steady-state flux of a compound (J = moles/cm/s) per unit path length (δ, cm) is proportional to the concentration gradient (ΔC) and the diffusion coefficient (D, cm^2/s). The negative sign indicates that the net flux is in the direction of the lower concentration. This equation applies to diffusion-mediated processes in isotropic solutions under steady-state conditions. Fick's second law predicts the flux of compounds under nonsteady-state conditions. Diffusion is an effective transport mechanism over very short distances, but not over long ones. The relationship between the time (Δt) it takes for a molecule to migrate along a path length (x) and its diffusion coefficient is governed by the equation:

$$\Delta t = x^2/2D.$$

For example, the diffusion coefficient for water in an aqueous solution is: 2.5×10^{-5} cm^2/s, suggesting that a water molecule would migrate over a 10-μm path (the equivalent of the width of the stratum corneum) in 0.4 ms. However, because diffusion depends upon the square of the distance, longer distances are not efficiently covered; a 100-μm path would take 40 ms.

THREE-COMPARTMENT MODEL

Although pharmacokinetic analysis of topical preparations may require the description of a relatively large number of compartments, this discussion is confined to the three outlined in Figure 215-1: (1) the skin surface, (2) the stratum corneum, and (3) the viable tissue. The formulation itself forms a reservoir, from which the compound must be released; in order to undergo percutaneous absorption, the compound then must penetrate the stratum corneum, diffuse into and through

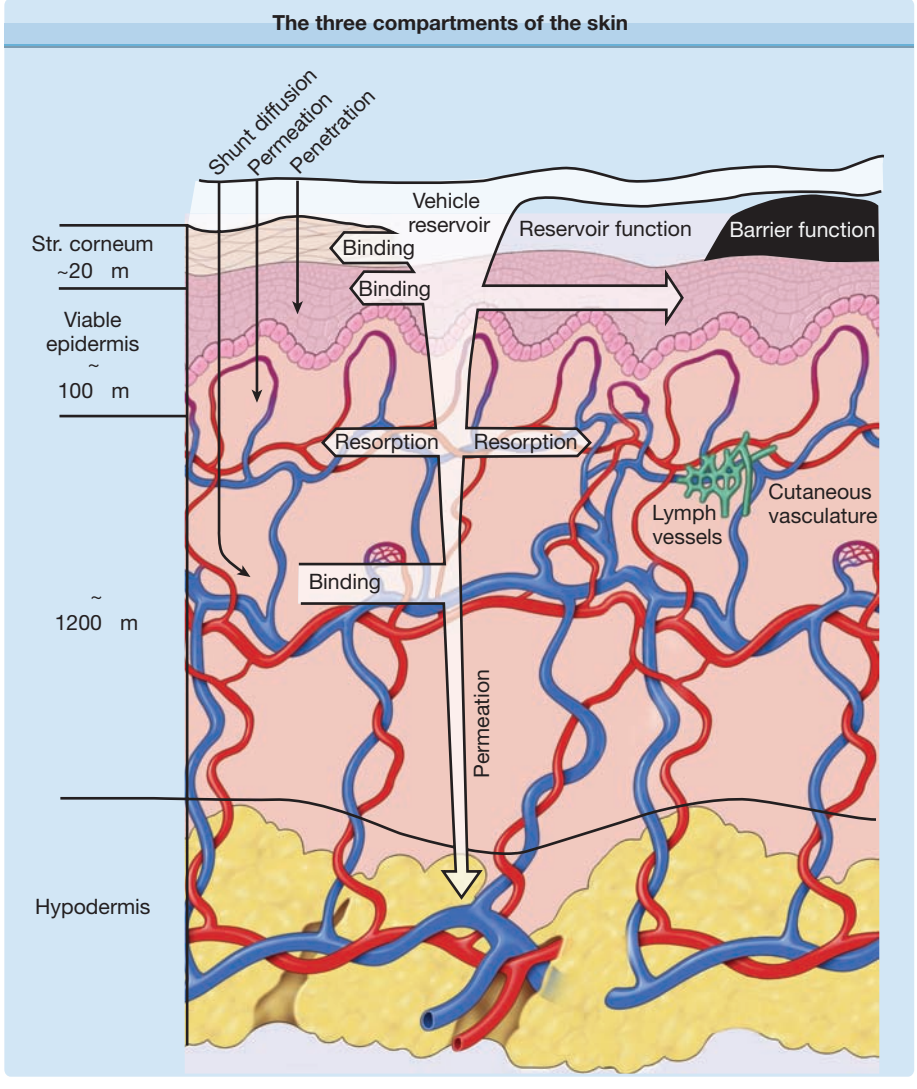

Figure 215-1 Diagrammatic representation of three compartments of the skin: surface, stratum (Str.) corneum, and viable tissues. After surface applications, evaporation and structural/compositional alterations in the applied formulation may play an important role in determining the bioavailability of drugs. The stratum corneum, the outermost layer, plays the most significant role in determining the diffusion of compounds into the body. After absorption, compounds may bind or diffuse within the viable tissues, or become resorbed by the cutaneous vasculature.

TABLE 215-1
Compartments Encountered by Substances Undergoing Percutaneous Absorption: General Relevance of Processes to Bioavailability

Compartment	Processes	General Relevance to Bioavailability
Vehicle	Diffusion	++
	Thermodynamic activity	++
	Evaporation	+
	Precipitation	±
Stratum corneum	Reservoir function	+++
	Diffusion	+++
	Binding	+
	Metabolism	–
Epidermis	Diffusion	±
Cutaneous vasculature	Metabolism	±
	Binding	++
	Resorption	+
Underlying tissues including dermis	Diffusion	±
	Metabolism	±
	Binding	–

– = although theoretically possible, this process is probably not of general relevance; ± = this process is of direct relevance, but only in a restricted number of cases; + = the process is in general relevant, but not as important as ++ or +++.

the viable epidermis into the dermis, and, finally, gain access to the systemic compartment through the vascular system. In addition, the substance may diffuse through the dermal and hypodermal layers to reach underlying tissues. As summarized in Table 215-1, within each compartment, the compound may diffuse down along its concentration gradient, bind to specific components, or be metabolized. The size or characteristics of each compartment may alter with time, and the factors determining diffusion within each compartment may be affected by disease state as well as the nature or the pharmacologic/biologic activity of the drug or its excipients.

THE SKIN SURFACE

SURFACE APPLICATIONS OF FORMULATIONS. Formulations differ in their physicochemical properties, and, as discussed in Section "Formulations," this influences the kinetics of release and/or absorption. However, the principal consideration is that topically applied drug products represent a physically small compartment, which limits the amount of compound that can be applied to the skin surface. When a patient applies a dermatologic preparation, the layer of a formulation covering the skin is very thin (approximately 0.5–2.0 mg/cm^2). Thicker layers are felt as "unpleasant" and are consciously or subconsciously rubbed off or spread to larger surfaces. This restricts the amount of an active compound that can effectively come in contact with the skin surface to approximately 5–20 µg/cm^2 for a 1% (wt/wt) topical formulation.

However, even after being rubbed in, formulations do not remain homogeneous over the time course of penetration. For example, topical applications containing water, alcohol, or similar solvents undergo rapid evaporation.[5] This phenomenon is readily recognized by patients as a cooling sensation. The evaporation results in rapidly increasing concentrations of nonvolatile substances on the skin surface, which may result in the formation of supersaturated "solutions" or, alternatively, precipitation of active ingredients. Formulations may also mix with skin-surface lipids or undergo time-dependent changes in their composition as excipients and drugs undergo absorption. Altogether, these considerations suggest that dramatic changes in the composition and structure of formulations may occur following surface application, all of which may determine the subsequent bioavailability of active ingredients.

RESERVOIR. The reservoir function was first described by Vickers,[6] who observed that simple occlusion leads to the renewed onset of a glucocorticoid-mediated vasoconstriction several hours after it had declined. He interpreted this effect as renewed liberation of the glucocorticoid from a "reservoir" stored in the upper skin layers.

We define as *reservoir* the amount of an active ingredient that is still in contact with the nonvolatile constituents of its formulation after the latter had been massaged into the skin surface. The compound has not yet penetrated, but it cannot be removed by simple rubbing or contact with clothing or other tissues.

The reservoir thus adheres to the skin surface and resides in the wrinkles and the upper layers of the stratum corneum. Reservoirs on eczematous skin may become even more prominent because of the scaliness of the skin. Recently, we discovered that the upper volume of the follicular channels serves also as a reservoir, which may result in a relative increase in absorption through appendages. In-vivo laser scanning microscopy measurements found that the hair follicles represent an efficient reservoir for topically applied formulations, which can be compared with the reservoir of the stratum corneum on several body sites.[7,8] This phenomenon may be increased in formulations that contain particles or precipitates, given the evidence that appropriately sized particles can rapidly penetrate along the shafts of hair follicles to a depth of up to 100–500 µm.[9–12]

The optimum size of the particles for penetration into hair follicles is between 300 and 600 nm, which corresponds to the cuticular structure of the hairs.[13,14] It was assumed that the rigid hair shaft acts as a geared pump, because this effect could only be observed in the case of moving hairs.[14] The follicular reservoir may result in a relative increase in the absorption of topically applied substances. No evidence has been found that topically applied substances penetrate efficiently into the sweat glands. This may be due to sweat outflow or other, unknown reasons.

FORMULATIONS. Formulations can be differentiated on the basis of whether they are designed to remain on the skin surface (sunscreen products and cosmetics), to be delivered to compartments in the skin (topical formulations), or to migrate across the skin into the central compartment (transdermal formulations).

Formulations may affect the kinetics and the degree of percutaneous absorption and, subsequently, the onset, duration, and extent of a biologic response. In the context of percutaneous absorption, there are several different parameters that should be considered when selecting a formulation[1,15]: the thermodynamic activity of the active ingredient[16]; the amount of compound that can be incorporated into the formulation[17]; the stability of the formulation on the skin surface (e.g., emulsions may break easily)[18]; the partition coefficient of the active ingredient between the vehicle and the stratum corneum[19]; and the enhancer activity.

In general, percutaneous absorption is proportional to the thermodynamic activity of the compound. Thus, the greatest flux is observed at the active ingredient's maximum solubility in a vehicle. Vehicles that are very good solvents should be avoided because they may retain the active ingredient on the skin surface.

LIPOSOMES AS TRANSDERMAL DELIVERY SYSTEMS. Liposomes are microscopic spheres comprising a bilayer that encloses an inner aqueous core. A wide variety of cosmetics contain liposomes. Liposome-based formulations have proved to be safe, cosmetically attractive, and well accepted. There is considerable evidence that, at least for some preparations, application of liposomes is mildly occlusive and improves the hydration level of the stratum corneum. Interest in the use of liposomes to enhance the delivery of drugs across the skin has been spurred by several observations in animal models: liposome formulations were believed to enhance the penetration of compounds across the skin or to optimize the retention of bioactive compounds in target tissues.[20] However, these early studies, which relied largely on animal models, were followed by relatively few in-vivo studies for humans[17] conducted under standard conditions.

The action mechanism of liposomes is based on a partly damaged liquid layer of the stratum corneum, so that the liposomes can penetrate efficiently into the skin barrier. Deep in the stratum corneum, the liposomes get damaged and release their drug, which has to pass through the last cell layers of the stratum corneum by itself to reach the living cells.[21]

There is no clear evidence that liposomes can pass the skin barrier as intact structures, but intact liposomes can penetrate along the hair shaft and this route may be appropriate for delivery of bioactive compounds into sebaceous glands or hair follicles.[7,8] Rigid liposomes penetrate better into the hair follicles than flexible liposomes, which supports the assumption that the moving hairs act as a geared pump.[21]

THE SKIN BARRIER

(See Chapter 47.)

The primary compartment that limits the percutaneous absorption of compounds is the stratum corneum. This thin (10–20 µm) layer effectively surrounds the body and represents a highly differentiated structure that determines the diffusion of compounds across the skin. The physical description of the stratum corneum is well documented,[22] and it can be accurately described as "bricks" of bundled, water-insoluble proteins, embedded in a "mortar" of intercellular lipid.

The stratum corneum is a highly organized, differentiated structure. To participate fully in forming an effective barrier to diffusion, the biogenesis of the corneocytes as well as the synthesis and processing of the intercellular lipid must proceed in an orderly manner. Disruption in the kinetics of skin barrier formation by accelerating the division of the keratinocytes in the underlying layers will lead to a disruption in the barrier properties of the skin.[23] Thus, the concept of dead or dying skin forming a passive barrier to diffusion is now replaced by a model of the stratum corneum as a highly differentiated structure with unique properties that are particularly suited for its role in forming the skin barrier (see Chapter 47).[24]

APPENDAGES. A variety of appendages penetrate the stratum corneum and epidermis, facilitating thermal control and providing a protective covering. Appendages are potential sites of discontinuity in the integrity of the skin barrier. The density of the hair follicles varies on different body sites. Hair follicles represent a reservoir that may store topically applied substances. A detailed analysis of the reservoir of the hair follicles showed that the highest reservoir is

on the scalp, followed by the forehead and the calf.[25] On the forehead, there are a high number of small follicles, while the calf contains fewer but larger hair follicles. These reservoirs are comparable to the reservoir of the stratum corneum on these body sites. The percentage of the hair follicles on the total skin surface varies between 0.2% and 1.3%, depending on the body site.[25] Differences in the follicular penetration were observed in different ethnic groups.[26] Hair follicles appear to present an important pathway for percutaneous absorption in nondiseased skin.[11,12] This can be explained by the fact that only the upper wall of the follicular apparatus (the acroinfundibulum) is protected by a coherent stratum corneum, whereas in the lower part (infrainfundibulum), the corneocytes appear undifferentiated, and protection is incomplete, if not absent. Even solid particles may enter deep into the follicular orifice,[9,10,22] a phenomenon that lends itself to the concept of follicular targeting of drugs.[22]

It follows that in relationship to the integral protection against the passage of xenobiotics in general, and drugs specifically, the barrier function of the interfollicular stratum corneum is even more potent than previously believed, whereas more research is needed relative to the follicular pathway. Recent investigations hint to the presence of active follicles (open to penetration) and passive ones.[11]

PENETRATION PATHWAYS. In principle, three penetration pathways are possible: (1) the intercellular penetration, inside the lipid layers around the corneocytes; (2) the follicular penetration; and (3) the intracellular penetration. Although in the past, the transcorneal penetration was assumed to be the only penetration pathway, recent investigations, as cited above in Appendages, have demonstrated that penetration via the hair follicles should be taken into consideration.[25–27]

Up to the present time, no evidence is available that topically applied substances pass the skin barriers by means of the intracellular route.

Pathways across the Stratum Corneum. Several studies have directly visualized penetration pathways across the stratum corneum by electron microscopy. For example, osmium vapor can be used to precipitate *n*-butanol that has penetrated the stratum corneum.[28] After a brief (5–60 s) exposure of murine or human stratum corneum, the alcohol was found to be enriched in the intercellular spaces (threefold), although significant levels were also found in the corneocytes. By using a different approach that involved rapid freezing, water, ethanol, and cholesterol were also found preferentially concentrated in the intercellular lipid spaces.[29] Similarly, the penetration of mercury chloride through the intercellular lipid can be detected following precipitation with ammonium sulfide vapor.[30]

However, in most of these investigations, there was also significant localization of compounds in the corneocytes, more prevalent in the upper layers (stratum disjunctum). Thus, corneocytes undergoing desquamation appear to be relatively permeable, even to rather bulky ions such as mercury. There is additional evidence that other compounds can and do penetrate corneocytes. It is well established, for example, that occlusion or immersion of skin in a bath leads to swelling of the corneocytes, consistent with the entry of water. Other compounds have also been localized in corneocytes, such as the anionic surfactants that are bound to keratins. Low-molecular-weight moisturizers such as glycerol are likely to partition into the corneocytes and alter their water-binding capacity. Thus, the penetration of compounds into corneocytes cannot be excluded from considerations of percutaneous absorption pathways. The relevance of this step relates to whether it is rate determining, i.e., whether the diffusion of compounds within the intercellular lipid is restricted by the corneocytes.

Pathways across the Hair Follicles. Using the method of differential stripping—a combination of tape stripping with cyanoacrylate surface biopsies—the amount of formulation stored in the hair follicles can be quantified.[31] It was found that nanoparticles were stored 10 times longer in the hair follicles than in the stratum corneum.[14] It should be noted that when topically applied substances penetrate into the hair follicles, they do not necessarily penetrate through the skin barrier into the living tissue, because the hair follicles also have barrier properties.

On the other hand, the particles can be used as efficient carrier systems for drug delivery into the hair follicles. The hair follicles represent an important target structure because they are surrounded by a close network of blood capillaries. Additionally, they are hosting the stem and dendritic cells which are important for regenerative medicine and monomodulation.

For optimal action, the drug should be released from the particles after having penetrated deep into the hair follicles. The pharmacokinetics is determined mainly by the process of the drug release from the particles in this case.[61]

In the past, there have been several attempts to detect follicular penetration.[32–34] Experiments were performed on animal and human skin, with different densities of the hair follicles. Unfortunately, in all cases, the properties of the stratum corneum had also changed.

The analysis of the follicular penetration became possible after the development of a method that artificially closes the hair follicles in vivo.[35] Using this method, it was demonstrated that the small molecules, such as caffeine, may penetrate through the skin barrier not only by the transcorneal, but also by the follicular routes.[36]

INTER- AND INTRAINDIVIDUAL VARIATION IN SKIN BARRIER FUNCTION. Finally, it is worthwhile to consider the level of inter- and intraindividual variation in skin barrier activity, including that of follicles. The most accurate and reproducible measurement of skin barrier activity is transepidermal water loss.[37] The extent of variation of this parameter for the same individual is estimated to be 8% by site and 21% according to the day of measurement. The variations

between individuals are reported to be somewhat larger, ranging from 35%–48%.[38] There appear to be no significant gender- or ethnic-dependent differences in skin barrier activity. The skin barrier activity of premature babies[39] is markedly impaired, although skin barrier function appears normal for full-term infants. There seems to be no significant alteration in skin barrier activity as a function of age. Differences in skin barrier activity among different sites have been observed; barrier function can be ranked as arm ~ abdomen > postauricular > forehead.[37]

VIABLE TISSUE

Although the primary barrier to percutaneous absorption lies within the stratum corneum, diffusion within the viable tissue, as well as metabolism and resorption, also influence the bioavailability of compounds in specific skin compartments. These processes are interrelated, and factors that increase the rate of one of these processes inevitably influence the others. Because the development of dermatologic formulations is often focused on "targeted" delivery to living tissues, the manipulation of these processes offers a clear-cut rationale for increasing the therapeutic efficacy of dermatologic drugs.

The passage of compounds from the stratum corneum into the viable epidermis results in a substantial dilution. This is not only the relatively larger volume of the epidermis as compared with that of the stratum corneum, but also the lower resistance to diffusion within viable tissues, approximately corresponding to that of an aqueous protein gel.[38] Drug concentrations of 10^{-4}–10^{-6} M may be attained in the epidermis and dermis for substances that permeate readily. Although the actual concentration gradient of a compound is affected both by the physicochemical properties of the compounds as well as by the duration of application, a concentration gradient is present at all times. In other words, strategies to enhance percutaneous absorption generally result in a relatively uniform and parallel increase in the concentration of compounds in all compartments.

SKIN METABOLISM

The skin contains a wide range of enzymatic activities, including phase I oxidative, reductive, hydrolytic, and phase II conjugation reactions, as well as a full complement of drug-metabolizing enzymes.[40,62] Metabolic activity is a primary consideration in the design of prodrugs and may influence the bioavailability of drugs delivered via dermatologic or transdermal formulations. Alterations in skin metabolism have been implicated in a range of diseases, including hirsutism and acne, and they may be relevant to the risk of topical exposure to carcinogens. Metabolic processing of antigens by Langerhans cells is involved in the presentation of allergens to the immune system. Thus, metabolism in skin compartments plays a significant role in determining the fate of a topically applied active compound.

Significant cutaneous metabolism has been demonstrated for a wide variety of compounds of differing physicochemical properties, including the steroid hormones estrone, estradiol, and estriol, as well as glucocorticoids, prostaglandins, retinoids, benzoyl peroxide, aldrin, anthralin, 5-fluorouracil, nitroglycerin, theophylline, and propranolol.[27] Recently, it has been shown that arylamine-type hair dye ingredients are also subject to metabolism in human and animal skin, resulting in *N*-acetylated metabolites.[41–43] The enzyme responsible is believed to be epidermal *N*-acetyltransferase-1.[41] For example, cutaneous metabolism reduces the systemic bioavailability of nitroglycerin administered in a transdermal drug formulation in rhesus monkeys by 16%–21% and hydrolyzes virtually 100% of a salicylate diester.[44] It is convenient to classify metabolic reactions in terms of their cofactor dependence.[63] Processes that require cofactors are likely to be energy dependent, and these are located within viable tissues. Among the best-studied examples are the interconversion of steroids (e.g., estrone and estradiol), and the oxidation of polycyclic aromatic hydrocarbons with mixed-function mono-oxygenases. In contrast, cofactor-independent processes involve catabolism and may be located outside of viable tissues, i.e., in the transition region between the stratum corneum and stratum granulosum. The best characterized of these involve hydrolytic reactions such as nonspecific ester hydrolysis.

Metabolic activity is found in (1) skin-surface microorganisms, (2) appendages, (3) the stratum corneum, (4) the viable epidermis, and (5) the dermis. In considering the site of the most significant metabolism, one has to take into account the relevant enzymes and their specific activity, as well as their capacity relative to the size of the compartment. Thus, although the level of many enzymes is highest in the epidermis, the relatively large size of the dermal compartment may result in a significant role in the metabolism of topically applied substances. A further consideration is that enzymes involved in cutaneous metabolism may be induced upon exposure to xenobiotics. This has been well described for various mixed-function monooxygenases.[45] Finally, the qualitative and quantitative extrapolation of results from animal models to humans is uncertain, owing to the significant species differences in the metabolism of compounds.

Percutaneous absorption and metabolism of compounds can be viewed as two events in kinetic competition with each other.[46] Generally, compounds that remain in the skin for longer periods of time undergo significantly more metabolism. Furthermore, the type of metabolism of a substance may also be influenced by the nature of its formulation, as illustrated by investigations on the metabolism of several transdermal nitroglycerin formulations.[47] The inclusion of enhancers in the formulation not only increased the bioavailability of the nitroglycerin but also the ratio of one metabolic compound (1,2-glyceryl dinitrate) in relation to another (1,3-glyceryl dinitrate). This may limit the suitability of in-vitro experiments for estimating the significance of cutaneous metabolism because the vasculature is not functional in vitro. It further emphasizes that it is difficult to extrapolate quantitatively the

level of metabolism obtained for different formulations. This has significant implications for the estimation of bioequivalence.

However, despite the variety of skin-associated metabolic processes, the extent of metabolism is normally modest, i.e., 2%–5% of the absorbed compounds, although for *N*-acetylation of arylamines, metabolism may be quantitative.[43] Metabolism is limited not only by the relatively short period of time that a compound spends in the viable layers of the skin, but also by the overall low level of enzyme activity. Thus, under many circumstances, the available enzymes are saturated by the level of compound undergoing percutaneous absorption.[40]

RESORPTION

Resorption, defined as the uptake of compounds by the cutaneous microvasculature, is directly related to the surface area of the exchanging capillaries as well as their blood flow. Total blood flow to the skin may vary up to 100-fold, a process primarily regulated by vascular shunts, but also by recruitment of new capillary beds. It is estimated that, under resting conditions, only 40% of the blood flow passes via exchanging capillaries capable of acting as a sink for absorbed compounds. However, this value demonstrates considerable variation between body sites, individuals, and species and is influenced by disease states and environmental conditions. In particular, changes in temperature and humidity as well as the presence of vasoactive compounds may directly influence skin blood flow.[48]

For most compounds and situations, resorption does not limit the delivery of compounds to the central compartment after topical applications. This is a result of the relatively high resistance to diffusion within the stratum corneum as compared with uptake by the vasculature. However, for compounds or situations in which diffusion across the stratum corneum is rapid, resorption limits the maximum rate of absorption.[48] The evidence that resorption can limit the delivery of compounds to the central compartment comes primarily from studies that examined the influence of blood flow on this process. The percutaneous absorption of methyl salicylate is increased by elevated ambient temperature or strenuous exercise, an observation consistent with increased resorption as a result of cutaneous blood flow.[49] Moreover, intravenously administered nicotine (a vasoconstrictor) reduces the percutaneous absorption of topically applied nicotine.[50] Regional differences in the percutaneous absorption of piroxicam, a nonsteroidal anti-inflammatory agent, are dependent upon the local vasculature rather than upon skin barrier function.[51] Perhaps the most convincing evidence that resorption can limit delivery to the vasculature comes from in-vitro studies on the perfused porcine skin flap.[52]

An additional consideration is that the rate of resorption may indirectly influence the diffusion of compounds to the underlying musculature, tissues, and joints.[53] The principle of locally enhanced delivery to underlying musculature has been demonstrated for piroxicam as well as several local anesthetic preparations.[54]

INFLUENCE OF PATHOLOGIC PROCESSES ON SKIN BARRIER FUNCTION

Reduced skin barrier function has been observed in a number of pathologic conditions, including the ichthyoses,[55,56] psoriasis,[22,57] atopic dermatitis,[58] and contact dermatitis.[59] It is generally accepted that this is attributable to structural alterations in the stratum corneum.[22] These structural deficiencies may arise from an absence of an enzyme or structural protein in the underlying viable tissues or may be related to the improper formation of the stratum corneum resulting from an increase in keratinocyte proliferation.[64] Thus, in individuals predisposed to a defective barrier, a minor perturbation may become amplified as the skin "attempts to compensate" by increasing keratinocyte proliferation.[60] A further consideration is that the homeostatic mechanisms responsible for recovery of barrier activity after perturbation may be altered in some diseases or physiologic states.

For example, whereas the skin of aged people exhibits normal barrier function, the recovery of barrier activity after perturbation is markedly reduced.[55,56] This kinetic basis for reduced barrier function may also account for interindividual variation in barrier function and/or the apparently increased susceptibility of certain individuals to contact dermatitis.[59]

Chapter 216 :: Topical Corticosteroids

:: Isabel C. Valencia & Francisco A. Kerdel

TOPICAL CORTICOSTEROIDS AT A GLANCE

- Most frequently prescribed of all dermatologic drug products.
- Are effective at reducing the symptoms of inflammation, but do not address the underlying cause of the disease.
- Topical glucocorticoid research has focused on strategies to optimize potency while minimizing side effects.
- The new molecules have an overall higher anti-inflammatory effect, good compliance (only once daily application), rarely induce cross-sensitivity reactions and have weak atrophogenic properties.

MECHANISM OF ACTION

Corticosteroids have specific and nonspecific effects that are related to different mechanisms of action, including anti-inflammatory, immunosuppressive, antiproliferative, and vasoconstrictive effects. Most of their actions are mediated by an intracellular receptor called the glucocorticoid receptor. The glucocorticoid receptor α-isoform is located in the cytosol, binds glucocorticoids, and translocates to a region of the nuclear DNA known as the corticosteroid responsive element, where it is then able to stimulate or inhibit transcription of the adjacent genes, thus regulating the inflammatory process.[1] The glucocorticoid receptor β-isoform does not bind glucocorticoids, but is able to bind the antiglucocorticoid/antiprogestin compound RU-486 to regulate gene expression.[2] The glucocorticoid receptor β can attenuate the ligand-mediated transactivation of hormone-sensitive genes by the α-isoform and may be an important marker of steroid insensitivity.[3]

ANTI-INFLAMMATORY EFFECTS

Corticosteroids are thought to exert their potent anti-inflammatory effects by inhibiting the release of phospholipase A_2, an enzyme responsible for the formation of prostaglandins, leukotrienes, and other derivatives of the arachidonic acid pathway. Corticosteroids also inhibit transcription factors, such as activator protein 1 and nuclear factor κβ, which are involved in the activation of proinflammatory genes. Genes known to be upregulated by corticosteroids and that play a role in the resolution of inflammation include lipocortin and p11/calpactin-binding proteins, both involved in the release of arachidonic acid.[1,4,5] Lipocortin I inhibits phospholipase A_2, reducing the release of arachidonic acid from phospholipids.[1,6,7] Corticosteroids also decrease the release of interleukin-1α (IL-1α), an important proinflammatory cytokine, from keratinocytes.[1,8] Other proposed mechanisms for the anti-inflammatory effects of corticosteroids include inhibition of phagocytosis and stabilization of lysosomal membranes of phagocytizing cells.[9]

IMMUNOSUPPRESSIVE EFFECTS

The effectiveness of corticosteroids is, in part, also due to their immunosuppressive properties. Corticosteroids suppress the production and effects of humoral factors involved in the inflammatory response, inhibit leukocyte migration to sites of inflammation, and interfere with the function of endothelial cells, granulocytes, mast cells, and fibroblasts.[1,10–12] Several studies have shown that corticosteroids can cause mast cell depletion in the skin.[13] Experiments have also shown that topical corticosteroids cause local inhibition of chemotaxis of neutrophils in vitro, and decrease the number of Ia+ Langerhans cells in vivo.[14,15] Corticosteroids reduce eosinophilia in patients with asthma. They also reduce T-cell proliferation and induce T-cell apoptosis, in part from inhibition of the T-cell growth factor IL-2.[1,16] In addition, several cytokines are directly affected by corticosteroids, including IL-1, tumor necrosis factor-α, granulocyte-macrophage colony-stimulating factor, and IL-8. These effects may also be a result of the steroid action on antigen presenting cells.[17]

ANTIPROLIFERATIVE EFFECTS

The antiproliferative effect of topical corticosteroids is mediated by inhibition of DNA synthesis and mitosis, partly explaining the therapeutic action of these drugs in scaling dermatoses.[18] They are known to reduce the keratinocyte size and proliferation. Fibroblast activity and collagen formation are also inhibited by topical corticosteroids.[19]

VASOCONSTRICTION

The mechanism by which corticosteroids induce vasoconstriction is not yet completely clear. It is thought to be related to inhibition of natural vasodilators such as histamine, bradykinins, and prostaglandins.[1,20,21] Topical steroids cause capillaries in the superficial dermis to constrict, thus reducing erythema. The ability of a given corticosteroid agent to cause vasoconstriction usually correlates with its anti-inflammatory potency, and thus, vasoconstriction assays are often used to

predict the clinical activity of an agent. These assays, in combination with double-blind clinical trials, have been used to separate the topical corticosteroids into seven classes based on potency. Class 1 includes the most potent, while class 7 contains the least potent. eTable 216-0.1 in online edition lists many of the available topical corticosteroids according to this classification. Notice that the same drug can be found in different potency classifications depending on the delivery vehicle used.

PHARMACOKINETICS

Corticosteroids have a basic skeletal structure comprising 17 carbon atoms arranged in three six-membered rings and one five-membered ring. Modifications of cortisol (Fig. 216-1), by addition or alteration of functional groups at certain positions, have led to compounds with variable anti-inflammatory potency, glucocorticosteroid versus mineralocorticoid activity, and adverse effects.[22]

Topical corticosteroid research has focused on strategies to optimize potency while minimizing side effects. One strategy is to develop compounds with enhanced anti-inflammatory effects and minimal unwanted atrophogenic and adrenal suppressive effects. In this sense, progress has been made with the development of glucocorticoid molecules that, while retaining high activity in the skin following topical application, are quickly broken down into inactive metabolites, thereby mitigating systemic and possibly some local toxic effects ("soft" glucocorticoids). Some of these compounds include the diesters 17,21-hydrocortisone aceponate and hydrocortisone 17-butyrate-21-propionate, prednicarbate, mometasone furoate, methylprednisolone aceponate, alclometasone dipropionate, and carbothioates such as fluticasone propionate.[1,23] This last agent is classified as a potent corticosteroid with lower potential to cause skin atrophy and adrenal suppression due to its high lipophilicity, high glucocorticoid receptor binding and activation and rapid metabolism in the skin.[24] It offers the advantage of once daily application and infrequent local allergic reactions. Mometasone furoate also has highly anti-inflammatory effects with low incidence of adrenal suppression.[1] Hydrocortisone aceponate, prednicarbate, and methylprednisolone aceponate have significant anti-inflammatory effects, but the least capacity to induce skin atrophy; therefore, they can be used to treat areas such as the face, the scrotum, and large body surface areas in children, with minimal adverse effects.[1,25]

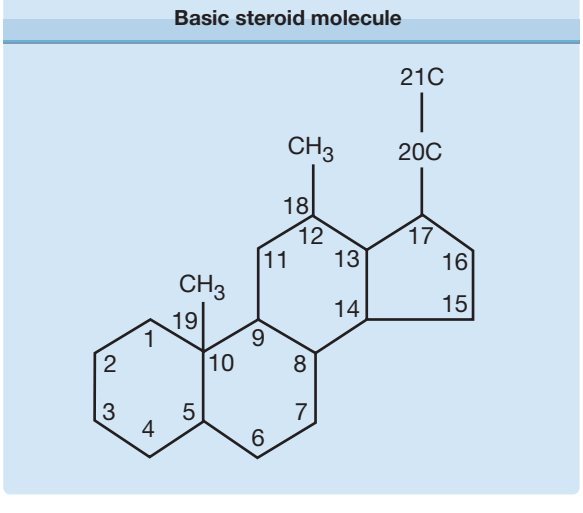

Figure 216-1 Basic steroid molecule.

Before choosing a topical glucocorticoid preparation, one must consider the patient-related and drug-related factors that can affect its systemic absorption. The age of the patient, the extent and location of the body surface area to be treated and the presence or absence of skin inflammation, greatly affect the activity of the topical agent. Penetration of the glucocorticoid varies according to the skin site, which, in turn, is related to the thickness of the stratum corneum and the vascular supply to the area. For example, penetration of topical steroids through the eyelids and scrotum is four times greater than for the forehead and 36 times greater than for the palms and soles. Inflamed, moist, and denuded skin also shows increased penetration. Areas of the body where the skin is inherently thin not only allow for increased penetration of the drug but also are more susceptible to develop side effects than other areas where the skin is thick. Potent topical steroids (classes 1 and 2) should rarely, if ever, be used in the areas with the highest level of penetration, such as the eyelids. The concentration of the therapeutic agent used, the duration of the application, the use of occlusive dressings, the elected vehicle, and the intrinsic characteristics of the chosen molecule, can also affect the absorption and the degree of adverse effects.[26,27] The target site for topical corticosteroids is the viable epidermis or dermis, and clinical response to a formulation is directly proportional to the concentration of corticosteroid achieved at the target site. A comparison study of skin concentrations after topical versus oral corticosteroid treatment found that most topical corticosteroids have the potential to achieve greater effective drug levels in the superficial layers of the skin than those achieved with standard doses of oral prednisone. Therefore, the apparently greater efficacy of oral corticosteroid therapy may be due in part to poor patient compliance with topical therapy.[28]

Topical corticosteroids are compounded in several formulations and with varying strengths. Recent research has emphasized the importance of treatment adherence in the management of skin conditions. As such, newer formulations including spray, foam, lotion, hydrogel, and shampoo formulations have been developed to improve patient convenience and acceptance, without sacrificing the efficacy, safety and tolerability of the traditional ointment and cream formulations. A recent systematic review of the literature found that while there are few direct comparison studies between clobetasol propionate, a class 1 steroid, in different vehicles, the efficacy rates for more recent formulations is roughly comparable to that of clobetasol ointment in the treatment of psoriasis. The most common adverse effect was mild and transient stinging/burning at the lesion site, which may be due to the

alcohol content found in these formulations.[29] None of the clinical trials directly compared these formulations with one another.[30,31]

Increasing hydration of the stratum corneum can enhance absorption of topical corticosteroids by four to five times. Absorption is also enhanced by ten times with occlusion.[32] A retrospective study of wet dressings used with topical corticosteroids (hydrocortisone 1% cream to the face and folds and triamcinolone 0.1% cream from the neck down) for adults with recalcitrant pruritic dermatoses of different etiologies, alleviated the pruritus in 98% of the patients at dismissal. The enhanced corticosteroid penetration is only one of the numerous benefits of the wet dressings.[33]

INDICATIONS

Topical corticosteroids are recommended for their anti-inflammatory activity in inflammatory skin diseases, but they can also be used for their antimitotic effects and their capacity to decrease the synthesis of connective tissue molecules.[1] Certain variables must be considered when treating skin disorders with topical glucocorticoids. For example, the responsiveness of diseases to topical glucocorticoids varies. In this setting, diseases can be divided into the three categories shown in Table 216-1: (1) highly responsive, (2) moderately responsive, and (3) least responsive.

PEDIATRIC USES

Topical glucocorticoids are highly effective, and few side effects are observed when a low-potency preparation is used for brief periods of time without occlusion in children. However, children and, in particular, infants, are at an increased risk of absorbing topical corticosteroids for several reasons. They have a higher ratio of skin surface area to body weight and application to a given area results in a greater potentially systemic dose of steroid. Infants may also be less able to metabolize potent glucocorticoids rapidly.[34] Premature infants are especially at risk because their skin is thinner and the penetration rate of topically applied drugs is greatly increased.[35] Application of topical steroids to the diaper area results in occlusion of the steroid by the diaper, and increased penetration occurs. Excess absorption of topical glucocorticoids can suppress endogenous cortisol production. Consequently, subsequent cessation of topical steroid therapy after an extended treatment period can, albeit rarely, result in an addisonian crisis. Deaths from addisonian crisis have been reported with the use of topical steroids, and the risk of this occurring is greater in children.[36] Chronic suppression of cortisol production can also lead to growth retardation. A morning plasma cortisol level can be performed to screen for adrenal suppression, although ACTH stimulation testing with cosyntropin is more accurate. If suppression is present, the child should be slowly weaned from the steroids to prevent these complications.

Corticosteroids have been used with success for atopic dermatitis for several decades. Placebo-controlled trials have found them effective in 75% or more of patients with atopic dermatitis when compared with fewer than 30% of placebo-treated patients.[37] They are important for managing acute flares. As with other skin conditions, selecting the appropriate strength according to the body site, the extent of involvement and the flare intensity is essential for treatment success.[27] Education of the patients and caregivers is critical to improve adherence to the prescribed medication and optimize compliance. Results from large-scale surveys show that patients/caregivers overestimate the actual risks of topical corticosteroids ("steroid phobias") leading to treatment noncompliance.[38,39] Adequate time should be spent transmitting the important role of intermittent topical corticosteroid therapy, and the beneficial risk-benefit ratio with their appropriate use.[40]

Hemangiomas of infancy show a good or partial response to treatment with ultrapotent topical glucocorticoids in 74% of infants. The majority reported accelerated cessation of growth. Small, superficial hemangiomas, particularly at sites prone to ulceration, disfigurement or both, and small periocular lesions that have not yet caused significant visual impairment

TABLE 216-1
Responsiveness of Dermatoses to Topical Application of Corticosteroids

Highly Responsive	Moderately Responsive	Least Responsive
■ Psoriasis (intertriginous)	■ Psoriasis	■ Palmoplantar psoriasis
■ Atopic dermatitis (children)	■ Atopic dermatitis (adults)	■ Psoriasis of nails
■ Seborrheic dermatitis	■ Nummular eczema	■ Dyshidrotic eczema
■ Intertrigo	■ Primary irritant dermatitis	■ Lupus erythematosus
	■ Papular urticaria	■ Pemphigus
	■ Parapsoriasis	■ Lichen planus
	■ Lichen simplex chronicus	■ Granuloma annulare
		■ Necrobiosis lipoidica diabeticorum
		■ Sarcoidosis
		■ Allergic contact dermatitis, acute phase
		■ Insect bites

are the best candidates for therapy.[41] The mechanism of action by which corticosteroids act in hemangiomas to decrease proliferation is unknown. Intralesional corticosteroid injection of hemangiomas before and after treatment, have revealed an increase in mast cells, reduced transcription in several cytokines and enhanced transcription of *cytochrome b* gene.[42]

GERIATRIC USES

Elderly patients similarly can have thin skin, which allows for increased penetration of topical glucocorticoids. They are also more likely to have preexisting skin atrophy secondary to aging and may be diaper dependent, so the same precautions used in the treatment of infants should be used when treating elderly patients.

USES IN PREGNANCY

Appropriate human studies using topical glucocorticoids in pregnancy have never been undertaken. Studies in animals, however, show that topical steroids are systemically absorbed and may cause fetal abnormalities, especially when used in excessive amounts, under occlusive dressings, for prolonged periods of time, or when the more potent agents are used. Most topical steroids are rated by the US Food and Drug Administration as category C drugs, which imply that caution must be exercised when used in pregnancy. A recent, systematic review of the safety of topical corticosteroids in pregnancy performed by Chi et al, found that the current data is inconclusive and limited and unable to detect an association between topical corticosteroids and congenital abnormalities, preterm delivery, mode of delivery or stillbirth. The current evidence shows no statistically significant effects for pregnant women who use topical corticosteroids compared with unexposed women. However, in a small cohort study of participants from a single maternity center, there appears to be an association of highly potent corticosteroids with low birth weight. Most of the previous studies only assessed the risk for congenital abnormality or orofacial cleft. Further cohort studies with comprehensive outcome measures (including fetal growth, preterm birth, and birth death), consideration of corticosteroid potency, dosage and indications, and a large sample size are required in order to detect a small risk.[43] It is currently unknown whether topical glucocorticoids are excreted in breast milk; however, they should be used with caution in breastfeeding mothers and should never be used on the breasts before breastfeeding.

DOSING REGIMEN

The frequency of topical application of corticosteroids was developed in an empirical manner, with most textbooks and physicians recommending twice-daily use. For superpotent corticosteroids, once-daily application is considered as beneficial as twice-daily application. Likewise, there is at best a slight difference with once versus twice daily application of potent or moderately potent corticosteroids. These observations suggest that once-daily application of topical corticosteroids may be as effective as twice daily, while decreasing the risks of side effects, tachyphylaxis, and cost of therapy, and improving patient compliance.[44] Tachyphylaxis has been demonstrated in experimental conditions by diminished vasoconstriction, rebound of DNA synthesis, and recovery of histamine wheals after application of topical steroids in patients with a history of long-term topical steroid usage.[45]

As a working rule in adults, no more than 45 g/week of potent or 100 g/week of weak or moderately potent topical corticosteroid should be applied (without occlusion) if systemic absorption is to be avoided.[46]

INITIATING THERAPY

Some general principles should be remembered when initiating topical corticosteroids; these are outlined in Box 216-1.[1,47]

MONITORING THERAPY

Application of corticosteroids to large surface areas, occlusion, higher concentrations, or more potent derivatives directly increases the risk of hypothalamic–

BOX 216-1 PRINCIPLES WHEN INITIATING TOPICAL STEROID THERAPY[40]

- Initiate lowest potency to sufficiently control disease.
- Prolonged use of an agent of insufficient potency should be avoided.
- When large surface areas are involved, treatment with low to medium potency preparations is recommended.
- Highly responsive diseases will usually respond to weak steroid preparations, whereas less-responsive diseases require medium or high-potency topical steroids.
- Low-potency, ideally nonhalogenated preparations should be used on the face and intertriginous areas.
- Very potent corticosteroids, frequently under occlusion, are usually required for hyperkeratotic or lichenified dermatoses and for involvement of palms and soles.
- Because of increased body surface area to body mass index ratio and increased risk of systemic absorption, high potency preparations and halogenated-medium potency preparations, should be avoided in infants and young children, other than for short-term application.

pituitary–axis (HPA) suppression. If the latter is suspected, laboratory analyses that include a complete blood cell count, a chemistry panel, and a baseline morning cortisol level should be performed. In a patient with confirmed HPA suppression, gradual reduction of potency and amount of topical steroid, and possibly the simultaneous institution of oral steroid supplementation, are needed.[48]

RISKS AND PRECAUTIONS

Local as well as systemic side effects have been documented with the use of topical corticosteroids. Under normal conditions, up to 99% of the applied topical corticosteroid is cleared from the skin, and only 1% is therapeutically active. Cutaneous adverse effects can result from the small percentage of percutaneously absorbed corticosteroid or may also result from its transient presence onto the skin. Continued use of topical corticosteroids may also lead to tachyphylaxis.[49]

Considerations for prescribing topical corticosteroids to prevent side effects should be followed[1,47,50,51] (Box 216-2).

COMPLICATIONS

Local adverse effects of topical corticosteroid use are more prevalent than systemic reactions. They are largely due to the antiproliferative effects of these agents.[49]

BOX 216-2 CONTINUING USE OF TOPICAL STEROIDS

- Highly potent formulations should be used for short periods (2 to 3 weeks) or intermittently.
- Once disease control is partially achieved, the use of a less potent compound should be initiated.
- Reduce frequency of application (e.g., application only in the morning, alternate-day therapy, weekend use) once disease control is partially achieved.
- Topical corticosteroids should be avoided on ulcerated or atrophic skin, and on skin with coexistent infectious dermatoses.
- Sudden discontinuation should be avoided after prolonged use to prevent rebound phenomena.
- Special guidelines should be followed when treating certain body areas (e.g., intertriginous areas) or certain populations (e.g., children or the elderly) to prevent the occurrence of local or systemic adverse effects.
- Laboratory tests should be considered if systemic absorption of corticosteroids is suspected.
- Use combination therapy when clinically indicated (e.g., addition of topical calcineurin inhibitor, tretinoin or calcipotriene).

ATROPHIC CHANGES

Skin atrophy is the most prominent cutaneous adverse effect, and involves both the epidermis and dermis. Dermal atrophy develops from the direct antiproliferative effects of topical corticosteroids on fibroblasts, with inhibition of collagen and mucopolysaccharide synthesis, resulting in loss of dermal support. Decreased synthesis of types I and III collagens after topical glucocorticoid use has been shown in numerous studies.[52–54] Reduction of glycosaminoglycan production has also been described.[55] Levels of hyaluronan, the major glycosaminoglycan in the skin, are also rapidly decreased after short-term glucocorticoid treatment, because of decreased of hyaluronan synthesis.[56] Fragmentation and thinning of elastic fibers develop on the upper layers, whereas deeper fibers form a compact and dense network. As a result of these atrophic changes, there is vascular dilatation, telangiectasias, purpura, easy bruising, stellate pseudoscars (purpuric, irregularly shaped, and hypopigmented atrophic scars), and ulceration. Although atrophy is, to some extent, reversible, formation of striae, visible linear scars that form in areas of dermal damage presumably during mechanical stress, are permanent.[46]

ACNEIFORM REACTIONS

The development or exacerbation of dermatoses of the face, including steroid rosacea, acne, and perioral dermatitis, is a well-known side effect of topical corticosteroids. Although steroids initially lead to the suppression of inflammatory papules and pustules, patients become addicted because they notice that the lesions flare when treatment is withdrawn. This frequently leads to the continued use of greater potency topical corticosteroids. For these reasons, steroid use should be discouraged in the treatment of rosacea and perioral and periocular dermatitis.

Prolonged corticosteroid treatment can also result in "steroid acne," which is characterized by crops of dense, inflamed pustules in the same developmental stage. These lesions occur on the face, chest, and back (see Chapter 80). Patients with psoriasis are also susceptible to a papulopustular flare after withdrawal of high-potency, topical corticosteroid therapy to an extensive surface area for a prolonged period of time.[40]

HYPERTRICHOSIS

Hypertrichosis occurs rarely in women and children who apply potent corticosteroids to the face. The mechanism is still unknown.[1]

PIGMENTARY CHANGES

Decreased pigmentation is a common side effect of topical steroid use. The pigment generally returns after discontinuation of therapy.

TABLE 216-2
Classification of Corticosteroids by Cross-Reactivity

Structural Class	A	B	C	D1	D2
Type	Hydrocortisone	Triamcinolone Acetonide	Betamethasone	Betamethasone dipropionate	Methylprednisolone aceponate
Structure	C16-no methyl substitution Probable C21-short chain ester		C16 methyl substitution	C16 methyl substitution C17/21 long chain ester	C16-no methyl substitution, no halogenation
Cross-reactions	Cross-reacts with D2	Budesonide specifically cross-reacts with D2			Cross-reacts with A and budesonide
Patch-test substance	Tixocortol-21-pivalate	Budesonide Triamcinolone acetonide		Clobetasol-17-propionate	Hydrocortisone-17-butyrate

Adapted from Jacob SE, Steele T: Corticosteroid classes: a quick reference guide including patch test substances and cross-reactivity. *J Am Acad Dermatol* **54**(4):723-727, 2006

DEVELOPMENT OF INFECTIONS

Topical corticosteroids are responsible for exacerbating and/or masking cutaneous infectious diseases. The incidence of skin infection during corticosteroid therapy varies but is probably between 16% and 43%.[57] Tinea versicolor, disseminated *Alternaria* infection, and dermatophytosis, including tinea incognito (masked dermatophyte infection), can develop. Granuloma gluteale infantum, characterized by reddish–purplish granulomatous lesions on the diaper area, is a well-known complication of diaper dermatitis that is being treated with corticosteroids. *Candida albicans* is commonly recovered in these patients. Topical corticosteroids have also an effect on prolongation or worsening of herpes simplex, molluscum contagiosum, and scabies infection.

ALLERGIC REACTIONS

Allergic contact dermatitis from steroids should be suspected when its use worsens the dermatitis, does not lead to improvement or changes the clinical pattern of disease. It occurs more commonly in patients with an impaired barrier function, such as patients with stasis dermatitis, leg ulcers and atopic dermatitis.[58] The prevalence of topical corticosteroid sensitization ranges between 0.2% and 6.0%, and increases with prolonged exposure and selection of certain drugs.[49,59,60] In a 6-year retrospective study, 127 of 1,188 patients (10.7%) patch tested with topical corticosteroids showed a positive reaction to at least one agent, with 56 patients reacting to multiple topical corticosteroids.[61] Topical corticosteroids were recognized as the American Contact Dermatitis Society's 2005 allergen of the year based on their prevalence.[62] A classification has been created to determine cross-reactivity among the various available preparations. This classification has four groups on the basis of structure and cross-reactivity patterns (Table 216-2). Each class is represented by an agent.[63] Class A is represented by the hydrocortisone type, class B by the acetonide steroids, class C by the betamethasone type and class D, subdivided into two groups, D1 represented by betamethasone dipropionate and D2 by methylprednisolone aceponate. Patch-test reactions to class A steroids are most common, whereas patch-test reactions to class C steroids are extremely rare. When an allergy to a topical corticosteroid is highly suspected and patch testing is not available, the clinician should prescribe a class C steroid with a vehicle that contains no allergens. Desoximethasone 0.25% ointment and 0.05% gel are the only two products that meet these criteria.[64] The vehicle or the preservative can also be responsible for the allergy to the corticosteroid preparation. A systematic review of ingredients in corticosteroid vehicles was recently published. The authors found seven vehicle ingredients that are commonly used in topical corticosteroid preparations and are well-known allergens: (1) propylene glycol, (2) sorbitan sesquioleate, (3) formaldehyde-releasing preservatives (imidazolidinylurea and diazolidinylurea), (4) parabens, (5) methylchloroisothiazolinone/methylisothiazolinone, (6) lanolin, and (7) fragrance (see Box 216-3). Of 166 topical corticosteroids, 128 (including all creams) had at least one of

BOX 216-3 POTENTIAL ALLERGENS IN TOPICAL CORTICOSTEROIDS VEHICLES

- Propylene glycol
- Sorbitan sesquioleate
- Methylchloroisothiazolinone/methylisothiazolinone
- Lanolin
- Parabens
- Formaldehyde releasing preservatives (imidazolidinylurea/diazolidinylurea)
- Fragrance

these vehicle components. More generic products were free of allergens than were the branded products. Solutions and ointments were the least allergenic vehicles. The most commonly present potential allergens were propylene glycol and sorbitan sesquioleate.[64]

SYSTEMIC ADVERSE EFFECTS

OCULAR EFFECTS. The development of glaucoma from the use of topical corticosteroids around the eye has been described.[65–67] Prolonged corticosteroid use has also led to vision loss.[68]

SUPPRESSION OF THE HYPOTHALAMIC–PITUITARY–ADRENAL AXIS. Suppression of the HPA axis has been described with the use of potent topical corticosteroids. Iatrogenic Cushing syndrome and corticosteroid-related Addison crises have been described after prolonged use of potent topical corticosteroid preparations. A dose of 14 g/week of clobetasol propionate or 49 g/week of betamethasone dipropionate is sufficient to suppress plasma cortisol levels.[19] It is generally assumed that systemic effects are more prevalent with high potency topical corticosteroids; however, a recent case report described a pediatric patient with Netherton syndrome who developed Cushing syndrome from percutaneous absorption of hydrocortisone 1%, a low-potency corticosteroid agent.[69] Literature reviewing the potential effect of topical corticosteroids and vertical growth in atopic dermatitis is overall reassuring but has mixed results. Cross-sectional studies have demonstrated that children with atopic dermatitis have diminished growth,[70,71] while others have found that temporary changes in cortisol levels do not affect eventual adult height.[72] A recent controlled questionnaire study found that the overall height of children with atopic dermatitis treated with topical corticosteroids was unaffected.[73]

METABOLIC SIDE EFFECTS. Increased glucose production and decreased glucose use induce hyperglycemia and may lead to diabetes mellitus. Femoral avascular necrosis rarely has been associated with the use of topical corticosteroids.[74–76]

Chapter 217 :: Topical Retinoids

:: Anna L. Chien, John J. Voorhees, & Sewon Kang

RETINOIDS AT A GLANCE

- Definition: any molecule that by itself or through metabolic conversion binds to and activates retinoic acid receptors.
- Retinoid receptors: ligand-dependent transcription factors.
- Predominant retinoid receptors in human skin: retinoic acid receptor-γ (RAR-γ) and retinoid X receptor-α (RXR-α).
  - RAR-γ/RXR-α heterodimers bind to retinoic acid-responsive elements and are responsible for retinoid signaling.
- Clinical use of topical retinoids:
  - Approved indications—acne, psoriasis, cutaneous T-cell lymphoma, Kaposi sarcoma, melasma, and photoaged skin.
  - Unapproved indications with clinical studies supporting benefit—postinflammatory hyperpigmentations early stretch marks and natural aging.
- Local skin irritation: mainly due to retinoid-induced epidermal hyperplasia. Clinical use should be titrated based on the severity of local reactions.

In topical preparations, retinoids are widely used as prescription drugs as well as cosmeceuticals. In some of these products, retinoids are naturally occurring compounds while others are synthetic molecules. All retinoids, however, share predictable pharmacology in eliciting human skin responses due to the fact that retinoid effects are primarily mediated through their intranuclear retinoid receptors acting as transcription factors. Indeed, the discovery and characterization of retinoic acid receptors (RARs) and retinoid X receptors (RXRs) have been pivotal to our understanding of the retinoid action mechanism and gave rise to the idea that retinoids act similarly to hormones.[1,2] In 1976, Michael Sporn and his colleagues originally defined retinoids as both the naturally occurring compounds with vitamin A activity and the synthetic analogs of retinol. This concept is no longer adequate. Now, retinoid is defined as any molecule that, by itself or through metabolic conversion, binds to and activates the RARs, thereby eliciting transcriptional activation of retinoic acid-responsive genes that results in specific biologic responses.

MECHANISM OF ACTION

RETINOID RECEPTORS

The discovery and characterization of RARs as having molecular features that are similar to steroid/thyroid hormone receptors were landmark findings.[1,2] A characteristic common to these receptors is that they bind to regulatory regions in DNA called *hormone response elements*, or *target sequences*, and activate gene transcription in a ligand-dependent manner. Therefore, they are referred to as *ligand (hormone)-dependent transcription factors*. These receptors bind to specific DNA sequences as dimers. Unlike receptors for the steroid hormones, which form homodimers (two identical monomers); RAR, vitamin D receptor (VDR), and thyroid hormone receptors (TR) bind to their elements with greater affinity as heterodimers (two different monomers). The critical partner for heterodimerization and ultimate functioning of RAR, VDR, and TR is the RXR,[3] whose physiologic ligand is 9-*cis*-retinoic acid.[4] The ability of RXRs to interact with many receptors suggests their importance as regulatory proteins. There are three different members of RAR (α, β, and γ) and RXR (α, β, and γ), each encoded by different genes. Furthermore, each of the receptors has isoforms, adding to the diversity of retinoid receptors.

RECEPTOR-SELECTIVE RETINOIDS

The identification and functional characterization of retinoid receptor families cleared the way for drug discovery. Many synthetic compounds have no structural similarities to all-*trans*-retinol or retinoic acid, yet are still considered retinoids by virtue of their ability to activate the receptor(s), therefore mediating the retinoid effect. Adapalene, tazarotene, and bexarotene are three synthetic retinoids that fit this description and have been used topically in humans (Fig. 217-1). Adapalene has restricted receptor specificity, possessing poor affinity for RAR-α, higher affinity for RAR-β and -γ, and no interaction with RXR-α.[5] Tazarotene cannot directly bind to RARs or RXRs. However, its metabolite, tazarotenic acid, has receptor selectivity for RARs (RAR-β > RAR-γ > RAR-α),[6] and is felt to be the principal active form. Bexarotene is an RXR-selective retinoid (rexinoid), which is 100-fold more potent at binding to RXR than to RAR receptor.[7]

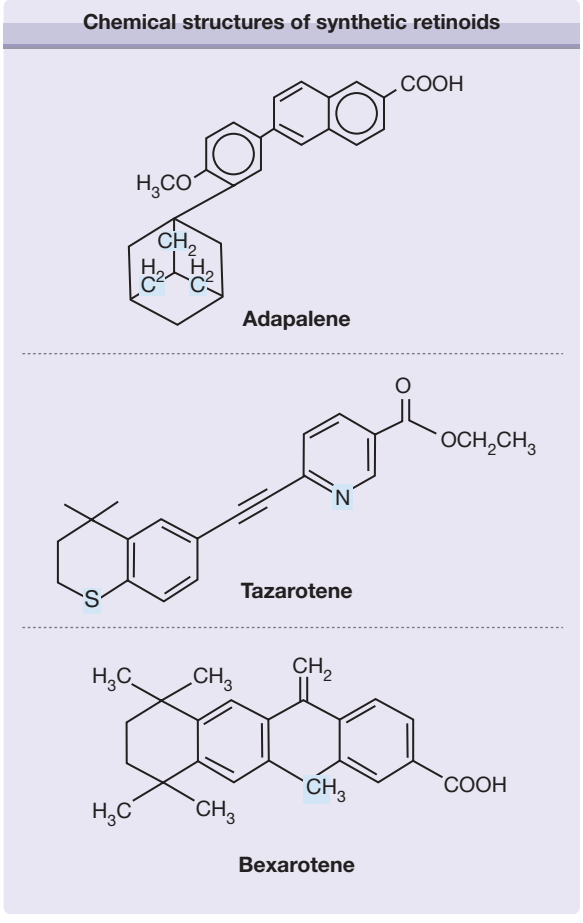

Figure 217-1 Chemical structures of the synthetic retinoids adapalene, tazarotene, and bexarotene.

RETINOID RECEPTORS IN HUMAN SKIN

Systematic analysis of relative levels of each RAR and RXR has been made in human skin and shows that the human epidermis expresses RAR-α, RAR-γ, RXR-α, and RXR-β messenger RNAs (mRNAs).[8,9] The relative levels of retinoid receptor mRNAs mirror their relative protein levels. In nuclei from human epidermal cells, there are five times more total RXRs than RARs.[9] For RAR proteins, 87% are RAR-γ and 13% are RAR-α with no detectable RAR-β. Of the RXR proteins, 90% are RXR-α. Furthermore, only RXR-α and RAR (mostly γ) heterodimers bind to retinoic acid-responsive

elements (RAREs).[9,10] At their physiologic levels, RARs and RXRs in human skin bind RAREs as heterodimers and transactivate these response elements in response to RAR, but not to RXR ligands. However, the RXR is key, as the heterodimer will not bind to the RARE without the presence of the RXR protein. Ultraviolet (UV) irradiation of human skin causes a rapid and significant reduction of retinoid receptors, both RAR-γ and RXR-α.[11] Although this decrease in the receptor levels is transient and returns to pre-UV treatment levels within 2 days, UV irradiation results in functional impairment of receptor-dependent retinoid responsiveness in human skin. Interestingly, pretreatment of skin with all-*trans*-retinoic acid before UV irradiation reduces receptor loss and accelerates receptor recovery.[11]

RETINOID TARGET GENES AND THEIR ACTIVATION CASCADE IN HUMAN SKIN

Retinoid actions are mediated by retinoid receptors. Given that the receptors are transcription factors, the ultimate skin effects of retinoids (phenotypic changes) must be accomplished through regulated gene expression. The best-established mechanism by which retinoid receptors modulate gene expression is activation of retinoid target genes through direct binding to RARE in the gene promoter, thereby stimulating the basal transcriptional machinery. In skin, cellular retinoic acid binding protein (CRABP) II, cellular retinol binding protein (CRBP), retinoic acid 4-hydroxylase (CYP26), and keratin 6—all of which contain RAREs—are regulated by all-*trans*-retinoic acid.[12–15] However, the products of these genes are unlikely to be the effectors of the retinoid response and thus cannot account for the pleiotropic effects of retinoids in skin. Undoubtedly, additional RARE-regulated genes will be identified that encode for proteins that function to modulate cutaneous growth and differentiation either directly or indirectly. A likely scenario is that these protein products, in turn, activate other non-RARE-containing genes in a cascading reaction to produce the clinical features of retinoid action in skin (Fig. 217-2).

Molecular description responsible for the most striking histologic feature of all-*trans*-retinoic acid-treated skin, the marked thickening of the epidermis, illustrates this point.[12,16] The epidermal hyperplasia is caused by the increased proliferation of basal keratinocytes. There is also an increase in differentiation markers involucrin, loricrin, filaggrin, and epidermal transglutaminase.[15] These epidermal changes collectively translate to clinical desquamation and peeling. This hyperproliferative response of epidermis to retinoic acid is mediated by its nuclear receptor.[17,18] Among the genes regulated by retinoid receptors involved in the cell growth control (keratinocyte proliferation), ligands for epidermal growth factor (EGF) receptor appear to be critically important. In human skin in vivo, topical retinoic acid induces heparin-binding (HB)-EGF and amphiregulin (AR), which stimulate basal cell growth via the cell surface EGF

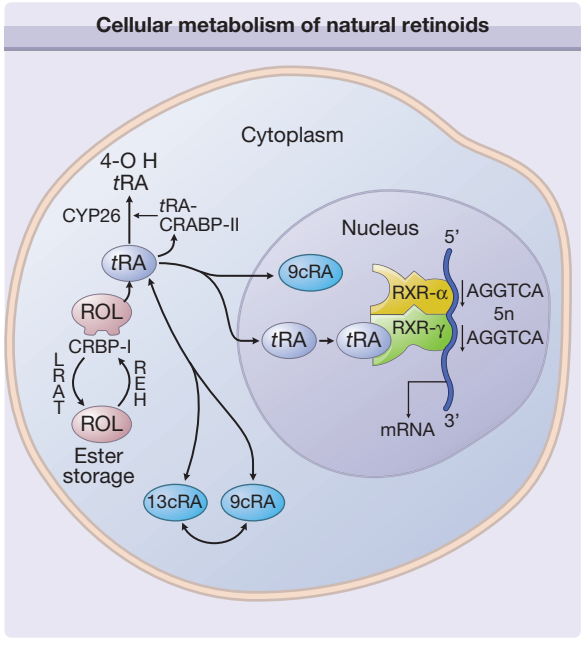

Figure 217-2 Cellular metabolism of natural retinoids and molecular mechanism of retinoid specific gene activation. Retinol (ROL) delivered to a cell is bound to cellular retinol binding protein-I (CRBP-I). ROL can be esterified, via lecithin:retinol acyltransferase (LRAT), and stored as ROL-esters. Hydrolysis of ROL-ester by its hydrolase (REH) yields free ROL. Sequential oxidation of ROL generates retinoic acid (RA), which is bound to cellular retinoic acid binding protein (CRABP). All-*trans*-RA (*t* RA) can be isomerized to 9-*cis*-RA (9*c* RA). Hydroxylation of *t* RA by cytochrome-P_{450} enzyme CYP26 generates 4-OH RA, which is relatively inactive. RARs and RXRs are intranuclear receptors for retinoids. In human skin, RAR-γ and RXR-α heterodimers bound to RA-response elements (such as AGGTCA direct repeats) transduce retinoid effects in the presence of RAR ligands. mRNA = messenger RNA.

receptor activation.[19,20] Interestingly, neither HB-EGF nor AR possesses any putative RARE. Therefore, a direct modulation of HB-EGF or AR by RARE promoters seems unlikely. Rather, RAR/RXR is likely regulating other transcription factor(s) that would, in turn, regulate AR and HB-EGF gene expression (Fig. 217-3). The identity of such transcription factor(s) remains to be determined.

PHARMACODYNAMICS

NOMENCLATURE

All-*trans*-retinoic acid (tretinoin), which binds to and activates RARs, is derived from sequential oxidation of all-*trans*-retinol (or vitamin A) and all-*trans*-retinaldehyde. It is a 20-carbon molecule that consists of a cyclohexenyl ring, a side chain with four double bonds (all arranged in *trans*-configuration), and a carboxylic-acid end group (Fig. 217-4A). The numbering of the carbon atoms is as shown in Figure 217-4B. The terms *9-cis-* (alitretinoin) and *13-cis-retinoic acid* refer to stereoisomers

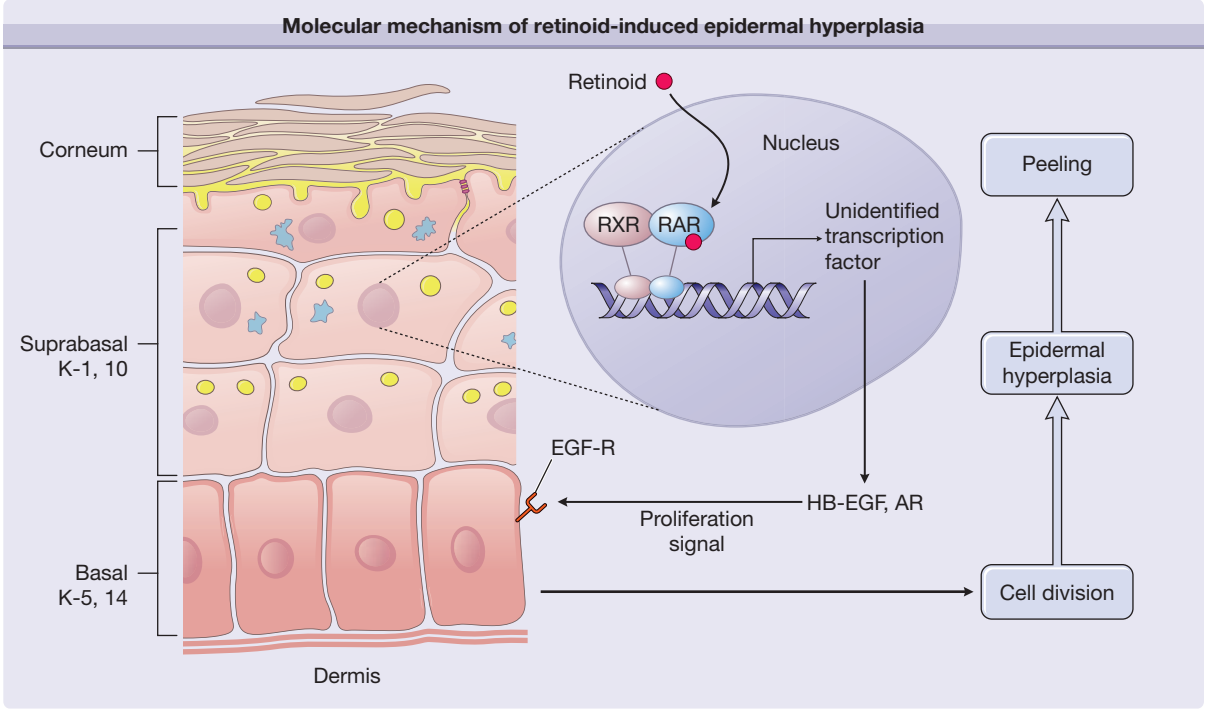

Figure 217-3 Molecular mechanism of retinoid-induced epidermal hyperplasia. Topical application of a retinoid activates retinoic acid receptor/retinoid X receptor (RAR/RXR) heterodimers in suprabasal keratinocytes, causing activation of yet unidentified transcription factors. These, in turn, activate the synthesis of heparin-binding epidermal growth factor (HB-EGF) and amphiregulin (AR). Through activation of epidermal growth factor-receptor (EGF-R), HB-EGF and AR cause proliferation of basal keratinocytes, thereby inducing thickened epidermis and consequent peeling/flaking of the stratum corneum. K = keratin.

of all-*trans*-retinoic acid in which the double bond that begins with the ninth and thirteenth carbon atoms, respectively, is in the *cis*- rather than *trans*-configuration. The *9-cis-retinoic acid* binds to the RXR-α receptor with high affinity, being 40 times more potent than all-*trans*-retinoic acid on RXR-α. *9-cis-retinoic acid* can also bind RAR receptors thus at times referred to as a *panagonist* of retinoid receptors.[4,21] The fourth carbon atom is located in the cyclohexenyl ring of retinoic acid and is involved in a hydroxylation reaction to generate 4-hydroxy-retinoic acid (see Fig. 217-4C). The addition of a hydroxyl group to the cyclohexenyl ring renders the molecule more polar, making it more amenable to excretion/elimination from cells and organisms. It is also much less active biologically. 4-Hydroxy-all-*trans*-retinoic acid can be further oxidized to 4-oxo-retinoic acid.

A group of compounds referred to as *retinyl esters* functions as the molecular storage form of retinol. The compounds are formed by esterification of retinol with fatty acids (see Fig. 217-4D), which specify the ester. For example, retinyl palmitate is generated when retinol is esterified with palmitic acid. Hydrolysis of retinyl esters regenerates retinol. Finally, β-carotene is a symmetric 40-carbon molecule (twice the number of carbons in retinol or retinoic acid) present in green and yellow–orange fruits and vegetables. As suggested by stoichiometry, one molecule of this carotenoid can potentially generate two molecules of retinol by cleavage of the central double bond (see Fig. 217-4E).

ESTERIFICATION AND OXIDATION OF RETINOL

Topical treatment of human skin with all-*trans*-retinol increases retinyl ester levels in the epidermal layer by more than tenfold.[12] This reaction is catalyzed by two enzymes: (1) lecithin/retinol acyltransferase and (2) acyl-coenzyme A/retinol acyltransferase. In human keratinocytes, lecithin/retinol acyltransferase has the predominant retinol-esterifying activity.[22]

Sequential oxidation of all-*trans*-retinol forms all-*trans*-retinoic acid, with all-*trans*-retinaldehyde as the intermediate metabolite. The first step (oxidation of all-*trans*-retinol to all-*trans*-retinaldehyde) is rate limiting for all-*trans*-retinoic acid formation. Topical application of all-*trans*-retinol to human skin results in histologic and molecular alterations that mimic those following all-*trans*-retinoic acid treatment.[12] These include epidermal hyperplasia, epidermal spongiosis, compaction of the stratum corneum, and induction of CRBP, CRABP-II, and CYP26.[22,23] In retinol-treated skin, all-*trans*-retinoic acid is minimally detectable and is no different from levels found in untreated normal skin. The lack of significant accumulation of all-*trans*-retinoic acid in retinol-treated skin is a result of the tightly regulated conversion of retinol to retinaldehyde and the effective hydroxylation of all-*trans*-retinoic acid that is formed by CYP26. The observation that all-*trans*-retinol and retinoic acid elicit similar responses in

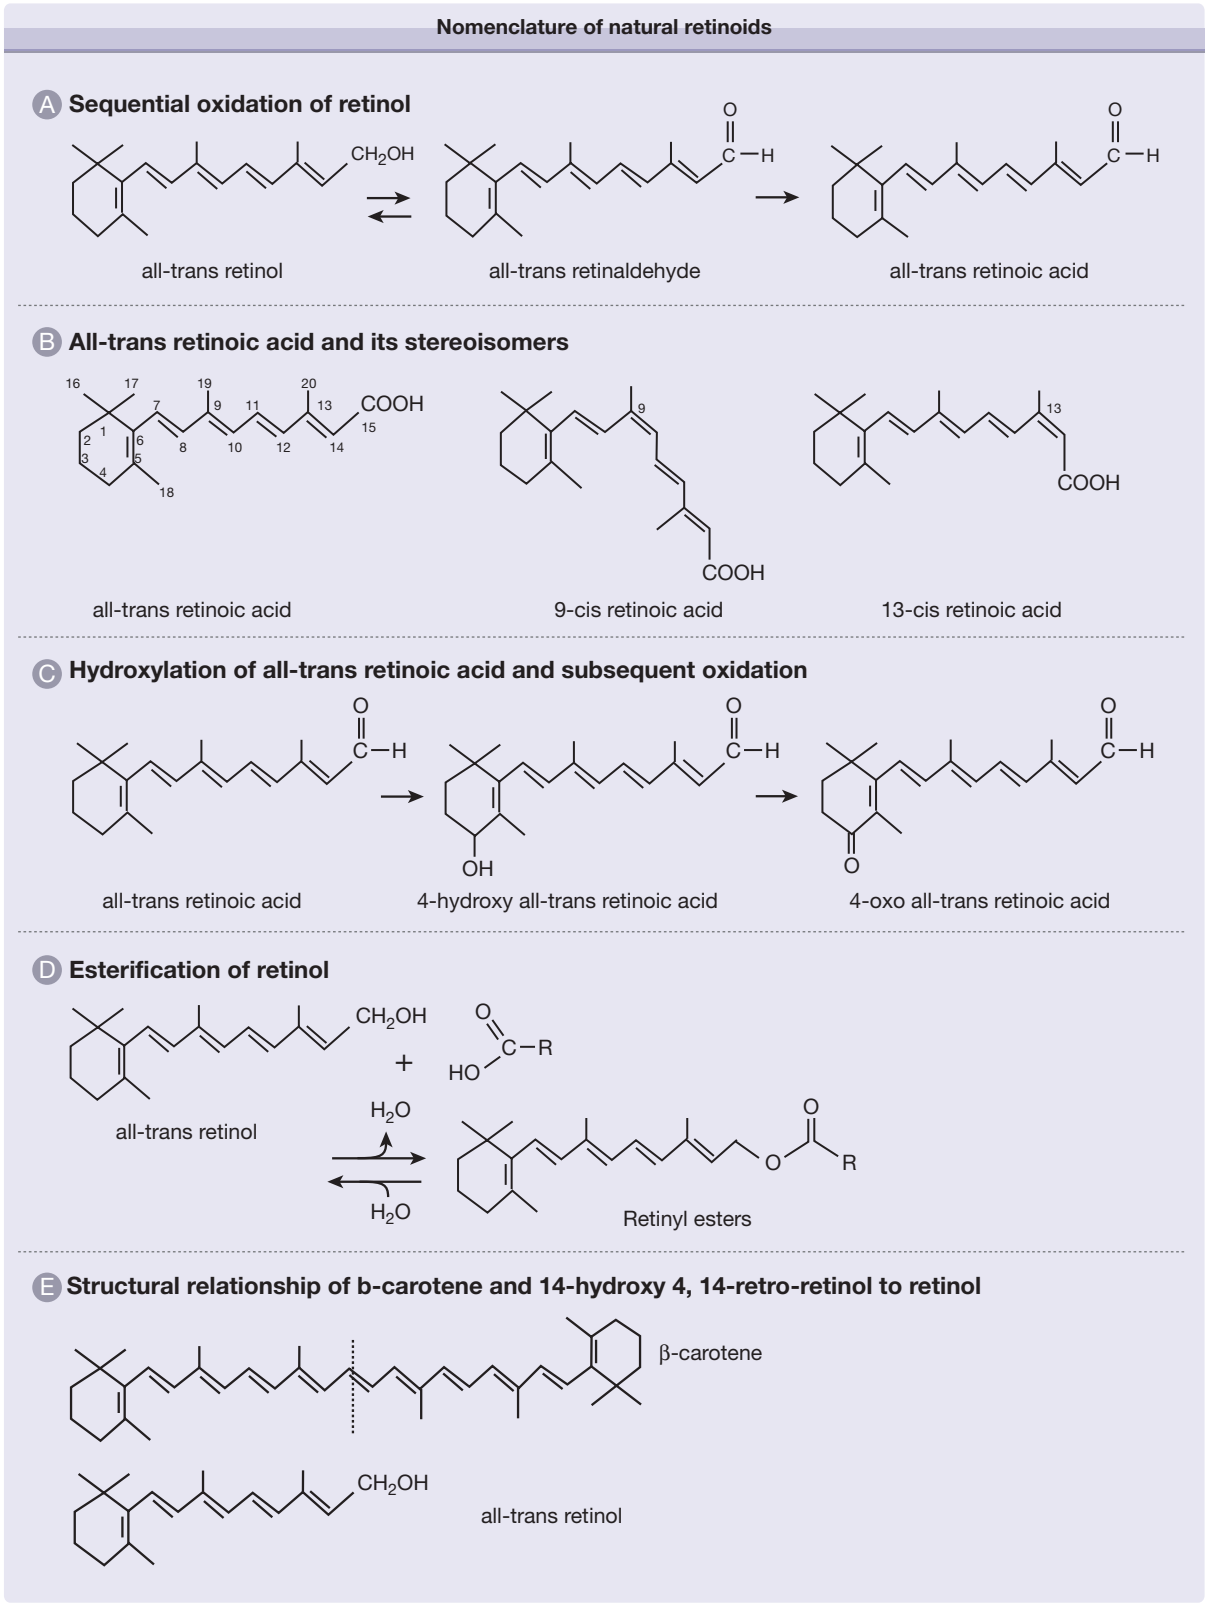

Figure 217-4 **A–E.** Nomenclature of natural retinoids.

human skin, but that retinol does so without detectable increases in retinoic acid levels, indicates that endogenously synthesized retinoic acid is a much more efficient activator of retinoid pathways than exogenously supplied retinoic acid.

HYDROXYLATION OF ALL-*TRANS*-RETINOIC ACID

In human skin all-*trans*-retinoic acid is catabolized primarily to the more polar 4-hydroxy-all-*trans*-retinoic acid, which is further metabolized to 4-oxo-retinoic acid. 4-Hydroxy-retinoic acid is tenfold less potent in inducing retinoid responses in human keratinocytes and mouse skin than all-*trans*-retinoic acid.[24] In untreated normal human skin, CYP26 activity is minimally detectable. Topical administration of all-*trans*-retinoic acid or all-*trans*-retinol to human skin, however, increases its activity several fold.[23,25] This hydroxylase activity is also induced in skin treated with 9-*cis*- or 13-*cis*-retinoic acid, but remarkably, it has substrate specificity for the all-*trans*-retinoic acid isomer only and does not hydroxylate 9-*cis*- or 13-*cis*-retinoic acid, retinol, or retinaldehydes.[23] With all-*trans*-retinoic acid, CYP26 activity is maximally induced after 24 hours of occlusive treatment. The CYP26 activity can be effectively inhibited by ketoconazole and a related azole, liarozole.[16,25] By blocking this major inactivation pathway of all-*trans*-retinoic acid, topical liarozole can serve as a retinoic acid mimetic or amplify human skin responses to all-*trans*-retinol and all-*trans*-retinoic acid.[16] This approach of targeting CYP26 has given rise to a novel class of new chemical entities referred to as *retinoic acid metabolism blocking agents* (RAMBAs). A study involving another RAMBA, talarozole, demonstrated that topical application led to increased mRNA expression of CRABP II and CYP26.[26] The drug development progress for RAMBA has been slow. A challenge for RAMBAs of the future is to selectively target CYP26 without affecting other enzymes such as steroid metabolizing aromatase or 17,20-lysase.

INDICATIONS

Until recently, clinical use of topical retinoids has been limited to all-*trans*-retinoic acid, which is approved in the United States for the treatment of acne, photoaged skin, and melasma. Topical adapalene and tazarotene have also received approval for acne; tazarotene has received approval for psoriasis and photoaging. More recently, bexarotene was approved for management of cutaneous T-cell lymphoma and alitretinoin was approved for patients with Kaposi sarcoma.

It is widely accepted that topical retinoids are extremely effective for acne therapy, especially for comedonal lesions. Of the different classes of antiacne medications, retinoids are thought to be the best, if not the only, agents to normalize the abnormal follicular epithelial differentiation/desquamation important in the pathogenesis of acne lesions. Therefore, the use of retinoids can also provide protection against the development of new lesions. This prophylactic property is the basis for including topical retinoid in almost all antiacne regimens. A potential for aggravating inflammation exists in treating inflammatory acne (i.e., papules and pustules) with topical retinoids, but when properly administered, this type of acne also responds well to retinoids (see Section "Dosing Regimen").

Fine wrinkles and dyspigmentation are two features of photoaged skin that are improved by topical tretinoin or tazarotene. Several weeks of treatment are required before clinical improvement is appreciated.[27–29] For the effacement of fine wrinkles by topical tretinoin, partial restoration of markedly reduced levels of collagen in sun-exposed skin toward those seen in sun-protected skin appears to be responsible.[28,30] Tretinoin's ability to improve photoaging is specific and does not result from the irritation or retinoid dermatitis frequently produced by this compound.[29] Topical adapalene is not approved for the treatment of photoaging; however, a recent study indicates that it also holds promise in ameliorating the clinical features of photodamage.[31]

Primary cutaneous T-cell lymphomas are characterized by clonal proliferation of skin-homing malignant T lymphocytes. As an RXR-selective retinoid, bexarotene inhibits tumor cell growth, encourages terminal differentiation, and induces apoptosis.[7] It may also play a role in chemoprophylaxis.[32,33]

Alitretinoin gel was approved in 1999 for the management of cutaneous Kaposi sarcoma (KS), which is caused by human herpes virus 8 (HHV-8). Alitretinoin's mechanism of action in KS is not entirely clear, but presumably relates to inhibition of cellular proliferation as well as induction of apoptosis seen with other retinoids. Other topical retinoids such as all-*trans*-retinoic acid and 13-*cis*-retinoic acid have been shown to inhibit KS cellular proliferation via inhibition of autocrine growth factors such as oncostatin M, tumor necrosis factor-α, and IL-6.[34–36] Furthermore, altretinoin and tretinoin have been reported to inhibit herpes simplex virus replication thus alitretinoin may have an antiviral role against HHV-8.[37] Alitretinoin has also been shown to have anti-inflammatory properties.[38] In clinical trials, most patients saw improvement after 4–8 weeks of treatment with the most significant response occurring after 14 weeks of therapy.[39]

Besides the approved indications, topical retinoids have been demonstrated to be effective in the treatment of several other conditions. Most studies have used tretinoin because it is the first topical retinoid to be developed and has been available the longest. Studied conditions include, but are not limited to, postinflammatory hyperpigmentation in blacks,[40] actinic dyspigmentation in Chinese and Japanese individuals,[41] and early stretch marks.[42] The controlled studies show more than therapeutic efficacies. They also provide valuable information to dispel some of the myths about retinoid use in humans. For example, African-Americans and Asians tolerate topical tretinoin as well as, if not better than,[40,41,43] Caucasians.[28,44] Furthermore, the often observed retinoid dermatitis does not usually lead to postinflammatory hyperpigmentation in those with greater constitutive pigmentation.

Many other skin disorders have been reported to be improved by topical retinoids, but most of these have not been rigorously studied; thus, their therapeutic claims should be interpreted with caution. Molluscum contagiosum, warts, and various forms of ichthyosis may be improved by topical retinoids to a variable degree. In psoriasis, especially, irritation of treated skin has limited the use. Topical tazarotene, which is approved for psoriasis, does not appear to have fully overcome the irritation problem[45]; thus, it is typically used in combination with topical steroids.

With such a wide variety of skin conditions treatable by topical retinoids, their use has included all age groups, perhaps with the exception of neonates. The use of topical retinoids in pregnancy is an emotional issue. As discussed in Section "Risks and Precautions," teratogenicity is not caused by topical retinoids. However, because none of the dermatologic conditions seen in pregnancy that may respond to topical retinoids (i.e., acne, melasma, stretch marks) is life-threatening to the mother or the fetus, it seems prudent to delay the treatment until after delivery. In a study that demonstrated that early, inflammatory stretch marks were improved by topical tretinoin, all pregnancy-related stretch marks were treated postpartum.[42] Therefore, even in this pregnancy-associated condition, the therapeutic benefit could be achieved by instituting the treatment after delivery.

DOSING REGIMEN

For decades, tretinoin was the only topical retinoid available for clinical use sold under the trade name Retin-A. Now, tretinoin is also available in other formulations (eTable 217-0.1 in online edition). Adapalene is also available in varying formulations and more recently, combination medications have been introduced (eTable 217-0.1 in online edition). For acne and psoriasis, topical tazarotene is available and for photoaging treatment, tretinoin and tazarotene are approved for use. Tretinoin 0.05%/hydroquinone 4%/fluocinolone 0.1% is a topical combination approved for the treatment of melasma. Different formulations allow some flexibility in terms of tailoring the therapy to an individual's skin dryness or oiliness. Finally, more recently approved topical retinoids include bexarotene and alitretinoin, sold in gel formulations.

Regardless of the retinoid preparation or the patient's age, the most important element in topical therapy is patient/guardian education. It must be clearly explained to each patient that, as part of the treatment, local skin irritation, characterized by redness and peeling, can be expected. The concept that clinical improvement correlates with the degree of irritation has been erased through a large, controlled clinical study in which 0.025% and 0.1% tretinoin were shown to be equally efficacious, but the former was significantly less irritating than the latter.[29] Therefore, unlike most medications for which the dosing schedule may be set as once or twice daily, administration of a topical retinoid should be titrated depending on the skin reaction. For some individuals, it may be applied only twice a week, for others four times a week, and this can be increased, as tolerated, to a once-daily regimen. This method of individualizing topical therapy minimizes unwanted acute retinoid dermatitis.

Under the nonprescription category, there are countless "natural retinoid" preparations with various claims (mostly antiaging) being sold throughout the world. Most of these contain retinyl esters, especially retinyl palmitate, retinaldehyde, or retinol. Whether any of these products can deliver retinoid activity to human skin is subject to question. Percutaneous absorption (especially for retinyl esters), adequate concentrations, and stable formulations (especially for retinol) are some of the important unknowns for this group of products. Based on human in-vivo work, all-*trans*-retinol and all-*trans*-retinaldehyde hold the most promise of these natural retinoids in being biologically active,[12,46] provided the stability of the compound can be maintained with a proper formulation. When the sun-protected skin of individuals older than 80 years of age was treated for 7 days with 1% retinol, fibroblast growth and dermal collagen were increased significantly.[47] Concomitantly, retinol markedly reduced the levels of matrix-degrading metalloproteinases that are elevated in aged skin. These findings suggest that retinol may reverse and partially prevent skin atrophy that accompanies intrinsic aging. A recent clinical study has confirmed that topical retinol improves the fine wrinkles associated with atrophic, naturally aged skin of the elderly.[48]

RISKS AND PRECAUTIONS

ADVERSE EFFECTS

By far the most common adverse effect associated with topical retinoid use is local skin irritation characterized by erythema, peeling, dryness, tightness, and burning sensation. This predictable skin response is temporary, but troubling, for many patients. It tends to peak within the first month of treatment and diminishes thereafter. It responds to a temporary reduction in the frequency or amount of retinoid application and to liberal use of emollients. The requirement for RAR/RXR receptors in retinoid stimulation of basal keratinocyte proliferation was presented in Section "Retinoid Target Genes and Their Activation Cascade in Human Skin." Retinoid activation of the receptors is followed by subsequent induction of HB-EGF and AR in human skin in vivo[19,20] (see Fig. 217-3). The importance of this signaling pathway in the hyperplastic response of the epidermis to topical retinoids was recently demonstrated when pharmacologic antagonists of EGF receptor tyrosine kinase activity blocked retinoid-induced epidermal thickening in human skin organ culture and in vivo.[19,20] This observation suggests that it may be possible to reduce the clinically undesirable effects of retinoids on epidermal keratinocytes. However, the erythema response following topical retinoic acid may not be retinoid-receptor mediated because all-*trans*-retinol, which induces epidermal hyperplasia and CRABP-II mRNA-like retinoic acid (two indicators of

receptor activation), is minimally associated with clinical erythema.[12]

For the more recently approved bexarotene and alitretinoin, local irritation is also the most common side effect. With alitretinoin, the local erythema can increase to edema and vesiculation with continued use. However, most reactions are mild-to-moderate with only 7% of patients requiring treatment withdrawal in clinical trials.[39] Finally, the central hypothyroidism seen with systemic bexarotene is not observed in the gel formulation.[49,50]

Systemic retinoid exposure has been well documented and established as a cause of embryonic death and congenital malformation, and understandably, there is concern about potential teratogenicity from long-term topical retinoid use. Systemic absorption of retinoids from topical application is negligible, and the levels of endogenous retinoic acid in the blood are not increased by twice daily application of 0.025% tretinoin to more than 40% of body area over 1 month. Furthermore, controlled topical administration of tretinoin at doses used for acne therapy (2 g of 0.025% gel applied daily to the face, neck, and upper part of the chest for 14 days) has less influence on plasma levels of endogenous retinoids than diurnal and nutritional factors.[51] Indeed, a large, population-based study demonstrated no excess risk of birth defects in offspring born to mothers who were exposed to topical tretinoin during pregnancy.[52] Therefore, no evidence exists for teratogenicity of topical tretinoin in humans.

"Sun sensitivity" is a frequently discussed subject with topical retinoid use and requires clarification. When formally tested in humans, topical tretinoin does not lower the minimal erythema dose of UVB light.[53] Because its presence in human skin does not increase the likelihood of sunburn reaction, tretinoin is not a phototoxic agent. The patients who complain of such sun sensitivity, describe an uncomfortable skin sensation that is felt within minutes of being in the sun rather than hours later. This timeline is not consistent with a typical sunburn reaction, which takes a few hours to be noticed. Furthermore, this sensation is often said to be accentuated in warmer temperatures, which suggests participation of infrared irradiation (heat).

Related to sun sensitivity is the issue of photocarcinogenesis. In an animal model of photocarcinogenesis, topical tretinoin has caused skin cancer. However, when human skin was grafted onto mice with severe combined immunodeficiency disease, gross inadequacy of the commonly used rodent model of photocarcinogenesis was demonstrated.[54] Specifically, the traditional rodent models significantly overestimate the human carcinogenic potential of tested agents. Topical retinoids, on the contrary, appear to have a protective effect against UV-induced premalignant and malignant lesions. In those predisposed by nevoid basal cell carcinoma syndrome or xeroderma pigmentosum to the development of nonmelanoma skin cancer, systemic retinoids have provided effective protection. In this regard, topical tretinoin's ability to prevent UV induction of c-Jun is relevant.[55] c-Jun is a proto-oncoprotein that is minimally detectable in normal human skin in vivo. Its partner c-Fos; however, is constitutively expressed. UV irradiation to human skin does not affect the level of c-Fos expression, but it markedly induces c-Jun protein, which can then heterodimerize with c-Fos, forming a complete active AP-1 transcription factor.[55] The critical importance of AP-1 in mediating carcinogenic transformation of papillomas has been demonstrated.[56] In human squamous cell carcinomas, c-Jun expression is elevated, and systemic retinoids prevent carcinomas of the head and neck. Mechanisms involved in this chemopreventive effect of the retinoid likely include c-Jun suppression. These clinically observed anticarcinogenic activities of retinoids are also supported by in vitro data, demonstrating that tretinoin treatment of human skin upregulates the antigen-presenting activity of Langerhans cells without concomitant increase in autoreactivity.[57] Such a retinoid effect would improve cutaneous immune responsiveness to tumor antigens. Therefore, topical retinoic acid is not a carcinogen in humans.

DRUG INTERACTION AND COMPATIBILITIES

Retinoids, in general, are photolabile and therefore can be photoinactivated. Based on this chemistry, it is prudent to apply the agents in the evening rather than before the start of the day. Because the major avenue of tretinoin inactivation is through CYP26, drugs that modulate the activity of this enzyme can potentially cause drug interactions. Ketoconazole and liarozole are effective inhibitors of CYP26 and, therefore, are RAMBAs.[16,25] Concurrent use of these azoles and topical tretinoin can increase the amount and prolong the half-life of tretinoin locally in the skin, thereby aggravating local side effect. Other than retinoids, no other compounds have been shown to induce CYP26.

The use of vitamin D_3 and its analogs has increased in dermatology, and, in particular, for psoriasis. Vitamin D effects in human skin are largely mediated via its nuclear receptor VDR. As previously discussed in Section "Retinoid Receptors," VDR is a member of the steroid/retinoic acid/thyroid hormone receptor superfamily. Like RAR, VDR functions in human skin mainly as a heterodimer with RXR (VDR-RXR). In contrast with retinoid signaling via RAR-RXR, in which the presence of RXR-ligand confers no additional effect, RXR-ligand provides a synergistic effect with VDR-ligand in vitamin D signaling.[58] Therefore, topical retinoids that possess, or through metabolic conversion, acquire RXR selectivity can positively influence vitamin D pharmacology in human skin.

Chapter 218 :: Topical Antibiotics

:: Mark W. Bonner & William D. James

TOPICAL ANTIBIOTICS AT A GLANCE

- Topical antibiotics are useful in the treatment of acne and rosacea.
- Use in impetigo may obviate the need for oral antibiotics.
- Use of topical antibiotics to prevent wound infection after clean surgical procedures is unnecessary.

Topical antibiotics play an important role in the management of many common dermatologic conditions (Table 218-1). They are prescribed most often by dermatologists for the management of mild-to-moderate acne vulgaris or as adjunctive treatment with oral agents. For localized superficial infections, such as impetigo, the use of a topical agent (e.g., mupirocin or retapamulin) may eliminate the need for oral antibiotics and the accompanying problems of compliance, gastrointestinal side effects, and potential drug interactions. Topical antibiotics are still frequently prescribed as prophylactic agents after minor surgery or cosmetic procedures (chemical peel or laser resurfacing) to reduce the risk of postoperative wound infection and to speed wound healing. The use of topical antibiotics for prophylaxis after such minor procedures has been proven to be unnecessary and incurs risk of inducing allergy. Petrolatum is recommended for use after clean surgical procedures.

AGENTS USED IN THE TOPICAL TREATMENT OF ACNE AND ROSACEA

The efficacy of topical antibiotics for the treatment of acne vulgaris and rosacea may be due to their direct antibiotic effect, but many of the topical antibiotics exhibit anti-inflammatory properties by suppressing neutrophil chemotactic factor or by other mechanisms.[1] There are concerns about the use of topical antibiotics in the treatment of acne vulgaris because of the increasing levels of antibiotic resistance. Combining the antimicrobial benzoyl peroxide with antibiotics reduces the development of antibiotic resistance.

ERYTHROMYCIN

Erythromycin belongs to the group of macrolide antibiotics and is active against both Gram-positive cocci and Gram-negative bacilli. It is used principally as a topical agent in the treatment of acne. Erythromycin binds to the bacterial 50S ribosome and blocks translocation of the peptidyl-transfer RNA (tRNA) molecule from the acceptor to the donor site, interfering with the formation of the polypeptide chain and inhibiting protein synthesis. In addition to its antibacterial properties, erythromycin has anti-inflammatory activity. Erythromycin is available as a 1.5% to 2.0% solution, gel, pledgets, and ointment as a single agent. It is also available in combination with benzoyl peroxide.

CLINDAMYCIN

Clindamycin is a semisynthetic lincosamide antibiotic that is derived from lincomycin. The mechanism of action is very similar to that of erythromycin, with binding to the 50S ribosome and suppression of bacterial protein synthesis. Clindamycin is used topically as a 1% gel, solution, suspension (lotion), and foam primarily for the treatment of acne. It is also available as a combination with benzoyl peroxide, which may slow the development of antibiotic resistance to clindamycin. Pseudomembranous colitis rarely has been reported to occur with the topical use of clindamycin.[2]

METRONIDAZOLE

Metronidazole, a topical nitroimidazole, is currently available as a 0.75% gel, cream, or lotion and as a 1%

Clindamycin	S, G, L	50S ribosome inhibition	
Fusidic acid	NA	Interferes with EF-G	
Silver sulfadiazine	C		
Mafenide acetate	O	Enzyme inhibition	Gr±
Nitrofurazone	C, S	Enzyme inhibition	Gr±
Metronidazole	G, C, L	Electrochemical	Anaerobes
Clioquinol	C, O	Unknown	Broad spectrum
Azelaic acid	C, G	Protein synthesis inhibition	Gr+

C = cream; EF-G = elongation factor G; G = gel; Gr+ = Gram-positive; Gr– = Gram-negative; Gr± = Gram-positive or -negative; L = lotion; NA = not available in the United States; O = ointment; P = pledget; S = solution.
[a]Bacteria refers to bacteria usually susceptible to antibiotic.

cream or gel for the topical treatment of rosacea. In the lower strength, it is applied twice daily, and in the higher strength, it is used once daily. Orally, metronidazole has broad-spectrum activity against many protozoal organisms and anaerobes.

AZELAIC ACID

Azelaic acid is a dicarboxylic acid found in food (whole-grain cereals and animal products). There is a normal human plasma level (20–80 ng/mL); topical application does not significantly alter this level. The mechanism of action is thought to be normalization of the keratinization process (decreased thickness of the stratum corneum, decreased number and size of keratohyaline granules, and decreased amount of filaggrin). There are reports of in-vitro activity against *Propionibacterium acnes* and *Staphylococcus epidermidis*, which may be due to protein synthesis inhibition. In aerobic microorganisms, there is inhibition of oxidoreductive enzymes (such as tyrosinase, mitochondrial enzymes of the respiratory chain, 5α-reductase, and DNA polymerases). In anaerobic bacteria, there is disruption of glycolysis. Azelaic acid is used principally in the treatment of acne vulgaris and rosacea, although there are some advocates for its use in the treatment of hyperpigmentation (such as melasma for which it was initially developed). However, the US Food and Drug Administration has not approved the drug for this indication. Azelaic acid is available as a 15% gel or 20% cream preparation.

SULFONAMIDES (SULFACETAMIDE)

Sulfacetamide is a topical sulfonamide used in the treatment of rosacea and acne. The antibacterial mechanism of action for most sulfonamides is competition with *para*-aminobenzoic acid (PABA) during the synthesis of folic acid. The mechanism of action for topical treatment of rosacea is not understood. Sulfacetamide is available as a 10% lotion and in combination with 5% sulfur in a gel, cream, suspension, cleanser, cloths, and mask.

DAPSONE

Topical 5% dapsone gel is approved by the FDA for the topical treatment of acne. The mechanism of action of dapsone in acne vulgaris is not known at this time; however, it is possible that inhabitation of neutrophils activity may be important. If benzoyl peroxide is applied after topical dapsone, temporary orange/yellow discoloration of skin and facial hair have been noted.

AGENTS USED FOR THE TOPICAL THERAPY OF SUPERFICIAL BACTERIAL INFECTIONS AND BURNS

Localized impetigo, superficial dirty abrasions, and secondarily infected chronic dermatoses are commonly treated with topical antibiotics. However, widespread

impetigo, infection of the lower extremities, or disease occurring in immunocompromised individuals should be treated with systemic antibiotics to reduce the risk of serious complications. Topical antibiotics are still at times used following minor surgical procedures. The result of a large study comparing bacitracin and petrolatum in more than 1,200 minor surgical procedures demonstrated that bacitracin did not statistically decrease the already low rate of infection. Several patients were, however, shown to be allergic to bacitracin. Petrolatum proved to be cheaper, of equal efficacy and to have fewer side effects than bacitracin.[3] When clean wounds are made during minor surgery, there is no need to use antibacterial ointment to aid in healing or prevent infection. Because burns produce a fertile ground for life-threatening secondary infection, prophylactic topical therapy is often used.

MUPIROCIN

Mupirocin, which was formerly known as *pseudomonic acid A*, is a topical antibiotic agent derived from *Pseudomonas fluorescens*. The drug reversibly binds to isoleucyl-tRNA synthetase and inhibits bacterial protein synthesis. The activity of mupirocin is limited to Gram-positive bacteria, especially staphylococci and most streptococci. Its activity is enhanced in an acid pH environment (5.5), which is the normal pH of the skin. Mupirocin is somewhat temperature-sensitive, and thus loses efficacy if exposed to high temperatures. Mupirocin ointment 2% is applied three times daily and is principally indicated for the treatment of localized impetigo caused by *S. aureus* and *Streptococcus pyogenes*. One study in the Tennessee Veterans' Affairs Hospital demonstrated that prolonged use of mupirocin ointment to control methicillin-resistant *S. aureus* (MRSA) carriage, especially in bedridden patients with decubitus ulcers, led to significant resistance.[4] Furthermore, Japanese researchers found that low serum concentrations of mupirocin are achieved after intranasal application and postulated that this might explain the selection of mupirocin-resistant strains of *S. aureus*.[5] A small pilot study using intranasal application of a combination antibiotic ointment containing bacitracin, polymyxin B, and gramicidin successfully decolonized 80% (9 out of 11) of MRSA-positive patients who remained clear after a mean follow-up of 2 months. All cases of mupirocin-sensitive MRSA were eradicated, whereas only three of five cases of mupirocin-resistant were eliminated.[6] New formulations that involve the use of the calcium salt of mupirocin (the calcium salt aids in chemical stability in the intranasal preparation) are available for intranasal use as a 2% ointment and a 2% topical cream.

RETAPAMULIN

Retapamulin is approved for topical treatment of impetigo in patients older than 9 months of age. It is a semisynthetic pleuromotilin antibiotic derived from fermentation in *Clitopilus paseckerianus* with activity against staphylococci. The antibacterial mechanism of action is inhibition of protein synthesis via 50S bacterial ribosomes at protein L3, near the peptidyl tranferase center. Retapamulin binding inhibits peptidyl tranferase and partial inhibition of binding of initiator tRNA to P-site of ribosome. Allergic contact dermatitis to the active ingredient has been reported.[7]

BACITRACIN

Bacitracin is a topical polypeptide antibiotic originally isolated from the Tracy-I strain of *Bacillus subtilis*. Bacitracin is a cyclic polypeptide with multiple components (A, B, and C). Bacitracin A is the major component of commercial products and is often used as the zinc salt. Bacitracin interferes with bacterial cell wall synthesis by binding to and inhibiting the dephosphorylation of a membrane-bound lipid pyrophosphate. It is active against Gram-positive cocci such as staphylococci and streptococci. Most Gram-negative organisms and yeast are resistant to the drug. It is available as bacitracin ointment and as zinc bacitracin, with 400 to 500 units per gram.

Topical bacitracin is effective for the treatment of superficial bacterial infections of the skin such as impetigo, furunculosis, and pyodermas. It is often combined with polymyxin B and neomycin as a triple antibiotic ointment applied several times daily for the treatment of secondarily infected eczematous dermatitis such as atopic dermatitis, nummular dermatitis, or stasis dermatitis. Unfortunately, the topical application of bacitracin carries with it the risk of allergic contact sensitization and, rarely, anaphylactic shock.[8]

POLYMYXIN B

Polymyxin B is a topical antibiotic derived from a spore-forming soil aerobe *B. polymyxa*. Polymyxin B is a mixture of polymyxin B_1 and B_2, which are both cyclic polypeptides. They function as cationic detergents that interact strongly with bacterial cell wall membrane phospholipids, thus disrupting the integrity of the cell membrane.

Polymyxin B is active against a wide range of Gram-negative organisms, including *P. aeruginosa*, *Enterobacter*, and *Escherichia coli*. Polymyxin B is available in ointment form (5,000 to 10,000 units per gram) in combination with bacitracin or as triple antibiotic ointment with bacitracin and neomycin. It should be applied one to three times a day.

TOPICAL AMINOGLYCOSIDES (NEOMYCIN AND GENTAMICIN)

The aminoglycosides are an important group of antibiotics used both topically and systemically for the treatment of infections caused by Gram-negative bacilli. Aminoglycosides exert their bactericidal effects by binding to the 30S ribosomal subunit and interfering with protein synthesis.

Neomycin sulfate, the aminoglycoside most often used topically, is a fermentation product of

Streptomyces fradiae. Commercial neomycin is a mixture of neomycin B and C, whereas framycetin, used in Canada and some European countries, is pure neomycin B.[9] Neomycin sulfate has activity against aerobic Gram-negative bacteria and is used most commonly for prophylaxis against infection in superficial abrasions, cuts, and burns. It is available in ointment form (3.5 mg/g) and is also packaged in combination with other antibiotics such as bacitracin, polymyxin, and gramicidin. Other agents, such as lidocaine, pramoxine, or hydrocortisone, also are available in combination with neomycin.

Neomycin is not recommended by many dermatologists because it is responsible for a large number of cases of allergic contact dermatitis. The prevalence of contact dermatitis is high, with 6% to 8% of patients undergoing patch testing being positive.[10] Neomycin sulfate (20%) in petrolatum is used to assess for contact allergy.

Gentamicin sulfate is derived as a fermentation product from *Micromonospora purpurea*. It is available as a topical 0.1% cream or ointment. It is used by some dermatologic surgeons when operating on the ear, especially in diabetic or other immunocompromised patients, to provide prophylaxis against malignant otitis externa due to *P. aeruginosa*. The ophthalmic formulation is useful in caring for operative wounds in the periorbital area.

SULFONAMIDES (SILVER SULFADIAZINE AND MAFENIDE ACETATE)

The sulfonamides are structurally similar to PABA and compete with it during the synthesis of folic acid. Sulfonamides are used to treat acne vulgaris, acne rosacea, and burns. Silver sulfadiazine is thought to release silver slowly and exerts its effect on the bacterial cell walls and membranes. The mechanism of action of mafenide is not the typical sulfonamide mechanism of action because PABA does not antagonize its performance. Mafenide acetate, if used over large areas of skin, has the potential to cause metabolic acidosis, and it can cause intense pain on topical administration. Both agents are broad-spectrum antibacterials useful in the treatment of burns. *Candida* superinfection may be a problem with mafenide cream.

NITROFURAZONE

Nitrofurazone (Furacin) is a nitrofuran derivative used for the treatment of burn patients. The mechanism of action involves the inhibition of bacterial enzymes involved in the aerobic and anaerobic degradation of glucose and pyruvate. Nitrofurazone is available as a 0.2% cream, solution, or soluble dressing, and its spectrum of activity includes staphylococci, streptococci, *E. coli*, *Clostridium perfringens*, and *Proteus* sp.

MISCELLANEOUS AGENTS

GRAMICIDIN

Gramicidin is a topical antibiotic derived from *B. brevis*. The gramicidins are linear peptides that form stationary ion channels in susceptible bacteria. The antibiotic activity of gramicidin is restricted to Gram-positive bacteria.

CLIOQUINOL

Clioquinol (also known as *iodochlorhydroxyquin*) is a broad-spectrum antibacterial/antifungal topical that is currently indicated for the treatment of inflammatory skin disorders and tinea pedis and has been used for minor bacterial infections. It is a synthetic hydroxyquinoline whose mechanism of action is unknown. The disadvantages of clioquinol include discoloration of clothing, skin, hair, and nails and the potential to cause irritation. Clioquinol may interfere with thyroid function determination when taken orally and possibly topically if used extensively. The iodine moiety interferes with tests that rely on iodine uptake (this effect can last for up to 3 months after application). However, clioquinol does not interfere with testing for T3 or T4.

Chapter 219 :: Topical Antifungal Agents

:: Whitney A. High & James E. Fitzpatrick

TOPICAL ANTIFUNGAL AGENTS AT A GLANCE

- Preferred treatment for superficial fungal infection of limited extent.
- Low cost, low incidence of drug interactions, few side effects and complications, ease of use.
- Use systemic agent when superficial fungal infection affects large surface area, involves terminal hair or nails, or is resistant to topical management.
- Topical antifungal classes: imidazoles, allylamines, benzylamines, polyenes.
- Ciclopirox olamine: unique topical antifungal with broad-spectrum activity, variety of indications.
- Side effects: irritant dermatitis, allergic contact dermatitis, urticarial reactions.
- Combination agents (antifungal and steroid): watch for side effects due to glucocorticoids.
- Combination agents: higher rate of treatment failure, disease relapse.

Superficial fungal infections, including dermatophytoses, candidiasis, and pityriasis versicolor, are most often restricted to the epidermis. In treating these infections, the clinician must select between topical or systemic management. Factors guiding management include, but are not limited to, the:

- extent and severity of the infection,
- site of involvement,
- comorbid conditions or potential drug interactions, if any,
- anticipated efficacy of treatment,
- cost and access to medication, and
- ease of use.

Patients with limited fungal infections confined to glabrous skin are usually best treated with topical agents. Conversely, those with extensive or recalcitrant disease, or with involvement of terminal hair or nails, may be better suited for systemic management. In some cases, either treatment option may be reasonably chosen.

Treatment with topical antifungal therapy enjoys several advantages over systemic management, including:

- fewer side effects,
- fewer drug interactions,
- localization of treatment, and
- generally lower cost.

Numerous topical antifungal medications are available (Table 219-1). For the most part, specific antifungal agents have replaced nonspecific topical treatments, such as keratolytics (salicylic acid) or antiseptics (gentian violet or Castellani paint), which were once the cornerstones of management.

The "ideal" topical antifungal is easily defined (Table 219-2), and is in sum, efficacious, inexpensive, well tolerated, and has low resistance within targeted fungi. Despite widespread availability, few topical antifungal agents have been directly compared with one another in clinical trials. Studies sponsored by the manufacturer often compare just the active agent to the vehicle. Extrapolation between studies is further complicated due to differences in study design, duration of therapy, site of infection, selection methodology, or treatment endpoint.

Most topical antifungals belong to one of three classes: (1) imidazoles, (2) allylamines and benzylamines, and (3) polyenes. Agents that do not fit well into this schema are discussed separately.

IMIDAZOLES

Imidazoles represent a broad class of antifungal medications. Certain of these, such as clotrimazole, have been around for decades, while others, such as sertaconazole, have only become available recently.

MECHANISM OF ACTION

Imidazoles impede synthesis of a component of the fungal cell wall through inhibition of lanosterol 14α-demethylase, a cytochrome P_{450}-dependent enzyme, which converts lanosterol to ergosterol.[1] Depletion of ergosterol results in membrane instability and hyperpermeability; changes incompatible with growth and survival of the fungus. Imidazoles are considered fungistatic in practical application, with the possible exception of sertaconazole when used to treat some *Candida* species.[2] While all imidazoles possess the same mechanism of action, in-vitro studies demonstrate that not all dermatophytes are uniformly susceptible to an imidazole at an equivalent concentration, and this may explain some treatment failures.[3–5]

Topical imidazoles possess anti-inflammatory activity via inhibition of neutrophil chemotaxis, calmodulin activity, synthesis of leukotrienes and prostaglandins,

TABLE 219-1
Topical Antifungal Agents Commonly Used in Dermatology

Generic Name(s)	Trade Name(s)	Formulation	Pregnancy Class	Rx/OTC
Imidazoles				
Clotrimazole	Cruex Lotrimin AF Mycelex[a]	1% cream, lotion, lozenges/troches	C	OTC and Rx
Econazole	Spectazole	1% cream	C	Rx
Ketoconazole	Nizoral Nizoral AD	1% and 2% cream and shampoo[b]	C	Rx and OTC
Miconazole	Micatin Monistat-Derm Lotrimin AF Zeasorb AF Vusion[c]	2% cream, lotion, powder, spray powder, spray liquid	C	Rx and OTC
Oxiconazole	Oxistat	1% cream, lotion	B	Rx
Sertaconazole	Ertaczo	2% cream	C	Rx
Sulconazole	Exelderm	1% cream, solution	C	Rx
Allylamines				
Naftifine	Naftin	1% cream, gel	B	Rx
Terbinafine	Lamisil AT	1% cream, gel, spray solution	B	OTC
Benzylamines				
Butenafine	Mentax Lotrimin Ultra	1% cream	B	Rx and OTC
Polyenes				
Nystatin	Bio-Statin Mycostatin Nystop Pedi-Dri	100,000 U/g cream, lozenge/troche, ointment, powder, solution	C[d]	Rx
Other Topical Antifungals				
Ciclopirox olamine	Loprox Penlac	0.77% cream or lotion, 1% shampoo or solution, 8% nail lacquer	B	Rx
Tolnaftate	Equate (Wal-Mart) Tinactin	1% cream, powder, spray powder, spray solution, solution	N/A	OTC
Undecylenic acid	Elon Dual Defense[e] Sally Hansen No More Fungus Fungi-Nail	25% cream, 25% liquid	N/A	OTC
Combination Agents				
Clotrimazole-betamethasone dipropionate	Lotrisone	1% clotrimazole and 0.05% betamethasone dipropionate in cream or lotion	N/A	Rx
Nystatin-triamcinolone acetonide	Mycolog II	100,000 U/g nystatin and 0.1% triamcinolone acetonide	N/A	Rx

N/A = not applicable; OTC = over-the-counter agent; Rx = prescription agent.
[a]Only troches; only sold as branded drug available by prescription.
[b]Recently developed 2% gel (Xolegel™) and 2% foam (Extina™) are approved for seborrheic dermatitis only.
[c]Combination ointment of miconazole nitrate (0.25%), zinc oxide (15%), and white petrolatum (81.35%) with indication for diaper dermatitis complicated by candidiasis.
[d]Varying pregnancy class depends on form; majority of forms are Category C.
[e]Contains also tea tree oil and grapefruit seed extract.

TABLE 219-2
Properties of an Ideal Topical Antifungal Agent

- Broad spectrum of action
- Fungicidal at therapeutic concentration
- Absence of resistance within the targeted fungi
- Keratinophilic with penetration of the cornified envelope without systemic absorption
- Nonirritating and hypoallergenic
- Possess anti-inflammatory properties
- Once-per-day application (or less)
- Short duration of therapy for cure
- Availability in multiple formulations (cream, solution, etc.) and sizes
- Inexpensive

TABLE 219-3
Indications for the Use of Topical Imidazoles

- Dermatophytoses
  - Tinea pedis/tinea manum
  - Tinea cruris
  - Tinea corporis
  - Tinea faciei (the unbearded face)
- Pityriasis versicolor
- Mucocutaneous candidiasis[a]
  - Cutaneous candidiasis
  - Vulvovaginal candidiasis[b]
  - Oral candidiasis (thrush)[c]
  - Perlèche
- Seborrheic dermatitis[d]

[a]Oxiconazole and sulconazole have relatively weaker activity against *Candida*.
[b]Clotrimazole, econazole, miconazole, terconazole, and tioconazole are available as vaginal preparations.
[c]Clotrimazole-dissolving troches are used for oral thrush.
[d]Ketoconazole is used for seborrheic dermatitis, and this includes newer formulations using a foam- or gel-based vehicle (see Table 219-1).

and histamine release from mast cells.[6–8] Some agents, such as ketoconazole, yield anti-inflammatory effects equivalent to 1% hydrocortisone.[9] Topical imidazoles also demonstrate limited antibacterial properties, particularly with respect to Gram-positive organisms.[10,11]

PHARMACOKINETICS

All marketed imidazoles demonstrate excellent penetration of the stratum corneum with strong keratinophilic behavior. Sulconazole may be detected in the stratum corneum up to 96 hours after application.[12] Similarly, sertaconazole, the newest of all marketed imidazoles, has a half-life within the stratum corneum of more than 60 hours.[13] Because of this high affinity for keratin, systemic absorption of imidazoles is low, with urinary excretion usually in the range of 0.3%–1.0% of the applied dose. Even when applied to inflamed skin, absorption of imidazoles does not usually exceed 4% of the applied dose. Again, sulconazole is unique in that percutaneous absorption in the range of 8%–11% of the applied dose exceeds that of all other imidazoles.[12]

INDICATIONS

Indications for topical imidazole use are detailed in Table 219-3. Because of inherent antibacterial activity, some topical imidazoles have demonstrated modest efficacy in treating erythrasma, impetigo, and ecthyma. Because there are more potent antibacterial agents, this is *not* a preferred indication for imidazole use.[9,14,15]

Cure rates for superficial fungal infection treated with imidazoles are variable and often depend upon study design. For example, topical miconazole has demonstrated a 63%–100% cure rate, depending upon the study quoted. A thorough review of the literature provides no compelling evidence that significant differences in cure or relapse exist among the various topical imidazoles; however, other considerations may dictate selection of a particular imidazole.

Topical imidazoles are available as a cream or lotion. Although lotions are better suited for use over large areas or upon hair-bearing skin, limited studies suggest a cream may be marginally more effective. In studies performed by the manufacturer, oxiconazole cream yielded a clinical and mycologic cure in 52% of tinea pedis cases while the lotion yielded the same cure in just 41% of cases. Additionally, the potential for irritancy must be considered. In one study of topical clotrimazole for treatment of tinea cruris, erosive reactions developed in 4 of 27 patients while sulconazole did not cause any erosions in the same population.[16] Similarly, in a second study, severe irritant reactions were reported with miconazole use but not with sulconazole use.[17] Until formal studies of irritancy are performed, we often recommend use of sulconazole in sensitive areas such as the groin. Finally, ease of use may be a factor to consider, as some imidazoles are specifically approved for once-daily dosing (see Section "Dosing Regimen").

DOSING REGIMEN

Topical imidazoles are available in a multitude of forms (see Table 219-1). Econazole, ketoconazole, and oxiconazole are approved for once-daily dosing but twice-daily dosing is recommended for the remainder. Nevertheless, although twice-daily dosing is recommended for sulconazole, a study comparing once-daily to twice-daily dosing in tinea corporis and tinea cruris reported an identical rate of cure.[16] This might have been predicted based upon the 60-hour half-life within the stratum corneum.[13] Application of all topical antifungals, including imidazoles, should include normal skin for a radius of 2 cm beyond the affected area. Duration of treatment with imidazoles has varied. In general, tinea corporis and tinea cruris require treatment for approximately 2 weeks, whereas tinea pedis may require treatment for up to 4 weeks.[18] Treatment should be continued for at least 1 week after all symptoms have abated.[19]

TABLE 219-4
Adverse Reactions to Topical Antifungals

- Irritant contact dermatitis (worsened by occlusion)
- Allergic contact dermatitis (to active agent or more likely to other ingredients/preservatives)
- Urticarial reactions (rare)
- Inappropriate treatment due to misdiagnosis (more likely with over-the-counter agents)

RISKS AND PRECAUTIONS

Risks associated with the use of topical imidazoles include those inherent to all topical medications (Table 219-4), and consist chiefly of irritant and allergic reactions. Additionally, clotrimazole is marketed in combination with the topical glucocorticoid, betamethasone dipropionate. It was assumed that the addition of the steroid would more rapidly relieve inflammation, scaling, and pruritus. Early studies demonstrated the combination was indeed more effective than clotrimazole alone in alleviating symptoms.[20,21] However, betamethasone dipropionate is a potent topical steroid, and striae and other cutaneous side effects from the steroid component may occur.[22] Longer term studies also reported a higher relapse rate (36%) with the combination product.[23,24]

This combination product may comprise 50% or more of antifungal prescriptions by primary care providers, compared to less than 7% among dermatologists.[25] It is likely that overuse by nonspecialists occurs because of the mistaken assumption either that the steroid agent is mild, or that the combination will be a "better choice" when the differential diagnosis is unresolved.[26] The US Food and Drug Administration has twice revised the product warnings for clotrimazole-betamethasone dipropionate, discouraging use on thin skin, for prolonged periods, or when the diagnosis is in doubt.

COMPLICATIONS

Use of topical imidazoles is associated with few complications. Because of low systemic absorption, drug reactions with topical imidazoles are rare. Nevertheless, in a single study, increased serum tacrolimus levels were observed in renal transplant recipients who used clotrimazole troches for mucocutaneous candidiasis.[27] For this reason, use of nystatin may be preferred when treating thrush in transplant patients using tacrolimus.

Concerns of resistance must also be considered. Resistance of *Candida albicans* to clotrimazole has been described in human immunodeficiency virus-positive patients with mucocutaneous candidiasis.[28] Low levels of in-vitro resistance of various *Candida* species to other topical imidazoles has also been documented.[29] Often, this resistance is associated with resistance to oral fluconazole.

ALLYLAMINES AND BENZYLAMINES

Allylamines and benzylamines are closely related compounds. Currently, two topical allylamines and single topical benzylamine are marketed in the United States (see Table 219-1).

MECHANISM OF ACTION

Allylamines and benzylamines share impede synthesis of ergosterol through inhibition of squalene epoxidase, an enzyme that converts squalene to squalene oxide.[30] Depletion of ergosterol results in membrane instability and hyperpermeability. Allylamines and benzylamines are considered fungicidal because the accumulation of intracellular squalene leads directly to cell death. The clinical significance of this cidal action is unclear. Unlike imidazoles, the activity of allylamines and benzylamines is independent of the cytochrome P_{450} enzyme system. When compared to naftifine, terbinafine demonstrates a 10–100-fold increased potency in vitro, although this does not appear to be relevant in clinical use.

Like imidazoles, allylamines, and benzylamines demonstrate anti-inflammatory activity.[6,31] Naftifine inhibits adhesion of polymorphonuclear cells to endothelium, interrupts chemotaxis, and inhibits the 5-lipoxygenase proinflammatory pathway.[32,33] It is assumed that terbinafine and butenafine yield anti-inflammatory effects through similar mechanisms. Allylamines and benzylamines also demonstrate limited antibacterial properties. A recent study showed lowered minimum inhibitory concentrations for both bacteria and fungi when terbinafine was used in combination with benzoyl peroxide.[34]

PHARMACOKINETICS

Allylamines and benzylamines are highly lipid soluble and efficiently penetrate the stratum corneum, where they may persist for extended durations.[35] Butenafine has been detected within the stratum corneum at minimum inhibitory concentration for at least 72 hours after application,[36] and terbinafine may persist at a similar level for up to 7 days after application.[37] Systemic absorption of these agents is quite low, with typical urinary excretion in the range of 3%–5% of the applied dose.[37]

INDICATIONS

Indications for the use of topical allylamines and topical benzylamines are detailed in Table 219-5. Despite antibacterial properties, terbinafine has proven inferior to mupirocin for treatment of impetigo,[38] and a traditional antibacterial agent should be used. Similarly, although allylamines and benzylamines do demonstrate activity against fungi involved in systemic infection, such as *Sporothrix schenckii*, *Blastomyces dermatitidis*,

TABLE 219-5
Indications for the Use of Topical Allylamines and Benzylamines

- Dermatophytoses
  - Tinea pedis/tinea manum
  - Tinea cruris
  - Tinea corporis
- Tinea faciei (the unbearded face)
- Pityriasis versicolor[a]

[a]Although butenafine is approved by the US Food and Drug Administration for use in pityriasis versicolor, the availability of numerous, more cost-effective remedies limits use in this clinical situation.

and *Histoplasmosis capsulatum*, topical therapy is inappropriate.

Limited evidence suggests that topical allylamines or benzylamines may be preferred over topical imidazoles for certain dermatophyte infections. Some trials for tinea pedis indicate that 1 week of topical terbinafine is as effective as 4 weeks of topical imidazoles, with cure resulting in 53%–95% of cases.[39–42] Use of this abbreviated treatment with terbinafine has been confirmed in trials using the active agent versus vehicle alone.[43] In some instances, resolution of tinea pedis using terbinafine has occurred with as few as three doses.[44]

Generic terbinafine 1% cream is more expensive than an equivalent amount of clotrimazole 1%,[45] but considering the frequency of application, the amount of medication required, the likelihood of patient compliance and ease of use, and the rapidity of results, some experts recommend topical terbinafine over topical imidazoles for tinea pedis.[46–48]

DOSING REGIMEN

Topical allylamines and benzylamines are available in a number of forms (see Table 219-1). Each agent has a slightly different dosing regimen based upon the formulation and the location and severity of infection (Table 219-6).

RISKS AND PRECAUTIONS

Risks associated with use of topical allylamines and benzylamines are those inherent to all topical medicaments (see Table 219-4).

COMPLICATIONS

A recent case report highlighted a possible interaction between topical terbinafine and acenocoumarol, and speculated this might be due to high protein binding of terbinafine, with displacement of the anticoagulant,[49] but this is likely exceptional; complications arising from use of topical allylamines or benzylamines are few.

POLYENES

Polyenes were among the first agents discovered to possess specific antifungal properties. The two major topical polyene antifungals are nystatin and amphotericin B. Only topical nystatin is actively marketed in the United States (see Table 219-1).

MECHANISM OF ACTION

Like all polyenes, nystatin binds irreversibly to membrane sterols present in susceptible species of *Candida*.[50] The polyene molecules demonstrate a higher affinity for fungal sterols, including ergosterol, than for human sterols, yielding imperfect selective toxicity. This irreversible binding alters membrane permeability, causing leakage of essential intracellular components and fungal death. In low concentrations, nystatin

TABLE 219-6
Recommended Use of Topical Allylamines and Benzylamines

	Recommendations	
Agent	**Frequency of Application**	**Duration of Application**
Naftifine	Cream—once daily Gel—twice daily	General instructions for use 2 weeks beyond resolution of symptoms
Terbinafine	Tinea pedis (interdigital)—twice daily Tinea pedis (plantar)—twice daily Tinea elsewhere—once or twice daily	At least 1 week At least 2 week At least 1 week, up to 4 weeks
Butenafine	Tinea pedis—once to twice daily Tinea elsewhere—once daily Pityriasis versicolor—once daily[a]	At least 1 week if twice daily, and at least 4 weeks if once daily At least 2 weeks At least 2 weeks

[a]Although butenafine is approved by the US Food and Drug Administration for use in pityriasis versicolor, the availability of numerous, more cost-effective remedies limits use in this clinical situation.

is fungistatic, but, at high concentrations, it may be fungicidal.[51]

PHARMACOKINETICS

Nystatin is insoluble in water and is not absorbed from intact skin, the gastrointestinal tract, or the vagina.[52]

INDICATIONS

Topical nystatin is used to treat mucocutaneous candidiasis caused by *C. albicans*, and other susceptible species such as *C. parapsilosis*, *C. krusei*, and *C. tropicalis*. Repeated studies have demonstrated that topical imidazoles are more effective than nystatin in treating vulvovaginal candidiasis, and use of nystatin for this indication has diminished in recent years.[53,54] Nystatin is not effective against dermatophytes or *Pityrosporum*; and hence, it is not indicated for treatment of tinea or pityriasis versicolor.

DOSING REGIMEN

Nystatin is available as a powder, cream, ointment, suspension, and pastille. To treat oral candidiasis (thrush), the suspension or pastille is used four to five times daily, usually for 2 weeks. To treat cutaneous infection, the powder, cream, and ointment are used twice daily for approximately 2 weeks.

RISKS AND PRECAUTIONS

Risks associated with use of topical nystatin are those inherent to all topical medicaments (see Table 219-4). A significant number of cases of allergic contact dermatitis attributed to nystatin alone have been reported. These reactions have been reported with topical and oral use.[55,56] Anaphylaxis has been described with use of nystatin-containing vaginal suppositories but the reaction was attributed to ingredients other than nystatin.[57]

A combination agent consisting of nystatin and triamcinolone acetonide is widely marketed. The addition of triamcinolone may provide additional benefit over nystatin alone during the first few days of treatment when inflammation is maximal.[58] After this initial period, the manufacturer recommends a transition to nystatin alone or to other topical antifungal agents. Although triamcinolone acetonide is only a midpotency agent, cutaneous sequelae, including striae, skin atrophy, and steroid-induced acne, have been reported.[59] Because candidiasis often involves thin and fragile skin, such as that of the intertriginous areas, the risk of damage is likely potentiated. Finally, many of the combined formulations contained, or may still contain, ethylenediamine, a sensitizer that may cause allergic contact dermatitis.[60] As with clotrimazole-betamethasone dipropionate, the combination agent of nystatintriamcinolone acetonide is more often prescribed by nondermatologists.

COMPLICATIONS

Complications with topical polyenes are few. Nystatin resistance may be encountered in some *Candida* sp.[61,62] This resistance may either be seen in wild strains (primary type) or it may be induced during therapy (secondary type). Although *C. albicans* maintains a low rate of spontaneous resistance to nystatin,[63] particularly in comparison to resistance to imidazoles,[64] other species, such as *C. tropicalis*, *C. guilliermondi*, *C. krusei*, and *C. stellatoides*, rapidly acquire resistance upon exposure to nystatin.

OTHER AGENTS

Some topical antifungals, such as ciclopirox olamine, tolnaftate, and undecylenic acid, do not fit well into the major classes and are instead discussed separately.

CICLOPIROX OLAMINE

Ciclopirox olamine is a hydroxypyridone antifungal agent with a unique structure and mode of action.

MECHANISM OF ACTION. Unlike most other topical antifungals, ciclopirox olamine does not interfere with sterol synthesis.[65] Instead, it interrupts active membrane transport of essential cellular precursors, particularly trivalent cations.[66] Ultimately, this disrupts cellular function, leading to demise of the fungus. If concentrations of the drug are high enough, the membrane integrity of the fungus may actually be impaired.

Ciclopirox olamine also has inherent anti-inflammatory activity exerted through inhibition of prostaglandin and leukotriene synthesis within polymorphonuclear cells.[67] Broad-spectrum antibacterial properties have also been attributed to ciclopirox olamine. In one study, topical ciclopirox olamine had broader coverage against Gram-positive and Gram-negative organisms than did topical imidazoles or topical allylamines.[68]

PHARMACOKINETICS. When applied to the skin, ciclopirox olamine remains in high concentration within the epidermis and upper dermis. Ciclopirox olamine penetrates keratin easily, with cadaveric skin demonstrating concentrations in the epidermis that were 10–15 times the minimum inhibitory concentration for a sensitive species.[67] This ability to penetrate keratin recommends use for onychomycosis, as the drug is also capable of penetrating the nail plate material.[69] Studies of drug metabolism have demonstrated that, with typical use, approximately 10% of the administered dose is excreted in the urine.[70]

INDICATIONS. Ciclopirox olamine is indicated for the treatment of dermatophytoses and onychomycosis, candidiasis, pityriasis versicolor, seborrheic dermatitis, and even cutaneous infections with unusual saprophytes.[71] In tinea pedis, a mycologic cure rate of up

to 85% has been observed, and in seborrheic dermatitis, a significantly larger percentage of users had >75% improvement with 2 weeks of use than those using the shampoo vehicle alone.[72,73]

Although treatment with ciclopirox olamine for tinea pedis and seborrheic dermatitis has yielded results on par with other modalities, use in onychomycosis has met with more modest success. Often, an assessment of efficacy depends upon whether a mycologic cure (culture-negative) or clinical cure (a disease-free nail) defines success.[74] Although a disease-free nail is often the patient's true goal, ciclopirox olamine achieved such a response in just 5.5%–8.5% of those treated with a standard 48-week course.[74,75] Two recent trials demonstrated increased efficacy when using oral terbinafine in combination with topical ciclopirox olamine, as opposed to oral terbinafine alone.[76,77] Debate regarding the use of ciclopirox olamine as an independent or adjunct treatment for onychomycosis is ongoing.

DOSING REGIMEN. Ciclopirox olamine is available in a wide range of forms (see Table 219-1). Cutaneous candidiasis, dermatophytoses, and pityriasis versicolor should be treated twice daily for 2 weeks to 1 month, but treatment for tinea pedis should continue 1 month or longer. When using ciclopirox shampoo for seborrheic dermatitis, treatment may continue twice weekly for an indefinite duration. Improvement is generally noted in 2–4 weeks. Finally, in treating onychomycosis, the nail lacquer is applied daily to the nail and hyponychium for 48 weeks and excess medication is removed weekly with alcohol.

RISKS AND PRECAUTIONS. Risks associated with use of topical ciclopirox olamine are those inherent to all topical medicaments (see Table 219-4). Allergic contact dermatitis has been reported only rarely, and ciclopirox olamine is considered a weak sensitizer.[78] In patients with an allergic reaction to ciclopirox, imidazoles may be used with relative safety because of a markedly different chemical structure.

COMPLICATIONS. Serious complications with topical ciclopirox olamine are few.

OLDER AGENTS

Tolnaftate and undecylenic acid are older agents now available only in over-the-counter products (see Table 219-1). Repeated studies have now demonstrated that they are approximately equal in efficacy,[79,80] and that both are less efficacious than topical imidazoles, allylamines, benzylamines, and ciclopirox olamine. Additionally, tolnaftate is ineffective for treating candidiasis. Topical tolnaftate and topical undecylenic acid share the same risks and precautions inherent to all topical medications (see Table 219-4). Additionally, topical forms of undecylenic acid may yield an unpleasant "fishy smell" that further discourages use. Both agents are considered less efficacious than imidazoles.

TOLNAFTATE

Tolnaftate is a thiocarbamate first developed in the 1960s but now contained only in over-the-counter antifungal remedies.

MECHANISM OF ACTION. The precise mechanism of action for tolnaftate is unknown. It is thought to impair ergosterol synthesis via inhibition of squalene epoxidase but in a different manner than that of allylamines and benzylamines.[80] Tolnaftate may be fungistatic or fungicidal, depending upon the concentration. No antibacterial properties have been attributed to tolnaftate.

PHARMACOKINETICS. Little data exists regarding the pharmacokinetics of tolnaftate. Like other topical antifungals, systemic absorption is assumed to be negligible from a clinical standpoint.

INDICATIONS. Tolnaftate is indicated for the treatment of dermatophytosis and pityriasis versicolor. Early studies demonstrated a cure rate for tinea pedis as high as 73 percent to 93 percent, but later studies demonstrated lower efficacy, essentially equivalent to undecylenic acid.[77,81] Although direct comparisons are lacking, topical tolnaftate is widely considered less effective than topical imidazoles, allylamines, and benzylamines. Tolnaftate is ineffective for candidiasis.

DOSING REGIMEN. Tolnaftate is available in a variety formulations (see Table 219-1). Twice-daily use for at least 2 to 4 weeks, and up to 6 weeks on hyperkeratotic skin, is recommended. To diminish the incidence of recurrence, others simply recommend treatment be continued 2 weeks beyond apparent resolution.

RISKS AND PRECAUTIONS. Risks associated with use of topical tolnaftate are those inherent to all topical medicaments (see Table 219-3). Allergic contact dermatitis has been reported on occasion.[82,83]

COMPLICATIONS. Serious complications with use of topical tolnaftate are few.

UNDECYLENIC ACID

MECHANISM OF ACTION. Despite more than 60 years of use, the mechanism of action for undecylenic acid is largely unknown. It appears that the organic acid interacts with components in the fungal cell wall. In *C. albicans,* the inhibition of germ tube formation has been recently identified, and a similar effect has been noted in conidia formation in *Trichophyton rubrum.*[84,85]

PHARMACOKINETICS. Undecylenic acid is available as a zinc, calcium, or copper salt. As tissue pH rises, this salt fails to dissociate, and the antifungal properties of the medication diminish.[86] The acid is practically insoluble in water, but is miscible in ethanol, water, or ether. With topical use, systemic absorption is

negligible. The zinc contained in the zinc undecylenate form, the most common in clinical use, provides some astringent action that may aid in reducing rawness and irritation.

INDICATIONS. Topical undecylenic acid is used for the treatment of dermatophytosis and candidiasis. Although early studies indicated a cure rate in excess of 80 percent, subsequent studies demonstrated cure rates of 53 percent or less.[87] Undecylenic acid and its salts are widely considered less effective than miconazole, clotrimazole, or tolnaftate in the treatment of tinea pedis.

A trial of topical undecylenic acid for herpes labialis demonstrated a decreased incidence and duration of viral shedding, with a decrease in pain and tenderness.[88] The antiviral effect was of short duration and most pronounced when acid was applied during the prodrome. Other long chain alcohols enjoy specific approval for abbreviation of herpes labialis and appear more effective.[89]

DOSING REGIMEN. Undecylenic acid and its salts are available as a powder, aerosol, cream, and solution. Standard dosing for children and adults is twice-daily for 4 weeks of use.

RISKS AND PRECAUTIONS. Risks associated with use of topical undecylenic acid are those inherent to all topical medicaments (see Table 219-3). Allergic contact dermatitis has been recently reported, and a protocol for patch testing exists if such an allergy is suspected.[90] Topical forms of undecylenic acid may yield an unpleasant "fishy smell" that discourages use.

COMPLICATIONS. Complications with topical undecylenic acid are few. Because undecylenic acid is widely accepted to be less effective than imidazoles, clinical monitoring for treatment failure is indicated.

FUTURE DEVELOPMENTS

Amorolfine is a morpholine derivative unapproved for use in the United States. Elsewhere in the world, it is approved for use as a 5% nail lacquer. Amorolfine is fungicidal against most dermatophytes, yeasts, and some molds. With 6 months of biweekly use, amorolfine 5% nail lacquer resulted in complete cure in up to 54% of patients.[91] Side effects were similar to those of ciclopirox nail lacquer. Also, similar to ciclopirox olamine, a recent study using amorolfine lacquer and oral terbinafine in combination resulted in a significantly higher cure rate and lower cost per patient cured.[92] In the future, approval of amorolfine in the United States may be pursued.

Benzoxaboroles, derivatives of boronic acid, represent a burgeoning new class of topical antifungal agents. The most explored of these compounds, 5-fluoro-1,3-dihydro-1-hydroxy-2,1-benzoxaborole (AN2690), inhibits an aminoacyl–transfer RNA (tRNA) synthetase that catalyzes attachment of the correct amino acid to corresponding tRNA during translation of the genetic code, blocking protein synthesis.[93] The active agent penetrated well the nail plate when applied in an ethanol/propylene glycol vehicle, leading to considered use in onychomycosis.[94] Future discovery with regard to this new class of antifungal agents is anticipated.

CONCLUSIONS

Because of relatively low cost, acceptable efficacy, ease of use, and low potential for side effects, complications, or drug interactions, topical antifungals are preferred for most superficial fungal infections of limited extent. Alternatively, use of a systemic agent is justified when a superficial fungal infection covers a large surface area, involves terminal hair or nails, or has proven recalcitrant to prior topical management. Imidazoles provide a reasonable balance of efficacy and affordability and are indicated for treatment of dermatophytoses, mucocutaneous candidiasis, and pityriasis versicolor. Despite higher cost, allylamines and benzylamines may be advantageous in some cases of tinea pedis, due to shorter treatment courses. Ciclopirox olamine is a topical antifungal with a unique mechanism of action and a broad range of indications. Topical nystatin is useful in treating mucocutaneous candidiasis, but is ineffective for dermatophyte infections. Use of tolnaftate and undecylenic acid is decreasing due to lower efficacy compared with other available agents. New topical agents for treatment of onychomycosis are being pursued.

Chapter 220 :: Topical and Intralesional Cytotoxic Agents

:: Aieska De Souza, Megan M. Moore, & Bruce E. Strober

TOPICAL CYTOTOXIC AGENTS AT A GLANCE

- Topical and intralesional cytotoxic agents are effective in the treatment of skin cancers and inflammatory and infectious dermatologic conditions.
- They aim for maximum efficacy against cutaneous targets while sparing normal tissue and minimizing systemic toxicity.
- They comprise 5-fluorouracil, nitrogen mustard, carmustine, vinblastine, bleomycin, methotrexate, podophyllin, and miltefosine.

5-FLUOROURACIL

MECHANISM OF ACTION AND FORMULATIONS

Topical 5-fluorouracil (5-FU) has been used in clinical practice since the 1960s. It is a structural analogue of thymine that blocks DNA synthesis by inhibiting thymidylate synthetase (Table 220-1). Topical 5-FU is commercially available as a 0.5% cream carried in a microsphere vehicle, as a 1% solution or 1% cream, as a 2% or 5% solution, and as a 5% cream. The solution can also be used for intralesional injection.

INDICATIONS

5-FU 5% cream has been approved by the US Food and Drug Administration (FDA) since 1970 for the treatment of actinic keratoses in any location and superficial basal cell carcinomas; 5-FU 0.5% cream is FDA approved for treatment of actinic keratoses of the face and anterior scalp. 5-FU is used twice daily until an inflammatory response is seen, usually 2–4 weeks. The 0.5% cream can be used once daily. 5-FU may also be a useful adjunct before cryosurgery of actinic keratoses.[1] Pretreatment with a keratolytic agent, prolonged therapy, more frequent applications, or the use of occlusive dressings may increase therapeutic response.

TREATMENT CONSIDERATIONS

Irritation during treatment sometimes requires reduction or interruption of treatment and the addition of emollients or topical corticosteroids to help quell brisk inflammation. A number of approaches to decrease irritation have been devised; whether or not efficacy is preserved is disputed.[2] Weekly pulse dosing involves applying the medication for 1–2 days per week for 6–7 weeks. Use of the 0.5% 5-FU cream with microsphere vehicle may allow for a more tolerable irritation profile.[3]

During 5-FU treatment, previously subclinical actinic keratoses, basal cell carcinomas, and squamous cell carcinomas may become apparent and respond to treatment. A systematic review of 13 randomized controlled trials on the effectiveness of 5-FU for the treatment of actinic keratoses demonstrated that about 50% of patients obtain complete clearance after treatment and an overall reduction of 80% in lesion count can be expected.[1] However, about two-thirds of patients will require retreatment after 1 year. Histological cure rates for superficial basal cell carcinomas after 5-FU treatment are between 90% to 93%; however, it is not recommended in nodular and high-risk, basal cell carcinomas since the drug does not seem to control deeper tumor growth,[4] and there is a possibility that treatment can mask the persistence or recurrence of basal cell cancer.

Verrucae vulgaris, verrucae plana, plantar warts, and condylomata acuminata have been treated with varying response rates with topical and intralesional 5-FU. Additionally, actinic cheilitis, mucosal leukoplakia, radiodermatitis, Bowen disease, Bowenoid papulosis, and erythroplasia of Queyrat have all been reported to respond to treatment with topical 5-FU. Further, there are reports of the successful treatment of both psoriasis and keratoacanthomas with topical and intralesional 5-FU,[4] and of infantile digital fibromatosis treated with intralesional 5-FU.[5] Combined use of ablative Er:Yag laser and topical 5-FU is an effective treatment option for giant keratoacanthomas if surgery is contraindicated.[4] Intralesional 5-FU has also been reported to be effective in the treatment of keloids and hypertrophic scars.[6,7] Controversial results have been observed with treatment of nail psoriasis with 5-FU: one trial demonstrated a 25% reduction in pitting and hyperkeratosis in twenty patients with nail psoriasis treated with 1% 5-FU solution for 6 months,[4] while a second randomized, double-blind study failed to demonstrate difference between the treatment group and placebo.[4] Vitiligo patients may benefit from the combination of dermabrasion and 5% 5-FU cream, or 5-FU alone under occlusive dressings.[4]

The systemic absorption of topically applied 5-FU is limited, with absorption selectively greater from abnormal skin than from surrounding normal skin. Microsphere-based formulations may retain 5-FU at

TABLE 220-1
Topical and Intralesional Cytotoxic Agents Used in Dermatology: Mechanism of Action, Formulation, Main Indications, and Common Side Effects

Drug	Mechanism of Action	Formulations	Indications	Common Side Effects
5-fluorouracil	Blockage of DNA synthesis by inhibition of thymidylate synthetase	0.5% cream (microsphere vehicle) 1%, 5% cream 1%, 2%, 5% solution Intralesional injection	Actinic keratoses Superficial basal cell carcinomas	Local irritation, erythema, pain, swelling, pruritus, dyspigmentation, allergic contact dermatitis, photosensitivity
Mechlorethamine (nitrogen mustard)	Alkylating activity, immune stimulation	Compounded: 0.01%–0.04% aqueous solution, ointment	Mycosis Fungoides Stages IA, IB	Irritant or allergic contact dermatitis, immediate-type hypersensitivity, secondary cutaneous malignancies, dyspigmentation
Carmustine	Alkylation agent: inhibits DNA, RNA, and protein synthesis	Compounded: solution or ointment 10 mg or 20 mg/dL	Mycosis fungoides Stages IA, IB	Myelosupression, leukopenia, erythema, skin tenderness, and telangiectasia
Vinblastine	Antimitotic agent: acts by disrupting microtubules, blocking cell division in metaphase	Intralesional injection: 0.1–0.6 mg/mL in saline solution	Kaposi sarcoma	Local pain, hyperpigmentation Rarely: mononeuropathy, transient flu-like syndrome
Bleomycin	Disrupts DNA synthesis and causes scission of DNA strands	Intralesional injection: 1 U/mL solution	Viral warts, hemangiomas, keloids and hypertrophic scars	Local pain and swelling
Methotrexate	Antimetabolite: interferes with DNA synthesis (inhibition of dihydrofolate reductase)	Intralesional injection: 5–75 mg	Keratoacanthoma	Hematologic toxicity, hepatotoxicity, nausea, abdominal pain, oral aphthae, reversible alopecia, pancytopenia
Podophyllin	Binds tubulin, disrupting the cellular cytoskeleton	0.5% ethanol 0.15% cream	Anogenital warts Facial angiofibromas	Erythema, erosions, tenderness
Miltefosine	Cytotoxic: promotes phospholipid turnover and modulates membrane signal transduction by inhibition of protein kinase C	6% solution	Cutaneous metastases of breast cancer Cutaneous lymphomas Cutaneous mastocytosis	Local: burning, erythema, and fine scaling

the target site, with less drug reaching the systemic circulation.[8] Rarely, systemic effects of 5-FU include nausea and anorexia, stomatitis, diarrhea, myelosuppression, alopecia, and cardiac and neurologic toxicity. Side effects of the topical preparation include local irritation, erythema, pain, swelling, pruritus, dyspigmentation, allergic contact dermatitis, and photosensitivity. Unusual reactions may include onycholysis, onychodystrophy, and the appearance of telangiectasias. The use of injectable preparations may be complicated by pain, local ulceration, erosion, desquamation, and dyspigmentation.[6]

MECHLORETHAMINE (NITROGEN MUSTARD)

MECHANISM OF ACTION AND FORMULATIONS

Mechlorethamine [methyl-*bis* (2-chloroethyl) amine hydrochloride] was the first nitrogen mustard (NM) to be used in clinical medicine. Mechlorethamine acts as an alkylating agent and is not cell-cycle specific;

however, its greatest effect is on cells in the late G1 or S phases. The primary target of mustard is the 7-nitrogen atom of guanine. The main role of topical NM in dermatology is in the treatment of the patches and plaques of cutaneous T-cell lymphoma (CTCL). The utility of NM in treating mycosis fungoides (MF), the most common type of CTCL, was first described in 1959. The topical activity of NM has been attributed not only to its alkylating activity, but also to its potential for immune stimulation. The delayed-type hypersensitivity reaction induced by nitrogen mustard is mediated by Th1-type response, while the malignant T-cells in MF express Th2-type cytokines. The contact hypersensitivity reaction can potentially stimulate malignant T-cells to shift from Th2 to Th1-type cytokine expression and activity leading to apoptosis of the malignant T-cells and tumor regression.[9]

Mechlorethamine hydrochloride (Mustargen) is available in powder form, 10-mg per glass vial. Topical NM is prepared as either an aqueous solution or an ointment preparation. A variety of ointment bases can be used, including Aquabase®, Aquaphor®, hydrophilic petrolatum, a 50/50 mixture of liquid paraffin-white soft paraffin, and white soft paraffin.[10] Aqueous solutions can be made to desired concentrations by dissolving the NM powder in tap water (one vial of 10-mg powder dissolved in 100-mL water yields a 10 mg% concentration). The solution is unstable and should be applied immediately to the skin using a sponge or cloth. Ointment preparations can be compounded by pharmacists.[9] Nitrogen mustard compounded in Aquaphor® formulations showed higher stability than in Transcutol®, Labrasol®, and Aquaphilic® ointments. However, a significant increase in stability can be obtained when the free radical inhibitor BHT (butylated hydroxytoluene) is added to Transcutol® or Labrasol® formulations.[10]

With either preparation, concentrations of 10–20 mg% are generally used and are applied daily, with increases in concentration and frequency of application pending clinical response. One approach is to apply the preparation to the entire body (sparingly to intertriginous sites, and excluding the genitalia) initially to avoid missing areas of subclinical involvement and thus theoretically increase the potential for cure.[10] Alternatively, treatment may be limited to only clinically affected areas. Treatment should be continued daily until complete response is attained. The benefit of a prolonged maintenance period in preventing disease relapse has not been shown.[9] With proper application, there is minimal contamination of the surrounding environment, but those assisting in the application of the drug should limit their exposure and wear protective gloves. Effort should be made to dispose of empty vials or unused solution in accordance with Environmental Protection Agency guidelines.

INDICATIONS

Many large retrospective series support the use of topical NM in MF. NM has been reported to produce complete response rates of 67%–80% for MF patients with limited patch/plaque disease (stage IA) and 35%–68% for patients with generalized patch/plaque (stage IB) disease.[9] Relapses are common even with the continuation of therapy.[11] The efficacy of aqueous and ointment-based preparations is similar.[9] Topical NM as primary monotherapy has limited use in patients with tumor stage or erythrodermic disease.[9] Topical NM has also been used in the treatment of psoriasis,[12] alopecia areata,[13] and histiocytosis X.[14]

TREATMENT CONSIDERATIONS

Unlike the systemic preparation, there are no reports of systemic side effects following topical NM application. Furthermore, topical NM has been used safely in pediatric patients.[9] Local side effects include irritant or allergic contact dermatitis, immediate-type hypersensitivity, secondary cutaneous malignancies, and dyspigmentation. Irritant contact dermatitis is generally mild and resolves with reduction in concentration and/or frequency, or with topical steroid treatment. Allergic contact dermatitis has been reported to develop in up to 35%–66% of patients on long-term treatment with aqueous NM and in fewer than 10% of those using the ointment preparation.[9] If hypersensitivity occurs, patients may be treated with dilutions below the threshold for clinically observable contact dermatitis. However, delayed-type hypersensitivity may be of therapeutic benefit. Twice-weekly dosing of topical NM in combination with betamethasone cream may offer a balance of tolerability and efficacy.[15] Up to 8% of patients may develop an urticarial immediate-type hypersensitivity to topical NM, often necessitating treatment discontinuation. Changes in pigmentation may also occur secondary to use of topical mechlorethamine. Hyper- and hypopigmentation are prone to develop in areas of previous CTCL and tend to resolve spontaneously, although slowly.

There have been reports of secondary cutaneous malignancies developing in patients treated with NM, including basal and squamous cell carcinomas, keratoacanthomas, and isolated reports of lentigo maligna and primary melanoma.[9] It is difficult to determine causality in these cases, as many of these patients were treated with multiple therapies, including known carcinogenic therapies such as psoralen and ultraviolet A phototherapy and radiation.

BLEOMYCIN

MECHANISM OF ACTION AND FORMULATIONS

Bleomycin is a cytotoxic antibiotic produced by *Streptomyces verticillatus*. Bleomycin disrupts DNA synthesis and causes scission of DNA strands by causing oxidative damage to the deoxyribose of thymidylate and other nucleotides.[19] The result is an arrest in cell cycle with subsequent apoptosis and leakage of intracellular components, triggering the innate immune response. Individual eosinophilic keratinocytes with small dark

pyknotic nuclei, subepidermal and intraepidermal hemorrhage, and neutrophil accumulation with formation of microabcesses in the granular layer can all be observed after bleomycin injection.[19] Bleomycin also has a sclerosant effect on endothelial cells. In dermatology, intralesional bleomycin has largely been used in the treatment of recalcitrant viral warts.[21]

Bleomycin is available as a powder (Blenoxane). It should be reconstituted with sterile saline to the desired concentration, generally 1 U/mL solution. Stability in this formulation has been shown at 6–8 weeks if the preparation is refrigerated at 4°C (39.2°F), and for several months if stored at –20°C (–4°F). Drug uptake can be greatly increased by the combination with local anesthetics such as lidocaine, procaine, dibucaine, butacaine, and tetracaine, since local anesthetics can disrupt cell membrane structure.[19] Proper injection is indicated by the blanching of the skin.

INDICATIONS

There have been no large, randomized, double-blind, placebo-controlled studies of intralesional bleomycin treatment of viral warts, however smaller studies have demonstrated its efficacy. A study comparing intralesional bleomycin with cryotherapy showed significantly higher clearance rates for patients treated with bleomycin injection (94.9%) when compared to cryotherapy (76.5%).[22] A paired, controlled study of intralesional bleomycin 1 U/mL injected intralesionally until blanching in resistant warts in 38 patients reported a 77% cure rate for warts on extremities; however, the rate fell to about 48% for plantar warts.[23] To overcome the problem of adequate infiltration of the wart without unwanted infiltration of normal skin, various approaches, including repeated pricking of the wart,[21] the use of bifurcated needles,[24] and pretreatment with pulsed dye laser,[25] have been described. An uncontrolled study of 70 patients with plantar, palmar, mosaic, and periungual warts treated monthly with "pricking" of 1 U/mL bleomycin solution using a Monolet needle reported a 92% success rate.[21]

Multiple prospective studies of vascular malformations and hemangiomas treated with intralesional bleomycin have reported significant reduction in the size of lesions in approximately three-fourths of patients.[19] Imaging with magnetic resonance to evaluate the extent of soft tissue and bone involvement is indicated before any injections are made. A reduced dose of bleomycin should be used in children: 0.2–0.4 mg/kg diluted in normal saline.[19] Successful treatment of keloids and hypertrophic scars[26] has been reported in several case series, with complete regression in one-half to three-fourths of cases. A small, randomized, controlled trial and open-label prospective study have described the benefit of topical 1% bleomycin in dimethylsulfoxide in treating oral leukoplakia.[27] Isolated case reports and small series have reported benefit from topical bleomycin ointment in treating recurrent Paget disease of the vulva[28] and from intralesional bleomycin in treating keratoacanthomas.[29]

TREATMENT CONSIDERATIONS

Bleomycin has relatively low toxicity. Flu-like symptoms have been reported after intralesional use, but significant systemic toxicity is rare. Pulmonary fibrosis has been well described in association with systemic bleomycin chemotherapy but is dose related. Local side effects of pain and swelling are common with intralesional use. Combinations of bleomycin and lidocaine may reduce the pain associated with injection, but children may require general anesthesia for treatment. Local injection for periungual warts may result in permanent nail loss or dystrophy.[30] Raynaud phenomenon, dyspigmentation, ulceration, cellulitis, and superficial scarring may also occur.[24,31] There is a case report of flagellate hyperpigmentation after intralesional injection of bleomycin.[32] Contraindications include Raynaud phenomenon, peripheral vascular disease, pregnancy, and nursing.[19]

METHOTREXATE

MECHANISM OF ACTION AND FORMULATIONS

Methotrexate (MTX) is an antimetabolite that interferes with DNA synthesis through inhibition of dihydrofolate reductase. MTX also alters the metabolism of adenosine, an endogenous anti-inflammatory mediator.[33]

INDICATIONS

In multiple case reports[34] and small case series,[35] intralesional methotrexate has been used to effectively treat solitary, giant, and eruptive keratoacanthomas, demonstrating up to 92% complete response rate.[35] The proposed mechanism of action is the cessation of thymidylate synthesis by inhibition of dihydrofolate reductase in the rapidly dividing tumor cells, with consequent blockage of DNA synthesis.[34] Intralesional MTX should be considered as a treatment option for biopsy-confirmed keratoacanthomas located in aesthetically important areas or for which surgery is contraindicated.[34] Injection parameters have included total doses from 5–75 mg, in 1 to 5 injections, with single doses ranging from 5–50 mg, and intervals of 1–2 weeks between injections. Leakage of roughly 50% of the injection dose is expected due to poor cohesion between tumor cells. In a review of 38 cases treated with MTX, the clearance rate was 83% with an average cumulative dose of 38.2 mg and injections spaced 12–38 days apart.[35]

TREATMENT CONSIDERATIONS

Methotrexate has well-studied adverse effects, including hematologic toxicity, hepatotoxicity, nausea, abdominal pain, oral aphthae, and reversible alopecia. Pancytopenia has been reported in two patients after

receiving a single 25-mg dose of intralesional MTX. Both patients had renal failure and were hemodialysis dependent.[35] Caution is warranted when using methotrexate in patients with renal insufficiency, advanced age, hepatic disease, or the concomitant use of medications that may interfere with its excretion.[34] Pregnant or breastfeeding patients must be excluded. Injections have been reported to be generally well tolerated, with moderate pain and minimal scarring.

PODOPHYLLIN AND PODOPHYLLOTOXIN

MECHANISM OF ACTION AND FORMULATIONS

Podophyllin is a crude resin derived from either the American mandrake, *Podophyllum peltatum*, or the Indian podophyllum, *P. emodi*. Podophyllotoxin is an extract of podophyllin with antineoplastic and antiviral activity. Podophyllotoxin binds tubulin disrupting the cellular cytoskeleton, blocking mitosis and arresting the cell cycle at G2.[36]

Podophyllin is produced as a 10%–40% ethanolic or benzoin crude extract. Composition is not standardized, and the most potent active ingredient, podophyllotoxin, rapidly crystallizes out, leading to a short shelf life.

INDICATIONS

In dermatology, topical podophyllin and podophyllotoxin are used in the treatment of anogenital warts. A recent report describes the successful use of podophyllin 25% extract in benzoin tincture for treatment of facial angiofibromas of tuberous sclerosis in a 27-year-old female. Most of the lesions regressed after 3 monthly applications.[37]

TREATMENT CONSIDERATIONS

Podophyllin should be applied under medical supervision with a protective inert ointment to surrounding skin and washed off 4–6 hours after application. Treatment is generally at weekly intervals.[38] Podophyllotoxin, the purified active ingredient of podophyllin, is available as 0.5% ethanol and 0.15% cream formulations. These preparations are to be self-applied in one or several 3-day cycles.[38] Self-treatment with podophyllotoxin has been shown to be more effective and more cost effective compared with podophyllin applied in the clinic, although relapse rates are high with both treatments.[39] Systemic toxicities—including central nervous system and respiratory depression—have been reported after excessive podophyllin treatment of large anogenital warts, subdermal injection, or accidental ingestion, and podophyllin is reported to have mutagenic potential.[38] Local side effects, such as erythema, erosions, and tenderness, are common with both podophyllin and podophyllotoxin. Scarring or depigmentation rarely occurs. Given reports of the low efficacy, high toxicity, and mutagenicity profile of podophyllin, some authors have urged that it be removed from clinical treatment protocols and replaced by podophyllotoxin or other treatments.[38]

MILTEFOSINE (HEXADECYLPHOSPHOCHOLINE)

MECHANISM OF ACTION AND FORMULATIONS

Miltefosine (hexadecylphosphocholine) is a cytotoxic alkyl phosphocholine that exerts its effects on the cell membrane. Miltefosine promotes phospholipid turnover and modulates membrane signal transduction, including inhibition of protein kinase C. Miltefosine is considered to be a prototype lipid raft modulator. The compound inhibits anti-IgE induced histamine release from human skin mast cells. In addition, miltefosine significantly attenuated the allergic sensitization in the model of ovalbumin-induced delayed-type hypersensitivity in mice.[40] Miltefosine is available as a 6% solution in a defined mixture of three short-chain glycerol ethers that increases penetration (Miltex).

INDICATIONS

Miltefosine has shown promise as a treatment for cutaneous metastases from breast cancer and CTCL. In a phase II trial of milfetosine in 12 patients with CTCL, the response rate was 58% with a median duration of response of 12 months.[41] However, limited skin penetration, local metabolism, and clearance via dermal blood vessels may interfere with efficacy. There are also isolated reports of the successful use of miltefosine in the treatment of cutaneous metastases of squamous cell carcinoma.[42] Milfetosine was found to be effective in treating cutaneous mastocytosis, with significant reduction of mast cell number in the upper dermis.[43] Furthermore, the compound modulates T-cell function in models for Th1 and Th2 related activity,[40] suggesting that it can be used for the treatment of T-cell-related allergic diseases.

TREATMENT CONSIDERATIONS

Application in clinical trials and case series is generally daily for a week, then twice daily thereafter. Miltefosine 6% solution applied in this manner showed modest efficacy against cutaneous metastases of breast cancer in a randomized, double-blind, placebo-controlled, multicenter trial.[44]

When administered systemically, miltefosine causes significant gastrointestinal toxicity. However, systemic side effects, such as nausea, vomiting, and anorexia, have rarely been observed with topical application.[43] Local skin reactions are common, including burning, erythema, and fine scaling, but rarely necessitate discontinuation of therapy.

Chapter 221 :: Topical Immunomodulators

:: Edward M. Esparza & Robert Sidbury

Topical immunomodulators are nonsteroidal agents that target the immune system for therapeutic effect in the skin. The macrolactams, pimecrolimus and tacrolimus, act as anti-inflammatory agents by binding immunophilin and inhibiting cytokine production. The imidazoquinoline amine, imiquimod, induces interferon (IFN) production and enhances immune responses, although several more potent analogs are under clinical investigation.

MECHANISM OF ACTION

TOPICAL CALCINEURIN INHIBITORS

Intracellular signaling pathways are tightly controlled to maintain immune homeostasis. The nuclear factor of activated T cells (NFAT) family of transcription factors has emerged as a central regulator in immune signaling pathways that control lymphocyte activation and cytokine production.[1] In the absence of receptor-mediated, calcium-dependent signaling, NFAT is sequestered in the cytoplasmic compartment in an inactive, phosphorylated state (Fig. 221-1). Signaling pathways emanating from antigen receptors induce calcium-dependent activation of calcineurin, which removes the phosphorylation from NFAT that leads to nuclear translocation and upregulation of proinflammatory gene expression. Tacrolimus and pimecrolimus turn off inflammation by interacting with FK-506 binding protein (FKBP). This drug-protein interaction prevents calcineurin from dephosphorylating NFAT, thereby inhibiting its nuclear translocation.[2] The pleiotropic effects of calcineurin inhibitors include decreased T-cell proliferation and reduced inflamma-

TOPICAL CALCINEURIN INHIBITORS: PIMECROLIMUS AND TACROLIMUS AT A GLANCE

- Topical nonsteroidal anti-inflammatory agents.
- US Food and Drug Administration approved for the short-term and intermittent long-term therapy of atopic dermatitis in patients older than 2 years.
- Approved in Europe for twice weekly prophylactic therapy for atopic dermatitis in patients older than 2 years.
- Extensively studied with an excellent record of short-term safety and efficacy when used appropriately.
- Burning and stinging at the application site is the most common adverse event occurring in 10%–40%.
- Theoretical risk of systemic immunosuppression and malignancy has resulted in the addition of a postmarketing, black-box warning label.
- Widespread off-label use has been discouraged until long-term safety is more definitely established.

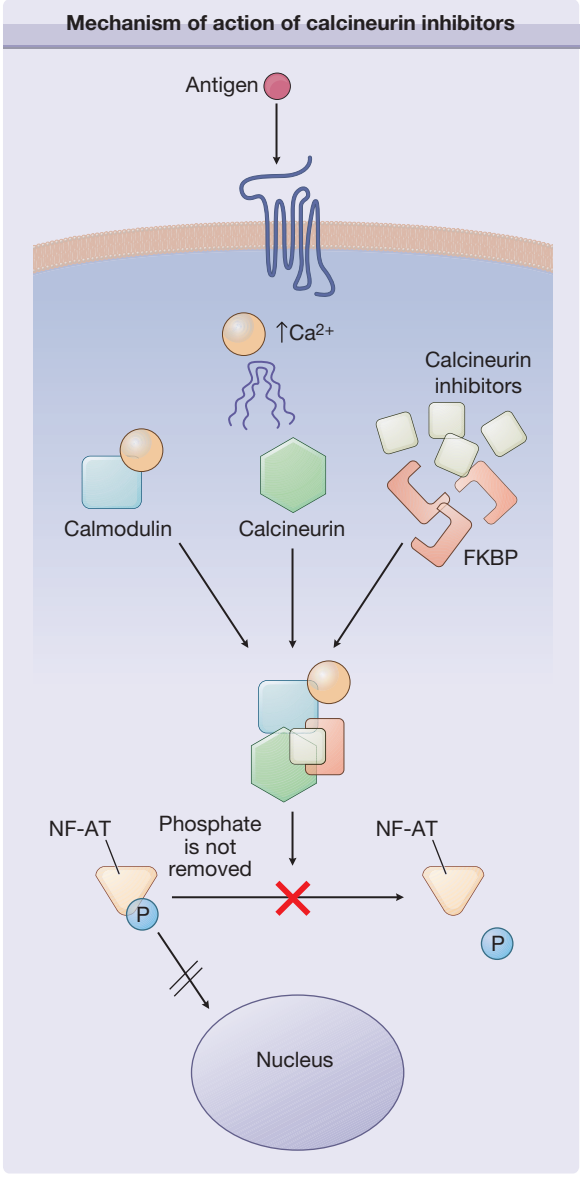

Figure 221-1 Mechanism of action of calcineurin inhibitors. Ca = calcium; FKBP = FK-506 binding protein; NF-AT = nuclear factor of activated T cells.

tory cytokine production of interleukin-2 (IL-2), IL-3, IL-4, IL-12, tumor necrosis factor, and IFN-γ.

Compared to cyclosporine, tacrolimus is 10–100 times more potent, has lower molecular weight, and penetrates the skin better. These enhanced pharmacological properties of tacrolimus provided a basis for experiments demonstrating topical inhibition of contact hypersensitivity and subsequent development as an ointment for treating atopic dermatitis.[3,4] With topical tacrolimus therapy, more than 70% of patients have had moderate-to-excellent improvement in 3-week controlled trials, and 30%–40% have had greater than 90% improvement.[5] In general, response to topical tacrolimus has been best observed in treating thinner skin areas such as the face and neck. During remissions, dosing may be reduced in frequency, but flares occur with discontinuance. Response is slow (over days to weeks), often incomplete on extremities (especially hands and feet), and in patients with lichenified lesions. Roughly 25% of patients, especially those with the most severe disease, do not have a satisfactory therapeutic response. Additionally, patients should realize that exacerbations of atopic dermatitis may occur and require occasional intervention with topical or systemic corticosteroid therapy. The main advantage of topical tacrolimus is the provision of chronic maintenance therapy without the need for continuous topical corticosteroids. Koo et al demonstrated up to 91% reduction in affected body surface area in a study of nearly 8,000 adults and children using topical tacrolimus for up to 18 months without significant adverse events.[6] Other long-term studies with tacrolimus have specifically shown no evidence of cutaneous atrophy, little or no increased infectious risk other than a slightly increased rate of herpes simplex virus in some trials, hypertension, renal toxicity, or cumulative blood levels in patients older than 2 years of age.[7]

Adverse effects have been primarily an intense burning and itching in 30%–40% of patients at application sites, especially in areas of flaring, excoriation, and erosion.[5,7,8] These symptoms usually subside in a few days, in concert with healing of the skin. However, some patients continue to have bothersome burning, and this effect seems to be more prominent when the skin is exposed to heat such as during summer weather, or in baths or hot tubs. In general, these problems with burning sensations seem to be less in children. Up to 10% of adults experience symptoms of flushing with alcohol ingestion.[9] Both acneiform and rosaceiform eruptions have been observed in conjunction with tacrolimus and pimecrolimus use and should be monitored.[10–12] Other common side effects include flu-like symptoms and headache.[3]

Infections have not been a notable problem in tacrolimus-treated patients.[3,5,7] Occasional staphylococcal skin infections occur, but they are no worse than before treatment, and studies actually demonstrate a reduction in *Staphylococcus aureus* colonization during prolonged therapy. In spite of the theoretical concern about immunosuppression, there have been no significant increases in frequency or severity of warts, varicella, or molluscum contagiosum infections. Some cases of eczema herpeticum have been noted in clinical trials, but the risk of this complication may also stem from underlying atopic dermatitis.

Immunosuppression with systemic calcineurin inhibitors is known to raise the relative risk of post-transplant lymphoproliferative disorder and ultraviolet light-induced cutaneous carcinomas in transplant patients, which carries theoretical concern for malignancy with long-term use of topical formulation of the same agents. A smattering of postmarketing reports of lymphoma or malignancy in patients using topical tacrolimus and a biologically plausible risk related to TCI use were the major factors in the US Food and Drug Administration (FDA) calling for a black-box warning label. Recently, a case-control study evaluated the association between topical immunosuppressants and lymphoma in a cohort of patients with atopic dermatitis and found no increased risk of lymphoma with the use of TCIs.[13] Extensive review of the case reports by independent oncologists and allied task forces has

not found evidence of an increased risk of lymphoma or other malignancy.[14–16] However, predisposition to malignancy may require several years of constant immunosuppression. Therefore, close surveillance is indicated if TCIs are used chronically.

In addition to the concerns about hematologic malignancy, there have been reports of pigmented neoplasms in association with TCI use. In a case series of three patients, focal pigmented lesions developed where TCIs were used that were confirmed histologically to represent lentigines.[17] Similarly in our experience, lentigines have arisen at the location of TCI use. The implication of these cases is whether chronic TCI use predisposes to melanoma. There has been a case report of rapid growth of melanoma develop in a child during the course of treating vitiligo with topical tacrolimus.[18] Although this remains an isolated case report, it would be prudent to counsel patients to use sun protection while using TCIs. Furthermore, the utility of self-surveillance of changing moles and thorough clinical skin examination should be discussed when using TCIs.

Pimecrolimus has a similar structure to tacrolimus and interacts with the same FKBP to inhibit calcineurin activation of NFAT.[19] However, clinical efficacy is less than that of tacrolimus as reflected by decreased protein-binding affinity, which necessitates a higher drug concentration in the topical medication.[7] Topical pimecrolimus also appears to have little systemic immunosuppressive effect, which may reflect a wider margin of safety. Clinical trials have included infants as young as 3 months of age, although FDA approval has been limited to 2 years of age and older. A recent study of 76 infants and children revealed sustained benefit without significant adverse effect with pimecrolimus therapy for 2 years.[20] Two patients in the study developed eczema herpeticum. As with tacrolimus, occasional postmarketing reports of lymphoma and malignancy moved the FDA to affix the black-box warning label to the entire class of medication, but these concerns remain at present theoretical.[16] Blood levels have been detected in occasional patients, but no high or prolonged levels have been detected. Initial studies of oral pimecrolimus were promising, but, in the wake of the black-box controversy, development has been suspended.

IMIQUIMOD

Imiquimod is unique in that it appears to enhance both acquired and innate immune function (Fig. 221-2).

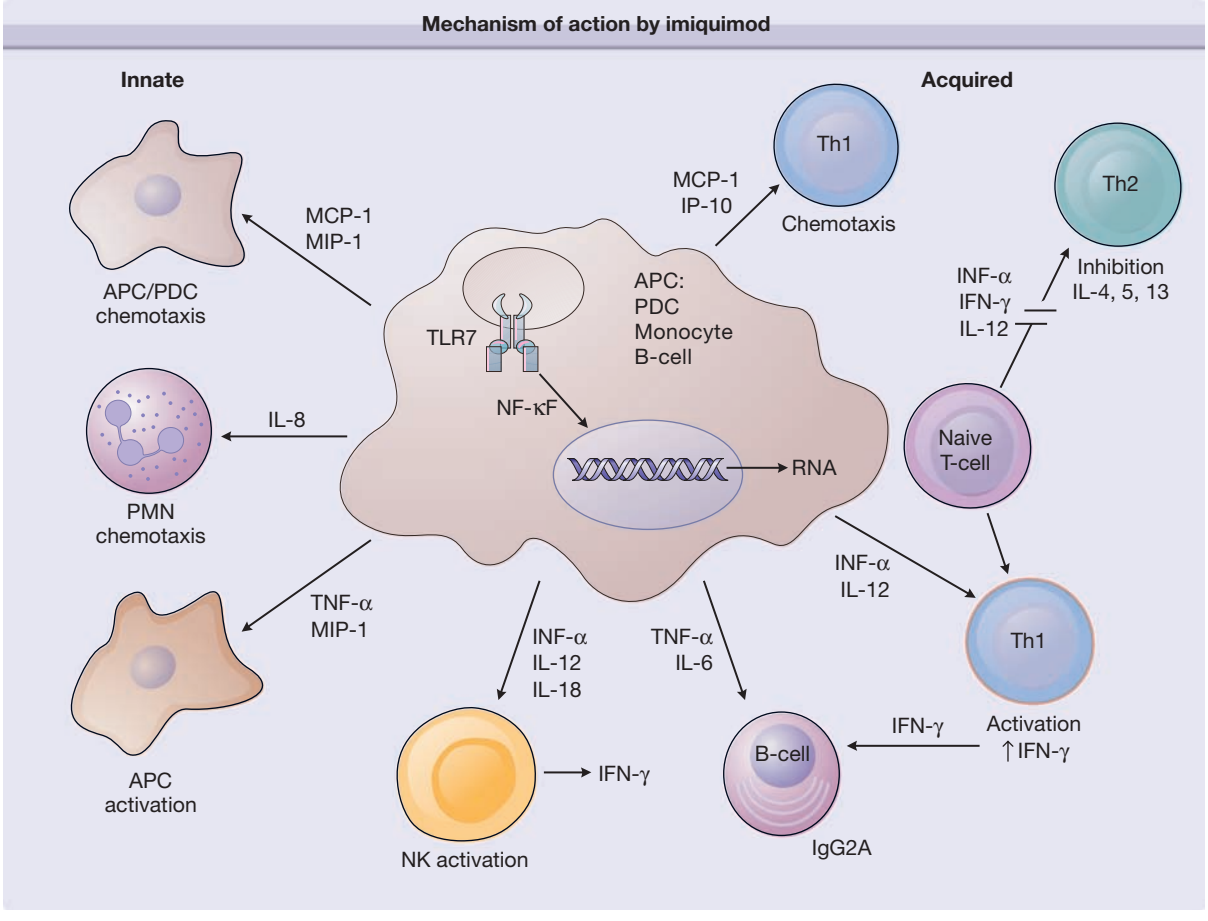

Figure 221-2 Mechanism of action by imiquimod. APC = antigen-presenting cell; IFN = interferon; IgG2A = immunoglobulin G2A; IL = interleukin; IP-10 = interferon-inducible protein 10; MCP-1 = macrophage chemoattractant protein 1; MIP = macrophage inflammatory protein; NF-κB = nuclear factor κB; NK = natural killer cell; PDC = peripheral dendritic cell; PMN = polymorphonuclear neutrophil; Th = T helper; TLR = Toll-like receptor; TNF-α = tumor necrosis factor-α.

IMIQUIMOD AT A GLANCE

- Topical immunotherapy indicated for anogenital warts, superficial basal cell carcinoma, and actinic keratosis.
- Small molecule immune response modifier in the imidazoquinoline family.
- Induces heterogeneous, immune-mediated responses including antiviral, antitumoral, antiangiogenic, and vaccine adjuvant activity.
- Targeted therapy that results in production of the inflammatory cytokines tumor necrosis factor-α and IFN-γ, thereby enhancing cell-mediated immune response.
- Application site stinging and irritant contact dermatitis are the most common adverse events.

Topically applied imiquimod induces local cytokine production from keratinocytes and other cells.[21,22] Imiquimod acts as an agonist of the Toll-like receptor (TLR)-7 and -8-mediated signaling cascades, resulting in the secretion of proinflammatory cytokines, such as IFN-α and IFN-γ, tumor necrosis factor-α, IL-1, IL-1 receptor antagonist, IL-6, IL-10, IL-12, granulocyte colony-stimulating factor, granulocyte-monocyte colony-stimulating factor, and the chemokines IL-8, macrophage inflammatory protein 1α, and monocyte chemotactic protein 1.[23,24] Imiquimod also stimulates the innate immune response by increasing natural killer cell activity, activating macrophages and Langerhans cells, and inducing proliferation and maturation of B lymphocytes. Additionally, imiquimod has direct proapoptotic activity on tumor cells.

Imiquimod has been shown to be an effective treatment for anogenital warts. A 16-week study of 311 immunocompetent adults with external anogenital warts compared three times weekly 5% imiquimod cream, 1% imiquimod cream, and placebo.[25] Clearance was achieved in more than 70% of women and 30% of men with the 5% cream and with both strengths significantly better than placebo. Response rates greater than 30% have been seen in uncircumcised males treated under the foreskin, suggesting that increased moisture may account for this gender discrepancy. Similarly, local factors may account for lower response rates in nongenital warts. The primary benefit of imiquimod cream relative to other available wart therapies is ease of administration. In adults, home therapy for genital warts is preferred, given the sensitive nature of this problem. Likewise in children, genital warts may be a result of sexual abuse (although in the minority of younger children), and an atraumatic topical therapy that can be rapidly applied in a nonthreatening environment is ideal. Recurrence rates following use of imiquimod cream have ranged from 13%–19%.[25]

In vitro evidence of antitumor effects formed the basis for evaluation of imiquimod in the treatment of cutaneous neoplasms. A multicenter, randomized, open-label dose-response trial showed an almost 90% histologic clearance rate of superficial basal cell carcinoma (BCC) when 5% imiquimod cream was applied daily for 6 weeks. Twice daily application led to an improved response rate but a higher incidence of local skin reactions.[26] Geisse et al subsequently reported that two phase III double-blind, randomized, vehicle-controlled trials showed histologic clearance of 82% with five times weekly treatment.[27] Daily therapy was no more effective, and response was positively correlated with signs of inflammation, including erythema, erosion, and crusting. These studies formed the foundation for using imiquimod to treat small, superficial BCC in low-risk locations such as the trunk and extremities. These are anatomical sites that may tolerate the lower cure rates better than more cosmetically sensitive areas.[23] The use of imiquimod as monotherapy in this context was endorsed by a recent systematic review.[28]

Imiquimod has also been approved as a treatment for actinic keratosis of the head and neck. Hadley et al recently reviewed the use of imiquimod for actinic keratoses. In five randomized controlled trials lasting 12–16 weeks involving 1,293 patients, complete clinical clearance was seen in 50% of imiquimod patients versus 5% using vehicle. Adverse events were significantly higher in imiquimod-treated groups, including erythema (27%), crusting/scabbing (21%), flaking (9%), erosion (6%), edema (4%), and weeping (3%).[29] Lower potency imiquimod preparations (2.5, 3.75%) are currently under development for the treatment of head and neck AKs. These compounds theoretically permit increased frequency of use without prohibitive application site reaction, while also allowing a greater surface area to be treated. Early safety and efficacy trials are promising.[30]

Although not yet clinically indicated as an antiangiogenic agent, imiquimod has demonstrated antiangiogenic properties in vitro and in a series of case reports. The antiangiogenic properties of imiquimod stem from the production of antiangiogenic cytokines, including IFN-γ, IL-10, and IL-12; the upregulation of endogenous antiangiogenic mediators, including tissue inhibitor of matrix metalloproteinase; and downregulation of the proangiogenic factors, basic fibroblast growth factor, and matrix metalloproteinase 9.[31] In a mouse model of hemangioendothelioma, imiquimod application resulted in fewer and smaller tumors.[32] Numerous clinical reports have noted clinical response treating vascular neoplasms, including hemangiomas of infancy and pyogenic granulomas.[33–36] Ongoing clinical trials are further defining the role of imiquimod in the treatment of various vascular lesions.[37]

Derived from its antiviral effects, imiquimod has been used successfully to treat molluscum contagiosum. In an observer-blinded, randomized trial of 74 children, imiquimod resulted in slower clearance with higher expense, but was tolerated with less pain and improved cosmesis when compared to liquid nitrogen.[38] There have been few cases in which imiquimod

was effective in treating granuloma annulare when used for 6–12 weeks.[39,40] Whether the efficacy is the result of proapoptotic effects of imiquimod remains to be determined. While not intended to be exhaustive, other published off-label uses of imiquimod include treating extramammary Paget disease, scar cosmesis, low-grade vulvar intraepithelial neoplasms, dysplastic nevi, lentigo maligna, ecthyma contagiosum, porokeratoses, and lymphomatoid papulosis.[41–47] These off-label uses of imiquimod await confirmation and precise dosing recommendation from randomized clinical trials.

Adverse effects relate primarily to cutaneous irritation at the application site, leading to moderate erythema and erosion in roughly one-third and one-tenth of patients, respectively. Studies suggest that both the response rate, particularly in males, and the likelihood of side effects will increase with daily therapy. Imiquimod is a category C drug, and it is not known to what extent topically applied imiquimod is excreted in the breast milk of nursing mothers. Imiquimod has not been thoroughly studied in children younger than 18 years of age. Imiquimod has been investigated for a variety of other infectious conditions with varying degrees of success.

PHARMACOKINETICS

PIMECROLIMUS AND TACROLIMUS

Tacrolimus ointment, 0.03% and 0.1% applied twice daily, was studied extensively in clinical trials that included adults and children as young as 2 years of age.[2] Pharmacokinetic studies showed low percutaneous absorption initially in 10%–20% of patients with atopic dermatitis, but generally blood levels were undetectable by 1 week as healing and re-establishment of the skin barrier occurred. Rarely were blood levels greater than 2 ng/mL, in contrast with trough levels of 5–15 ng/mL in transplant patients treated systemically with tacrolimus.[5] The notable exception is the use of topical tacrolimus in patients with Netherton syndrome, where blood levels within or above the established therapeutic trough range for oral tacrolimus in organ transplant recipients may be observed.[48]

In an open label study of twice-daily pimecrolimus use in infants ranging in age from 5.7–11.9 months at baseline with moderate-to-severe atopic dermatitis, Lakhanpaul et al found no accumulation of the drug and systemic levels ranging from below the limit of detection to 1.94 ng/mL.[49] There were no significant adverse events over the course of this 1-year-long trial.

IMIQUIMOD

The half-life of systemically administered imiquimod, either oral or subcutaneous, is 2–4 hours in healthy volunteers. The half-life of intravenously administered imiquimod is 14 hours, and less than 1% of the drug is recovered in the urine after a single topical application. The major systemic metabolite of imiquimod, S26704, is a hydroxylation product that achieves plasma concentrations of less than 20% of the parent compound.[50]

BOX 221-1 INDICATIONS FOR USE

PIMECROLIMUS AND TACROLIMUS
- Second-line therapy for atopic dermatitis
- Children older than 2 years
- Adults
- Short-term, noncontinuous chronic therapy

IMIQUIMOD
- External anogenital warts
- Actinic keratosis
- Superficial BCC smaller than 2 cm on trunk, neck, extremities
- Immunocompetent adults
- When surgical options less appropriate
- Biopsy confirmed

Higher levels have been noted with both intravaginal administration in healthy volunteers or systemic administration in chronically ill patients. With topical administration in healthy volunteers, there is very little measurable imiquimod and no detectable S26704.

Imiquimod	5% cream	Anogenital warts Actinic keratosis Superficial BCC	3×/week, Maximum: 16 weeks 2×/week for 16 weeks 5×/week for 6 weeks

FDA = Food and Drug Administration; BCC = basal cell carcinoma.

ing label, initiation of TCI therapy should begin by addressing parental and patient concerns. These agents should be considered second line and are indicated when standard therapy, including topical steroids and emollients, are either ineffective or harmful. Comparisons of these agents with standard therapy have not as yet consistently shown a relative clinical or pharmacoeconomic benefit compared with topical steroids.[51] Once the decision to initiate TCI therapy has been made, consideration must be given to the choice of either pimecrolimus or tacrolimus. Pimecrolimus is available as a 1% cream formulation and is indicated for mild-to-moderate atopic dermatitis. Tacrolimus is available as an ointment in two strengths, 0.03% for children 2–15 years old as an on-label indication, and 0.1% in patients 16 years and older. Topical tacrolimus is indicated for moderate to severe atopic dermatitis. In Europe, the application twice weekly to prevent recurrence at sites of repeated flares is an approved indication; this 2–3 times weekly application to sites of involvement during quiescence has been shown to decrease the requirement for topical steroid use.[52]

Both products have been extensively studied and have excellent safety and efficacy records compared with placebo in the short term. Therefore, patient vehicle preferences and disease severity help determine the appropriateness of either agent for an individual patient. Paller et al found tacrolimus to be more effective than pimecrolimus with a similar side effect profile in three comparison trials.[53]

Pimecrolimus or tacrolimus should be applied sparingly only to affected areas of skin twice daily. The smallest amount of medicine should be used, and therapy should be discontinued where signs and symptoms of redness and itch have resolved for 1 week. Adjunctive therapies, such as emollients, should be continued. If applied after bathing, as often recommended, pimecrolimus or tacrolimus should be applied first to affected areas, and emollients subsequently to unaffected skin. Application site stinging from TCIs may be more severe in areas of excoriation. Efforts to limit these open areas of skin by pretreating for 2–7 days with a topical steroid may improve adherence to therapy.

IMIQUIMOD

Imiquimod should be applied sparingly to affected areas when treating warts or superficial BCC. A broader but circumscribed treatment area is recommended either on the face or scalp, but not both, when treating actinic keratosis. For anogenital warts, initial frequency should be three times weekly. If little or no effect is seen after 2–4 weeks, advancing to daily use may enhance efficacy, although risk of an irritant dermatitis commensurately will increase. Application before sleeping is generally recommended and imiquimod should be left on the skin for 6–10 hours. It should be made clear to patients treating warts that imiquimod therapy does not eliminate the risk of transmission of human papilloma virus to physical contacts. The frequency of application for the treatment of superficial BCC (five times weekly) and actinic keratosis (two times weekly) differs as noted in the Table 221.1.

MONITORING THERAPY

PIMECROLIMUS AND TACROLIMUS

If effective, TCIs may be incorporated into the long-term therapeutic regimen for atopic dermatitis. Prescribing physicians must ensure that patients are using these products intermittently and only to treat active dermatitis. Adverse events, including application site reactions, should be monitored. Patients should be evaluated for cutaneous infections with particular vigilance against eczema herpeticum, which was noted with slightly increased frequency in some premarketing trials. Any evidence of lymphadenopathy should be documented and followed closely. Skin examinations for signs of cutaneous malignancy are prudent. No routine serologic monitoring is indicated; however, if clinical evidence suggests the possibility of systemic immunosuppression, serum levels of tacrolimus or pimecrolimus may be obtained. If blood levels are sought, care must be taken to first remove any residual medication, particularly at the antecubital location, a common site for both venipuncture and atopic dermatitis. Failure to do so may lead to spuriously elevated drug levels. Despite reassuring safety data, the lesson of the black-box controversy is that definitive long-term safety has not been established; and therefore, ongoing vigilance for potential TCI adverse effects, including immunosuppression and malignancy, must continue.

IMIQUIMOD

Imiquimod therapy for warts, if tolerated, should be continued until complete clearance of warts or a maximum of 4 months before declaring a treatment failure. If no response or clinical deterioration is seen at 8 weeks, other therapeutic options should be entertained. If an incomplete response is obtained, continuing therapy may be warranted. Increasing from three times weekly to daily treatment may be indicated if imiquimod is well tolerated. No serologic monitoring is necessary. Irritant reactions may be treated initially by temporary cessation of therapy in addition to or followed by appropriate topical anti-inflammatory intervention. Imiquimod therapy can then be resumed as necessary at a decreased frequency as indicated. Similar principles govern the use of imiquimod for superficial BCC and actinic keratosis, but closer clinical follow-up is indicated.

RISKS AND PRECAUTIONS

(Box 221-3)

BOX 221-3 RISKS AND PRECAUTIONS

PIMECROLIMUS AND TACROLIMUS

- Application site reactions, including itch, burning, stinging, redness, flushing with alcohol
- Avoid use on premalignant or malignant skin conditions, including cutaneous T-cell lymphoma
- Skin infections, including *S. aureus*, dermatophytosis, and herpes simplex
- Lymphadenopathy
- Light exposure, including phototherapy
- Immunocompromised
- Netherton syndrome
- Renal insufficiency
- Pregnancy category C
- Lactation
- Flu-like symptoms
- Worsening acne

IMIQUIMOD

- Erythema, erosion, edema, ulceration, excoriation/flaking
- Hypo- or hyperpigmentation
- Pregnancy category C
- Safety not established in children younger than 12 years old
- Soreness
- Flu-like symptoms
- Myalgia
- Headache
- Multiple treatment courses for superficial BCC or actinic keratosis at same site
- Basal cell nevus syndrome
- Superficial BCC of the head, neck, or anogenital area
- Xeroderma pigmentosum

BOX 221-4 COMPLICATIONS

PIMECROLIMUS AND TACROLIMUS

- Elevated blood levels and risk of systemic immunosuppression
- Unclear long-term risk of lymphoproliferative disease
- Unclear long-term malignancy risk
- Eczema herpeticum

IMIQUIMOD

- Irritant contact dermatitis
- Ulceration
- Incomplete treatment of malignancy

COMPLICATIONS

(Box 221-4)

Chapter 222 :: Other Topical Medications

:: Craig N. Burkhart & Kenneth A. Katz

OTHER TOPICAL MEDICATIONS AT A GLANCE

- Topical medications not sufficiently covered in other sections of this text comprise:
  - Analgetics.
  - Anti-inflammatory agents.
  - Antimicrobial and antiparasitic agents.
  - Antiperspirants, antipruritics, and astringents.
  - Bleaching and keratolytic agents.
  - Topical psoriasis and wart therapies.

This chapter reviews topical therapies not covered elsewhere in the text that are used to treat dermatologic diseases. The topic headings are those of the drug designation of the US Pharmacopeia and at times reflect clinical usage rather than specific pharmacologic mechanisms. All topicals when applied to large areas of skin, particularly in the presence of skin disease or to infants and children, have the potential for systemic side effects.

ANALGESICS

CAPSAICIN

Capsaicin is the molecule that confers the "hotness" to hot peppers of the genus *Capsicum*, including cayenne, jalapeno, and Tabasco peppers.[1] Initial topical application results in itching, pricking, and burning as nociceptor activate. Repeated applications, however, are hypothesized to lead to degeneration of epidermal nerve fibers and nociceptor desensitization, thereby producing hypalgesia.[1]

Topical capsaicin has been used to treat postherpetic neuralgia, diabetic neuropathy, reflex sympathetic dystrophy, Raynaud phenomenon, nostalgia paresthetica, arthralgias, plantar warts, diabetic neuralgia, and hemodialysis-related pruritus.[1] A recent placebo-controlled trial of a high-concentration capsaicin dermal patch showed that the patch significantly reduced postherpetic neuralgia pain with transient application site pain reactions managed effectively with analgesics.[2] Other therapies for postherpetic neuralgia should also be considered.[3]

TOPICAL ANESTHETICS

Numerous topical anesthetics are available.[4] Eutectic mixture of local anesthetics (EMLA) cream contains the sodium-channel-blocking amide anesthetics lidocaine 2.5% and prilocaine 2.5%. Application under occlusion to intact skin or genital mucous membranes for at least 1 hour before performance of a painful procedure, including debridement of venous leg ulcers,[5] can provide local anesthesia that may persist for up to 2 hours. The cream may cause transient local blanching followed by transient local erythema. Like all products containing lidocaine, it should not be used in patients with hypersensitivity to amide anesthetics. Additionally, the prilocaine component has been linked to cases of methemoglobinemia in patients for whom applications exceeded the recommended dose, application area, or application time.[6] Those particularly susceptible to methemoglobinemia include patients who are very young, those with glucose-6-phosphate dehydrogenase deficiency, and those taking oxidizing drugs such as sulfonamides and antimalarials.

Caution regarding dosing should also be used in patients susceptible to systemic effects of lidocaine or prilocaine, including acutely ill, debilitated, and elderly patients. Finally, as EMLA is ototoxic, it should not be used if there is a concern that it could penetrate or migrate beyond the tympanic membrane to the middle ear.

Various topical anesthetic products contain only lidocaine, typically at concentrations of 4% or 5%, which may be applied with or without occlusion. Systemic toxicity from topical lidocaine prepared in a 30% concentration has been reported.[7] In 2007, FDA reported that two women, aged 22 and 25, experienced seizure, coma, and death after using compounded topical formulations of lidocaine and tetracaine, under occlusion, prior to laser hair removal procedures. Cases of arrhythmia and apnea were also reported. Those adverse events prompted FDA to warn the public about potential hazards of use of topical numbing products for cosmetic procedures,[8] and pharmacies against violating regulations in compounding such products.[9]

ANTI-INFLAMMATORY AGENTS

COAL TAR

Coal tar has been used to treat inflammatory dermatoses for up to 2 millennia, although currently it is used primarily to treat psoriasis.[10] Coal tar has been shown to inhibit DNA synthesis and mitosis in epidermal cells, an effect potentiated by ultraviolet A exposure.[11] Coal tar also has anti-infective, antipruritic, photosensitizing, and vasoconstrictive effects and, with

repeated applications, causes epidermal atrophy. The precise mechanism by which it treats inflammatory skin diseases has not been fully described.

In 1925, Goekerman pioneered the concomitant use of coal tar and ultraviolet B therapy for psoriasis.

Coal tar has historically been messy to use, has an unpleasant odor, and can stain clothing, making its use challenging for some. Newer formulations, however, might be better tolerated.[12,13] Systemic adverse effects are uncommon, whereas local adverse effects can include tar folliculitis, acneiform eruptions, irritant dermatitis, burning, and stinging, allergic contact dermatitis, atrophy, telangiectases, pigmentation, exfoliative dermatitis, and keratoacanthomas.[10] Although occupational exposure to coal tar has been associated with increased risk of developing skin cancer, epidemiologic studies of coal tar-treated psoriasis have not demonstrated an increased risk of skin cancer due to coal tar.[14]

WOOD TAR

Produced by distillation of wood under controlled conditions, wood tar can be added to arachis oil (peanut oil) or other bases. The preparation is then typically used to treat scalp psoriasis. Most commonly derived from juniper (oil of cade), wood tar may also be derived from beech, birch, and pine. Contact sensitivity to wood tar has been reported.[15]

SHALE OIL

Shale oil (also referred to as *ammonium bituminosulphonate*, *ichthyol*, *ichthammol*, or *black salve*) is derived from oil shale, a sulfur-rich sedimentary rock. Further processing of extracted shale oil yields light- and dark-colored components. The light component is also referred to as *pale sulfonated shale oil* (PSSO) or *ichthyol pale*.[16] Shale oil decreases inflammation by inhibiting lipoxygenase.[17] A recent trial of PSSO cream for atopic dermatitis showed that it was more effective than vehicle in treating atopic dermatitis.[18] A study of PSSO to treat venous leg ulcers showed that the size of ulcers treated with PSSO gel, compared with vehicle, significantly decreased, although there was no difference in complete epithelialization of granulation of ulcers.[19] PSSO has also been used to treat acne, psoriasis, seborrhea, eczema, rosacea, and pruritus.[16,20]

ANTIMICROBIAL AGENTS

(Table 222-1)

CHLORHEXIDINE

Chlorhexidine gluconate is a bisbiguanide that binds to the stratum corneum, providing sustained bactericidal and fungicidal activity for over 6 hours, even when wiped from the field. Although it does not kill bacterial spores or mycobacteria, it does inhibit their growth. Because it does not lose its effectiveness in the presence of organic material, such as whole blood, it is an important antiseptic, disinfectant, antibacterial dental rinse, and preservative. Due to ototoxicity and the risk of conjunctivitis and corneal ulceration, chlorhexidine is not recommended for preoperative preparation of the face or head.

DYES

Dyes are useful topical treatments because they are inexpensive and chemically and physically stable. The topical antiseptic dyes used in dermatology, gentian violet (methylrosaniline chloride), brilliant green (*p*-diethylamine triphenylmethanol), malachite green, and fuchsine, are all derivatives of triphenylmethane. The dyes are effective against *Candida* species and several aerobic Gram-positive bacteria, including methicillin-resistant *Staphylococcus aureus*. Gentian violet is a known contact sensitizer and may cause skin necrosis in concentrations greater than 2% aqueous solution or when used undiluted in skin folds.[21]

HYDROGEN PEROXIDE

Hydrogen peroxide has been used for a number of years as a cleansing agent and for the removal of debris. It has antibacterial properties against both Gram-positive and -negative bacteria, and its effervescent quality helps débride wounds.

IODINATED COMPOUNDS

Iodine solution is bactericidal, sporicidal, and viricidal. Iodophors are complexes of iodine with a carrier that slowly liberates inorganic iodine on contact with reducing substances. This preserves the antimicrobial activities of iodine without the irritant effects of the free tincture. Iodophors must be applied to dry skin as they are inactivated by contact with blood, serum proteins, and sputum.

POVIDONE-IODINE. Povidone iodine has a wide spectrum of in-vitro activity against Gram-negative and -positive bacteria, fungi, and viruses. Systemic absorption can occur with resultant renal and thyroid dysfunction if large or prolonged quantities are used.

CLIOQUINOL. Clioquinol, 5-chloro-8-hydroxy-7-iodoquinolinol, is weakly antifungal and antibacterial. It is effective alone or combined with a topical steroid to treat inflammatory dermatoses, especially in intertriginous areas. Adverse reactions include a yellowish discoloration on clothing or skin, delayed contact hypersensitivity, and contact dermatitis. In the early 1970s, it was linked to subacute myelo-optic neuropathy in Japan[22] and was banned in many countries, including the United States. This link was questioned by subsequent epidemiologic studies,[23] but product

TABLE 222-1
Topical Antimicrobials and Astringents

Drug	Group	Antibacterial Mechanism	Antimicrobial Spectrum	Major Side Effects or Contraindications	Use (Selected)	US Food and Drug Administration Pregnancy Category
Chlorhexidine	Bisbiguanide	(1) Binds to negatively charged bacterial cell wall and cytoplasmic components leading to altered osmotic equilibrium and (2) precipitation of cytoplasmic components	Gram-positive, Gram-negative bacteria, enveloped viruses, and fungi	Keratitis, ototoxicity	Antiseptic surgical hand scrub and surgical site preparation	B
Gentian violet	Dye	Unknown	Some vegetative Gram-positive bacteria (e.g., *Staphylococcus* sp.) and yeast	Potential skin necrosis at high concentrations or when occluded; stains skin and clothing; tattooing when applied over granulation tissue; mutagenic	Impetiginized eczema; mycotic skin infections; oral candidiasis; superficial skin infections	C
Brilliant green	Dye	Unknown	Similar to gentian violet	Potential skin necrosis; stains skin and clothing	Similar to gentian violet	Not used in Western medicine
Hydrogen peroxide	Peroxide	Oxidizes microbial molecules	Broad spectrum antimicrobial	Avoid in abscesses; bleaches hair	Cleansing of wounds, suppurating ulcers, and local infections	—
Povidone-iodine	Iodophor	Oxidation and release of free iodine	Gram-positive, Gram-negative, enveloped viruses, fungi, sporicidal, *Mycobacterium tuberculosis*	Caution in patients with thyroid disorders; potential systemic toxicity in neonates or when applied to large body surface area; neutralized by blood, serum proteins, and sputum	Antiseptic surgical hand scrub, prevention or treatment of topical site infection associated with surgery, burns, minor cuts/scrapes	C
Clioquinol	Iodophor	Oxidation and release of free iodine; chelates bacterial surface and trace metals needed for bacterial growth	Gram-positive, Gram-negative, enveloped viruses, fungi, sporicidal, *M. tuberculosis*	Possible irreversible optic atrophy and peripheral neuropathy (oral); contraindicated in children <2 years of age; contraindicated for diaper rash; stains skin yellow; neutralized by blood, serum proteins, and sputum	Approved for fungal infections; also used for pyoderma, folliculitis, and impetigo	—

(continued)

TABLE 222-1
Topical Antimicrobials and Astringents (Continued)

Drug	Group	Antibacterial Mechanism	Antimicrobial Spectrum	Major Side Effects or Contraindications	Use (Selected)	US Food and Drug Administration Pregnancy Category
Metronidazole	Imidazole	Creation of reduced intermediate compounds and free radicals	Anaerobes, protozoa, and microaerophilic bacteria	Contraindicated during first trimester of pregnancy	Rosacea	B
Mupirocin	Fermentation product of *Pseudomonas fluorescens*	Inhibits bacterial isoleucyl-t-RNA synthetase	Gram-positive, some Gram-negative, spares normal flora	Potentially toxic amounts of polyethylene glycol contained in vehicle may be absorbed in patients with extensive burns or open wounds	Non-bullous impetigo, eradication of nasal carriage of *S. aureus*	B
Retapamulin	Pleuromatilin	Inhibits 50S subunit of prokaryotic ribosome	Gram-positive	Allergic contact dermatitis [dermatitis 2009]	Non-bullous impetigo	B
Azelaic acid	Dicarboxylic acid	Possibly through inhibition of microbial respiratory chain	*Propionibacterium acnes* and *S. epidermidis*	Hypopigmentation	Acne	B
Benzoyl peroxide	Peroxide	Oxidizes microbial molecules	Broad-spectrum antimicrobial	Bleaches dark clothing	Acne	C
Aluminum salts	Astringent	Coagulation of proteins	Broad-spectrum antimicrobial	Do not use under impervious material to prevent evaporation	Weeping, impetiginized skin disorders	—
Potassium permanganate	Astringent	Oxidizes microbial molecules	Broad-spectrum antimicrobial	Skin discoloration; caustic at high concentrations or with contact of undissolved crystals	Weeping, impetiginized skin disorders	—
Silver nitrate	Astringent	Precipitation of bacterial proteins by free silver ions	Gram-positive and Gram-negative bacteria	Black skin discoloration, caustic at high concentrations; potential methemoglobinemia	Weeping, impetiginized skin disorders, cauterization of wounds, removal of granulation tissue, aseptic prophylaxis of burns	C

labeling still warns of possible irreversible optic atrophy and peripheral neuromuscular disease.

METRONIDAZOLE

Metronidazole is an imidazole with activity against anaerobic bacteria and protozoa that is most often used in dermatology for rosacea. In addition to its antibiotic properties, its mode of action in rosacea may involve the impedance of leukocyte chemotaxis and selective suppression of cellular immunity.

MUPIROCIN

Mupirocin, also known as *pseudomonic acid*, is bactericidal at the concentration achieved with topical application to the skin and mucous membranes. As mupirocin has a unique mechanism of action, in which it prevents the incorporation of isoleucine into proteins by inhibiting bacterial isoleucyl-t-RNA synthetase, there is no cross-resistance with other antimicrobials.[25] It has activity against staphylococci, streptococci, and certain Gram-negative bacteria, but is inactive against much of the normal skin flora. It is the treatment of choice for nonbullous impetigo and the most effective topical antibiotic for the elimination of *S. aureus* nasal colonization.[24]

RETAPAMULIN

Retapamulin is a member of the pleuromatilin class of antibiotics prescribed as a 1% topical ointment. It is bacteriostatic and inhibits the elongation phase of protein synthesis through selective binding to the 50S subunit of prokaryotic ribosomes. It is FDA approved for treatment of methicillin sensitive *S. aureus* and *Streptococcus pyogenes*, but is effective in vitro against isolates resistant to B-lactams, macrolides, quinolones, fusidic acid, and mupirocin.[25]

AZELAIC ACID

Azelaic acid is a naturally occurring aliphatic dicarboxylic acid that is a competitive inhibitor of tyrosinase. Azelaic acid is a reversible inhibitor of cytochrome P_{450} reductase and 5α-reductase in microsomes and a reversible inhibitor of some enzymes in the respiratory chain. In-vitro azelaic acid has antimicrobial affects against *Propionibacterium acnes* and *Staphylococcus epidermidis*. Its efficacy against acne and rosacea is attributed to activity against *P. acnes*, normalization of keratinization, and a direct anti-inflammatory effect.[26]

BENZOYL PEROXIDE

Benzoyl peroxide is a nonspecific bactericidal agent that derives its biologic function through decomposition into benzoyloxy and phenyl radicals that react with numerous constituents of microbial cells. This effect may be enhanced by the addition of antibiotics or other molecules containing tertiary amines or transitional metals. As a topical therapy, benzoyl peroxide is mainly used for acne, although it is also occasionally used to speed healing of chronic wounds. When used for acne, it is frequently combined with topical antibiotics, as such combination therapy may reduce the development of antibiotic resistance by *P. acnes*.[27]

ANTIPARASITIC AGENTS

(See Chapter 208; Table 222-2)

CROTAMITON

Crotamiton (crotonyl-*N*-ethyl-*O*-toluidine) is a colorless or pale yellow oil used in the treatment of scabies, pediculosis capitis, and pruritus. Its mode of action is unknown. Other antiparasitic formulations, such as lindane (see next section) 1% and permethrin cream (see later) 5%, are more effective than crotamiton,[28] which is rarely a sensitizer. It is approved for use in infants and children, but is pregnancy category C.

γ-BENZENE HEXACHLORIDE

γ-Benzene hexachloride, also known as *hexachlorocyclohexane* or *lindane*, is a chlorinated hydrocarbon pesticide that is effective against lice, scabies, and fleas as a 1% lotion or shampoo. Scabies and lice resistant to γ-benzene hexachloride have been reported.[28] Furthermore, multiple side effects of topical application including central nervous system toxicity, seizures, and aplastic anemia have been reported leading to the US Food and Drug Administration recommendation that γ benzene hexachloride only be used as a second-line agent.[29] Patients with seizure disorders, children weighing less than 50 kg, and patients with acutely inflamed or raw skin should avoid γ benzene hexachloride.

MALATHION

Malathion is an organophosphate insecticide that acts by irreversibly binding to acetylcholinesterase.[30] It is approved in the United States as a 0.5% lotion for the treatment of head lice. The lotion, containing 78% isopropyl alcohol, is flammable. Safety for children younger than 6 years of age has not been established, and it is pregnancy category B.

PERMETHRIN

Permethrin is a synthetic pyrethroid modeled after the natural insecticide found in the pyrethrum flower, *Chrysanthemum cinerariaefolium*. It acts on parasitic nerve cell membranes, causing paralysis and death.

TABLE 222-2
Topical Antiparasitic Agents

Treatment	Group or Composition	Mechanism	Major Side Effects or Contraindications	Use	US Food and Drug Administration Pregnancy Category
Permethrin (1% or 5%)	Synthetic pyrethroid	Inhibits nerve cell sodium ion influx	Itching and stinging on application; contraindicated for infants <2 months of age	Lice and scabies; used on clothing as an insect repellant	B
Synergized pyrethrins	Natural botanical	Pyrethrins inhibit nerve cell sodium ion influx; piperonyl butoxide inhibits cytochrome P_{450}	Itching and stinging on application; ragweed or chrysanthemum allergy	Lice	C
Malathion (0.5%)	Organophosphate	Cholinesterase inhibitor	Flammable; not approved for children <6 years of age	Lice	B
Crotamiton (10%)	Crotonyl-*N*-ethyl-*O*-toluidine	Unknown	Poor efficacy	Scabies	C
Lindane (1%)	Organochlorine	Cholinesterase inhibitor	May cause seizures, muscle spasms, aplastic anemia; not for use in children <3 years, pregnant or breastfeeding women, patients with underlying neurologic disorders, or over broken skin	Lice and scabies	C
Spinosad (0.9%)	Fermentation product	Generalized central nervous system excitation leading to paralysis	No major side-effects in preclinical trials	Lice	Not rated

It is available over-the-counter as a 1% cream rinse, which is left on dry hair for 10 minutes. A single application is often effective against head lice and nits. Due to increasing resistance, however, two applications, 7–10 days apart, are generally recommended. There is a lack of safety data for its use in children younger than 2 months of age, and in pregnant and breastfeeding women. Prescription strength permethrin 5% cream is also effective against pediculosis capitis resistant to the 1% cream, pediculosis pubis, scabies, and mite infestations including cheyletiella.[31] The 5% cream is applied to dry skin and hair overnight (8–14 hours).

PYRETHRINS

Pyrethrins are the naturally occurring esters of chrysanthemumic acid. In combination with piperonyl butoxide, it is available as a liquid, gel, oil, aerosol spray, foam, and shampoo. Pyrethrins are neurotoxins, and piperonyl butoxide inhibits pyrethrin metabolism, potentiating the effects of pyrethrins. It is also effective against fleas, mosquitoes, and houseflies. As it is derived from the extract of chrysanthemums, the American Academy of Pediatrics suggests that individuals who are sensitive to chrysanthemums or ragweed should avoid this medication.[32] However, this recommendation is controversial as patch and prick testing of commercially available synergized pyrethrins fail to elicit a response in ragweed-allergic patients.[33] The aerosol spray should never be prescribed to patients with a history of asthma.

SPINOSAD

Spinosad is a fermentation product of the soil bacterium *Saccharopolyspora spinosa* that causes widespread excitation of the insect central nervous system resulting in paralysis. It is being developed as a 0.9% cream rinse for the treatment of head lice. It is both pediculocidal and ovicidal with a 10-minute application.[34]

ANTIPERSPIRANTS

ALUMINUM COMPOUNDS

Aluminum chloride solutions are typically used as a first-line therapy for hyperhidrosis in 15% to 20% solutions in the axilla and up to 30% on the palms and soles.[35] The solution is applied for a week at night, when eccrine glands are less active, and if tolerated up to twice daily. After control is achived, it can be applied every 1–3 weeks as maintenance therapy. Use may lead to irritation.[35]

IONTOPHORESIS

Iontophoresis is a procedure in which current is used to transport ions through the skin.[36] The mechanism by which iontophoresis acts to decrease sweating is not fully understood,[37] although it is hypothesized that ion channels in eccrine glands are reversibly disrupted. In an iontophoretic treatment, a hyperhidrotic area of skin to be treated is covered with lukewarm tap water. Electrodes are then inserted into the water and a direct current delivered, usually at 8–20 amperages. The amperage is increased until a tingling sensation is experienced and applied for 10–20 minutes three to four times weekly. Improvement is typically noted in approximately 2 weeks and full improvement within 1 month. Maintenance treatments once or twice weekly can be helpful thereafter. Anticholinergic agents such as glycopyrronium bromide may be added to the tap water for refractory patients. Adverse effects may include irritation, hyperesthesia, and blisters.[36] Iontophoresis using botulinum toxin type A for treatment of palmar hyperhidrosis has also been reported.[38,39]

ANTIPRURITIC AGENTS

(Table 222-3)

ANTIHISTAMINES

(See Chapter 229.)

DOXEPIN

(See Chapter 229.)

TABLE 222-3
Topical Antipruritics

Drug	Group	Mechanism	Precautions	US Food and Drug Administration Pregnancy Category
Diphenhydramine	Antihistamine	Local anesthesia; histamine antagonism	Significant percutaneous absorption; potential sensitization with cross-sensitization to oral diphenhydramine and related compounds	B
Doxepin	Tricyclic antidepressant	Histamine antagonism, interference with neuronal synaptic communication; decreased awareness through production of drowsiness	Potential contact sensitization; significant systemic absorption resulting in drowsiness and drug interactions; contraindicated in patients taking monoamine oxidase inhibitors	B
Menthol	Cyclic terpene alcohol	Counter-irritant. The cooling sensation may be the result of a direct interaction of menthol with cold receptors and/or nerve fibers.[39,44]	—	C when combined with camphor (i.e., Sarna)
Phenol	—	Local anesthesia	Avoid in pregnant women and infants[45]; irritant in diaper area and skin folds	Should be avoided[45]
Pramoxine hydrochloride	Surface anesthetic	Local anesthesia	—	C

MENTHOL

Menthol is a highly lipid-soluble cyclic terpene alcohol, often used with camphor. It is derived from naturally occurring plant oils or prepared synthetically. Menthol is a counterirritant that, by induction of a cool sensation, "crowds out" the sensation of itch. The cooling sensation may be the result of a direct interaction of menthol with cold receptors and/or nerve fibers.[40,41]

PHENOL

Phenol in low concentrations (0.5% to 2.0%) acts as an antipruritic agent through its anesthetic effect. It is percutaneously absorbed and should be avoided in pregnant women and infants.[41] In higher concentrations, it is caustic and is used for deep chemical peels (see Chapter 251).

PRAMOXINE HYDROCHLORIDE

Pramoxine hydrochloride is effective in cases of mild to moderate pruritus. As with other local anesthetics, it inhibits conduction of nerve impulses by altering the cell membrane permeability to ions. The onset of action of pramoxine products is 2–5 minutes.

ASTRINGENTS

In medical practice, astringents are agents that cause contraction of the tissues, arrest of secretion, or control of bleeding. The US Food and Drug Administration more strictly defines astringent drugs as "a drug product that is applied to the skin or mucous membranes for a local and limited protein coagulant effect."[42]

ALUMINUM SALTS

Aluminum acetate tablets diluted 1:10 to 1:40 (Burow solution) are an effective astringent and germicidal agent. Over-the-counter aluminum sulfate and calcium acetate (Domeboro) are available and, when dissolved in water, a chemical reaction occurs forming aluminum acetate and a precipitate of calcium sulfate (modified Burow solution). These solutions may be used as wet dressings, compresses, or soaks.

POTASSIUM PERMANGANATE

Potassium permanganate is an oxidizing agent, astringent, antiseptic, and antifungal that may be used to clean or deodorize wounds. Solutions of 1:4,000 to 1:16,000 may be used as wet compresses to reduce weeping or at 1:25,000 as a medicated bath. This agent may cause permanent staining of clothing and ceramics and temporary brown or bright purple staining of the skin, which may be removed with a weak solution of oxalic acid or sodium thiosulfate.

SILVER NITRATE

Silver nitrate in 0.5% aqueous solution is an astringent and antimicrobial that is applied as a wet dressing in the treatment of infected eczema, gravitational ulcers, and other weeping and/or infected skin lesions caused by Gram-positive or Gram-negative bacteria. It is also available in a solid form that may be used as a hemostat. At low concentration (0.5% formulation, used clinically), it is bacteriostatic, while bactericidal at higher concentrations (10%). As methemoglobinemia has been noted secondary to topical treatment, methemoglobin levels should be followed with prolonged use.[43]

BLEACHING AGENTS

HYDROQUINONE

Usually used in concentrations of 2% to 5%, hydroquinone decreases pigmentation by inhibiting tyrosinase, thereby blocking the conversion of dopa to melanin.[44] It may also act by inhibiting DNA and RNA synthesis, degrading melanosomes, and destroying melanocytes. Hydroquinone 4% in combination with tretinoin 0.05%, and fluocinolone acetonide 0.01% has been shown to be effective in the treatment of melasma.[45] Adverse effects include irritant dermatitis, contact dermatitis, postinflammatory pigmentation, and cutaneous ochronosis. In 2006, FDA announced that it was considering new rules on marketing of hydroquinone, based on safety concerns.[46] The American Academy of Dermatology and others have argued that stricter rules are not necessary.[47,48]

TRETINOIN (RETINOIC ACID)

(See also Chapter 217.)

Tretinoin is thought to inhibit transcription of tyrosinase, leading to decreased pigmentation.[44] It is typically used in concentrations of 0.05% to 0.1% to treat melasma.[44] Local adverse effects include erythema and desquamation, and postinflammatory hyperpigmentation has been reported. Concerns about systemic toxicity of topical tretinoin, including mortality resulting from lung and cardiovascular disease seen in a randomized controlled trial, have also been raised,[49,50] although others have defended tretinoin's safety.[51,52]

AZELAIC ACID

Azelaic acid is hypothesized to mediate decreased pigmentation by inhibition of mitochondrial oxidoreductase activity, DNA synthesis, and tyrosinase. Treatment of melasma is typically with concentrations of 15% to 20%. Side effects include burning, itching, and erythema.

MONOBENZYL ETHER OF HYDROQUINONE

Occasionally used to depigment skin in individuals with widespread vitiligo, monobenzyl ether of

hydroquinone typically causes irreversible depigmentation by causing melanocyte necrosis.[53]

KERATOLYTIC AGENTS

(Table 222-4)

Keratolytics are agents that cause keratolysis, or peeling, of the epidermis. At low concentrations, most keratolytics act as humectants, or moisturizing agents.

α-HYDROXY ACIDS

(See Chapter 251.)

α-Hydroxy acids (lactic acid, glycolic acid, citric acid, glucuronic acid, and pyruvic acid) reduce the thickness of hyperkeratotic stratum corneum by an incompletely understood mechanism wherein the acids may directly solubilize the protein components of desmosomes or activate endogenous hydrolytic enzymes by changing the pH of the stratum corneum, resulting in keratolysis. Also, by diffusing into the stratum corneum and binding water, the acids act as humectants increasing the water content of the stratum corneum. This decreases the formation of dry scales on the skin surface and allows gentle rubbing of the skin during bathing to mechanically remove cornified tissue. The concentration of α-hydroxy acid, pH of the preparation, and composition of the base in which they are compounded are important in determining their efficacy. In general, more anhydrous preparations are less irritating, allowing higher concentrations of acid to be tolerated.

PROPYLENE GLYCOL

Propylene glycol is a humectant, occlusive, and keratolytic agent. It is often combined with other medications to enhance their penetration. A combination of 20% propylene glycol with 5% lactic acid in a semiocclusive cream base is used as a highly effective and well-tolerated keratolytic in patients with lamellar ichthyosis and may be used in various other hyperkeratotic diseases.[54]

SALICYLIC ACID

Salicylic acid has been used in concentrations ranging from 0.5% to 60% in almost any base. In concentrations of 3% to 6%, it causes shedding of scales by softening the stratum corneum, dissolving the intracellular matrix, and

TABLE 222-4
Topical Keratolytic Agents

Agent	Dosage	Indications (Selected)	Side Effects/ Comments	US Food and Drug Administration (FDA) Pregnancy Category
α-Hydroxy acids	2%–20% as nonpeeling agent, >20% as peeling agent	Photoaging, scaling, hyperkeratosis, acne, hyperpigmentation	Increased photosensitivity	Not contraindicated in pregnancy[61]
Propylene glycol	40%–60% under occlusion qhs; may be combined with salicylic acid (Keralyt gel) or Lactic acid (Epilyt); 2% vehicle in many preparations	Ichthyosis, hyperkeratosis, psoriasis	Enhances absorption of other topical agents; possible central nervous system effects	—
Salicylic acid	Scaly dermatoses: FDA-approved bid–qid at 1.8%–3.0%; callouses, corns, and warts: FDA-approved at 12%–40% for plaster vehicles, 12.0%–17.6% in collodion-like vehicles[62]	Hyperkeratosis, scaling	Salicylism (headache, drowsiness, and tinnitus). Maximum topical dose of 2 g/24 hours in adults	C
Urea	Bid–qid in 10%–40% creams and lotions	Xerosis, pruritus, hyperkeratosis, eczema, ichthyosis, psoriasis, nail avulsion	Some patients experience burning; enhances absorption of other topical agents	C
Lactic acid (an α-hydroxy acid)	Bid–qid in 5%–12% preparations	Ichthyosis, xerosis, eczema, photoaging	Hypothetical risk of metabolic acidosis	Not contraindicated in pregnancy[61]

loosening connections between corneocytes.[55] In concentrations higher than 6%, salicylic acid is destructive to tissue. Salicylism has been reported with widespread and prolonged use, especially in children who should apply no more than 2 g (33 mL of a 6% solution) to their skin in a 24-hour period. Sensitization is rare, and irritation can be minimized if introduced at lower concentrations.

UREA

Urea is a humectant that is proteolytic at high concentrations. Urea has been added to some topical glucocorticoid preparations to possibly increase their penetration.[56] It is in preparations for dry skin and nail plate destruction.

LACTIC ACID

Lactic acid is a humectant and keratolytic that is available at concentrations up to 12%. In addition to being a keratolytic, lactic acid increases ceramide production by keratinocytes improving water barrier function.[57]

PSORIASIS THERAPIES

(See Chapter 18.)

ANTHRALIN

(See Chapter 18.)

CALCIPOTRIENE

(See Chapter 18.)

A vitamin D analog, calcipotriol inhibits epidermal proliferation, induces epidermal differentiation, and exerts anti-inflammatory effects. Its effectiveness in psoriasis has been demonstrated in systematic reviews.[58,59] Hypercalcemia may occur if more than 100 g is used per week. It is applied initially twice daily, and maximal improvement can be expected within 6–8 weeks. Cutaneous irritation may occur in up to 20% of patients, particularly when used on the face or in intertriginous areas. Calcipotriene is currently marketed in the United States only as a combination product with betamethasone dipropionate for treatment of psoriasis.[60,61] Other Vitamin D analogs, including calcitriol and tacalcitol, are available and used to treat psoriasis outside of the United States.[61]

WART THERAPIES

DIPHENYLCYCLOPROPENONE

Diphenylcyclopropenone (DPCP), also known as *diphencyprone*, is a potent contact allergen used in the treatment of viral warts and alopecia areata. It is not available in pharmaceutic quality. Theories for its mechanism of action include alterations in cytokine levels, nonspecific inflammation causing wart regression, and binding of DPCP to wart protein inducing a specific immune response.[62] Cross-sensitivity to other chemicals, apart from its precursor, α,α-dibromodibenzyl ketone, has not been reported.[62] Many clinics recommend avoiding DPCP in children younger than 12 years of age, although children with alopecia areata less than 12 years of age have been successfully treated with DPCP.[62]

SQUARIC ACID DIBUTYL ESTER

Squaric acid dibutyl ester is a potent topical sensitizer with a similar mechanism of action and use as DPCP. It requires refrigeration to maintain its potency.

DINITROCHLOROBENZENE

Dinitrochlorobenzene is a potent sensitizer with a similar mechanism of action and use as DPCP. Although dinitrochlorobenzene is mutagenic in vitro, there is no evidence of carcinogenicity in clinical practice.[62]

5-FLUOROURACIL

(See Chapter 220.)

FORMALDEHYDE

Formaldehyde is a powerful disinfectant that causes anhidrosis, desiccation, and sometimes, hypersensitivity when applied to skin. It can cause hardening and fissuring of the skin, so normal surrounding skin should be protected from it by petrolatum, zinc paste, or meticulous application. Individuals with eczema or allergies should avoid formaldehyde as sensitization is problematic being that it is a ubiquitous component of many personal products.

GLUTARALDEHYDE

Glutaraldehyde is viricidal. It also combines chemically with keratin producing polymers that harden the wart surface thereby facilitating paring.

MONO-, DI-, AND TRICHLOROACETIC ACIDS

Monochloroacetic acid, dichloroacetic acid, and trichloroacetic acid in concentrations of 50% to 90% are all effective in the management of warts.[59] Trichloroacetic acid is also commonly used at lower concentrations (10% to 35%) for facial peels (see Chapter 252). Anal and vaginal lesions are occasionally treated with trichloroacetic acid, whereas monochloroacetic acid is most commonly used on plantar warts under salicylic acid plaster occlusion. The application needs to be repeated at 1- to 2-week intervals until complete resolution.

PODOPHYLLIN RESIN

(See Chapter 196.)

PODOFILOX

Podofilox is podophyllotoxin, the active ingredient of podophyllin. It does not contain any of the ingredients responsible for the toxicity of podophyllin. It should not be used during pregnancy unless the potential benefit justifies the potential risk for the fetus.

SALICYLIC ACID

The effectiveness of salicylic acid in treating warts is thought to be related to keratolysis and local irritation of the skin in which the virus is present. Salicylic acid is the most established agent in terms of efficacy and safety in the treatment of viral warts.[63]

SINECATECHINS

Sincatechins ointment is an extract of green tea leaves from *Camellia sinensis* used in the treatment of external genital warts. It is available as a 15% ointment applied three times daily until all warts have cleared up to a maximum of 16 weeks. The mechanism of clearance may be related to the immunostimulatory, antiproliferative, and antitumor properties of catechins within sinecatechins ointment. It appears to have a clinical efficacy comparable to the other currently available topical therapies for external genital warts.[64,65]

Chapter 223 :: Photoprotection

:: Henry W. Lim

PHOTOPROTECTION AT A GLANCE

- Photoprotection measures include seeking shade during the peak ultraviolet (UV) B hours of 10:00 am to 2:00 pm and the use of high sun protection factor broad-spectrum sunscreen, clothing, wide-brimmed hat, and sunglasses.
- New generation photostable UV filters are now available in Europe and many parts of the world and are beginning to enter the US market.
- UV protection factor is a UV protection rating for fabrics. Several chemical treatments can increase the natural UV protection factor.
- Glass that filters out more than 99.9% of UV from 300–380 nm is now commercially available.
- Sunglass standards, mandatory in Australia and voluntary in the United States, specify a maximum percentage of light allowed to be transmitted and a minimum vertical dimension of sunglasses.

With increased attention to physical fitness and outdoor recreational activities, daily exposure to sunlight is common. Although sun exposure may have beneficial effects such as mood elevation and vitamin D_3 photosynthesis, unwanted effects are well known. Acute effects of sun exposure include sunburn and delayed tanning. Chronic sun exposure is strongly associated with photoaging, actinic keratoses, and squamous cell carcinoma; intermittent sun exposure is associated with basal cell carcinoma and melanoma. Complete avoidance of sun exposure is neither necessary nor practical, nor will it be accepted by the general public. As such, behavioral modification of seeking shade during peak ultraviolet B (UVB) hours of 10:00 am. to 2:00 pm and the use of photoprotective measures, such as sunscreen, clothing, wide-brimmed hat, and sunglasses, and when appropriate, intake of vitamin D supplements, have become the public health message to deliver. This chapter discusses the currently available, commonly used photoprotective measures.[1]

SUNSCREEN

HISTORY

The first UVB filter, PABA (*para*-aminobenzoic acid), was patented in 1943, and the first UVA filter, a

benzophenone, was introduced in 1962. In 1972, the US Food and Drug Administration (FDA) reclassified sunscreens from cosmetics to over-the-counter (OTC) drugs, resulting in more stringent regulation. In 1979, long UVA filters, dibenzoylmethane derivatives, became available. In 1990s, the need for protection against UVA, as well as against UVB, was recognized, which led to further development of UVA filters.

SUN PROTECTION FACTOR

The sun protection factor (SPF) was first developed by an Austrian, Franz Greiter, in 1962 and was adopted by the FDA in 1978.[2] Current FDA guidelines specifically require that products be tested using a solar simulator with emission spectrum covering the wavelength range of 290–400 nm, and that the sunscreen product be applied at a concentration of 2 mg/cm^2.

By definition, SPF is the ratio of minimal erythema dose (MED) of a subject's sunscreen-protected skin over the MED of the unprotected skin. Because the end point is erythema, SPF is a reflection of protection against the biologic effect of UVB (290–320 nm), and to a lesser extent, UVA2 (320–340 nm) (see Chapter 90). The effect of sunscreens with different SPFs on the transmission of erythemogenic rays is shown in Figure 223-1.[3] If an individual develops slight erythema after 10 minutes of sun exposure, 30 minutes of unprotected sun exposure result in a 3 MED sunburn. In contrast, when wearing an SPF 15 or SPF 30 sunscreen, the same 30-minute exposure would result in only 20% or 10%, respectively, of an MED. With chronic exposure, the added protection from an SPF 30 sunscreen halves the cumulative UV damage compared to the SPF 15 sunscreen, even though both products prevent sunburn.

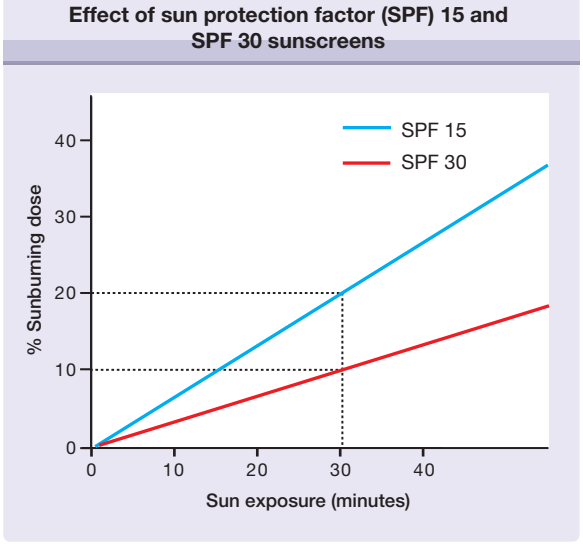

Figure 223-1 Effect of sun protection factor (SPF) 15 and SPF 30 sunscreens on an individual who would develop minimal erythema after 10 minutes of unprotected sun exposure. After a 30-minute sun exposure, 20% of a sunburning dose is achieved after the application of SPF 15 sunscreen; after the application of SPF 30 sunscreen, only 10% of a sunburning dose reaches the skin.

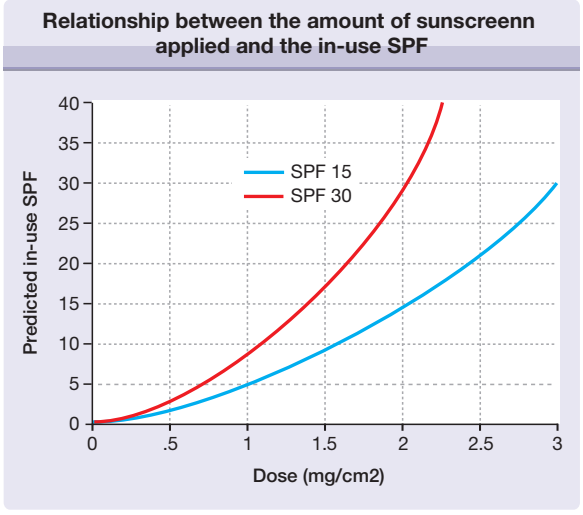

Figure 223-2 Relationship between the dose of sunscreen applied and the in-use sun protection factor (SPF). (Used with permission from JF Nash, Procter & Gamble, Cincinnati, OH.)

The concentration of sunscreen specified for SPF testing (2 mg/cm^2) is the equivalent of 1 oz (30 mL) of sunscreen to cover the entire body surface. Studies of the actual sunscreen usage by individuals have consistently demonstrated that the amount of sunscreen applied is closer to 0.5–0.8 mg/cm^2, so that the actual in-use SPF is significantly lower than the label SPF.[4] The relationship is not linear, and an SPF 30 product (at 2 mg/cm^2) has an SPF of only 3 if applied at 0.5 mg/cm^2 (Fig. 223-2).[5] This situation causes many users to overestimate their degree of photoprotection and also confounds epidemiologic studies that rely on self-reported sunscreen use to judge the efficacy of sun protection in preventing, for example, skin cancer, including melanoma.

ASSESSMENT OF ULTRAVIOLET A PROTECTION

SPF is accepted as the worldwide standard for the assessment of protection against the erythemogenic effects of UVB and UVA2. Among the several methods to evaluate protection against UVA, the persistent pigment darkening (PPD) method has become the most widely used in the past few years.[5,7] In the PPD method, the dose of UVA required to induce persistent pigment darkening observed 2–24 hours after exposure of sunscreen protected skin is compared to that of sunscreen-unprotected skin; the ratio is then expressed as the UVA protection factor (UVA-PF). In June, 2011,

the US FDA decided to use an in vitro critical wavelength test as an assessment of UVA protection of sunscreens sold in the US.[8]

IMMUNE PROTECTION FACTOR

SPF for a sunscreen product correlates poorly with its ability to protect against immunosuppression. This has resulted in the development of the concept of immune protection factor (IPF), quantifying the ability of sunscreen products to prevent immunosuppression.[9] Several different methods have been used, including contact sensitization, and intradermal injection, all of which are quite laborious and time consuming to perform. Until the time that a simple and reliable method can be easily performed in a large number of test subjects, it is unlikely that IPF will be used to rate commercial products.

ULTRAVIOLET FILTERS

There are three different nomenclatures used by the sunscreen industry and regulatory agencies around the world: (1) International Nomenclature of Cosmetic Ingredients (INCI), (2) United States Adopted Name (USAN), and (3) trade name. USAN is the nomenclature used in the FDA Sunscreen Monograph. For example, for a widely used UVA1 filter, the INCI name is butyl methoxydibenzoylmethane, the USAN is avobenzone, and a trade name is Parsol 1789. In this chapter, when available, the USAN nomenclature is used.

The term *sunblock* is commonly used to refer to sunscreens and their active ingredients, but it is a misnomer, and the FDA Sunscreen Monograph does not sanction the term. All sunscreen active ingredients are filters that absorb part of the incident UV radiation, but a portion of the radiation is always transmitted. Microfine inorganic filters additionally reflect and scatter UV radiation.

In the United States, all active sunscreen ingredients are regulated by the FDA as OTC drugs.[6] Only UV filters listed in the Sunscreen Monograph issued by the FDA may be marketed in the United States (16 active ingredients; Table 223-1). In addition, filters approved by the FDA as active ingredients of final products through the New Drug Application (NDA) process can also be marketed in the US, as was done for the latest UVA filter available in the US market, ecamsule (Mexoryl SX™). In 2002, the FDA instituted the Time and Extend Application (TEA) process as an alternate to filing the NDA.[10] With the TEA process, for the first time, data generated outside the United States can be used for the application, provided that the sunscreen product has been marketed for OTC purchase for a minimum of 5 years in the country where testing was performed. In the EU, South America, many Asian countries, and Africa, sunscreens are regulated as cosmetics, resulting in a simpler and more expeditious approval process compared to the United States, usually resulting in approval within 1–2 years of filing.

UV filters can be divided into two categories, *organic* and *inorganic*. These terms are recommended by FDA to replace the term *chemical* and *physical* filters, respectively. Organic filters can be subdivided further into UVB filters and UVA filters. The most widely used UVB filter worldwide is octinoxate (ethylhexyl methoxycinnamate), whereas the most widely used UVA filter is oxybenzone (benzophenone-3). Currently, unless products are approved as new drugs through the NDA process, the FDA guidelines do not allow avobenzone to be combined with inorganic filters (titanium dioxide, zinc oxide).

ULTRAVIOLET FILTERS AND PHOTOSTABILITY.

Avobenzone (butyl methoxydibenzoylmethane; Parsol 1789) is an excellent UVA1 filter but is photounstable and degrades during UV exposure. There are several other UV filters with this characteristic, including UVB filters padimate O (ethylhexyl dimethyl *para*-aminobenzoic acid) and octinoxate (ethylhexyl methoxycinnamate).[11] It is possible to incorporate other agents to increase the photostability of the final product (Fig. 223-3). Most of these agents are photostable UV filters (e.g., octocrylene, salicylates, oxybenzone) that absorb photons to minimize the effect on the photounstable UV filter; they also serve as receptor molecules for energy transfer from excited state photounstable filter, hence minimizing the photodegradation of the latter (see Fig. 223-3).[4,12]

In vitro, sunscreens containing photostabilized avobenzone have been shown to retain up to 90% of the active filter following 25 MED (50 J/cm^2) of solar simulated radiation, the equivalent of approximately 5 hours of sun exposure.[12] Under ideal circumstance, this would allow user to apply sunscreen only once daily. However, it should be noted that sunscreens do migrate on skin surface towards follicular orifices, resulting in an uneven distribution of UV filters; furthermore, sunscreens do get removed from rubbing and water or sweat exposure. That is the reason that the FDA, in the final rule, advises that sunscreen should be reapplied every 2 hours.[6]

ULTRAVIOLET FILTERS AND PHOTOALLERGY.

Oxybenzone (benzophenonone-3) is the most common cause of UV filter photoallergy. In contrast, the most widely used UVB filter, octinoxate (ethylhexyl methoxycinnamate), is rarely a photoallergen.[13] It should be noted that although UV filters are the most common cause of photoallergy in many studies in the United States and the United Kingdom, considering the number of individuals using sunscreens, the prevalence of photoallergy to UV filters is very low (well less than 1%). No photoallergy has been reported with inorganic UV filters (titanium dioxide and zinc oxide), the organic filter meradimate

TABLE 223-1
Ultraviolet (UV) Filters Listed in the US Food and Drug Administration Sunscreen Monograph

US Adopted Name[a]	International Nomenclature of Cosmetic Ingredients	λ_{max} (nm); or Absorption Range	Comment
Organic filters: UVB			
▪ PABA derivatives			
▪ PABA	PABA	283	Stains clothing. Not widely used
▪ Padimate O	Ethylhexyl dimethyl PABA	311	Most commonly used PABA derivative. Photounstable
▪ Cinnamates			
▪ Octinoxate	Ethylhexyl methoxycinnamate	311	Most widely used UVB filter. Photounstable
▪ Cinoxate	Cinoxate	289	—
▪ Salicylates			
▪ Octisalate	Ethylhexyl salicylate	307	Weak UVB absorbers. Improves photostability of other filters
▪ Homosalate	Homosalate	306	
▪ Trolamine salicylate	Triethanolamine salicylate	260–355	Weak UVB absorbers. Good substantivity—used in water-resistant sunscreens and hair-care products
▪ Others			
▪ Octocrylene	Octocrylene	303	Photostable. Improves photostability of photolabile filters
▪ Ensulizole	Phenylbenzimidazole sulfonic acid	310	Water soluble. Enhances sun protection factor of the final product
Organic filters: UVA			
▪ Benzophenones			
▪ Oxybenzone	Benzophenone-3	288, 325	Most commonly used UVA filter. Most common cause of photoallergic contact dermatitis to UV filters.
▪ Sulisobenzone	Benzophenone-4	366	—
▪ Dioxybenzone	Benzophenone-8	352	—
▪ Others			
▪ Avobenzone	Butyl methoxydibenzoylmethane	360	Photounstable. Enhances the photodegradation of octinoxate.
▪ Meradimate	Menthyl anthranilate	340	A weak UVA filter. No sensitization reaction reported.
Inorganic filters			
▪ Titanium dioxide	Titanium dioxide	See below[b]	No report of sensitization reaction. Photostable; used to enhance photostability of the final product. Micronized zinc oxide has better UVA1 protection compared to microfine titanium dioxide. Micronized zinc oxide has lower refractive index compared to microfine titanium dioxide and thus appears less white. Commonly coated with dimethicone or silica to maintain effectiveness as sunscreen.
▪ Zinc oxide	Zinc oxide	See below[b]	

PABA = *para*-aminobenzoic acid.
[a]This is the name used by the US Food and Drug Administration in the listing.
[b]λ_{max} ranges from visible to UVA to UVB range, depending on the particle size. As titanium dioxide is micronized (10–50 nm in diameter), λ_{max} shifts toward UVB; microfine zinc oxide maintains a flat absorption profile spanning from UVB to UVA.
Data from Kullavanijaya P, Lim HW: Photoprotection. *J Am Acad Dermatol* **52**:937, 2005 and Department of Health and Human Services, Food and Drug Administration: Sunscreen drug products for over-the-counter human use; final monograph. *Federal Register* **64**: 27666, 1999

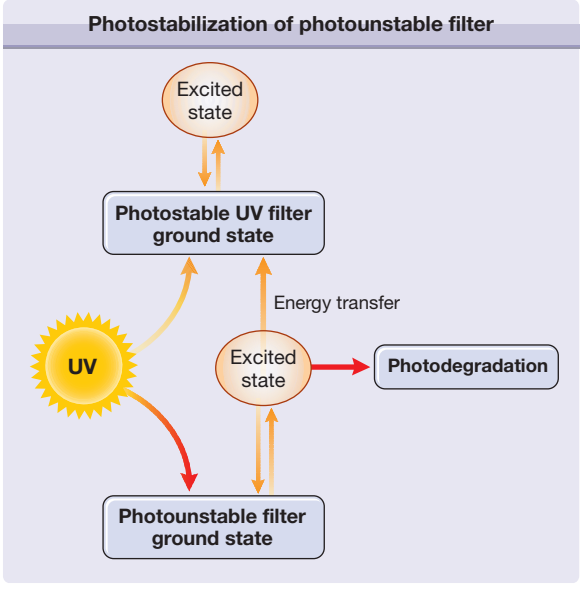

Figure 223-3 Photostabilization of photounstable filter. Photostable ultraviolet (UV) filter absorbs a portion of incident photons, hence decreasing the number of photons absorbed by the photounstable filter. Photostable UV filter also serves as a receptor for energy transfer from the excited-state photounstable filter, minimizing the photodegradation of the latter.

(menthylanthranilate), or the new photostable organic filters listed in Box 223-1.[14]

SUNSCREEN USE IN CHILDREN

Because of the concern about percutaneous absorption of sunscreens, the 1999 FDA Sunscreen Monograph recommends that the physician should be consulted on the use of sunscreens in children under the age of 6 months.[6] For this group of patients, it is prudent to use other means of photoprotection such as clothing.[4]

BOX 223-1 NEW GENERATION PHOTOSTABLE UV FILTERS

UVA FILTERS

- Mexoryl SX (ecamsule)[a]
- Neoheliopan AP
- Uvinul A Plus

UVB + UVA FILTERS

- Mexoryl XL (silatriazole)
- Tinosorb M (bisoctrizole)
- Tinosorb S (bemotrizinol)

[a]Names in parenthesis are the US Adopted Names (USAN). Ecamsule is the only one in this list that has been approved by the US FDA through an NDA process.

CONTROVERSIES

NON-MELANOMA SKIN CANCER AND MELANOMA. While there have been questions in the past, the protective role of sunscreens in the prevention of skin cancer development has now been established. In a 4.5 years study with an 8 years follow up of over 1,600 individuals in Australia, it was shown that the group that was assigned to use SPF 16, broad spectrum sunscreen had a decrease of incidence of squamous cell carcinoma and basal cell carcinoma by 38%, and 25%, respectively.[15] In a 10 years follow up, 11 melanomas developed in the sunscreen group, compared to 22 in the control group.[16]

VITAMIN D. Another area of controversy is the concern that photoprotection may compromise health by decreasing serum vitamin D level, specifically the level of the highly variable "storage form" (25-OH-vitamin D) that is the precursor to the tightly regulated active form [1,25-$(OH)_2$-vitamin D)]. There are only three sources of vitamin D. Exposure to the UVB spectrum of sunlight converts 7-dehydrocholesterol in the skin to previtamin D and thus allows its subsequent hydroxylation by the liver and kidney to the active form of the vitamin. The peak action spectrum for previtamin D synthesis is 300 ± 5 nm. Another source is dietary intake, although only a few naturally occurring foods contain a significant amount of vitamin D [e.g., oily salt water fish (herring, salmon, and sardines), cod liver oil, and egg yolk]. In the United States, milk, orange juice, margarine, butter, cereals, and chocolate mixes are fortified with vitamin D. Last, vitamin D supplements are readily available as vitamin D_3 (cholecalciferol, the form produced in skin) or vitamin D_2 (ergocalciferol); at present, vitamin D_3 is more commonly used than vitamin D_2 because the former is considered to be more stable.[17]

The effect of application of sunscreens on vitamin D levels has been evaluated. A recent review of all the published evidence concluded that normal usage of sunscreens does not generally result in vitamin D insufficiency,[18] this is primarily due to the inadequate application of sunscreens, and people using sunscreens may expose themselves to more sun than nonusers. However, in patients who practiced diligent photoprotection (for example, those with lupus erythematosus and those with erythropoietic protoporphyria), a large percentage of them did have inadequate serum vitamin D levels.[19,20] A comprehensive review by the US Institute of Medicine, released in November 2010, concluded that the strongest evidence for the beneficial effect of vitamin D on health is only for bone health; for extraskeletal outcomes, the IOM indicated that the current evidence is inconsistent and inclusive, and as such is insufficient to make public health recommendation.[21] Because the action spectrum for cutaneous vitamin D synthesis (i.e., UVB) is the same as for DNA damage and photocarcinogenesis, it is not advisable to use sun exposure as a means of obtaining vitamin D. For those individuals who are concerned or are at risk for vitamin D insufficiency, a balanced diet and

a daily 600 IU vitamin D_3 supplement, along with 1 g of calcium, is recommended.[21,22] This recommendation applies especially to elderly individuals who are homebound or dark-skinned individuals with modest sun exposure, and those who practice rigorous photoprotection.

NANOPARTICLES. Metal oxide inorganic UV filters, titanium dioxide and zinc oxide, have been widely used in microfine form. This is to minimize the reflection of visible light, thus enhancing the esthetic appearance of the final product. Nanoparticles are defined as particles less than 100 nm. In vitro, these particles can induce free radical formation in the presence of UV radiation, resulting in cell damage. In 2009, the Australian Government Therapeutic Goods Administration concluded that the weight of current evidence shows that these particles remain on the surface of the skin[23]; however, further studies are warranted, especially if these are used on inflamed skin, or in infants.

GARMENTS

CLOTHING AS A PHOTOPROTECTIVE MEASURE

Clothing, including hats, is an integral part of photoprotection. Compared to sunscreens, they are easy to put on, durable, and a social necessity. However, in most cultures, there are body sites that are infrequently covered by clothing, such as the face, the V area of neck, and dorsal hands. During hot (and sunny) weather, garments tend to cover even less skin.

ULTRAVIOLET PROTECTION FACTOR

UV protection factor (UPF) is the in vitro measurement used in many countries, including the United States, to quantify the ability of fabrics to protect against UV. Because erythema is the factor considered, similar to the SPF, UPF is a better reflection of UVB than UVA protection.[24] In the United States, garments are classified as having good protection (UPF 15–24), very good protection (UPF 25–39), or excellent protection (UPF 40–50+).

As summarized in Box 223-2, several factors affect the UV protectiveness of garments.[4,24] Polyester fibers are the best UV absorber, whereas cotton and rayon are the poorest.[25] Laundering garments made from cotton or rayon increases the UPF because of shrinkage, causing a decrease in the porosity of the fabrics. Wetness decreases the UV-protection of a light colored (especially white) garment. This is because the protective effect of white cotton fabric is mainly due to light-scattering at the fiber/air interface: when wet, the fabric no longer scatters light, and the garment becomes more transparent to both UV and visible light. In contrast, dark-colored garments absorb light and thus do not become see-through or less UV protective when wet. Chemical treatments include the incorporation of UV absorbers to the fabrics during the manufacturing (mill finishing) process, addition of UV absorber as laundry additives, and addition of optical whitening agents widely incorporated in many laundry detergents in the United States and Europe. These latter agents absorb UV radiation at 360 nm and convert it to visible light wavelength of 430 nm; therefore, these agents decrease UV transmission through the fabric. The emission of visible light from the fabric makes the fabric look "brighter."

It is a common misperception that color of the fabric linearly correlates with the UPF. In experiments with cotton fabric with UPF of 4.1, red fabric with the same dye concentration had UPF of 41, 31, and 20, depending on the type of red dye used. A yellow fabric had UPF of 25, whereas a violet one had UPF of 24.[24,26] This is because color is a reflection of the *visible light* that the eye would see and the brain would perceive; it does not therefore necessarily correlate with the transmission of UV rays through the fabric.

BOX 223-2 FACTORS AFFECTING SUN PROTECTION OF GARMENTS

- Style of garment
- Number of layers
- Fabric thickness
- Type of fibers (polyester > wool, silk, nylon > cotton, rayon)
- Stretching
- Laundering
- Wetness
- Chemical treatments

Modified from Lim HW, Hönigsmann H: Photoprotection. In: *Photodermatology*, edited by HW Lim, H Hönigsmann, JLM Hawk. New York, Marcel Dekker, 267, 2007.

GLASS

GLASS USED IN BUILDINGS AND CARS

It is well known that UVB is effectively filtered by glass.[27] Many types of glass now also have very good UVA2 and UVA1 protection (up to 380 nm). It should be noted that windshields of cars are made of laminated glass, which allows less than 1% of UV (300–380 nm) to pass through, whereas side and rear windows are usually made from nonlaminated glass that allows a higher level of UVA transmission. This explains why common sites of involvement for patients with a photodermatosis are the side of the face and forearm closest to the side window of the car.[28]

SUNGLASSES

Australia has led the world in sunglass standards, developing the world's first national mandatory standard for sunglasses for general use in 1971; it was last

revised in 2003 (AS/NZ 1067:2003).[29] The amount of visible light transmitted through the lens is called *luminous transmittance*; a lens with 20% luminous transmittance would allow 20% of the visible light to pass through. Lenses are grouped into five categories (0 to 4), ranging from fashion sunglasses (lens category 0) to special-purpose sunglasses for very high sun-glare reduction (lens category 4); category 4 lens are not to be worn during driving. Category 0 lenses are allowed to have luminous transmission of 80% to 100%, whereas category 4 transit 3% to 8%. The Standard requires that the UVB transmittance be 5% of the luminous transmittance, specifically, if the luminous transmittance is 20%, then the allowed UVB transmittance is 5% of 20%, which is 1%. The UVA transmittance for lens categories 0 to 2 must be no more than the luminous transmittance, while for lens categories 3 and 4, 50% of the luminous transmittance. The Standard also mandates that the minimum vertical diameter for adult sunglasses is 28 mm, and for children, 24 mm. The 2003 Australian Standard is similar to the European Standard EN 1836:2005, which has four transmittance ratings.

The US sunglass standard was first published in 1972 by the American National Standards Institute and last revised in 2001 (ANSI Z80.3-2001). However, unlike the Australian Standard, compliance with the US Standard is voluntary and is not followed by all manufacturers[30]; therefore, consumers share the burden of responsibility. The US Standard classified sunglasses as Normal Use (e.g., from home to the car to the office) or High or Prolonged Exposure (e.g., at the beach, fishing, skiing). Lenses are classified for intended function as special, dark, general purpose, or cosmetic tint. For example, for general purpose sunglasses, ANSI Z80.3 requires less than 1% of the wavelengths below 310 nm to be transmitted. No minimum vertical dimension of the sunglasses is stated in the US Standard.

SECTION 37 Systemic Therapy

Chapter 224 :: Systemic Glucocorticoids

:: Victoria P. Werth

SYSTEMIC GLUCOCORTICOIDS AT A GLANCE

- Systemic glucocorticoids are potent immunosuppressives and anti-inflammatory agents frequently used for severe dermatologic diseases.
- Complications are increased with fluorinated compounds, higher doses, longer duration of therapy, and more frequent administration.
- Intralesional, intramuscular, intravenous, and oral routes of administration can be used.
- Careful monitoring of electrolytes, glucose, triglycerides, cholesterol, weight, fevers, skeletal or abdominal pain, bone density, and eyes are important.
- New treatments to prevent glucocorticoid-induced osteoporosis should be used in most patients.

Glucocorticoids (GCs) are a mainstay of dermatologic therapy because of their potent immunosuppressive and anti-inflammatory properties. In 1949, Hench and coworkers[1] described the beneficial effects of cortisone in patients with rheumatoid arthritis. By understanding the properties and mechanisms of action of glucocorticoids, one can maximize their efficacy and safety as therapeutic agents.

MECHANISM OF ACTION

The major naturally occurring glucocorticoid is cortisol (hydrocortisone). It is synthesized from cholesterol by the adrenal cortex. Normally, less than 5% of circulating cortisol is unbound; this free cortisol is the active therapeutic molecule. The remainder is inactive because it is bound to cortisol-binding globulin (CBG, also called transcortin) or to albumin. The daily secretion of cortisol ranges between 10 and 20 mg, with a diurnal peak around 8:00 am.[2] Cortisol has a plasma half-life of 90 minutes. It is metabolized primarily by the liver, although it exerts hormonal effects on virtually every tissue in the body. The metabolites are excreted by the kidney and the liver.

The mechanism of glucocorticoid action involves passive diffusion of the glucocorticoids through the cell membrane, followed by binding to soluble receptor proteins in the cytoplasm.[3] This hormone-receptor complex then moves to the nucleus and regulates the transcription of a limited number of target genes. There are three main mechanisms of glucocorticoid action. The first is direct effects on gene expression by the binding of glucocorticoid receptors to glucocorticoid-responsive elements, leading to the induction of proteins like annexin I and MAPK phosphatase 1. Annexins reduce phospholipase A_2 activity, which reduces the release of arachidonic acid from membrane phospholipids,[4] limiting the formation of prostaglandins and leukotrienes.[5,6] The second mechanism is indirect effects on gene expression through the interactions of glucocorticoid receptors with other transcription factors. Some of the most important appear to be inhibitory effects on the transcription factors AP-1 and NF-κB, coupled with increased IκB, an inhibitor of NF-κB,[7] This decreases the synthesis of a number of proinflammatory molecules, including cytokines, interleukins, adhesion molecules, and proteases. The third is glucocorticoid-receptor-mediated effects on second messenger cascades through nongenomic pathways such as the PI3K-Akt-eNOS pathway.[8,9]

The human GC receptor (GR) messenger RNA has alternative splice variants, glucocorticoid receptor–α and –β. The relative levels of these two variants influence the cell's sensitivity to glucocorticoid, with higher levels of GR-β being one of many mechanisms leading to glucocorticoid resistance.[9,10]

There is usually a delay in the onset of pharmacologic activity of glucocorticoids relative to their peak blood concentrations, which is probably consequent to altering the transcription of genes,[8] although some actions appear to be independent of transcription.[11] Glucocorticoids may also exert their effects by nongenomic mechanisms such as membrane-bound receptors and/or physicochemical interactions with cellular membranes.[12] Some effects of glucocorticoids

are too rapid to be mediated by genomic glucocorticoid action.[13] This mechanism might explain the additive benefits of very high-pulse glucocorticoids.

The recognition that desired clinical effects of GC treatment on the GR are mediated by transrepression mechanisms, while transactivation mediates side effects, have led to the development of compounds—selective GR agonists (SEGRAs)—that potentially will give glucocorticoid effects without the same amount of toxicity.[8,14,15] The multiplicity of biologic effects produced by glucocorticoids emphasizes that currently there is no unifying hypothesis to explain the therapeutic efficacy of these extremely potent anti-inflammatory and immunosuppressive agents.

CELLULAR EFFECTS OF CORTICOSTEROIDS

Glucocorticoids profoundly affect the replication and movement of cells. They induce monocytopenia, eosinopenia, and lymphocytopenia and have a greater effect on T cells than on B cells.[16] The lymphocytopenia appears to be caused by a redistribution of cells as they migrate from the circulation to other lymphoid tissues, and it has been suggested that glucocorticoids induce apoptosis.[17] The increase in circulating polymorphonuclear leukocytes is related to demargination of cells from the bone marrow and a diminished rate of removal from the circulation, at least partially mediated by the increase in annexin 1[18]; there also appears to be inhibition of neutrophil apoptosis.[19]

Glucocorticoids affect cell activation, proliferation, and differentiation. They modulate the levels of mediators of inflammation and immune reactions, as seen with the inhibition of interleukin-1, -2, and -6 (IL-1, -2, -6), and tumor necrosis factor synthesis (or release).[20,21] Macrophage functions—including phagocytosis, antigen processing, and cell killing—are decreased by cortisol,[22,23] and this decrease affects immediate and delayed hypersensitivity.

BOX 224-1 MOST COMMON INDICATIONS OF SYSTEMIC STEROIDS

- Serious blistering diseases (pemphigus, bullous pemphigoid, cicatricial pemphigoid, linear IgA bullous dermatoses, epidermolysis bullosa acquisita, herpes gestationis, erythema multiforme, toxic epidermal necrolysis)
- Connective-tissue diseases (dermatomyositis, systemic lupus erythematosus, mixed connective-tissue disease, eosinophilic fasciitis, relapsing polychondritis)
- Vasculitis
- Neutrophilic dermatoses (pyoderma gangrenosum, acute febrile neutrophilic dermatosis, Behçet disease)
- Sarcoidosis
- Type I reactive leprosy
- Hemangioma of infancy
- Panniculitis
- Urticaria/angioedema

Glucocorticoids suppress monocyte and lymphocyte function (both Th1 and Th2 cells) more than polymorphonuclear leukocyte function.[24] This effect is clinically important because granulomatous infectious diseases, such as tuberculosis, are prone to exacerbation and relapse during prolonged glucocorticoid therapy. The antibody-forming cells, B lymphocytes and plasma cells, are relatively resistant to the suppressive effects of glucocorticoids. Very high doses of glucocorticoids are needed to suppress antibody production.[25]

INDICATIONS

There is a long list of indications for skin disorders (see Box 224-1). In addition, short courses of glucocorticoids may be used for a variety of forms of severe

TABLE 224-1
Glucocorticoids

	Equivalent Glucocorticoid Potency (mg)	Mineralocorticoid Potency	Plasma Half-Life (min)	Duration of Action (h)
Short-acting				
Hydrocortisone (Cortisol)	20	0.8	90	8–12
Cortisone	25	1	30	8–12
Intermediate-acting				
Prednisone	5	0.25	60	16–36
Prednisolone	5	0.25	200	12–36
Methylprednisolone	4	0	180	12–36
Triamcinolone	4	0	300	12–36
Long-acting				
Dexamethasone	0.75	0	200	36–54

dermatitis, including contact dermatitis, atopic dermatitis, photodermatitis, exfoliative dermatitis, and erythrodermas. Low doses of glucocorticoids may be administered at bedtime if acne and hirsutism result from adrenogenital syndromes and are unresponsive to more conservative therapy. The use of glucocorticoids is controversial in the treatment of erythema nodosum, lichen planus, cutaneous T-cell lymphoma, and discoid lupus erythematosus.

DOSING REGIMEN

Systemic glucocorticoids can be administered intralesionally, orally, intramuscularly, and intravenously. The route and regimen are determined by the nature and extent of the disease being treated.

Intralesional glucocorticoid administration allows direct access to either a relatively few lesions or a particularly resistant lesion. The concentration depends on the site of injection and the nature of the lesion. Lower concentrations (2–3 mg/mL) are used on the face to prevent atrophy of the skin, whereas keloids may require concentrations of 40 mg/mL. In conditions requiring sustained effects, such as keloids and alopecia areata, longer-acting glucocorticoids, such as Aristospan, can be administered alone or mixed with the more typically used Kenalog. It is best to limit the total monthly dose of Kenalog to 20 mg to ensure that the hypothalamic-pituitary-adrenal (HPA) axis will not be suppressed.[27]

There are serious drawbacks to intramuscular administration because of erratic absorption and lack of daily control of the dose. Because Kenalog is longer-acting than prednisone, Kenalog has more potential side effects, including increased HPA suppression and myopathy.

When oral glucocorticoids are prescribed, prednisone is most commonly selected. Glucocorticoids are usually administered daily or every other day; although for acute disease split, daily doses can be administered. The initial dose is most often daily to control the disease process and can range from 2.5 mg to several hundred milligrams daily. If used for less than 3–4 weeks, glucocorticoid therapy can be stopped without tapering. The lowest possible dose of a short-acting agent every other morning minimizes side effects. Because cortisol levels peak at around 8 A.M., the HPA axis is least suppressed with this morning dosage, and maximal feedback suppression of adrenocorticotropic hormone (ACTH) secretion by the pituitary is already occurring. The low levels of glucocorticoids at night allow for normal secretion of ACTH. Low doses of prednisone (2.5–5 mg) at bedtime have been used to maximize adrenal suppression in cases of acne or hirsutism of adrenal origin.

Intravenous glucocorticoids are used in two situations. One is for stress coverage for patients who are acutely ill or are undergoing surgery and who have adrenal suppression from daily glucocorticoid therapy. The other is for patients with certain diseases—such as resistant pyoderma gangrenosum, severe pemphigus or bullous pemphigoid, serious SLE, or dermatomyositis—to gain rapid control of the disease and thus minimize the need for long-term, high-dose, oral steroid therapy.[28] Methylprednisolone is used at a dose of 500 mg to 1 g daily because of its high potency and low sodium-retaining activity. Serious side effects associated with intravenous administration include anaphylactic reactions, seizures, arrhythmias, and sudden death. Other adverse reactions include hypotension, hypertension, hyperglycemia, electrolyte shifts, and acute psychosis. Slower administration over 2–3 hours has minimized many of the serious side effects, and as long as vital signs are determined frequently, patients without underlying renal or cardiac disease do not need to be treated in a monitored bed.[29] It is important to monitor serum electrolytes before and after pulse therapy, particularly when patients are on concomitant diuretic therapy. Some studies question whether there is a role for high-dose IV pulse therapy.[27]

INITIATING THERAPY

FUNDAMENTAL PRINCIPLES

Before therapy with glucocorticoids is begun, the benefit that can realistically be expected should be weighed against the potential side effects. Alternative or adjunctive therapies should be considered, especially if long-term treatment is contemplated. Coexisting illnesses such as diabetes, hypertension, or osteoporosis need to be considered. The predisposition of the patient to side effects should be included in an assessment of risk.

CHOOSING AMONG GLUCOCORTICOIDS

A number of considerations bear on the choice of glucocorticoids. First, a preparation with minimal mineralocorticoid effect is usually picked to decrease sodium retention. Second, the long-term oral use of prednisone or a similar drug, with an intermediate half-life and relatively weak steroid-receptor affinity, may reduce side effects. Long-term use of drugs like dexamethasone, which has a longer half-life and high glucocorticoid-receptor affinity, may produce more side effects without any better therapeutic effects. Third, if a patient does not respond to cortisone or prednisone, the substitution of the biologically active form, cortisol or prednisolone, should be considered. In general, even in severe liver disease, substitution has not proved to be very important. Fourth, methylprednisolone is used for pulse therapy because of its low sodium-retaining characteristics and high potency.

EVALUATION BEFORE TREATMENT

To minimize potential problems, the baseline evaluation should include a personal and family history, with special attention to predisposition to diabetes, hypertension, hyperlipidemia, glaucoma, and associated diseases that could be affected by steroid therapy.

Baseline blood pressure and weight should be measured. If prolonged administration is anticipated, an eye examination and a purified protein derivative (PPD) test should be performed and an anergy panel applied. Examination for other covert infections should be based on history and physical examination. For instance, a stool culture for *Strongyloides* should be performed for immigrants from third-world countries and for Vietnam veterans.[30] If long-term administration of glucocorticoids is anticipated, baseline spinal bone-density measurement should be obtained by quantitative computed tomography (CT), dual-photon absorptiometry, or dual-energy X-ray absorptiometry (DEXA).[29]

MONITORING THERAPY

At follow-up visits, patients receiving chronic glucocorticoid therapy should be questioned about polyuria, polydipsia, abdominal pain, fevers, sleep disturbances, and psychological effects. There may be serious changes in effects on affect and even psychosis in patients treated with high doses of glucocorticoids. Weight and blood pressure should be monitored. Serum electrolytes, fasting blood sugar, and cholesterol and triglyceride levels should be measured on a regular basis. Stool should be examined for occult blood. Follow-up eye examinations should be performed with careful monitoring for the development of cataracts and glaucoma.

RISKS AND PRECAUTIONS

(Table 224-2)

DIET

Diet should be low in calories, fat, and sodium, and high in protein, potassium, and calcium. Protein intake is important to reduce steroid-induced nitrogen wasting.[31] Use of alcohol, coffee, and nicotine should be minimized. Exercise should be encouraged.

INFECTIONS

Patients with a positive PPD or Quantiferon TB Test should be given prophylaxis with isoniazid.[32] Anergic patients should have a baseline chest X-ray to search for evidence of previous tuberculosis. Fevers or focal findings should be evaluated with appropriate cultures and diagnostic approaches. Some advocate use of Bactrim prophylaxis (1 DS Bactrim 3 days a week) against *Pneumocystic carinii* when patients receive concomitant cytotoxic therapy.[26]

IMMUNIZATIONS

Immunization with live vaccines can be done if the duration of glucocorticoid use is less than 2 weeks at any dose, if the dose of glucocorticoid is <2 mg/kg or

TABLE 224-2
Preventive Measures for Chronic (≥3 months) Glucocorticoid Use

Side Effect	Preventative Measures
Hypertension	Blood pressure (baseline; repeat with each visit)
Weight gain	Weight (baseline; repeat with each visit)
Reactivation of infection	Purified protein derivative, anergy panel at baseline (can be done up to 12 days after starting prednisone) Hepatitis screen Consider *Pneumocystis carinii* pneumonia prophylaxis (Bactrim 1 DS three times a week)
Metabolic abnormalities	Electrolytes, lipids, glucose [baseline; repeat early after starting therapy; repeat annually; more frequent monitoring with known factors (e.g., diabetes, hyperlipidemias)]
Osteoporosis	Bone density (baseline; repeat annually is early bone prophylaxis done) Instruct about diet, exercise, other measures Calcium and vitamin D supplementation Start bisphosphonate for men, postmenopausal women Evaluate postmenopausal women for hormone replacement therapy Serum testosterone after treatment started in men; if low (<300 ng/mL), check prostate specific antigen, prostate examination before starting testosterone replacement
Eyes	
Cataracts	Slit-lamp examination (every 6–12 months)
Glaucoma	Intraocular pressure examination (at 1 month and every 6 months)
Peptic ulceration	In patients with two or more risk factors, consider prophylaxis with and H_2-antagonist or proton pump inhibitor
Suppression of hypothalamic-pituitary-adrenal axis	Single, early morning doses, preferably every other day Check 8:00 am serum cortisol before tapering prednisone <3 mg/day. If <10 g/dL, repeat every 1–2 months and maintain low prednisone dose until baseline cortisol adequate

20 mg/day of any duration, and if long-term alternate-day treatment with short-acting preparations is done. Immunization with live vaccines should not be done for at least 3 months after receiving high doses of glucocorticoids (>2 mg/kg or greater than 20 mg/day) for more than 2 weeks.[33]

GASTROINTESTINAL COMPLICATIONS

Although there is controversy about whether an increase in the incidence of peptic ulcer disease occurs in otherwise unaffected patients receiving glucocorticoids, there is almost a ninefold increase in patients taking both glucocorticoids and nonsteroidal anti-inflammatory agents.[32,34,35] In patients with two or more risk factors (such as those taking nonsteroidal anti-inflammatory medications, a previous history of peptic ulceration, advanced malignant disease, or a total dose of glucocorticoids >1,000 mg), prophylaxis may be considered. Prophylaxis can include antacids, H_2-receptor blockers (cimetidine, ranitidine, nizatidine, or famotidine with the evening meal), or proton pump inhibitors (Prilosec or Prevacid).

ADRENAL SUPPRESSION

Patients receiving daily glucocorticoid therapy for longer than 3–4 weeks must be assumed to have adrenal suppression that requires tapering of the glucocorticoids to allow for recovery of the HPA axis. Tapering is best performed by switching from a single daily dose to alternate-day doses, followed by a gradual reduction of the amount of the drug. The daily dose is first gradually tapered to 40 or 50 mg of prednisone. Then either the dose can be kept constant on one day and reduced on the alternate day by 5-mg decrements down to 5 mg/day, or, the steroid dose can be increased on one day and reduced by a similar amount on the alternate day. More studies are needed to determine optimal tapering schedules.[36]

After the prednisone dose is tapered to 5 mg on alternate days, the need for maintenance therapy must be assessed. The 8:00 am plasma cortisol level is measured 4 weeks after the 5-mg dose has been reached. The morning dose of prednisone is held until the plasma cortisol level is determined. If the plasma cortisol level is less than 10 µg/dL, the alternate-day prednisone dose should be decreased by 1 mg every 1–2 weeks to a maintenance dose of 2 mg/day. Then the 8:00 am plasma cortisol level should be rechecked every 2 months until it is greater than 10 µg/dL, at which point maintenance glucocorticoids can be terminated.[37] Recovery of the HPA axis can take longer than 9 months.[38] At that point and at any point when the patient is receiving tapering doses of steroids, a stress caused, for example, by trauma, surgery, diarrhea, or fever >38°C (101°F) can precipitate acute adrenal insufficiency related to an inadequate stress response. Patients should wear bracelets or carry cards indicating that they are receiving glucocorticoids. During such stressful situations, it is necessary to give high doses of glucocorticoids, generally 25–70 mg/day of prednisone or 100–300 mg/day of cortisol in divided doses.[39] Patients must be educated about the need for stress coverage.

The amount of glucocorticoids to give for coverage for surgery should probably be individualized to the severity of the operation. Minor operations lasting less than 1 hour are associated with, at most, 50 mg/day (12.5-mg prednisone) of cortisol in response to the surgery. Moderate-to-major surgeries are associated with the production of 75–200 mg/day of cortisol.[40,41] Thus, recent guidelines suggest that adrenally suppressed patients receive 25 mg of hydrocortisone equivalents for minor surgeries, 50–75 mg for moderate surgeries, and 100–150 mg for major surgery for 2–3 days, beginning when the patient is on call for surgery.[40] Only two randomized controlled trials have been done, and data is sparse, with one recent study suggesting even lower doses are adequate.[42,43]

In general, adrenal insufficiency resolves within 1 year of the termination of glucocorticoid therapy. An ACTH (cosyntropin) stimulation test may be performed after maintenance glucocorticoids are terminated to assess adrenal reserve. This test is performed in the office by determining a baseline cortisol level, giving an injection of 0.25 mg of cosyntropin, and measuring the serum cortisol level again 1 hour later.[37] The adrenal response is suppressed if the serum cortisol level fails to increase by at least 5 µg/dL to a stimulated value 60 minutes later of more than 20 µg/dL. If adequate adrenal response to stress is demonstrated, there is less concern about the endogenous cortisol response to stress.[26] However, such a response is not a guarantee of adequate adrenal reserves if severe stress occurs, and many physicians would choose routine stress coverage with glucocorticoids without performing an ACTH stimulation test.[44]

COMPLICATIONS

Complications associated with systemic glucocorticoid therapy (eBox 224-0.2 in online edition)[45,46] increase with higher doses, longer duration of therapy, and more frequent administration. However, osteoporosis and cataracts develop with alternate-day dosing, and avascular necrosis (AVN) can be seen after only short courses of glucocorticoids.

OSTEOPOROSIS

Osteoporosis occurs in 40% of individuals treated with systemic glucocorticoids; it is especially prominent in children, adolescents, and postmenopausal women.[47] Approximately one-third of patients have evidence of vertebral fractures after 5–10 years of glucocorticoid treatment, but this proportion is higher in postmenopausal women.[48,49] Bone loss occurs most rapidly in the first 6 months of glucocorticoid use, but continues at a slower rate after that, with loss of 3%–10% of bone per year in many patients.[47,50] Recent studies show that even low doses of prednisone

(2.5 mg per day) adversely affect bone and increase vertebral and hip fractures.[51,52] Some of the bone loss may be reversible after glucocorticoids are stopped, at least in the young.[53]

Glucocorticoids inhibit osteoblasts, increase calcium excretion by the kidney, decrease intestinal calcium absorption, and, concomitantly, increase bone resorption by osteoclasts. They also reduce estrogen and testosterone levels, which is likely to be an important factor in the pathogenesis of osteoporosis. Serum osteocalcin, a measure of osteoblast function, decreases within a day after a dosage regimen of as little as 10 mg of prednisone a day is begun; a dosage regimen of 7.5 mg of prednisone a day or more often causes significant bone loss and an increased fracture rate.[54–56] Trabecular bone is primarily affected, leading to painful vertebral fractures.

AVASCULAR NECROSIS

AVN is manifest by pain and limitation of motion in one or more joints. There is intraosseous hypertension, leading to bone ischemia and necrosis.[57] It is likely that intraosseous lipocyte hypertrophy causes this intraosseous hypertension in persons taking glucocorticoids. In addition, glucocorticoids induce apoptosis of osteoblasts, likely contributing to AVN. Underlying diseases, such as systemic lupus erythematosus (SLE), increase the likelihood of steroid-induced AVN.[58] Studies suggest that many patients who develop AVN have either thrombophilia or hypofibrinolysis, which leads to thrombotic occlusion of venous outflow from the bone, decreased arterial perfusion, and subsequent infarction of bone.[59]

ATHEROSCLEROSIS

Glucocorticoids enhance many risk factors that are associated with atherosclerosis, including arterial hypertension, insulin resistance, glucose intolerance, hyperlipidemia, and central obesity. It is thus not surprising that patients taking glucocorticoids have an increased risk of atherosclerosis.[60] Patients with untreated Cushing disease have a four times higher mortality rate from cardiovascular complications, including coronary artery disease, congestive heart failure, and cardiac stroke.[61] The risk factors for atherosclerosis persist for at least 5 years after normalization of the serum cortisol level in Cushing disease, and similar findings may be true in those treated with chronic glucocorticoids.[62]

SUPPRESSION OF THE HYPOTHALAMIC–PITUITARY–ADRENAL AXIS

The hypothalamic–pituitary–adrenal (HPA) axis is rapidly suppressed after the onset of glucocorticoid therapy. However, if therapy is limited to 1–3 weeks, the recovery of the HPA axis is rapid. Longer daily glucocorticoid therapy is associated with suppression of the HPA axis for up to 1 year after therapy is terminated.[38] Symptoms of adrenal suppression include lethargy, weakness, nausea, anorexia, fever, orthostatic hypotension, hypoglycemia, and weight loss.

There also exists a steroid withdrawal syndrome, in which patients experience symptoms of adrenal insufficiency despite having an apparently normal cortisol response to ACTH. Symptoms most commonly include anorexia, lethargy, malaise, nausea, weight loss, desquamation of the skin, headache, and fever. Less commonly, vomiting, myalgias, and arthralgias occur. These patients have adjusted to high levels of glucocorticoids, and symptoms disappear after the glucocorticoids are restarted. This problem can be treated by slower tapering of the glucocorticoids, often by 1 mg of prednisone every few weeks.[63]

PSYCHIATRIC EFFECTS

Mood and cognitive changes are dose dependent and can appear shortly after the start of glucocorticoids. Hypomania and mania are the most common symptoms early, but prolonged use is associated more frequently with depression. Antipsychotics, antiseizure medications, and antidepressant can help normalize mood changes, although there are not controlled trials.[64]

DRUG INTERACTIONS

Glucocorticoids are associated with a number of important drug interactions. Drugs such as barbiturates, phenytoin, and rifampin, which induce hepatic microsomal enzymes, may accelerate the metabolism of glucocorticoids.[65] Drugs such as cholestyramine, colestipol, and antacids, impair absorption of glucocorticoids. Glucocorticoids reduce the serum salicylate level and necessitate a higher dose of warfarin for anticoagulation.

IMMUNOLOGIC SIDE EFFECTS

Glucocorticoids impair delayed-type hypersensitivity reactions because of their inhibition of lymphocytes and monocytes. Prednisone at daily doses of 15 mg or more suppresses the response to tuberculin, although it takes an average of 13.6 days for oral prednisone at 40 mg/day to inhibit the response to tuberculin.[66] Thus, even in situations requiring immediate use of prednisone, it is possible to perform simultaneously a PPD test of tuberculin and an anergy panel. Overall, there is an increased incidence of infections attributable to both the glucocorticoids and the immunologic changes related to the underlying disease.[67]

CONCERNS DURING PREGNANCY AND LACTATION

Glucocorticoids cross the placenta, but they are not teratogenic. Exposed infants as well as breast-fed infants

of mothers receiving glucocorticoids should be monitored for adrenal and growth suppression. Based on animal experiments, there is some concern about the contribution of glucocorticoids to low-birth weight and childhood cognition.[68]

ISSUES SPECIFIC TO PEDIATRICS. In the pediatric population, glucocorticoids cause growth retardation and early osteoporosis.[69,70] Growth retardation is caused by a direct action on cell metabolism, effects on calcium and phosphorus metabolism, and a decrease in growth hormone secretion, with inhibition of bone matrix formation. Growth retardation is not prevented by alternate day GC regimens.[71] Recent studies show that human growth hormone replacement has a significant effect on growth, as well as a significant effect on lean body mass.[72]

Osteoporosis. Attention to the prevention of osteoporosis is becoming increasingly important as newer therapies that may deter bone loss become available. Calcium and vitamin D supplements, sex hormone replacement, a weight-bearing exercise program, and sodium restriction are suitable first-line therapies.[73,74] Calcium and vitamin D together, but not calcium alone, preserve bone mass in patients receiving long-term treatment with glucocorticoids at an average of 15 mg/day.[73,74] Patients taking glucocorticoids should be given elemental calcium, 1,500 mg/day, and vitamin D_2, 400 units twice daily. Activated forms (alfacalcidiol, 1 µg/day, or calcitriol, 0.5–1 µg/day) can be given, but more frequent monitoring is required for hypercalciuria and hypercalcemia. Patients with a history of renal stones should not receive supplemental calcium and vitamin D.[75,76] For patients receiving calcium and vitamin D_2, calcium levels should be measured in serum and in 24-hour urine collections every 3 months or whenever glucocorticoid doses are substantially altered. If the urinary calcium level exceeds 250–350 mg/dL, the addition of 12.5–25 mg/day of thiazide will reduce the renal excretion of calcium.[77] If thiazide is not added, calcium and vitamin D supplementation should be adjusted.

Atherosclerosis. Blood pressure, serum lipids, and glucose levels should be measured serially. Abnormalities should be treated with dietary manipulation and medication as necessary. Patients who smoke should be encouraged to stop. Female sex hormones protect against the development of atherosclerosis, and thus HRT for postmenopausal women on glucocorticoids makes sense. However, recent data suggest that women with established atherosclerosis actually do worse with HRT, and there was a 58% increase in coronary heart disease events in the first year after myocardial infarction in patients treated with an estrogen/progestin combination.[80] If patients develop increased levels of cholesterol or triglycerides while taking glucocorticoids, there are now good approaches to treatment, particularly with some of the newer statins, that impact on the development of atherosclerosis and prevent myocardial infarctions. Patients should be treated or referred for treatment on the basis of guidelines that emphasize the importance of assessing the risk of atherosclerosis. These guidelines recommend treatment when patients have low-density lipoprotein (LDL) cholesterol levels greater than 160 mg/dL and fewer than two coronary heart disease risk factors (high LDL cholesterol, smoking, hypertension, diabetes, male sex, family history of premature heart disease), LDL cholesterol levels greater than 130 mg/dL with two or more additional risk factors for heart disease, and LDL cholesterol levels greater than 100 mg/dL for patients with established coronary artery disease.[120] High-density lipoprotein (HDL) cholesterol levels lower than 35 mg/dL independently predict increased coronary mortality rates in men and should be taken into account in therapeutic decisions. Several trials have demonstrated reduction in both coronary heart disease and total mortality rates with statin therapy.[121–123] Patients should supplement the diet with folate and B_6 to control any elevations in homocysteine.

Avascular Necrosis. Early detection is important because early intervention may prevent progression to degenerative joint disease requiring joint replacement. Twenty percent of patients with AVN have normal X-rays. Bone scan and magnetic resonance imaging (MRI) are more sensitive techniques for evaluating AVN. Patients should be regularly questioned about pain and limitation of motion of joints. If abnormalities develop, an X-ray, bone scan, or MRI should be ordered. If imaging shows AVN, an orthopedic surgeon skilled in early intervention with core decompression may be able to halt progression of the disease. Patients with AVN have an increased risk that other joints will be affected. The progression of AVN to destructive joint disease may require joint replacement surgery.[124]

Chapter 225 :: Dapsone

:: Joni G. Sago & Russell P. Hall III

DAPSONE AT A GLANCE

- Dapsone (4,4′-diaminodiphenylsulfone) is classified as sulfonamide but has unique pharmacologic properties.
- Diseases with consistent response to dapsone are dermatitis herpetiformis, erythema elevatum diutinum, linear immunoglobulin A dermatosis/chronic bullous disease of childhood and bullous eruption of systemic lupus erythematosus.
- Diseases with sporadic response to dapsone encompass a wide spectrum and are as diverse as collagen vascular/autoimmune diseases and acne. In these diseases, dapsone can be used as a corticosteroid sparing agent.
- A unifying feature of responsive diseases is neutrophilic and eosinophilic granulocytes.
- Dapsone is also effective in certain infections such as leprosy, actinomycetoma, or rhinosporidiosis.
- Adverse effects are hemolysis and methemoglobulinemia. Glucose-6-phosphate dehydrogenase (G6PD) level should be obtained before beginning dapsone treatment. Dapsone should only be given with great caution to patients with G6PD deficiency.
- Other adverse effects are neuropathy, a mononucleosis-like hypersensitivity syndrome termed the *sulfone syndrome*, and agranulocytosis.

MECHANISM OF ACTION

Dapsone's interference with the folate biosynthetic pathway accounts for its antibiotic effect and it is still sometimes used as an antibiotic in pneumocystis pneumonia prophylaxis (PCP) and in combinations for treatment of leprosy and malaria. However, dapsone is used in dermatology for its anti-inflammatory effect, the mechanisms of which are still incompletely characterized. Dapsone inhibits migration of neutrophils to areas of inflammation by inhibiting neutrophil chemotaxis to the chemoattractant signals F-met-leu-phe[1,2] and leukotriene B_4 (LTB_4).[3–5] In addition to this effect on neutrophil migration, dapsone also inhibits the adherence of neutrophils to skin-localized IgA[6] and endothelium.[7] Additionally, dapsone has been shown to inhibit the release of inflammatory mediators including interleukin-8 (IL-8),[8] PGD_2, and tumor necrosis factor-α (TNF-α).[9] Finally, dapsone has been shown to inhibit the myeloperoxidase H_2O_2-halide-mediated cytotoxic system,[10–11] perhaps by inhibiting the calcium flux necessary for these events.[12] Myeloperoxidase is the enzyme in the azurophilic granules of neutrophils and in the lysosomes of monocytes that catalyzes the conversion of hydrogen peroxide and chloride ions into hypochlorous acid, a potent oxidant that causes cell damage.

PHARMACOLOGY

Figure 225-1 shows the chemical structure of dapsone [4,4′-diaminodiphenylsulfone].[13,14] Although dapsone is classified as a sulfonamide, cross-reactions occur in only 7%–22% of sulfa-allergic patients. They are usually mild and do not necessitate stopping dapsone.[15,16] If side effects are substantial, sulfapyridine may be tried. Sulfapyridine is thought to have similar mechanisms of action although with a reduced activity level and a lower incidence of toxicity. However, in the United States, it is available only on a compassionate-use basis from the manufacturer.

Dapsone tablets are available in 25- and 100-mg sizes; therapeutic doses for various conditions range from 25 mg to approximately 400 mg. Dapsone is well absorbed from the gut with peak levels being reached 2–6 hours after a single dose. The steady-state half-life, however, is quite long (approximately 30 hours) due to enterohepatic recirculation.[17] This allows for once-daily dosing and explains the utility of activated charcoal in reducing drug levels during accidental or intentional overdose.[18] Dapsone and its metabolites

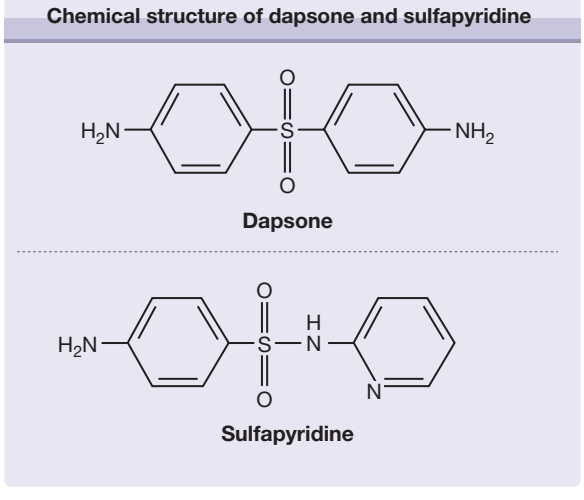

Figure 225-1 Chemical structure of dapsone and sulfapyridine.

may be transmitted through human milk, and hemolysis has occurred in nursing infants.[19–21] No teratogenicity has been observed, although no controlled studies have been performed in humans, and it is classified as pregnancy category C.[22,23]

Topical dapsone in a 5% gel formulation was approved in 2005 for acne vulgaris.[24,25] Twice daily application on up to 22% of subjects' body surface area resulted in systemic levels of dapsone and its metabolites that were 100-fold less than oral dapsone at a therapeutic dose. There was no hemolytic anemia or methemoglobinemia, even in patients who were glucose-6-phosphate dehydrogenase (G6PD) deficient.[26–29] Therefore, in 2008, the US Food and Drug Administration removed the requirement for pretreatment G6PD testing.

Dapsone is metabolized in the liver. The two major metabolic pathways involve acetylation[30,31] and *N*-hydroxylation.[32–34] Dapsone is acetylated polymorphically, i.e., some patients rapidly acetylate dapsone to monoacetyldapsone (MADDS) whereas in others, this process occurs slowly. However, in all patients, MADDS is rapidly deacetylated. Thus, equilibrium between MADDS and dapsone is quickly reached and sustained. Dapsone's efficacy, half-life, and toxicities appear unrelated to the rate of acetylation and checking acetylator phenotype is unnecessary prior to use of dapsone.

The most clinically significant metabolic pathway involves hydroxylation of one of the amino groups by cytochrome 2C19,[32] 3A4, and, to a lesser extent, 2C9 and 2C8[33] to form dapsone hydroxylamine. Dapsone hydroxylamine is a potent oxidant that is important in the development of methemoglobinemia, hemolysis and liver injury (see Section "Risks and Precautions").[34–37] Dapsone hydroxylamine is reduced back to the parent compound dapsone by methemoglobin reductase in erythrocytes and cytochrome b_5 reductase and cytochrome P2D in hepatocytes. Reduced levels of these enzymes have been detected in dapsone-treated patients who developed symptomatic methemoglobinemia; genetic variability in detoxifying enzymes may therefore explain patients' differential development of this side effect.[38] Recent studies have also shown that dapsone can be hydroxylated by keratinocytes themselves. These hydroxylated metabolites then form drug-protein adducts that generate stress signals, which are delivered to draining lymph nodes. This may be important in the pathogenesis of some of the cutaneous side effects of dapsone.[39–41]

Although extensively hepatically metabolized, a small study of dapsone administration in cirrhotic patients demonstrated no need for dose adjustment.[42] However, caution is still recommended when using dapsone in patients with hepatic insufficiency.

Probenecid[43] and trimethoprim[44] have been shown to lead to higher blood levels of dapsone; exercise caution when using them concurrently. Conversely, rifampicin reduces dapsone blood levels by upregulating the P_{450} system.[45] Interestingly, cimetidine and omeprazole, which block *N*-hydroxylation of dapsone, have been used to mitigate some of the side effects of dapsone. Cimetidine dosed 400 mg three times a day has reduced methemoglobin levels in reported patients by 27%–60%.[47–50]

Dapsone and its metabolites are excreted by the kidneys, hence the recommendation to check a pretreatment creatinine and avoid dapsone in patients with significant renal impairment.

INDICATIONS

Since its introduction into clinical medicine, dapsone has had therapeutic trials and anecdotal successes in a multitude of diseases (see Box 225-1). However, there are only a few conditions for which dapsone is considered the drug of choice. These are: dermatitis herpetiformis,[51,52] erythema elevatum diutinum,[53,54] linear IgA dermatosis/chronic bullous dermatosis of childhood,[55–58] and the bullous eruption of systemic lupus erythematosus.[59,60] Patients with these disorders achieve a clinical response within 24–48 hours and their condition flares over the same time course with drug withdrawal.

Other noninfectious conditions in which dapsone has found sporadic success span the spectrum of dermatologic disease (see Box 225-1).[60–135] As a unifying feature, most of these diseases have granulocytes (neutrophils or eosinophils) as the predominant infiltrating cell, especially early in the pathologic process. The response to dapsone therapy is not as rapid, regular, or predictable in any of these diseases. However, dapsone may have a role as a second-line or steroid-sparing agent. Trials may need to last 3–6 months to ascertain effect.

A therapeutic clinical response to dapsone can usually be seen at doses ranging from 25–200 mg per day. Rarely, patients may require 300 mg per day before a response is seen. The initial dosage chosen should be between 50–100 mg per day in order to minimize potential pharmacologic adverse effects. If a therapeutic trial of dapsone is successful, the dose of dapsone should be decreased to a point at which lesions recur to be sure that the improvement was indeed due to dapsone and that there is a continuing need for the drug. An ongoing effort to reduce the dose of dapsone to the lowest effective dose is an important means to minimize potential adverse effects.

Topical dapsone (5% gel) is FDA approved for acne vulgaris in adults[24–29] and adolescents[61] down to age 12. It has demonstrated low rates of irritation and erythema and in clinical trials resulted in a mean total lesion count reduction of between 39% and 49%.[24,27,29,61] Greater activity has been noted for inflammatory than noninflammatory lesions. It can be used in conjunction with other acne medications, including adapalene and benzoyl peroxide gel[62]; however, if topical dapsone is used at the same time as benzoyl peroxide, a chemical reaction causes it to turn a yellow-orange that is washable from skin but may stain clothing.[63]

RISKS AND PRECAUTIONS

Dapsone therapy, although generally well tolerated, has important pharmacologic and idiosyncratic side effects. The pharmacologic side effects—hemolysis and methemoglobinemia—develop to some degree in all treated patients in a dose-dependent fashion.[136] These adverse effects are caused by the hydroxylated

BOX 225-1 THERAPEUTIC INDICATIONS FOR DAPSONE

FIRST LINE (CONSISTENT RESPONSE SEEN IN 24–48 HOURS)

- Dermatitis herpetiformis
- Erythema elevatum diutinum
- Linear IgA dermatosis/chronic bullous dermatosis of childhood, idiopathic or drug-induced
- Bullous SLE

SECOND LINE (OFTEN USED IN COMBINATION)

- Autoimmune blistering diseases
  - Pemphigus (foliaceus, vulgaris, and IgA variants)
  - Bullous pemphigoid, especially in children
  - Epidermolysis bullosa acquisita, especially in children
  - Mucous membrane pemphigoid
  - Lichen planus pemphigoides, especially in children
- Neutrophilic dermatoses
  - Subcorneal pustular dermatosis (Sneddon-Wilkenson), both idiopathic and drug-induced
  - Acute febrile neutrophilic dermatosis (Sweet syndrome)
  - Pyoderma gangrenosum
- Autoimmune diseases
  - Rheumatoid arthritis
  - Rheumatoid papules
  - Relapsing polychondritis
  - Subacute cutaneous lupus
  - Chronic cutaneous lupus
  - Lupus panniculitis
- Vasculitidies
  - Cutaneous polyarteritis nodosa (PAN)
  - Urticarial vasculitis
  - Henoch-Schönlein purpura (although reports suggest it is effective only for the cutaneous manifestations and does not prevent nephritis or relapse)
  - Chronic leukocytoclastic vasculitis without internal organ involvement
  - Behcet disease
- Acne and related conditions
  - Acne, including agminata and conglobata variants, although high required doses and availability of systemic retinoids have relegated dapsone to third line
  - Hidradenitis suppurativa
  - Granuloma faciale
  - Perifolliculitis capitis abscedens et suffodiens (dapsone with isotretinoin)
- Miscellaneous inflammatory conditions
  - Chronic idiopathic thrombocytopenic purpura (ITP)
  - Chronic urticaria
  - Aphthous stomatitis
  - Granuloma annulare
  - Psoriasis
  - Brown recluse spider envenomation
  - Mesotherapy complications, including granulomatous reaction and panniculitis
  - Melkersson-Rosenthal syndrome
  - Eosinophilic fasciitis
  - Alpha-1-antitrypsin deficiency-related panniculitis
  - Neutrophilic eccrine hidradenitis
  - Insect bite-like reaction in patient with leukemia and presumed immune dysregulation
  - Erythema multiforme
  - Rosai-Dorfman
  - Idiopathic angioedema
- Infectious diseases (details of treatment beyond the scope of this chapter)
  - Malaria
  - Leprosy
  - Leishmania
  - Nocardia
  - Pneumocystis prophylaxis

metabolite, dapsone hydroxylamine, which is a potent oxidant.[137–144] Within erythrocytes, dapsone hydroxylamine generates reactive oxygen species which oxidize oxyhemoglobin into methemoglobin. The oxidized hemoglobin becomes microscopically visible as Heinz bodies. These Heinz bodies and hydroxylated metabolite/cellular protein adducts may label the red blood cells as senescent, targeting them for removal by the spleen. Glutathione within the erythrocytes is responsible for reversing oxidative damage; however, production of glutathione is largely dependent on glucose-6-phosphatase dehydrogenase (G6PD). Patients with G6PD deficiency are less tolerant of pharmacologic oxidative stress and are at risk for substantial hemolysis. There are two types of G6PD deficiency that are screened for with the same laboratory assay: "A-type" G6PD deficiency occurs in African-Americans and is more mild than the type seen in patients of Mediterranean heritage.[145] G6PD deficiency should be ruled out before initiating therapy in all patients.[146] Hemolysis is more profound at the initiation of therapy and should be accompanied by a compensatory reticulocytosis. Patients with preexisting iron or B_{12}/folate deficiency may not be able to mount appropriate erythropoesis and are at greater risk for symptomatic drops in hemoglobin. Thus, baseline anemias should be worked up before starting dapsone. The frequency of symptomatic anemia is 10%,[147] but might be higher in certain populations such as solid organ allograft recepients (23%).[148,149] This higher rate of hemolysis may be due to the greater frequency of renal insufficiency in this patient population or a potential interaction with medicines such as sirolimus. If dapsone therapy is efficacious but hemolysis is limiting therapy,

coadministration of darbepoetin may allow continuation of drug at therapeutic doses.[150,151]

Methemoglobinemia is another predictable consequence of dapsone therapy, again due to dapsone hydroxylamine's generation of reactive oxygen species.[152–159] Methemoglobin is the form of hemoglobin in which the iron molecule is in the oxidized ferric (Fe^{3+}) state rather than in the ferrous state (Fe^{2+}). As such, the standard complete blood count will show the hemoglobin value as normal (or slightly low due to hemolysis) but the molecule itself is unable to carry oxygen or carbon dioxide.[154] The signs and symptoms of methemoglobinemia are those of poor oxygenation, including cyanosis, headache, shortness of breath, chest pain, and fatigue. And although some degree of methemoglobinemia occurs in most patients, symptomatic methemoglobinemia is rare. Symptoms usually occur with methemoglobin levels of 20%–30%.[158,159] Patients with an inability to tolerate decreased oxygen carrying capacity, such as those with preexisting cardiopulmonary disease or anemia, may develop symptoms at a lower percentage methemoglobin. Pulse oximetry is a reasonable screening test for methemoglobinemia, as a normal value excludes significant methemoglobin levels. However, an abnormal value must be followed up with a direct methemoglobin determination.[158–160] This is because the pulse oximeter measures light absorbance at two wavelengths, 660 and 940 nm, for oxy- and deoxyhemoglobin, respectively. It calculates the oxygen saturation via the ratio of light absorbance. In the presence of a dyshemoglobin such as methemoglobin, carboxyhemoglobin, or inherited abnormal hemoglobins such as hemoglobin Rothchild, this method is not accurate in determining oxygen saturation. Clinical cyanosis is a very insensitive indicator of methemoglobinemia and should not be relied upon. Since methemoglobin does not carry oxygen, supplemental oxygen generates little improvement until the methemoglobin level is reduced. As mentioned previously, cimetidine, which blocks the hydroxylation of dapsone, has been used intentionally to lower methemoglobin levels in dapsone-treated patients by 27%–60%.[46–50] Lipoic acid, a dietary supplement with antioxidant properties, as also been shown in vitro to decrease methemoglobin formation and 90 mg daily of lipoic acid daily has been suggested for dapsone-treated patients.[161]

While G6PD-deficient individuals are at greater risk for hemolytic anemia and methemoglobinemia, the clinician should remember that these events are also seen in patients without G6PD deficiency.[162] Therefore, all patients should undergo regular monitoring. (See Section "Initiating and Monitoring of Dapsone Therapy.")

The other adverse effects of dapsone are idiosyncratic or allergic in nature.[163–206] Most common are rashes of various morphologies and nonspecific symptoms such as fatigue and headache (see Box 225-2). However, the clinician should be alert for rashes that present with fever and other systemic symptoms, as these may be manifestations of a serious hypersensitivity reaction called the sulfone syndrome.[163–179] Incidence of this syndrome ranges from 0.2%–5% of treated patients.[163–166] The sulfone syndrome is a drug-induced hypersensitivity syndrome like those seen with some anticonvulsants and other medications.[167–168] These syndromes are postulated to be due to drug-allergy-induced immunosuppression[39,40,167,168] leading to a reactivation of human herpesvirus 6 (HHV6) or other latent viruses such as CMV and EBV. They develop between 2 and 7 weeks after initiating the medication and inevitably include the triad of fever, rash, and hepatitis. The rash is most often an exfoliative dermatitis,[169] but maculopapular and Stevens–Johnson-like lesions have occurred. The hepatitis has a mixed hepatocellular and cholestatic picture with elevations in both transaminases[170–175] and alkaline phosphatase.[176] Features of the sulfone syndrome are listed in Table 225-1. Treatment of the sulfone syndrome involves prompt discontinuation of dapsone. Corticosteroids have proved helpful but doses up to 1g/day of methylprednisolone for 3 days may be required, followed by a prednisone taper over 4–6 weeks. It is the reactivation of HHV6 that is thought to cause the late flaring of rash, fever, and hepatitis that is characteristically

BOX 225-2 ADVERSE EFFECTS OF DAPSONE

- Pharmacologic effects
  - Hemolysis
  - Methemoglobinemia
- Sulfone syndrome (see Table 225-1)
- Cutaneous
  - Morbilliform eruptions
  - Erythema nodosum eruptions
  - Erythema multiforme
  - Exfoliative dermatitis
  - Stevens–Johnson syndrome/toxic epidermal necrolysis[139]
  - Photosensitivity (12 reports)[210–212]
- Gastrointestinal
  - Nausea
  - Anorexia
  - Gastric irritation
  - Cholestatic jaundice
  - Transamimitis
  - Hypoalbuminemia
- Neuropsychiatric
  - Psychosis
  - Peripheral neuropathy (almost always motor)
  - Acute myopia
- Hematologic
  - Leukopenia, including agranulocytosis
  - Pure red cell aplasia
  - Aplastic anemia
  - Hemophagocytic syndrome
- General
  - Fatigue
  - Headache

Data from Lang PG: Sulfones and sulfonamides in dermatology today. *J Am Acad Dermatol* **1**:479, 1979; Katz SI et al: Dermatitis herpetiformis: The skin and the gut. *Ann Intern Med* **93**:857, 1980; Alexander JO: Dermatitis herpetiformis. TABLE 225-1
Features of the Sulfone Syndrome

- General signs/symptoms
  - Fever (92%)
  - Lymphadenopathy (81%)
  - Pallor (77%)
  - Elevated ESR (92%)
  - Weakness
  - Sore throat
  - Headache
- Cutaneous signs
  - Rash (100%), most commonly maculopapular progressing to exfoliative (69%)
  - Itching (85%)
- Gastrointestinal system involvement
  - Liver dysfunction
    - Elevated transaminases (100%)
    - Elevated bilirubin (85%)
  - May be clinically jaundiced (81%)
  - Cholangitis
    - Hepatomegaly (73%)
    - Hypoalbuminemia (42%)
- May have coincident pedal edema (54%) or even anasarca
  - Pancreatitis
- Hematologic abnormalities
  - Leukocytosis (69%)
    - Atypical lymphocytosis
    - Leukemoid reaction
  - Anemia (46%)
- Other major organ system findings
  - Renal hypersensitivity vasculitis
    - May progress to renal failure
  - Hypersensitivity (eosinophilic) pneumonitis
    - Pleural effusions
  - Hypersensitivity myocarditis
    - With complete arterioventricular block
  - Thyrotoxicosis

seen in this class of drug reactions, necessitating such a long steroid taper.[167] Additionally, any other end-organ damage must be managed supportively (dialysis for renal failure,[165] diuretics for myocarditis,[163] etc.) Plasma exchange has also been successfully used in a case where tapering of steroids led to recrudescence of symptoms.[179] Rechallenge with dapsone followed resolution of the sulfone syndrome is contraindicated as reinitiation of drug can produce severe symptoms within 2 to 6 hours.

The other reported side effects of dapsone are rare. These include various gastrointestinal complaints such as nausea, stomach irritation, and abnormalities in liver function tests[180–181] in the absence of the sulfone syndrome. Also reported are varied neurologic side effects, including a distal motor neuropathy, most often without a sensory component.[182–184] This is reversible with dose decrease or discontinuation. Checking a patient's distal motor strength at follow-up visits may alert the clinician to its development. Other neurologic side effects include the induction of acute psychosis.[185–187] There is a single report of dapsone-induced acute myopia that was reversible with drug discontinuation[188] and one report of anterior ischemic optic neuropathy.[189]

Agranulocytosis is another rare, idiosyncratic side effect that has been estimated to occur in 0.2%–0.4% of treated patients.[136,146,162,190–195] If agranulocytosis occurs, its onset is almost always during the first 3 months of therapy. Although usually reversible within days when patients stop therapy, it may be fatal due to superseding infection. Symptoms of agranulocytosis often include fever, pharyngitis, dysphagia, and oral ulcerations.[136,146] Patients should be warned to seek medical care immediately if these symptoms develop, especially within the first three months. Recombinant granulocyte colony stimulating factor has been used to produce a more rapid resolution of agranulocytosis.[196] Individual case reports of other hematologic sequelae of dapsone include two cases of pure red cell aplasia[197] and a single case of hemophagocytic syndrome induced by dapsone.[198]

In the case of accidental or intentional overdose, the clinician should be prepared for significant hemolysis (which may be delayed by up to 9 days due to enterohepatic recirculation) and methemoglobinemia.[199–202] Massive intravascular hemolysis seen in dapsone overdose has been linked to optic ischemic injury.[203–205] Although dapsone is 50%–80% protein bound in the circulation, the unbound portion can be dialyzed off and repeated dialysis has been helpful in the case of overdose.[206] Because of dapsone's enterohepatic recirculation, administration of activated charcoal will reduce drug levels by removing drug from the gut. Intravenous methylene blue, 1% solution given 1–2 mg/kg slowly IV,[207,208] can be used to decrease the degree of methemoglobinemia. Methylene blue is a cofactor for methemoglobin reductase after first being reduced by cellular stores of NADPH to leukomethylene blue. G6PD-deficient patients should not be given methylene blue, as they may have insufficient NADPH and unreduced methylene blue is its own direct hemolytic agent. Ascorbic acid 1,000 mg intravenously every twelve hours has also been used in a case of overdose and certainly could be used until G6PD status is reviewed so that methylene blue can be administered. Ascorbic acid's effect is due to its ability to increase methemoglobin reductase activity.[200]

INITIATING AND MONITORING OF DAPSONE THERAPY

Before therapy with dapsone is commenced, a targeted history and physical examination to screen for significant preexisting cardiopulmonary disease (these patients might be poorly tolerant of anemia or methemoglobinemia) or peripheral neuropathy should be completed. Initial labs should include a complete blood cell count to determine baseline white blood cell count and hemoglobin. G6PD deficiency should be ruled out, as should significant hepatic or renal dysfunction. After therapy has begun, a white blood cell count with differential and hemoglobin levels should be obtained weekly for the first month and then twice a month during the next 2 months.[136,146] A drop in hemoglobin of 1–2 g/dL should be anticipated and, in the absence of symptoms, should not prompt drug discontinuation. Monitoring reticulocyte counts will also provide an estimation of the adequacy of compensation for hemolysis. A profoundly elevated reticulocyte count suggests that

erythropoiesis is at its maximum and that further dose increases are not likely to be well tolerated. Even during long-term therapy, complete blood cell counts should be obtained periodically. Checking methemoglobin levels is unnecessary in the absence of symptoms. Follow-up visits should include pulse oximetry (any abnormal value should be followed up with methemoglobin determination), checking distal muscle strength, peripheral reflexes and reminding patients to not alter their dosage without physician guidance (to limit their risk for dose-dependent methemoglobinemia and hemolysis). Patients should also be told to carry a medication card so that in event of an emergency, treating physicians will know they are on a drug with hemolytic and methemoglobin-generating potential. It is important that all patients be made aware of the potential clinical manifestations of adverse events. Especially during the first three months of therapy when the risk of agranulocytosis and the sulfone syndrome is highest, patients should be reminded to seek medical attention immediately for significant fever, pharyngitis, dysphagia, swollen lymph nodes, oral ulcerations, and rash.[136,146] Patients with diabetes should also be made aware that dapsone causes falsely low HgA1c values due to the accelerated RBC turnover; monitoring fructosamine levels avoids this potential confounder.[209] It might be suggested to patients who have mild symptoms of anemia or methemoglobinemia to take cimetidine 400 mg three times daily and lipoic acid 90 mg a day to see if these might ameliorate symptoms enough for dapsone administration to continue.[47–50,161]

Chapter 226 :: Aminoquinolines

:: Susannah E. McClain, Jeffrey R. LaDuca, & Anthony A. Gaspari

AMINOQUINOLINES AT A GLANCE

- Aminoquinolines have been used in clinical medicine for more than a century, initially as antimalarial compounds.
- Multiple mechanisms of action, particularly impaired lysosomal acidification by antigen presenting cells, inhibition of natural killer and T-cell activation, and inhibition of lipid mediators of inflammation.
- Propensity for melanin pigment, absorb ultraviolet light, and exhibit photoprotective properties against ultraviolet-mediated injury of the skin.
- Aminoquinolines used to treat dermatologic conditions include hydroxychloroquine, chloroquine, and quinacrine.
- Hydroxychloroquine is the most commonly used aminoquinoline for skin conditions and is well studied for chronic cutaneous lupus erythematosus.
- Other aminoquinoline-responsive conditions: porphyria cutanea tarda, polymorphous light eruption, cutaneous sarcoidosis, dermatomyositis, and other conditions.
- Laboratory monitoring is mandatory during aminoquinoline therapy to detect hematologic abnormalities (hemolysis and drug-induced cytopenias), liver injury, and ophthalmologic toxicity (retinopathy).
- Children are especially susceptible to aminoquinoline toxicities, and lower doses must be used than in adults.
- Drug interactions are possible, and cigarette smoking decreases efficacy of aminoquinolines by inducing cytochrome P_{450} enzymes.

Antimalarial compounds have been used to treat skin diseases for more than a century. Three compounds, chloroquine (CQ), hydroxychloroquine (HCQ), and quinacrine (QE), have been most studied. The 4-aminoquinolines are a family of compounds derived from quinine, a naturally occurring alkaloid originally procured from the South American cinchona bark tree.[1] CQ and HCQ, the principal members of this class of compounds, are the most often used for therapeutic use in dermatology. QE, classified as an acridine, has also been used in dermatologic therapy. Interestingly, the use of these medications for treatment and prophylaxis of malaria is waning due to increased resistance.

MECHANISM OF ACTION

The precise mechanisms by which antimalarial compounds exert their actions are still unknown. However, several discrete mechanisms for each compound have been determined. In the treatment of malaria, aminoquinolines concentrate in the *Plasmodium* digestive vacuole and prevent polymerization of toxic heme released during proteolysis of hemoglobin.[2] Mechanisms by which these compounds influence skin diseases are varied and include, among others, their effects on antigen presentation, cytokines, toll-like receptors, and prostaglandins.

CQ and HCQ are lipophilic weak bases that pass through plasma membranes in their protonated state, become trapped, and accumulate inside acidic vesicles such as lysosomes,[1,3,4] accounting for their effects in *Plasmodium*. HCQ induces signs of lysosomal and mitochondrial membrane permeabilization.[5] By raising intralysosomal pH from 4–6, acidic proteases become inactivated and subsequent proteolysis is inhibited. Subsequently, antigen processing and presentation by dendritic cells may be impaired because of an inability to digest these foreign antigens within the lysosomal compartment.[6] Additionally, CQ has been shown to disrupt antigenic peptide loading on class II MHC molecules and subsequent presentation to the opposing T cell.[1,7] Inhibition of calcium signaling within the T cell may be an additional mechanism.[8] Conversely, CQ has been more recently shown to enhance human $CD8^+$ T cell responses.[9] QE inhibits Na-K adenosine triphosphatase activity and stabilizes cell membranes.[10] It also concentrates in lysosomes. The effects are most appreciated in macrophages and phagocytic cells where phagocytosis and chemotaxis are impaired.[11,12] Additionally, cellular enzymes and receptors dependent on lysosomes for function or activation are also affected, thus altering cells' responsiveness to mitogenic stimuli.[3]

Antimalarials decrease T-cell release of interleukin (IL)-1, IL-6, tumor necrosis factor-α, and interferon-γ.[13,14] IL-1, IL-6, and tumor necrosis factor-α play a role in the hepatic production of acute-phase reactants.[15] Low concentrations of CQ and QE inhibit the pro-IL-6 stimulatory effect of cytosine-phosphorothiolated guanine-oligodeoxynucleotides on human peripheral blood mononuclear cells.[16,17] More recently, it has been found that CQ elevated the expression of B7–2 (CD86, a costimulatory molecule) and intercellular adhesion molecule-1 (CD54, an adhesion molecule) in peripheral mononuclear cells, thus increasing IL-10-producing cells.[18] CQ has also been implicated in the inhibition of natural killer cell activity, decreased production of IL-2 from activated lymphocytes, and alteration of antigen-antibody complexes. QE also inhibits natural killer cells and blocks the primary proliferative response of cytotoxic T cells to allogeneic non-T-cell antigens.[15] Last, the arachidonic acid pathway is affected by antimalarial compounds. CQ inhibits phospholipase A_2 and C.[15] QE also inhibits phospholipase A_2 production[19,20] and increases nitric oxide release.[21] Thus prostaglandin, leukotriene, bradykinin, and histamine levels can all be decreased. QE antagonizes the generation of superoxide anions.[22]

A novel mechanism of action of the antimalarials has recently been elucidated with respect to its inhibition of toll-like receptor (TLR) 9 family receptors.[1] TLRs are intracytoplasmic receptors whose activation of the innate immune system in response to microbial peptides induces a significant inflammatory response. Additionally, further research has highlighted the importance of the innate immune response underlying the pathogenesis of systemic lupus erythematosus (SLE).[23] Consequently, these TLRs who, as a class, are known as "pattern recognition receptors" (PRRs), have become a subject of intense investigation underlying the pathogenesis of SLE. It has recently been shown that host immune complexes containing DNA or RNA play an important role in activating endogenous TLRs (especially TLR-9 and TLR-7), thus leading to the eventual activation of the innate immune system, of which interferon alpha plays a crucial role.[24,25] Additionally, TLR-9 expression is strongly associated with SLE activity.[25] These specific nucleic acid binding TLRs bind their ligands in the lysosome, where an acidic environment promotes this binding.[26] As the antimalarial agents specifically target microsomes by disrupting endosomal maturation and changing the pH, they block the TLR interaction (TLR-3, -7, and -9) with nucleic acid ligands.[27] In vitro studies have identified that nanomolar concentrations of chloroquine specifically were potent inhibitors of IL-6 production by monocytes, an effect now known to be directly mediated by the inhibition of TLR-9.[1] Antigen presenting cells are the primary targets of these interactions, thus accounting for a clinically slower response, as they initiate and prime the subsequent immune reactions.[1] The 4-aminoquinolines have an affinity for melanin pigment. In the epidermis (as well as retina), they bind in high concentrations. In the skin, CQ absorbs ultraviolet (UV) light in a concentration-dependent manner.[28] There is an increase in minimal erythema doses (MEDs) to UVB in lupus patients after taking oral chloroquine for 3 months, theoretically resulting from the anti-inflammatory and/or photoprotective mechanisms of the drugs.[1,29] Topical CQ applied before UV irradiation protects against UVB- and UVA-induced erythema.[30] QE has also been shown to inhibit photodynamic actions.[31] It has been proposed that the beneficial effect of the HCQ and CQ in various photodermatoses may result from the ability of these drugs to enhance the protective early limb of the UV response.[32]

CQ and QE have been shown to bind cellular DNA by intercalation between base pairs, thus stabilizing the DNA.[33–35] RNA transcription and subsequent translation are inhibited. These may be the mechanisms by which these molecules affect lupus.[36]

Antimalarial compounds also exhibit a myriad of ancillary effects. HCQ has been shown to improve lipid profiles, specifically causing a 15%–20% reduction in serum total cholesterol, triglycerides, and LDL levels.[37] Both CQ and HCQ improve glucose profiles by decreasing insulin degradation[38,39] and inhibit platelet aggregation.[40] High doses of CQ may produce an antioxidant effect.[41] Through membrane stabilization, antimalarials can produce a local anesthetic effect.[3] In vitro, HCQ has been shown to induce apoptosis in B-chronic lymphocytic leukemia cells.[42] CQ, HCQ, and QE have all been shown to interfere with human immunodeficiency virus type 1, SARS coronavirus, and influenza replication and function possibly due to disruption of protein glycosylation.[43–46]

PHARMACOKINETICS

The molecular structures of CQ, HCQ, and QE are closely related (Fig. 226-1). CQ and HCQ are 4-aminoquinolines, with HCQ differing from CQ by the presence of a hydroxyl group at the end of the side chain.[1] The addition of a benzene ring classifies QE as an acridine. The pharmacokinetics and pharmacology of these compounds are similar, but importantly there is no cross reactivity between the aminoquinolines and QE (Table 226-1). All are bitter, water-soluble, and readily absorbed from the gastrointestinal tract with relatively good bioavailability, achieving peak concentrations within 8–12 hours. CQ and HCQ have large volumes of distribution (over 100 L/kg) and prolonged half-lives.[47] The volume of distribution for QE may be even larger than that of CQ and HCQ. QE is extensively bound to plasma proteins, whereas CQ and HCQ are only partially bound (60%).[48–50] The half-life of QE is substantially less than the other compounds.[50] CQ is metabolized (dealkylated) in the liver by P_{450} enzymes into two active metabolites, desethylchloroquine and bisdesethylchloroquine.[51] The metabolic fate of QE is less certain. CQ and its metabolites are stored in relatively high concentrations in the liver, spleen, lungs, adrenals, and kidneys with the highest concentration found in melanin-containing cells of the retina and skin.[52] Approximately 50% of CQ is eliminated by the kidneys unchanged.[48] HCQ is also metabolized in the liver (*N*-desethylated) into three chief metabolites: (1) desethylhydroxychloroquine, (2) desethylchloroquine, and (3) bisdesethylchloroquine.[47] The parent compound and metabolites are taken up by lysosomes and concentrated in lysosome-rich tissues. Renal clearance accounts for approximately 15%–25% of the total clearance.[53] The renal excretion of CQ, HCQ, and QE can be enhanced with acidification of the urine.[54] QE is excreted in urine, bile, sweat, and saliva.[50] Renal excretion only accounts for approximately 11% of its clearance. The highest tissue concentrations of QE are found in the liver and spleen.[52] Equivalent doses of these

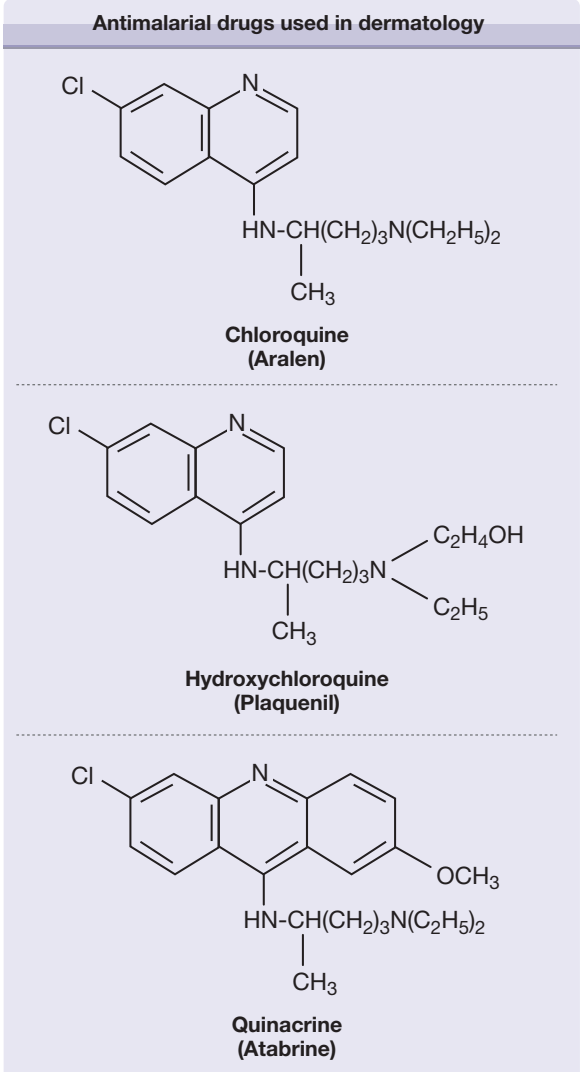

Figure 226-1 Antimalarial drugs used in dermatology.

compounds are 250 mg of CQ, 400 mg of HCQ, and 100 mg of QE. Smoking may alter the pharmacokinetics of antimalarial compounds, as clinical evidence of decreased efficacy of these medications in smokers has been documented.[55] Decreased absorption, increased plasma clearance, or induction of the cytochrome P_{450} system may be mechanisms by which smoking alters the metabolism of these compounds.[56]

A recent study has highlighted the relationship between whole blood concentrations of HCQ and disease activity in SLE patients.[57] Results of whole blood levels in 143 SLE patients who had received 6 months of HCQ at a dose of 400 mg/day demonstrated large variability in blood concentrations (possibly due to compliance). The mean concentration of patients with inactive disease was 1,079 ng/mL compared with the mean level of patients with active disease, which was 694 ng/mL. Additionally, the authors found that a low blood level of HCQ was associated with disease exacerbation in the follow-up period. The conclusion was that whole drug concentrations of HCQ should

Equivalent doses	250 mg	400 mg	100 mg

be maintained above 1,000 ng/mL, indicating a need for regular drug assaying and individualized dosing schedules to maintain this level.

Typical doses used in dermatology are 250–500 mg/day for CQ, 200–400 mg/day for HCQ, and 100–200 mg/day for QE. Evidence of efficacy is generally seen after 1–3 months of use, but it may take up to 3–6 months to achieve maximum clinical efficacy. After this time, the dose may be tapered to a minimum effective dose. Again, there is no cross-reactivity between QE and CQ and HCQ.[58] Thus, the use of QE in combination with HCQ and/or CQ has been deemed safe, and an adverse reaction to the 4-aminoquinolone group does not preclude the use of QE. In refractory skin conditions, addition of QE to HCQ or CQ has been deemed beneficial, and response may be seen in 6–8 weeks after the addition of QE.[59] If QE is added to CQ, the dose of CQ may need to be decreased to reduce potential for toxicity. Triquin, a combination of CQ (65 mg), HCQ (50 mg), and QE (25 mg) was used in the early 1970s. Nevertheless, the concomitant use of CQ and HCQ increases the risk for retinopathy (see Section "Complications"). Thus, this combination should be restricted to only severe cases. QE is not currently commercially available; production stopped in 1992. QE powder (veterinary grade, Sigma) can be formulated into capsules. Panorama Pharmacy in California, with an additional purification step, will prepare QE capsules.

INDICATIONS

The US Food and Drug Administration-approved indications for CQ, HCQ, and QE are limited. As is often seen in dermatology, these compounds are frequently used in an off-label manner. Treatment of malaria is the only indication shared by all three drugs. HCQ has the most labeled uses, including rheumatoid arthritis, discoid lupus, and systemic lupus erythematosus. Extraintestinal amebiasis is the only other approved use for CQ. QE had been approved for treatment of giardiasis when it was manufactured. Experience with HCQ in dermatology is more extensive. Its lower incidence of ocular toxicity (see Section "Complications") makes it a favored choice. In recalcitrant disease, CQ is often substituted with increased efficacy. The current difficulty in obtaining QE may account for the relatively fewer indications (Table 226-2).

CUTANEOUS LUPUS ERYTHEMATOSUS

(See Chapter 155)

Antimalarial drugs have been used for the cutaneous manifestations of lupus (acute cutaneous, subacute cutaneous, and chronic cutaneous LE) since the 1930s.[60] CQ and QE were found to be effective in the treatment of cutaneous lupus also during World War II.[61] A double-blind trial of HCQ for discoid lupus showed a 70% response rate and that it was more efficacious than placebo at 3 months and 1 year of treatment.[62] A review of 20 clinical trials involving the use of QE for cutaneous lupus showed an overall 73% response rate.[63] Antimalarials are typically used as steroid-sparing agents in patients whose symptoms cannot be controlled by topical steroids and sun protection. Widespread cutaneous lesions, hypertrophic and verrucous lesions,

and longstanding discoid lesions do not respond as well. Systemic symptoms such as fever, renal, or hematologic abnormalities seen in systemic lupus erythematosus typically do not respond to antimalarial therapy, but fatigue, arthralgias, myalgias, serositis, and mucosal ulcerations do respond to therapy.[64] In addition, antimalarials have effectively treated nonspecific cutaneous manifestations of LE, such as mucosal ulcerations, calcinosis cutis, lupus panniculitis, and photosensitivity.[65] Lupus panniculitis specifically has been reported to respond well to antimalarial therapy, with 23 out of 33 patients in one study demonstrating clinical improvement.[66] The onset of action for antimalarial therapy is typically 4–8 weeks; after which time, one may consider adding or changing therapies. More rapid response may be seen with the addition of QE.[63] When HCQ is ineffective as a monotherapy, CQ may be more efficacious, but the combination of HCQ and CQ is generally avoided to prevent retinal toxicity. The use of QE alone or in combination with either HCQ or CQ has also been suggested as providing a response in recalcitrant patients. A recent report evaluating 34 patients unresponsive to HCQ therapy alone identified the majority of patients rapidly and significantly responded to the addition of QE to their therapeutic regimen.[67] Triquin, a combination of all three drugs, has also been used in cutaneous lupus erythematosus with success.

POLYMORPHOUS LIGHT ERUPTION

(See Chapter 91)

Polymorphous light eruption (PMLE) is an inflammatory reaction seen on sun-exposed skin. IL-1, -6, and -8 may play a role in the inflammatory process.[68] Chloroquines decrease IL-1 and -6 and release and absorb UVA light. Although generally not used as first-line treatments, these drugs have been used for PMLE for several years[69,70] and placebo-controlled trials have proven efficacy for this indication.[71] Two trials demonstrated increased sun tolerance and moderate clinical improvement identified by skin rash reduction, which was statistically significant.[1,72,73] Intermittent HCQ at doses of 200–400 mg/day prior to sun exposure can be effectively tried if photoavoidance and/or prophylactic UVB/UVA are not viable options. Topical sunscreens should also be used in conjunction with antimalarial therapy. In northern climates, discontinuation of therapy during winter months may decrease cumulative side effects of antimalarial therapy.

PORPHYRIA CUTANEA TARDA

(See Chapter 132)

The first reported case of CQ therapy for porphyria cutanea tarda (PCT) was published in 1957,[74] and its use

can lead to long-term remission.[1,75] Chloroquines inhibit porphyrin synthesis and mobilize lysosomal stores of porphyrins, allowing for the formation of water-soluble complexes, which are then excreted by the kidneys.[76] Although phlebotomy remains the primary treatment of choice for PCT, antimalarial therapy may be used in conjunction with phlebotomy or when phlebotomy is contraindicated or has previously been used without success. Hepatotoxicity is a concern, and liver enzymes should be followed closely during therapy. Headache, nausea, fever, elevated transaminases, and urinary excretion of porphyrins occur 3–4 days after initiation of therapy with CQ at 250 mg/day.[77] Prolonged remissions have been reported with short courses of high dose HCQ (250 mg three times daily), but high doses routinely lead to marked increases in liver transaminases.[78] Low-dose CQ therapy (125 mg twice weekly for 2 weeks followed by 250 mg twice weekly thereafter) gave a 94% response rate in one study of 53 patients.[79] Alternatively, HCQ used at 100 mg three times weekly for 1 month, then 200 mg three times weekly for 1 month, then advanced to 200 mg daily has been proposed.[80] These lower dosing schedules seem to alleviate the severe acute hepatotoxicity. A combination of phlebotomy before initiation of CQ therapy may also reduce the severity of hepatotoxicity.[81]

SARCOIDOSIS

(See Chapter 152)

Antimalarial therapy for cutaneous manifestation of sarcoidosis was first described nearly half a century ago. Original reports on the efficacy of antimalarials in the treatment of sarcoidosis demonstrated initial clinical improvements on treatment during a 6-month course, with little further improvement after 1 year, indicating the treatment was likely suppressive rather than curative.[82] Additionally, relapses off of these medications are common, further supporting the notion that these therapies are not curative.[82–87] The proposed mechanism of action relies on the antimalarials' capacity to block antigen processing and presentation to CD-4$^+$ T cells, thus inhibiting granuloma formation.[83,88] A 1996 review of the subject concluded that antimalarials were highly effective, with greater than 70% response rate.[89] Two to three mg/kg/day of HCQ has been reported as being effective in 12 of 17 patients treated.[90] CQ therapy initiated at 500 mg/day for 2 weeks, then a maintenance dose of 250 mg/day has been described as safe and effective.[91] Therapy may also be effective for associated hypercalcemia. Another granulomatous disease, generalized granuloma annulare, has also been reported to respond to HCQ.[1,92–94]

CUTANEOUS DERMATOMYOSITIS

(See Chapter 156)

Although the muscle disease in this condition often responds well to systemic corticosteroids, the cutaneous lesions are generally recalcitrant to this therapy. Cutaneous symptoms unresponsive to traditional therapies have been reported to respond well to antimalarial therapy. It is in these patients that antimalarial therapy be strongly considered, as well as in those patients with cutaneous involvement without any muscle involvement ("amyopathic dermatomyositis").[1] Monotherapy with either HCQ 200 mg bid (less than 6.5 mg/kg/day) or CQ 250 mg qd (less than 3.5 mg/kg/day) is often adequate to control skin manifestations. The addition of QE to either HCQ or CQ has been shown to be beneficial in patients who do not respond to a 4-aminoquinolone alone.[59]

ORAL LICHEN PLANUS

Because the lesions of oral LP are clinically indistinct from those of mucosal LE, an open trial enrolling oral LP patients was undertaken to assess their response to HQC.[95] Nine out of the ten enrollees exhibited a rapid, excellent response to therapy with 200–400 mg/day HQC, with a minority flaring after discontinuation of therapy (3 months). Although corticosteroids are the first-line therapy for this disorder, recalcitrant lesions may respond to antimalarial therapy.

CHRONIC ULCERATIVE STOMATITIS

There are only a handful of cases reported in the literature describing this rare disorder which occurs primarily in older female patients. Clinicopathologically, this disease mimics erosive lichen planus but is traditionally unresponsive to corticosteroid therapy. The cases reported, however, demonstrated a complete response to antimalarial therapy lasting for several months to years. These medications are now considered first-line therapy for this rare condition.[96]

MISCELLANEOUS

Antimalarials have been reported to be useful in cases of epidermolysis bullosa, eosinophilic fasciitis, atopic dermatitis, solar urticaria, scleroderma, urticarial vasculitis, and reticular erythematous mucinosis, and Sjögren syndrome.[1,96–101]

DOSING REGIMENS

Use of antimalarial compounds in dermatology is varied. Each disease state is treated differently with special concerns pertaining to the disease entity. As such, dosing for each condition is dependent on the underlying pathology. Usual starting doses for HCQ are between 200 and 400 mg/day. Equivalent dosing for CQ is 250–500 mg/day, and for QE, 100–200 mg/day. However, initiation of therapy and maintenance dosing may be different for each disease. Combination therapy with these medications also alters the dosing.

INITIATING THERAPY

Given the degree of variation among dermatoses potentially responsive to antimalarials, many principles govern the initiation of therapy. Of utmost importance is the establishment of the correct diagnosis through clinical, histologic, and serologic evaluations. Next, one must make the determination as to whether antimalarials have been shown efficacious in the diagnosed dermatosis (see Table 226-2). After an established diagnosis has been made, one should determine whether the patient is an appropriate candidate for antimalarial therapy based on comorbid conditions and medication interactions. A rigorous laboratory monitoring protocol must be established, as adverse hematologic and metabolic side effects have been reported with the use of these medications. Patients who are deficient in the glucose-6-phosphate dehydrogenase (G6PD) enzyme are more prone to a hemolytic anemia. Thus, baseline evaluation of G6PD enzyme, complete blood cell count, and serum chemistry panel should be performed before initiation of therapy in all patients. Ocular toxicity is a serious side effect associated with the use of HCQ and CQ, and baseline evaluation by an ophthalmologist is necessary. Slit-lamp assessment, fundoscopic examination, and assessment of visual acuity and fields should be included.

MONITORING THERAPY

Laboratory monitoring should include a complete blood count performed monthly for 3 months to evaluate for the presence of hemolytic (or, less commonly, aplastic) anemia. Thereafter, quarterly to semiannual complete blood counts should be obtained. A comprehensive metabolic panel should be checked monthly for 3 months, then every 4–6 months thereafter, paying special attention to the liver enzymes, particularly in those patients who are taking hepatotoxic medications and in those patients with porphyria. Quarterly to semiannual chemistries should be followed while on maintenance therapy.

Proposed guidelines for monitoring for the development of ocular toxicity vary widely in the literature. At baseline and on each follow-up visit, patients must be asked about any changes in visual acuity and simple screening tests for acuity may be sufficient. Should patients report changes in vision, an ophthalmologist referral is then appropriate. Current American Academy of Ophthalmology (AAO) screening guidelines recommend that patients be prescribed doses of hydroxychloroquine ≤6.5 mg/kg/day or chloroquine ≤3mg/kg/day.[102,103] Additionally, the guidelines divide patients into those who are "low risk" (receive lower dose for <5 years) and "high risk" (receive higher doses, have other risk factors such as high body fat level, concomitant kidney, liver, or retinal disease, or >60 years of age). Patients should have a baseline ophthalmologic examination within 1 year of beginning the medication, which includes a baseline slit-lamp, fundoscopic, visual field, and acuity examinations. The "low-risk" group requires no further testing (if they have a normal baseline evaluation) until the 5-year therapy mark has been reached; the "high-risk" group should have annual ophthalmologic examinations. After 5 years of continuous therapy, annual examinations are recommended because of the risk for ocular toxicity reported in patients on long-term therapy.[103]

COMPLICATIONS

Most side effects of antimalarial therapy are reversible (Box 226-1). Decreased dosing or drug withdrawal may completely alleviate a majority of side effects encountered with these drugs. Without proper monitoring, however, these drugs have the potential for serious and permanent side effects.[104]

Gastrointestinal complaints of anorexia, nausea, vomiting, diarrhea, and weight loss are the most commonly encountered side effects (10% for HCQ; 20% for CQ; 30% for QE).[105] Acute symptoms from high doses of CQ and HCQ include blurred vision, cardiovascular toxicities, hypotension, neurotoxicity, and respiratory or cardiac arrest.[48,49] In children, as little as 0.75 g of CQ can be fatal (2.25–3.0 g in adults).[106] Lethal doses of HCQ are considered to be in a similar range.[48,49] Several cases of overdose have been reported. Management of overdose consists of gastric lavage, ventilation, and inotropic support.[107–111] As little as one or two tablets of CQ or HCQ can be dangerous in children. Appropriate monitoring is necessary after accidental ingestion.[112] A lethal dose of QE has not been determined.

Patients with G6PD deficiencies are susceptible to CQ- and HCQ-induced hemolytic anemia, although rarely when taken in therapeutic ranges. Aplastic anemia with QE[113,114] and agranulocytosis with CQ or QE have also been reported. All of the antimalarials have reportedly caused severe, reversible leukopenia.[1]

Adverse cutaneous effects can be seen with antimalarial therapy. Exacerbation of preexisting psoriasis in as many as 18% of patients with psoriasis has been documented with the use of these medications.[115] CQ is responsible for most psoriatic flareups, while QE is more likely to induce exfoliative erythroderma. HCQ is much less likely to exacerbate psoriasis.[116]

In the general population, incidence of pruritus and rashes secondary to antimalarial use is reported to be 10%–20%.[117] Dose-related QE-induced drug eruptions were reported during World War II. One in 2,000 soldiers taking 100 mg daily reported an adverse reaction, whereas 1 in 600 soldiers taking 200 mg daily had an adverse reaction.[114] Lichenoid reactions accounted for approximately 20% of the cutaneous reactions in this series.

The antimalarials have a high affinity for melanin, which may account for the blue-black cutaneous discoloration in 10% to 30% of patients treated with these compounds for a prolonged course. The shins, face, hard palate, and nail beds are most commonly affected.[118,119] The discoloration may fade slowly over

BOX 226-1 RISKS AND PRECAUTIONS

- Possible side effects from antimalarial compounds
  - Gastrointestinal: anorexia, nausea, vomiting, diarrhea, weight loss, hepatotoxicity
  - Hematologic: hemolytic anemia (glucose-6-phosphate dehydrogenase deficiency), aplastic anemia, agranulocytosis, pancytopenia
  - Mucocutaneous: pigmentation—blue gray, yellow (quinacrine), rashes (urticaria, morbilliform, lichenoid, exfoliative dermatitis, acute generalized exanthematous pustulosis), pruritus, worsening psoriasis
  - Ophthalmologic: neuromuscular eye toxicity (diplopia, blurred vision, loss of accommodation), corneal deposits (halos around lights, photophobia), retinopathy (pre-maculopathy—reversible and true retinopathy—irreversible; not seen with quinacrine therapy)
  - Neuromuscular: nightmares, vertigo, tinnitus, nervousness, irritability, toxic psychosis, seizures, neuromyotoxicity, myasthenia-like syndrome, ototoxicity, rhabdomyolysis
  - High doses: cardiovascular toxicities, hypotension, neurotoxicity, respiratory or cardiac arrest, death
- Drug interactions
  - Penicillamine and digoxin levels may be increased with concurrent use of CQ or HCQ
  - Cyclosporin levels may be increased with use of CQ
  - Metoprolol levels may be increased with use of HCQ
  - Ampicillin bioavailability may be decreased when used with CQ
  - Antacids and kaolin may decrease gastrointestinal absorption of CQ
  - Cimetidine may increase CQ levels
  - Mefloquine used with CQ may increase risk of seizures
  - Smoking decreases efficacy of antimalarial drugs by inducing the cytochrome P_{450} system
- Special precautions
  - Dosing in children must consider weight to decrease risk of toxicity
  - Use in pregnancy is relatively contraindicated (congenital defects are rare)
  - Use in breastfeeding is relatively contraindicated (CQ and HCQ are excreted in breast milk)

CQ = chloroquine; HCQ = hydroxychloroquine.

months after the drug is discontinued. QE may cause an even more pronounced hyperpigmentation than that seen with CQ or HQC. Histopathological evaluation of lesional skin sections shows the presence of melanin granules and hemosiderin deposition within the dermis. More commonly, a dose-related yellowish staining occurs with QE and affects the skin, sclera, and bodily secretions. This discoloration also fades after drug withdrawal. Stevens-Johnson syndrome has also been reported in a patient treated with HCQ.[120]

Ocular toxicity is the most worrisome side effect of antimalarial therapy. Neuromuscular eye toxicity, corneal deposits, and potentially irreversible retinopathy can all occur. Blurred vision and reduction in accommodation power can occur from the depressive effect on ocular muscles during the initial weeks of therapy (transient and self-limited). CQ is deposited in the basal epithelium of the cornea. Deposition of HCQ can also occur but is less likely at therapeutic doses.[121] These depositions can be responsible for patient complaints of blurred vision, halos around lights, and photophobia upon initiating therapy.[122] The corneal deposits are dose related, reversible with cessation of therapy, and not a contraindication for continued therapy. CQ has an affinity for retinal pigment epithelium and can be stored there for years, even after discontinuation of therapy. Antimalarial-induced retinopathy can be reversible (premaculopathy) or irreversible (true retinopathy). Premaculopathy includes changes in visual fields or fundoscopic examination, not associated with vision loss. These changes may progress to irreversible disease if the offending drug is continued. True retinopathy is associated with bilateral, permanent visual field abnormalities. Risk of true retinopathy from antimalarial therapy has been studied and debated. It appears as though the risk is greater for CQ than HCQ.[121,123] Doses less than 3.0 mg/kg/day for CQ and less than 6.5 mg/kg/day for HCQ are believed to decrease the risk of a true retinopathy.[124] Higher doses and impaired renal function may increase the risk. The true risk of HCQ-induced retinopathy is felt to be quite rare. As such, the question of screening as a cost-effective measure is debated. A case of bull's eye maculopathy has been associated with QE therapy for malaria.[125]

Other, less likely side effects of antimalarial therapy include neurotoxicity (most commonly headaches and nightmares),[1] myotoxicity (myalgias, fatigue),[126] ototoxicity,[127,128] acute generalized exanthematous pustulosis,[129] cardiotoxicity (conduction disturbances, congestive heart failure),[57] and rhabdomyolysis.[130]

DRUG INTERACTIONS

There are several important medication interactions to consider when prescribing antimalarials. Most importantly, it is recommended that HCQ and CQ not be coadministered due to the potential for retinal toxicity. CQ or HCQ may increase penicillamine and digoxin levels when used simultaneously with these medications.[48,49] Cyclosporine levels may be increased by CQ.[48] Metoprolol levels may be increased with use of HCQ.[131] CQ may reduce the bioavailability of ampicillin.[48] Antacids and Kaolin may decrease the

GI absorption of CQ. A minimum of 4 hours should exist between administration of antacids and antimalarials.[48] Cimetidine may increase CQ levels,[48] increasing potential for other side effects. Concurrent use of CQ and mefloquine may increase the risk of seizures. CQ increases the risk of hepatotoxicity when administered with other hepatotoxic agents. Monitoring liver enzymes is recommended.[48] Finally, smoking induces the cytochrome P_{450} enzyme system and may alter the bioavailability of antimalarial therapy. Decreased efficacy of antimalarial therapy in smokers has been published.[132]

PEDIATRIC USE

CQ and HCQ have been used in the pediatric population.[133,134] However, concern over toxicity exists.[135,136] Antimalarials are now considered generally safe in children when treating rheumatic disorders, such as lupus erythematosus, dermatomyositis, juvenile rheumatoid arthritis, and morphea, as well as in panniculitis and PCT.[137] When the dose is appropriately adjusted for body weight, the risk for toxicity in children is felt to be no greater than for adults.

PREGNANCY

Use of antimalarial drugs in pregnancy is now generally accepted as safe. It is recognized that 4-aminoquinalines cross the placenta and accumulate in fetal tissues.[52] Congenital defects have been rarely reported with antimalarial drug use in pregnancy.[138] In one study of 27 pregnancies exposed to HCQ or CQ, no congenital anomalies were identified.[139] Another review of 33 lupus patients with 36 pregnancies exposed to HCQ reported no evidence of teratogenic effects.[140] Larger reviews in Britain and North America support the use of 4-aminoquinalines during pregnancy.[141–143] In addition, discontinuation of antimalarial therapy for the treatment of lupus may cause a significant flare-up of disease, which can be associated with prematurity, growth retardation, and increased fetal loss.[144–147] The safety of QE is less well documented.

BREASTFEEDING

Antimalarial use during breastfeeding is relatively contraindicated. CQ and HCQ are both excreted in breast milk, albeit in small amounts.[1,148] In the case of HCQ, infants are exposed to 2% of the maternal dose per kilogram per day and 1% of the maternal dose of CQ.[58] As the half-life is long and elimination slow, potential exists for accumulation of drug in the infant.[149]

Chapter 227 :: Cytotoxic and Antimetabolic Agents

:: Whitney A. High & James E. Fitzpatrick

CYTOTOXIC AND ANTIMETABOLIC AGENTS AT A GLANCE

- Cytotoxic and antimetabolic agents are used in dermatology to treat serious, life-threatening, and recalcitrant disease.
- Common agents used in dermatology include methotrexate, azathioprine, mycophenolate mofetil, thioguanine, hydroxyurea, cyclophosphamide, chlorambucil, and liposomal doxorubicin.
- Methotrexate is US Food and Drug Administration (FDA) approved for treatment of psoriasis and advanced mycosis fungoides, whereas cyclophosphamide is FDA approved for advanced mycosis fungoides only, and liposomal doxorubicin is approved for acquired immunodeficiency syndrome-related Kaposi sarcoma; other uses of the agent in this chapter occur on an "off-label" basis.
- Cytotoxic and antimetabolic agents act through inhibition and/or interruption of the cell cycle.
- Side effects and complications with these potentially dangerous medications are numerous, and close clinical follow-up and laboratory evaluation is necessary.
- Cytotoxic agents used in dermatology, as well as those initiated for other purposes, may yield distinctive cutaneous eruptions and cutaneous sequelae.

Cytotoxic and antimetabolic agents may be used to treat severe or refractory skin disease. The toxicities of such agents are significant and must be balanced against therapeutic advantage. In treating skin disease, most of these agents are utilized at immunomodulatory rather than cytotoxic dosages.

Cytotoxic and antimetabolic drugs modulate the behavior of inflammatory and other cells through inhibition of cell growth and development. The cell cycle represents a conceptual schema for the sequence of growth experienced by essentially all cells (see Chapter 46). The cycle begins with the G_1 phase, which is directed toward preparing the cellular apparatus for DNA synthesis. The S phase follows G_1 and is devoted to DNA synthesis. At the end of DNA synthesis, the G_2 phase occurs. The G_2 phase is followed by the M phase, or actual cell division. Some cells may also enter a resting state of indeterminate length, termed G_0. Specific cytotoxic drugs may be effective at different stages of the cell cycle.

The cytotoxic drugs commonly used in dermatology fall into two classes: (1) antimetabolites and (2) alkylating agents. Antimetabolites mimic natural molecules and are most active while DNA is being synthesized (S phase). Alkylating agents exert effect through physicochemical interactions with DNA, such as alkylation, cross-linking, and carbamylation. The effects of alkylating agents are generally independent of the cell cycle.

The immunosuppressive properties of cytotoxic agents (see also Chapter 233) provide benefit in immunologically mediated disease, yet these agents may predispose to infection as well. Potentially lethal infections may arise quickly in an immunosuppressed patient. Those placed on cytotoxic agents should be queried at each visit for symptoms of infection, such as fever, chills, sweating, shortness of breath, cough, headache, dysuria, and arthritis. Prompt reporting of symptoms should be encouraged.

ANTIMETABOLIC AGENTS

METHOTREXATE

Methotrexate remains one of the most frequently employed antimetabolic agents in dermatology. With appropriate monitoring, an impressive record of safety with methotrexate has accumulated. Concerns regarding use of methotrexate are best addressed through increased drug awareness, rational patient selection, appropriate laboratory monitoring, and, most recently, folate supplementation.

MECHANISM OF ACTION. Methotrexate (Fig. 227-1) is an analog of folate that competitively and irreversibly inhibits dihydrofolate reductase (Fig. 227-1). Methotrexate also partially inhibits thymidylate synthetase. Through inhibition of these enzymes, methotrexate decreases the availability of reduced folate and thymidylate necessary for RNA and DNA synthesis. Other inhibitors of folate metabolism, such as trimethoprim-sulfamethoxazole, may potentiate the toxicity of methotrexate (see Section "Drug Interactions").

Like folate itself, the activity of methotrexate is enhanced by glutamylation. Glutamylation also yields additional anti-inflammatory properties.[1] First, by inhibiting aminoimidazole carboxamide ribonucleoside transformylase, methotrexate-polyglutamate increases the local tissue concentration of adenosine, which has potent anti-inflammatory action. Second, by decreasing available tetrahydrofolate, methotrexate decreases the production of S-adenyl methionine, which also results in decreased inflammation.

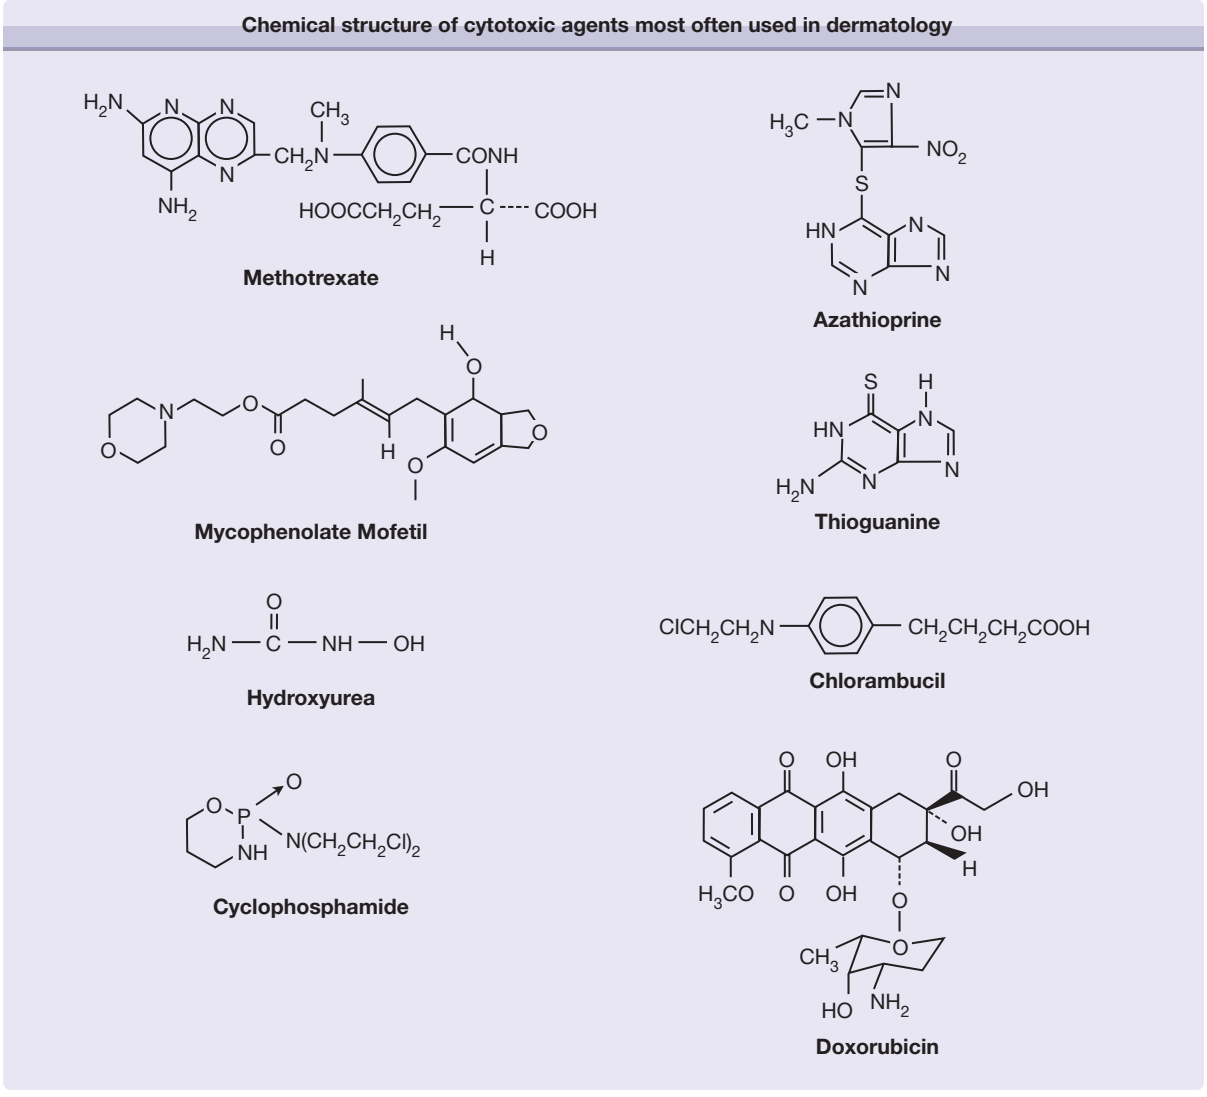

Figure 227-1 Chemical structure of cytotoxic agents most often used in dermatology.

PHARMACOKINETICS. Oral methotrexate is absorbed rapidly through the gastrointestinal tract. In children, absorption is decreased by concurrent ingestion of food and milk, but this has not been observed in adults. In adults, the mean bioavailability is 67% of the administered dose. Peak plasma levels occur 1–3 hours after administration. The half-life of the drug is 4–5 hours. For doses higher than 25 mg/week, gastrointestinal absorption is more erratic, and some experts recommend intramuscular dosing above this level.[2]

Methotrexate is eliminated chiefly by the kidneys, with 60%–95% excreted unchanged. Decreases in glomerular filtration or tubular secretion may lead to methotrexate toxicity. Approximately 50% of methotrexate within the blood is protein bound. Weak organic acids, such as aspirin or many other nonsteroidal anti-inflammatory agents, may displace methotrexate, altering blood levels and renal excretion (see Section "Drug Interactions").

INDICATIONS. Methotrexate is used for many purposes in dermatology, but its chief indication is for treatment of severe psoriasis. The effects of methotrexate in psoriasis were first recognized in the late 1950s and 1960s,[3] and by the late 1980s, more than one-half of dermatologists reported using methotrexate to treat severe psoriasis.[4] The impact of an increasing number of systemic treatments for psoriasis (the "biologics"; see Chapter 234) on the use of methotrexate has not been fully studied, but recent analysis has confirmed that methotrexate represents the most affordable and a very effective systemic treatment for psoriasis.[5] Methotrexate has also been used in a variety of other autoimmune and connective tissue diseases, vasculitides, inflammatory dermatoses, and papulosquamous conditions (Box 227-1).

DOSING REGIMEN. Typical oncologic doses of methotrexate (100–250 mg/m^2/week) are cytotoxic; however, lower doses (7.5–25.0 mg/week) are

BOX 227-1 USES FOR METHOTREXATE IN DERMATOLOGY

- US Food and Drug Administration-approved indications
  - Severe psoriasis (± psoriatic arthritis)
  - Mycosis fungoides (advanced disease)
- "Off-label" uses
  - Dermatomyositis
  - Cutaneous lupus erythematosus
  - Scleroderma
  - Pemphigus vulgaris
  - Bullous pemphigoid
  - Cutaneous polyarteritis nodosa
  - Behçet disease
  - Pyoderma gangrenosum
  - Lymphomatoid papulosis
  - Pityriasis lichenoides et varioliformis acuta
  - Pityriasis rubra pilaris
  - Sarcoidosis
  - Severe atopic dermatitis
  - Chronic hand dermatitis

immunomodulatory. In dermatology, methotrexate doses are typically less than 30 mg/week, and are often less than 17.5 mg/week. Cumulative dose should be tracked and recorded, as this may impact monitoring with continued use (see Section "Monitoring Therapy").

Methotrexate is available in 2.5-mg tablets. For those with economic limitations, methotrexate liquid (25 mg/mL) may be more affordable for peroral use.[6] Either a single weekly dose or a weekly dose divided into three portions separated by 12 hours is used. These dosing regimens are equally efficacious, but split dosing may lessen gastrointestinal upset.

INITIATING THERAPY. Evaluation before methotrexate use includes a careful history and physical examination, and assessment of concomitant conditions or medications that may limit methotrexate use. Exclusion of patients inappropriate for methotrexate therapy is an important first step in management. Relative contraindications to methotrexate use include abnormalities in renal or liver function (including viral hepatitis), cirrhosis, excessive alcohol consumption, concomitant use of hepatotoxic drugs, active infection, immunosuppression, recent vaccination (particularly live vaccines), obesity (body mass index >30), diabetes mellitus, poor reliability, and an active desire to conceive (men and women).[7] In general, the elderly are often less amenable to methotrexate therapy due to declining renal function. Administration of methotrexate to pregnant women or nursing mothers is strictly contraindicated. While use of methotrexate is often avoided in the setting of HIV, it may be appropriate in select circumstances; caution is advised.[8]

Baseline laboratory studies (Table 227-1) include a complete blood cell count (CBC); platelet count; liver function testing; serologic assessment for hepatitis A, B, and C antibodies (if indicated or preferred by the clinician); renal function assessment; and pregnancy and HIV screening (where indicated).[7] While a baseline screen for tuberculosis using purified protein derivative (PPD) is not expressly mandated, the Centers of Disease Control and Prevention recommends consideration of such testing for any patient placed on immunosuppressive medication.[9] Similarly, screening for strongyloides infection may be appropriate in some populations.[10]

Initiation of methotrexate therapy typically involves use of a single 5- to 10-mg test dose. Repeat laboratory studies, a skin examination, and a review of systems are conducted 1 week later. Performance of repeat laboratory studies sooner than 5–6 days after dosing yields only expected elevated liver transaminases and may confound interpretation.

If the test dose is tolerated and laboratory studies are satisfactory, weekly therapy may commence using a typical starting dose of 7.5–10 mg/week, depending on the severity of disease, overall health, and ideal body weight of the patient. Some authorities may begin with a dose as high as 15 mg/week in certain settings. The dose may be increased by 2.5–5.0 mg every 4–8 weeks until adequate control is achieved or toxicity ensues.[7] When improvement has stabilized, the dose may be tapered in 2.5-mg decrements to a point at which disease activity increases slightly. The goal is to allow for mild- or low-grade psoriasis to avoid an unacceptably high dose. It is important to discuss this expectation with the patient to prevent confusion regarding the endpoint. Concomitant topical therapy may also lower the methotrexate dose needed for satisfactory control.

If a patient does not demonstrate satisfactory improvement on a dose of 20–25 mg/week, consideration of alternative agents is indicated. Occasional patients with refractory disease may respond better to parenteral methotrexate, typically intramuscular dosing. In refractory cases, methotrexate may be combined with ultraviolet B (UVB) phototherapy, psoralen and UVA light (PUVA), cyclosporine, oral retinoids, or biologics to enhance efficacy.[7]

MONITORING THERAPY. Ongoing laboratory evaluation during methotrexate therapy (Table 227-1) should include a CBC with manual differential and platelet count and liver function tests weekly for 2–4 weeks for the first few months, then every 1–3 months.[7] Repeat testing with any dose escalation or intercurrent illness. Liver function testing should not be performed earlier than 5 days after dosing to avoid confounded results. Renal function tests should be performed every 2 to 3 months,[7] or with any suspicion of altered renal function.

Recent developments have altered recommendations regarding liver biopsy in the setting of methotrexate use for psoriasis. For patients without risk factors for liver injury (Table 227-2), current recommendations for liver biopsy are similar to those issued by the American College of Rheumatology with regard to use

TABLE 227-1
Safety Monitoring for Methotrexate Use

Initial Evaluation	Ongoing Laboratory Monitoring
■ Careful history and physical examination ■ Identification of proper patient characteristics and risk factors	■ CBC with differential/platelets ■ Every 2–4 weeks for first few months ■ Then approximately every 1–3 months in a stable patient ■ Repeat approximately 1 week after any dosage escalation
■ Survey for interacting medications (aspirin, nonsteroidal anti-inflammatory drugs, trimethoprim-sulfamethoxazole, etc.)	■ Liver function tests ■ Monthly for first 6 months (but perhaps more often if hepatic risk factors exist) ■ Then every 1 to 3 months thereafter ■ Perform at least 5–6 days after any dose to prevent confounding ■ Repeat with any dose escalation
■ Baseline laboratories: ■ CBC with differential/platelets ■ Liver function tests (AST, ALT, alkaline phosphatase, serum albumin) ■ Serology for hepatitis A/B/C ■ Renal function testing (serum creatinine/blood urea nitrogen) ■ Human immunodeficiency virus screening (if applicable) ■ Pregnancy testing (if applicable)	■ Renal function tests ■ Perform at 2–3 month intervals or with any possible change in renal function ■ Liver biopsy ■ Low risk patient (see Table 227-3)—follow ACR guidelines similar to use in rheumatoid arthritis ■ High risk patient (Table 227-3)—consider delayed baseline biopsy (2–6 months after initiation) and at 1.0–1.5 g cumulative dose

CBC = complete blood cell count; AST= aspartate aminotransferase; ALT = alanine transaminase.

of methotrexate in rheumatoid arthritis. However, for patients with risk factors for methotrexate-induced liver injury, a delayed baseline liver biopsy should be considered (usually after 2–6 months of use, when it is apparent the medication is efficacious, well tolerated, and likely to be continued), and again at a cumulative dose of 1.0–1.5 g. Monitoring via measurement of the aminoterminal peptide of procollagen III (PIIINP) is popular in some European countries, but the test is not approved for use in the United States.[7]

RISKS AND PRECAUTIONS. Absolute and relative contraindications and common adverse effects of methotrexate are summarized in Box 227-2.

TABLE 227-2
Risks Factors for Liver Injury with Methotrexate Use and Recommendations for Hepatic Monitoring/ Liver Biopsy Based on Risk

Risk Factors for Hepatic Toxicity	Recommendations for Low-Risk Patients
■ History of or current alcohol consumption ■ Persistent abnormal liver function tests ■ History of liver disease (including Hepatitis B or Hepatitis C) ■ Family history of inheritable liver disease ■ Diabetes mellitus ■ Obesity ■ Hyperlipidemia ■ History of significant exposure to hepatotoxic agents ■ Lack of folate supplementation	■ No baseline liver biopsy ■ Monitor liver function (per Table 227-2) ■ for minor elevations in liver enzymes (<2× normal) repeat in 2–4 weeks ■ for moderate elevations in liver enzymes (2–3× normal) closely monitor, repeat in 2–4 weeks, dose reduction if necessary ■ for persistent elevations in AST in 5 of 9 studies over 12 months or for decline in albumin with good nutrition perform liver biopsy ■ Consider liver biopsy after cumulative dose of 3.5–4.0 g, *OR* switch to alternative agent, *OR* continue to follow as above without liver biopsy. **Recommendations for High-Risk Patients** ■ Consider an alternative agent ■ Consider baseline biopsy after 2–6 months of use (when it is apparent that use will continue) ■ Repeat liver biopsy at cumulative dose of 1.0–1.5 g

BOX 227-2 RISKS AND PRECAUTIONS WITH METHOTREXATE USE

- Absolute contraindications
  - Pregnancy (Category X)
  - Lactation
- Relative contraindications
  - Renal dysfunction (dose may be reduced)
  - Hematologic disease (dose may be reduced)
  - Hepatic disease or hepatic dysfunction
  - Unreliable patient
  - Excessive alcohol consumption
  - Diabetes mellitus and/or obesity
  - Active infection and/or potential reactivation of infection (tuberculosis)
  - Human immunodeficiency virus infection
  - Man or woman contemplating impending conception
- Common adverse effects
  - Gastrointestinal distress (minimized with folate supplementation)
  - Myelosuppression (acute)
  - Toxic hepatitis
  - Liver fibrosis/cirrhosis (chronic)

COMPLICATIONS. Adverse reactions to methotrexate range from the trivial to life threatening.

Gastrointestinal Effects. Nausea and vomiting with oral administration is common and dose related. Such effects may be seen with parenteral dosing as well. Indeed, 10%–30% of all patients placed on methotrexate may experience some gastrointestinal upset. Symptoms may even occur before dosing or 24–36 hours afterward, suggesting a psychosomatic or anticipatory basis in select cases. Supplementation with folate (1–5 mg/day) reduces gastrointestinal symptoms without compromising efficacy.[11–14] A recent study on folate supplementation (5 mg daily) suggested a slight decrease in methotrexate efficacy,[15] but others questioned the methodology,[16] and most authorities continue to advocate strongly for supplementation.[7]

Hepatic Effects. Induction of liver fibrosis is a major concern with methotrexate use. Methotrexate is hepatotoxic, and some elevation in liver transaminases is expected with use. These elevations occur near to administration and are not strictly predictive of those predisposed to fibrosis. Dose reduction or discontinuance is indicated if transaminases exceed two- to threefold normal values when measured at least 5–6 days after the last dose.

The gold standard for assessing methotrexate-induced liver fibrosis is percutaneous needle biopsy. The procedure is not without risk; minor bleeding occurs in 1 in 1,000 patients, and the risk of death is estimated at 1 in 10,000.[17] Liver specimens are assessed for lobular architecture, inflammation and fibrosis, and fat infiltration. A grading scheme using a scale of I to IV is widely employed (Table 227-3). Patients with grades I and II histology may continue methotrexate, those with grade IIIA histology may continue with a repeat liver biopsy in 6 months, and those with grades IIIB and IV histology should discontinue methotrexate.[7]

A noninvasive test for liver fibrosis would be ideal. Ultrasound alone has demonstrated conflicting results.[18,19] Radionuclide scans and the aminopyrine breath test have proven inadequate for independent detection of methotrexate-induced fibrosis.[20,21] Serum assay of the PIIINP may suggest fibrosis; however, specificity is limited. PIIINP is simply a marker of fibrogenesis, and it may be elevated during fibrosis of any organ system.[22] It is unreliable in patients with psoriatic arthritis. A compelling argument has been made to use an amalgam of tests, such as ultrasound, dynamic radionuclide scanning, and PIIINP assay, to reduce the number of required liver biopsies. Nevertheless, at present, percutaneous liver biopsy remains the gold standard for evaluation when methotrexate-induced liver disease is suspected.[23]

Hematologic Effects. The most important acute adverse effect of methotrexate is myelosuppression. Anemia, neutropenia, and thrombocytopenia may result from methotrexate use. Risk factors for bone marrow toxicity include advanced age, poor renal

TABLE 227-3
Classification of Liver Biopsy Findings for Methotrexate Use

Biopsy Grade	Histopathologic Findings	Recommended Action
I	Normal; fatty infiltration (mild), portal inflammation (mild)	Continue methotrexate
II	Fatty infiltration (moderate to severe), portal inflammation (moderate/severe)	Continue methotrexate
IIIA	Fibrosis (mild)	Continue methotrexate; repeat biopsy in 6 mon
IIIB	Fibrosis (moderate to severe)	Discontinue methotrexate
IV	Frank cirrhosis	Discontinue methotrexate

function, and concurrent administration of conflicting medications (see Section "Drug Interactions").

Mucosal and Cutaneous Effects. Oral ulcerations or stomatitis may be noted with methotrexate use. Skin ulceration, particularly of the lower legs, may herald bone marrow suppression. In patients treated with methotrexate for psoriasis, rapid ulceration of psoriatic plaques may also suggest toxicity.[24] Laboratory studies and dose reduction or complete discontinuance is indicated when mucocutaneous ulcerations or skin ulcerations develop, respectively. Methotrexate may also engender a cutaneous "recall reaction" in areas of prior irradiation or recent sunburn.[25] Mild alopecia has been described with methotrexate use. Other cutaneous manifestations include acral erythema, epidermal necrosis, and vasculitis.

Carcinogenecity. Low-dose methotrexate use has not been definitively associated with carcinogenesis, but a recent study examining patients using methotrexate for rheumatoid arthritis demonstrated a 50% increased risk of malignancy relative to the general population, with a threefold increased risk in melanoma, a fivefold increased risk in non-Hodgkin lymphoma, and a nearly threefold increase in lung cancer.[26] Conversely, in a cohort study from the United Kingdom, a slight increase in lymphoma was observed among psoriatic patients, but use of methotrexate was not discriminatory.[27]

Mutagenecity and Teratogenecity. Methotrexate is a Category X agent during pregnancy, and administration is absolutely contraindicated (see Box 227-2). Pregnancies that occur after the discontinuation of methotrexate appear unaffected, but it is generally advocated that men wait 3 months after discontinuance before attempting conception; women should wait one complete menstrual cycle. Reliable contraception is requisite while taking methotrexate.[7]

Pulmonary Effects. Acute pneumonitis and pulmonary fibrosis have been reported with methotrexate use in psoriasis, although such reactions are more common in rheumatoid arthritis patients.[28] Pulmonary toxicity likely represents an idiosyncratic reaction. Chest radiographs and pulmonary function testing are not useful in the detection or prevention of pulmonary fibrosis.[29] A chest X-ray should be performed in those with symptoms of pneumonitis. Discontinuance is recommended if examination findings are concerning.

Opportunistic Infections. Opportunistic infections (e.g., *Pneumocystis* pneumonia, cryptococcosis, and histoplasmosis) have been reported in otherwise healthy individuals receiving low-dose methotrexate.[10,30–33] Admittedly, such patients were often using other immunosuppressive medications as well; often prednisone.

Anaphylaxis. Systemic anaphylaxis with low-dose methotrexate has been reported.[34] Many patients suffering from anaphylaxis had received methotrexate before, at comparable doses, without untoward effects.

Folate and Folinic Acid Supplementation. Daily supplementation with 1–5 mg of folate has reduced nausea, vomiting, stomatitis and oral ulceration, elevated transaminases, and mild myelosuppression without compromising the efficacy of methotrexate.[11–14] Pneumonitis, and moderate-to-severe myelosuppression are not mitigated by folate supplementation. Elevated homocysteine levels, common with methotrexate use and an independent risk factor for coronary artery disease, are decreased with folate supplementation.[35]

Folinic acid may also be used as supplementation, but it should not be given concurrently with methotrexate dosing. Instead, it is dosed at 5 mg by mouth every 12 hours for 3 doses, beginning 12 hours after the last weekly methotrexate dose. Unlike folinic acid, folate does not compete with methotrexate for cellular uptake, and it can be taken daily. Both are available as generic medications. One drawback to folate supplementation is the potential masking of vitamin B_{12} deficiency. Use of folate supplementation with methotrexate therapy is well established.[7]

Overdose. Methotrexate overdose is more likely in patients with declining renal function, in those who misunderstand dosing directions, or in those concomitantly exposed to a second folate antagonist, such as trimethoprim-sulfamethoxazole. Overdose should be treated promptly with folinic acid (leucovorin). Folinic acid is metabolized in vivo to tetrahydrofolate in the absence of dihydrofolate reductase, providing an alternative supply of DNA and RNA precursors.

Folinic acid should be given early, preferably within the first 24–36 hours after overdose. Folinic acid itself has very little toxicity. Therefore, an oral dose of 10 mg/m^2 should be given on first suspicion of methotrexate overdose without delay for a serum assay.[7] Peroral or parenteral doses may be continued every 6 hours until the serum concentration of methotrexate falls to less than 10^{-8} M. Practically speaking, or when a serum assay is unavailable, this recommendation is often equivalent to 15–25 mg of folinic acid by mouth every 6 hours for six to ten doses.

Drug Interactions. Although any drug that may enhance methotrexate toxicity should be avoided during therapy, there are several near-absolute contraindications (Box 227-3), including aspirin, many nonsteroidal anti-inflammatory agents, probenecid, and trimethoprim-sulfamethoxazole.[36] Conversely, many cyclooxygenase-2 selective inhibitors, like celecoxib, do not impact the pharmacokinetics of methotrexate.[7]

BOX 227-3 DRUG INTERACTIONS OF METHOTREXATE[a]

[a]Near absolute contraindications

AZATHIOPRINE

Azathioprine is a synthetic analog of natural purine bases used in RNA and DNA synthesis (see Fig. 227-1). Although many thiopurine derivatives exist, azathioprine is the agent most often used in dermatology.

MECHANISM OF ACTION. Azathioprine is a prodrug that is metabolized in the body to 6-mercaptopurine (6-MP). 6-MP is further anabolized via hypoxanthine-guanine phosphoribosyl transferase (HGPRT), ultimately to a purine analog, 6-thioguanine (6-TG), that inhibits RNA and DNA synthesis and repair, yielding immunosuppression. HGPRT activation is critical. Yet patients with Lesch-Nyhan syndrome (HGPRT deficiency) experience no immunosuppression or untoward effects while taking azathioprine.[37]

PHARMACOKINETICS. Azathioprine and its metabolite, 6-MP, are equally potent when administered parenterally, but azathioprine enjoys improved bioavailability, with 88% of the oral dose being absorbed through the gastrointestinal tract. After absorption, azathioprine is converted to 6-MP, mostly within erythrocytes. The fate of 6-MP is determined by one of three competing metabolic pathways: (1) it may be anabolized to an ultimate active form (6-TG) via HGPRT, (2) it may be catabolized to an inactive form via xanthine oxidase (XO), or (3) it may be catabolized to an inactive form by thiopurine methyltransferase (TPMT).[38]

Elucidation of the TPMT-dependent catabolic pathway has revolutionized the clinical use of azathioprine. In humans, expression of TPMT is variable due to genetic polymorphisms. Patients may be categorized into three subgroups: (1) a large majority possesses high levels of TPMT expression (~90%), (2) intermediate expression is demonstrated in ~10%, and (3) less than 1% demonstrate very low TPMT activity (about 1 in 300 persons).[39] Commercial assays for TPMT activity allow for graduated azathioprine dosing, with improved efficacy and a lesser incidence of unforeseen side effects (see Section "Dosing Regimen").[40,41]

XO is another enzyme involved in the catabolism of 6-MP. Allopurinol, used in the treatment of gout, is a potent inhibitor of XO; toxicity may result in those taking both medications.[42] Unlike TPMT, there is very little genetic variation in XO expression, and it is unnecessary to assess innate XO expression before azathioprine dosing. A careful medication history, however, is critical (see Section "Drug Interactions").

INDICATIONS. In dermatology, azathioprine is used "off-label" chiefly as a steroid-sparing agent for immunobullous disorders, including pemphigus, cicatricial pemphigoid, and severe or recalcitrant bullous pemphigoid (Box 227-4).[43] In a prospective, long-term study of pemphigus vulgaris patients treated with glucocorticoids and azathioprine, 45% achieved remission.[44] The steroid-sparing effect of azathioprine in pemphigus has been challenged in literary review, but not in a clinical trial; it remains a common regimen among practicing dermatologists.[45]

BOX 227-4 USES FOR AZATHIOPRINE IN DERMATOLOGY

- US Food and Drug Administration-approved indications
  - None
- "Off-label" uses
  - Dermatomyositis
  - Severe cutaneous lupus erythematosus
  - Scleroderma
  - Relapsing polychondritis
  - Pemphigus vulgaris
  - Bullous pemphigoid
  - Cicatricial pemphigoid
  - Cutaneous polyarteritis nodosa
  - Severe or recalcitrant leukocytoclastic vasculitis
  - Behçet disease
  - Pyoderma gangrenosum
  - Sarcoidosis
  - Severe psoriasis
  - Severe lichen planus
  - Severe atopic dermatitis
  - Chronic actinic dermatitis
  - Severe contact dermatitis
  - Severe polymorphous light eruption

DOSING REGIMEN. Azathioprine is supplied as 50-mg tablets and also as an injectable. Traditionally, a dose of 1–2 mg/kg/day of azathioprine was used, often concurrent with high-dose prednisone. Increasingly, the appropriate dosage is now based on a patient's own TPMT expression (Table 227-4).[40] Impaired renal function may be associated with greater toxicity, and the dosage may still be adjusted for this reason.

INITIATING THERAPY. Before therapy, the patient should receive a complete history and physical examination. Exclusion of patients with severe comorbidities,

TABLE 227-4
Dosing of Azathioprine Based on Thiopurine Methyltransferase (TPMT) Enzyme Assay[41]

TPMT Erythrocyte Assay	Maximum Azathioprine Dose
>19.0 U (high expression)	2.5 mg/kg/day
13.7–19.0 U (intermediate expression)	1.5 mg/kg/day
5.0–13.7 U (low expression)	0.5 mg/kg/day
<5.0 U (very low expression)	Do not use

active infections, or the possibility of reactivation of an infection (tuberculosis) is recommended. All women of childbearing age should receive a pregnancy test. Patients with a history of exposure to alkylating agents should likely not receive azathioprine unless unavoidable, as an increased risk of lymphoproliferative disease exists when used in succession.

Baseline laboratory tests include a CBC with manual differential and platelet count, renal and liver function testing, and an erythrocyte TPMT activity assay should be performed. There are reports of mycobacterial infection in those taking azathioprine, and tuberculin screening should be considered. In steroid-responsive bullous disorders and in connective tissue disease, experienced practitioners often initiate azathioprine concurrently with high-dose steroids.

MONITORING THERAPY. During therapy, a CBC with manual differentiation and platelet count should be obtained biweekly for the first 2 months, monthly for the next 2 months, and every 2 months thereafter; liver function testing should occur every month for 3 months and then bimonthly thereafter.[46] Additional laboratory testing is necessary with dosage increases or if an initial TPMT level cannot be determined. Biannual physical examinations should pay particular attention to evidence of possible lymphoreticular disease and skin cancer, particularly squamous cell carcinoma (SCC). Safety guidelines used during azathioprine therapy are summarized in Box 227-5.

Recently, optimal erythrocyte levels of 6-TG necessary for disease remission in patients with immunobullous disease treated with azathioprine were determined.[47] Optimal levels of 6-TG in erythrocytes for disease remission were 150–300 pmol/8×10^8 erythrocytes. Lower levels were observed in lesser disease states. High levels of the inactive metabolite 6-methylmercaptopurine and induction of TPMT were associated with recalcitrant disease.

In fact, TPMT induction (>10 U from baseline) explains why some patients fail to respond to high azathioprine doses (at least 2.5 mg/kg/d), even when baseline measurement suggested an intermediate level of enzyme activity within erythrocytes. Experts were quick to recognize the clinical value of this observation; this type of nonresponder should be switched to an alternative agent.[48] Similarly, measurement of TPMT activity (at baseline and during use) and 6-TG levels within erythrocytes allows for an algorithmic approach to discriminate among the underdosed, noncompliant, and those experiencing TPMT-induction (Table 227-5).[47,48] Furthermore, TPMT genotype determination may be used when RBC enzyme activity is near the cutoff between high activity and intermediate activity, to allow for more aggressive azathioprine dosing.[47]

RISK FACTORS AND PRECAUTIONS. Absolute and relative contraindications and common adverse effects of azathioprine are summarized in Box 227-6.

COMPLICATIONS. With careful monitoring, azathioprine is generally safe. Adverse effects tend to occur in those patients with lower TPMT activity levels, higher doses of azathioprine, or concomitant use of allopurinol.

BOX 227-5 SAFETY MONITORING FOR AZATHIOPRINE USE

- Initial evaluation
  - Careful history and physical examination
  - Identification of proper patient characteristics and risk factors
  - Survey for interacting medications (allopurinol, aminosalicylates)
  - Baseline laboratories:
    - Thiopurine methyltransferase erythrocyte assay
    - CBC with differential/platelets
    - Basic serum chemistry profile
    - Liver function tests
    - Urinalysis
    - Pregnancy testing for women of child-bearing age
    - Tuberculin testing (if indicated)
    - Consider TPMT genotype assay if borderline intermediate/high expression by erythrocyte measurement
- Ongoing laboratory monitoring
  - CBC with differential/platelets
    - Biweekly for 2 mon, monthly for 2 mon, then bimonthly thereafter
  - Liver function testing
    - Monthly for 3 mon, then bimonthly monthly thereafter
  - Consider erythrocyte 6-TG level, repeat TPMT (to check for induction)
- Follow-up clinical evaluation
  - Biannual complete physical examinations
    - Particular attention to possible lymphoreticular disease (adenopathy)
    - Careful survey for non-melanoma skin cancer (squamous cell carcinoma)

CBC = complete blood cell count.

Hematologic Effects. Myelosuppression is a major side effect of azathioprine use. Generalized depression of all blood cell lines is most common,[49] but depression of any single lineage may be observed. Thrombocytopenia is a common initial presentation of bone marrow toxicity. Bone marrow suppression tends to occur at higher doses,[50] and in those with lower TPMT expression. Discontinuance usually results in complete marrow recovery.

Opportunistic Infections. Most patients treated with azathioprine also receive large doses of glucocorticoids. Therefore, it is often difficult to quantify the independent role of azathioprine in any predisposition toward infection. Herpes virus infections, human

TABLE 227-5
Use of Erythrocyte Assay of TPMT and Azathioprine Metabolites to Categorize Patient Subtypes

Test/Value	Optimal Responder	Underdosed	Noncompliant	TPMT Induction
TPMT (erythrocyte)	Near baseline	Near baseline	Near baseline	Elevated above baseline (>10 U)
6-Thioguanine (active metabolite)	Optimal	Low	Low	Low
6-Methylmercaptopurine (inactive metabolite)	Elevated	Low	Low	Elevated significantly
Azathioprine dose	Adequate	Inadequate, potentially will respond to increase[a]	Presumed adequate[a]	May respond to increase[b]

TPMT = thiopurine methyltransferase.
[a]With a dose escalation, an underdosed patient will move toward the profile of an optimal responder. With improved compliance, a noncompliant patient will move toward an optimal responder or will emerge as an underdosed or TPMT-induction.
[b]If the maximal safe dose has not been exceeded, it is possible that a patient with TPMT induction may respond to dose escalation; but, if a maximal dose has been reached and there is an inadequate response, trial of a different agent is indicated.

papilloma infection, and scabies infestation have been reported in those taking azathioprine.[50]

Gastrointestinal Effects. Patients receiving high doses of azathioprine may experience nausea, vomiting, and diarrhea. Such symptoms are not usually treatment limiting and may be reduced by administration with food.

Hepatic Effects. Toxic hepatitis has developed in approximately 1% of patients treated with azathioprine for rheumatoid arthritis, and it is usually reversible.[51] Other adverse effects include hepatic veno-occlusive disease and associated pancreatitis. Discontinuance is warranted with evidence of liver toxicity.

BOX 227-6 RISKS AND PRECAUTIONS WITH AZATHIOPRINE USE

- Absolute contraindications
  - Hypersensitivity to azathioprine
  - Active or ongoing infection
- Relative contraindications
  - Pregnancy/lactation (Category D, but myelosuppression of fetus/infant common—avoid)
  - Allopurinol use (dose must be reduced by 75%)
  - Prior lymphoproliferative disease or prior use of alkylating agents
- Common adverse effects
  - Gastrointestinal distress (minimized by administration with food)
  - Myelosuppression
  - Possible increased risk of lymphoproliferative disease or skin cancer
  - Possible opportunistic infections

Anaphylaxis. Azathioprine-induced shock and hypersensitivity reactions have been reported in patients with cutaneous disease. In most cases, hypotensive collapse occurred within hours of the initial dose. Drug fever has also been reported with azathioprine (see Chapter 41).

Carcinogenesis. An increased risk of lymphoproliferative disease has been documented in renal transplant recipients, rheumatoid arthritis patients, and, most recently, inflammatory bowel disease patients treated with chronic azathioprine.[52–54] In one study, the relative risk was increased roughly 10- to 13-fold, or one lymphoma per 1,000 patient-years of azathioprine treatment. Dermatologic doses of azathioprine are often lower and the duration of treatment shorter, leading to speculation that the risk of lymphoma is probably lower in those treated for cutaneous disease. However, the most recent meta-analysis of patients treated with azathioprine for inflammatory bowel disease who developed lymphoma included those on "low-dose" regimens.[54] In light of this information, it seems prudent to inform patients that the exact magnitude of any increased risk for lymphoma with "low-dose" azathioprine is largely unknown. Patients with a prior exposure to alkylating agents may have a prohibitive risk of lymphoma if treated subsequently with azathioprine; great caution is suggested in this population.

Aggressive behavior of SCC has been described in patients taking azathioprine for eczema, atopic dermatitis, and chronic actinic dermatitis.[55] It was recently suggested that azathioprine used in solid organ transplant recipients may sensitize DNA to UVA radiation, leading to the increased incidence of SCC in this population.[56] Admittedly, confounding risk factors exist, but a later small series confirmed a reduced minimal erythema dose to UVA irradiation with coadministration of azathioprine.[57] Dermatologists should be aware of

this emerging research, as only broad spectrum sunscreens mitigate UVA exposure, and such rays are not blocked by glass.

Mutagenecity and Teratogenecity. Azathioprine is a Category D agent during pregnancy. The prodrug and the active metabolites readily cross the placenta. The rate of congenital malformation appears to be low (4.3%), but myelosuppression and immunosuppression are significant occurrences in neonates and breastfed infants. Fertility of men or women appears unaffected by azathioprine.[58]

Drug Interactions. A major drug interaction occurs between azathioprine and allopurinol. When allopurinol must be used concurrently, the azathioprine dose must be decreased by 75%. There is evidence that aminosalicylates may inhibit TPMT activity, and it may be prudent to minimize or avoid such medications in patients using azathioprine.

THIOGUANINE

Thioguanine (see Fig. 227-1) is a less utilized member of the thiopurine family of drugs. It has a metabolism and mechanism of action similar to that of azathioprine.

MECHANISM OF ACTION.

Thioguanine is a prodrug that produces nucleoside analogues through the action of purine nucleoside phosphorylases present in tissues. These guanine analogues undergo enzymatic conversion to nucleotides and ultimately yield cytotoxic activity via incorporation into cellular DNA. Apoptosis is induced preferentially against activated T lymphocytes. The clinical response to thioguanine has been correlated to decreased T lymphocyte counts in psoriatic skin lesions, irrespective of systemic lymphocyte counts.[59]

PHARMACOKINETICS.

Thioguanine is administered orally, but it has incomplete and unpredictable absorption. Peak plasma concentrations may vary tenfold and occur 2–4 hours after ingestion.[60]

INDICATIONS.

In dermatology, thioguanine is used chiefly for the treatment of psoriasis, particularly in those with recalcitrant disease or with contraindications to other systemic therapies (Box 227-7). In a recent retrospective study of patients with recalcitrant psoriasis, 14 of 18 patients experienced greater than 90% improvement with thioguanine, including patients with psoriatic arthritis, palmoplantar disease, or scalp involvement.[61] Thioguanine has been used effectively, although infrequently, to treat lupus and atopic dermatitis.

BOX 227-7 USES FOR THIOGUANINE IN DERMATOLOGY

- US Food and Drug Administration-approved indications
  - None
- "Off-label" uses
  - Severe psoriasis
  - Severe cutaneous lupus erythematosus
  - Severe atopic dermatitis

DOSING REGIMEN.

Thioguanine is supplied as 40-mg tablets. Classically, treatment was initiated with a 40 mg/day dose, with close monitoring for myelosuppression. After 1 month, if the clinical response was inadequate, the dose was increased to 80–120 mg/day. A pulsed regimen of 100 mg to 120 mg twice weekly, increasing up to 160 mg three times per week, has been reported effective.[62] The most recent guidelines suggest an amalgam of these strategies, beginning with a dose of 80 mg twice weekly with possible advancement by 20 mg every 2 to 4 weeks, to a maximum dose of 160 mg three times weekly.[46]

Similar to azathioprine, use of commercial assays for TPMT activity improve thioguanine dosing. The latest review of thioguanine use in severe psoriasis recommends an assessment of TPMT levels before treatment so as to guide the selection of an adequate starting dose.[61] Patients with high levels of TPMT expression can likely tolerate higher initial doses.

INITIATING THERAPY.

All patients should undergo a thorough history and physical examination before initiation of treatment. Patients with severe comorbidities, particularly hematologic disturbances, or active infection should be excluded. Women of childbearing age should receive a pregnancy test. Recommended baseline laboratory studies include a CBC with manual differential and platelet count, liver function studies, and a TPMT activity assay.

MONITORING THERAPY.

Repeat blood counts and liver function tests should be followed weekly at first, transitioning to biweekly as the dose stabilizes, then monthly for 3 months, and quarterly thereafter. Always perform complete and broad laboratory testing when a dose is escalated or there is a change in the patient's health status. Safety guidelines used during thioguanine therapy are summarized in Box 227-8.

RISKS AND PRECAUTIONS.

Absolute and relative contraindications and common adverse effects of thioguanine are summarized in Box 227-9.

COMPLICATIONS.

Common adverse effects of thioguanine include myelosuppression and gastrointestinal disturbances. In the largest series of patients using thioguanine for psoriasis, just less than one-half experienced myelosuppression, yet only 20% required complete discontinuance.[63] In one series, thrombocytopenia was the earliest indicator of myelosuppression.[61] Pulsed dosing of thioguanine has been associated with a lower rate of myelosuppression, but, admittedly, TPMT testing was not performed in this study.[62]

Gastrointestinal disturbances include nausea, excessive flatulence, taste changes, esophageal reflux, and

BOX 227-8 SAFETY MONITORING FOR THIOGUANINE USE

- Initial evaluation
  - Careful history and physical examination
  - Identification of proper patient characteristics and risk factors
  - Survey for interacting medications (aminosalicylates)
- Baseline laboratories:
  - Thiopurine methyltransferase erythrocyte assay
  - CBC with differential/platelets
  - Liver function tests
  - Renal function testing (creatinine/blood urea nitrogen)
- Ongoing laboratory monitoring
  - CBC with differential/platelets and liver function tests
    - Perform weekly initially, then
      - Transition to biweekly as the dose stabilizes, then
      - Monthly for 3 mon and quarterly thereafter
      - Perform laboratory testing with any dose escalation

CBC = complete blood cell count.

diarrhea, symptoms that are often tolerated without discontinuance. In a single study, elevated liver transaminases occurred in 25% of patients, yet many had been taking methotrexate before the study.[63] Generally, thioguanine is not considered particularly hepatotoxic; liver biopsy is not indicated during treatment. Rare cases of toxic hepatic veno-occlusive disease have been described in patients using thioguanine for psoriasis.[64] Low-dose thioguanine use in pregnant women has been reported with inflammatory bowel disease; however, use during pregnancy is generally avoided.[65]

BOX 227-9 RISKS AND PRECAUTIONS WITH THIOGUANINE USE

- Absolute contraindications
  - Hypersensitivity to thioguanine
- Relative contraindications
  - Pregnancy/lactation (Category D)
  - History of hepatovenular occlusive disease
  - Hematologic disorders
- Common adverse effects
  - Myelosuppression (most common side effect)
  - Gastrointestinal distress (often tolerated)
  - Toxic hepatitis (less common than with other cytotoxic agents)

Drug Interactions. Thioguanine metabolism is not dependent on XO; it may be administered concurrently with allopurinol without dose reduction. Aminosalicylates may inhibit TPMT activity, and it may be prudent to minimize or avoid such medications in patients taking thioguanine.

HYDROXYUREA

Hydroxyurea was first synthesized in 1869, and through the years it has been used to treat a variety of conditions, including hematologic malignancies, sickle cell anemia, and psoriasis.

MECHANISM OF ACTION. Hydroxyurea impairs DNA synthesis through inhibition of ribonucleotide diphosphate reductase, an enzyme that reduces nucleotides to deoxynucleotides. This inhibition limits the supply of DNA bases available for synthesis. Strand breakage and cell death result. Hydroxyurea also prevents cells from repairing damage from UV or ionizing radiation, acting as a radiosensitizer. Finally, hydroxyurea yields hypomethylation of genes, altering expression,[66] and this may contribute to normalization of psoriatic skin through improved keratinocyte differentiation. Hydroxyurea is most active in cells with a high proliferative index. It is preferentially concentrated within leukocytes.

PHARMACOKINETICS. Hydroxyurea is a small molecule that is well absorbed after oral administration. Serum levels peak within 2 hours of dosing. Hydroxyurea has a rapid onset of action, with tissue effects noted within 5 hours. The actual metabolism of hydroxyurea is incompletely understood, but at least 80% is excreted by the kidney. Within 24 hours of dosing, negligible amounts of hydroxyurea remain in the body.

INDICATIONS. In dermatology, hydroxyurea is used chiefly for treatment of psoriasis (Box 227-10).

BOX 227-10 USES FOR HYDROXYUREA IN DERMATOLOGY

- US Food and Drug Administration-approved indications
  - Squamous cell carcinoma of the head and neck (rare use)
  - Metastatic melanoma and gastrointestinal melanoma (rare use)
- "Off-label" uses
  - Severe psoriasis (often an option for those with liver disease that limits other options)
  - Pyoderma gangrenosum
  - Sweet syndrome
  - Cryoglobulinemia
  - Scleromyxedema
  - Hypereosinophilic syndrome

Efficacy has been demonstrated in plaque, pustular, and erythrodermic forms. Still others believe hydroxyurea is only moderately effective and prefer to reserve use as a maintenance therapy once initial clearance has been achieved via other modalities.

In a large series of 60 patients treated with hydroxyurea for severe psoriasis, 50%–60% achieved a response.[67] A more recent study compared use of methotrexate (15–20 mg/week) and lower-dose hydroxyurea (3–4.5 g/week) and found a 77% mean reduction versus a 49% mean reduction in the mean PASI score, respectively.[68] When hydroxyurea is effective, a response generally occurs within 2–3 weeks, with maximal improvement at 6–8 weeks. Because hydroxyurea has relatively little hepatic toxicity, it may be a viable alternative for those with liver disease, which precludes use of methotrexate.

DOSING REGIMEN. Hydroxyurea is available as 500-mg tablets. Typical doses range from 1–2 g daily, usually as a divided dose. Doses above 2 g daily are unlikely to yield additional benefit and are increasingly toxic.[69] Hydroxyurea is usually well tolerated, but if dyspepsia occurs, the medication may be taken with food, milk, or antacids.

INITIATING THERAPY. Patients placed on hydroxyurea should have a complete history and physical examination. Exclusion of patients with severe comorbidities or active infections is often indicated. All women of childbearing age should receive a pregnancy test. Baseline laboratory evaluation should include a CBC with manual differential and platelet count, a serum chemistry evaluation, and urinalysis. Older patients and those with renal impairment are more susceptible to toxicity with hydroxyurea and should receive starting doses of only 500 mg/day.

MONITORING THERAPY. CBCs should be repeated weekly during early therapy; this may be increased to biweekly, and, later, to monthly if results remain stable. Liver function studies and urinalysis should be monitored monthly. Close surveillance for non-melanoma skin cancer at follow-up visits is indicated. Discontinuance of hydroxyurea is indicated if a satisfactory response is not achieved with 8 weeks of therapy. Safety guidelines used during hydroxyurea therapy are summarized in Box 227-11.

RISKS AND PRECAUTIONS. Absolute and relative contraindications and common adverse effects of hydroxyurea are summarized in Box 227-12.

COMPLICATIONS. In one large study of hydroxyurea for psoriasis, 57% of those who received 1.5 g/day of hydroxyurea experienced no side effects, and only 18% discontinued therapy because of adverse effects.[70] The most common adverse effect with hydroxyurea is myelosuppression. Mild megaloblastic changes are ubiquitous among patients receiving hydroxyurea and are not a reason for discontinuance. Frank anemia is present in 12%–34% of treated patients, leukopenia in 7%, and thrombocytopenia in 2%–3%. Myelosuppression due to hydroxyurea usually resolves rapidly on discontinuance.

Patients taking hydroxyurea may experience a variety of cutaneous side effects, including a dermatomyositis-like eruption,[71,72] a lichenoid drug eruption, leg ulcers, alopecia, photosensitivity with radiation

BOX 227-11 SAFETY MONITORING FOR HYDROXYUREA USE

- Initial evaluation
  - Careful history and physical examination
  - Identification of proper patient characteristics and risk factors
  - Survey for interacting medications (cytarabine)
  - Baseline laboratories:
    - CBC with differential/platelets
    - Basic serum chemistry profile
    - Urinalysis
    - Renal function testing (creatinine/ blood urea nitrogen)
- Ongoing laboratory monitoring
  - CBC with differential/platelets
    - Perform weekly initially, then
      - Transition to biweekly or monthly after 1 mon
      - Perform testing with any dose escalation
      - Decrease/discontinue if hemoglobin decreases by 3 g/dL, white blood cell count <4,000/mm^3, or platelets <100,000/mm^3
  - Serum chemistry and urinalysis
    - Perform monthly initially, then
      - Transition to every 3–6 months if stable
      - Perform testing with any dose escalation

CBC = complete blood cell count.

BOX 227-12 RISKS AND PRECAUTIONS WITH HYDROXYUREA USE

- Absolute contraindications
  - Hypersensitivity to hydroxyurea
- Relative contraindications
  - Pregnancy/lactation (Category D)
  - History of hepatovenular occlusive disease
  - Chronic anemia
  - Renal disease
- Common adverse effects
  - Myelosuppression (most common side effect)
  - Dermatomyositis-like drug eruption
  - Renal toxicity (elevated creatinine/blood urea nitrogen, hematuria, proteinuria)
  - Increased risk of secondary hematologic malignancies when used for polycythemia vera

recall, and hyperpigmentation of the skin and nails. In patients treated with hydroxyurea for myeloproliferative disorders, nonmelanoma skin cancer has been reported as an association.[73,74] It is unclear if this represents a true risk factor for those treated for cutaneous disease or if confounding circumstances exist.

Other reported side effects of hydroxyurea include lupus erythematosus, mild gastrointestinal distress, and secondary malignancies when used in patients with primary hematologic disorders, such as polycythemia vera. A rare but important adverse effect of hydroxyurea is fever with a flu-like illness. Hydroxyurea is a Category D agent during pregnancy, and use is generally avoided. There is a single report of hydroxyurea use for polycythemia vera during pregnancy without any apparent fetal or neonatal complications.[75]

Drug Interactions. Hydroxyurea appears to have few significant drug interactions, with the exception of coadministration with other myelosuppressive agents and cytarabine. Use of such agents with hydroxyurea may lead to additive bone marrow toxicity.

MYCOPHENOLIC ACID AND MYCOPHENOLATE MOFETIL

Mycophenolic acid (MPA) (see Fig. 227-1) is a lipid-soluble, weak organic acid with antifungal, antibacterial, antiviral, and immunosuppressive properties. MPA was first used as an oral agent for moderate-to-severe psoriasis in the 1970s, but use was discontinued due to intolerability. Mycophenolate mofetil (MMF) represents a derivative of MPA, with greater bioavailability, improved tolerance, and enhanced immunosuppression. Properties and use of this agent is discussed in detail in Chapter 233.

ALKYLATING AGENTS

CYCLOPHOSPHAMIDE

Cyclophosphamide (see Fig. 227-1) is a derivative of nitrogen mustard, and it acts primarily by cross-linking DNA. In oncology, cyclophosphamide is used as an antineoplastic agent. In dermatology, it is used as an immunosuppressive and steroid-sparing agent, particularly for autoimmune blistering disorders and systemic vasculitis (Box 227-13).

BOX 227-13 USES FOR CYCLOPHOSPHAMIDE IN DERMATOLOGY

- US Food and Drug Administration-approved indications
- Mycosis fungoides (advanced disease)
- "Off-label" uses
  - Granulomatosis with polyangiitis (Wegener's)
  - Lymphomatoid granulomatosis
  - Polyarteritis nodosa
  - Severe and recalcitrant leukocytoclastic vasculitis
  - Dermatomyositis
  - Scleroderma
  - Relapsing polychondritis
  - Severe cutaneous lupus erythematosus
  - Pemphigus vulgaris
  - Bullous pemphigoid
  - Pyoderma gangrenosum
  - Scleromyxedema/lichen myxedematosus
  - Multicentric reticulohistiocytosis
  - Cytophagic panniculitis
  - Severe and recalcitrant eczematous conditions

MECHANISM OF ACTION. Cyclophosphamide is a classic cell-cycle nonspecific drug; its cytotoxic effect is independent of the proliferative index. Active metabolites of cyclophosphamide form covalent bonds with the nucleophilic centers of DNA. This alkylation leads to DNA cross-linking, abnormal base-pair formation, imidazole ring cleavage with depurination, and chain scission. Ultimately, these mutations lead to cell death and possibly mutagenesis and carcinogenesis. Cyclophosphamide has a greater effect on B lymphocytes than T lymphocytes and a greater effect on suppressor T cells than helper T cells.[76] Resistance to cyclophosphamide may occur due to decreased cellular penetration, increased competition from other nucleophilic substances, improved DNA repair, or increased drug metabolism.

PHARMACOKINETICS. Oral cyclophosphamide has a bioavailability of 74%. Peak plasma levels are achieved within 1 hour of administration. The half-life of the drug is between 2 and 10 hours. Cyclophosphamide undergoes hepatic metabolism via the cytochrome P_{450} system.[77] It is first converted to 4-hydroxycyclophosphamide, an active molecule that exists in equilibrium with aldophosphamide. Aldophosphamide may be cleaved to phosphoramide mustard, another active metabolite, and acrolein, an inactive metabolite. Aldehyde dehydrogenase may also convert aldophosphamide into a second inactive metabolite, carboxyphosphamide. The kidneys excrete just 10%–20% of the drug unchanged but excrete 50% of the active metabolites.

INDICATIONS. In dermatology, cyclophosphamide is used chiefly as a steroid-sparing agent for life-threatening diseases (Box 227-13). In particular, pemphigus vulgaris may be treated with cyclophosphamide in combination with steroids, and evidence supports its steroid-sparing benefits.[78] Cyclophosphamide has also been used for the treatment of cicatricial pemphigoid and has been cautiously and inconsistently reported as beneficial in Stevens-Johnson syndrome and toxic epidermal necrolysis.[79,80]

Survival of patients with many forms of vasculitis has been improved with combination therapy with

cyclophosphamide and steroids.[81] Diseases such as granulomatosis with polyangiitis (Wegener's), Churg-Strauss syndrome, polyarteritis nodosa, and lymphomatoid granulomatosis often require cyclophosphamide therapy. Other diseases that may respond to cyclophosphamide include lupus erythematosus, Behçet disease, pyoderma gangrenosum, lichen planus, and lichen myxedematosus; yet, with the availability of safer immunosuppressive agents, cyclophosphamide is not a typical choice for nonlethal inflammatory diseases.

DOSING REGIMEN. Cyclophosphamide is available as 25- and 50-mg tablets and also as an injectate. Oral doses are typically 1–3 mg/kg/day either divided or as a single morning dose. Intravenous pulse dosing of 0.5–1.0 g/m^2 monthly may be associated with fewer side effects than daily oral dosing. Vigorous hydration, beginning 24 hours before and continuing throughout therapy, is recommended to reduce bladder toxicity.

INITIATING THERAPY. Patients being considered for cyclophosphamide therapy should have a thorough history and physical examination. Cyclophosphamide is contraindicated in patients with a history of transitional cell carcinoma of the bladder.[82] Patients with a history of a lymphoproliferative disorder must be treated with extreme caution. Use in pregnant or lactating patients is contraindicated. Baseline laboratory evaluations include a CBC with manual differential, serum chemistry profile, liver function testing, and urinalysis. Initiation of cyclophosphamide therapy is often contraindicated if the total white blood cell count is less than 5,000/mm^3 or if the granulocyte count is less than 2,000/mm^3.

MONITORING THERAPY. Blood counts and urinalysis should be repeated weekly but may be reduced to biweekly or monthly over 2–3 months. Liver function testing should continue monthly but may be reduced to every 3 months, if stable. Urine cytology is indicated when the cumulative dose exceeds 50 g and every 6 months thereafter, or on any occasion of hemorrhagic cystitis. Some authorities recommend a chest X-ray every 6 months. Follow-up physical examination should pay particular attention to any evidence of lymphoproliferative disease (lymphadenopathy). Patients taking cyclophosphamide should have all age-appropriate cancer screening, including stool guaiac examination and Papanicolaou smears for women. Safety guidelines used during cyclophosphamide therapy are summarized in Box 227-14.

RISKS AND PRECAUTIONS. Absolute and relative contraindications and common adverse effects of cyclophosphamide are summarized in Box 227-15.

COMPLICATIONS. Because of its activity independent of the cell cycle, the toxic effects of cyclophosphamide are significant and numerous.

Gastrointestinal Effects. Nausea and vomiting are the most common gastrointestinal side effects associated with cyclophosphamide use. Coadministration of ondansetron and dexamethasone reduces these side effects. The addition of aprepitant to this combination therapy may provide even greater antiemetic action.[83]

Hematologic Effects. Hematologic disturbances are frequent with cyclophosphamide, especially leukopenia and thrombocytopenia. A nadir in blood counts occurs 8–12 days after initiation of therapy. Myelosuppression is not requisite to immunosuppression, but it often represents a dose-limiting side effect.

Genitourinary Effects. Bladder toxicity is a well-recognized consequence of cyclophosphamide use. Hemorrhagic cystitis occurs in 5%–40% of patients treated with oral cyclophosphamide.[84] This cystitis occurs during therapy and is believed to be caused by the metabolite, acrolein. A scavenging agent, mesna (sodium 2-mercaptoethane sulfonate), binds acrolein in the bladder and reduces irritation. Mesna is used primarily with high-dose cyclophosphamide regimens, but it may be used in low-dose therapy as well.[85] It may be administered orally or intravenously

BOX 227-14 SAFETY MONITORING FOR CYCLOPHOSPHAMIDE USE

- Initial evaluation
  - Careful history and physical examination
  - Identification of proper patient characteristics and risk factors
  - Survey for interacting medications (allopurinol, cimetidine)
  - Baseline laboratories:
    - CBC with differential/platelets
    - Basic serum chemistry profile
    - Urinalysis
    - Renal function testing (creatinine/ blood urea nitrogen)
- Ongoing laboratory monitoring
  - CBC with differential/platelets and urinalysis
    - Perform weekly initially, then
      - Transition to biweekly or monthly after 2–3 months
      - Perform testing with any dose escalation
      - Decrease/discontinue if white blood cell count <4,000/mm^3, or platelets <100,000/mm^3
      - Discontinue and refer to urologist if red blood cells appear in urine
  - Basic serum chemistry and liver function tests
    - Perform monthly initially, then
      - Transition to every 3–6 months if stable
  - Urine cytology testing
    - Perform when cumulative dose >50 g or if patient has hemorrhagic cystitis

CBC = complete blood cell count.

BOX 227-15 RISKS AND PRECAUTIONS WITH CYCLOPHOSPHAMIDE USE

- Absolute contraindications
  - Hypersensitivity to cyclophosphamide (can cross-react with chlorambucil)
- Relative contraindications
  - Pregnancy/lactation (Category D; fetal loss common)
  - History of transitional cell carcinoma of the bladder
  - Depressed bone marrow function
  - Impaired hepatic or renal function
- Common adverse effects
  - Gastrointestinal distress (minimized with antiemetic medications)
  - Myelosuppression (often dose limiting)
  - Hemorrhagic cystitis due to elimination of toxic metabolites (minimized with mesna)
  - Carcinogenicity (transitional cell carcinoma of bladder, lymphoproliferative disease)
  - Reproductive consequences (amenorrhea, azoospermia, gonadal failure)

and may cause a maculopapular drug rash in some patients. Hemorrhagic cystitis and untreated bladder toxicity are thought responsible for the markedly increased risk of transitional cell carcinoma of the bladder (8- to 10-fold increased risk) among those taking chronic cyclophosphamide. Bladder cancer may arise years after therapy, and continued monitoring of the lower urinary tract is indicated.

Carcinogenecity. Cyclophosphamide therapy has been associated with non-Hodgkin lymphoma, leukemia, transitional cell carcinoma of the bladder, and SCC. Much of these data involves transplant and oncology patients exposed to chronic use or higher doses, but a slight increased risk of non-Hodgkin B-cell lymphoma has been demonstrated in those treated for rheumatologic conditions as well.[86,87] The risk of cancer in those using cyclophosphamide for dermatologic conditions is likely lower than that for other indications.

Cutaneous Effects. Anagen effluvium has been reported in 5%–30% of those treated with cyclophosphamide.[88] In some cases, the hair loss is permanent, but generally, it is not. A permanent pigmented band on the teeth is another consequence of cyclophosphamide therapy. Diffuse hyperpigmentation of the skin and nails and acral erythema has been described. Rarely, urticaria, mucosal alterations, or induction of Stevens-Johnson syndrome have been reported.[89]

Mutagenicity and Teratogenicity. Cyclophosphamide is a Category D agent during pregnancy. A report of four pregnant women exposed to cyclophosphamide for systemic lupus resulted in uniform pregnancy loss in all cases.[90] Azoospermia and amenorrhea may also occur with cyclophosphamide use. The risk of amenorrhea has ranged from 27%–60% of women treated, with up to 80% of those so affected manifesting premature ovarian failure.[91] Age and cumulative dose are most determinative of the risk of gonadal failure. In men, testosterone administration may lessen the risk of gonadal failure, whereas in women, leuprolide acetate may provide a similar partial protection.[92,93] Cryopreservation of reproductive material may be used, but it is far more practical and economical for men than women. Cyclophosphamide should not be a first-line therapy for men or women who wish to conceive after treatment.

Drug Interactions. Because the microsomal enzyme system responsible for activation of cyclophosphamide is involved in the metabolism of many other drugs, the potential for multiple drug interactions exists. Allopurinol, cimetidine, and chloramphenicol all increase cyclophosphamide toxicity. The effects of succinylcholine are potentiated by cyclophosphamide. Digoxin absorption is diminished with coadministration of oral cyclophosphamide.

CHLORAMBUCIL

Chlorambucil is another alkylating agent derived from nitrogen mustard. In comparison to cyclophosphamide, chlorambucil is used infrequently in dermatology.

MECHANISM OF ACTION. Like cyclophosphamide, chlorambucil exerts its affects independent of the cell cycle through cross-linking of DNA.

PHARMACOKINETICS. Chlorambucil is well absorbed, with 87% bioavailability after oral administration. The drug is 99% protein bound in plasma. It has a plasma half-life of approximately 1.5 hours. Less than 1% of the drug is excreted by the kidney. Although the drug is extensively metabolized by the liver, it does not require hepatic activation, unlike cyclophosphamide. In comparison to cyclophosphamide, chlorambucil has a slower onset of effect.

INDICATIONS. Chlorambucil is rarely used in dermatology. Isolated reports detail use of chlorambucil as a steroid-sparing agent in pemphigus vulgaris, bullous pemphigoid, primary cutaneous B-cell lymphoma, aggressive pyoderma gangrenosum, and Behçet disease (Box 227-16). Interestingly, chlorambucil use has also been described in erythrodermic cutaneous T-cell lymphoma and necrobiotic xanthogranuloma.[94,95] Complicating management decisions, the US Food and Drug Administration-approved package insert states that chlorambucil should not be used for nonmalignant diseases.

DOSING REGIMEN. Chlorambucil is supplied as 2-mg tablets. The recommended dosage is 0.05–0.2 mg/kg/day. Doses for cutaneous disease should usually remain toward the lower end of this range.

BOX 227-16 USES FOR CHLORAMBUCIL IN DERMATOLOGY

- US Food and Drug Administration-approved indications
  - None
- "Off-label" uses
  - Granulomatosis with polyangiitis (Wegener's)
  - Lymphomatoid granulomatosis
  - Dermatomyositis
  - Scleroderma
  - Relapsing polychondritis
  - Severe cutaneous lupus erythematosus
  - Pemphigus vulgaris
  - Bullous pemphigoid
  - Epidermolysis bullosa acquisita
  - Pyoderma gangrenosum
  - Scleromyxedema/lichen myxedematosus
  - Langerhans cell histiocytosis
  - Mycosis fungoides/Sézary syndrome
  - Necrobiotic xanthogranuloma with paraproteinemia
  - Sarcoidosis
  - Severe disseminated granuloma annulare

INITIATING THERAPY. Patients being considered for chlorambucil therapy should have a thorough history and physical examination. When considering chlorambucil use, patients with a history of a lymphoproliferative disorder must be approached with extreme caution. Use in pregnant or lactating patients is contraindicated. Baseline laboratory evaluations should include a CBC with manual differential, serum chemistry profile, liver function testing, and urinalysis.

MONITORING THERAPY. Blood counts should be repeated weekly initially but may be reduced to biweekly or monthly with time. Liver function testing and urinalysis should continue monthly but may be reduced to every 3 months if stable. Some authorities recommend a chest X-ray every 6 months. Follow-up physical examination should pay particular attention to any evidence of lymphoproliferative disease (lymphadenopathy). Patients taking chlorambucil should have all age-appropriate cancer screening, including stool guaiac examinations and Papanicolaou smears for women. Safety guidelines during chlorambucil therapy are summarized in Box 227-17.

RISKS AND PRECAUTIONS. Absolute and relative contraindications and common adverse effects of chlorambucil are summarized in Box 227-18.

COMPLICATIONS. Chlorambucil is considered the least toxic nitrogen mustard. Common side effects include nausea and vomiting, azoospermia, amenorrhea, pulmonary fibrosis, seizures, and hepatotoxicity.

BOX 227-17 SAFETY MONITORING FOR CHLORAMBUCIL USE

- Initial evaluation
  - Careful history and physical examination
  - Identification of proper patient characteristics and risk factors
  - Survey for interacting medications (vaccinations, other immunosuppressives)
  - Baseline laboratories:
    - CBC with differential/platelets
    - Basic serum chemistry profile
    - Urinalysis
    - Renal function testing (creatinine/ blood urea nitrogen)
- Ongoing laboratory monitoring
  - CBC with differential/platelets and urinalysis
    - Perform weekly initially, then
      - Transition to biweekly or monthly after 2–3 months
      - Perform testing with any dose escalation
      - Decrease/discontinue if white blood cell count <4,000/mm3, or platelets <100,000/mm3
  - Basic serum chemistry and liver function tests
    - Perform monthly initially, then
      - Transition to every 3–6 months if stable

CBC = complete blood cell count.

Chlorambucil increases the risk of lymphoproliferative disorders among transplant recipients. Increased SCC, particularly of the skin, has also been demonstrated in this same population. It is unclear how these risks are manifested when chlorambucil is used

BOX 227-18 RISKS AND PRECAUTIONS WITH CHLORAMBUCIL USE

- Absolute contraindications
  - Hypersensitivity to chlorambucil (can cross-react with cyclophosphamide)
- Relative contraindications
  - Pregnancy/lactation (Category D)
  - Active infection (dependent on severity)
  - Impaired hepatic function
  - Childhood (may have increased risk of seizures)
- Common adverse effects
  - Myelosuppression (often dose-limiting)
  - Gastrointestinal distress (minimized with antiemetic medications)
  - Carcinogenicity (lymphoproliferative disease, squamous cell carcinoma)
  - Reproductive consequences (amenorrhea, azoospermia)

for dermatologic disease. Other cutaneous side effects of chlorambucil include alopecia, a morbilliform rash, urticaria, and mucosal ulcerations. Chlorambucil is a Category D agent during pregnancy, and it is generally avoided in this setting.

Drug Interactions. Through strong immunosuppression, chlorambucil may decrease the efficacy of viral vaccinations. Concomitant use of additional immunosuppressive drugs may potentiate any risk of infection or carcinogenesis.

ANTHRACYCLINES

Anthracyclines are antibiotic molecules that possess potent antineoplastic properties. These agents act specifically during the S phase of cell division. Pegylated liposomal doxorubicin (PLD) (see Fig. 227-1) is an anthracycline sometimes employed in dermatology for the treatment of Kaposi sarcoma.[96,97]

MECHANISM OF ACTION.

Anthracyclines, such as doxorubicin, are intercalated within DNA and RNA. Through template disorder and steric obstruction, this incorporation leads to defective synthesis. Cell death typically results, but mutagenesis and carcinogenesis may also occur.

PHARMACOKINETICS.

PLD has pharmacokinetic properties similar to standard doxorubicin; however, the liposomal formulation results in improved tolerance. Encapsulating liposomes have a diameter of approximately 100 nm and are designed to prevent phagocytosis of the agent by the reticuloendothelial system. The result is a plasma half-life of more than 55 hours and improved tumor penetrance.

INDICATIONS.

PLD is approved by the US Food and Drug Administration for the treatment of acquired immunodeficiency syndrome-related (epidemic) Kaposi sarcoma.

DOSING REGIMEN.

PLD is administered at a dose of 20–30 mg/m^2 infused intravenously over 30–60 minutes once every 2–3 weeks.

INITIATING THERAPY.

A thorough history and physical examination is required before initiation of therapy with PLD. Prior use of anthracyclines is an indication for caution, as additive cardiotoxicity may occur. Physical evidence of existing cardiac failure should be sought. Baseline laboratory studies should include a CBC with manual differential and platelet count, a CD4 count, an HIV viral load assay, and liver function studies, including a total bilirubin.

MONITORING THERAPY.

Before each dose of PLD, all patients should have a repeat blood count, CD4 count, and liver function tests with total bilirubin. Specific tests for cardiotoxicity, such as a multiple-gated acquisition scan, are indicated for cumulative doses greater than 450 mg/m^2 or if signs or symptoms of congestive heart failure develop.

BOX 227-19 RISKS AND PRECAUTIONS WITH DOXORUBICIN USE

- Absolute contraindications
  - Hypersensitivity to anthracyclines
- Relative contraindications
  - Pregnancy/lactation (Category D)
- Common adverse effects
  - Myelosuppression
  - Gastrointestinal distress
  - Toxic hepatitis
  - Hyperpigmentation of the skin and nails

RISKS AND PRECAUTIONS.

Absolute and relative contraindications and common adverse effects of doxorubicin are summarized in Box 227-19.

COMPLICATIONS.

Myelosuppression is the most common side effect of PLD. A nadir in blood counts is expected during the second week of therapy. Any resultant neutropenia should be treated aggressively with granulocyte-macrophage colony-stimulating factor or granulocyte colony-stimulating factor. Characteristically, the HIV viral load does not change substantially during treatment, but CD4 counts may be lowered slightly. Abrupt or precipitous decreases in a CD4 count may be a reason to suspend treatment.

Although it is presumed that PLD has myocardial toxicity, it would appear less cardiotoxic in comparison to nonliposomal forms of doxorubicin. Although many still encourage testing for congestive heart failure with cumulative doses in excess of 450 mg/m^2, multiple studies have shown no adverse cardiac impact with cumulative doses of up to 1,040 mg/m^2. Hepatotoxicity has been described with PLD, and this may be additive to any such toxicity caused by antiretroviral medications. Nausea and vomiting with dosing is also common. Doxorubicin is a Category D agent during pregnancy. It is embryotoxic and an abortifacient and should be avoided in women who are pregnant or who are planning to conceive during treatment.

A small percentage of patients may experience an initial infusion reaction, which typically resolves and does not occur with later dosing. Other cutaneous effects include hyperpigmentation of the skin and nails, alopecia, acral erythema and dysesthesias, urticaria, radiation recall reactions, or a pustular psoriasiform drug eruption.

Drug Interactions. To date, no drug interaction studies have been conducted with PLD, but it is reasonable to conclude it may interact with drugs known to interact with conventional doxorubicin, specifically digoxin, cyclosporine, calcium channel blockers, and ciprofloxacin, to name a few.

Despite continued introduction of highly targeted immunomodulating drugs ("biologics") (see Chapter 234), cytotoxic agents remain as important medications

TABLE 227-6
Summary of Cytotoxic Agents Commonly Used in Dermatology

Drug	Common Indications	Mechanism of Action	Typical Dose	Key Side Effects
Methotrexate	Psoriasis Connective tissue disease	Inhibition of dihydrofolate reductase	10.0–17.5 mg/week	Myelosuppression Toxic hepatitis Liver fibrosis/cirrhosis
Azathioprine	Bullous disorders Connective tissue disease	Forms purine analogues that interrupt DNA/RNA synthesis	0.5–2.5 mg/kg/day (dependent on innate TPMT expression)	Myelosuppression Gastrointestinal distress Increased risk of malignancy
Mycophenolate mofetil	Psoriasis Connective tissue disease	Inhibition of inosine monophosphate dehydrogenase	1.5–2.0 g/day	Gastrointestinal distress Myelosuppression
Thioguanine	Psoriasis	Forms purine analogues that interrupt DNA/RNA synthesis	80–120 mg/day or 120–160 mg 3×/week (dependent on innate TPMT expression)	Myelosuppression
Hydroxyurea	Psoriasis	Inhibition of ribonucleotide diphosphate reductase	1–2 g/day	Myelosuppression Dermatomyositis-like reaction
Cyclophosphamide	Vasculitis Connective tissue disease Advanced cutaneous T-cell lymphoma	Metabolites undergo physiochemical reactions with DNA (alkylation)	1–3 mg/kg/day or 0.5–1.0 g/monthly	Gastrointestinal distress Myelosuppression Hemorrhagic cystitis Bladder carcinogenesis
Chlorambucil	Vasculitis Connective tissue disease	Physiochemical reactions with DNA (alkylation)	0.05–0.2 mg/kg/day	Gastrointestinal distress Myelosuppression Increased risk of malignancy
Doxorubicin (liposomal)	Acquired immunodeficiency syndrome-related Kaposi sarcoma	Intercalation into DNA with termination of synthesis	20–30 mg/m^2 every 2–3 week	Gastrointestinal distress Toxic hepatitis Possible cardiotoxicity Infusion site reactions

TPMT = thiopurine methyltransferase.

in the therapeutic arsenal of dermatologists. Table 227-6 summarizes the major indications, principal mechanism of action, and common toxicities of these agents.

MUCOCUTANEOUS REACTIONS TO CYTOTOXIC AGENTS

Specific cytotoxic agents may be used by dermatologists for treatment of severe and recalcitrant dermatologic disease, but typically only certain agents are employed, and dosages are typically less than those used for other indications. Mucocutaneous reactions to these medications initiated by other providers are commonly seen in patients during consultation. A morphologic approach to those reactions is useful. To this end, subcategories of mucocutaneous reactions to various cytotoxic agents are examined, paying particular attention to those that may provoke characteristic mucocutaneous reactions.

HAIR FOLLICLE COMPLICATIONS

ALOPECIA. One of the most widely recognized cutaneous effects of cytotoxic agents is alopecia, often creating great distress within the patient. Cytotoxin-induced alopecia is typically a form of anagen effluvium caused by interruption of the rapidly dividing cells of the hair matrix. The particular agent, dose, schedule, and route of administration impact the degree of hair loss; yet, at equivalent dosages, intravenous administration is generally more deleterious than oral administration. Numerous cytotoxic agents produce alopecia, but doxorubicin, cyclophosphamide, and vincristine are often implicated (Box 227-20).[98,99]

Cytotoxin-induced alopecia usually begins 2–4 weeks after therapy and may progress for several months. Up to 85%–90% of the hair may be lost; the remaining fraction spared is that normally in telogen. Loss of hair on the scalp and eyebrows is most noticeable, but eyelashes and body hair may be shed as well

BOX 227-20 CYTOTOXIC AGENTS ASSOCIATED WITH ALOPECIA

- Bleomycin
- Busulfan (significant risk of permanent loss)
- Cytarabine
- Dacarbazine
- Daunorubicin
- Docetaxel
- **Doxorubicin**
- Etoposide
- Fluorouracil
- **Hydroxyurea**
- **Methotrexate**
- Nitrogen mustard derivatives (**cyclophosphamide**, **chlorambucil**)
- Nitrosoureas
- Paclitaxel
- Procarbazine
- Thiotepa
- Vinca alkaloids

Agents in **bold** represent a medicine more often employed by dermatologists in treating cutaneous illness.

(Fig. 227-2). The alopecia typically resolves with cessation of treatment, although regrowth may occur with a different color, quality, or texture. Permanent alopecia has occurred most often with high-dose busulfan.[100] Scalp cooling has been used with limited success to minimize hair loss, likely by reducing biochemical activity, but it may create a haven for malignant cells; it remains a controversial intervention, particularly for hematologic malignancies.[98,101] Topical minoxidil shortened the duration of alopecia in breast cancer patients receiving adjuvant chemotherapy and in patients with gynecologic malignancies who received cyclophosphamide, doxorubicin, or cis-platinum, but it did not induce significant regrowth in patients with permanent alopecia due to busulfan or cyclophosphamide.[98,102]

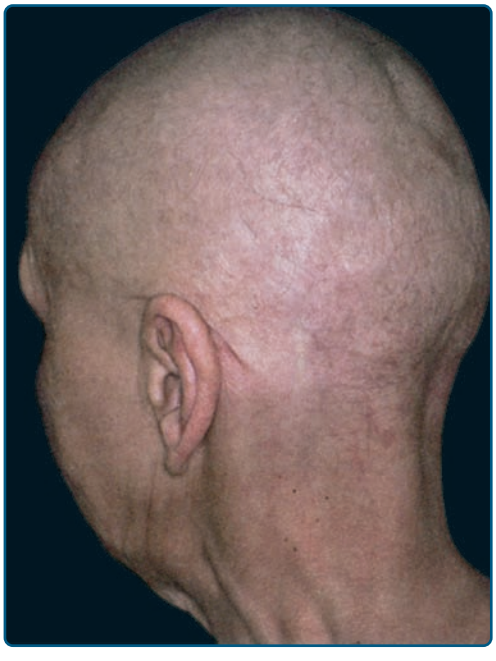

Figure 227-2 Alopecia after the administration of combined chemotherapy with cyclophosphamide, doxorubicin, and vincristine.

FOLLICULITIS ("ACNEIFORM" ERUPTION).

Classic cytotoxin-induced folliculitis begins as erythematous macules, followed in days by the appearance of papules, and then pustules. Lesions predominate on the face and upper trunk. The eruption typically resolves over 2 weeks, but comedones may persist, or postinflammatory hyperpigmentation may result. Simple acne vulgaris may also be aggravated by androgens used in conjunction with chemotherapeutic agents in some multidrug regimens. Folliculitis is most often associated with actinomycin D and less often with methotrexate or cisplatin.[103] Recently, a case of eosinophilic folliculitis with combined therapy with cyclophosphamide, methotrexate, and fluorouracil was reported.[104]

NAIL COMPLICATIONS

MALFORMED NAIL PLATES (DYSTROPHY).

Nail changes are often noted with cytotoxic agents (Box 227-21). Mild nail reactions produce Beau lines. Severe reactions may produce onycholysis or onychomadesis (Fig. 227-3). The great toenail is most often affected.[105] Less common nail problems due to cytotoxic drugs include nail bed pain, thickening or thinning of the nail plate, and splinter hemorrhage or subungual hemorrhage. Anthracyclines (doxorubicin) and taxanes (paclitaxel, docetaxel) most often yield onychodystrophy, with paclitaxel and docetaxel producing nail changes in up to 30%–40% of those treated.[105,106]

NAIL PIGMENTATION.

Cytotoxins may yield leukonychia or hyperpigmentation of the nail plate.

BOX 227-21 CYTOTOXIC AGENTS ASSOCIATED WITH NAIL PLATE MALFORMATIONS (DYSTROPHY)

- Bleomycin
- **Cyclophosphamide**
- Daunorubicin
- Docetaxel
- **Doxorubicin**
- Fluorouracil
- **Hydroxyurea**
- Mitoxantrone

Agents in **bold** represent a medicine more often employed by dermatologists in treating cutaneous illness.

Figure 227-3 Presence of proximal indented Beau line and distal band of leukonychia due to cyclophosphamide 3 months after bone marrow transplantation.

Leukonychia produces a white discoloration in the nail; the mechanism is unknown, but is presumed to be cytotoxic in nature. An excellent example of patterned leukonychia are Mees lines, which were described in 1919 as transverse white lines with arsenic exposure.[107] Cytotoxic agents that most often lead to leukonychia are doxorubicin, vincristine, cyclophosphamide, methotrexate, and 5-fluorouracil.[108]

Nail hyperpigmentation usually develops weeks or months after chemotherapy. Hyperpigmentation of the nail may be oriented longitudinally, horizontally, diffusely, or in a perilunar fashion.[109] Various mechanisms have been proposed, including genetic predisposition, toxic effect on the nail matrix, photosensitization, or focal stimulation of melanocytes. Blacks are more often affected, presumably due to increased numbers of melanocytes within the nail matrix.[110] Cyclophosphamide, doxorubicin, hydroxyurea, and bleomycin are most often implicated in nail hyperpigmentation.[111] Typically, leukonychia or nail hyperpigmentation due to cytotoxic agents resolves with cessation of therapy.

ECCRINE GLAND COMPLICATIONS

NEUTROPHILIC ECCRINE HIDRADENITIS.

Neutrophilic eccrine hidradenitis (NEH) consists of tender, erythematous macules, papules, and plaques on the trunk, neck, and extremities that develop days to months after exposure to cytotoxic agents (Fig. 227-4).[112,113] Lesions resolve spontaneously over a period of days. Histologic changes include a perieccrine neutrophilic infiltrate. Apocrine gland involvement has also been identified.[114] Concentration of the cytotoxic agent within sweat is the likely mechanism of injury. NEH is most often associated with cytarabine, but other agents have been implicated (Box 227-22). A similar condition unassociated with cytotoxic agents is recognized, suggesting the lesions represent a final common pathway of adnexal injury. In a single case report, prophylactic dosing of dapsone prevented NEH in a patient who had had multiple prior eruptions due to lomustine, an alkylating agent.[115]

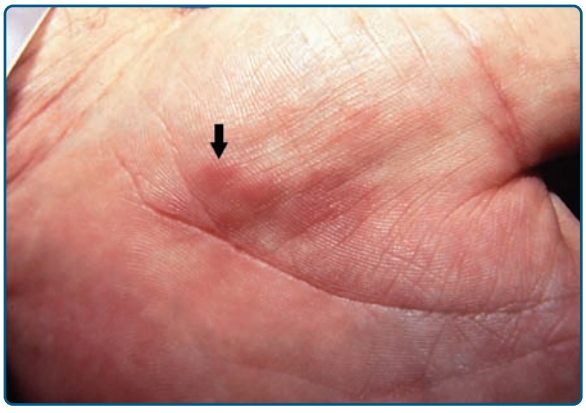

Figure 227-4 Neutrophilic eccrine hidradenitis (*arrow*). (From the Archives of Fitzsimmons Army Medical Center.)

SYRINGOSQUAMOUS METAPLASIA.

Chemotherapy-induced syringosquamous metaplasia (CISM) is closely related to NEH. Like neutrophilic hidradenitis, direct cytotoxic injury of sweat ducts is implicated. Clinically, CISM presents as erythematous papular eruptions, similar to miliaria, which erupt 2–39 days after administration of the cytotoxic agent.[116,117] The papules resolve approximately 4 weeks after discontinuance. Histologic examination demonstrates prominent squamous metaplasia of the upper sweat duct, with necrotic ductal epithelial cells; inflammation is minimal. On occasion, CISM may even mimic SCC.[118] Cytarabine has been most often associated with CISM (see Box 227-22).

BOX 227-22 CYTOTOXIC AGENTS ASSOCIATED WITH ADNEXAL TOXICITY

NEUTROPHILIC ECCRINE HIDRADENITIS	ECCRINE SYRINGOSQUAMOUS METAPLASIA
Bleomycin	Bleomycin
Chlorambucil	Cytarabine (common)
Cytarabine (common)	
Daunorubicin	Daunorubicin
Doxorubicin (common)	**Doxorubicin**
Mitoxantrone	Mitoxantrone
Vincristine	Suramin

Agents in **bold** represent a medicine more often employed by dermatologists in treating cutaneous illness.

EPIDERMAL COMPLICATIONS

CHEMOTHERAPY-INDUCED ACRAL ERYTHEMA. Multiple cytotoxic agents may yield a distinct cutaneous reaction known as *acral erythema*. The reaction usually develops 4–23 days after initiation of chemotherapy as painful, sharply demarcated erythema of the palmoplantar surfaces, with associated edema (Fig. 227-5).[119] In severe cases, large bullae may extend over the dorsum of the hands and feet.[120] Pain may limit ambulation or use of the hands. Therapy is limited mostly to analgesics and emollients, although pyridoxine supplementation may improve dysesthesias. The reaction is self-limited and resolves over 2–4 weeks. Recurrence with subsequent exposure is highly variable. The cause of acral erythema is unknown, but concentration of cytotoxic agents within eccrine structures of acral skin has been proposed. In support of such a theory, coexistent syringosquamous metaplasia has been demonstrated.[121,122] Acral erythema is most common with cytarabine, doxorubicin, fluorouracil, and methotrexate (Box 227-23). Long-term hydroxyurea therapy may produce a unique form of acral erythema that is linear and resembles dermatomyositis, without any corresponding muscle findings (drug-induced pseudodermatomyositis); rarely, the face may be involved.[71,72]

INFLAMMATION OF ACTINIC KERATOSES. A number of different cytotoxic agents and chemotherapeutic protocols yield inflammation of actinic keratoses. Systemic fluorouracil is the most common cause of inflamed actinic keratoses, and this should come as no surprise to dermatologists.[123] The reaction usually develops within 1 week of initiating chemotherapy. The actinic keratoses may resolve or remain after completion of the therapy. A similar reaction within seborrheic keratoses has been reported to occur with cytarabine and may mimic the sign of Leser-Trélat or herpes zoster.[124,125]

CUTANEOUS HYPERPIGMENTATION. Bleomycin may produce a unique form of flagellate (linear) hyperpigmentation of the skin in 8%–66% of those exposed; typically after cumulative doses of 90–285 mg.[126,127] Lesions begin as linear, erythematous, pruritic lesions that are slowly replaced by hyperpigmentation and are present hours to weeks after dosing (Fig. 227-6). The eruption usually resolves without treatment over weeks to months. The pathogenesis is unknown, but some investigators have induced flagellate lesions by rubbing the skin during bleomycin administration; others have been unable to replicate this result. Bleomycin may also produce patchy pigmentation in areas of pressure, within the palmar creases, or within striae distensae. Other unique forms of cutaneous hyperpigmentation are recognized, such as the serpentine supravenous hyperpigmentation that may accompany fluorouracil infusions[128] or the polycyclic bands of pigmentation on the scalp occurring with daunorubicin.[110]

BOX 227-23 CYTOTOXIC AGENTS ASSOCIATED WITH ACRAL ERYTHEMA

- Bleomycin
- **Cyclophosphamide**
- Cytarabine
- Daunorubicin
- Docetaxel
- **Doxorubicin**
- Etoposide
- Fluorouracil
- **Hydroxyurea** (dermatomyositis-like eruption possible)
- Lomustine
- Mercaptopurine
- **Methotrexate**
- Paclitaxel
- Suramin
- Vinblastine

Agents in **bold** represent a medicine more often employed by dermatologists in treating cutaneous illness.

Figure 227-5 Cytarabine-induced painful acral erythema with edema.

Figure 227-6 Flagellate hyperpigmentation occurs 2 weeks after administration of bleomycin.

Figure 227-7 Hyperpigmentation at sites of occlusion during administration of thiotepa.

Numerous antineoplastic drugs may yield other forms of hyperpigmentation, including patchy, acral, photoaccentuated, polycyclic, occlusion accentuated, pressure accentuated (Fig. 227-7), or generalized patterns (Box 227-24).[103] The cause of cutaneous hyperpigmentation is largely unknown. Postulated mechanisms include a direct toxic effect on melanocytes, increased drug deposition due to increased blood flow, local toxicity due to concentration in sweat, associated endocrinologic abnormalities, and drug-induced depletion of tyrosinase inhibitors.[109]

BOX 227-24 CYTOTOXIC AGENTS ASSOCIATED WITH SKIN HYPERPIGMENTATION

DRUG	PATTERN OF PIGMENTATION
Bleomycin	Flagellate
Busulphan	Dusky, may appear similar to Addison disease
Cisplatin	Pressure-induced
Cyclophosphamide	May be localized to palms, soles, or nails
Dactinomycin	Diffuse
Daunorubicin	Sun-exposed areas
Doxorubicin	Diffuse, particularly nails
Etoposide	Occluded areas
Fluorouracil	Sun-exposed areas, areas of prior irradiation, nails
Hydroxyurea	Diffuse, particularly nails
Ifosfamide	Hands, feet, and occluded areas
Methotrexate	Sun-exposed areas, hair may develop "flag sign"
Nitrosoureas	Occluded areas
Paclitaxel	Localized
Plicamycin	Localized
Procarbazine	Diffuse
Tamoxifen	Hair pigmentation
Thiotepa	Occluded areas
Vinca alkaloids	Localized

Agents in **bold** represent a medicine more often employed by dermatologists in treating cutaneous illness.

PHOTOSENSITIVITY. Most chemotherapy-induced photosensitivity is phototoxic rather than photoallergic in nature (Box 227-25; see also Chapter 92). Phototoxic reactions begin rapidly after administration and often mimic sunburns, with burning, erythema, and even vesicles or bullae. Photoallergic reactions typically present as a more eczematous process. Furthermore, photoallergic processes are dependent on sensitization and may be delayed weeks or months after an initial exposure.

RADIATION RECALL REACTION. Recall reactions consist of erythema confined to an area of prior radiation exposure or sunburn. Severe cases may

BOX 227-25 CYTOTOXIC AGENTS WITH RADIATION REACTIONS

Figure 227-8 Reactivation of solar erythema 2 days after high-dose methotrexate administration to a young woman with choriocarcinoma. (From Bronner AK, Hood AF: Cutaneous complications of chemotherapeutic agents. *J Am Acad Dermatol* **9:**645, 1983, with permission.)

develop vesiculation (Fig. 227-8). True radiation recall may occur years after irradiation, and the pathogenesis is unknown. It has been postulated that radiation-damaged keratinocytes are further damaged by the administration of the cytotoxic agent (see Box 227-25).[129] Methotrexate often engenders a unique recall reaction to sunburn when dosed 1–3 days after exposure, although at least one case occurred as late as 8 days afterward.[130] Folinic acid supplementation (leucovorin rescue) does not prevent UV sunburn recall reactions due to methotrexate.

RADIATION ENHANCEMENT REACTIONS. Radiation enhancement is a synergistic reaction between an antineoplastic agent and irradiation. This radiosensitization is often desired in antineoplastic treatment, but it may lead to adverse effects on the skin. The result may be radiation dermatitis that presents initially as pain and erythema followed by desquamation and hyperpigmentation. Although a number of chemotherapeutic agents may produce this reaction, doxorubicin and dactinomycin are most often implicated (see Box 227-25).[103]

DERMAL COMPLICATIONS

LOCAL INJURY. Extravasation of chemotherapeutic agents may occur in up to 6% of adults treated with infusions and is likely an even more common occurrence among pediatric patients.[109,131] As expected, the degree of injury is related to the drug used, the rate of delivery, the concentration of the agent, and the amount extravasated.

Agents with minimal toxicity on extravasation may produce only a chemical cellulitis or phlebitis and are classified as irritants. Chemical cellulitis manifests as erythema, induration, and pain at the injection site. Sometimes it may follow the course of a vein. It is often of short duration and resolves without treatment.

Figure 227-9 Severe tissue necrosis after extravasation of doxorubicin.

Chemotherapy-induced phlebitis manifests as linear cords, often with accompanying discomfort.

Vesicants are agents, which on extravasation yield direct-tissue necrosis. Chemotherapy-induced tissue necrosis can be a devastating complication. Extravasation should always be treated by immediate discontinuance of the infusion and the application of either hot or cold packs. Cold packs are used for all chemotherapeutic agents except vinca alkaloids to localize the drug and promote degradation. Vinca alkaloids are treated with hot packs because application of cold promotes tissue necrosis.[132] Doxorubicin is perhaps the most dangerous of all vesicants, and extravasation of this agent may yield ulcers that progress for months that may even erode into tendon or bone (Fig. 227-9). Severe ulcerations caused by extravasation may require wide excision and skin grafting.

Other treatments advocated for specific situations include: (1) topical dimethyl sulfoxide (DMSO); (2) local injection of hyaluronidase; or (3) potent topical, intralesional, or oral steroids. DMSO is a topical solvent that has free-radical scavenging and antioxidant properties; it may hasten removal of extravasated drugs. Studies suggest that topical DMSO may have benefit in anthracycline-induced skin ulceration.[133,134] Hyaluronidase degrades hyaluronic acid, breaking down subcutaneous tissue, and promoting drug diffusion through the interstitial space. It appears effective in vinca alkaloid, epipodophyllotoxin, and paclitaxel extravasations, but should not be used in anthracycline extravasation.[135,136] Hyaluronidase is contraindicated in sites involved with malignancy or superinfection. Finally, histologic examination of extravasation injuries has demonstrated surprisingly few inflammatory cells in areas of tissue damage, perhaps explaining why corticosteroids are, in general, of little value in management.[137,138]

SCLEROTIC DERMAL REACTIONS. Bleomycin and docetaxel produce sclerotic tissue reactions that may be localized, regional, or diffuse in extent.[139,140] Localized tissue reactions may mimic morphea or systemic sclerosis. Melphalan has been reported to produce a unique form of reticulate scleroderma

after limb perfusion. The mechanism of tissue sclerosis has not been well established. Biopsies of cytoxin-induced dermal sclerosis may be indistinguishable from morphea or systemic sclerosis. In some cases, the sclerosis resolved after withdrawal of the offending agent.

RAYNAUD PHENOMENON. Secondary Raynaud phenomenon, with or without digital ulceration, is most often associated with bleomycin, vincristine, cisplatin, or cisplatin with gemcitabine.[141–143] This reaction may occur with systemic chemotherapy or after intralesional injection to treat verruca vulgaris. The mechanism of development is unknown, but bleomycin is known to be toxic to endothelial cells. In a large study of 90 patients receiving bleomycin for testicular cancer, 37% developed Raynaud phenomenon, with 7% having transient disease.[141] Risk factors for the development of Raynaud phenomenon include combination therapy with vinblastine or high cumulative doses of bleomycin.

MUCOSAL COMPLICATIONS

Oral complications may occur in up to 40% of those receiving chemotherapy. Because of a high inherent proliferative index, the mucosa is susceptible to the effects of multiple cytotoxic agents. Young patients and those with preexisting oral disease appear even more susceptible.[109]

MUCOSITIS/STOMATITIS. A wide range of cytoxic agents has been implicated in stomatitis (Box 227-26).

BOX 227-26 CYTOTOXIC AGENTS ASSOCIATED WITH MUCOSITIS

- Bleomycin
- **Cyclophosphamide**
- Cytarabine
- Dactinomycin
- Daunorubicin
- Docetaxel
- **Doxorubicin**
- Fluorouracil
- **Hydroxyurea**
- Mercaptopurine
- **Methotrexate**
- Mitomycin
- Nitrosoureas
- Paclitaxel
- Plicataxel
- Plicamycin
- Procarbazine
- Vinblastine

Agents in **bold** represent a medicine more often employed by dermatologists in treating cutaneous illness.

Figure 227-10 Stomatitis induced by combined chemotherapy with cytarabine, doxorubicin, and methotrexate. (Used with permission from Allan C. Harrington, MD.)

Patients with cytoxin-induced stomatitis typically note burning and mucosal erythema days after administration. Painful erosions and ulcerations often follow (Fig. 227-10). The mouth is most often affected, especially the buccal mucosa and tongue, but any mucosal surface may be involved. Mucositis may be complicated by secondary bacterial or fungal infection. Meticulous, but not overly aggressive, hygiene may reduce the incidence of secondary infection, and antibiotics and antifungal agents are often used. A recent meta-analysis of treatments for chemotherapy-induced mucositis found that simple modalities, such as ice chips, had equivalent benefit as more aggressive interventions.[144] Finally, oral hemorrhage may be secondary to chemotherapy-induced thrombocytopenia, and a careful clinical examination is always required.

MUCOSAL HYPERPIGMENTATION. Many cytotoxic agents induce mucosal hyperpigmentation. Mucosal hyperpigmentation may manifest various patterns, including linear, patchy, and macular forms. Some agents tend to affect certain anatomic areas such as the gingival margin (cyclophosphamide) or tongue (fluorouracil). The mechanism of mucosal hyperpigmentation is not well understood. Typically, cytotoxin-induced hyperpigmentation resolves slowly over weeks to months after discontinuance. One notable exception is mucosal hyperpigmentation caused by cyclophosphamide, which may be permanent. Cyclophosphamide may also produce a permanent pigmented band on the teeth.

Chapter 228 :: Retinoids

:: Anders Vahlquist & Jean-Hilaire Saurat

RETINOIDS AT A GLANCE

- The biologic functions and actions of retinoids (excluding vision) include:
  - Reproduction, embryonic growth, and morphogenesis.
  - Modulation of proliferation and differentiation of epithelia.
  - Decrease in sebaceous gland size (isotretinoin).
  - Immunologic and anti-inflammatory effects.
  - Tumor prevention and treatment.
  - Effect on extracellular matrix components.
- Four types of oral retinoids and the major indications for their use are isotretinoin (acne), alitretinoin (chronic hand eczema), acitretin/etretinate (psoriasis, keratinizing disorders), and bexarotene (cutaneous T-cell lymphoma). Contraindications to their use include pregnancy, breastfeeding, and nonadherence to contraceptive regimen. Retinoids should always be taken with food or milk to enhance intestinal absorption. Dosing once a day is usually sufficient.
- Mucocutaneous side effects (cheilitis, xerosis, skin peeling, conjunctivitis) are common, as are reversible abnormal results on laboratory tests [hyperlipidemia, increased liver enzyme levels, and hypothyroidism (bexarotene)]. Musculoskeletal and central nervous system side effects are rare.

Retinoids include both naturally occurring molecules and synthetic compounds that have specific biologic activities that resemble those of vitamin A or bind to the nuclear receptors for retinoids. Vitamin A from natural sources was already being used in the 1930s in high dosages to treat certain hyperkeratotic diseases, often with toxic side effects. Three generations of synthetic retinoids have since been developed (Fig. 228-1).

First generation: All-*trans*-retinoic acid (tretinoin, ATRA), a naturally occurring metabolite of retinol, was the first retinoid synthesized but had no significant advantages over vitamin A in treatment of dermatologic diseases. It is used as a differentiation-inducing agent to treat acute promyelocytic leukemia.

Isotretinoin (13-*cis*-retinoic acid), clinically available since the 1970s, was found to cause prolonged remissions in patients with previously treatment-resistant cystic acne [it has been approved by the US Food and Drug Administration (FDA) for this indication since 1982].[1]

The latest approved systemic retinoid is alitretinoin (9-*cis*-retinoic acid), which is approved in several

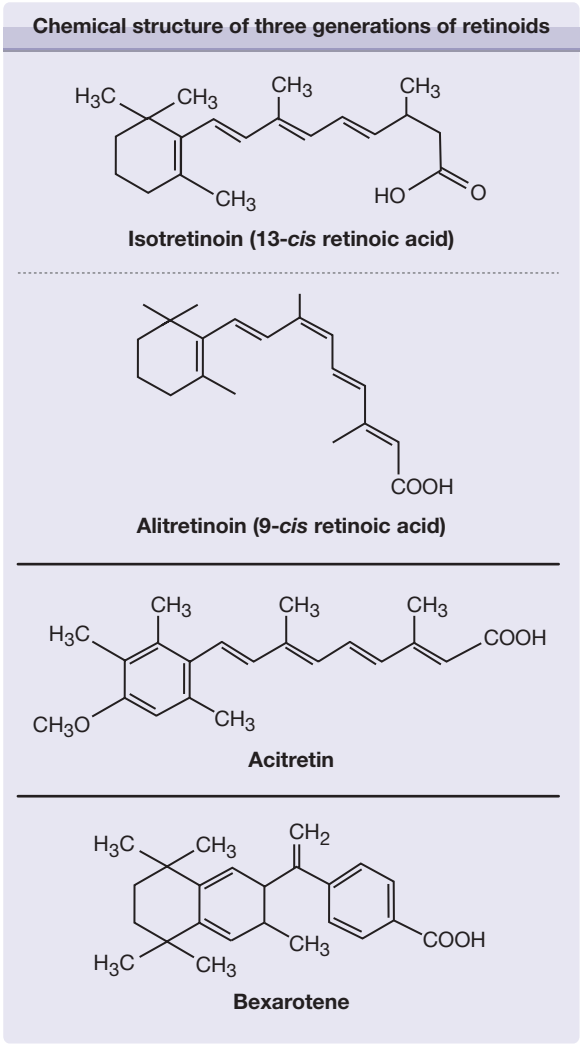

Figure 228-1 Chemical structure of three generations of retinoids. Isotretinoin is first generation; in second-generation (e.g., acitretin) the β-ionone ring, is replaced with an aromatic structure. Bexarotene is an example of a third-generation retinoid.

European countries and Canada for treatment of chronic hand eczema.

Second generation: Through replacement of the β-ionone ring in ATRA with an aromatic structure, newer retinoids with better therapeutic margins were synthesized in the 1970s. Etretinate and its free acid metabolite, acitretin, showed a therapeutic index ten times more favorable than that of ATRA. Etretinate (approved in Europe 1983 and by the FDA in 1987) and acitretin (approved 1987 and 1997, respectively) became a standard treatment for psoriasis. Acitretin has replaced etretinate in most countries, but not in Japan and a few other countries.

Third generation: The discovery of retinoic acid receptors (RARs)[2,3] allowed research directed toward receptor-specific, third-generation retinoids with a safer therapeutic index and a more selective action. Bexarotene, approved by the FDA in 1999 for systemic use in treating cutaneous T-cell lymphoma (CTCL), is a prime example. Bexarotene belongs to a subclass of arotinoids called *rexinoids*, because they bind to the retinoid X receptors (see Section "Bexarotene").

MECHANISM OF ACTION

Retinoids affect cell growth and differentiation, exert immunomodulatory action, and alter cellular adhesiveness.[4] Their effect on RARs is discussed in detail in Chapter 217.

Under normal conditions, virtually all effects of vitamin A in the skin are mediated by ATRA, the cellular level of which is meticulously controlled. Endogenous ATRA has been at the focus in the development of a new class of compounds called *retinoic acid metabolism-blocking agents*, which are basically cytochrome P_{450} (CYP) enzyme 26 inhibitors that impede the oxidative degradation of ATRA and thus increase the retinoid activity in target tissues.[5] Two such drugs (liarozole and rambazole) are under development and are not yet on the market.

PHARMACOKINETICS

Isotretinoin, alitretionin, acitretin/etretinate, and bexarotene differ not only in their spectra of clinical efficacy but also in their toxicities and pharmacokinetics. Due to their lipophilicity, the oral bioavailability of all retinoids is markedly enhanced when they are administrated with food, especially with fatty meals. Retinoids are metabolized mainly by oxidation and chain shortening to biologically inactive and hydrophilic metabolites, which facilitates biliary and/or renal elimination. The oxidative metabolism is induced primarily by the retinoids themselves and other agents that induce hepatic CYP isoforms.[6]

ISOTRETINOIN AND OTHER FIRST-GENERATION RETINOIDS

Isotretinoin, alitretinoin, and ATRA are three partially interconvertible isomers that differ in their elimination half-lives—approximately 20 hours for isotretinoin and 1 hour for ATRA. Isotretinoin undergoes first-pass metabolism in the liver and subsequent enterohepatic recycling. In plasma, isotretinoin is more than 99% bound to plasma protein, mainly albumin. It is stored in neither the liver nor adipose tissue, in sharp contrast to vitamin A and etretinate. The major metabolite is 4-oxoisotretinoin, which has reduced bioactivity; both compounds are excreted in urine and feces. After the end of treatment, endogenous concentrations of isotretinoin and its major metabolite are reached within 2 weeks. Therefore, a 1-month post-therapy period of contraception provides an adequate safety margin.[7] No clear affinity for any RARs has been identified with isotretinoin, whereas ATRA binds to RARs and alitretinoin uniquely binds to both RARs and RXRs.

ACITRETIN AND ETRETINATE

Etretinate is a prodrug of acitretin that undergoes extensive hydrolysis in the body to yield the corresponding acid metabolite. In animal studies and in clinical studies in patients with severe keratinizing disorders, acitretin is as effective as etretinate.[8] However, acitretin has a great pharmacokinetic advantage because it is eliminated more rapidly than etretinate.[9] Etretinate is approximately 50 times more lipophilic than acitretin and binds strongly to plasma lipoproteins, whereas acitretin binds to albumin. This fact has a profound influence on the respective pharmacokinetic properties of the two drugs.

Even when etretinate and acitretin are taken with food, the absorption of the two drugs varies.[10] Etretinate is stored in adipose tissue from which it is released slowly; it has a terminal half-life of up to 120 days. In contrast, acitretin has an elimination half-life of only 2 days.[9] However, small amounts of etretinate can be formed in patients receiving acitretin if it is taken simultaneously with alcohol.[11] This has prompted the manufacturer to extend the time of compulsory contraception in patients taking acitretin to 2 years (3 years in the United States).[12] Acitretin still has a pharmacokinetic advantage over etretinate; however, all women must strictly avoid alcohol consumption during treatment and for 2 months thereafter.[9]

Acitretin metabolism primarily involves isomerization instead of oxidation. The major metabolite of acitretin is its 13-*cis*-isomer, which is inactive. Paradoxically, acitretin activates all three RAR subtypes but binds poorly to them.[13]

BEXAROTENE

Bexarotene is approximately 100-fold more potent in activating retinoid X receptors than RARs. Its absorption is particularly increased by taking it with fatty meals. In plasma, bexarotene is highly bound (more than 99%) to proteins that have not yet been characterized, and the ability of bexarotene to displace drugs bound to plasma proteins and the ability of drugs to displace bexarotene is unknown. Bexarotene probably has a clearance profile similar to that of isotretinoin with a terminal half-life of between 7 and 9 hours.[14] Bexarotene is metabolized by CYP 3A4 and generates its own inactive oxidative metabolites via hepatic CYP 3A4 induction. Neither bexarotene nor its metabolites are excreted in urine; elimination is thought to occur primarily via the hepatobiliary system.[15]

INDICATIONS

ACNE

Isotretinoin is remarkably effective in curing acne, possibly because it affects—primarily or secondarily—all etiologic factors implicated in the pathogenesis of acne: sebum production, comedogenesis, and colonization with *Propionibacterium acnes*.[16] Of all the natural and synthetic retinoids used in humans, only isotretinoin suppresses sebum excretion and reduces sebaceous gland size.

In the early 1980s, isotretinoin treatment was restricted to patients with severe nodulocystic acne. With increasing experience, however, its use has been extended to patients with less severe disease who respond unsatisfactorily to conventional therapies such as long-term antibiotics because of the increased resistance of *P. acnes* to many antibiotics.[17,18]

PSORIASIS

The retinoid of first choice for oral treatment of psoriasis is acitretin. Acitretin appears to be as effective as etretinate and can be used in the same combination regimens.[19–23] The best results have been obtained in pustular psoriasis of the palmoplantar or generalized (von Zumbusch) type.[19,24,25] Rebound does not usually occur after treatment is stopped, and reintroduction of the drug when it does occur produces a beneficial response.[26] Although complete clearing of plaque-type psoriasis is achieved in only approximately 30% of treated patients, significant improvement is obtained in a further 50%.[5,27,28] The decrease in the psoriasis area and severity index is approximately 60%–70%, depending on the dosage.[5,8] Approximately 20% of patients may be considered to experience treatment failures. Combination of acitretin with other antipsoriatic agents may then be required (see Section "Dosing Regimens").

In a 20-week treatment study,[29] six of eleven patients (54%) with HIV infection who had psoriasis showed good-to-excellent responses to acitretin monotherapy (75 mg/day). Both skin and joint manifestations responded to acitretin therapy in most patients. The adverse effects were moderate and well tolerated, and measures of immune parameters did not indicate exacerbation of immunosuppression in most patients.

Isotretinoin has less effect on psoriasis than acitretin or etretinate, although some efficacy has been shown in combination with psoralen plus ultraviolet A light (PUVA) therapy.[12] Nevertheless, some dermatologists use isotretinoin to treat women with psoriasis who need systemic retinoids to avoid the long postacitretin contraception period required.

CHRONIC HAND ECZEMA

Alitretinoin was recently approved in several European countries and in Canada for treatment-resistant chronic hand eczema. Between 3 and 6 months of therapy is usually required to fully appreciate the effect.[30]

Acitretin and etretinate have been used for many years "off-lable" to treat hyperkeratotic (tylotic) hand and foot eczema.

CUTANEOUS T-CELL LYMPHOMA

In 1999, the FDA approved bexarotene as oral therapy for the treatment of CTCL that is refractory to at least

one systemic therapy. In early (IA-IIA) and advanced (IIB-IVB) stages of CTCL (see Chapter 145), oral bexarotene monotherapy produced approximately 60% and 50% response rates, respectively, at a dosage of 300 mg/m^2 or more per day within the first 2 months in most patients.[32,33]

Older studies showed that etretinate may induce clinical improvement in patients with CTCL (e.g., mycosis fungoides or Sézary syndrome) with no internal involvement; better results were obtained when etretinate was combined with PUVA treatment or interferon-α therapy. Use of the combination of acitretin or isotretinoin with oral vitamin D_3 (calcitriol) to obtain synergistic effects in the treatment of CTCL has been reported.[31]

CLINICAL USES NOT APPROVED BY THE US FOOD AND DRUG ADMINISTRATION

Multiple other skin disorders respond to retinoids, but for only a few of them is the effect established in controlled studies.[34] In many reports the choice of etretinate/acitretin rather than isotretinoin was based not on pharmacologic considerations but on availability of the product. Bexarotene and alitretinoin have not been tested extensively for indications other than CTCL and hand eczema, respectively.

ICHTHYOSIS. Among the different types of ichthyosis, the best results are obtained with acitretin for autosomal recessive congenital ichthyoses such as lamellar ichthyosis. Treatment of epidermolytic ichthyosis (bullous ichthyosiform erythroderma) may lead to an initial increase in bullae. Good results also have been achieved in treating recessive X-linked ichthyosis, ichthyosis vulgaris, and palmoplantar keratoderma; if they are of limited severity, these diseases often do not require retinoid therapy (see Chapters 49 and 50).

DARIER DISEASE. Moderate-to-severe forms of Darier disease (Darier-White disease) are good indications for retinoid therapy. Care should be taken to initiate therapy with a low dosage, such as 10 mg/day of acitretin, to prevent initial exacerbation of the disease; usually 20 mg/day is sufficient for significant improvement. Long-term treatment is usually needed to prevent relapse. Low-dose isotretinoin therapy has been used especially in women with Darier disease. Combination of retinoids with antibiotics may enhance the clinical effects, because skin lesions are frequently infected (see Chapter 51).

PITYRIASIS RUBRA PILARIS. Early treatment with retinoids appears to offer the best chance for clearing of pityriasis rubra pilaris. In extensive cases, concomitant use of methotrexate may be advantageous, but this combination carries an increased risk for toxicity. Etretinate is considered to be superior to isotretinoin in the treatment of adult-onset pityriasis rubra pilaris (see Chapter 24).[35]

ROSACEA. In severe forms or in treatment-resistant rosacea, isotretinoin therapy may be more effective for inflammatory lesions than for vascular lesions.[36] A low daily dose (10 mg) is often sufficient. The best indications are severe cases of rosacea associated with significant seborrhea (see Chapter 81).

HIDRADENITIS SUPPURATIVA. Isotretinoin has limited effect on hidradenitis suppurativa, but some investigators recommend this therapy during the weeks or months preceding surgical treatment. Prolonged therapy with acitretin/etretinate has been used with some success, especially in treating extensive, inflammatory lesions unsuitable for surgery (see Chapter 85).[37,38]

PREMALIGNANT AND MALIGNANT SKIN LESIONS. Etretinate and acitretin are effective in the treatment of premalignant skin lesions, including human papillomavirus-induced tumors and actinic keratoses. In basal cell nevus syndrome and in xeroderma pigmentosum, these drugs reduce dramatically the incidence of malignant degeneration of the skin lesions. A double-blind study demonstrated that acitretin at a dosage of 30 mg/day for 6 months prevented the development of premalignant and malignant skin lesions in renal transplant recipients (see Chapters 113, 114, 115 and 116.)[39]

LICHEN SCLEROSUS. Acitretin/etretinate is an effective treatment for severe lichen sclerosus et atrophicus of the vulva and may be recommended intermittently for patients who are intolerant of or resistant to local therapies (see Chapter 65).[40]

LUPUS ERYTHEMATOSUS. Both isotretinoin and acitretin have been used successfully in patients with various forms of lupus erythematosus. However, the lesions recur after completion of treatment as quickly as the initial improvement appeared. Acitretin and hydroxychloroquine are equally effective in the treatment of chronic discoid lupus erythematosus and subacute cutaneous lupus erythematosus (see Chapter 155).[12]

DOSING REGIMENS

(Table 228-1)

ISOTRETINOIN

The initial consensus was that optimal benefit in acne would be achieved with a high daily dose of isotretinoin, approximately 1 mg/kg of body weight per day.[16] This high dose induces undesirable side effects, however, and similar short-term therapeutic results are obtained with a dose below 0.5 mg/kg provided the treatment is maintained over a longer period of time.[41] Empirical data from several centers indicate that post-therapy relapse is minimized by administering a cumulative dose of at least 120 mg/kg,[42] and no

TABLE 228-1
Dosing Regimens (mg/kg/day) of Retinoids in Major Indications

Drug	Indication	Initially	Sustained	Length of Therapy (months)
Isotretinoin	Acne	0.3–0.5	0.5–1.0	4–6
Acitretin	Psoriasis DOK[a]	0.2–0.5 0.3–0.6	0.3–0.8 0.5–1.0	>3 >3
Alitretinoin	hand eczema	10–30[b]	210–30[b]	>6
Bexarotene	CTCL	4–8	2–4 (8)	>2

[a]Lower dosing is recommended for Darier-White disease.
[b]Daily dose in milligrams.

further therapeutic gain is seen beyond approximately 150 mg/kg.[18] This implies 6–8 months of therapy. A lag period of 1–3 months may occur before the onset of the therapeutic effect. A flare-up of disease during the first few weeks of treatment and the evolution of acne cysts into lesions resembling pyogenic granuloma may be observed (see Chapter 80).

Continued healing of acne after the discontinuation of therapy regularly occurs. Approximately one-third of patients with acne require a second course of therapy for either persistent disease or relapse. The only factors predictive of resistance to isotretinoin treatment are the presence of closed comedonal acne and microcystic acne.[43]

ALITRETINOIN

The recommended dose in chronic hand eczema is 10–30 mg/day. Treatment periods of up to 6 months are often needed before a full evaluation of the therapeutic effects can be made (see Chapter 16 and 48).

ACITRETIN AND ETRETINATE

The maintenance dosage in most acitretin-responsive diseases, except Darier-White disease and epidermolytic ichthyosis, is 0.5–1 mg/kg (30–70 mg/day); the treatment is usually continued for at least 3 months. In psoriasis, a therapeutic dosage scheme with an initially low dose (10–25 mg/day) of acitretin (etretinate usually requires 20%–30% higher dosing, partially because of a higher molecular weight), followed by progressively increasing doses, seems to avoid the increase in the extent of the psoriatic lesions that may occur within a few days of the start of treatment at dosages of 0.5–1.0 mg/kg/day.[10]

Although the efficacy of a dosage of 10 mg/day was not significantly different from that of the placebo in one psoriasis study,[10] individual patients may respond to dosages as low as 5 mg/day. Possibly these patients have a reduced pharmacokinetics or increased pharmacodynamics of acitretin as compared to other patients.

Total clearing of the lesions often requires a combination of treatments, such as retinoids plus topical glucocorticoids, topical vitamin D derivatives, dithranol (anthralin), ultraviolet B irradiation, or photochemotherapy (PUVA treatment) (see Chapter 238).[44–48]

BEXAROTENE

The recommended initial dosage of bexarotene is 300 mg/m^2/day, administered as a single oral dose with meals. Based on the severity of adverse effects, the dosage may be adjusted down to 100 or 200 mg/m^2/day, or administration may be suspended temporarily. If CTCL does not respond after 8 weeks of therapy, the dosage may be increased to 400 mg/m^2/day with careful monitoring (see Chapter 145).[32,33]

INITIATION AND MONITORING OF THERAPY

ISOTRETINOIN

Women with childbearing potential must have a negative result on a pregnancy test and must practice effective contraception during treatment and for 1 month (2 months in some countries) after the completion of therapy.[49] The iPLEDGE program (http://www.ipledgeprogram.com) has been put into effect by the FDA and the manufacturer to minimize the risk of isotretinoin teratogenicity. Similar but less strict programs exist in Europe and elsewhere.

ALITRETINOIN

In addition to the usual precautions during systemic retinoid therapy, patients should be asked about headaches and also be screened for thyroid hormone levels.

ACITRETIN AND ETRETINATE

Ensuring that the patient avoids pregnancy during therapy is as imperative when prescribing acitretin and etretinate as when prescribing isotretinoin. However, because of the frequent prospect of long-term

treatment of more chronic diseases (e.g., psoriasis and ichthyosis) and the slow elimination of aromatic retinoids from the body after interruption of therapy, acitretin (or etretinate) therapy is usually not recommended for female patients with childbearing potential.

Additional precautions before initiating acitretin therapy include measurement of baseline serum lipid and liver enzyme levels, and exclusion by history of skeletal abnormalities. It is also important to inform the patient beforehand about the possibility of increased hair shedding and other mucocutaneous side effects that will appear during therapy.

Monitoring of serum lipid and liver enzyme levels for the first 2 months and then at 3-month intervals is adequate in patients with normal baseline levels and absence of risk factors (obesity, high alcohol intake, diabetes).

BEXAROTENE

The recommendations given for the other retinoids should also be followed for bexarotene, and, in addition, patients who will receive bexarotene should be screened for thyroid disease. Thyroid hormone and lipid levels in blood should be monitored frequently during therapy.

RISKS AND PRECAUTIONS

(Table 228-2)

Teratogenesis is the most serious adverse effect of oral retinoids. The side effects of systemic retinoids qualitatively resemble hypervitaminosis A syndrome, although important differences exist. The acute retinoid toxicities include mucocutaneous lesions (most patients) and abnormal laboratory test results (less common but may be substantial), whereas the chronic retinoid toxicities involve bony changes (rare).

TERATOGENIC EFFECTS

Retinoid-induced birth defects include auditory, cardiovascular, craniofacial, ocular, axial and acral skeletal, central nervous system (hydrocephalus, microcephaly), and thymus gland abnormalities.[50] The putative mechanism is toxic effects on neural crest cells, particularly with exposure during the fourth week of gestation.[51]

In men, retinoid therapy does not appear to produce abnormalities in spermatogenesis, sperm morphology, or sperm motility.[52] However, it is usually recommended that men who are actively trying to father children avoid systemic retinoid therapy.

SKIN AND MUCOUS MEMBRANE ADVERSE EFFECTS

Most patients receiving retinoids develop dryness of the lips, skin, and mucous membranes. These dose-related effects reflect mainly decreased sebum production, reduced stratum corneum thickness, and altered skin barrier function. Cheilitis is the earliest and the most frequent sign, followed by blepharoconjunctivitis, dry eyes, dry nose, and dry mouth. Xerosis of the skin, associated with pruritus and peeling, especially of the palms and soles, occurs frequently. Skin fragility and fissuring of fingertips sometimes create a problem, especially for those who work with their hands. Photosensitivity is observed especially with isotretinoin and probably reflects the reduction of thickness of the stratum corneum. Bexarotene appears to induce fewer mucocutaneous and ocular side effects than other classes of retinoids; localized or extensive exfoliative dermatitis is the most common cutaneous side effect with bexarotene.[14] *Staphylococcus aureus* colonization tends to correlate with isotretinoin-induced reduction in sebum production and may lead to overt cutaneous infections.[53] Various ill-defined skin eruptions, called

TABLE 228-2
Adverse Effects of Systemic Retinoids: A Summary

	isotretinoin	Alitretinoin	Acitretin	Bexarotene
Teratogenicity	+	+	+	+
Mucocutaneous	+	+	+	+
Ocular	++	+	+	+
Alopecia	(+)	+	+	+
Headache	+	++	+	+
Musculoskeletal	++	+	+	+
Hepatotoxicity	(+)	(+)	+	+
Neutropenia	–	–	–	+
Hyperlipidemia	++	+	+	++
Hypothyreodism	–	+	–	+

retinoid dermatitis, are observed frequently. The erythema is sometimes difficult to differentiate from an underlying psoriasis or atopic dermatitis.

OCULAR ADVERSE EFFECTS

Blepharoconjunctivitis occurs with varying severity in about one-third of patients treated with isotretinoin and may prevent the use of contact lenses. Bacterial conjunctivitis occurs to a lesser extent than *S. aureus* colonization.[54] If artificial tears and topical ophthalmologic antibiotic therapy fail to alleviate the conjunctivitis, ophthalmologic consultation should be sought. Alterations in visual function, mainly poor night vision, excessive glare sensitivity, and changes in color perception, also have been reported.[55]

HAIR FOLLICLE AND OTHER APPENDEAL COMPLICATIONS

Diffuse or localized hair loss (telogen effluvium), which is more severe during treatment with acitretin than with isotretinoin, is a common complaint, although objective alopecia tends to occur only at higher dosage levels and after several months of therapy. Nail thinning and paronychia-like changes with periungual granulation tissue may occur.

MUSCULOSKELETAL ADVERSE EFFECTS

Skeletal toxicity was first observed in retinoid-treated patients maintained on a high dosage and after an extended period of continuous treatment for disorders of keratinization. Bone pain without objective evidence of any abnormalities and without sequelae is frequent in retinoid-treated patients. Several reports with conflicting results have implicated synthetic retinoids in the formation of diffuse idiopathic skeletal hyperostosis (DISH) syndrome-like bone changes and calcification of tendons and ligaments.[56–58] Prospective studies have shown that the hyperostotic effects of retinoids are mostly asymptomatic and likely involve worsening of pre-existing skeletal overgrowth rather than de novo changes.[59,60] Osteoporosis has been observed with hypervitaminosis A and after long-term therapy with etretinate and to a lesser extent isotretinoin.[61,62] In children, only a few cases of skeletal abnormalities and premature epiphyseal closure[63–65] have been reported. No baseline radiographs are required, although monitoring patients at high risk who receive prolonged high-dose retinoid treatment may be useful.

Muscle pain and cramps rarely occur in patients taking etretinate or acitretin; however, these muscle effects are not infrequent with isotretinoin, particularly in individuals involved in vigorous physical activity (sometimes accompanied by elevations in creatine phosphokinase levels). Increased muscle tone and axial muscle rigidity and myopathy were reported to be related to etretinate and acitretin therapy.[66]

CENTRAL NERVOUS SYSTEM AND OTHER NEUROLOGIC ADVERSE EFFECTS

Central nervous system side effects are rare. Although individual signs of increased intracranial pressure such as headache, nausea, and vomiting are observed occasionally, the complete syndrome with papilledema (pseudotumor cerebri) and impaired vision is exceptional.[67] Concomitant use by isotretinoin-treated patients of tetracyclines, which rarely produce increased intracranial hypertension, is the major risk factor for development of pseudotumor cerebri.

Anecdotal reports suggest a causal association between isotretinoin therapy and severe depression with suicide attempts.[68] However, large-scale epidemiologic studies provide no evidence that isotretinoin exposure is associated with any greater risk of psychiatric disorders than is antibiotic use in patients with acne.[69]

PANCREATITIS

One case of fatal fulminant pancreatitis with acitretin treatment has been reported.[70] Pancreatitis occurred in three patients treated with oral bexarotene, 300 mg/m^2 or more per day, in association with marked elevations of fasting serum triglyceride levels.[32]

HYPOTHYROIDISM

Clinical and biochemical central hypothyroidism occurred in 40% of patients in the trials of bexarotene therapy for CTCL. It was rapidly and completely reversible with cessation of therapy without any clinical sequelae.[32,71] The same adverse effect has been noted with alitretinoin, which is not unexpected since both drugs bind to RXR that dimerizes with the nuclear thyroid receptor.

RENAL ADVERSE EFFECTS

Renal toxicity has not been a characteristic consequence of retinoid administration. Isotretinoin has been administered safely to patients with end-stage kidney disease who were undergoing hemodialysis. However, case reports describing reversible renal function impairment during etretinate therapy advise monitoring of renal function, particularly in patients with a history of renal disorders.[72]

INFLAMMATORY BOWEL DISEASE

In very rare cases, isotretinoin has been linked to exacerbation of inflammatory bowel disease. A 5-year prospective study did not demonstrate an increased risk of inflammatory bowel disease or of cancer, diabetes, or cardiovascular disease in association with long-term etretinate use for psoriasis[70]; similar safety of

long-term acitretin, bexarotene or alitretinoin therapy has not been established.

HYPERLIPIDEMIA

Serum lipid changes are the most frequent abnormalities in laboratory test results seen with retinoid therapy. Depending on the type and dosage of retinoid, triglyceride levels are elevated in 50%–80% and cholesterol levels in 30%–50% of treated patients.[32,56,73] Disturbance of blood lipid levels is generally higher with isotretinoin and bexarotene than with acitretin. In cases of severe retinoid-induced hypertriglyceridemia, eruptive xanthomas and acute pancreatitis may occur. Discontinuation of therapy is required if the triglyceride level reaches 800 mg/dL. A less severe increase may be treated by dosage reduction or reduction in alcohol and tobacco consumption. In some instances, use of lipid-lowering agents may be indicated.[74] Coadministration of atorvastatin with bexarotene is recommended.[14] Retinoids probably cause hyperlipidemia by increasing the expression of apolipoprotein-C3, which prevents the uptake of lipids from very-low-density lipoproteins into cells.[75]

LIVER TOXICITY

Transitory abnormal elevations in serum transaminase levels have been reported in approximately 20% of patients treated with etretinate or acitretin and occur much less frequently with other retinoids. Changes in liver function test results usually occur between 2 and 8 weeks after therapy is begun. Transaminase elevations of more than three times the upper normal range should lead to discontinuation of retinoid therapy. Severe or persistent hepatotoxic reactions occur in fewer than 1% of patients. No cross-reaction with nonaromatic retinoids has been observed. Acitretin therapy elicited no biopsy-proven hepatotoxicity in a 2-year prospective study.[76] No specific studies have evaluated the use of retinoids in patients with hepatic insufficiency, although this is likely to interfere with drug elimination.

HEMATOLOGIC TOXICITY

A high incidence (28%) of dose-related neutropenia has been reported with the use of bexarotene therapy for CTCL, occurring as early as 2–4 weeks after initiation of treatment.[32] Hematologic abnormalities are much less common with other retinoids. Bleeding complications due to isotretinoin-induced fibrinolysis has been reported.[77]

COMPLICATIONS

Most adverse effects associated with retinoids are preventable and manageable with proper patient selection, dosage adjustments, discontinuation of treatment, and routine monitoring for potential toxicity. Absolute contraindications are pregnancy or an attempt to become pregnant, nonadherence to a contraceptive regimen, and breastfeeding. Relative contraindications are leukopenia, alcoholism, elevated cholesterol, or triglyceride levels, significant hepatic or renal dysfunction, and hypothyroidism (bexarotene and alitretinoin).

The concurrent use of retinoids with other therapies having similar side effects may increase the risk of these adverse events. Tetracyclines (increased intracranial pressure, phototoxicity), alcohol (increased conversion of acitretin to etretinate, hepatoxicity), methotrexate (hepatoxicity), and vitamin A supplements (hypervitaminosis A) should be avoided. The concomitant administration of bexarotene and gemfibrozil may result in increased plasma concentrations of bexarotene, at least partially related to CYP 3A4 inhibition by gemfibrozil. In addition, retinoid drug levels may increase with the use of CYP inhibitors such as azoles and macrolides and the CYP competitor cyclosporine, whereas antituberculosis drugs (rifampicin) and anticonvulsants (phenytoin and carbamazepine) actually decrease the drug levels via CYP 3A4 induction.

Chapter 229 :: Antihistamines

:: Robert A. Wood

ANTIHISTAMINES AT A GLANCE

- H_1 are first-line therapy for chronic idiopathic and physical urticarias.
- H_1 may be useful in treating other conditions with histamine-driven pruritus.
- Limited evidence supports the use of H_1 in treatment of atopic dermatitis.
- Certain special patient populations, including children, the elderly, and patients with renal or hepatic impairment, may require dosage adjustments when using H_1 antihistamines.
- The use of H_1 is contraindicated in patients who have narrow angle glaucoma or who are also taking monoamine oxidase inhibitors.
- H_2 antihistamines may be a useful adjunct to H_1 antihistamine therapy in refractory cases of chronic idiopathic urticaria/angioedema and pruritus.

Histamine is a low-molecular-weight amine derived from L-histidine that is produced throughout the body. By means of four known types of receptors, histamine affects cellular growth and proliferation, modulates inflammation, and acts as a neurotransmitter. Both H_1 and H_2 histamine receptors are widely expressed. H_1 receptors are found on neurons, smooth muscle, epithelium and endothelium, and multiple other cell types. H_2 receptors are located in the gastric mucosa parietal cells, smooth muscle, epithelium and endothelium, heart, and other cell types as well. H_3 and H_4 receptors have more limited expression. H_3 receptors are found primarily on histaminergic neurons, whereas H_4 receptors are highly expressed in bone marrow and on peripheral hematopoietic cells.

H_1 ANTIHISTAMINES

MECHANISM OF ACTION

H_1 antihistamines are inverse agonists that reversibly bind and stabilize the inactive form of the H_1 receptor, thereby favoring the inactive state[1] (Box 229-1). The backbone structure of H_1 antihistamines is depicted in Fig. 229-1. By means of the H_1 receptor, H_1 antihistamines decrease production of proinflammatory cytokines, expression of cell adhesion molecules, and chemotaxis of eosinophils and other cells (Fig. 229-2).[2] H_1 antihistamines may also decrease mediator release from mast cells and basophils through inhibition of calcium ion channels. In addition to having antihistamine actions, first-generation H_1 antihistamines can also act on muscarinic, α-adrenergic, and serotonin receptors and cardiac ion channels. Some of the more serious adverse effects associated with first-generation H_1 antihistamines, such as urinary retention, hypotension, and cardiac arrhythmias, are mediated through these other receptors. The first-generation antihistamines are divided into six groups on the basis of chemical structure: (1) ethylenediamines, (2) ethanolamines, (3) alkylamines, (4) phenothiazines, (5) piperazines, and (6) piperidines[3] (see Fig. 229-1). The presence of multiple aromatic or heterocyclic rings and alkyl substituents enhances the lipophilicity of these compounds, which allows penetration of the blood-brain barrier.

Many of the low-sedating or second-generation H_1 antihistamines are chemically derived from first-generation agents.[2] For example, cetirizine is a metabolite of hydroxyzine. The second-generation H_1 antihistamines bind noncompetitively to the H_1 receptor. They are not easily displaced by histamine, dissociate slowly, and have a longer duration of action than first-generation H_1 antihistamines.[3] Due to the selectivity of second-generation drugs for the H_1 receptor and their reduced lipophilicity, these drugs are far less likely to

BOX 229-1 BASIC PHARMACOLOGY OF ANTIHISTAMINES

- Both H_1 and H_2 are inverse agonists that reversibly bind and stabilize the inactive form of the histamine receptor, thereby favoring the inactive state.
- First-generation H_1 are relatively lipophilic, which enhances penetration of the blood-brain barrier and leads to sedation.
- Second-generation, nonsedating H_1 bind selectively to peripheral H_1 receptors and have fewer central nervous system effects.
- H_1 may interact with other drugs metabolized by the hepatic cytochrome P_{450} system.
- Double-blind, placebo-controlled trials show no evidence of the development of tolerance or tachyphylaxis in the suppression of skin test reactivity by H_1.
- Suppression of skin test reactivity may be observed for up to 7 days after discontinuation of a regularly used sedating H_1 antihistamine.

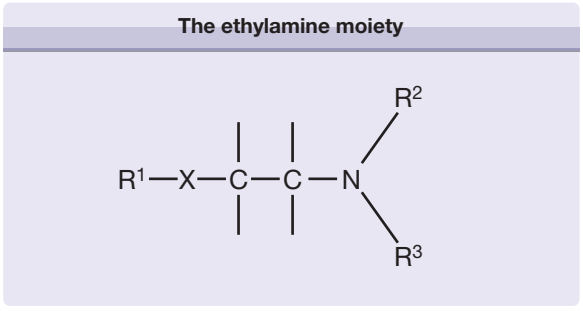

Figure 229-1 The ethylamine moiety is the backbone structure of most of the first-generation H_1 antihistamines. R = aromatic and/or heterocyclic groups; X = linkage such as nitrogen, oxygen, or carbon.

cause sedation and have different safety profiles than the first-generation drugs.

Some low-sedating H_1-type antihistamines affect the trafficking of cells in the skin and other tissues, presumably by modulating the release of inflammatory mediators and the expression of adhesion molecules. In a skin chamber challenge model, cetirizine administration reduced eosinophil influx after allergen challenge. This effect seems to be specific to cutaneous allergic responses, because similar studies involving nasal challenges have not shown any decrease in eosinophil accumulation in nasal secretions. In vitro, cetirizine inhibits eosinophil, monocyte, and T-lymphocyte chemotaxis to *N*-formyl-methionyl-leucyl-phenylalanine and platelet-activating factor.[4] H_1 antihistamines may also modulate the expression of cellular adhesion molecules such as antigen-induced intercellular adhesion molecule 1 on keratinocytes, Langerhans cells, and endothelium, and influence the release of inflammatory mediators from leukocytes.[5] Desloratadine and emedastine were found to inhibit platelet-activating factor-induced eosinophil chemotaxis, tumor necrosis factor-α-induced eosinophil adhesion, and spontaneous and phorbol myristate-induced superoxide generation.[6,7]

PHARMACOKINETICS

SEDATING, FIRST-GENERATION H_1 ANTIHISTAMINES. After oral administration, effects of sedating H_1 antihistamine can be observed within 30 minutes to 1 hour and generally persist for 4–6 hours, although the effects of some agents may last for 24 hours and longer.[8] For example, after oral administration of a single dose, the serum half-lives of brompheniramine, chlorpheniramine, and hydroxyzine exceed 20 hours in adults. H_1 antihistamines are metabolized by hepatic cytochrome P_{450} (CYP) enzyme 3A4, forming glucuronides before excretion in urine.

The potency and relative concentration in the skin of H_1 antihistamines can be compared by their inhibition of the cutaneous wheal-and-erythema response to histamine injected cutaneously. In placebo-controlled,

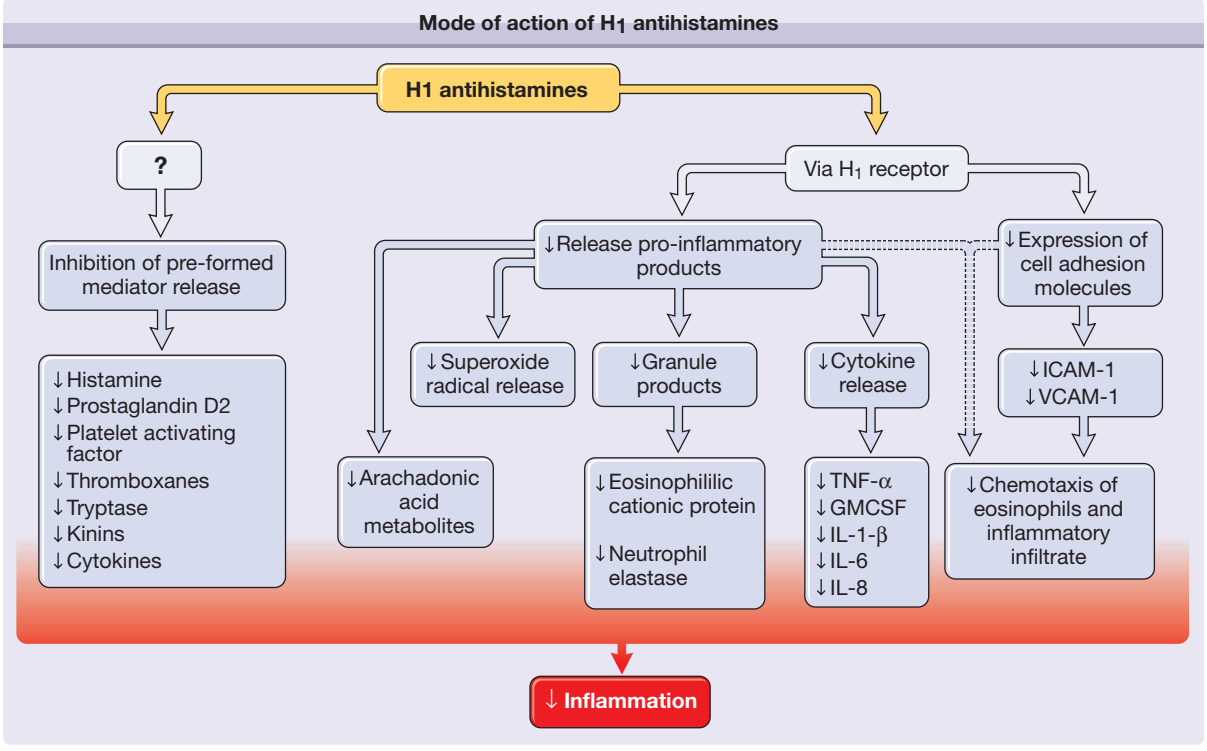

Figure 229-2 Mode of action of H_1 antihistamines. By means of the H_1 receptor, H_1 antihistamines inhibit the release of preformed mediators and decrease the production of proinflammatory cytokines, the expression of cell adhesion molecules, and chemotaxis of eosinophils and other cells. ↓ = decreased; GMCSF = granulocyte-macrophage colony-stimulating factor; ICAM-1 = intercellular adhesion molecule 1; IL-1β, IL-6, IL-8 = interleukin-1β, interleukin 6, interleukin 8; TNF-α = tumor necrosis factor-α; VCAM-1 = vascular cellular adhesion molecule 1.

double-blind studies, no evidence of tolerance or tachyphylaxis was demonstrated in suppression of skin test reactivity over a 3-month period.[2] Suppression of skin test reactivity may be observed for up to 7 days after discontinuation of a regularly used sedating H_1 antihistamine.

Oral sedating H_1-type antihistamines are typically administered in divided doses at intervals of 4–8 hours (see Section "Dosing Regimens"), although once-daily dosing may suffice for agents with longer serum half-lives. Topical formulations for dermatologic use are available, although these preparations tend to be less effective and are associated with the development of delayed contact reactions.

LOW-SEDATING, SECOND-GENERATION H_1 A ANTIHISTAMINES. Most low-sedating, or second-generation, H_1 antihistamines are administered once or twice daily and achieve peak plasma concentrations within two half-lives, although this interval can vary among different drugs and individuals. These drugs generally achieve higher concentrations in the skin than their first-generation counterparts, and a single dose can suppress the wheal and erythema reaction from 1–24 hours.[9–12] Regular use prolongs this effect; for example, 6 days of daily cetirizine use results in 7 days of suppression of the wheal and erythema response.

Terfenadine, astemizole, loratadine, acrivastine, mizolastine, ebastine, and oxatomide are metabolized in the liver via the hepatic enzyme CYP 3A4. Cetirizine, fexofenadine, levocabastine, desloratadine, and levocetirizine undergo minimal hepatic metabolism, which reduces the likelihood of interactions with other drugs.[8]

In healthy adults, cetirizine and levocetirizine reach peak concentrations around 1 hour after administration, with an elimination half-life of approximately 8 hours.[13] Lower dosages are used in patients with impaired renal or hepatic function. Fexofenadine generally reaches peak concentration at 2–3 hours, with an elimination half-life of 14 hours.[13] Dosage adjustment is recommended for patients with decreased creatinine clearance, including the elderly; however, patients with hepatic disease do not require dosage adjustment because fexofenadine undergoes almost no hepatic metabolism.[13] Loratadine's half-life ranges on average from 8–24 hours, depending on hepatic function. Ebastine, which is metabolized to form its carboxylic acid metabolite, carebastine, has a half-life of 15 hours.[13] The dosage should be adjusted in patients with impaired renal function. Pharmacogenetics may also influence drug metabolism and clearance. In a series of pharmacokinetic studies, approximately 7% of all subjects and 20% of African-Americans were slow metabolizers of desloratadine.[14] Comparable differences may exist for other H_1 antihistamines.

INDICATIONS

(Box 229-2)

H_1 antihistamines are used to treat pruritus of various etiologies, urticaria, and angioedema (Box 229-2). In particular, H_1 antihistamines appear to be effective in treating physical urticarias and dermatographism, in addition to chronic idiopathic urticaria. They are not as effective in treating hereditary and acquired angioedema syndromes and urticarial vasculitis. Few well-controlled, blinded studies of the first-generation H_1-type drugs exist. The general tendency for most chronic urticarias to improve with time and the difficulty in making quantitative assessment of the condition further complicate clinical studies. Comparative studies of the groups of H_1-type antihistamines have shown them to be of equal efficacy.[2] If an agent from one therapeutic group of H_1-type antihistamines proves ineffective, then a trial with an agent from another group may be initiated. In several double-blind, placebo-controlled, or parallel studies, the low sedating H_1-type antihistamines terfenadine, astemizole, cetirizine, loratadine, fexofenadine, desloratadine, acrivastine, mizolastine, azelastine, ebastine, and oxatomide were superior to placebo in the treatment of urticaria and angioedema.[15–20] Trials comparing different second-generation antihistamines with one another have not shown any one agent to be consistently superior, although cetirizine and levocetirizine have overall fared best in comparative trials.[2,15,21–24]

Both sedating and low-sedating H_1 antihistamines are used to treat pruritus in patients with atopic dermatitis, although their efficacy has not been proved by rigorous clinical trials. In the 18-month Early Treatment of the Atopic Child study, cetirizine afforded a steroid-sparing benefit to children with the most severe atopic dermatitis, but no consistent benefit was observed in children with more moderate disease.[25] A meta-analysis of 16 studies conducted from 1966 through 1999 does not indicate a major role for either first- or second-generation H_1 antihistamines in the treatment of atopic dermatitis, although no randomized, double-blind, placebo-controlled studies are included in this analysis.[26]

H_1 antihistamines are commonly used to treat cutaneous and systemic mastocytosis, although large comparative treatment trials are not available.[27] One early double-blind, placebo-controlled study demonstrated the efficacy of H_1 and H_2 antihistamines in the treatment of systemic mastocytosis.[28] In a later small trial, azelastine compared favorably with chlorpheniramine in the suppression of pruritus in patients with mastocytosis.[29]

Pruritus associated with other conditions, such as allergic contact dermatitis and other forms of eczematous dermatitis, lichen planus, systemic mastocytosis, mosquito bites, infestations, and pruritus secondary to

BOX 229-2 INDICATIONS FOR TREATMENT WITH H_1 ANTIHISTAMINES

- Acute urticaria
- Chronic idiopathic urticaria
- Physical urticarias and dermatographism
- Atopic dermatitis (less evidence)
- Systemic mastocytosis
- Pruritus associated with other conditions

underlying medical disorders or idiopathic pruritus, also may be relieved by H_1 antihistamines, although controlled trials do not exist.[30] In these conditions, the sedative effects of the first-generation agents may be advantageous, permitting more restful sleep. H_1 antihistamines are also used as pretreatment before certain procedures for patients with a history of radiocontrast media and transfusion reactions.

DOSING REGIMENS

The dosing regimens for H_1 antihistamines are shown in Table 229-1. Doses of second generation antihistamines as high as four times the recommended dosage have been advocated in international guidelines on chronic urticaria[31,32] However, the limited number of published studies evaluating this approach have not demonstrated a clear increase in efficacy.[33]

INITIATION OF THERAPY

The H_1 antihistamines are considered first-line therapy in the treatment of chronic idiopathic and physical urticarias and may be useful in treating other conditions in which histamine-driven pruritus is a major feature. The lowest effective dosage is preferred to minimize dose-related side effects, such as sedation. After several days of therapy, the dosage may be increased and titrated. Occasionally, gradual escalation of dosing permits the development of tolerance to sedation,

TABLE 229-1
Dosing Regimens for H_1 Antihistamines[2,3,8,13,14,28]

Drug	Formulation	Dosage	Conditions Requiring Dosage Adjustment
First-generation H_1			
Chlorpheniramine	2-, 4-, 8-, 12-mg tablet 2 mg/5 mL syrup	Adult: 4 mg tid, qid; 8–12 mg bid Age 6–11 years: 2 mg q4–6h	Hepatic impairment
Cyproheptadine	4-mg tablet 2 mg/5 mL syrup	Adult: 4 mg tid, qid Age 7–14 years: 4 mg bid, tid	Hepatic impairment
Diphenhydramine	25-, 50-mg tablet 12.5 mg/5 mL syrup 50 mg/15 mL syrup 6.25 mg/5 mL syrup 12.5 mg/5 mL syrup	Adult: 25–50 mg q4–6h Age 6–12 years: 12.5–25 mg q4–6h Age <6 years: 6.25–12.5 mg q4–6h	Hepatic impairment
Hydroxyzine	10-, 25-, 50-, 100-mg tablet 10 mg/5 mL syrup	Age ≥6 years: 25–50 mg q6–8h or qhs Age <6 years: 25–50 mg qd	Hepatic impairment
Tripelennamine	25-, 50-, 100-mg tablets	Adult: 25–50 mg q4–6h	Hepatic impairment
Second-generation H_1 antihistamines			
Acrivastine[a]	8-mg tablet	Adult: 8 mg tid	Renal impairment
Azelastine	2-mg tablet[b] 0.1% nasal spray	Adult: 2–4 mg bid Age 6–12 years: 1–2 mg bid 2 sprays/nostril bid	Renal and hepatic impairment
Cetirizine	5-, 10-mg tablet 5 mg/mL syrup	Age ≥6 years: 5–10 mg qd Age 2–6 years: 5 mg qd Age 6 months–2 years: 2.5 mg qd	Renal and hepatic impairment
Desloratadine	2.5-, 5-mg tablet 5 mg/mL syrup	Age ≥12 years: 5 mg qd Age 6–12 years: 2.5 mg qd Age 1–6 years: 1.25 mg qd Age 6–12 months: 1 mg qd	Renal and hepatic impairment
Ebastine[b]	10-mg tablet	Age ≥6 years: 10–20 mg qd Age 6–12 years: 5 mg qd Age 2–5 years: 2.5 mg qd	Renal impairment
Fexofenadine	30-, 60-, 120-, 180-mg tablet	Age ≥12 years: 60 mg qd, bid; 120–180 mg qd Age 6–12 years: 30 mg qd, bid	Renal impairment
Levocetirizine	5-mg tablet	Age ≥6 years: 5 mg qd	Renal and hepatic impairment
Loratadine	10-mg tablet 5 mg/mL suspension	Age ≥6 years: 10 mg qd Age 2–9 years: 5 mg qd	Renal and hepatic impairment
Mizolastine[b]	10-mg tablet	Adult: 10 mg qd	Hepatic impairment

[a]Available in the United States only as a fixed-dose combination with pseudoephedrine hydrochloride, 120 mg.
[b]Not currently available in the United States.

BOX 229-3 FACTORS FOR RISK-BENEFIT ASSESSMENT OF H_1 ANTIHISTAMINE THERAPY

- Risks
  - History of cardiac arrhythmias, particularly ventricular arrhythmias
  - First trimester of pregnancy
  - Prostatic hypertrophy
- Contraindications
  - Narrow-angle glaucoma
  - Concomitant use of monoamine oxidase inhibitors

BOX 229-4 ADVERSE EFFECTS OF H_1 ANTIHISTAMINES

- Sedation (primarily first-generation agents)
- Other central nervous system disturbances
  - Dizziness
  - Tinnitus
  - Blurred vision
  - Irritability or nervousness
  - Insomnia
  - Tremor
- Gastrointestinal complaints
  - Nausea and vomiting
  - Diarrhea or constipation
  - Anorexia
- Anticholinergic effects
  - Dry mucous membranes
  - Urinary retention
  - Postural hypotension
- Cardiac arrhythmias (particularly prolongation of the QT interval, ventricular arrhythmias, torsades de pointes)
- Hypersensitivity reactions (rare)

which allows higher dosages to be used to treat certain conditions, such as refractory chronic urticaria. Ingestion of the medication with food may alleviate any gastrointestinal discomfort, although patients should be advised to avoid taking fexofenadine with antacids, which can interfere with drug absorption. Individuals with comorbid conditions, such as renal or hepatic disease, may require lower dosages due to impaired metabolism of these drugs. Certain special patient populations, including children, the elderly, and pregnant or breastfeeding women, may also need dosage adjustments (see Section "Special Patient Populations"). Some situations may call for more careful assessment of H_1 antihistamine therapy[2] (Box 229-3).

MONITORING OF THERAPY

Therapeutic endpoints are evaluated by observation of clinical signs and symptoms (e.g., severity of pruritus; wheal number, size, and frequency). As for drug toxicity, no particular monitoring beyond the usual surveillance for adverse effects is required in most cases. Certain individuals, such as patients with impaired metabolism or other comorbid conditions and those taking other medications, may require closer monitoring and counseling regarding the use of H_1 antihistamines. Because of reports of hepatotoxicity, some sources recommend periodic liver transaminase evaluation when cyproheptadine is used.[34]

RISKS AND PRECAUTIONS

Adverse effects are listed in Box 229-4. Sedation is the most commonly reported problem, primarily with first-generation H_1 antihistamines.[2,3,8] The sedative effect is more pronounced with the ethanolamine and phenothiazine groups and is less marked with the alkylamine group. The sedative effect may diminish after a few days of continual use of H_1-type antihistamines. If tolerance to sedation does not occur, an agent from another group should be tried. The use of H_1-type antihistamines has been associated with an increase in occupational injuries and automobile accidents.[35] Other central nervous system (CNS) effects include dizziness, tinnitus, disturbed coordination, inability to concentrate, blurred vision, and diplopia. Stimulatory CNS effects, which occur especially with the alkylamine group, include nervousness, irritability, insomnia, and tremor.

Gastrointestinal complaints, including anorexia, nausea, vomiting, epigastric distress, diarrhea, and constipation, are another frequent side effect, especially with the ethylenediamine group.[3] The administration of these agents with food may reduce these manifestations.

Anticholinergic effects include dry mucous membranes, urinary retention and hesitancy, postural hypotension, dizziness, erectile dysfunction, and constipation.[2] These effects are often associated with the ethanolamine, phenothiazine, and piperazine groups. The anticholinergic effects of H_1-type antihistamines preclude their use in patients with narrow-angle glaucoma and require close monitoring in patients with prostatic hypertrophy (see Box 229-3 and Box 229-4).

Arrhythmias, particularly prolongation of the QT interval and torsades de pointes, are the most serious cardiac toxicity.[2,3] These dose-dependent effects are mediated through blockade of potassium channels unrelated to the H_1 histamine receptor. Transient hypotension may develop after intravenous therapy, especially if the drug is administered rapidly.[36]

The occurrence of cutaneous reactions after the administration of oral H_1-type antihistamines is uncommon. Reported reactions include eczematous dermatitis, allergic contact dermatitis, urticaria, petechiae, fixed drug eruptions, and photosensitivity. Some of these reactions may be secondary to excipients in the drug.

Due to the selectivity of the low-sedating H_1 antihistamines for peripheral H_1 receptors, these drugs lack

both the sedative and anticholinergic side effects commonly associated with the first-generation drugs.[37] For the second-generation drugs, sedation is most often reported in a subset of patients taking cetirizine and acrivastine. Although far less sedating than its parent compound hydroxyzine, cetirizine causes sedation in approximately 10%–15% of users.[38] This effect appears to be dose dependent and can often be mitigated by dosing adjustment.[39] Fifteen percent to thirty-five percent of patients report somnolence secondary to acrivastine use.[40] In contrast, fexofenadine, loratadine, and desloratadine cause negligible sedation.[41]

Two early second-generation H_1 antihistamines, terfenadine and astemizole, have been removed from the US market due to risk of QT interval prolongation and torsade de pointes. Other second-generation agents have an approximately 1,000-fold lower affinity for cardiac ion channels, and ventricular arrhythmias have not been associated with later second-generation agents.[2] A theoretical risk remains, however, and may be a consideration before initiating therapy in patients susceptible to tachyarrhythmias.

DRUG INTERACTIONS

The H_1 antihistamines may interact with other drugs metabolized by the hepatic CYP system, such as imidazole antifungals, cimetidine, and macrolide antibiotics.[3] Diphenhydramine, chlorpheniramine, clemastine, promethazine, hydroxyzine, and tripelennamine inhibit the hepatic enzyme CYP 2D6 in vitro.[42] In vivo, diphenhydramine has been noted to increase levels of other drugs metabolized by the CYP 2D6 system, including metoprolol and venlafaxine.[43,44] H_1-type antihistamines are contraindicated for patients receiving monoamine oxidase inhibitors.

Central depressive effects may be accentuated when H_1-type antihistamines are combined with alcohol or other CNS depressants such as benzodiazepines. These interactions are generally not observed with second-generation H_1 antihistamines.[3]

In rare circumstances, antihistamines of the phenothiazine group may block and reverse the vasopressor effect of epinephrine. If individuals receiving a phenothiazine require a vasopressor agent, norepinephrine or phenylephrine should be used.

SPECIAL PATIENT POPULATIONS

CHILDREN. Many of the sedating and low-sedating H_1 antihistamines can be safely used in children with appropriate dosing. Children may be more susceptible to certain side effects associated with first-generation drugs, such as excitation and insomnia. Acute poisoning may develop but is rare; hallucinations, ataxia, incoordination, athetosis, and convulsions are the major features.

ELDERLY. Caution should be used when treating elderly patients, and decreased creatinine clearance, comorbid conditions, and potential drug interactions should be taken into account. Older individuals may also be more susceptible to anticholinergic effects, particularly urinary retention and hesitancy, constipation, and postural hypotension.[3]

PREGNANT WOMEN. There are limited guidelines for the use of H_1 antihistamines to treat pregnant women. Most H_1 antihistamines are classified as US Food and Drug Administration (FDA) pregnancy category B or category C. Based on earlier reports linking H_1 antihistamines to fetal malformations, particularly cleft palate defects, H_1 antihistamines are customarily avoided in the first trimester of pregnancy.[45] However, more recent studies, including a meta-analysis of 200,000 first-trimester exposures to first-generation antihistamines, do not indicate any increased risk of congenital malformations associated with H_1 antihistamine use.[46] In a prospective trial, astemizole administered to pregnant women was not associated with intrauterine growth retardation or perinatal complications.[47] The rate of birth malformations was identical to that in the control group and to that in the general population.

BREASTFEEDING WOMEN. No formal studies have been performed on the safety of H_1 antihistamines during breastfeeding. Theoretically, first-generation drugs may diminish milk supply via anticholinergic effects. Clemastine, diphenhydramine, promethazine, triprolidine, cetirizine, loratadine, fexofenadine, desloratadine, and levocetirizine are all known to be excreted in breast milk; their effects on the nursing infant are not known.[3]

H_2 ANTIHISTAMINES

MECHANISM OF ACTION

Similar to their H_1-binding counterparts, H_2 antihistamines are inverse agonists that bind H_2 receptors located throughout the body, including epithelial and endothelial cells. More recently, there is evidence that H_2 receptors are expressed on mast cells and dermal dendritic cells as well. Through binding of these receptors, H_2 antihistamines may mediate cutaneous vascular permeability, local release of inflammatory mediators and cellular recruitment, and antigen presentation, but these pathways remain poorly understood, and their clinical significance is unknown.

PHARMACOKINETICS

H_2-type antihistamines are rapidly absorbed from the gastrointestinal tract with peak levels occurring between 1 and 2 hours after administration. They undergo extensive hepatic metabolism with renal clearance. Only a small proportion of cimetidine is absorbed from the stomach; most of its absorption occurs in the small intestine. The half-life of cimetidine in plasma is 2 hours. Approximately 69% is excreted unchanged in the urine.[48] The plasma half-life of ranitidine is 2–3 hours in healthy adults, longer in individuals with liver or kidney disease and in the elderly.[49] The drug and

BOX 229-5 DERMATOLOGIC INDICATIONS FOR TREATMENT WITH H_2 ANTIHISTAMINES

- Acute allergic reactions
- Chronic urticaria
- Urticaria pigmentosa and systemic mastocytosis
- Pruritus associated with other conditions

its metabolites are excreted principally in the urine. Famotidine has a plasma half-life of 3–8 hours. In patients with renal failure, the half-life of famotidine may exceed 20 hours.[50] Nizatidine has a plasma half-life of 1–2 hours, and its duration of action is up to 10 hours.[51] Nizatidine is primarily eliminated by the kidneys within 16 hours. The oral bioavailability of nizatidine is not affected by food. These agents are relatively lipophilic with limited penetration of the blood-brain barrier.

INDICATIONS IN DERMATOLOGY

There are few data from controlled studies supporting the use of H_2 blockers to treat dermatologic conditions (Box 229-5). Most often, these agents are used in addition to H_1 antihistamines in refractory cases of chronic urticaria and angioedema. In a double-blind crossover study, greater reductions in pruritus and wheal number, size, and severity were observed with the combination of hydroxyzine and cimetidine than with hydroxyzine alone.[52] Similar observations have been made for chlorpheniramine combined with cimetidine.[53] Combination H_1 and H_2 antihistamine therapy may also be helpful in reducing the pruritus and whealing associated with systemic mastocytosis and urticaria pigmentosa. A double-blind crossover trial of chlorpheniramine and cimetidine suggested that the combination was effective in reducing the pruritus and whealing.[28]

There are anecdotal reports of the use of cimetidine to treat pruritus secondary to various medical conditions such as polycythemia vera[54] and carcinoid flush.[55] High doses of cimetidine were successful in the treatment of verruca vulgaris in some individuals.[56]

DOSING REGIMENS

The dosing regimens for H_2 antihistamines are given in Table 229-2.

INITIATION OF THERAPY

For treatment of dermatologic conditions, H_2 antihistamines are generally used in conjunction with H_1 antihistamines, usually following an unsuccessful trial of H_1 antihistamines alone. In most cases, treatment with H_2 antihistamines may be initiated without any particular laboratory screening. The inhibition of the hepatic CYP system and the potential for drug interactions is usually the greatest concern, and patients' medication lists should be reviewed carefully before initiating therapy. Ranitidine is less inhibitory of the CYP system than cimetidine and may be the preferred H_2 antihistamine in situations in which drug interactions are a particular concern.[49] Patients with decreased creatinine clearance require dosage adjustment.[57] In patients taking the cardiac drug dofetilide, cimetidine is absolutely contraindicated because of the risk of prolongation of the QT interval and life-threatening cardiac arrhythmias.[58]

MONITORING OF THERAPY

Therapeutic endpoints are evaluated by observation of clinical signs and symptoms (e.g., severity of pruritus;

TABLE 229-2
Dosing Regimens for H_2 Antihistamines[42–45]

Drug	Formulation	Dosage	Conditions Requiring Dosage Adjustment
Cimetidine	100-, 200-, 300-, 400-, 800-mg tablet 300 mg/5 mL syrup 200 mg/20 mL syrup	Adult: 400–800 mg bid	Renal or hepatic impairment
Ranitidine	75-, 150-, 300-mg tablet 15 mg/mL syrup 150-mg granules	Adult: 75–150 mg bid Pediatric: 5–10 mg/kg/day divided in two doses	Renal impairment
Famotidine	10-, 20-, 40-mg tablet 40 mg/5 mL syrup	Adult: 20–40 mg bid Age 1–16 years: 1 mg/kg/day Divided in two doses, up to 40 mg bid	Renal impairment
Nizatidine	150-, 300-mg capsule 15-mg/5-mL syrup	Age ≥12 years: 150 mg qd, bid	Renal impairment

BOX 229-6 ADVERSE EFFECTS OF H_2 ANTIHISTAMINES

- Central nervous system disturbances
  - Confusion
  - Headache
  - Dizziness
  - Drowsiness
- Gastrointestinal effects
  - Nausea or vomiting
  - Diarrhea or constipation
  - Abdominal pain
  - Increased transaminases and hepatitis (rare)
- Gynecomastia
- Increased susceptibility to pneumonia
- Hematologic (rare)
  - Thrombocytopenia
  - Anemia
- Hypersensitivity to H_2 (uncommon)
- Drug interactions
- Cardiac effects (with concomitant administration of dofetilide; dofetilide use is therefore a contraindication)

wheal size, frequency, and intensity). As far as drug toxicity is concerned, no particular monitoring beyond the usual surveillance for adverse effects is required in most cases. For patients with a history of thrombocytopenia, a complete blood count may be warranted once H_2 antihistamine therapy is initiated, because thrombocytopenia has been reported as an idiosyncratic effect of these drugs in a few individuals.[59]

RISKS AND PRECAUTIONS

H_2 antihistamines may have several CNS effects, including confusion, headache, and dizziness[60] (Box 229-6). These effects seem to be partly dose related. Other side effects include drowsiness, malaise, muscular pain, diarrhea, and constipation. There are rare reports of granulocytopenia. By their suppression of gastric acid secretion, H_2 antihistamines may facilitate oral infections and increase the risk of pneumonia in immunocompromised individuals, including diabetic patients, the elderly, and patients with immunodeficiency.[61] As a class, these drugs may mask symptoms of gastric carcinoma. Cimetidine and ranitidine both inhibit alcohol dehydrogenase activity, which leads to increased blood alcohol levels.

Uncommon side effects of cimetidine include gynecomastia with or without elevated prolactin levels in men; galactorrhea with elevated prolactin levels in women; and loss of libido, impotence, and reduction of sperm counts in young men.[48,62] Modest elevations in serum creatinine levels and hepatic transaminase levels have both been reported and are reversible after the drug is withdrawn.[49,62] Rare dermatologic adverse effects, including alopecia and urticarial vasculitis, have also been reported.[63]

Ranitidine does not bind to androgen receptors and does not enhance cell-mediated immune responses.[49] Ranitidine may affect physiologic autonomic control of the cardiovascular system by altering parasympathetic and sympathetic control functions.[64] This altered cardiac sympathovagal balance may lead to a susceptibility to arrhythmias, particularly bradyarrhythmias, after intravenous infusion.

Famotidine and nizatidine are associated with few side effects; they also cause less inhibition of the CYP system and therefore are involved in fewer drug interactions.[54,51]

DRUG INTERACTIONS

Through inhibition of the CYP system, cimetidine increases the serum levels of numerous drugs, including some of the most common medications used in the care of the medical patient.[62] Of note, cimetidine increases levels of warfarin and may cause dangerous increases in prothrombin time and risk of bleeding. Cimetidine also interacts with many cardiac drugs—several β blockers, calcium channel blockers, amiodarone, antiarrhythmic agents, among others. As already mentioned (see Section "Initiation of Therapy"), cimetidine use is contraindicated in patients taking dofetilide. Other common drugs with which cimetidine interacts are phenytoin, several benzodiazepines, metformin, sulfonylureas, and selective serotonin reuptake inhibitors.

Although ranitidine interacts with other medications less frequently than does cimetidine, significant interactions with fentanyl, metoprolol, midazolam, nifedipine, theophylline, and warfarin have been observed.[49] Ranitidine may decrease the absorption of diazepam and reduce its plasma concentration by 25%. Famotidine and nizatidine are associated with fewer drug interactions.

SPECIAL PATIENT POPULATIONS

CHILDREN. Of the H_2 antihistamines, ranitidine and famotidine have pharmacokinetics that have been relatively well studied in children, and these drugs have acceptable safety profiles with appropriate dosing. Cimetidine and nizatidine are not recommended for children for uses other than reducing gastric acidity. One adverse effect unique to children is an uncommon but drug class-wide risk of necrotizing enterocolitis in neonates.[65]

ELDERLY. Older patients may require downward adjustment of dosage to accommodate decreased creatinine clearance, as well as careful review of medication lists. Elderly patients also appear more susceptible to CNS disturbances such as confusion and dizziness.

PREGNANT WOMEN. The H_2 antihistamines are classified as FDA pregnancy category B drugs. Cimetidine, ranitidine, famotidine, and nizatidine are all

excreted in breast milk; potential effects on the nursing infant have not been studied.[49–51,62]

OTHER THERAPEUTIC AGENTS WITH ANTIHISTAMINIC ACTIVITY

TRICYCLIC ANTIDEPRESSANTS

Tricyclic antidepressants bind both H_1 and H_2 receptors. The tricyclic antidepressant most commonly used in dermatology is doxepin. Oral doxepin has been used successfully in the treatment of refractory chronic idiopathic urticaria, physical urticaria, and pruritus associated with systemic conditions.[66,67] In a double-blind, crossover study (n = 50), doxepin proved more efficacious than diphenhydramine in the treatment of chronic idiopathic urticaria.[68] Topical preparations are also available. In double-blind, vehicle-controlled trials, topical doxepin cream reduced pruritus in patients with atopic dermatitis and lichen simplex chronicus.[69]

Sedation is the most common adverse effect with both the oral form and the topical form, which is absorbed percutaneously, although some patients may develop tolerance with regular use. Oral doxepin has been classified by the FDA as a pregnancy category C drug; topical doxepin is classified as a pregnancy category B drug.[70] Use of both oral and topical forms is contraindicated during breastfeeding. The safety and efficacy of doxepin therapy in children under the age of 12 has not been established. The drug should be used with caution in elderly patients, who may be more susceptible to its anticholinergic effects, including urinary retention and blurred vision.[66] Doxepin should not be used concurrently with monoamine oxidase inhibitors, and all patients with underlying depression should be closely monitored for signs of suicidal ideation when initiating drug therapy. Doxepin may also cause a sudden increase in intraocular pressure and should not be used in patients with glaucoma.

KETOTIFEN

Ketotifen, a benzocycloheptathiophene derivative, is an H_1-type antihistamine with additional mast cell- and basophil-stabilizing properties.[1] Ketotifen has been used successfully in the treatment of chronic idiopathic urticaria, physical urticaria, and urticaria pigmentosa.[71–73] In a double-blind trial involving 305 patients with chronic idiopathic urticaria ketotifen alleviated pruritus more effectively than clemastine or placebo.[74] More recent studies comparing ketotifen with low-sedating H_1 antihistamines are not available. Results of one early open-label trial suggested that ketotifen not only reduces the pruritus and pain of neurofibromatosis but also slows the growth of neurofibromas[75]; however, these results have not been confirmed by other investigators. Sedation and atropine-like effects are common.[76] There are no studies evaluating the safety of ketotifen in pregnant or breastfeeding women. Ketotifen is available in the United States only as an ophthalmic solution.

MIRTAZAPINE

Mirtazapine is a tetracyclic antidepressant with H_1 antihistamine properties.[67] Several case series have reported its successful use in reducing pruritus attributable to uremia, cholestasis, and various cancers, but it has not been well studied as a primary dermatologic agent. Patients taking mirtazapine require monitoring of blood counts and lipid levels for hyperlipidemia and the rare but serious adverse effects of agranulocytosis and neutropenia. Mirtazapine carries an FDA black-box warning of possible increased risk of suicide, particularly during initiation of therapy, and its concomitant use with monoamine oxidase inhibitors is contraindicated. It is classified as an FDA pregnancy category C drug, and its safety during breastfeeding and in children has not been established.

Chapter 230 :: Antibiotics

:: Christopher C. Gasbarre, Steven K. Schmitt & Kenneth J. Tomecki

ANTIBIOTICS AT A GLANCE

- β-Lactam antibiotics (penicillins and cephalosporins) are mainstays of therapy for the treatment of uncomplicated skin and soft-tissue infections (SSTI).
- Empiric therapy of uncomplicated SSTIs is largely successful.
- Antibiotic resistance is a growing concern. Culture and sensitivity testing may allow for better management of these infections.
- β-Lactam antibiotics (penicillins and cephalosporins) and vancomycin act by inhibition of bacterial cell wall synthesis.
- Several antibiotic classes interfere with bacterial protein synthesis by binding ribosomal subunits: tetracyclines at 30S; lincosamides(clindamycin), macrolides, streptogramins, and oxazolidinones (linezolid) at 50S.
- New agents approved for the treatment of SSTIs include linezolid, quinupristin/dalfopristin, daptomycin, ertapenem, and tigecycline.

Antibiotics are soluble compounds produced by an organism that inhibit bacterial growth; the term also includes synthetic compounds such as fluoroquinolones. The majority of skin and soft-tissue infections (SSTI) are caused by Gram-positive organisms, most of which are susceptible to well-known agents with a relatively narrow spectrum of antimicrobial activity. In these cases, β-lactams, macrolides, and fluoroquinolones have been the mainstays of therapy.[1] Increased use and misuse of these antibiotics has led to selection and propagation of resistant bacteria. Community-acquired resistant pathogens, such as methicillin-resistant *Staphylococcus aureus* (MRSA), have recently emerged as causes of SSTIs such as cellulitis, folliculitis, furunculosis, impetigo, erysipelas, and abscesses. More ominous is the emergence of complicated SSTIs with resistant pathogens, for example, MRSA and vancomycin-resistant *Enterococci* (VRE). Complicated cutaneous infections include those involving deeper tissues, those requiring surgical intervention, or those coincidental with underlying diseases that may complicate therapy. Combination therapy with well-established antimicrobials has been effective in many cases, and new antibiotics have broadened treatment options. However, given the relative paucity of new antimicrobials on the horizon, dermatologists are likely to be faced with growing treatment challenges. Understanding the pharmacologic properties of antibiotics ensures the most judicious use of these agents, and familiarity with antibiotic dosing schedules and adverse events will lead to therapeutic choices that achieve the highest degree of patient compliance.

PENICILLINS

MECHANISM OF ACTION

One of the oldest and largest groups of antibiotics, penicillins are members of the β-lactam family.[6] All penicillins have a nucleus composed of a thiazolidine ring and β-lactam ring, which is required for antibiotic activity. Different side chains alter activity and resistance to degradation, but all β-lactams share a similar bacteriocidal mechanism of action. They bind to specific penicillin binding proteins (PNBs), inhibit cell-wall peptidoglycan synthesis, and inactivate an inhibitor of autolytic enzymes present on bacterial cell walls.

There are several groups of penicillins, largely separated by their chemical structure and resistance to bacterial degradation. The natural penicillins exhibit the narrowest spectrum of activity and are susceptible to enzymatic degradation by β-lactamases. Penicillin G is the most useful drug in this group. Administered parenterally, it is active against *Streptococcus*, *Neisseria meningitidis*, *Clostridium* sp., spirochetes, *Pasteurella multocida*, *Eikenella corrodens*, *Erysipelothrix rhusiopathiae* and non-β-lactamase producing *Staphylococci*. Penicillin G is the treatment of choice for *Treponema pallidum* infection in all forms. Penicillin V is the oral form of the drug and is generally less potent than Penicillin G because of lower achievable blood levels.

Aminopenicillins (ampicillin, amoxicillin), carboxypenicillins (carbenicillin, ticarcillin), and ureidopenicillins (piperacillin) provide a broader spectrum of activity. All of these semisynthetic agents are susceptible to β-lactamase. Aminopenicillins are oral agents and have limited activity against *Staphylococci* and enteric organisms. They are routinely used for infections of the upper airway, head, and neck (bronchitis, sinusitis, otitis), and have no activity against *Pseudomonas* sp. Carboxypenicillins have some activity against *Pseudomonas* sp. and *Proteus* sp., and are often administered with aminoglycosides for the treatment of serious pseudomonal infections. The ureidopenicillins have a similar Gram-positive profile. Derived from ampicillin, they have greater activity against Gram-negative bacteria than the carboxypenicillins. Amoxicillin, ticarcillin, and piperacillin are often coupled

with β-lactamase inhibitors to enhance activity against *S. aureus*. β-Lactamase inhibitors include tazobactam, clavulanic acid, and sulbactam, and work best against β-lactamases encoded on plasmids.

The final group of penicillins (oxacillin, dicloxacillin, and nafcillin) are inherently β-lactamase resistant and exhibit excellent activity against *S. aureus*; they have no activity against *Enterococci* or enteric Gram-negative organisms. β-lactamase-resistant penicillins remain an excellent choice for empiric therapy of uncomplicated SSTIs such as folliculitis, impetigo, furunculosis, and cellulitis where community-acquired MRSA is not suspected.

PHARMACOKINETICS

Absorption of oral penicillins is variable and depends on each compound's acid stability and amount bound to food. Most oral penicillins should be taken at least 1 hour before or 1 hour after meals. Absorption of amoxicillin is unaffected by food. Unabsorbed penicillin is degraded by gastrointestinal flora. Penicillin G, nafcillin, carbenicillin, ticarcillin, and piperacillin are poorly absorbed and unstable at low pH; as such, they are administered parenterally. Penicillins are widely distributed in body fluids and tissues, but areas of poor availability include the cerebrospinal fluid, prostate, and intraocular fluid. These drugs do not typically cross the blood-brain barrier, but can reach effective levels in patients with meningitis due to increased meningeal permeability. Natural penicillins can interact with amines (such as procaine and benzathine) to form salts with relatively low solubility; administered intramuscularly, penicillin is released more slowly, prolonging drug delivery. Most free penicillin is excreted renally. Penicillins are excreted in breast milk in low quantity, and are considered safe to use during breastfeeding. Indications are listed in Box 230-1.

DOSING REGIMEN

(See Table 230-1)

BOX 230-1 INDICATIONS FOR PENICILLIN THERAPY

- Syphilis and nonvenereal treponematoses
- SSTIs caused by *Streptococcus* sp. (erysipelas, scarlet fever, impetigo, etc.)
- Erysipeloid
- Anthrax (if sensitive)
- Lyme disease (where tetracyclines are contraindicated)
- Actinomycosis
- Listeriosis
- Leptospirosis
- Infected human and animal bites

Dosing adjustment for patients with renal insufficiency is necessary.

RISKS AND PRECAUTIONS

(See Box 230-2)

COMPLICATIONS

(Table 230-2)

Hypersensitivity reactions are the most common adverse events reported with penicillins.[7] Reported incidence varies from 0.7%–10%, and manifestations range from mild to severe (Table 230-2). Penicillin hypersensitivity is probably overreported by patients, but 2%–4% of true allergic reactions are life threatening. For true penicillin-allergic patients, treatment warrants use of another class of antibiotic. If penicillin allergy is uncertain and if penicillin treatment is required, skin prick testing may be performed to detect type I hypersensitivity, followed by intradermal testing if negative. Negative testing may be followed by a challenge dose of oral penicillin under observation. Approximately 10%–20% of patients with a history of "penicillin allergy" have a positive skin test, and approximately 3% of those with a negative skin test and a history of allergy have an allergic response after a challenge dose of penicillin. These reactions tend to be mild. Patients with positive skin tests can undergo desensitization therapy when a β-lactam must be given.

CEPHALOSPORINS

MECHANISM OF ACTION

Cephalosporins are β-lactams with the same mechanism of action as penicillins, i.e., they inhibit bacterial cell-wall synthesis by blocking peptidoglycan incorporation.[8] Cephalosporins differ structurally from penicillins by their dihydrothiazine ring versus the thiazolidine ring of penicillins. Most cephalosporins have some activity against both Gram-positive (excluding *Enterococci*) and Gram-negative organisms, though the spectrum of activity varies widely among the group. The cephalosporins are comprised of four "generations" based on spectrum of activity and evolution of development. The first generation includes cephalexin, cefadroxil, and the parenteral agents cefazolin and cephalothin, all of which have good activity against methicillin-sensitive *S. aureus* and *Streptococcus* sp. and limited activity against Gram-negative organisms; for example, *Escherichia coli* and *Klebsiella* sp. The second generation includes cefprozil, cefaclor, cefuroxime axetil, and the parenteral agents cefotetan, cefoxitin, and cefuroxime, offering expanded Gram-negative activity over the first generation agents, specifically against *Hemophilus influenzae* and *Moraxella catarrhalis*. Third generation agents include cefdinir, cefditoren, and the parenteral agents cefotaxime, ceftriaxone, ceftazidime, and

TABLE 230-1
Dosing Regimens of Commonly Prescribed Antibiotics for the Treatment of SSTIs

Class	Generic Name	Route	Adult Dosing
β-Lactam	penicillin G	IM, IV	2–24 million units qd divided q 4 hours[a] (18–24 million units qd for neurosyphilis)
	benzathine pen G	IM	2.4 million units ×1 (early syphilis)[a] 2.4 million units weekly × 3 (syphilis >1 year)
	dicloxacillin	PO	500 mg q 6 hours
	nafcillin	IM, IV	IM: 500 mg q 4–6 hours IV: 0.5–2 g q 4–6 hours
	oxacillin	IM, IV	1–2 g q 4–6 hours
	amoxicillin	PO	500 mg q 8 hours[a]
	amoxicillin/clavulanate	PO	875 mg q 12 hours[a]
	cephalexin	PO	500 mg q 6 hours
	cefdinir	PO	300 mg q 12 hours
	cefprozil	PO	250 mg q 12 hours
Tetracycline	tetracycline	PO	500 mg q 6 hours (bid for acne)[a]
	doxycycline	PO	100 mg q 12–24 hours[a]
	minocycline	PO	100 mg q 12 hours[a]
Macrolide	erythromycin base	PO	500 mg q 6 or 12 hours
		IV	1 g q 6 hours[a]
	clarithromycin	PO	250–500 mg q 12 hours
	azithromycin	PO	500 mg on day 1, then 250 mg qd × 2—5 Chlamydia: 1-g single dose
		IV	500 mg q 24 hours
Fluoroquinolone	ciprofloxacin	PO, IV	gonorrhea: 500 mg × 1[b] gonococcemia: 500 mg q 12 hours × 7 days[c] chancroid: 500 mg q 12 hours × 3 days cutaneous anthrax: 10–15 mg/kg q 12 hours ×60 days
	levofloxacin	PO, IV	uncomplicated: 500 mg q 24 hours[a] complicated: 750 mg q 24 hours[a]
Lincosamide	clindamycin	PO	150–450 mg q 6 hours
		IV	600–900 mg q 8 hours
Trimethoprim-sulfamethoxazole (cotrimoxazole)		PO	180 mg/ 800 mg (DS) q 12 hours[a]
		IV	5 mg/kg q 6–8 hours[a]

[a]Adjustments in dose or frequency of administration may be required in patients with renal impairment.
[b]CDC recommendations for the treatment of gonococcal urethritis/cervicitis include concomitant therapy with azithromycin or doxycycline.
[c]Following a single dose of 1-g ceftriaxone IM/IV.

cefoperazone. They exhibit an expanded spectrum of activity against Gram-negative pathogens, but are less effective against Gram-positive organisms. As such, they are extremely helpful for Gram-negative nosocomial infections. Cefotaxime and ceftriaxone cross the blood-brain barrier and are effective treatment for meningitis caused by *H. influenzae*, *N. meningitidis*, and penicillin-sensitive *S. pneumoniae*. Ceftazidime and cefoperazone are active against *Pseudomonas aeruginosa*, and cefdinir and cefditoren are useful in the treatment of SSTIs due to their activity against *S. aureus* as well as *Streptococcus* sp. The only "fourth generation" cephalosporin available in the United States is cefepime, a parenteral agent with good activity against a broad spectrum of Gram-positive and Gram-negative organisms, including *P. aeruginosa*.

BOX 230-2 RISKS AND PRECAUTIONS OF PENICILLIN THERAPY

- Known hypersensitivity to penicillin
- Increased penicillin levels with probenecid and disulfiram
- Enhanced effect of methotrexate and warfarin

PHARMACOKINETICS

Cephalosporins are a chemically diverse class of antibiotics with unique pharmacokinetic and pharmacodynamic properties. Most orally administered

TABLE 230-2
Adverse Events

Antibiotic Class	Pregnancy Class	Common Adverse Effects	Uncommom Adverse Effects
Penicillins	B	Hypersensitivity reactions: Exanthem, urticaria Diarrhea	Hypersensitivity reactions: Exfoliative dermatitis, SJS, vasculitis, AGEP Angioedema, anaphylaxis, serum sickness Anaphylactoid reaction Hepatitis, interstitial nephritis Neurotoxicity (high dose) Pulmonary infiltrate with eosinophilia (PIE) Immune-mediated hematologic reactions Pseudomembranous colitis
Cephalosporins	B	Hypersensitivity as above Diarrhea	Hypersensitivity as above Renal tubular necrosis Disulfiram-like reaction (specific) Thrombophlebitis (IV site) Serum sickness-like reaction (cefaclor, cefprozil) Pseudocholelithiasis (ceftriaxone)
Tetracyclines	D	Skin and nail hyperpigmentation (minocycline) Dental hyperpigmentation (infants, children) Gastrointestinal irritation	Photosensitivity (doxycycline) Photo-onycholysis Fixed drug eruption Pseudotumor cerebri Esophageal erosion/stricture Skeletal hypoplasia Serum sickness Renal toxicity Vestibular toxicity (minocycline) Fanconi Syndrome (outdated tetracycline) Thyroid discoloration SJS, TEN Pancreatitis Blood dyscrasias (long-term use) Hypersensitivity reactions (various) Pseudomembranous colitis
Fluoroquinolones	C	Nausea, vomiting Cephalgia, dizziness	Exanthem, photosensitivity Delerium, seizure Tendon rupture, arthropathy (in the immature) QT prolongation Hepatitis (trovafloxacin-withdrawn from United States)
Trimethoprim-sulfamethoxazole	C	Exanthem, photosensitivity Nausea, vomiting, anorexia Glossitis, stomatitis (Rare/ severe reactions are more common in HIV/AIDS patients)	SJS, TEN, vasculitis, urticaria Pustular eruption, Sweet syndrome Cholestatic hepatitis, hepatic necrosis Blood dyscrasias Severe hypersensitivity reaction Cephalgia, hallucination, tremor Nephrolithiasis, interstitial nephritis
Lincosamides (Clindamycin)	B	Diarrhea Exanthem, urticaria	Pseudomembranous colitis Erythema multiforme, SJS, TEN Elevated hepatic transaminases (reversible) Blood dyscrasias Neuromuscular blockade
Macrolides	B/C	Nausea, diarrhea, abdominal pain Dysguesia (clarithromycin)	Cholestatic hepatitis Pseudomembranous colitis Prolonged QT/Torsade de points Anaphylaxis SJS

AGEP = acute generalized exanthematous pustulosis, SJS = Stevens-Johnson Syndrome, TEN = toxic epidermal necrolysis.

BOX 230-3 INDICATIONS OF CEPHALOSPORIN THERAPY

- Uncomplicated SSTIs due to *Staphylococcus aureus* and *Streptococcus pyogenes* (first- and second-generation agents, plus cefdinir and cefditoren)
- Gonorrhea
- Lyme disease (ceftriaxone: meningitis and late disease; cefuroxime: early disease)
- Bacterial meningitis (ceftriaxone, cefotaxime)

cephalosporins can be taken without food. The esterified cephalosporins (cefuroxime and cefpodoxime) should be taken with food to prolong mucosal contact time since they require enzymatic cleavage in the intestinal tract. Agents that lower the gastric pH may also reduce absorption of these two drugs. Cefaclor is an extended release formulation and should similarly be given with food. Most cephalosporins are renally excreted. Cephalosporins are excreted in breast milk to varying degrees. First, second, and third generation cephalosporins are compatible with breastfeeding, and excretion in breast milk occurs in varying degrees.

INDICATIONS

(See Box 230-3)

DOSING REGIMEN

(Table 230-1)

RISKS AND PRECAUTIONS

(See Box 230-4)

COMPLICATIONS

(Table 230-2)

BOX 230-4 RISKS AND PRECAUTIONS OF CEPHALOSPORIN THERAPY

- Known hypersensitivity to cephalosporin or penicillin (see Section "Complications")
- Reduced absorption of cefdinir with antacids and iron salts
- Increased cyclosporin levels with ceftriaxone and ceftazidime
- Altered effect of warfarin with cefotetan, cefamandole, cefoperazone, cefixime, and cefaclor
- Impaired renal excretion of most cephalosporins with probenecid

Cephalosporins cross-react with penicillin in up to 20% of penicillin allergic patients, with most reactions occurring between penicillins and first- or second-generation cephalosporins.[9] The common β-lactam ring is responsible for the shared mechanism of action and some antigenic cross-reactivity, and the respective side chains for hypersensitivity reactions. Cephalosporins and penicillins with similar side chains are more likely to produce a cross-reactive hypersensitivity reaction in penicillin allergic patients. Cefoxitin, cefamandone, cefaloram, cephalothin, and cephaloridine have side chains structurally similar to penicillin, while cefaclor, cephalexin, cefprozil, cephradine, and cefadroxil have side chains similar to amoxicillin or ampicillin. Some oral agents that lack side chain similarity to penicillin, ampicillin, or amoxicillin include cefdinir, cefpodoxime, cefditoren, and cefuroxime, and these agents may be safer for use in patients reporting a penicillin class allergy. Patients reporting a penicillin allergy with a negative penicillin allergy skin test have no greater risk of an allergic reaction to β-lactams than the general population. Cephalosporins, due to their greater variety of metabolite structures than other β-lactams, are able to elicit cephalosporin-specific allergic responses.

TETRACYCLINES

MECHANISM OF ACTION

Tetracyclines inhibit bacterial protein synthesis by binding to the 30s ribosomal subunit and blocking transfer RNA binding to the mRNA-ribosome complex.[10] Doxycycline and minocycline are semisynthetic second-generation tetracyclines most commonly used in dermatology. More lipophilic, they generally exhibit greater activity than tetracycline, especially versus *S. aureus* and community-acquired strains of MRSA.[11] As a class, tetracyclines have a broad spectrum of activity, including many Gram-positive and Gram-negative bacteria, spirochetes, *Mycoplasma, Rickettsia, Chlamydia*, and some protozoa. Doxycycline is preferred therapy for the treatment of infections due to *Borrelia* sp., *Brucella* sp., *Chlamydia* sp., *Ehrlichia sp.* (monocytic and granulocytic ehrlichiosis), *Calymmatobacterium granulomatis* (granuloma inguinale), *Coxiella burnetii* (Q fever), *Leptospira* sp., *Mycoplasma* sp., *Rickettsia* sp., and *Francisella tularensis*. It is also treatment for infections caused by *Actinomyces* sp., *Bacillus anthracis*, *Mycobacterium marinum*, and *Vibrio vulnificus*. In patients allergic to penicillins, doxycycline is commonly used to treat animal bites and syphilis. Tetracyclines can be helpful for the treatment of acne, rosacea, perioral dermatitis, autoimmune blistering disease (bullous pemphigoid, linear IgA bullous dermatosis, and dermatitis herpetiformis), and confluent and reticulated papillomatosis (Gougerot-Cartaud), probably because of their anti-inflammatory properties.

PHARMACOKINETICS

Tetracycline is incompletely absorbed primarily in the stomach and small intestine, necessitating its ingestion on an empty stomach. Doxycycline and minocycline are unaffected by the presence or absence of food and have longer half-lives than tetracycline, requiring less frequent dosing. They also have much greater lipid solubility than tetracycline, allowing for excellent tissue penetration, with rapid availability in secretions of the prostate, respiratory tract, female reproductive tract, and bile. Nonetheless, patients should avoid concurrent ingestion of iron preparations, aluminum hydroxide gels, calcium and magnesium salts, or milk products, as these significantly lower absorption of the entire class. Tetracycline is excreted primarily by the kidneys, and patients with renal failure require dosing adjustment. Doxycycline is excreted in the feces and no adjustments for renal or hepatic failure are necessary. Minocycline is largely metabolized before excretion, but does not accumulate in patients with hepatic failure. Tetracyclines cross the placenta and appear in high concentrations in breast milk. Because of their ability to accumulate in developing bone and teeth, their use during pregnancy, while nursing, and throughout childhood should be avoided.

INDICATIONS

(See Box 230-5)

DOSING REGIMEN

(Table 230-1)

BOX 230-5 INDICATIONS FOR TETRACYCLINE THERAPY

- Actinomycosis
- Animal bites (*Pasteurella multocida*)
- Anthrax (*Bacillus anthracis*) infections
- Bacillary angiomatosis
- *Borrelia* sp. infections
- *Chlamydia* sp. infections
- Ehrlichiosis
- Lyme disease
- MRSA infections
- *Mycobacterium marinum*
- *Nocardia* sp. infections
- Rhinoscleroma
- Rickettsial diseases
- Syphilis (penicillin-allergic granuloma inguinale patients)
- Tularemia
- *Vibrio vulnificus* infections
- *Yersinia pestis* infections

BOX 230-6 RISKS AND PRECAUTIONS OF TETRACYCLINE THERAPY

- Patients with renal failure (impaired excretion and antianabolic properties)
- Photosensitivity (doxycycline)
- Nursing, pregnancy, and childhood years (<9 years of age)
- Impaired absorption by calcium, magnesium, aluminum (other cations), iron, sodium bicarbonate, and cimetidine
- Increased metabolism of doxycycline with the use of phenytoin, carbamazepine, barbiturates, and alcohol
- Reduced insulin requirements in diabetic patients
- Increased serum levels of digoxin, lithium, and warfarin
- Methoxyflurane anesthesia (renal failure)

RISKS AND PRECAUTIONS

(See Box 230-6)

COMPLICATIONS

(See Table 230-2)

CLINDAMYCIN

MECHANISM OF ACTION

Clindamycin is a lincosamide antibiotic derived through chemical modification of lincomycin.[12] Its absorption and spectrum of activity are better than its predecessor, which is now obsolete. Clindamycin binds to the bacterial 50s ribosomal subunit and inhibits protein synthesis through blockade of peptide chain initiation. The binding site overlaps the sites of other antibiotics that bind the 50s subunit such as macrolides (erythromycin), accounting for the antagonism noted between the drugs. Clindamycin facilitates opsonization and phagocytosis and decreases bacterial adhesion (to host cells) and production of staphylococcal exotoxin. Persistent binding at the 50s subunit leads to prolonged antibiotic effect in some organisms. Drug resistance by mutation at the 50S ribosomal binding site.

Clindamycin is effective against most Gram-positive cocci, anaerobes, and some protozoa. In dermatologic practice, it is active against most *Streptococcus* species (including *S. viridans*), methicillin-sensitive *S. aureus*, and *S. epidermidis*. Its anaerobic spectrum of activity includes *Peptococci*, *Peptostreptococci*, propionibacteria, *Clostridium perfringens*, and fusobacteria. *Toxoplasma gondii* is often effectively treated with combinations including clindamycin. It is ineffective against strains of *Enterococcus* and JK group corynebacteria.

BOX 230-7 INDICATIONS FOR CLINDAMYCIN THERAPY

Uncomplicated SSTIs due to susceptible bacteria and protozoa (see Mechanism of Action)

- Deep tissue infections: streptococcal myositis, necrotizing fasciitis, or infections with *Clostridium perfringens* in conjunction with surgical debridement
- Surgical prophylaxis in penicillin allergic patients
- Prophylaxis for recurrent staphylococcal infection
- Diabetic foot ulcers (in combination with agents for Gram-negative infection)
- Hidradenitis suppurativa
- Bacterial vaginosis

PHARMACOKINETICS

Clindamycin is not inhibited by food intake and reaches therapeutic levels in most tissue except cerebrospinal fluid. The drug preferentially accumulates in polymorphonuclear leukocytes, which may explain its benefit as treatment for abscesses. Clindamycin is primarily metabolized by the liver and excreted in the bile, though 10% is excreted in the urine. Dosing adjustments are necessary for patients with hepatic failure or combined hepatic and renal failure. It is not removed by dialysis.

INDICATIONS

(See Box 230-7)

DOSING REGIMEN

(Table 230-1)

RISKS AND PRECAUTIONS

(See Box 230-8)

COMPLICATIONS

(Table 231-2)

Clindamycin frequently causes gastrointestinal upset and diarrhea (2%–20% of patients), and may occasionally cause pseudomembranous colitis attributed to *Clostridium difficile*, a life-threatening complication reported in 0.1%–10% of patients. Despite its classic association with clindamycin, pseudomembranous colitis may occur following administration of virtually any antibiotic. Treatment includes discontinuation of the drug and administration of metronidazole.

BOX 230-8 RISKS AND PRECAUTIONS OF CLINDAMYCIN THERAPY

- Hepatic failure
- Enhancement of neuromuscular blockade with tubocurare and pancuronium
- Possible antagonism with erythromycin

MACROLIDES

MECHANISM OF ACTION

Erythromycin is the prototypical macrolide antibiotic; derivatives include dirithromycin, clarithromycin, and azithromycin. All are bacteriostatic and inhibit bacterial protein synthesis by reversibly binding the 50s ribosomal subunit. Structural modifications of clarithromycin and azithromycin confer increased acid stability, tissue penetration, and spectrum of activity.[13] The macrolides have good but varied activity against Gram-positive pathogens: clarithromycin > erythromycin > azithromycin. Streptococcal resistance to macrolides is fairly common (up to 40% of group A isolates), and *S. aureus* may be variably susceptible to erythromycin. Streptococcal resistance to macrolides is class-wide rather than drug specific. Erythromycin has poor activity against most Gram-negative pathogens, but azithromycin and clarithromycin have good activity against *H. influenzae, N. gonorrhoeae, M. catarrhalis, Chlamydia, Mycoplasma pneumoniae, H. pylori, Toxoplasma gondii, Treponema pallidum, Borrellia burgdorferi,* and nontuberculous mycobacteria. Azithromycin has good activity against *Pasteurella multocida* and *Eikenella corrodens*, making it a useful alternative in the treatment of infected bites. Clarithromycin is the most active macrolide against *M. leprae* and is widely used for skin infections with several other nontuberculous mycobacteria, notably *M. chelonae, M. abscessus*, and *M. fortuitum*.

PHARMACOKINETICS

Macrolides accumulate intracellularly in polymorphonuclear leukocytes and macrophages, and in part account for their activity against intracellular pathogens. Erythromycin base is absorbed in the small intestine and inactivated by gastric acidity, hence its availability as enteric-coated tablets or capsules. (Food lowers gastric pH and may delay absorption.) Erythromycin esters (erythromycin estolate, stearate, and ethylsuccinate) are less acid labile than the base form. Except its extended-release formulation, which should be given with food, clarithromycin may be given with or without food. Tissue concentrations of macrolides typically exceed plasma levels. Concentrations of erythromycin in breast milk are approximately 50% of maternal serum levels. Erythromycin can cross the placenta, but except clarithromycin (pregnancy category C), the macrolides are category B. Clarithromycin and azithromycin have longer half-lives, allowing for less frequent dosing (Table 230-1). Azithromycin remains in tissue longer and accumulates at high levels intracellularly (tissue fibroblasts) allowing for daily short-term dosing after a loading dose. Clarithromycin is metabolized by

BOX 230-9 INDICATIONS FOR MACROLIDE THERAPY

- Uncomplicated SSTIs (folliculitis, erysipesas, cellulitis, etc.)
- *Bartonella* infections (except Orroyo fever-*Bartonella bacilliformis*)
- Bites—animal and human *(Pasteurella multocida, Eikenella corrodens*—azithromycin)
- Lyme disease
- Chlamydia
- Nontuberculous mycobacterial skin disease (clarithromycin)

the liver and excreted by the kidneys. Patients with renal failure require dosing adjustments. Adjustments are not necessary for erythromycin, azithromycin, or dirithromycin, which primarily undergo hepatic metabolism. Erythromycin and clarithromycin interact with the cytochrome P-450 system, which can prompt numerous potential drug interactions (see Risks and Precautions). Erythromycin and clarithromycin inhibit CYP 3A4, and erythromycin also inhibits CYP 1A2.

INDICATIONS

(See Box 230-9)

DOSING REGIMEN

(Table 230-1)

RISKS AND PRECAUTIONS

(See Box 230-10)

BOX 230-10 RISKS AND PRECAUTIONS OF MACROLIDE THERAPY

- CYP 3A4 inhibition-
  - Increased drug toxicity (increased serum levels)
    - Warfarin, carbamazepine, buspirone, benzodiazepines, corticosteroids (methylprednisolone), HMG CoA reductase inhibitors, oral contraceptives, cyclosporine, tacrolimus, disopyramide, felodipine, ergot alkaloids
- CYP 1A2 inhibition-
  - Increased drug toxicity (increased serum levels)
    - Theophylline, omeprazole
- Other
  - Digoxin (levels elevate due to change in drug metabolism by gut flora)
  - Fluconazole (increased clarithromycin levels)

COMPLICATIONS

(See Table 230-2)

FLUOROQUINOLONES

MECHANISM OF ACTION

Fluoroquinolones are fluorinated derivatives of the first quinolone, nalidixic acid.[14] They act by inhibiting the action of bacterial topoisomerases II (DNA gyrase) and IV, leading to impaired DNA replication, transcription, and repair. In Gram-positive organisms, the primary target is topoisomerase IV; in Gram-negative bacteria the target is topoisomerase II. Agents available in the United States are ciprofloxacin, levofloxacin, ofloxacin, moxifloxacin, and gemifloxacin.[15,16] Fluoroquinolones have a broad spectrum of activity, with appreciable bacteriocidal activity against a variety of Gram-negative organisms including *Salmonella, Shigella, Enterobacter, Campylobacter*, and *Neisseria*. Ciprofloxacin is most active against *Pseudomonas aeruginosa*. As a class, the fluoroquinolones have limited anaerobic activity, but the newer agents gemifloxacin and moxifloxacin exhibit lower MICs against these organisms. These newer fluoroquinolones have better activity against Gram-positive organisms. Moxifloxacin, in particular, has been approved for the treatment of uncomplicated SSTIs. Some of the newer fluoroquinolones (levofloxacin, moxifloxacin) exhibit good activity against *Streptococcus*, but often develop resistance to *S. aureus* rapidly. They should not be first line therapy for uncomplicated SSTIs, but they should be instrumental in the treatment of complicated, polymicrobial, and/or Gram-negative infections such as diabetic ulcers or deep tissue infections. Ciprofloxacin and levofloxacin are effective agents for gonorrhea, chlamydia, erysipeloid, granuloma inguinale, and chancroid (see Indications). Ciprofloxacin, ofloxacin, levofloxacin, moxifloxacin, and gatifloxacin are effective against some *Mycobacterium* species including *M. tuberculosis, M. chelonae, M. fortuitum*, and *M. kansasii*, though available data are limited.

PHARMACOKINETICS

Fluoroquinolones are rapidly absorbed after oral ingestion with a large volume of distribution. Food does not inhibit absorption. Unlike β-lactams, fluoroquinolones act in a concentration-dependent manner and can be administered twice daily. Most are excreted by the kidneys, and adjustments for renal failure are usually necessary. Moxifloxacin is eliminated in the liver by conjugation with glucuronide and sulfate. None of the fluoroquinolones are removed by dialysis. Most are excreted in breast milk in small and almost negligible quantities, but rare side effects have occurred in breast-feeding infants. Ciprofloxacin has been associated with phototoxicity, pseudomembranous colitis, and green teeth upon eruption. Norfloxacin is not found in the

BOX 230-11 INDICATIONS FOR FLUOROQUINOLONE THERAPY

FIRST-LINE THERAPY

Anthrax
Skin and soft-tissue infections (SSTIs) due to Gram-negative pathogens (see Mechanism of Action)
Pseudomonas aeruginosa infections[a] (otitis externa, ecthyma gangrenosum, SSTI)
Rhinoscleroma

SECOND-LINE THERAPY

Bartonella sp.infections
Chancroid
Chlamydia
Ehrlichiosis
Erysipeloid
Gonorrhea
Granuloma inguinale
Rickettsia sp.
Vibrio vulnificus infections

[a]ciprofloxacin

breast milk of mothers taking the drug, while ofloxacin and levofloxacin are excreted in smaller quantities than ciprofloxacin. Ciprofloxacin and ofloxacin are compatible with breastfeeding according to American Academy of Pediatrics guidelines.

INDICATIONS

(See Box 230-11)

DOSING REGIMEN

(Table 230-1)

RISKS AND PRECAUTIONS

(See Box 230-12)

BOX 230-12 RISKS AND PRECAUTIONS OF FLUOROQUINOLONE THERAPY

- Decreased bioavailability with antacids (aluminum, magnesium, alum), iron, zinc, and sucralfate
- Inhibited theophylline/aminophylline metabolism (ciprofloxacin)
- Arthropathy in studies of immature animals
- Tendon rupture (in patients with renal disease, hemodialysis, or steroid use)
- Decreased seizure threshold
- Decreased warfarin and cyclosporin metabolism

COMPLICATIONS

(See Table 230-2)

TRIMETHOPRIM/ SULFAMETHOXAZOLE

MECHANISM OF ACTION

Trimethoprim/sulfamethoxazole (cotrimoxazole) is a combination of trimethoprim (TMP) and sulfamethoxazole (SMX) in a 1:5 ratio. Both compounds inhibit nucleic acid synthesis by inhibiting two enzymes in the bacterial tetrahydrofolic acid synthesis pathway. Together, these compounds exhibit synergistic action that is relatively specific to bacterial cells.

TMP/SMX is a broad-spectrum antibiotic with good activity against many aerobic Gram-positive cocci including *S. aureus*, *S. pyogenes*, and *S. viridans*; it is often effective in the treatment for community-acquired MRSA.[11] Other susceptible pathogens include: *H. influenzae, E. coli, Proteus mirabilis, Klebsiella pneumoniae, Shigella, Yersinia, and Brucella*. While *Pseudomonas aeruginosa* is resistant, other *Pseudomonas* species and *Stenotrophomonas maltophilia* are generally sensitive. TMP/SMX can be effective therapy for infections with *Nocardia* and atypical mycobacteria. The drug has no activity against anaerobes.

PHARMACOKINETICS

TMP and SMX are well absorbed but achieve different serum concentrations following administration of equal quantities of drug. A serum ratio of 1:20 (TMP:SMX) is necessary for optimal synergy against the largest variety of pathogens, which can be achieved by administration of the drug in a fixed 1:5 ratio. Both compounds are rapidly distributed to tissues, including the CSF and sputum. Excretion is via the kidneys.

INDICATIONS

(See Box 230-13)

DOSING REGIMEN

(Table 230-1)

BOX 230-13 INDICATIONS FOR TMP-SMX THERAPY

- Community-acquired MRSA
- *Nocardia asteroides* infections
- Uncomplicated SSTIs due to susceptible pathogens (see Mechanism of Action)
- Granuloma inguinale; chancroid

BOX 230-14 RISKS AND PRECAUTIONS OF TMP-SMX THERAPY

- More severe reactions in patients with HIV/AIDS
- Prolonged prothrombin time in patients on warfarin
- Contraindicated in patients on methotrexate

RISKS AND PRECAUTIONS

(See Box 230-14)

COMPLICATIONS

(Table 230-2)

NEWER OR LESS COMMONLY USED AGENTS

While the aforementioned compounds comprise the vast majority of antibiotics used in dermatologic practice, several new or infrequently used medications bear mentioning for the treatment of complicated SSTIs or systemic infections due to resistant pathogens.[17] In many hospitals, these drugs have restricted use, predicated on approval by an infectious disease specialist.

VANCOMYCIN

Vancomycin (Vancocin) is a glycopeptide antibiotic effective against Gram-positive bacteria only; specifically Gram-positive infections resistant to β-lactams or when their use is contraindicated.[18] In dermatology, vancomycin has been a first-line therapy for complicated and/or severe SSTIs due to hospital-acquired MRSA. In recent years, vancomycin-resistant isolates of *S. aureus* and *Enterococcus faecium* have been isolated. Vancomycin inhibits bacterial-cell-wall peptidoglycan synthesis. Dosing is determined by the patient's weight (15–20 mg/kg), and frequency of administration by the patient's creatinine clearance. As such, renal function requires monitoring during therapy. Potential adverse reactions include nephrotoxicity, ototoxicity, phlebitis at the injection site, hypersensitivity reactions, and leukopenia. "Red man syndrome," secondary to histamine release, is an uncommon reaction, thought to be due to drug impurities. More refined preparations and slower infusions minimize this reaction. Drug-induced linear IgA disease is a rare cutaneous side effect. Two new glycopeptides, dalbavancin and oritavancin, are currently in clinical trials for the treatment of SSTIs.

LINEZOLID

Currently the only available oxazolidinone, linezolid (Zyvox) is currently approved by the FDA for the treatment of complicated SSTIs due to MRSA, as well as other drug-resistant Gram-positive infections including vancomycin-resistant *Enterococcus faecium* (VRE) and vancomycin-resistant *S. aureus* (VRSA).[19] Its spectrum of activity includes Gram-positive organisms (including anaerobes), as well as nontuberculous mycobacteria such as *M. chelonae* and *M. fortuitum*. Largely bacteriostatic, linezolid inhibits the initiation of protein translation by binding to the 23S portion of the 50S ribosomal subunit, a unique mechanism of action which minimizes cross-resistance to other antibiotics. Nonetheless, linezolid-resistant enterococcal infections have occurred. Though renally excreted, dosing adjustments for renal failure are not necessary. Linezolid is generally well tolerated, but reversible thrombocytopenia and leucopenia occur in approximately 2% of patients, which seems to correlate with duration of therapy. This dictates monitoring of complete blood counts during therapy. Dosing for complicated infections is 600 mg twice daily, usually intravenously at first. The ability to convert to oral administration makes this drug an attractive option.

QUINUPRISTIN/DALFOPRISTIN

Quinupristin/dalfopristin (Synercid) is a streptogram in antibiotic combination in a fixed 60:40 ratio.[17] Both quinupristin and dalfopristin irreversibly inhibit bacterial protein translation by binding to different sites on the 50s ribosomal subunit. They exhibit synergistic, largely bacteriocidal activity against a variety of multidrug-resistant Gram-positive organisms including MRSA and VRE. Like linezolid, they have also been used in the treatment of VRSA infections. The recommended dose is 7.5 mg/kg intravenously twice daily for at least 7 days, with lower dosing for those patients with hepatic insufficiency. Patient tolerability can be a problem, especially phlebitis (75%), if administered peripherally; arthralgia; and myalgia. Quinupristin/dalfopristin is metabolized by the liver and excreted in the bile. Elevation of hepatic transaminases and bilirubin has been reported, and concomitant administration with drugs metabolized by the CYP3A4 system is contraindicated. Quinupristin/dalfopristin should be used with caution in patients taking cyclosporine or agents that prolong the QT interval.

DAPTOMYCIN

Daptomycin (Cubicin) is a cyclic lipopeptide; a new class of antibiotic derived from the fermentation of *Streptomyces roseosporus*.[20] Daptomycin was recently approved in the United States for the treatment of complicated SSTIs caused by *S. aureus* (including methicillin-resistant strains), *Streptococcus pyogenes*, *Streptococcus agalactiae*, *Streptococcus dysgalactiae* subsp. *equisimilis* and *Enterococcus faecalis* (vancomycin-susceptible strains only). Its mechanism of action is unclear, but it acts rapidly and is bacteriocidal against Gram-positive bacteria. Dosing is 4 mg/kg intravenously every 24 hours for 7–14 days. Daptomycin is excreted primarily by the kidneys (78%), requiring

TABLE 230-3
Recommended Therapies

Organism	First-Line Therapy	Alternative Therapy
Actinomyces israelii	ampicillin or penicillin G	doxycycline, ceftriaxone, clindamycin, erythromycin
Bacillus anthracis	doxycycline or ciprofloxacin	penicillin G or amoxicillin (if penicillin sensitive)
Bartonella sp.	azithromycin (cat-scratch)	clarithromycin, ciprofloxacin erythromycin or doxycycline (BA)
Borrellia burgdorferi	doxycycline or amoxicillin	ceftriaxone, cefuroxime, cefotaxime
Borrellia recurrentis	doxycycline	erythromycin
Calymmatobacterium granulomatis	doxycycline or TMP/SMX	erythromycin, azithromycin, ciprofloxacin
Chlamydia trachomatis	doxycycline or azithromycin	erythromycin, ofloxacin, levofloxacin
Clostridium perfringens	penicillin G +/– clindamycin	doxycycline
Coxiella burnetii	doxycycline	erythromycin
Ehrlichia sp.	doxycycline	tetracycline, rifampin, ciprofloxacin
Eikenella corrodens	penicillin G or ampicillin	amoxicillin/clavulanate, TMP/SMX, fluoroquinolones
Erysipelothrix rhusiopathiae	penicillin G or ampicillin	fluoroquinolones
Francisella tularensis	streptomycin	gentamicin, tetracycline, chloramphenicol
Hemophilus ducreyi	azithromycin or ceftriaxone	erythromycin, ciprofloxacin
Klebsiella rhinoscleromatis	fluoroquinolones	rifampin[a] + TMP/SMX
Neisseria gonorrhoeae	ceftriaxone	fluoroquinolones, cefixime
Nocardia asteroides	TMP/SMX	minocycline, linezolid
Nocardia brasiliensis	TMP/SMX	amoxicillin/clavulanate
Pasteurella multocida	penicillin, ampicillin, or amoxicillin	doxycycline, TMP/SMX
Pseudomonas aeruginosa	ciprofloxacin	antipseudomonal penicillin or cephalosporin
Rickettsia sp.	doxycycline	chloramphenicol, fluoroquinolone
Staphylococcus aureus (MSSA)	oxacillin or nafcillin	clindamycin, macrolides
Staphylococcus aureus (HAMRSA)	vancomycin	linezolid, daptomycin, quinupristin/dalfopristin, tigecycline
Staphylococcus aureus (CAMRSA)	TMP/SMX	minocycline, clindamycin, rifampin[a], as above
Streptococcus pyogenes	penicillin	other β-lactams, macrolides
Treponema pallidum	benzathine penicillin G	doxycycline, tetracycline
Vibrio vulnificus	doxycycline + ceftazidime	cefotaxime, fluoroquinolones

BA = bacillary angiomatosis; CAMRSA = community-acquired MRSA; HAMRSA = hospital-acquired MRSA; TMP/SMX = trimethoprim/ sulfamethoxisole.
[a]Rifampin is not recommended as monotherapy due to significant development of resistance.

dosing adjustment for patients with renal impairment (C_{Cr} <30 mL/min). The drug is generally well tolerated, with headache and constipation being reported most commonly (4%). The primary serious adverse event is myopathy, which usually occurs at higher doses.

ERTAPENEM

Ertapenem (Invanz) is a long-acting carbapenem with a broad spectrum of antimicrobial activity similar to the older carbapenems, imipenem-cilastatin, and meropenem.[17] Unlike imipenem, it has poor activity against *Pseudomonas* and *Enterococci*. In clinical trials, it was comparable to piperacillin/tazobactam in the treatment of complicated SSTIs. Active against both Gram-positive and Gram-negative aerobes and anaerobes, its use should be reserved for polymicrobial infections not otherwise sensitive to agents with more narrow spectra of activity. An extended half-life allows for once daily intravenous administration (1 g per day for 7–14 days), but it should be used cautiously in patients with renal impairment. CNS effects and hypersensitivity reactions have been noted.

TIGECYCLINE

Tigecycline (Tygacil) is a glyclcycline antibiotic indicated for the treatment of complicated SSTI due to susceptible organisms, which include MRSA and VRE.[21] A derivative of minocycline, tigecycline shares the same 30s ribosomal binding site and has a spectrum of activity similar to the classic tetracyclines. However, tigecycline demonstrates a greater volume of distribution, better activity against organisms with tetracycline resistance, and better activity against *Streptococcus* species. Tigecycline dosing is 50 mg intravenously twice daily following a 100-mg loading dose. Renal dosing is not required, but lower dosing is necessary for patients with severe hepatic disease. The same precautions taken with the tetracycline class of antibiotics should be observed with tigecycline.

Chapter 231 :: Antiviral Drugs

:: Dirk M. Elston

ANTIVIRAL DRUGS AT A GLANCE

- Antivirals are now approved for treatment of a variety of viral infections.
- Antiviral resistance is a growing concern, especially in the treatment of human immunodeficiency virus infection.
- Antivirals work in a number of different ways, and their spectra of activity can be very specific (amantadine) or quite broad (ribavirin).
- The use of prodrugs of acyclovir and ganciclovir has greatly increased the oral bioavailability of these agents, which allows outpatient treatment of many herpesvirus infections.

The pace of development of new antiviral drugs has been accelerated by the human immunodeficiency virus (HIV) epidemic. Progress in our understanding of the molecular biology and pathogenesis of viral diseases has been remarkable. This chapter focuses on the antiviral drugs most likely to be used by dermatologists, as well as those that cause cutaneous side effects. The age of effective antiviral therapy is here, and they are used throughout all disciplines of medicine. We need to be prepared to evaluate patients on a wide variety of antiviral drugs, especially those currently used to treat HIV.

DRUGS FOR THE TREATMENT OF HERPESVIRUS INFECTIONS

(See Chapters 193 and 194)

ACYCLOVIR

MECHANISM OF ACTION. Acyclovir, 9-[(2-hydroxyethoxy) methyl] guanine, was the first orally available drug to be widely used for the treatment of herpes simplex virus (HSV) and varicella-zoster virus (VZV) infections. The triphosphate form of the drug is the active form, which has a potent inhibitory effect on herpesvirus-induced DNA polymerases but relatively little effect on host cell DNA polymerase. As such, it has a tremendous margin of safety when used to treat herpetic infections. Acyclovir triphosphate causes premature termination of the nascent viral DNA chain. HSV- and VZV-induced thymidine kinases result in efficient phosphorylation of acyclovir to acyclovir monophosphate, the first step in drug metabolism. This step is not accomplished efficiently by normal cellular kinases, resulting in greater concentrations of active drug in infected cells.

PHARMACOKINETICS. While acyclovir is available in oral, intravenous, and topical formulations, the oral bioavailability is only in the range of 15%–30%. Excretion is almost entirely renal, with approximately 85% of renally excreted drug being unmetabolized. Because of this reliance on renal excretion, the dose must be reduced for patients with a creatinine

clearance of less than 50 mL/min. Acyclovir is water soluble and achieves good levels in a variety of body fluids, including the contents of vesicles, cerebrospinal fluid, and vaginal secretions. Acyclovir has been marketed as a 5% ointment, but the efficacy is limited compared with systemic administration.

INDICATIONS

- Treatment of symptomatic primary or recurrent mucocutaneous HSV-1 or HSV-2 infection
- Suppression of recurrent HSV-1 and HSV-2 infections
- Treatment of mucocutaneous HSV infections in immunocompromised patients
- Prevention of perinatal HSV-1 and HSV-2 infection and treatment of neonatal HSV infection
- Treatment of primary VZV infection in adults and immunocompromised children
- Treatment of VZV infection to reduce the risk of postherpetic neuralgia
- Treatment of HSV-1 encephalitis
- Postexposure prophylaxis and treatment for *Herpes simiae* in the setting of a monkey bite

It has been suggested that suppression of genital HSV recurrences may reduce the risk of acquisition of HIV. It is common for those with HIV-1 infection to have outbreaks of HSV and frequent reactivation is associated with increased plasma and genital levels of the HIV-1 virus. Unfortunately, a randomized, placebo-controlled trial of suppressive acyclovir did not reduce the risk of disease transmission in couples in whom only one was initially seropositive for HIV-1. The failure to prevent transmission occurred despite a reduction in plasma HIV-1 RNA of 0.25log(10) copies per milliliter as well as a 73% reduction in the occurrence of genital HSV.[1] Acyclovir can produce direct suppression of HIV-1.[2] Newer monophosphorylated acyclovir derivatives (including those with the phosphate group masked by lipophilic groups) have greater potential to prevent viral transmission, as they suppress both HIV-1 and HSV-2 more effectively.[3] It is important to note that acyclovir can select for the HIV-1 V75I reverse transcriptase variant in vitro. While this variant has decreased sensitivity to some nucleoside analogs, it demonstrates an increased sensitivity to zidovudine.[4] [See Section "Drugs for the Treatment of Human Immunodeficiency Virus (HIV) Infection."]

Acyclovir given in late pregnancy to women with recurrent genital herpes has been shown to decrease the frequency of genital lesions as well as subclinical viral shedding. This can result in a decrease in the number of Caesarean sections performed.

Unfortunately, breakthrough lesions and viral shedding can still occur and recent evidence suggests that standard oral dosing of acyclovir in late pregnancy often results in insufficient levels at delivery to prevent viral shedding.[5]

Resistance is a growing problem, and data from corneal HSV-1 isolates suggests that infections commonly represent mixtures of acyclovir-sensitive and resistant viruses with different *thymidine kinase* gene sequences. The acyclovir-resistant HSV-1 can establish latency and reactivate intermittently to cause acyclovir-refractory disease.[6]

DOSING REGIMENS. Compliance with five times daily dosing regimens is poor, so the dosing regimens commonly used in clinical practice differ from those reflected in drug labeling (Table 231-1).

INITIATION OF THERAPY. Treatment for mucocutaneous HSV disease should begin as early as possible. For recurrent disease, treatment may be in the form of continuous suppression or episodic treatment beginning during the prodromal period. Treatment for varicella is most effective if it can be started within 24 hours of onset of vesicles. In immunocompetent patients, treatment for zoster has proven benefit if started within 72 hours of onset of the eruption.

MONITORING OF THERAPY. The dose should be adjusted for patients with a creatinine clearance level of less than 50 mL/min, but drug level assays are not routinely performed.

RISKS AND PRECAUTIONS. Renal (5% incidence of adverse reactions)

- Crystallization in renal tubules leading to obstructive nephropathy
- Interstitial nephritis

Central nervous system (1% incidence)

- Lethargy
- Tremors
- Confusion
- Seizures

Miscellaneous

- Phlebitis with intravenous administration
- Rash
- Recall dermatitis
- Fixed drug eruption
- Elevated liver function tests
- Neutropenia

COMPLICATIONS. Acyclovir is generally very well tolerated. The major risk is renal tubular crystallization with rapid intravenous administration. Caution must be exercised with high doses and in the setting of dehydration. Interstitial nephritis has also been reported. Central nervous system toxicity is uncommon, but may manifest as lethargy, tremors, or seizures. Patients with these side effects commonly have underlying diseases involving the central nervous system. Thrombophlebitis is a known complication of infusion, and appears to be related to the high pH of the reconstituted solution (pH 11). The plasma half life is only 2.5 hours, requiring repeated administration, but newer nanoparticle preparations are being developed with an increased half-life to reduce the need for repeat parenteral administration.[7] Nanoparticle technology is also being used to improve the bioavailability of oral forms of the drug.[8] In the future, antiviral susceptibility testing may allow selection of the optimal drug in

TABLE 231-1
Commonly Used Dosing Regimens for Acyclovir

Condition	Dosage	Route	Duration
Primary HSV infection, immunocompetent host	400 mg tid	Oral	7–10 days
Recurrent genital HSV infection, immunocompetent host	400 mg tid *or* 800 mg tid	Oral Oral	5 days 2 days[4]
Recurrent oral labial HSV infection, immunocompetent host	400 mg 5×/day *or* 5% cream 6×/day	Oral Topical	5 days 7 days
Oral labial HSV infection, immunocompromised host	5 mg/kg q8h *or* 400 mg 5×/day	IV Oral	7 days 14–21 days
Perinatal HSV infection	10–20 mg/kg q8h	IV	10–21 days
Chronic suppression of HSV infection	400 mg bid *or* 800 mg qd	Oral	
HSV-1 Encephalitis	10 mg/kg q8h	IV	14–21 days
Varicella: adolescent/adult	800 mg 5×/day	Oral	5–7 days
Varicella: pneumonia or third trimester pregnancy	800 mg 5×/day *or* 10 mg/kg q8h	Oral IV	5 days 5 days
Herpes zoster: normal host or not severe disease in immunocompromised host	800 mg 5×/day	Oral	7–10 days
Herpes zoster: severe disease or immunocompromised host	10–12 mg/kg q8h	IV	7–14 days

HSV = herpes simplex virus.

those at increased risk for adverse reactions.[9] These assays show the greatest potential in the setting of concurrent HIV infection.[10]

VALACYCLOVIR

MECHANISM OF ACTION AND PHARMACOKINETICS.

Valacyclovir, the L-valine ester of acyclovir, was developed to provide increased oral bioavailability of the active drug acyclovir.[11] Valacyclovir is readily absorbed from the gastrointestinal tract and almost entirely converted to acyclovir by intestinal and hepatic esterases. The mechanism of action and spectrum of activity of valacyclovir are identical to those of acyclovir. Following a 1-g oral dose of valacyclovir, peak plasma concentrations of acyclovir in the range of 5.7 µg/mL are achieved in 1.75 hours, and area-under-the-curve (AUC) concentrations are similar to those achieved with 5 mg/kg of acyclovir given intravenously.

INDICATIONS

- Treatment of initial and recurrent HSV genital infections
- Suppression of frequently recurring genital HSV infections
- Treatment of herpes zoster

The cost-effectiveness of long-term herpes suppression and intermittent therapy has been debated, but patients are generally quite appreciative of therapy.[12,13] Treatment decreases the frequency of clinical outbreaks as well as the incidence of viral shedding. In the setting of HSV-2 seropositive subjects without a history of symptomatic genital herpes infection, 84% of subjects had no shedding while receiving 1 g daily of valacyclovir versus 54% of subjects on placebo (P <0.001).[14] Recent data suggest a higher frequency of total and subclinical HSV-2 shedding following newly diagnosed HSV-2 infection than reported in earlier studies. Valacyclovir 1 g daily resulted in a 78% reduction in viral shedding in this population compared to placebo, and 79% of subjects had no clinical recurrences while receiving valacyclovir compared with 52% of subjects receiving placebo (P <0.01).[15]

The drug has been used to suppress recurrence of ocular disease.[16] In the setting of oral herpes simplex, valacyclovir has been used alone or combined with oral corticosteroids. In one study, there were more aborted lesions in the valacyclovir-clobetasol arm than in the placebo group (50% vs. 15.8%, P = 0.04)[17], but further study is needed to assess the independent contribution of the corticosteroid.

Valacyclovir demonstrates in-vitro activity against Epstein-Barr virus (EBV). It is being studied in the settings

TABLE 231-2
Dosing Regimens for Valacyclovir

Condition	Dosage	Route	Duration
Primary HSV infection, immunocompetent host	1,000 mg bid	Oral	10 days
Recurrent genital HSV infection, immunocompetent host	500 mg bid	Oral	3 days
Recurrent oral labial HSV infection, immunocompetent host	2,000 mg bid	Oral	1 day
Oral labial HSV infection, immunocompromised host	500 mg bid	Oral	5–10 days
Chronic suppression of HSV infection	1,000 mg qd	Oral	Undefined/ indefinite
Varicella: adolescent/adult	1,000 mg tid	Oral	5 days
Herpes zoster: normal host or not severe disease in immunocompromised host	1,000 mg tid	Oral	7 days

HSV = herpes simplex virus.

of infectious mononucleosis, hepatitis, encephalopathy, and post-transplant lymphoproliferative disease. Unfortunately, in a recent trial, valacyclovir treatment was not effective in decreasing peripheral blood EBV viral loads in pediatric liver transplantation patients.[18] In healthy volunteers, long-term administration of valacyclovir effectively reduces the number of EBV-infected B cells, although it does not reduce the number of EBV DNA copies per B cell.[19]

DOSING REGIMENS. Standard doses for adults with herpetic infections are listed in Table 231-2.[20] The drug has also been evaluated in children with malignancy.[21] In this setting, valacyclovir (15 mg/kg) was well tolerated and demonstrated excellent bioavailability.[22] Those less than 3 months of age demonstrate decreased clearance of the drug. Among children 3 months through 11 years of age, a 20-mg/kg dose of an extemporaneously compounded valacyclovir oral suspension produced favorable acyclovir blood levels and was well tolerated. The authors noted that among children 2 through 5 years of age, a dose increase from 20–25 mg/kg resulted in near doubling of the peak concentration [C(max)] and the area under the curve (AUC)[23]

INITIATION OF THERAPY. As with acyclovir, valacyclovir therapy should be initiated as soon as possible after the onset of an HSV or VZV infection.

RISKS AND PRECAUTIONS. In addition to side effects noted with acyclovir, thrombotic thrombocytopenic purpura/hemolytic uremic syndrome (TTP/HUS) can occur in patients with advanced HIV disease and in transplant recipients receiving dosages of 8 g/day. The drug has also been reported to produce both immediate hypersensitivity and a symmetrical drug-related intertriginous and flexural exanthem.[24,25]

COMPLICATIONS. Most adverse effects are those that also occur with acyclovir, including a potential for CNS effects.[26] Severe and even fatal cases of TTP/HUS have been reported in patients with acquired immunodeficiency syndrome (AIDS) and transplant recipients who were given high dosages of valacyclovir. The basis for and causal relationship have not been completely established, and TTP/HUS has not been reported in patients taking conventional dosages (up to 3 g/day) of valacyclovir. In a study of high-dose valacyclovir administered to six subjects with normal renal function and three subjects with chronic renal impairment (CrCl approximately 15–30 mL/min), average steady-state concentrations of acyclovir and its metabolites, 9-[(carboxymethoxy) methyl]guanine and 8-hydroxy-acyclovir were greater in both serum and CSF among the subjects with impaired renal function. In contrast, the CSF penetration of each metabolite did not differ based on renal function. This suggests that it is simply the higher concentrations in the systemic circulation that result in proportionally higher concentrations in the CSF.[27]

FAMCICLOVIR AND PENCICLOVIR

MECHANISM OF ACTION. Famciclovir, [9-(4-hydroxy-3-hydroxy-methylbut-1-yl) guanine, is the prodrug of penciclovir, [9-(4-hydroxy-3-hydroxy-3-hydroxymethylbut-1-yl) guanine]. Once absorbed, penciclovir is phosphorylated to penciclovir triphosphate. The initial phosphorylation of penciclovir to penciclovir monophosphate is efficiently carried out by HSV- or VZV-induced thymidine kinases in a manner similar to that of the initial phosphorylation of acyclovir. Phosphorylation to diphosphate and triphosphate forms of penciclovir then occurs via cellular kinases. Penciclovir triphosphate inhibits viral DNA polymerases and inhibits extension of the nascent viral DNA chain in a manner similar to acyclovir; however, because of the presence of the hydroxyl group on the acyclic side chain of penciclovir, some DNA chain extension may occur.

PHARMACOKINETICS. Famciclovir is marketed as an oral formulation, which is converted to penciclovir by deacetylation and oxidation in the liver and

intestine. The bioavailability of oral famciclovir is 77%, with a peak plasma concentration of 3.3 µg/mL reached 1 hour after oral administration of 500 mg of famciclovir. The plasma half-life of penciclovir is 2 hours, and 60%–70% of the drug is excreted unchanged in the urine. This occurs via both glomerular filtration and tubular secretion. As with acyclovir, the dose of penciclovir should be reduced in patients with advanced renal dysfunction. Compared with the intracellular half-life of acyclovir triphosphate, that of penciclovir triphosphate is markedly prolonged in both HSV-infected cells (10–20 hours) and VZV-infected cells, allowing the drug to be administered two to three times daily. Penciclovir is available as a 1% ointment for the treatment of recurrent oral HSV. At least in some vehicles, topical penetration of penetration of penciclovir is superior to that of acyclovir.[28] Microemulsion and nanoparticle formulations are being evaluated.[29,30,31]

INDICATIONS

- Treatment of initial and recurrent HSV genital infections
- Suppression of frequently recurring genital HSV infections
- Treatment of herpes zoster

DOSING REGIMENS. Standard adult doses are given in Table 231-3.[32] In one study of recurrent genital HSV, a 2-day course of 500 mg initially, then 250 mg twice daily was noninferior to the standard 5-day course of 125 mg twice daily.[33] In another study, single-day famciclovir (1,000 mg administered twice daily) was similar in efficacy to 3-day valacyclovir (500 mg administered twice daily) for the treatment of recurrent genital herpes.[34] Single day treatment is associated with high patient satisfaction.[35] Some data suggest that suppressive treatment may be superior to episodic treatment.[36] Studies in children are ongoing, and currently the drug is used less commonly in this population.[37,38] While famciclovir has shown efficacy in general populations, one study of patient-initiated episodic treatment of recurrent genital herpes in immunocompetent black patients showed efficacy similar to that of placebo.[39]

RISKS AND PRECAUTIONS. Like acyclovir and valacyclovir, famciclovir is generally well tolerated. The dose should be reduced for patients with a creatinine clearance less than 60 mL/min. The drug has been used safely along with hydration in patients with prior renal toxicity related to acyclovir.[40] Leukocytoclastic vasculitis has been reported with the drug.[41] Common side effects include:

- Headache
- Nausea
- Diarrhea
- Dizziness

COMPLICATIONS. Serious toxicity is uncommon. Prolonged high-dose administration of famciclovir to rats has been associated with an increased incidence of mammary adenocarcinomas in females, but the clinical significance of this observation for humans treated with the drug is unknown.

TRIFLURIDINE

MECHANISM OF ACTION AND PHARMACOKINETICS. Trifluridine, 5-trifluoromethyl-2′-deoxyuridine, is a pyrimidine nucleoside analog. Trifluridine monophosphate acts as an irreversible competitive inhibitor of thymidylate synthetase, and trifluridine triphosphate inhibits HSV DNA polymerase. Trifluridine triphosphate also inhibits cellular DNA polymerases, although it does so to a lesser extent than viral DNA polymerases. Because of systemic toxicity, trifluridine is approved only for topical application in the form of a 1% ophthalmic aqueous solution. The elimination half-life for the ophthalmic solution is 12–18 minutes.

TABLE 231-3
Dosing Regimens for Famciclovir and Penciclovir

Condition	Dosage	Route	Duration
Primary HSV infection, immunocompetent host	250 mg tid	Oral	7–10 days
Recurrent genital HSV infection, immunocompetent host	125 mg bid or 1,000 mg bid	Oral Oral	5 days 1 day
Recurrent oral labial HSV infection, immunocompetent host	500 mg bid *or* 1% penciclovir cream q2h	Oral Topical	7 days 5 days or until lesions healed
Oral labial HSV infection, immunocompromised host	500 mg bid	Oral	7 days
Chronic suppression of HSV infection	250 mg bid	Oral	Up to 1 year
Varicella: adolescent/adult	500 mg tid	Oral	5 days
Herpes zoster: normal host or not severe disease in immunocompromised host	500 mg tid	Oral	7 days

HSV = herpes simplex virus.

TABLE 231-4
Dosing Regimens for Trifluridine

Condition	Dosage	Route	Duration
Primary HSV conjunctivitis	1 drop 1% solution q2h (maximum, 9 drops/24 hours)	Topical	Maximum, 21 days
Recurrent HSV epithelial keratitis	1 drop 1% solution q2h (maximum, 9 drops/24 hours)	Topical	Maximum, 21 days
Acyclovir-resistant HSV infection in AIDS	1% solution q8h	Topical	10–14 days or until lesions resolve

AIDS = acquired immunodeficiency syndrome; HSV = herpes simplex virus.

INDICATIONS

- Treatment of primary HSV conjunctivitis
- Treatment of recurrent HSV keratitis
- Treatment of acyclovir-resistant mucocutaneous HSV infections in patients with AIDS

EFFICACY. A recent meta-analysis of data from 99 randomized trials including a total of 5,363 participants concluded that the topical application of trifluridine, vidarabine, acyclovir, or ganciclovir all resulted in a high proportion of participants healing within 1 week of therapy and no agent emerged as significantly better than the others for the treatment of dendritic epithelial keratitis.[42] Other authors have suggested that although the drug is effective, it may result in delays in re-epithelialization.[43] There may be additional benefit from topical interferon in those treated with this agent.[44]

DOSING REGIMENS. Standard dosing regimens are given in Table 231-4.

RISKS AND COMPLICATIONS

- Mild burning
- Palpebral edema
- Punctate keratopathy
- Stromal edema

DRUGS FOR THE TREATMENT OF CYTOMEGALOVIRUS INFECTIONS

GANCICLOVIR AND VALGANCICLOVIR

MECHANISM OF ACTION AND PHARMACOKINETICS

Valganciclovir,L-valine2-[(2-amino-1,6-dehydro-6-oxo-9H-purin-9-yl) methoxy]-3-hydroxypropyl ester, is the L-valyl ester of ganciclovir. It is more efficiently absorbed and acts as a prodrug for ganciclovir. After oral administration, valganciclovir is converted to ganciclovir by intestinal and hepatic esterases. The oral availability of valganciclovir is approximately 60% and is increased by administration with food. After a 900-mg dose of valganciclovir, the maximum plasma concentration of ganciclovir is 5.61 g/mL, and the plasma concentration–time curve is similar to that achieved with ganciclovir given intravenously at a dose of 5 mg/kg.

INDICATIONS

- Treatment of CMV retinitis in patients with AIDS
- Suppression and prevention of CMV disease in transplant recipients

Viral clearance varies, even in the face of adequate plasma levels, so patients should be monitored for clinical response.[45,46] The drug has some activity against herpesvirus 6, but resistance has been reported.[47]

DOSING REGIMENS. Standard dosing regimens are provided in Table 231-5. Pediatric dosing regimens have also been published.[48]

RISKS AND COMPLICATIONS. Potential side effects include diarrhea, nausea, loss of appetite, headache, dizziness, confusion, nervousness, vivid dreams, tremor, weakness, peripheral edema and pain at the injection site.

FOSCARNET

MECHANISM OF ACTION. Foscarnet, trisodium phosphonoformate, is a pyrophosphate-containing antiviral drug that noncompetitively inhibits viral DNA polymerases at the pyrophosphate binding site. In contrast to the nucleoside analogues, foscarnet does not require phosphorylation and is therefore active against many strains of virus that are resistant to acyclovir, famciclovir, or ganciclovir as a result of absent or reduced kinase activity.[49–51] Salvage therapy with foscarnet plus a thymidine analog has been shown to be effective in patients with advanced-stage HIV disease and viruses harboring multiple drug-resistance mutations including thymidine-associated mutations.[52] Unfortunately, resistance to combined ganciclovir and foscarnet therapy has been reported in the setting of dual-strain cytomegalovirus coinfection.[53] Valproic acid has been reported to impair the antiviral activity of ganciclovir, cidofovir, and foscarnet.[54]

TABLE 231-5
Dosing Regimens for Valganciclovir

Condition	Dosage	Route	Duration
CMV retinitis	Induction: 900 mg bid Maintenance: 900 mg qd	Oral Oral	21 days Until CD4 count >100 after 6 mon of HAART

CMV = cytomegalovirus; HAART = highly active antiretroviral therapy.

PHARMACOKINETICS. Foscarnet is available as an intravenous preparation that has poor solubility and must be administered by an infusion pump in a dilute solution over 1–2 hours. The plasma half-life of the drug includes an initial phase of 4–8 hours and a terminal component of 88 hours or longer, which reflects a deposition in bone of up to 20% of the dose. Eighty percent of the dose is excreted unaltered by the kidney. The dose must therefore be reduced in patients with renal dysfunction.

INDICATIONS

- Treatment of CMV retinitis in patients with AIDS
- Treatment of CMV colitis
- Treatment of CMV polyradiculopathy in combination with ganciclovir
- Treatment of acyclovir-resistant HSV infections
- Treatment of ganciclovir-resistant CMV infections

DOSING REGIMENS. Standard dosing schedules are provided in Table 231-6.

RISKS AND COMPLICATIONS. Renal (30% incidence)

- Increased creatinine levels
- Proteinuria
- Nephrogenic diabetes insipidus
- Hypokalemia, hypocalcemia, hypomagnesemia

Miscellaneous

- Headache
- Fatigue
- Fever
- Seizures
- Low white blood cell count, anemia

MONITORING OF THERAPY. Renal toxicity is the major risk with foscarnet, and close monitoring of renal function is required. Saline hydration before administration and slow infusion of the drug may reduce nephrotoxicity. Electrolyte and metabolic abnormalities including hypocalcemia and hypercalcemia, hypophosphatemia and hyperphosphatemia, hypomagnesemia, and hypokalemia have been described.

CIDOFOVIR

MECHANISM OF ACTION. Cidofovir, (S)-1-[3-hydroxy-2(phosphonylmethoxy)-propyl] cytosine, is a phosphonate nucleotide analog.[55] In contrast to the nucleoside analogues, it does not require initial phosphorylation by virus-induced kinases. Rather, it is converted by host cell enzymes to cidofovir diphosphate, a competitive inhibitor of viral DNA polymerases.

PHARMACOKINETICS. Cidofovir is approved for intravenous administration. A topical formulation has been developed and compounded formulas have been used. An intravenous dose of 5 mg/kg results in a peak plasma concentration of 11.5 g/mL. The plasma half-life of cidofovir is 2.6 hours, and the drug is excreted almost entirely by the kidney. Cidofovir diphosphate has a markedly prolonged intracellular half-life (in excess of 48 hours), and may be given at a dose of 5 mg/kg twice a week for the first 2 weeks, followed by one dose every 2 weeks.

INDICATIONS

- CMV retinitis in AIDS
- Treatment of resistant HSV and CMV infections

TABLE 231-6
Dosing Regimens for Foscarnet

Condition	Dosage	Route	Duration
CMV retinitis	Induction: 90 mg/kg q12h Maintenance: 90 mg/kg q24h	IV IV	14–21 days Until CD4 count >100 on 6 months of HAART
Acyclovir-resistant HSV infection	40 mg/kg q8h *or* 60 mg/kg q12h	IV IV	 2–3 week or until clinical resolution

CMV = cytomegalovirus; HAART = highly active antiretroviral therapy; HSV = herpes simplex virus.

TABLE 231-7
Dosing Regimens for Cidofovir

Condition	Dosage	Route	Duration
CMV retinitis	Induction: 5 mg/kg every week Maintenance: 5 mg/kg every 2 week	IV IV	2 week Until CD4 count >00 after 6 months on HAART

CMV = cytomegalovirus; HAART = highly active antiretroviral therapy.
Note: Cidofovir IV administration must be accompanied by prehydration and probenecid.

Cidofovir also has antiviral activity against pox and parapoxviruses, including vaccinia and variola (small pox), orf, monkeypox, and molluscum contagiosum.[56,57] It has been used successfully off-label in topical form for the treatment of the lesions of human papillomavirus infection, Kaposi sarcoma, and HSV infection.[58–64] Coadministration of cidofovir with smallpox vaccine reduced the incidence of side effects but interfered with the vaccine-elicited immune responses and immunity to monkeypox.[65]

DOSING REGIMENS.

Standard dosing regimens are provided in Table 231-7. Data regarding the use in pediatric patients are accumulating.[66]

RISKS AND COMPLICATIONS.

Renal (59% incidence)

- Renal tubular damage
- Dose-dependent proximal tubular injury (Fanconi-like)
- Proteinuria
- Elevated serum creatinine levels

Proteinuria, serum creatinine elevations of ≥0.4 mg/dL, or decreased creatinine clearance ≤55 mL/min, occurred in 79 of 135 patients at a maintenance dose of 5 mg/kg every other week.

Miscellaneous

- Nausea (48% incidence)
- Alopecia (16% incidence)
- Rash
- Fever
- Myalgia

PRECAUTIONS.

The incidence of nephrotoxicity can be reduced by vigorous hydration before and after infusion, along with the administration of probenecid. Renal function must be assessed prior to each dose. Cidofovir has been used to treat human papillomavirus (HPV)-related recurrent respiratory papillomatosis,[67] but there are reports of squamous cell carcinoma associated with intralesional injection of cidofovir in this setting and evidence that the drug can both increase cell survival and induce alterations in gene expression associated with malignant transformation.[68,69] There are reports that the drug can induce HPV E6 protein expression.[70] Herpes simplex virus stomatitis has been reported to occur during prophylactic cidofovir therapy despite in vitro susceptibility of HSV to the drug.[71]

RISKS AND COMPLICATIONS

- Adverse reactions noted during placebo-controlled and open-label studies include asthenia, headache, abdominal pain, diarrhea, nausea, dyspepsia, flatulence, increased creatinine, pancreatitis, and hypophosphatemia.
- The drug should not be used concurrently with tenofovir disoproxil fumarate.
- Resistance to adefovir dipivoxil can result in viral load rebound and liver decompensation. In order to reduce the risk of resistance, adefovir dipivoxil should be used in combination with lamivudine and not as monotherapy.
- In patients with underlying renal dysfunction, chronic administration may result in nephrotoxicity. Patients should be monitored closely. The dosing

TABLE 231-8
Dosing Regimens for the Interferons

Condition	Dosage	Route	Duration
Condyloma acuminata	IFN-α2b 1 million units 3×/week	Intralesional	3 week
Chronic hepatitis C (with ribavirin)	PegIFN-α2a 180 μg once a week *or* PegIFN-α2b 1.5 μg/kg once a week	Subcutaneous	Dependent on response and genotype
Chronic hepatitis B	PegIFN-α2a 180 μg once a week *or* PegIFN-α2b 1.5 μg/kg once a week	Subcutaneous	At least 1 year

IFN = interferon; PegIFN = peginterferon.

interval should be modified in adult patients with baseline creatinine clearance <50 mL/min.
- HIV resistance may emerge in chronic hepatitis B patients with unrecognized or untreated HIV.

INTERFERON

(see also Chapter 234)

MECHANISM OF ACTION. Interferons are cytokines derived from a variety of cells. They have broad antiviral and immunomodulating effects.

PHARMACOKINETICS. Interferon is commonly given subcutaneously, but may also be administered intravenously or intramuscularly. It has a plasma half-life of 2–3 hours after intravenous administration, and 4–6 hours after subcutaneous or intramuscular administration. A prolonged half-life can be obtained with pegylated interferon.

INDICATIONS. Interferon therapy has been used for a variety of viral infections as well as for a number of neoplastic diseases, including melanoma and mycosis fungoides. In the setting of viral infections, interferon-α has been studied most extensively.

VIRAL DISEASES TREATED WITH INTERFERON

- Condylomata acuminata (intralesional treatment)
- Chronic hepatitis C infection in combination with ribavirin
- Chronic hepatitis B infection

DOSING REGIMENS. Common dosing regimens are provided in Table 231-8.

RISKS AND COMPLICATIONS. Side effects with interferon are common and often result in discontinuation of the drug. The most common cutaneous side effects include injection site reactions, alopecia, psoriasis, fixed drug eruptions, eczematous drug reactions, sarcoidosis, lupus, pigmentary changes and lichenoid eruptions.[82,83] Blood counts and metabolic panels should be monitored and patients must be monitored for depression, cognitive changes, and peripheral neuropathy.

Major Side Effects

- Flu-like syndrome
- Myalgia/arthralgia
- Gastrointestinal symptoms
- Granulocytopenia/thrombocytopenia
- Neurotoxicities
  - Depression
  - Cognitive disorders
- Alopecia
- Hepatotoxicity
- Autoantibody formation and induction of autoimmunity (including lupus erythematosus and Sjögren syndrome)[84]
- Induction of sarcoidosis[85]

TABLE 231-10
Dosing Regimen for Enfuvirtide

Drug	Dosage	Considerations Special	Main Toxicities	Principal Drug Interactions
Enfuvirtide (Fuzeon)	90 mg subcutaneously bid	Rotate injection sites Must be reconstituted ≤24 hours before use	Local injection site reactions Peripheral neuropathy Insomnia Increased risk of bacterial pneumonia	None known

Precautions. Interferon-α can cause serious depression in up to one-third of patients, and this must be monitored closely. Interferon-α should not be used to treat hepatitis B-related cirrhosis or decompensated liver disease because hepatitis flares could lead to further decompensation.

ACKNOWLEDGMENT

The authors thank Drs. Hay and Reichman for their work on this chapter in previous editions.

Chapter 232 :: Oral Antifungal Agents

:: Reza Jacob & Nellie Konnikov

ORAL ANTIFUNGALS AT A GLANCE

- Indicated for extensive fungal skin infections, tinea pedis, onychomycosis, and tinea capitis.
- Preventive therapy for the immunosuppressed.
- Major classes of antifungal medications used in outpatient settings are the allylamines (terbinafine), triazoles (itraconazole, fluconazole) and imidazoles (ketoconazole), griseofulvin, polyenes (nystatin, amphotericin B), and ciclopirox olamine.
- Speciation of fungal infections can be important in defining length of treatment and choosing the appropriate medication.

Oral antifungal agents are widely and frequently used for the treatment of fungal infections of the skin, nails, and mucous membranes.[1] This chapter summarizes the four most widely used oral antifungal agents in dermatology: (1) terbinafine, (2) itraconazole, (3) fluconazole, and (4) griseofulvin.

ALLYLAMINES: TERBINAFINE

Terbinafine hydrochloride is a topical and oral antimycotic agent that belongs to the family of compounds known as the *allylamines*. Naftifine, a topical antifungal agent, also belongs to this class. All allylamine derivatives possess a tertiary allylamine, a structural component crucial for antifungal activity (Fig. 232-1).[2] In vitro, terbinafine is highly active against dermatophytes but less active against molds, dimorphic fungi, and yeasts.[2]

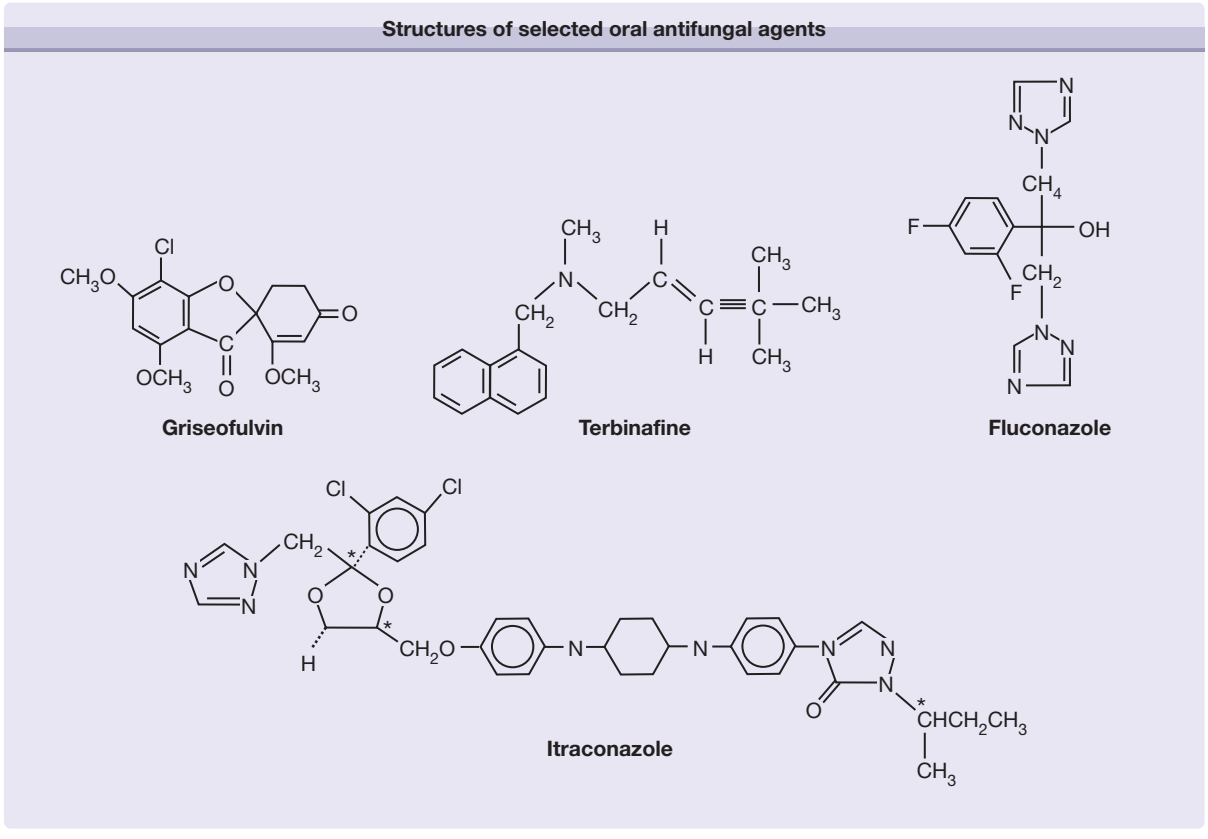

Figure 232-1 Structures of selected oral antifungal agents.

MECHANISM OF ACTION

Terbinafine inhibits the enzyme squalene epoxidase in the fungal cell membrane, thereby blocking the biosynthesis of ergosterol (Fig. 232-2).[3] Squalene epoxidase, a complex, microsomal noncytochrome P450 enzyme, catalyzes the first enzymatic step of ergosterol synthesis: the conversion of squalene into squalene epoxide. Consequently, terbinafine causes an abnormal intracellular accumulation of squalene and a deficiency in ergosterol.[4] In-vitro accumulation of squalene accounts for the drug's fungicidal activity by weakening the cell membrane, while deficiency of ergosterol is associated with the drug's fungistatic activity, as ergosterol is a component of fungal membranes required for normal growth.[4]

PHARMACOLOGY

Terbinafine is well absorbed from the gastrointestinal tract, mostly in chylomicrons. The distribution half-life is 1.5 hours, and the elimination half-life is 22 hours.[5] Terbinafine is highly lipophilic and keratophilic in nature and, therefore, is widely distributed upon absorption throughout skin and adipose tissue. Terbinafine is extensively biotransformed by the liver through oxidation by CYP2D6. More than 80% of the drug is excreted in urine; the rest is eliminated with feces.[6]

INDICATIONS

The US Food and Drug Administration has approved terbinafine tablets for the treatment of onychomycosis

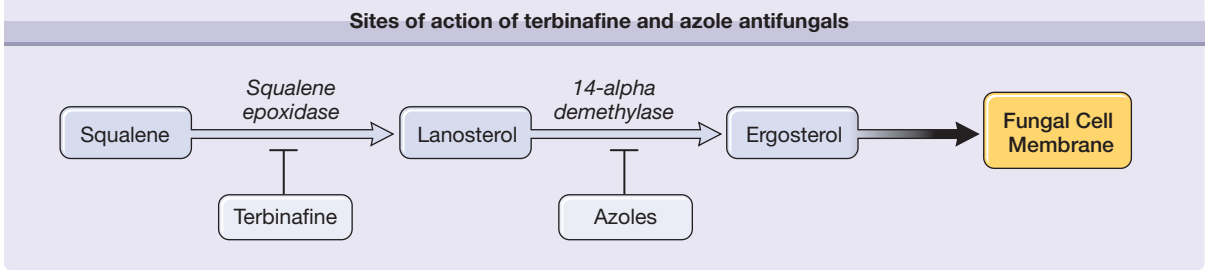

Figure 232-2 Sites of action of terbinafine and the azole antifungals.

BOX 232-1 TERBINAFINE TREATMENT OF FUNGAL INFECTIONS

- US Food and Drug Administration indications
  - Onychomycosis due to dermatophytes (tinea unguium of fingernails and toe-nails)
  - Tinea capitis in patients older than 4 years
- Other common uses
  - Onychomycosis due to *Candida* sp.
  - Tinea corporis and its subtypes
  - Tinea cruris
  - Tinea pedis

due to dermatophytes. Terbinafine oral granules are approved for the treatment of tinea capitis in patients over 4 years old. Terbinafine also has clinically proven efficacy for select cases of tinea corporis, tinea pedis, or tinea cruris that are widespread, severe, or resistant to topical treatment (Box 232-1).

PEDIATRIC. For the treatment of tinea capitis in children, terbinafine oral granules may be sprinkled over food such as pudding. The dosage is based on weight, with children weighing less than 25 kg receiving 125 mg/day, children weighing between 25 and 35 kg receiving 187.5 mg/day, and children weighing over 35 kg receiving 250 mg/day.[7] The standard treatment course is 6 weeks.[7] A study comparing a 6-week course of terbinafine 5–8 mg/kg versus a 6-week course of griseofulvin 10–20 mg/kg showed that mycological cure and complete (mycological plus clinical) cure rates were significantly higher for terbinafine than for griseofulvin.[8] However, subgroup analysis revealed that among patients infected with *Microsporum canis*, mycological and complete cure rates were superior with griseofulvin.[8] Conversely, among patients infected with *Trichophyton tonsurans*, mycological and complete cure rates were superior with terbinafine.[8]

Terbinafine can also be safely used in children for onychomycosis when dosed by weight as for tinea capitis.[9]

ADULT. Terbinafine is indicated for the treatment of onychomycosis of the toenails and fingernails caused by dermatophytes.[10] A dose of 250 mg/day for 12 weeks is typically used.

Several studies have compared the standard 12-week regimen of terbinafine to itraconazole, used in either a continuous or pulsed fashion. Terbinafine produced higher rates of clinical and mycological cures.[11–14] In a study comparing continuous terbinafine with intermittent itraconazole (1 week of treatment per four weeks) in the treatment of toenail onychomycosis, terbinafine was significantly more effective than pulsed itraconazole.[11] At week 72, the mycological cure in those patients treated with a 3-month daily course of terbinafine was 76%, compared with a mycological cure rate of 38% in those patients treated with a 3-month course of intermittent pulse therapy with itraconazole. A longer follow-up of these patients at an average of 54 months revealed 46% cure after continuous terbinafine versus 13% cure after the pulsed itraconazole[12]; similar results were found by others at 2-year follow-up.[13] Twelve weeks of terbinafine 250 mg/day is clearly superior to itraconazole 200 mg/day, with mycological cure rates of 73% versus 46% after 48 weeks of follow-up.[14]

Studies comparing various intermittent dosing regimens of terbinafine to the gold standard of continuous 12-week therapy for toenail onychomycosis have yielded mixed results.[15,16]

No increase in mycological cure rate is gained by aggressive debridement of the toenail when combined with terbinafine; however, the clinical appearance of the nail is improved with debridement.[17] Additionally, aggressive nail debridement, when combined with oral terbinafine, improves treatment satisfaction and reduces symptom frequency.[18] The addition of a topical lacquer such as ciclopirox 8% lacquer or amorolfine 5% lacquer (see Chapter 219) enhances clinical efficacy when used with terbinafine and then continued for 6–9 months after the cessation of terbinafine.[19,20]

Tinea corporis, tinea cruris, and tinea pedis can be treated with oral terbinafine with high clinical and mycological cure rates. In a study of 22 patients with tinea corporis and tinea cruris who used terbinafine 250 mg daily for 1 week, 100% clinical and mycological clearing was observed at 6 weeks.[21] In a study of moccasin tinea pedis and tinea manuum, after a 2-week course of terbinafine, 250 mg daily, there was an 86% mycological cure rate at 8 weeks.[22] Two placebo-controlled trials demonstrated that a 4- to 6-week course of terbinafine 250 mg daily is effective in the treatment of seborrheic dermatitis[23,24] (see Chapter 22). Interestingly, terbinafine is not effective orally for the treatment of tinea versicolor,[21] but twice daily application of topical terbinafine 1% solution, cream or gel, has been effective in randomized placebo-controlled trials.[25]

GERIATRIC. Terbinafine is well tolerated by the elderly and requires no further cautions than those for the general population.[26] A study of 504 patients older than 65 years of age confirmed efficacy and tolerance of the standard adult regimen for onychomycosis, with no reported drug interactions.[27]

PREGNANCY CONSIDERATIONS. Terbinafine is a pregnancy category B drug.[10]

DOSAGE SCHEDULES AND FORMULATIONS

Terbinafine is supplied as a 250-mg tablet or packets of oral granules. See Table 232-1.

INITIATING THERAPY

Positive tests [potassium hydroxide (KOH), culture, histology] for fungal infection should be documented before initiation of oral terbinafine therapy. Pretreatment

TABLE 232-1
Terbinafine Oral Dosing Regimens

	Adult	Pediatric
Onychomycosis	Fingernails: 250 mg/day × 6 weeks Toenails: 250 mg/day × 12 weeks	3–6 mg/kg/day × 6–12 weeks
Tinea capitis	250 mg/day × 2–8 weeks	Under 25 kg: 125 mg/day × 6 weeks 25–35 kg: 187.5 mg/day × 6 weeks Over 35 kg: 250 mg/day × 6 weeks
Tinea corporis, tinea cruris	250 mg/day × 1–2 weeks	3–6 mg/kg/day × 1–2 weeks
Tinea pedis (moccasin)	250 mg/day × 2 weeks	
Seborrheic dermatitis	250 mg/day × 4–6 weeks	

serum transaminase tests are advised for all patients before taking terbinafine, and the drug is not recommended for patients with liver or renal disease.[22]

MONITORING THERAPY

Many physicians advocate monitoring liver function after 6 weeks of therapy, although the incidence of hepatic toxicity is very low [see Sections "Complications (Adverse Effects)" and "Risks and Precautions"]. Because of transient lymphopenia observed in patients on terbinafine, complete blood cell counts should be monitored in immunodeficient patients who are receiving terbinafine for longer than 6 weeks.[28] If signs or symptoms of secondary infection occur in patients while on terbinafine, a complete blood count should be performed to rule out neutropenia.[28] Cautions and monitoring in children are the same as for adults, but there is evidence that children may suffer fewer adverse events.[9]

COMPLICATIONS (ADVERSE EFFECTS)

Because of its high selectivity, terbinafine is generally well tolerated with a low incidence of adverse side effects. The most common side effects after oral administration are of a gastrointestinal nature (3.5%–5.0%).[29] Other rare side effects include headache, exanthematous eruption, acute generalized exanthematous pustulosis, pustular psoriasis, subacute cutaneous lupus erythematosus, chest pain, elevated laboratory parameters, loss of taste, fatigue, and malaise.[28–33] A few cases of hepatocellular injury (including fulminant hepatic failure),[34,35] reversible agranulocytosis,[36] and severe skin reactions, including toxic epidermal necrolysis and erythema multiforme, were also reported.[37]

RISKS AND PRECAUTIONS

Terbinafine should be prescribed with caution in patients with hepatic disease or history of hepatic toxicity with other medications (Box 232-2). Furthermore, there is insufficient data to recommend its use in patients with renal impairment. Because terbinafine rarely causes a lupus-like rash and neutropenia, patients with known systemic lupus erythematosus or immunodeficiency also may not be good candidates for this medication.[10]

DRUG INTERACTIONS

Terbinafine is not contraindicated with any specific drug. However, cytochrome P450 (CYP) enzymes metabolize terbinafine. Plasma clearance of terbinafine is increased by the P450-inducer rifampin and decreased by the P450-inhibitor cimetidine.[38] Terbinafine is also reported to decrease cyclosporine levels by increasing cyclosporine clearance.[22,39] Isolated reports of interactions with warfarin have been reported; however, prospective pharmacokinetic studies have not revealed any clinically significant reactions.[39] It was shown that terbinafine inhibits CYP2D6, a cytochrome P450 isoenzyme that metabolizes tricyclic antidepressants and other psychotropic drugs.[40] Other drugs predominantly metabolized by this enzyme include β-blockers, selective serotonin reuptake inhibitors, and monoamine oxidase inhibitors type B.[22] In a postmarketing surveillance study of patients on terbinafine, no adverse drug interactions with CYP2D6 substrates

BOX 232-2 TERBINAFINE RISKS AND PRECAUTIONS

- Contraindications
  - Hypersensitivity to terbinafine
- Precautions
  - Pregnancy (category B) and lactation
  - Chronic or active hepatic impairment[a]
  - Renal impairment (creatinine clearance <50 mL/min)
  - Immunodeficiency or immunosurpression[b]

[a]If clinical or laboratory evidence of liver injury exists, terbinafine should be discontinued.
[b]In these patients, CBC at baseline and every 6 weeks while under treatment is recommended. Terbinafine should be discontinued if the neutrophil count is less than 1000/mm^3.

were reported.[41] However, there have been two reports of nortriptyline intoxication induced by terbinafine.[42,43]

TRIAZOLES

Both itraconazole and fluconazole are triazole antimycotic agents sharing a common structural moiety—a triazole ring—not found in azoles of the imidazole family.

ITRACONAZOLE

Itraconazole (Fig. 232-1) is a highly lipophilic compound that has a wide spectrum of activity.[44] In vitro, it is fungistatic and effective against dermatophytes, yeast, molds, and dimorphic fungi.[45–47]

MECHANISM OF ACTION. Itraconazole inhibits 14-α-demethylase, a microsomal cytochrome P450 enzyme, in the fungal membrane (Fig. 232-2).[48] 14-α-Demethylase is necessary for the conversion of lanosterol to ergosterol, which is the principal structural component of the fungal cell membrane.[46] Consequently, the accumulation of 14-α-methylsterols leads to the impairment of membrane permeability and membrane-bound enzyme activity and to the arrest of fungal cell growth.

PHARMACOLOGY. The serum concentration of itraconazole is influenced by several parameters, including food and gastric acidity.[49,50] Itraconazole is extensively metabolized, primarily by the CYP3A4 isoenzyme system to more than 30 metabolites. Hydroxyitraconazole is the main metabolite. Approximately 54% of the metabolized drug is excreted in the feces, and 34% is excreted in the urine. After single-dose administration, the terminal elimination half-life is 21 hours for itraconazole and 12 hours for its active metabolite. The pharmacokinetic variables of itraconazole are not affected in patients with renal insufficiency.[51] In patients with liver cirrhosis, the absorption is slightly increased and the half-life is prolonged because of a reduced first-pass metabolism. Absorption of the standard tablet formulation is decreased in patients with acquired immunodeficiency syndrome as a result of gastric hypochlorhydria.[51] A new hydroxypropyl-β-cyclodextrin oral solution formulation is better absorbed in a fasting state than with food,[52] appropriate for patients who cannot ingest large amounts of food or have high gastric pH. Young children, especially those less than 5 years of age, have lower serum levels than adults and usually require twice daily dosing.[53]

INDICATIONS. Itraconazole has the broadest efficacy compared to other commonly prescribed antifungals.[47] Thus, it is a first-line therapy for infections due to *Candida* and other nondermatophyte species (Box 232-3).

Pediatric. Itraconazole can be used to treat tinea capitis in children. It is more often prescribed in the capsule formulation with food or acidic beverages such as colas because the cyclodextrin in the liquid form of itraconazole causes more gastrointestinal side effects such as diarrhea and also due to reports of neoplasms associated with high doses in murine and rat models.[54] Nevertheless, for children who cannot swallow capsules or take capsules with food, the solution has a pleasant taste and is considered to be safe.[55] Itraconazole is dosed at 5 mg/kg per day for 4–6 weeks.[56] Children who weigh between 15 and 30 kg require one 100 mg capsule daily; children weighing 30–40 kg require 100 mg 1 day alternating with 200 mg the next day, to average 150 mg daily.[57] Children weighing over 50 kg can be dosed as adults.[55] Tinea capitis caused by *T. tonsurans* requires a course lasting 2–4 weeks[58]; however, a longer treatment course is recommended for *M. canis*.[59] Because onychomycosis is less common in children than in adults, there is much less data available for treatment of pediatric onychomycosis. For better compliance due to decreased adverse effects, lower cost, and overall reduced exposure to drug, one can prescribe a pulsed regimen of 5 mg/kg/day for 1 week alternating with 3 weeks off; two pulses are recommended for fingernail involvement and three pulses for toenail involvement.[9]

The oral solution is a good option for oropharyngeal or esophageal candidiasis in children, even in fluconazole-resistant infections.[53]

Adult. Itraconazole has been approved for the treatment of onychomycosis caused by dermatophytes[54] and is effective as continuous or pulse therapy. A 2-month course of itraconazole pulse therapy is necessary for fingernail onychomycosis, while toenail onychomycosis requires a 3-month course. A single course consists of 200 mg twice daily for 1 week per month. Itraconazole pulse therapy is at least equal in efficacy, if not superior, in the treatment of toenail onychomycosis

BOX 232-3 ITRACONAZOLE TREATMENT OF FUNGAL INFECTIONS

- US Food and Drug Administration indications
  - Onychomycosis due to dermatophytes in immunocompetent patients
    - Continuous therapy for fingernails and toenails
    - Pulsed therapy for fingernails
  - Systemic mycoses (blastomycosis, histoplasmosis, aspergillosis)
  - Empiric antifungal therapy in febrile neutropenia (oral solution)
  - Oropharyngeal candidiasis (oral solution)
  - Esophageal candidiasis (oral solution)
- Other common uses
  - Onychomycosis due to *Candida* sp.
  - Tinea corporis and its subtypes
  - Tinea cruris
  - Tinea pedis
  - Tinea capitis

when compared to continuous itraconazole therapy.[60] Itraconazole has been used for the treatment of tinea pedis. A 1-week course of itraconazole, 200 mg twice daily, is more effective than 200 mg or 100 mg daily for 2–4 weeks.[61] Nonetheless, itraconazole is less effective in the treatment of dermatophyte infections than terbinafine (see Section "Allylamines: Terbinafine"). Itraconazole at a dose of 200 mg daily for 5–7 days is effective in the treatment of pityriasis versicolor.[62] Recurrence, which is common in this disease, can be prevented by taking 200 mg twice daily for 1 day a month.[62]

Geriatric. Itraconazole (pulse) therapy is effective and safe in the elderly and only requires caution in the setting of comorbidities and drug interactions [see Section "Complications (Adverse Effects)"].[26]

Pregnancy Considerations. Itraconazole is a pregnancy category C drug, and therefore, is not recommended during pregnancy or while nursing because it is excreted in human milk.[54]

DOSAGE SCHEDULES AND FORMULATIONS.

Itraconazole is supplied in 100-mg capsules, a 10-mg/mL oral solution, and an intravenous solution. Capsules should be taken with a full meal to ensure maximum absorption[54] (see Table 232-2).

INITIATING THERAPY.

Positive tests (KOH, culture, histology) for fungal infection should be documented before initiation of oral itraconazole therapy. Baseline evaluation of hepatic function is recommended in patients with preexisting liver disease, or if lengthy treatment is anticipated.[54]

MONITORING THERAPY.

Hepatic function monitoring is indicated through therapy only for those patients with preexisting liver disease or those with a history of hepatic toxicity with other medications.[54,63] When itraconazole must be administered with medications, it is known to compete with for hepatic enzymes, appropriate monitoring for drug levels or toxic effects of these medications is indicated (see Section "Drug Interactions").

COMPLICATIONS (ADVERSE EFFECTS).

The most common reported side effects associated with itraconazole therapy are of a gastrointestinal nature.[64] Less-frequent adverse effects are hypertriglyceridemia, edema,[65] urticaria, anaphylaxis, erythema multiforme, headache, neuropathy, impotence, hypertension, leukopenia, nephrotic syndrome, and mildly elevated liver enzymes.[54,64] Instances of hepatic injury and, rarely, fulminant hepatotoxicity are associated with the administration of itraconazole. There are also rare reports of congestive heart failure and pulmonary edema. When administered intravenously to dogs and healthy human volunteers, negative inotropic effects were noted.[66]

RISKS AND PRECAUTIONS.

Administration of itraconazole to patients with a history of heart failure is contraindicated, and it is not recommended for patients with a history of liver disease.[54] There are also several significant drug interactions to be aware of (see Box 232-4).

DRUG INTERACTIONS.

Itraconazole inhibits 14-α-demethylase, a fungal P450 enzyme[48] and a member of the same group of enzymes present in the human liver that is responsible for the metabolism of many drugs (Fig. 232-2). Itraconazole specifically inhibits CYP3A4, and consequently, may increase plasma concentrations of drugs metabolized by this pathway. The concomitant use of itraconazole and sildenafil can lead to a reduction in sildenafil clearance.[67] Cisapride, terfenadine, quinidine, dofetilide, oral midazolam, pimozide,

TABLE 232-2
Itraconazole Oral Dosing Regimens

	Adult	Pediatric
Onychomycosis	Fingernails: 200 mg bid × 1 week/month × 2 pulses Toenails: 200 mg/day × 12 weeks *Or* 200 mg bid × 1 week/month × 3 pulses	Fingernails: 5 mg/kg/day × 1 week/month × 2 pulses[a] Toenails: 5 mg/kg/day × 1 week/month pulsed × 3 pulses
Tinea capitis	250 mg/day × 2–8 weeks	*Trichophyton* infections: 5 mg/kg/day × 2–4 weeks Microsporum infections: 5 mg/kg/day × 4–8 weeks
Tinea corporis, tinea cruris, tinea pedis	200 mg bid × 1 week *or* 100–200 mg/day × 2–4 weeks	Dose by weight × 1–4 weeks
Oropharyngeal candidiasis Pityriasis versicolor	Swish and swallow solution 100–200 mg/day 200 mg/day × 5–7 days, prevent recurrence with 200 mg bid once/month	Swish and swallow solution by weight[a]

[a]Pediatric weight-based dosing: 100 mg/day (15–30 kg), 100 mg/day alternating with 200 mg/day (30–40 kg), 200 mg/day (>40 kg).

BOX 232-4 ITRACONAZOLE RISKS AND PRECAUTIONS

- Contraindications
  - Hypersensitivity to itraconazole or vehicle components
  - **Coadministration with certain drugs metabolized by CYP3A4**, including cisapride, midazolam, pimozide, quinidine, dofetilide, and levacetylmethadol (levomethadyl); serious cardiovascular events, including QT prolongation, torsades de pointes, ventricular tachycardia, cardiac arrest, or sudden death may occur
- Risks and precautions
  - Hypersensitivity to other azoles
  - Hepatic disease or insufficiency
  - History or risk of **heart failure** or **ventricular dysfunction**, angina, or valvular disease (negative inotropic effect observed)
  - Pregnancy (category C) or lactation
  - Achlorhydria (drug not absorbed)
  - Co-administration with certain drugs metabolized by CYP3A4, including midazolam, triazolam, lovastatin, and simvastatin

Boldfaced type indicates a US Food and Drug Administration Black Box warning.

triazolam, and 3-hydroxy-3-methylglutaryl coenzyme A–reductase inhibitors metabolized by CYP3A4, such as lovastatin and simvastatin, are contraindicated with itraconazole. Because itraconazole is metabolized by CYP3A4, inducers or inhibitors of CYP3A4 may alter itraconazole levels. Absorption of itraconazole may be decreased by the concomitant administration of antacids, H_2-blockers, and proton pump inhibitors.[3]

FLUCONAZOLE

Fluconazole (Fig. 232-1) is fungistatic in vitro[68] and is effective against many yeasts (with the exception of *Candida krusei*) and dermatophytes.[69]

MECHANISM OF ACTION. Fluconazole, like itraconazole, inhibits 14-α-demethylase, a microsomal cytochrome P450 enzyme, in the fungal membrane (Fig. 232-2).[48]

PHARMACOLOGY. The pharmacokinetic parameters of fluconazole are similar for both intravenous and oral administration.[69] Near complete absorbtion of the triazole appears to be comparable in both postprandial and fasting states; absorbtion is not dependent on stomach acidity.[50,70] Fluconazole exhibits a long half-life of 25–30 hours, and a steady-state level is reached after 7 days of once-daily administrations. Fluconazole is only weakly bound to plasma proteins, with about 90% of the drug circulating free in the plasma. The drug is resistant to hepatic metabolism, and hence, approximately 80% of fluconazole is excreted unchanged in urine, with 2% in feces and approximately 11% as metabolites in urine.[71] The ability to diffuse substantially into the cerebrospinal fluid distinguishes this compound from many other antimycotic agents.[72] The levels of fluconazole in cerebrospinal fluid, saliva, vaginal tissue, sputum, skin, and blister fluids are reported to be comparable with or to exceed simultaneous plasma concentrations.[73] Altered fluconazole pharmacokinetics, including decreased plasma clearance, are detected in patients with cirrhosisand renal impairment.[74,75] In children over 3 months of age, fluconazole clearance is more rapid than in adults.[53]

INDICATIONS. Fluconazole is established as a first-line therapy for mucocutaneous candidiasis (Box 232-5). It is useful for its convenient once-weekly dosing schedule (Table 232-3).

Pediatric. Fluconazole has been used successfully to treat tinea capitis at 6 mg/kg/day for 20 days for *T. tonsurans* infection and at 5 mg/kg/day for 30 days.[57,76] A course as brief as 2 weeks may be equally effective as terbinafine and itraconazole for *Trichophyton* infections.[58] When *M. canis* is present, a longer treatment course is recommended.[59] A 6-week course of fluconazole 6 mg/kg/day produced comparable mycological and clinical cure rates compared to griseofulvin 11 mg/kg/day microsize formulation.[77]

Adult. Vaginal candidiasis can conveniently and safely be treated with a single 150-mg dose of fluconazole, or weekly for 6 months or longer in the case of recurrent vulvovaginal candidiasis.[78] Interestingly, a daily oral probiotic *Lactobacillus* supplement enhances

BOX 232-5 FLUCONAZOLE TREATMENT OF FUNGAL INFECTIONS

- US Food and Drug Administration indications
  - Vaginal candidiasis
  - Oropharyngeal and esophageal candidiasis
  - Cryptococcal meningitis
  - Prophylaxis against candidiasis in bone marrow transplant patients
- Other common uses
  - Onychomycosis due to dermatophyte and *Candida* sp.
  - Cutaneous and chronic mucocutaneous candidiasis
  - Tinea corporis and its sub-types
  - Tinea cruris
  - Tinea pedis
  - Tinea capitis
  - Pityriasis versicolor
  - Sporotrichosis

TABLE 232-3
Fluconazole Oral Dosing Regimens

	Adult	Pediatric
Oropharyngeal candidiasis	200 mg once, then 100 mg/day × 14 days	6 mg/kg once, then 3 mg/kg/day × 14 days[a]
Vaginal candidiasis	150 mg once	
Tinea pedis, cruris, or corporis	150 mg/week × 3–4 weeks	
Tinea capitis		6 mg/kg/day × 2–6 weeks

[a]For neonates 0–14 days: 6 mg/kg on the first day, followed by 3 mg/kg every 72 hours.

rates of clinical and mycological cure in vulvovaginal candidiasis after treatment with 150-mg single-dose fluconazole.[79]

When used to treat oropharyngeal candidiasis, fluconazle is typically given at doses of 200 mg on day 1 followed by 13 days of 100 mg per day. However, a single dose of 750 mg is as effective as the standard 14-day regimen in patients with HIV and offers greater convenience.[80]

For the treatment of tinea pedis, weekly doses of fluconazole 150 mg have been given for a period of 3–4 weeks,[81] with a 75% mycological cure rate at 4 weeks. Fluconazole at a dose of 150 mg weekly for 24 weeks is significantly inferior to terbinafine 250 mg daily for 12 weeks in the treatment of onychomycosis.[82] Pityriasis versicolor can be effectively treated with a single 400-mg dose of fluconazole.[83] In a small, open-label randomized study of pityriasis versicolor treatment comparing a single 400-mg dose of fluconazole with a single 400-mg dose of itraconazole, fluconazole led to greater cure than itraconazole (65% vs. 20%, respectively) with fewer relapses noted (35% vs. 60%, respectively) at an 8-week follow-up assessment by KOH and culture tests.[84] Oral fluconazole is not the treatment of choice for seborrheic dermatitis, as two 300 mg doses spaced one week apart showed essentially no improvement over placebo.[85]

Geriatric. Fluconazole is well tolerated in the elderly; however, dose modification is required in elderly patients with renal impairment.[73,86]

Pregnancy Considerations. Fluconazole is a pregnancy category C drug and is not recommended in pregnant or nursing mothers.[87]

DOSAGE SCHEDULES AND FORMULATIONS. Fluconazole is available in 50-mg, 100-mg, 150-mg, and 200-mg tablets; in 10-mg/mL and 40-mg/mL oral solutions; and in an intravenous form. It is approved for use in children age 6 months and older, although not specifically for tinea capitis (see Table 232-3).

INITIATING THERAPY. Positive tests (KOH, culture, histology) for fungal infection should be documented before initiation of oral fluconazole. There are no specific recommendations for baseline laboratories before starting fluconazole therapy.[87]

MONITORING THERAPY. There are no specific monitoring recommendations other than drug levels in renal disease. Because fluconazole is prescribed as a one-time dose or once weekly, there is little need for laboratory monitoring other than that indicated by side effects.[87]

COMPLICATIONS (ADVERSE EFFECTS). The most common recognized side effects of fluconazole therapy are gastrointestinal.[88] Adverse reactions such as fixed drug eruptions, thrombocytopenia, transient amenorrhea, elevated liver function tests, mild increase in levels of serum creatine phosphokinase, dizziness, anorexia, and alopecia have been observed, and most resolve with continuing fluconazole therapy.[87,89] There are rare reports of fatal hepatotoxicity associated with fluconazole, but most studies in both humans and rats have shown less hepatoxicity when compared to other azoles.[90] There are even fewer reports of torsades de pointes, with or without concomitant medications or underlying cardiac arrhythmias.[91]

RISKS AND PRECAUTIONS. To prevent serious hepatic and cardiac toxicity, one should exercise caution when prescribing to patients with multiple comorbidities, immunosuppression or preexisting liver or cardiac disease; close monitoring may be helpful in these patients (see Box 232-6).

DRUG INTERACTIONS. In humans, fluconazole inhibits both CYP3A4 and CYP2C9 in a dose-dependent manner,[3] and consequently may increase plasma concentrations of drugs metabolized by these pathways. Therefore, a number of drugs that are metabolized by CYP3A4 or CYP2C9 are contraindicated or require close monitoring. Coadministration of terfenadine or cisapride with fluconazole is contraindicated.[87] (See Box 232-6.)

VORICONAZOLE

Voriconazole is a second-generation triazole agent available in oral and intravenous formulations that is

BOX 232-6 FLUCONAZOLE RISKS AND PRECAUTIONS

- Contraindications
  - Hypersensitivity to fluconazole
  - Coadministration with cisapride
- Risks and precautions
  - Hypersensitivity to other azoles
  - Proarrhythmic cardiac conditions
  - Hepatic impairment
  - Renal impairment (dose adjustment required)
  - Pregnancy (category C) or lactation

used widely outside of dermatology for the treatment of invasive fungal diseases, particularly invasive aspergillosis.[92] Although this drug in infrequently prescribed by dermatologists, voriconazole has several important adverse effects that the dermatologist should be familiar with.[93] Cutaneous adverse effects occur in fewer than 10% of patients taking voriconazole.[94] Voriconazole can induce a spectrum of photosensitivity reactions, ranging from sunburn-like reactions after minimal photoexposure[94,95] to premature photoaging in patients on long-term treatment[96] to pseudoporphyria, with erythema and blistering in photoexposed areas accompanied by cheilitis.[97,98] Photosensitivity and pseudoporphyria induced by voriconazole disappear promptly after discontinuation of the drug.[93–98] In addition to photosensitivity, voriconazole is also a known cause of Steven-Johnson syndrome and life-threatening toxic epidermal necrolysis, although these reactions are rare.[99,100] Skin cancers including melanoma in situ has been reported.[101]

IMIDAZOLES: KETOCONAZOLE

Ketoconazole was introduced in the 1970s as the first effective oral azole antifungal. However, because of the drug's many adverse reactions and the availability of safer, efficacious medications, it is no longer used as a first-line agent for the treatment of dermatophyte or yeast infections.

MISCELLANEOUS: GRISEOFULVIN

Griseofulvin (Fig. 232-1; Box 232-7) has been used since 1958 for the treatment of dermatophyte infections.[59] Griseofulvin is not effective for candidiasis, deep fungal infections, or pityriasis versicolor.

MECHANISM OF ACTION

Griseofulvin is fungistatic in vitro,[59] and has a narrow spectrum of antimycotic activity. It disrupts microtubule mitotic spindle formation, thereby causing mitotic arrest at the metaphase stage.[102]

BOX 232-7 GRISEOFULVIN TREATMENT OF FUNGAL INFECTIONS

- US Food and Drug Administration indications
  - Onychomycosis due to dermatophytes (tinea unguium of fingernails and toenails)
  - Tinea capitis
  - Tinea corporis
  - Tinea cruris
  - Tinea barbae
  - Tinea pedis

PHARMACOLOGY

The absorption of griseofulvin is enhanced by several factors, including concurrent intake of a fatty meal and a smaller particle size formulation. Griseofulvin is mainly metabolized by the liver before excretion.[103]

INDICATIONS

As one of the early antifungal medications, griseofulvin has been US Food and Drug Administration approved for several dermatophyte infections. However, because of its limited spectrum of coverage compared to other agents and the lengthy courses required, griseofulvin is not used as a first-line therapy for fungal infections other than tinea capitis.

PEDIATRIC. Griseofulvin is an acceptable choice for the first-line treatment of tinea capitis in children.[68] Griseofulvin is recommended at a dosage higher than that suggested by the manufacturers at 20–25 mg/kg/day (microsize), or 15–20 mg/kg/day (ultramicrosize) to complete a minimum course of 6–8 weeks for *T. tonsurans*.[57] However, longer treatment with griseofulvin is recommended for *M. canis* infections.[57]

ADULT. Although griseofulvin is indicated for the treatment of fingernail and toenail onychomycosis, therapy is prolonged with low cure and high relapse rates, requiring approximately 6 months for the treatment of fingernails and 12 months for toenails.[102]

GERIATRIC. The safety of griseofulvin therapy in the elderly has not been formally evaluated in trials. However, studies including elderly patients have not specifically reported an increased incidence of adverse effects among this age group.[104,105]

PREGNANCY CONSIDERATIONS. Griseofulvin is a pregnancy category C drug. Because griseofulvin interferes with chromosomal distribution during cell division, males should wait at least 6 months after completing griseofulvin therapy before fathering a child.[106]

TABLE 232-4
Griseofulvin Oral Dosing Regimens

	Adult		Pediatric (over 2-years-old)	
	Microsize	**Ultramicrosize**	**Microsize[a]**	**Ultramicrosize[b]**
Tinea corporis or cruris	500 mg/day × 2–4 weeks	300–375 mg/day × 2–4 weeks	10–20 mg/kg/day × 2–4 weeks	5–10 mg/kg/day × 2–4 weeks
Tinea capitis	500 mg/day × 4–8 weeks	300–375 mg/day × 4–8 weeks	15–20 mg/kg/day × 6–12 weeks	5–10 mg/kg/day × 6–12 weeks
Tinea pedis	750–1,000 mg/day × 4–8 weeks	660–750 mg/day × 4–8 weeks	10–20 mg/kg/day × 4–8 weeks	5–10 mg/kg/day × 4–8 weeks
Fingernail onychomycosis	750–1,000 mg/day × 4 months	660–750 mg/day × 4 months	10–20 mg/kg/day × 4 months	5–10 mg/kg/day × 4 months
Toenail onychomycosis	750–1,000 mg/day × 6 months	660–750 mg/day × 6 months	10–20 mg/kg/day × 6 months	5–10 mg/kg/day × 6 months

[a]Max dose of 1000 mg/day.
[b]Max dose of 750 mg/day.

DOSAGE SCHEDULES AND FORMULATIONS

Griseofulvin is formulated as ultramicrosize tablets in 125-mg, 165-mg, 250-mg, and 330-mg doses.[107] It is also formulated as griseofulvin microsize and is available as 250-mg and 500-mg tablets and in a 125-mg/5-mL suspension.[108] To maximize absorption, it should be taken with fatty foods. The manufacturers recommend 5–10 mg/kg/day (ultramicrosize) or 10–20 mg/kg/day (microsize). See Table 232-4.

INITIATING THERAPY

Positive tests (KOH, culture, histology) for fungal infection should be documented before initiation of therapy. There are no specific recommendations for baseline laboratories before starting griseofulvin therapy.

MONITORING THERAPY

There are no specific monitoring recommendations.

COMPLICATIONS (ADVERSE EFFECTS)

The most common side effects are related to the gastrointestinal tract and the central nervous system, such as headache, dizziness, and insomnia.[102] The drug is reported to precipitate lupus erythematosus and, rarely, severe skin reactions, including Stevens-Johnson and angioedema. As a result of impaired porphyrin metabolism, griseofulvin therapy is associated with photosensitivity reactions. Griseofulvin is contraindicated in patients with porphyria and hepatocellular failure.[107]

RISKS AND PRECAUTIONS

Patients should be warned about potential photosensitivity induced by griseofulvin and the possibility of lupus erythematosus or a lupus-like syndrome.[108] See Box 232-8.

DRUG INTERACTIONS

Griseofulvin induces CYP3A4, leading to lower plasma levels of drugs metabolized by this pathway.[3] Two important examples are decreased anticoagulation by warfarin and potential decreased effectiveness of oral contraceptive pills.

ORAL ANTIFUNGALS IN THE IMMUNOCOMPROMISED

Oral antifungal therapy is increasingly important for the treatment and prevention of infection in

BOX 232-8 GRISEOFULVIN RISKS AND PRECAUTIONS

- Contraindications
  - Hypersensitivity to griseofulvin
- Risks and precautions
  - Hepatic impairment
  - Porphyrias (drug interferes with porphyrin metabolism)
  - Systemic lupus erythematosus (drug can exacerbate SLE)
  - Pregnancy (category C) or lactation

immunocompromised individuals, even in an outpatient setting. For example, as more patients survive organ transplantation,[109,110] more fungal infections are likely to be observed. In one report of 100 consecutive liver transplant patients seen by a dermatology clinic, fungal infections were much more common (19% of total skin infections) than bacterial (5%) or viral (2%).[111]

Candidiasis and aspergillosis are the most common opportunistic fungal infections in many immunocompromised populations. The extensive use of fluconazole prophylactically in patients with acquired immunodeficiency syndrome, transplants, hematologic malignancies, and other causes of immunosuppression has led to decreased susceptibility of some *Candida* infections to fluconazole.[112] Itraconazole solution, 100 mg/day for 14 days, is equivalently effective as fluconazole, 100 mg/day for 14 days, with the added advantages of broader coverage than fluconazole, greater bioavailability than itraconazole capsules on an empty or hypochloridic stomach, easier swallowing by dysphagic patients, and potential effectiveness in cases of fluconazole-resistant strains of *C. albicans*.[113,114] Itraconazole solution has shown superior prevention of death from disseminated candidiasis and aspergillosis than fluconazole solution in immunosuppressed pediatric patients.[53] One should keep in mind, however, that itraconazole solution has more drug interactions and potential compliance issues due to nausea and diarrhea. *Posaconazole* is an extended-spectrum triazole with activity against strains of fluconazole-resistant *Candida*. In patients with oropharyngeal candidiasis and HIV/AIDS, a comparison of a two-week course of posaconazole to fluconazole demonstrated that posaconazole was as effective as fluconazole in producing a successful clinical outcome, yet posaconazole was more effective in sustaining clinical success after treatment was stopped.[115]

New antifungal medications with activity against resistant species and excellent safety profiles continue to be developed. The new class of antifungals, *echinocandins*, provides both benefits by specifically targeting fungal cell wall β-1,3-D-glucan synthesis (absent in mammalian cells). However, poor oral bioavailability currently limits these drugs to intravenous formulations.[116]

EVIDENCE-BASED MEDICINE CONSIDERATIONS

Interpretation of competing studies continues to be difficult because endpoints have not been uniform. Such endpoints may be mycological cure, clinical cure, complete cure, and effective treatment. Criticisms of these studies include the fact that many were open label, leading to investigator bias.[117] Many studies fail to take into account the physiology of nail growth.[13] Toenails can take up to 18 months to grow out fully. Therefore, studies at 48–52 weeks might not accurately reflect clinical or mycological cure.

Several studies of the treatment of tinea pedis did not specify the type of tinea pedis, despite known variations amongst forms of tinea pedis in response rate to therapy. Studies of moccasin tinea pedis are preferred, as successful treatment usually indicates that the antifungal drug will be effective in the milder forms of tinea pedis as well as tinea corporis and tinea cruris.[117] Finally, the efficacy of antifungal agents depends on the sensitivity of the dermatophyte. For example, in the treatment of tinea capitis, if the causative organism is *M. canis*, longer treatments may be needed than if the organism is *T. tonsurans*.[44] In North America, most tinea capitis is caused by *T. tonsurans*, while surveys in the United Kingdom demonstrate that the predominant dermatophyte is *M. canis*.[59] Consequently, trials assessing the efficacy of a drug may be influenced by the culprit dermatophyte and indirectly by the location of the study.

EMERGING PARADIGMS

Both tinea capitis and onychomycosis due to dermatophytes remain challenging infections to cure. Oral terbinafine has emerged as a safe and effective treatment of tinea capitis, surpassing griseofulvin in mycological and complete cure rates for patient infected with *T. tonsurans*.[8] Oral terbinafine has remained the most effective monotherapy for onychomycosis.[11–14] Moreover, the addition of a topical antifungal lacquer such as ciclopirox 8% lacquer or amorolfine 5% lacquer enhances clinical efficacy when used with terbinafine and then continued for 6–9 months after the cessation of terbinafine.[19,20]

Chapter 233 :: Immunosuppressive and Immunomodulatory Drugs

:: Jeffrey P. Callen

IMMUNOSUPPRESSIVE AND IMMUNOMODULATORY DRUGS AT A GLANCE

- The main goals in immunotherapy are safety and effectiveness.
- Unlike immunomodulators, immunosuppressive drugs are all characterized by a narrow therapeutic window requiring precise dosing and close side-effect monitoring.
- The highest level of safety and effectiveness in immunotherapy therapy is currently accomplished by the use of combined regimens.
- An additive or synergistic combined immunotherapeutic regimen allows significant reduction of dose-dependent drug side effects maintaining or improving the effectiveness, respectively.
- A comprehensive knowledge of the pathophysiology of the treating disease as well as of the pharmacokinetics and pharmacodynamics concepts is crucial for delineating the most effective and safest therapeutic regimens.

There has been significant progress in the search for selective immunomodulation; the most significant advance in immunotherapy has been the reduction of systemic corticosteroid therapy by the early or concomitant introduction of immunosuppressive therapies. Immunosuppressants are characterized by (1) a low therapeutic index (narrow window between the therapeutic and toxic range) and (2) intra- and interindividual variation of the pharmacokinetics of these agents. These obstacles are usually overcome by precise drug dosing (ideal/lean body weight) as well as close monitoring of drug levels (parent and metabolite serum peak and trough levels) and end-organ toxicity. The main goals in immunotherapy are safety and effectiveness, which currently are accomplished by the use of combination therapy.[1,2] (See Fig. 233-1.) Although in transplantation medicine, agents are often combined, in dermatologic usage, these agents are usually used as corticosteroid-sparing agents and are less frequently used in combination except perhaps with methotrexate.[3] Within the dermatologic community, the use of cyclosporine and related macrolactam drugs has fallen with the introduction of biologic agents targeted more precisely at the presumed pathogenetic factors. In addition, many of the biologic agents have less toxicity than these broad-spectrum immunosuppressive therapies. However, the use of mycophenolate mofetil has increased within the dermatologic community.

MYCOPHENOLATE MOFETIL

Mycophenolate mofetil (MMF) is an ethyl ester of its active metabolite, mycophenolic acid (MPA)—a product of several *Penicillium* species.

MECHANISM OF ACTION

MMF is the reformulated product of MPA, but with enhanced bioavailability. MPA inhibits the type II isoform of inosine monophosphate dehydrogenase in the de novo pathway of purine synthesis. The proliferation of both T- and B-lymphocytes are susceptible to this drug effect, because they minimally use the hypoxanthine–guanine phosphoribosyl transferase salvage pathway for purine synthesis. Decreased delayed hypersensitivity and immunoglobulin levels have been observed in treated patients.

PHARMACOKINETICS

The drug is rapidly absorbed after oral administration, and antacids and cholestyramine may decrease its absorption. Approximately 5% of the drug is bound to albumin. It is nearly completely metabolized by glucuronyl transferase, and more than 90% of the drug is eliminated by the kidneys. The MMF glucuronide metabolite, which is increased in renal failure, increases MMF clearance by competing for its binding sites on albumin. MMF pharmacokinetics seems not to be affected by the concomitant administration of cyclosporine A (CsA). As with many other immunosuppressive agents, doses up to 20% higher may be required for children due to a physiologic increased liver metabolism. A new oral formulation of MPA, mycophenolate sodium-enteric coating (MP-EC), has been proved to be as effective as MMF at conversion dose as follows: 250 mg of MMF = 180 mg of MP-EC and 500 mg of MMF = 360 mg of MP-EC. This new formulation is less expensive and appears to have less gastrointestinal side effects.

INDICATIONS

There are no approved indications for MMF in dermatology. However, it has been used for immunoblistering diseases, particularly pemphigus; for collagen

Modified median effect formula for combined therapeutic effect

$$Cix = \frac{A \text{ combined with } B}{A} + \frac{B \text{ combined with } A}{B}$$

Cix: index inhibition (Igs, disease activity, etc)
Cix: = 1 additive
< 1 synergistic
> 1 antagonistic

Figure 233-1 A modified, median-effect formula is widely used in organ transplant, which helps in finding the therapeutic windows of immunosuppressive drugs as well as the synergistic, additive, or antagonistic effect of a postulated drug combination. Igs = immunoglobulins. (From Chou TC, Talalay P: Quantitative analysis of dose-effect relationships: The combined effects of multiple drugs or enzyme inhibitors. *Adv Enzyme Regul* **22**:27, 1984.)

vascular diseases, including cutaneous lupus erythematosus, morphea and dermatomyositis; papulosquamous diseases including psoriasis, lichen planus and lichen planopilaris; pyoderma gangrenosum, cutaneous vasculitis, sarcoidosis, and chronic atopic dermatitis.[3,18,19] There is no high level of evidence for any of these conditions being effectively treated with MMF. MMF may be combined with other traditional immunosuppressive agents because of potential synergism, however, the risk of infection and neoplasia likely increase in patients utilizing combined regimens.

DOSING REGIMEN

(Table 233-1)

INITIATING THERAPY

MMF is commonly used in synergistic and safe combination with CsA and corticosteroids.

MMF is commonly used with systemic corticosteroids as adjuvant therapy. The full therapeutic effect of MMF or MP-EC, namely on antibody-mediated diseases, should not be expected until 2 or 3 months after therapy initiation. The therapeutic and toxic profiles of MMF have led this drug to be the substitute of azathioprine.

MONITORING THERAPY

Measurement of serum levels of MPA shows inconsistent predictive value to monitor effectiveness and toxicity in MMF-treated patients, and therefore is rarely used in the clinical setting. There is no specific monitoring guideline, but it seems prudent to monitor a complete blood cell count and a liver-derived enzyme on a regular basis at the onset of therapy and perhaps quarterly during chronic therapy.

RISKS AND PRECAUTIONS

Gastrointestinal side effects, occasionally with intractable diarrhea, namely in elderly patients, are common, but in the vast majority of the cases they disappear with continuation of therapy, dividing the total daily dose (e.g., three or four times a day), and taking the drug with food. Increased risk of herpes zoster virus reactivation is rather common, namely, in elderly patients and patients with autoimmune blistering disease (author's personal observation). Significant cytopenias could be expected when combined with mTORIs. Dose reduction should be made for patients with liver diseases. MMF is a pregnancy category D agent and therefore should be avoided in women of child-bearing age unless they are on adequate contraception.

COMPLICATIONS

Expected toxicities include nausea, upset stomach, vomiting, and diarrhea. There is no increase in nephrotoxicity, hepatotoxicity, hypertension, or neurotoxicity when MMF is used in conjunction with CsA and corticosteroids. The hematologic and gastrointestinal side effects are dose dependent and usually clinically insignificant. An increased incidence of lymphoproliferative diseases and lymphoma is reported with its use, as well as predisposition for infectious complication, and as a predisposition for infectious complications including progressive multifocal leukoencephalopathy.[30–38]

Other antimetabolite and immunosuppressive agents are discussed in Chapter 227.

TABLE 233-1
Mycophenolate Mofetil Dosing Regimen

	Daily Oral Dose
Cytotoxic T-cell mediated diseases	25–35 mg/kg
Antibody-mediated diseases	35–55 mg/kg

Note: 180 mg of mycophenolate sodium enteric coating is the equivalent of 250 mg of mycophenolate mofetil; 360 mg of mycophenolate sodium enteric coating is the equivalent of 500 mg of mycophenolate mofetil.[27,28]

MACROLACTAM DRUGS

Macrolactam drugs are immunomodulators derived from microorganism fermentation products that include calcineurin inhibitors (CnIs) [e.g., cyclosporine, tacrolimus (TCL), and pimecrolimus] and mammalian target of rapamycin inhibitors (mTORIs) [e.g., sirolimus (SRL) and everolimus (EVL)]. Macrolactams are versatile immunomodulators that selectively suppress T-cell response and have synergistic therapeutic effects when they are combined with virtually any other immunosuppressive drug.[1,2]

CALCINEURIN INHIBITORS

MECHANISM OF ACTION. (Figure 233-2). CnIs inhibit T-cell stimulation initiated by several pathways, of which the T-cell receptor (TCR) CD3 is the best understood.[3] Mechanisms involving B-7 and CD28/cytotoxic T lymphocyte antigen-4, and other costimulatory pathways seem not to be affected by CsA or other CnIs. The high-affinity receptor for CsA is a 17-kd immunophilin called *cyclophilin A* (*CyPA*). The other CnIs (TCL and pimecrolimus) bind a structurally unrelated, different immunophilin called *macrophilin-12* also known as *FK-506 binding protein-12* (*FKBP-12*). The drug-immunophilin complex binds to calcineurin (Cn), a serine/threonine protease composed of two subunits: (1) CnA and (2) CnB. CnA constitutes the catalytic unit possessing binding sites for CnB and calmodulin. Cn activity strictly correlates with interleukin-2 (IL-2) production via CD3 activation. Cn is also involved in the induction of apoptosis and degranulation of cytotoxic T lymphocytes. Experimental data show that the CsA, TCL, and pimecrolimus/Cn complex inhibits the nuclear translocation of the nuclear factor of activated T cells c molecule by blocking its dephosphorylation. This is thought to be the key step by which these drugs uncouple TCR activation from IL-2 transcription. TCL is 10- to 100-fold more potent than CsA in vitro in the inhibition of Cn activity.

In summary, CsA inhibits the T-cell activation mediated by antigen, but it does not inhibit the early phases of lymphocyte signal transduction occurring after antigen-mediated activation. The immunomodulatory effects of these drugs are intricate and subject to constant discoveries. A simplified explanation of the mechanism of action of these drugs is presented in the following sections and is illustrated in Fig. 233-2.

CYCLOSPORINE A. CsA is a hydrophobic lipophilic undecapeptide extracted from fungi.

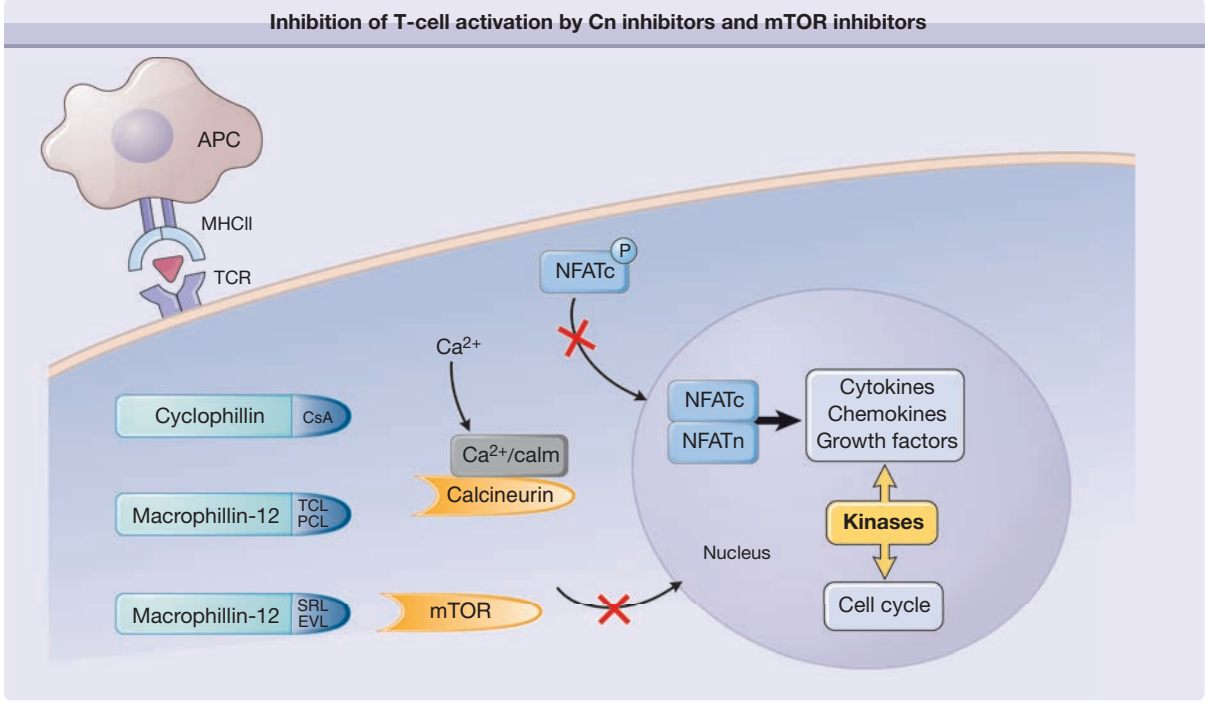

Figure 233-2 This diagram outlines the key mechanisms by which calcineurin (Cn) inhibitors and mammalian target of rapamycin (mTOR) inhibitors inhibit T-cell activation triggered by presentation of antigen via the T-cell receptor (TCR). The first step in antigen presentation involves presentation of a peptide that is bound within the peptide-binding groove of the major histocompatibility complex (MHC) class II molecule. This complex is then presented to the TCR. This causes transmembrane signaling that increases intracellular calcium concentrations. The liberated calcium, bound to calmodulin (calm), interacts with Cn, a calcium-dependent serine/threonine phosphatase that dephosphorylates nuclear factor of activated T cells (shown here as NFATc), and this causes NFAT to translocate to the nucleus. There it binds to other nuclear components of NFAT (shown here as NFATn). This complex regulates the transcription of many *cytokine* genes, shown in the diagram. Cyclosporine (CsA), tacrolimus (TCL), and pimecrolimus (PCL) diffuse freely into the cytoplasm of T cells and bind with their respective immunophilins. This drug/immunophilin complex binds to Cn and blocks its ability to dephosphorylate NFAT, and thereby inhibits the production of cytokines, chemokines, and growth factors [interleukin 2 (IL-2), IL-3, IL-4, tumor necrosis factor-α, interferon-γ, granulocyte-macrophage colony-stimulating factor, etc.] that would normally be induced after T-cell activation via the TCR. Sirolimus (SRL) has a more complex intracellular mechanism of action. Although SRL and everolimus (EVL) bind macrophilin-12 (also known as *FKBP-12*), the immunophilin of TCL and PCL, its mechanism of action does not appear to be mediated by Cn inhibition. mTOR inhibitors block cell kinases that would have a direct effect on the cell cycle by also an indirect effect in chemokine, cytokine, and growth factor synthesis. APC = antigen-presenting cell.

Pharmacokinetics. The microemulsion-based formulation of CsA has an improved bioavailability giving the drug more predictable absorption.[3,4]

CsA can also be administered intravenously as a 50-mg/mL solution made up in an ethanol-polyoxyethylated castor oil mixture. The accumulation of CsA in erythrocytes and leukocytes is the reason that whole-blood monitoring of CsA levels is much more accurate than measurement of plasma levels. Peak levels occur from 1.3–4.0 hours after oral administration. After gaining access to the circulation, CsA distributes widely and has a large apparent volume of distribution (13 L/kg). CsA is metabolized into greater than 30 cyclic, partly active metabolites by the liver cytochrome P_{450} 3A enzyme (CYP 3A).[5,6] Thus, drugs that compete for binding to CYP 3A will increase CsA levels, and drugs that induce P_{450} will accelerate metabolism and decrease blood levels (eTable 233-1.1 in online edition). Certain foods rich in bioflavonoids, especially grapefruit, seem to increase the drug's bioavailability through an interaction with cytochromes. Its elimination half-life is 6–12 hours in the absence of severe hepatic disease, and biliary excretion accounts for more than 90% of its elimination. CsA solution does have some penetration of mucosal surfaces, but this is not true of cornified epithelium.

Indications

- *Psoriasis*: Cyclosporin is approved for use in patients with moderate-to-severe psoriasis, but the approved dosage is 2.5–3.0 mg/kg/d which in author's experience is too low a dosage to achieve adequate control of most patients. The dosage that appears adequate is between 4 and 5 mg/kg/d, but, at this level, the risk of nephrotoxicity occurs with continued use. There are some patients that are able to achieve response, whose response is held at lower doses that can be used for longer periods. The use of cyclosporin in combination with methotrexate seems synergistic, but combination with biologic therapies has not been well studied and should be avoided other than for short periods of time. Although this drug is approved, its use has lessened except for short-term usage.
- *Pyoderma gangrenosum*: It was one of the first diseases in dermatology in which cyclosporin was noted to be beneficial. Even now in the age of biologic therapy, some patients are effectively managed with this and other macrolactams.
- *Paraneoplastic pemphigus*: Patients have been treated with cyclosporin, but it should be used cautiously because of its potential to allow tumors to grow. With the advent of rituximab usage for lymphoma and pemphigus, cyclosporin would not in my opinion be a first-line therapy.
- *Lichen planus*: Multiple case reports and small case series have demonstrated that cyclosporin is effective in patients with lichen planus, particularly those with oral or esophageal erosive disease. This is not a first-line therapy in this condition.
- *Atopic dermatitis*: Severe atopic dermatitis can be one of the most challenging dermatologic conditions to manage. While cyclosporin might be useful, as will all chronic diseases, its indefinite use is associated with increasing frequency of toxicity. Therefore, most of the patients treated should only have relatively short-term use.
- *Behçet disease*: Ocular and mucocutaneous forms; moderate to severe cases.
- *Dermatomyositis*: Patients with inflammatory myopathies have responded to cyclosporin. However, in author's experience, it is the rare patient whose skin disease will be controlled with cyclosporin.
- *Alopecia areata*: Since this drug or others in its class have not been demonstrated to alter the long-term course of the disease, it is a rare patient who can be treated.
- *Epidermolysis bullosa acquisita*: This is often a difficult disorder to control. There are no therapies that have been proven to be effective in well designated studies. Cyclosporin has been used in individual patients and has been reported to be effective and potentially corticosteroid-sparing in some patients.

Dosing Regimen. (Table 233-2)

Initiating Therapy. Doses higher than 5 mg/kg/day are not advisable other than for short periods of time. Some patients with acute uncontrolled disease might be treated with 'loading' doses in hopes of achieving more rapid control of their disease. The US Food and Drug Administration has approved CsA for psoriasis in doses up to 4 mg/kg/day, with a recommended starting dose of 2.5 mg/kg/day. Dosage increases should be performed after 4 weeks of therapy, and dose reductions are permitted at any time. Dosage increases should not exceed 0.5–1.0 mg/kg/day at 2- to 4-week intervals. Intravenous CsA formulation can be infused slowly over a period of 2–6 hours at about one-third of the usual oral dose, or about 2–3 mg/kg per day.[7]

Monitoring Therapy. When psoriatic patients improve, defined clinically, the CsA dose should be down-titrated. It is not clear with what rapidity this de-escalation of therapy should occur, but some have suggested that at least a 4-week interval should occur prior to further dose reduction. As therapy is decreased, there is a risk of relapse. Rebound is also possible, but is a relatively uncommon phenomenon.

Patients who seemingly do not respond to CsA should be assessed for compliance and absorption by measuring a trough level. The two most common assays for trough levels—high-performance liquid chromatography (HPLC) and radioimmunoassay—are performed in EDTA-containing whole blood. The recommended range is 200–400 ng/mL. Routine use of CsA levels in dermatology patients is not necessary.

Children have comparable bioavailability of orally ingested CsA, but have a higher renal drug clearance rate (11.8 mL/min per kg vs. 5.7 mL/min per kg in adults), and a correspondingly shorter blood level half-life (7.3 hours vs. 10.7 hours in adults). Children may therefore require somewhat higher dosages and more frequent administration to achieve comparable trough levels to adults.

TABLE 233-2
Dosing of Macrolactam Immunosuppressive Agents

Drug	Adult Dosage	Children's Dosage mg/kg/day
Cyclosporin—oral	2.5–5.0 mg/kg/day	5–7 mg/kg/day
Cyclosporin—intravenous	2–3 mg/kg/day	3–5 mg/kg/day
Tacrolimus—oral	150–200 µg/kg/day	200–300 µg/kg/day
Tacrolimus—intravenous	25–50 µg/kg/day	50–100 µg/kg/day
Sirolimus	3–10 mg/day for Patients of African or Asian descent 0.5–3 mg/d for Caucasian patients	1.5 mg/m^2
Everolimus	0.8–1.2 mg/m^2/day	0.75–1.5 mg twice daily

Risks and Precautions. Serum creatinine levels should be carefully monitored during CsA therapy. If creatinine levels increase more than 30% above baseline, the dosage should be reduced for 1–2 weeks. If, after that time, the creatinine levels decrease below the 30% elevation mark, continuation at the lower dose is advisable. In cases where the creatinine remains elevated by more than 30%, discontinuation of CsA is recommended until the creatinine returns to levels within 10% of pretreatment levels. More accurate studies monitoring the glomerular filtration rate clearance are used in individualized cases. From a practical standpoint, adequate monitoring of CsA dosage can be achieved by the avoidance of CsA doses higher than 5 mg/kg/day, evaluation of clinical response, and vigilance for signs of toxicity. This requires a detailed physical examination, including blood-pressure monitoring with threshold concern triggered by a persistent diastolic blood pressure above 90 mm Hg, a complete history with emphasis on concomitant drug ingestion and medical conditions that may potentiate CsA toxicity, and laboratory evaluations for complete blood count, creatinine and blood urea nitrogen, uric acid, liver enzymes, serum electrolytes and magnesium, and a urinalysis. In patients receiving long-term CsA therapy (>6 months), the serum creatinine and its clearance may not be a reliable predictor of altered renal function, and potentially irreversible chronic cyclosporine nephrotoxicity may ensue. In such circumstances, more reliable studies for the evaluation of renal function may be indicated.

Complications

Renal Function, Liver, and Neurologic. Overall, one in four patients taking CsA develops clinical and laboratory evidence of altered renal function, including hypertension. Two types of CsA-induced nephrotoxicity are encountered in dermatologic patients. The first type usually starts within 2–3 weeks after drug initiation, and it is usually associated with high CsA blood levels. In this toxicity, there is an insidious decrease in glomerular filtration rate along with hypertension, and tubular dysfunction in association with a complete recovery of renal function upon dose-lowering or discontinuing therapy. The second type is likely a result of cumulative subclinical chronic renal toxicity. This may occur in the absence of any detectable elevation of creatinine or blood pressure. Histologic changes include interstitial fibrosis, tubular atrophy, and some degree of vasculopathy. Although renal function can improve somewhat after discontinuation of the drug, this type of toxicity is generally irreversible. In psoriatic patients receiving 5 mg/kg/day CsA, elevation of serum creatinine may persist for more than 4 months after discontinuation of the drug. Several mediators, including endothelin-1, angiotensin II, osteopontin, and transforming growth factor-β1, have been implicated in the pathogenesis of CsA-associated nephrotoxicity and hypertension. Calcium channel antagonists exert beneficial effects on CsA-induced hypertension and nephrotoxicity, presumably through the inhibition of endothelin-1. Other drugs, including angiotensin converting inhibitors (enalapril, lisinopril, etc.) and angiotensin receptor blockers (losartan, valsartan, etc.), are also effective mainly when used in combination with other antihypertensive drugs. New drugs, such as endothelin A receptor blockers (bosentan, darusentan, etc.) and renin inhibitors (aliskiren), appear to be promising for CsA-treated patients.[8–10] Diuretics and nephrotoxic drugs should be used with caution in CsA-treated patients. Another uncommon adverse renal complication is the development of thrombotic microangiopathy/hemolytic uremic syndrome,[11,12] especially in allogenic bone marrow transplant patients receiving CsA for acute graft-versus-host disease. Hypomagnesemia and hyperkalemia or hypokalemia are not uncommonly encountered.

Nausea, vomiting, anorexia, and diarrhea commonly occur with the use of CsA. Elevations of liver enzymes greater than 100% over baseline should be managed by reduction of the CsA dose by 25% weekly, until enzyme levels normalize.

Headache is a common complaint, especially in patients with a history of migraines. It tends to resolve spontaneously as therapy continues. CsA-induced seizures appear to be associated with hypomagnesemia and concomitant use of high doses of systemic corticosteroids. Thus, serum magnesium levels should be always monitored and kept above the lower normal range in

CsA-treated patients. Cortical blindness, lethargy, confusion, seizures, hemiplegia, tremors, and paresthesias have also been described in patients receiving CsA.[8]

There is evidence of impaired fibrinolysis and endothelial damage and proliferation associated with CsA. Hypercoagulability seems to contribute to the progression of atherosclerosis and glomerular damage in CsA-treated patients. Significant cytopenias have rarely been reported with the use of CsA.

Hypercholesterolemia, elevation of low-density lipoproteins, and hypertriglyceridemia may be seen with CsA.

Cancer. CsA-treated transplant recipients have a relative risk for all skin cancers of 6.8 versus 2.2–5.5 in patients receiving other immunosuppressive therapies. CsA-treated dermatologic patients also have a higher risk of skin cancers, including squamous cell carcinomas, basal cell carcinomas, human papilloma virus-associated anogenital carcinoma, and Kaposi sarcoma. The high incidence of squamous cell carcinoma in psoriatic patients treated with CsA could be biased by previous exposures to psoralen and ultraviolet A light or ultraviolet B. Approximately 25% of nonvisceral Kaposi sarcomas can be expected to undergo complete or partial remission following cessation or reduction of immunosuppressive therapy. Epstein-Barr virus-associated post-transplant lymphoproliferative disorder (PTLD) is quite rare in dermatologic patients. PTLD frequently usually fails to respond to chemotherapy, but it may regress spontaneously after reduction and/or cessation of immunosuppression. The incidence of lymphoma in CsA-treated dermatologic patients appears to be less than 0.2%. The incidence of lymphoma in transplant patients receiving CsA alone or in combination with corticosteroids is less than 1%, whereas for those receiving CsA in conjunction with other immunosuppressive drugs is as high as 8%. In contrast to the high mortality rate attributed to lymphomas arising in immunosuppressed patients, lymphomas developing in CsA-treated patients seem to carry a better prognosis despite of having a shorter latency period seems.[13–15] In rheumatoid arthritis patients treated with CsA, there was no increase in malignancies in comparison with a matched control group of patients with rheumatoid arthritis who were not treated with CsA. Other neoplasms, including melanoma, are also reported in CsA-treated patients, although their true incidence is unknown.

Other Adverse Effects. Hypertrichosis occurs in virtually all patients on long-term CsA therapy. It is not limited to androgen-dependent, hair-bearing areas, and shows no tendency to spontaneous remission. Gingival hypertrophy is reported in up to 70% of CsA-treated patients; it is more common in children, individuals with poor oral hygiene and concomitant use of calcium channel drugs. Improvement of this gingival complication with topical or systemic azithromycin and metronidazole can be seen. An acneiform eruption, indistinguishable from that seen in steroid-induced acne, is frequently reported. A disseminated comedonal or cystic acneiform eruption can also occur. These side effects can appear at any time during CsA therapy, although they are more commonly described at the time of initiation of CsA therapy. Keratosis pilaris, sebaceous hyperplasia, warts, and epidermal inclusion cysts occur in up to one-third of CsA-treated patients.

Osteoporosis seems to result from the CsA's action on osteoblasts and osteoclasts, and by altering lymphokine release. CsA can induce hyperuricemia in up to 15% of patients, and it is also an indicator of early CsA-induced nephrotoxicity. Myopathy has been reported in transplant patients receiving high doses of CsA, and thus, cation should be used with the concomitant use of statins.

Pregnancy. CsA is categorized as a pregnancy category C and as such should only be used when the benefits outweigh the risks.[8] It does not seem to be mutagenic or teratogenic, although there is a higher than expected incidence of preterm newborns, fetal growth retardation, abortions, preeclampsia, and hypertension in mothers taking CsA, and these occurrences are magnified in transplant patients. There are no reports of neonatal complications in children born to fathers receiving CsA. Adequate contraceptive measures are recommended in women of childbearing potential. CsA crosses the placenta and is excreted in breast milk. CsA-treated transplant patients seem to have a relative risk for infectious, life-threatening complications that is much lower than that seen in patients receiving azathioprine and prednisolone. However, increased vigilance for infectious complications is recommended in CsA-treated patients.

TACROLIMUS.

TCL, a CnI formerly known as *FK506*, is a macrolactam drug first isolated from *Streptomyces tsukubaensis*.

Mechanism of Action.

The postulated mechanisms of action of TCL are similar, if not identical, to the ones described for CsA (see Section "Macrolactam Drugs").[16]

Pharmacokinetics.

TCL can be administered orally, topically, and intravenously. The pharmacokinetics of systemic TCL are characterized by a two-compartment model with a rapid initial drop and a long elimination half-life of 12–21 hours. TCL is metabolized in the liver with less than 1% of the drug excreted intact. TCL has not proved to be more effective than CsA, but it appears to have a better bioavailability. The topical formulations have a concentration of 0.3% and 0.1% in an ointment vehicle, and for more detailed information, see Chapter 221.

Dosing Regimen. (Table 233-2)

Initiating Therapy.

The dosage of systemic TCL should be reduced in the presence of hepatic dysfunction by 10%–30% of the standard dosing.

Monitoring Therapy.

There is a good correlation between enzyme-linked immunosorbent assay and HPLC mass spectrometry measurements in monitoring of whole blood concentrations of TCL. Enzyme-linked immunosorbent assays may also detect metabolites of the drug, and thus, caution should be taken in patients with liver diseases or with concomitant use of

CyP4503A-binding drugs. Blood levels of 5–15 ng/mL are recommended.

Risks and Precautions. The risks and precautions are quite similar to the ones applied for CsA. However, neurotoxicities and glucose intolerance are somewhat higher than with CsA use, and thus, close monitoring of magnesium and glucose serum levels and, if indicated based on personal or family history, glucose tolerance tests are strongly recommended. The risk for PTLD seems to be higher in children with hepatic transplants who received both TCL and anti-OKT3, but it has not been definitively proved in dermatologic patients or in different clinical scenarios. Dose reduction and close monitoring of TCL levels by HPLC mass spectrometry in patients with liver diseases are strongly recommended. A lesser graft-versus-leukemia effect in comparison with the one seen with CsA is observed in bone marrow transplant patients. A great deal of concern has been raised regarding the potential risk of lymphoproliferative diseases with this drug, which led to a highly controversial placement of a black-box warning by the US Food and Drug Administration with the topical formulation (see Chapter 221).

Complications. Mucocutaneous and metabolic side effects seem to be less frequent with the use of TCL. However, nephrotoxicity seems to be comparable to that seen with the use of CsA. The rest of the side effects are comparable with those seen with CsA use.

Indications. There are no approved indications for tacrolimus in dermatology. Its mechanism of action suggests that any patient who might be responsive to CsA would likely respond to tacrolimus. Therefore it might be useful in patients with psoriasis, pyoderma gangrenosum, dermatomyositis, lupus erythematosus, atopic dermatitis, and graft-versus-host disease, among other potential indications.[17–21]

Systemic TCL can be used virtually in any inflammatory and autoimmune skin disease in which systemic CsA has proved effective. For topical use of TCL, see Chapter 221.

PIMECROLIMUS.

Pimecrolimus, also known as *ASM 981*, is a derivative of the parent compound ascomycin originally isolated from the fermentation products of *S. hygroscopicus* var. *ascomyceticus*. Pimecrolimus has a similar mechanism of action as that of other CnIs. Pimecrolimus is formulated in vehicle cream at concentrations of 0.2%, 0.6%, and 1.0% (see Chapter 221).

MAMMALIAN TARGET OF RAPAMYCIN INHIBITORS

MECHANISM OF ACTION.

SRL and its derivatives EVL and temsirolimus are most widely known as *mTORIs*. Although mTORIs bind to FKBP-12 (macrophilin-12), this drug-immunophilin complex inhibits gene transcription through a complex mechanism that is independent from the one involving Cn.

PHARMACOKINETICS.

African and Asian descent patients require a higher initial and maintenance dose of SRL than Caucasians. EVL bears a stable 2-hydroxyethyl chain substitution at position 40 on the SRL structure, which has given a greater polarity than SRL, improving the pharmacokinetic and particularly its oral bioavailability. Oral EVL is absorbed rapidly and reaches peak concentration after 1.5 hours. In adults, EVL pharmacokinetic characteristics do not differ according to age, weight, or sex, but body weight-adjusted dosages are necessary in children.[25–26] The target trough concentration of EVL should range between 3 and 15 ng/dL. SRL topical formulation (2.2% and 8.0%) has been used in psoriasis patients (see Chapter 221).

INDICATIONS.

There are no approved indications for everolimus in dermatology. Its mechanism of action suggests that any patient who might be responsive to CsA or tacrolimus would likely respond to everolimus. Therefore, it might be useful in patients with psoriasis, pyoderma gangrenosum, dermatomyositis, lupus erythematosus, atopic dermatitis, and graft-versus-host disease, among other potential indications.

DOSING REGIMEN. (Table 233-2)

INITIATING THERAPY.

As mentioned in Table 233-2, due to ethnic differences, the SRL recommended oral loading dose is 6 mg and oral maintenance dose is 2 mg per day for Caucasian patients, and the oral loading dose is 10 mg and oral maintenance dose is 5 mg per day for African Americans. Asians also appear to require higher doses of this drug. EVL starting dose are the same regardless of sex and race. The usual dosing for adults is 0.75–1.5 mg bid and for children 0.8–1.2 mg/m^2.

MONITORING THERAPY.

Due to significant intra- and interindividual variability, measuring trough levels is critical with the use of mTORIs. Trough levels for SRL and EVL are 5–20 ng/dL and 3–15 ng/mL, respectively. Complete blood cell count, electrolytes, liver function test, and a lipid profile, along with a comprehensive clinical examination with periodic blood pressure measurement, are mandatory.

RISKS AND PRECAUTIONS.

Concomitant use of antimetabolite drugs, including mycophenolate mofetil (MMF) and azathioprine in patients with mTORIs of upper normal or higher trough blood levels (e.g., SRL: equal or higher than 20 ng/dL or EVL: equal or higher than 5 ng/mL), raises the risk of cytopenias, namely thrombocytopenia. Concomitant use of CnIs, namely TCL, may increase the risk of thrombotic microangiopathy/hemolytic uremic syndrome, and thus, monitoring of blood cell count, dyslipidemia, electrolyte abnormalities, edema, and increase of liver function tests are also associated with high trough levels of these drugs. Patients with extensive psoriasis treated with SRL should be monitored closely for capillary leak syndrome, a rare complication reported only in one series.[27]

COMPLICATIONS.

Cytopenias, namely thrombocytopenia, hypertriglyceridemia, hypercholesterolemia,

arthralgias, edema, and impaired wound healing, have been frequently associated with the use of mTORIs. Occurrence of cytomegalovirus appears to be lower than that observed with the use of CnIs. No gingival hyperplasia has been observed with SRL. Tremor or any other neurologic complications are not frequent. Hypertension and malignancies are significantly reduced in comparison with the use of CnIs. This is most likely related to the endothelial, mesangial antiproliferative and antineoplastic properties of mTORIs.

ACKNOWLEDGMENT
